This ardour of love laſts only three weeks, during which the ſtags take very little food, and neither ſleep nor reſt. Night and day, they are either walking, running, fighting, or enjoying the hinds. Hence, at the end of the rutting ſeaſon, they are ſo meagre and exhauſted, that they recover not their ſtrength for a conſiderable time. They generally retire to the borders of the foreſts, feed upon the cultivated fields, where they find plenty of nouriſhment, and remain there till their ſtrength is re-eſtabliſhed. The rutting ſeaſon of old ſtags commences about the beginning, and ends about the 20th day of September. In thoſe of ſix or ſeven years old, it begins about the 10th of September, and concludes in the beginning of October. In young ſtags, or thoſe in their third, fourth, or fifth year, it begins about the 20th of September, and terminates about the 15th of October; and at the end of October, the rutting is all over, excepting among the *prickets*, or thoſe which have entered into their ſecond year; becauſe they, like the young hinds, are lateſt of coming into ſeaſon. Hence, at the beginning of November, the ſeaſon of love is entirely finiſhed; and the ſtags, during this period of weakneſs and laſſitude, are eaſily hunted down. In ſeaſons when acorns and other nuts are plentiful, the ſtags ſoon recover their ſtrength, and a ſecond rutting frequently happens at the end of October; but it is of much ſhorter duration than the firſt.

In climates warmer than that of France, the rutting time, like the ſeaſons, is more forward. Ariſtotle informs us, that, in Greece, it commences in the beginning of Auguſt, and terminates about the end of September. The hinds go with young eight months and ſome days, and ſeldom produce more than one fawn. They bring forth in May or the beginning of June, and ſo anxiouſly conceal their fawns, that they often expoſe themſelves to be chaſed, with a view to draw off the dogs, and afterwards return to take care of their young. All hinds are not fertile; for ſome of them never conceive. Theſe barren hinds are groſſer and fatter than thoſe which are prolific, and alſo come ſooneſt in ſeaſon. The young are not called *fawns* or *calves* after the ſixth month: The (knobs of their horns then begin to appear, and they take the name of *knobbers* till their horns lengthen into *ſpears*, and then they are called *brocks* and *ſtaggards*. During the firſt ſeaſon they never leave their mothers. In winter, the ſtags and hinds of all ages, keep together in flocks, which are always more numerous in proportion to the rigour of the ſeaſon. They ſeparate in ſpring: The hinds retire to bring forth; and, during this period, the flocks conſiſt only of knobbers and young ſtags. In general, the ſtags are inclined to aſſociate, and nothing but fear or neceſſity obliges them to diſperſe.

The life of the ſtag is ſpent in alternate plenty and want, vigour and debility, health and ſickneſs, without having any change introduced into his conſtitution by theſe oppoſite extremes. He lives as long as other animals which are not ſubjected to ſuch viciſſitudes. As he grows five or ſix years, he lives ſeven times that number, or from 35 to 40 years. What has been reported concerning the longevity of the ſtag merits no credit. It is only a popular prejudice which prevailed in the days of Ariſtotle, and which that philoſopher conſidered as improbable, becauſe neither the time of geſtation nor of the growth of the young ſtag, indicated long life. This authority ought to have aboliſhed the prejudice; but it has been renewed, in the ages of ignorance, by a fabulous account of a ſtag taken by Charles VI. in the foreſt of Senlis, with a collar upon which was written this inſcription, *Cæſar hoc me donavit*. The love of the marvellous inclined men to believe that this animal had lived 1000 years, and had his collar from a Roman Emperor, rather than to ſuppoſe that he came from Germany, where all the emperors take the name of *Cæſar*.

The ſtag appears to have a fine eye, an acute ſmell, and an excellent ear. When liſtening, he raiſes his head, erects his ears, and hears from a great diſtance. When he is going into a coppice, or other half covered place, he ſtops to look round him on all ſides, and ſcents the wind, to diſcover if any object is near that might diſturb him. He is a ſimple and yet a curious and crafty animal. When hiſſed or called to from a diſtance, he ſtops ſhort, and looks ſteadfaſtly, and with a kind of admiration at carriages, cattle, or men; and if they have neither arms nor dogs, he moves on unconcernedly, and without flying. He appears to liſten with great tranquillity and delight to the ſhepherd's pipe; and the hunters ſometimes employ this artifice to encourage and deceive him. In general, he is leſs afraid of men than of dogs, and is never ſuſpicious, or uſes any arts of concealment, but in proportion to the diſturbances he has received. He eats ſlow, and has a choice in his aliment; and after his ſtomach is full, he lies down, and ruminates at leiſure. He ſeems to ruminate with leſs facility than the ox. It is only by violent ſhakes that the ſtag can make the food riſe from his firſt ſtomach. This difficulty proceeds from the length and direction of the paſſage through which the aliment has to go. The neck of the ox is ſhort and ſtraight, but that of the ſtag is long and arched; and therefore greater efforts are neceſſary to raiſe the food. Theſe efforts are made by a kind of hiccup, the movement of which is apparent, and continues during the time of rumination. His voice is ſtronger and more quivering, in proportion as he advances in years. The voice of the hind is ſhorter and more feeble. She never bellows from love, but from fear. The ſtag during the rutting ſeaſon, bellows in a frightful manner: He is then ſo tranſported, that nothing diſturbs or terrifies him. He is therefore eaſily ſurpriſed; as he is loaded with fat, he cannot keep long before the dogs. But he is dangerous when at bay, and attacks the dogs with a ſpecies of fury. He drinks none in winter nor in ſpring, the dews and tender herbage being then ſufficient to extinguiſh his thirſt; but during the parching heats of ſummer, to obtain drink, he frequents the brooks, the marſhes, and the fountains; and in the ſeaſon of love, he is ſo over-heated, that he ſearches every where for water, not only to ſatisfy his immoderate thirſt, but to bathe and refreſh his body. He then ſwims eaſier than at any other times on account of his fatneſs. He has been obſerved croſſing very large rivers. It has even been alleged, that, attracted by the odour of the hinds, the ſtags, in the rutting ſeaſon, throw themſelves into the ſea, and paſs from one iſland to another at the diſtance of ſeveral leagues. They leap ſtill more nimbly than they ſwim; for, when purſued, they eaſily clear a hedge or a pale fence of ſix feet high. Their food varies in different ſeaſons. In autumn, after rutting, they ſearch for the buds of green ſhrubs, the flowers of broom or heath, the leaves of brambles, &c. During the ſnows of winter, they feed upon the bark, moſs, &c. of trees; and in mild weather, they browſe in the wheat-fields. In the beginning of ſpring, they go in queſt of the catkins of the trembling popular, willow, and hazel-trees, the flowers and buds of the cornel tree, &c. In ſummer, when they have great choice, they prefer rye to all other grain, and the black berry-bearing alder to all other wood. The fleſh of the fawn is very good: that of the hind and knobber not abſolutely bad; but that of the ſtag has always a ſtrong and diſagreeable taſte. The ſkin and the horns are the moſt uſeful parts of this animal. The ſkin makes a pliable and very durable leather. The horns are uſed by cutlers, ſword-ſlippers, &c. and a volatile ſpirit, much employed in medicine, is extracted from them by the chymiſts.

In America, ſtags feed eagerly on the broad-leaved kalmia; yet that plant is a poiſon to all other horned animals: their inteſtines are found filled with it during winter. If their entrails are given to dogs, they become ſtupified, and as if drunk, and often are ſo ill as hardly to eſcape with life. The American ſtags grow very fat: their tallow is much eſteemed for making of candles. The Indians ſhoot them. As they are very ſhy animals, the natives cover themſelves with a hide, leaving the horns erect; under the ſhelter of which they walk within the reach of the herd. De Brie, in the 25th plate of the Hiſtory of Florida, gives a very curious repreſentation of this artful method of chaſe, when it was viſited by the French in 1564. Their ſkins are an article of commerce imported by the Hudſon's Bay Company; but brought from the diſtant parts far inland by the Indians, who bring them from the neighbourhood of the lakes. In moſt parts of North America they are called the grey mooſe, and the elk; this has given occaſion to the miſtaken notion of that great animal being found in Virginia and other ſouthern ſtates.

In Britain the ſtag is become leſs common than formerly; its exceſſive viciouſneſs during the rutting ſeaſon, and the badneſs of its fleſh, induce moſt people to part with the ſpecies. Stags are ſtill found wild in the Highlands of Scotland, in herds of four or five hundred together, ranging at full liberty over the vaſt hills of the north. Formerly the great Highland chieftains uſed to hunt with the magnificence of an eaſtern monarch, aſſembling four or five thouſand of their clan; who drove the deer into the toils, or to the ſtations the lairds had placed themſelves in: but as this pretence was frequently uſed to collect their vaſſals for rebellious purpoſes, an act was paſſed prohibiting any aſſemblies of this nature. Stags are likewiſe met with on the moors that border on Cornwall and Devonſhire; and in Ireland on the mountains of Kerry, where they add greatly to the magnificence of the romantic ſcenery of the lake of Killarney. The ſtags of Ireland during its uncultivated ſtate, and while it remained an almoſt boundleſs tract of foreſt, had an exact agreement in habit with thoſe that range at preſent through the wilds of America. They were leſs in body, but very fat; and their horns of a ſize far ſuperior to thoſe of Europe, but in form agreed in all points.

The chaſe of the ſtag has been formed into an art, and requires a ſpecies of knowledge which can only be learned by experience: It implies a royal aſſemblage of men, horſes, and dogs, all ſo trained, practiſed, and diſciplined, that their movements, their reſearches, and their ſkill, muſt concur in producing one common end. The huntſman ſhould know the age and the ſex of the animal; he ſhould be able to diſtinguiſh with preciſion, whether the ſtag he has harboured with his hound be a knobber, a young ſtag, in his ſixth or ſeventh year, or an old ſtag. The chief marks which convey this intelligence is derived from the foot, and the excrement. The foot of the ſtag is better formed than that of the hind, or female. Her leg is more groſs and nearer the heel. The impreſſions of his feet are rounder, and farther removed from each other. He moves more regularly, and brings the hind-foot into the impreſſion made by the fore-foot. But the diſtance between the ſteps of the hind are ſhorter, and her hind-feet ſtrike not ſo regularly the track of the fore-feet. As ſoon as the ſtag acquires his fourth horns, he is eaſily diſtinguiſhed; but to know the foot of a young ſtag from that of a hind, requires repeated experience. Stags of ſix, ſeven, &c. years, are ſtill more eaſily known; for their fore-foot is much larger than the hind-foot; the older they are, the ſides of their feet are the more worn; the diſtance of their ſteps are more regular than thoſe of young ſtags; they always place their hind-foot exactly in the track of the fore-foot, excepting when they ſhed their horns, the old ſtags miſplace at this ſeaſon, nearly as often as the young ones, but in this they are more regular than the hind or young ſtag, placing the hind-foot always at the ſide of the fore-foot, and never beyond or within it. When the huntſman, from the dryneſs of the ſeaſon, or other circumſtances, cannot judge by the foot, he is obliged to trace the animal backwards, and endeavour to find his dung. This mark requires, perhaps, greater experience than the knowledge of the foot; but without it the huntſman would be unable to give a proper report to the company. After the report of the huntſman, and the dogs are led to the refuge of the ſtag, he ought to encourage his hound, and make him reſt upon the track of the ſtag, till the animal be unharboured. Inſtantly the alarm is given to uncouple the dogs, which ought to be enlivened by the voice and the horn of the huntſman. He ſhould alſo diligently obſerve the foot of the ſtag, in order to diſcover whether the animal has ſtarted, and ſubſtituted another in his place. But it is then the buſineſs of the hunters to ſeparate alſo, and to recal the dogs which have gone aſtray after falſe game. The huntſman ſhould always accompany his dogs, and encourage, without preſſing them too hard. He ſhould aſſiſt them in detecting all the arts of eſcape uſed by the ſtag; for this animal has remarkable addreſs in deceiving the dogs. With this view he often returns twice or thrice upon his former ſteps; he endeavours to raiſe hinds or younger ſtags to accompany him, and draw off the dogs from the object of their purſuit: he then flies with redoubled ſpeed, or ſprings off at ſide, lies down on his belly, and conceals himſelf. In this caſe, when the dogs have loſt his foot, the huntſmen, by going backwards and forwards, aſſiſt them in recovering it. But if they cannot find it, they ſuppoſe that he is reſting within the circuit they have made, and go in queſt of him. But if they are ſtill unable to diſcover him, there is no other method left, but, from viewing the country, to conjecture where he may have taken refuge, and repair to the place. As ſoon as they have recovered his foot, and put the dogs upon the track, they purſue with more advantage, becauſe they perceive that the ſtag is fatigued. Their ardour augments in proportion to his feebleneſs; and their ſcent becomes more diſtinct as the animal grows warm. Hence they redouble their cries and their ſpeed; and though the ſtag practiſes ſtill more arts of eſcape than formerly, as his ſwiftneſs is diminiſhed, his arts and doublings become gradually leſs effectual. He has now no other reſource but to fly from the earth which he treads, and get into the waters, in order to cut off the ſcent from the dogs. The huntſmen go round theſe waters, and again put the dogs on the track of his foot. The ſtag, after taking to the water is incapable of running far, and is ſoon at bay. But he ſtill attempts to defend his life, and often wounds the dogs, and even the huntſmen when too forward, by blows with his horns, till one of them cuts his hams to make him fall, and then puts an end to his life, by a blow of a hanger. They now celebrate the death of the ſtag by a flouriſh of their horns: the dogs are allowed to trample upon him, and at laſt partake richly of the victory by devouring his fleſh.

4. The Tarandus, or Rein-deer, is a native of Lapland, and the northern parts of Europe, Aſia, and America. The horns are large, cylindrical, branched, and palmated at the tops. Two of the branches hang over the face. He is about the ſize of a buck, of a dirty whitiſh colour; the hairs of his ſkin are thick and ſtrong. To the Laplanders this animal is the ſubſtitute of the horſe, the cow, the goat, and the ſheep; and is their only wealth: the milk affords them cheeſe; the fleſh, food; the ſkin, cloathing; the tendons, bow-ſtrings; and when ſplit, thread; the horns, glue; the bones, ſpoons. During the winter it ſupplies the want of a horſe, and draws their ſledges with amazing ſwiftneſs, over the frozen lakes and rivers, or over the ſnow, which at that time covers the whole country. A rich Laplander is poſſeſſed of a herd of 1000 rein deer. In autumn they ſeek the higheſt hills, to avoid the Lapland gad-fly, which at that time depoſits its eggs in their ſkin; it is the peſt of theſe animals, and numbers die that are thus viſited. The moment a ſingle fly appears, the whole herd inſtantly perceives it; they fling up their heads, toſs about their horns, and at once attempt to fly for ſhelter amidſt the ſnows of the loftieſt Alps. In ſummer they feed on ſeveral plants; but during winter on the rein-liverwort, which lies far beneath the ſnow, which they remove with their feet and palmated brow antlers, in order to get at their beloved food.

The Samoieds, leſs intelligent than the Laplanders, conſider them in no other view than as animals of draught, to convey them to the chaſe of the wild reins; which they kill for the ſake of the ſkins, either to clothe themſelves, or to cover their tents. They know not the cleanly delicacy of the milk or cheeſe; but prefer for their repaſt the inteſtines of beaſts, or the half-putrid fleſh of a horſe, ox, or ſheep, which they find dead on the high road.—The Koreki, a nation of Kamtſchatka, may be placed on a level with the Samoieds. They keep immenſe herds of reins; ſome of the richeſt to the amount of 10 or 20 thouſand; yet ſo ſordid are they as to eat none except ſuch as they kill for the ſake of the ſkins; an article of commerce with their neighbours the Kamtſchatkans; otherwiſe they content themſelves with the fleſh of thoſe which die by diſeaſe or chance. They train them in the ſledge, but neglect them for every domeſtic purpoſe. Their hiſtorian ſays, they couple two to each carriage; and that the deer will travel 150 verſts in a day, that is 112 Engliſh miles. They caſtrate the males by piercing the ſpermatic arteries, and tying the ſcrotum tight with a thong.—The ſavage and uninformed Eſkimaux and Greenlanders, who poſſeſs, amidſt their ſnows, theſe beautiful animals, neglect not only the domeſtic uſes, but even are ignorant of their advantage in the ſledge. Their element is properly the water; their game the ſeals. They ſeem to want powers to domeſticate any animals except dogs. They are at enmity with all; conſider them as an object of chaſe, and of no utility till deprived of life. The fleſh of the rein is the moſt coveted part of their food; they eat it raw, dreſſed, and dried and ſmoked with the ſnow lichen. The wearied hunters will drink the raw blood; but it is uſually dreſſed with the berries of the heath: they eagerly devour the contents of the ſtomach, but uſe the inteſtines boiled. They are very fond of the fat, and will not loſe the leaſt bit. The ſkin, ſometimes a part of their cloathing, dreſſed with the hair on, is ſoft and pliant; it forms alſo the inner lining of their tents, and moſt excellent blankets. The tendons are their bow-ſtrings, and when ſplit are the threads with which they ſew their jackets.

The Greenlanders, before they acquired the knowledge of the gun, caught them by what was called the *clapper-hunt*. The women and children ſurrounded a large ſpace, and, where people were wanting, ſet up poles capped with a turf in certain intervals, to terrify the animals; they then with great noiſe drove the reins into the narrow defiles, where the men lay in wait and killed them with harpoons or darts. But they are now become very ſcarce.

The rein-deers are found in the neighbourhood of Hudſon's Bay, in moſt amazing numbers, columns of eight or ten thouſand are ſeen annually paſſing from north to ſouth in the months of March and April, driven out of the woods by the muſketoes, ſeeking refreſhment on the ſhore, and a quiet place to drop their young. They go to rut in September, and the males ſoon after ſhed their horns; they are at that ſeaſon very fat, but ſo rank and muſky as not to be eatable. The females drop their young in June, in the moſt ſequeſtered ſpots they can find; and then they likewiſe loſe their horns. Beaſts of prey follow the herds: firſt, the wolves, who ſingle out the ſtragglers (for they fear to attack the drove), detach and hunt them down: the foxes attend at a diſtance, to pick up the offals left by the former. In autumn the deer with the fawns remigrate northward. The Indians are very attentive to their motions; for the rein forms the chief part not only of their dreſs but of their food. They often kill multitudes for the ſake of their tongues only; but generally they ſeparate the fleſh from the bones, and preſerve it by drying it in the ſmoke; they alſo ſave the fat, and ſell it to the Engliſh in bladders, who uſe it in frying inſtead of butter. The ſkins are alſo an article of commerce, and uſed in London by the breeches-makers. The Indians ſhoot them in the winter. The Engliſh make hedges with ſtakes and boughs of trees along the woods for five miles in length, leaving openings at proper intervals beſet with ſnares, in which multitudes are taken. The Indians alſo kill great numbers during the ſeaſons of migration, watching in their canoes, and ſpearing them while paſſing over the rivers of the country, or from iſland to iſland; for they ſwim moſt admirably well.

5. The Dama or Fallow-deer, Buck and Doe; with horns branched, compreſſed, and palmated at the top. The colour is various; reddiſh, deep brown, white or ſpotted. This ſpecies is not ſo univerſal as the ſtag: rare in France and Germany. It is fonnd in Greece, the Holy Land, and the north of China. They are very numerous in England; but, except on a few chaſes, confined in parks. None originally in America. They are eaſily tamed; and their fleſh, which goes by the name of veniſon, is in high eſteem among the luxurious. During rutting-time they will contend

with each other for their miſtreſs, but are leſs fierce than the ſtag; during that ſeaſon, the male will form a hole in the ground, make the female lie down in it, and then often walk round and ſmell at her. Moore ſpeaks of a ſpecies found on the banks of the Gambia, in the interior parts of Africa, near Barracunda, called *Toncong,* which he ſays differed not in form from the Engliſh fallow-deer; only that its ſize was equal to that of a ſmall horſe, and weighed 300lb. It had alſo on its neck an erect black mane, four or five inches long.—Mr White, in his Natural Hiſtory of Pelborn, mentions as a piece of information to naturaliſts, that if ſome curious gentleman would procure the head of a fallow-deer, and have it diſſected, he would find it furniſhed with two *ſpiracula,* or breathing places, beſides the noſtrils; probably analogous to the *puncta lachrymalia* in the human head. When deer are thirſty they plunge their noſes, like ſome horſes, very deep under water, while in the act of drinking, and continue them in that ſituation for a conſiderable time; but, to obviate any inconveniency, they can open two vents, one at the inner corner of each eye, having a communication with the noſe. This ſeems, as our author obſerves, to be an extraordinary proviſion of nature; for it looks as if theſe creatures could not be ſuffocated, though their mouths and noſtrils were both ſtopped. This curious formation of the head, he farther remarks, may be of ſingular ſervice to beaſts of chaſe, by affording them free reſpiration; and no doubt theſe additional noſtrils are thrown open when they are hard run. Mr Pennant has obſerved the ſame curious organization in the antelope. See CAPRA.

6. The Capreolus, or Roe-buck, has erect cylindrical, branched horns, and forked at the top. His ſize is only three feet nine inches long, two feet three inches high before, and two feet ſeven inches high behind: weight from 50 to 60lb. Though the leaſt of the deer-kind, his figure is moſt elegant and handſome. His eyes are more brilliant and animated than thoſe of the ſtag. His limbs are more nimble, his movements quicker, and he bounds, ſeemingly without effort, with equal vigour and agility. His coat, or hair, is always clean, ſmooth, and gloſſy. He never wallows in the mire like the ſtag. He delights in dry and elevated ſituations, where the air is pureſt. He is likewiſe more crafty, conceals himſelf with greater addreſs, is more difficult to trace, and derives ſuperior reſources from inſtinct; for though he has the misfortune to leave behind him a ſtronger ſcent than the ſtag, which redoubles the ardour and appetite of the dogs, he knows how to withdraw himſelf from their purſuit, by the rapidity with which he begins his flight, and by his numerous doublings. He delays not his arts of defence till his ſtrength fails him; but, as ſoon as he finds that the firſt efforts of a rapid chaſe have been unſucceſsful, he repeatedly returns on his former ſteps; and after confounding by theſe oppoſite movements, the direction he has taken, after intermixing the preſent with the paſt emanations from his body, he riſes from the earth with a great bound, and retiring to a ſide, he lies down flat on his belly; and in this immoveable ſituation, he allows the whole troop of his deceived enemies to paſs very near him.

The roe-deer differs from the ſtag and fallow-deer in diſpoſition, temperament, manners, and almoſt every natural habit. Inſtead of aſſociating in herds, they live in ſeparate families. The father, mother, and young, go together, and never mix with ſtrangers. They are conſtant in their amours, and never unfaithful like the ſtag. As the females generally produce two fawns, the one male and the other female, theſe young animals, brought up and nouriſhed together, acquire ſo ſtrong a mutual affection, that they never quit each other, unleſs one of them meets with a misfortune, which never ought to ſeparate lovers. This attachment is more than love; for though always together, they feel the ardour of the rut but once a year, and it continues only fifteen days, commencing at the end of October, and ending before the fifteenth day of November. They are not then, like the ſtag, overloaded with fat: they have no ſtrong ſmell, no fury, in a word, nothing that can change the ſtate of their bodies. During this period, they indeed ſuffer not their fawns to remain with them. The father drives them off, as if he meant to oblige them to yield their place to thoſe which are to ſucceed, and to form new families for themſelves. However, after the rutting ſeaſon is paſt, the fawns return to their mother, and remain with her ſome time; after which they ſeparate for ever, and remove to a diſtance from the place which gave them birth.

The female goes with young five months and a half, and brings forth about the end of April or beginning of May. She produces two at a time, which ſhe is obliged to conceal from the buck while very young. In 10 or 12 days they acquire ſtrength ſufficient to enable them to follow her. When threatened with danger, ſhe hides them in a cloſe thicket, and, to preſerve them preſents herſelf to be chaſed. But notwithſtanding all her care and anxiety, the young are ſometimes carried off by men, dogs, or wolves.

Roe-bucks prefer a mountainous woody country to a plain one. They were formerly very common in Wales, in the north of England, and in Scotland; but at preſent the ſpecies nowhere exiſts in Great-Britain, except in the Scottiſh highlands. In France they are more frequent; they are alſo found in Italy, Sweden, and Norway; and in Aſia they are met with in Siberia. The firſt that are met with in Great-Britain, are in the woods on the ſouth ſide of Loch-Rannoch, in Perthſhire: the laſt in thoſe of Longwal, on the ſouthern borders of Caithneſs; but they are moſt numerous in the beautiful foreſts of Invercauld, in the midſt of the Grampian hills. They are unknown in Ireland. Wild roes, during ſummer, feed on graſs; and are very fond of the *rubus ſaxatilis,* called in the Highlands the roe-buck berry; but in the winter time, when the ground is covered with ſnow, they brouſe on the tender branches of the fir and birch.

7. The Guineenſis, about the ſize of a cat, is of a greyiſh colour, and black underneath. It is a native of Guinea, and the ſize and figure of its horns have not been hitherto deſcribed with any preciſion.

8. The Axis, or Speckled Deer, has ſlender trifurcated horns; the firſt branch near the baſe, the ſecond near the top, each pointing upwards. This ſpecies is about the ſize of the fallow-deer; of a light red colour; the body beautifully marked with white ſpots; along

along the lower part of the ſides, next the belly, is a line of white; the tail long, as that of a fallow-deer; red above, white beneath.—They are common on the banks of the Ganges, and in the iſle of Ceylon. Pliny deſcribes them well among the animals of India, and adds that they were ſacred to Bacchus. They will bear other climates; and have bred in the prince of Orange's menagery near the Hague. They are very tame, and have the ſenſe of ſmelling in an exquiſite degree. They readily eat bread, but will refuſe a piece that has been breathed on: many other animals of this, the antelope and goat kind, will do the ſame.

9. The Porcine or Hog-Deer, has ſlender trifurcated horns, 13 inches long: His body is thick and clumſy; his legs are fine and ſlender: The upper part of the neck, body, and ſides, are brown; belly and rump of a lighter colour.—They are found in Bengal; and called, from the thickneſs of their body, *hog-deer*. The ſame ſpecies is alſo found in Borneo. They are taken in ſquare pit-falls, about four feet deep, covered with ſome ſlight materials. Of their feet, as well as thoſe of the leſſer ſpecies of muſks and antelopes, are made tobacco-ſtoppers.

10. The Virginiana, or Virginian Deer, has ſlender horns bending very much forward; numerous branches on the interior ſides; no brow antlers. It is about the ſize of the Engliſh fallow-deer; of a light colour, cinereous brown. A quite diſtinct ſpecies, and peculiar to America. It inhabits all the provinces ſouth of Canada, but in the greateſt abundance in the ſouthern; but eſpecially the vaſt ſavannas contiguous to the Miſſiſippi, and the great rivers which flow into it. They graze in herds innumerable, along with the ſtags and buffaloes. This ſpecies probably extends to Guiana, and is the *baieu* of that country, which is ſaid to be about the ſize of a European buck, with ſhort horns, bending at their ends. They are capable of being made tame; and when properly trained, are uſed by the Indians to decoy the wild deer (eſpecially in the rutting ſeaſon) within ſhot. Both bucks and does herd from September to March; after that they ſeparate, and the does ſecret themſelves to bring forth, and are found with difficulty. The bucks from this time keep ſeparate till the amorous ſeaſon of September revolves. The deer begin to feed as ſoon as night begins; and ſometimes in the rainy ſeaſon, in the day; otherwiſe they ſeldom or never quit their haunts. An old American ſportſman has remarked that the bucks will keep in the thickets for a year, or even two.

Theſe animals are very reſtleſs, and always in motion, coming and going continually. Thoſe which live near the ſhore are lean and bad, ſubject to worms in their heads and throats, generated from the eggs depoſited in thoſe parts. Thoſe that frequent the hills and ſavannas are in better caſe, but the veniſon is dry. In hard winters they will feed on the long moſs which hangs from the trees in the northern parts.

Theſe and other cloven-footed quadrupeds of America are very fond of ſalt, and reſort eagerly to the places impregnated with it. They are always ſeen in great numbers in the ſpots where the ground has been torn by torrents or other accidents, where they are ſeen licking the earth. Such ſpots are called *licking-places*. The huntſmen are ſure of finding the game there; for notwithſtanding they are often diſturbed, the buffaloes and deer are ſo paſſionately fond of the ſavoury regale, as to bid defiance to all danger, and return in droves to theſe favourite haunts.

The deer are of the firſt importance to the ſavages. The ſkins form the greateſt branch of their traffic, by which they procure from the coloniſts, by way of exchange, many of the articles of life. To all of them the fleſh is the principal food throughout the year; for drying it over a gentle but clear fire, after cutting it into ſmall pieces, it is not only capable of long preſervation, but is very portable in their ſudden excurſions, eſpecially when reduced to powder, which is frequently done.

Hunting is more than an amuſement to theſe people. They give themſelves up to it not only for the ſake of ſubſiſtence, but to fit themſelves for war, by habituating themſelves to fatigue. A good huntſman is an able warrior. Thoſe who fail in the ſports of the field are never ſuppoſed to be capable of ſupporting the hardſhips of a campaign; they are degraded to ignoble offices, ſuch as dreſſing the ſkins of deer, and other employs allotted only to ſlaves and women. When a large party meditates a hunting-match, which is uſually at the beginning of winter, they agree on a place of rendezvous, often 500 miles diſtant from their homes, and a place perhaps that many of them had never been at. They have no other method of fixing on the ſpot than by pointing with their finger. The preference is given to the eldeſt, as the moſt experienced. When this matter is ſettled, they ſeparate into ſmall parties, travel and hunt for ſubſiſtence all the day, and reſt at night; but the women have no certain reſting-places. The ſavages have their particular hunting countries; but if they invade the limits of thoſe belonging to other nations, feuds enſue, fatal as thoſe between Percy and Douglas in the famed Chevy Chace. As ſoon as they arrive on the borders of the hunting country (which they never fail doing to a man, be their reſpective routes every ſo diſtant or ſo various), the captain of the band delineates on the bark of a tree his own figure with a rattleſnake twined round him with diſtended mouth; and in his hand a bloody tomahawk. By this he implies a deſtructive menace to any who are bold enough to invade their territories, or to interrupt their diverſion.—The chaſe is carried on in different ways. Some ſurpriſe the deer by uſing the ſtale of the head, horns, and hide; but the general method is performed by the whole body. Several hundreds diſperſe in a line, encompaſſing a vaſt ſpace of country, fire the woods, and drive the animals into ſome ſtrait or peninſula, where they become an eaſy prey. The deer alone are not the object; foxes, raccoons, bears, and all beaſts of fur, are thought worthy of attention, and form articles of commerce with the Europeans.

The number of deer deſtroyed in ſome parts of America is incredible; as is pretended, from an abſurd idea which the ſavages have, that the more they deſtoy, the more they ſhall find in ſucceeding years. Certain it is that multitudes are deſtroyed; the tongues only preſerved, and the carcaſes left a prey to wild beaſts. But the motive is much more political. The ſavages well diſcern, that ſhould they overſtock the market, they would certainly be over-reached by the European dealers, who take care never to produce more goods than are barely ſufficient for the demand of the ſeaſon, eſtabliſhing their prices according to the quantity of furs brought by the natives.

Cervus Volans, in natural hiſtory, a name given by authors to the ſtag-fly, or horned beetle, a very large ſpecies of beetle with horns ſloped, and ſomething like thoſe of the ſtag.

CERYX, in antiquity. The ceryces were a ſort of public criers appointed to proclaim or publiſh things aloud in aſſemblies. The *ceryx* among the Greeks anſwered to the *præco* among the Romans. Our criers have only a ſmall part of their office and authority.

There were two kinds of ceryces, *civil* and *ſacred*. The former were thoſe appointed to call aſſemblies and make ſilence therein; alſo to go on meſſages, and do the office of our heralds, &c. The ſacred ceryces were a ſort of prieſts, whoſe office was to proclaim ſilence in the public games and ſacrifices, publiſh the names of the conquerors, proclaim feaſts, and the like. The prieſthood of the ceryces was annexed to a particular family, the deſcendants of Ceryx, ſon of Eumolphus. To them it alſo belonged to lead ſolemn victime to ſlaughter. Before the ceremonies began, they called ſilence in the aſſembly, by the formula, Ευφημειτε σιγη ϖας εσω λεως; anſwering to the *favete linguis* of the Romans. When the ſervice was over, they diſmiſſed the people with this formula, Δαων αφεσις, *Ite miſſa eſt.*

CESARE, among logicians, one of the modes of the ſecond figure of ſyllogiſms; the minor propoſition of which is an univerſal affirmative, and the other two univerſal negatives: thus,

Ce No immoral books ought to be read;
Sa But every obſcene book is immoral;
Re Therefore no obſcene books ought to be read.

CECENA, a town of Romagna in Italy, with a biſhop's ſee, ſubject to the pope, and ſeated on the river Savio, in E. Long. 12. 46. N. Lat. 44. 8.

CESPITOSÆ plantæ (from *ceſpes*, turf or ſod) are thoſe plants which produce many ſtems from one root, and thence form a cloſe thick carpet on the ſurface of the earth.

Cespitosæ Paludes, turf-bogs.

CESSATION, the act of intermitting, diſcontinuing or interrupting the courſe of any thing, work, action or the like.

Cessation of Arms, an armiſtice or occaſional truce. See Truce.

When the commander of a place finds things reduced to an extremity, ſo that he muſt either ſurrender, or ſacrifice the garriſon and inhabitants to the mercy of the enemy, he plants a white flag on the breach, or beats the chamade; on which a ceſſation of arms and hoſtilities commences, to give room for a capitulation.

CESSIO bonorum, in Scots law, the name of that action by which an inſolvent debtor may apply for liberation from priſon, upon making over his whole real and perſonal eſtate to his creditors.

CESSION, in law, an act by which a perſon ſurrenders and tranſmits to another perſon a right which belonged to himſelf. Ceſſion is more particularly uſed in the civil law for a voluntary ſurrender of a perſon's effects to his creditors, to avoid impriſonment. See the article Bankrupt.

In ſeveral places the ceſſion carried with it a mark of infamy, and obliged the perſon to wear a green cap or bonnet; at Lucca, an orange one: to neglect this was to forfeit the privileges of the *ceſſion*. This was originally intended to ſignify that the ceſſionary was become poor through his own folly. The Italian lawyers deſcribe the ceremony of ceſſion to conſiſt in ſtriking the bare breech three times againſt a ſtone, called *Lapis Vituperii*, in preſence of the judge. Formerly it conſiſted in giving up the girdles and keys in court: the ancients uſing to carry at their girdles the chief utenſils wherewith they got their living; as the ſcrivener his eſcritoire, the merchant his bag, &c. The form of ceſſion among the ancient Gauls and Romans was as follows: The ceſſionary gathered up duſt in his left hand from the four corners of the houſe, and ſtanding on the threſhold, holding the door poſt in his right hand, threw the duſt back over his ſhoulders; then ſtripping to his ſhirt, and quitting his girdle and bags, he jumped with a pole over the hedge; hereby letting the world know, that he had nothing left, and that when he jumped all he was worth was in the air with him. This was the ceſſion in criminal matters. In civil caſes, it was ſufficient to lay a broom, a ſwitch or a broken ſtraw, on the threſhold: this was called *chrenecruda per durpillum et feſtucam*.

Cession, in the eccleſiaſtical law, is when an eccleſiaſtical perſon is created a biſhop, or when a parſon of a pariſh takes another benefice, without diſpenſation, or being otherwiſe qualified. In both theſe caſes their firſt benefices became void by ceſſion, without any reſignation; and to thoſe livings that the perſon had, who was created biſhop, the king may preſent for that time, whoſoever is patron of them; and in the other caſe the patron may preſent: but by diſpenſation of retainder, a biſhop may retain ſome or all the preferments he was intitled to before he was made biſhop.

CESTRUM, bastard jasmine: A genus of the monogynia order, belonging to the pentandria claſs of plants; and in the natural method ranking under the 28th order, *Luridæ*. The corolla is funnel-ſhaped; the ſtamina each ſending out a little tooth about the middle of the inſide. There are ſix ſpecies, all of them natives of the warmeſt parts of America; ſo cannot be preſerved in Britain without artificial heat. They are flowering ſhrubs, riſing in height from five to twelve feet, with flowers of a white, herbaceous, or pale yellow colour. The flowers of one ſpecies commonly called *Badmington Jaſmine*, have the property of ſending out a ſtrong ſcent after ſunſet. They may be propagated either by ſeeds or cuttings.

CESTUI, a French word, ſignifying *he* or *him*, frequently uſed in the Engliſh law writings. Thus, *Ceſtui qui truſt*, a perſon who has lands, &c. committed to him for the benefit of another; and if ſuch perſon does not perform his truſt, he is compellable to it in chancery. *Ceſtui qui vie*, one for whoſe life any lands, &c. are granted. *Ceſtui qui uſe*, a perſon to whoſe uſe any one is infeoffed of lands or tenements. Formerly the feoffees to uſes were deemed owners of the

the land, but now the poſſeſſion is adjudged in *ceſtui qui uſe*.

CESTUS, among ancient poets, a fine embroidered girdle ſaid to be worn by Venus, to which Homer aſcribes the power of charming and conciliating love. The word is alſo written *ceſtum* and *ceſton*: it comes from κεϛος, *a girdle*, or other thing embroidered or wrought with a needle; derived, according to Servius, from κεντειν, *pungere*; whence alſo *inceſtus*, a term uſed at firſt for any indecency by undoing the girdle, &c. but now reſtrained to that between perſons near akin. See INCEST.

CETACEOUS, an appellation given to the fiſhes of the whale kind; the characters of which are: they have no gills; there is an orifice on the top of the head, through which they breathe and eject water; and they have a flat or horizontal tail.

Nature on this tribe hath beſtowed an internal ſtructure in all reſpects agreeing with that of quadrupeds; and in a few others the external parts in both are ſimilar. Cetaceous fiſh, like land animals, breathe by means of lungs, being deſtitute of gills. This obliges them to riſe frequently on the ſurface of the water to reſpire, to ſleep on the ſurface, as well as to perform ſeveral other functions. They have the power of uttering ſounds, ſuch as bellowing and making other noiſes denied to genuine fiſh. Like land animals they have warm blood, are furniſhed with organs of generation, copulate, bring forth, and ſuckle their young, ſhowing a ſtrong attachment to them. Their bodies beneath the ſkin are entirely ſurrounded with a thick layer of fat (blubber), analogous to the lard on hogs. The number of their fins never exceed three, *viz.* two pectoral fins, and one back fin; but in ſome ſpecies the laſt is wanting. Their tails are placed horizontally, or flat in reſpect to their bodies; contrary to the direction of thoſe of all other fiſh, which have them in a perpendicular ſite. This ſituation of the tail enables them to force themſelves ſuddenly to the ſurface of the water to breathe, which they are ſo frequently conſtrained to do. Many of theſe circumſtances induced Linnæus to place this tribe among his *mammalia*, or what other writers call *quadrupeds**. To have preſerved the chain of beings entire, he ſhould in this caſe have made the genus of *phocæ* or *ſeals*, and that of the *tricheus* or *manati*, immediately precede the whale, thoſe being the links that connect the mammalia or quadrupeds with the fiſh: for the ſeal is, in reſpect to its legs, the moſt imperfect of the former claſs; and in the manati the hind feet coaleſce, aſſuming the form of a broad horizontal tail.

* See Zoology.

Notwithſtanding the many parts and properties which cetaceous fiſh have in common with land animals, yet there ſtill remain others which render it more natural to place them, with Ray, in the rank of fiſh: the form of their bodies agrees with that of fiſh; they are entirely naked, or covered only with a ſmooth ſkin; they live conſtantly in the water, and have all the actions of fiſh.

CETE, the name of Linnæus's ſeventh order of mammalia, comprehending the MONODON, BALÆNA, PHYSETER, and DELPHINUS.

CETERACH, in botany, the trivial name of a ſpecies of ASPLENIUM.

CETTE, a maritime town of France, in Languedoc, ſeated at the place where the canal of Languedoc begins, between Montpellier and Agde, on the bay of Magnelona in the Mediterranean ſea. E. Long. 3. 15. N. Lat. 43. 25.

CETUS, in aſtronomy, the whale; a large conſtellation of the ſouthern hemiſphere, under Piſces, and next the water of Aquarius. The ſtars in the conſtellation Cetus, in Ptolemy's catalogue, are twenty-two; in Tycho's twenty-one; in Hevelius's forty-five; in the Britannic catalogue ninety-ſeven.

Cetus is repreſented by the poets, as the ſea-monſter which Neptune, at the ſuit of the nymphs, ſent to devour Andromeda for the pride of her mother, and which was killed by Perſeus. In the mandible of cetus is a variable ſtar which appears and diſappears periodically, paſſing through the ſeveral degrees of magnitude both increaſing and diminiſhing, in about 333 days. See ASTRONOMY, n° 45.

CEVA, a ſtrong town of Piedmont in Italy, ſeated on the river Tanero, with a ſtrong fort, in E. Long. 8. 8. N. Lat. 44. 20.

CEVENNES, mountains of Languedoc in France, remarkable for the frequent meetings of the Proteſtants there as a place of ſecurity againſt the tyranny of their governors. In queen Anne's reign there was an attempt made to aſſiſt them by an Engliſh fleet in the Mediterranean; but to no purpoſe, for the French had occupied the paſſages.

CEUTA, a maritime town of Barbary in Africa, and in the kingdom of Fez, ſeated on the ſtraits of Gibraltar, oppoſite that place, in W. Long. 6. 25. N. Lat. 36. 35. John king of Portugal took it from the Moors in 1415, but it now belongs to Spain. In 1697, it ſuſtained a vigorous ſiege by the Moors.

CEYLON, a large iſland in the Eaſt Indies, about 250 miles in length and 200 in breadth. It abounds in trees and ſhrubs, valuable both on account of their timber and the gums or ſpices they produce. Among theſe Mr Ives enumerates the euphorbium, tulip-tree, ebony, red-wood, caſſia, cocoa-nut, cotton, lime, mangoe, citron, coffee; the trees producing balſam of capivi, gum gamboge, lac, and *cenquenomale*. This laſt is as yet unknown in Europe; but, according to the information of a Dutch ſurgeon, an oil or balſam is produced from it by diſtillation, which is of great uſe in paralytic complaints. There is alſo another gum named *badule*, which has been but lately diſcovered, and of which the uſe is as yet unknown. Here is alſo the black and yellow *teak*, the wood of which is of a moſt beautiful grain, but ſo hard that the cutting of it proves very duſtructive to the carpenters tools. But the moſt remarkable, as well as the moſt uſeful, of the vegetable productions of Ceylon, is the cinnamon-tree, which grows wild in every wood on the ſouth-weſt part of the iſland. The very young trees are not fit for rinding, and the old ones are cut down for firewood. The common flowering ſhrubs, of which the whole iſland is full, ſend forth a moſt agreeable fragrance every morning and evening. It abounds with high hills, between which the ſoil is a fat red earth; and the valleys are extremely pleaſant, having a clear rivulet running thro' almoſt every one of them. Thus the fineſt fruits grow in vaſt plenty, and may be had at the moſt trifling rates; a pine-apple being bought for leſs than a penny, and ſo of the reſt. Other proviſions are almoſt equally cheap ; a dozen of fowls or five ducks being ſold for a rupee, not quite half-a-crown of Engliſh money. Here the Dutch ſhow a poiſonous fruit called by them *Adam's apple.* In ſhape it reſembles the quarter of an apple cut out, with the two inſides a little convex, and a continued ridge along the outer edges ; and is of a beautiful orange colour. Pepper, ginger, and cardamoms, are alſo produced here ; as well as five kinds of rice, which ripen one after another.

Ceylon produces alſo topazes, garnets, rubies, and other precious ſtones, which are diſcovered by waſhing the ſoil wherein they grow. It has likewiſe ores of copper, iron, and probably of tin, with veins of black cryſtal.

Common deer are found in this iſland in great abundance, as well as Guinea-deer ; but the horned cattle are both very ſmall and ſcarce, ſix of them weighed all together, but 714 pounds, and one of theſe weighed, only 70 pounds. They have, however, the largeſt and beſt elephants in the world ; and their woods are infeſted by tygers, the moſt terrible of all ravenous beaſts. They abound alſo with ſnakes of a monſtrous ſize, one of which has been known to deſtroy a tyger and devour him at one meal. Mr Ives ſaw one 15 feet long and 30 inches in circumference. Spiders, centipedes, and ſcorpions, alſo grow here to an enormous ſize. Our author ſaw a ſpider here as large as a toad, with brown hair upon it, and legs as thick as the ſhank of a large tobacco-pipe. A ſcorpion, taken out of a piece of wood, was eight inches long, from head to tail, excluſive of the claws ; the ſhell was as hard as that of a crab : and our author killed a centipede more than ſeven inches long. Here the *mantis* or creeping leaf is met with ; which our author ſuppopoſes to be a ſpecies of graſshoppers, having every member we ſee in common inſects, though in ſhape and appearance it greatly reſembles a leaf. It is of a green colour. The ſea-coaſts abound with fiſh, which are to be had very cheap. Neither harp-ſhells nor ventletraps are to be met with here : but there are abundance of painted cockles, and others commonly called *panama ſhells.*

“ The natives of this iſland (ſays our author) are the ſtouteſt Indians I ever ſaw. Mr Knox in his hiſtory reports many ſtrange things of their religion and cuſtoms, none of which I had any opportunity of ſeeing. He ſays ‘ that they have various ways of treating their dead. Some burn them, which is not uncommon in India ; while others throw their limbs up into the forks of trees.’ This may be true, becauſe when our wood-cutters were once hewing down a ſtick of timber, there fell from it the ſkull and many bones of a human body ; and I alſo ſaw here a human body hanging on a tree. Other hiſtorians relate, that the natives of Ceylon feed on human fleſh ; nay, that they eat the bodies of their deceaſed parents, imagining that no other ſepulchre is ſo fit for them as their own bowels, ſince thereby they think they are changed into their own ſubſtance, and live again in themſelves. This ſhocking cuſtom is reported of the ancient Scythians, and poſſibly might have been uſed by the inhabitants of Ceylon, but is now in both countries entirely aboliſhed ; and yet even at this day theſe iſlanders are ſaid to make cups of their parents ſkulls, with a view, that in midſt of their mirth and jollity they may be ſure to preſerve a reſpectful remembrance of them.”

The Ceyloneſe make uſe of boats hollowed out of the trunks of trees, which are about 12 or 14 feet long, but only as many inches broad within. The tree part in the bottom is much larger ; but when the boat, on account of the ſize of the tree, is too ſmall, they make a trough on the top of it ſquare at both ends. Some boats, however, are much larger, being built between two trees ; and with theſe they coaſt along ſhore ; the others are for fiſhermen. It lies from E. Long. 78° to 82°, and from N. Lat. 6° to 10.

The conqueſt of this iſland was the firſt attempt of Albuquerque the celebrated Portugueſe admiral. He found it well peopled, and inhabited by two different nations, the *Bedas* inhabiting the northern, and the *Cinglaſſes* who dwelt in the ſouthern parts. The former were very barbarous, but the latter a good deal more poliſhed. Beſides the advantages already mentioned, which theſe nations derived from their mines of precious ſtones, they carried on the greateſt pearl-fiſhery in the Eaſt. Theſe nations the Portugueſe conquered, and tyrannized over in ſuch a manner, that they aſſiſted the Dutch in expelling them from the iſland ; and by their united efforts this was accompliſhed in 1658, after a bloody and obſtinate war. All the Portugueſe ſettlements fell into the hands of the Dutch Eaſt India company, who ſtill keep poſſeſſion of them, excepting a ſmall diſtrict on the eaſtern coaſt without any port, from whence the ſovereign of the country had his ſalt. Theſe ſettlements formed a regular track, extending from two to twelve leagues into the inland parts of the iſland. The company have appropriated all the productions of the iſland. The ſeveral articles of trade are, 1. Amethyſts, ſapphires, topazes, and rubies ; the laſt are very ſmall, and very indifferent. The Moors who come from the coaſt of Coromandel buy them, paying a moderate tax : and when they are cut, ſell them at a low price in the different countries of India. 2. Pepper, which the company buy for about 4d. *per* pound ; coffee, for which they only pay 2d. and cardamom, which has no fixed price. Theſe articles are all of an inferior quality, and through the indolence of the inhabitants will never turn to any account. 3. An hundred bales of handkerchiefs, pagnes, and ginghams, of a fine red colour, which are fabricated by the Malabars of Jafranapatan. 4. A ſmall quantity of ivory, and about 50 elephants, which are carried to the coaſt of Coromandel. 5. Areca, which the company buys at about 8s. 9d. the ammonan, and ſells on the ſpot at L. 1, 13s. to the merchants of Bengal, Coromandel, and the Maldives ; who give in return rice, coarſe linen, and cowries. 6. The pearl fiſhery, which was formerly of great conſequence ; but is now ſo much exhauſted as not to bring in more than L. 8,750 *per annum.* 7. After all, the great object of the company is cinnamon. They purchaſe the greateſt part of their cinnamon of the Indians who are ſubject to them, and, all expences deducted, it does not coſt them above 6d. *per* pound. The annual expences of the colony may amount to about L. 96,250 ; their revenues and ſmall branches of commerce produce only about L. 87,500. —This deficiency muſt be ſupplied out of the profits

fits ariſing from the cinnamon trade; and they are obliged to provide for the expences of the wars in which they are frequently engaged with the king of Candy, who is at preſent the ſole ſovereign of the iſland. Theſe are very detrimental to the intereſts of the Hollanders; for which reaſon they endeavoured to engage the good will of this monarch by ſhowing him all imaginable civilities. The harmony, however, has been often interrupted. In a bloody war which terminated on the 14th of February 1766, the Ceyloneſe monarch was driven from his capital, ſo that the Dutch made a very advantageous treaty. Their ſovereignty was acknowledged over all that part of the country they poſſeſſed before the troubles broke out; and that part of the coaſts held by the natives was ceded to them. They were allowed to gather cinnamon in all the plains; and the court was to ſell them the beſt ſort, which is produced in the mountains, at the rate of L. 1 : 16 : 8, for 18 *lb*. The government engaged to have no connection with any foreign power; and even to deliver up any Europeans who might happen to ſtray into the iſland. In return for ſo many conceſſions, the king was to receive annually the value of the produce of the ceded coaſts; and from thence his ſubjects were to be furniſhed gratis with as much ſalt as they had occaſion for. The Ceyloneſe are in the moſt miſerable ſituation: they are in a ſtate of total inactivity; live in huts without any furniture; and ſubſiſt upon fruits: thoſe who are the moſt affluent have no other covering than a piece of coarſe linen wrapt about their waiſt.

CHACE. See CHASE.

CHACO, a large country of South America ſituated between 19° and 37° S. Lat. It belongs to the Spaniards, by whom it was conquered in 1536. It is not naturally fruitful; but abounds in gold mines, which are ſo much the more valuable that they are eaſily worked. The works are carried on by about 8000 blacks, who deliver every day to their maſters a certain quantity of gold; and what they can collect above this, belongs to themſelves; as well as what they find on thoſe days that are conſecrated to religion and reſt, upon condition that during the feſtival they maintain themſelves. This enables many of them to purchaſe their liberty; after which they intermarry with the Spaniards.

CHADCHOD, in Jewiſh antiquity. Ezekiel mentions *chadchod* among the ſeveral merchandizes which were brought to Tyre. The old interpreters, not very well knowing the meaning of this term, continued it in their tranſlation. St Jerom acknowledges that he could not diſcover the interpretation of it. The Chaldee interprets it pearls; others think that the onyx, ruby, carbuncle, cryſtal or diamond is meant by it.

CHÆRONEA, (anc. geog.) the laſt town, or rather the laſt village, of Bœotia, towards Phocis; the birth-place of Plutarch: famous for the fatal defeat of the confederate Greeks by Philip of Macedon. This place was conſidered by Philip as well adapted to the operations of the Macedonian phalanx; and the ground for his encampment, and afterwards the field of battle, were choſen with equal ſagacity: having in view on one ſide a temple of Hercules, whom the Macedonians regarded as the author of their royal houſe, and the high protector of their fortune; and on the other the banks of the Thermodon, a ſmall river flowing into the Cephiſſus, announced by the oracles of Greece as the deſtined ſcene of deſolation and woe to their unhappy country. The generals of the confederate Greeks had been much leſs careful to avail themſelves of the powerful ſanctions of ſuperſtition. Unreſtrained by inauſpicious ſacrifices, the Athenians had left their city at the exhortation of Demoſthenes, to wait no other omen but the cauſe of their country. Regardleſs of oracles, they afterwards advanced to the ill-fated Thermodon, accompanied by the Thebans, and the ſcanty reinforcements raiſed by the iſlands and ſtates of Peloponneſus which had joined their alliance. Their army amounted to 30,000 men, animated by the nobleſt cauſe for which men can fight, but commanded by the Athenians Lyſicles and Chares; the firſt but little, and the ſecond unfavourably, known; and by Theagenes the Theban, a perſon ſtrongly ſuſpected of treachery: all three creatures of cabal and tools of faction, ſlaves of intereſt or voluptuouſneſs, whoſe characters (eſpecially as they had been appointed to command the only ſtates whoſe ſhame, rather than virtue, yet oppoſed the public enemy) are alone ſufficient to prove that Greece was ripe for ruin.

When the day approached for aboliſhing the tottering independence of thoſe turbulent republics, which their own internal vices, and the arms and intrigues of Philip, had been gradually undermining for 22 years, both armies formed in battle array before the riſing of the ſun. The right wing of the Macedonians was headed by Philip, who judged proper to oppoſe in perſon the dangerous fury of the Athenians. His ſon Alexander, only 19 years of age, but ſurrounded by experienced officers, commanded the left wing, which faced the Sacred Band of the Thebans. The auxiliaries of either army were poſted in the centre. In the beginning of the action, the Athenians charged with impetuoſity, and repelled the oppoſing diviſions of the enemy; but the youthful ardour of Alexander obliged the Thebans to retire, the Sacred Band being cut down to a man. The activity of the young prince completed their diſorder, and purſued the ſcattered multitude with his Theſſalian cavalry.

Meantime the Athenian generals, too much elated by their firſt advantage, loſt the opportunity to improve it; for having repelled the centre and right wing of the Macedonians, except the phalanx, which was compoſed of choſen men, and immediately commanded by the king, they, inſtead of attempting to break this formidable body by attacking it in flank, preſſed forward againſt the fugitives, the inſolent Lyſicles exclaiming in vain triumph, "Purſue, my brave countrymen! let us drive the cowards to Macedon." Philip obſerved this raſh folly with contempt; and ſaying to thoſe around him, "Our enemies know not how to conquer," commanded his phalanx, by a rapid evolution, to gain an adjacent eminence, from which they poured down, firm and collected, on the advancing Athenians, whoſe confidence of ſucceſs had rendered them totally inſenſible to danger. But the irreſiſtible ſhock of the Macedonian ſpear converted their fury into deſpair. Above a thouſand fell, two thouſand were taken priſoners; the reſt eſcaped by a precipitate and ſhameful flight. Of the Thebans more were killed than taken. Few of the confederates periſhed, as they had little ſhare in the action, and as Philip, perceiving his victory to be complete, gave orders to ſpare the vanquiſhed, with a clemency unuſual in that age, and not leſs honourable to his underſtanding than his heart; ſince his humanity thus ſubdued the minds, and gained the affections, of his conquered enemies.

According to the Grecian cuſtom, the battle was followed by an entertainment, at which the king preſiding in perſon, received the congratulations of his friends, and the humble ſupplications of the Athenian deputies, who craved the bodies of their ſlain. Their requeſt, which ſerved as an acknowledgement of their defeat, was readily granted; but before they availed themſelves of the permiſſion to carry off their dead, Philip, who with his natural intemperance had protracted the entertainment till morning, iſſued forth with his licentious companions to viſit the field of battle; their heads crowned with feſtive garlands, their minds intoxicated with the inſolence of wine and victory; yet the ſight of the ſlaughtered Thebans, which firſt preſented itſelf to their eyes, and particularly the ſacred band of friends and lovers, who lay covered with honourable wounds on the ſpot where they had been drawn up to fight, brought back theſe inſolent ſpectators to the ſentiments of reaſon and humanity. Philip beheld the awful ſcene with a mixture of admiration and pity; and, after an affecting ſilence, denounced a ſolemn curſe againſt thoſe who baſely ſuſpected the friendſhip of ſuch brave men to be tainted with criminal and infamous paſſions.

But this ſerious temper of mind did not laſt long; for having proceeded to that quarter of the field where the Athenians had fought and fallen, the king abandoned himſelf to all the levity and littleneſs of the moſt petulent joy. Inſtead of being impreſſed with a deep ſenſe of his recent danger, and with dutiful gratitude to Heaven for the happineſs of his eſcape and the importance of his victory, Philip only compared the boaſtful pretenſions with the mean performances of his Athenian enemies; and, ſtruck by this contraſt, rehearſed, with the inſolent mockery of a buffoon, the pompous declaration of war lately drawn up by the ardent patriotiſm and too ſanguine hopes of Demoſthenes. It was on this occaſion that the orator Demades at once rebuked the folly, and flattered the ambition of Philip, by aſking him, Why he aſſumed the character of Therſites when fortune aſſigned him the part of Agamemnon?

Whatever might be the effect of this ſharp reprimand, it is certain that the king of Macedon indulged not, on any future occaſion, a vain triumph over vanquiſhed. When adviſed by his generals to advance into Attica, and to render himſelf maſter of Athens, he only replied, "Have I done ſo much for glory, and ſhall I deſtroy the theatre of that glory?" His ſubſequent conduct correſponded with the moderation of this ſentiment. He reſtored without ranſom the Athenian priſoners; who, at departing, having demanded their baggage, were alſo gratified in this particular; the king pleaſantly obſerving, that the Athenians ſeemed to think he had not conquered them in earneſt. Soon afterwards he diſpatched his ſon Alexander, and Antipater, the moſt truſted of his miniſters, to offer them peace on ſuch favourable terms as they had little reaſon to expect. They were required to ſend deputies to the Iſthmus of Corinth, where, to adjuſt their reſpective contingents of troops for the Perſian expedition, Philip propoſed aſſembling early in the ſpring a general convention of all the Grecian ſtates: they were ordered to ſurrender the iſle of Samos, which actually formed the principal ſtation of their fleet, and the main bulwark and defence of all their maritime or inſular poſſeſſions; but they were allowed to enjoy, unmoleſted, the Attic territory, with their hereditary form of government.

CHÆROPHYLLUM, Chervil: A genus of the digynia order, belonging to the pentandria claſs of plants; and in the natural method ranking under the 45th order, *Umbellatæ*. The involucrum is reflexed-concave; the petals inflexed-cordate; the fruit oblong and ſmooth. There are ſeven ſpecies, two of which, called cow-weed and wild chervil, are weeds common in many places of Britain. The roots of the firſt have been found poiſonous when uſed as parſnips: the rundles afford an indifferent yellow dye; the leaves and ſtalks a beautiful green. Its preſence indicates a fertile and grateful ſoil. It ought to be rooted out from all paſtures early in the ſpring, as no animal but the aſs will eat it. It is one of the moſt early plants in ſhooting, ſo that by the beginning of April the leaves are near two feet high. The leaves are recommended by Geoffroy as aperient and diuretic, and at the ſame time grateful to the palate and ſtomach. He even aſſerts, that dropſies which do not yield to this medicine can ſcarcely be cured by any other. He directs the juice to be given in the doſe of three or four ounces every fourth hour, and continued for ſome time either alone, or in conjunction with nitre and ſyrup of the five opening roots.—The other ſpecies of chærophyllum are not poſſeſſed of any remarkable property.

CHÆTODON, in ichthyology, a genus of fiſhes belonging to the order of thoraci. The teeth are very numerous; thick, ſetaceous, and flexile; the rays of the gills are ſix. The back-fin and the fin at the anus are fleſhy and ſquamous. There are 23 ſpecies, diſtinguiſhed from each other principally by the figure of the tail, and the number of ſpines in the back-fin. The moſt remarkable is the roſtratus, or ſhooting-fiſh, having a hollow, cylindrical beak. It is a native of the Eaſt Indies, where it frequents the ſides of the ſea and rivers in ſearch of food, from its ſingular manner of obtaining which it receives its name. When it ſpies a fly ſitting on the plants that grow in ſhallow water, it ſwims on to the diſtance of four, five, or ſix feet; and then, with a ſurpriſing dexterity, it ejects out of its tubular mouth a ſingle drop of water, which never fails ſtriking the fly into the water, where it ſoon becomes its prey.

CHAFF, in huſbandry, the huſks of the corn, ſeparated by ſcreening or winnowing it. It ſignifies alſo the rind of corn, and ſtraw cut ſmall for the uſe of cattle.

Chaff-*Cutter*, a machine for making chaff to feed horſes.—The advantages of an eaſy and expeditious method of cutting ſtraw into chaff by an engine which could be uſed by common labourers have been long acknowledged, and various attempts have been made to bring ſuch an engine to perfection. But the objections to moſt of them have been their complicated ſtructure, their great price, and the noiſe they make in working; all which inconveniences ſeem to have been lately removed by an invention of Mr James Pike watchmaker of Newton Abbot in Devonſhire. Of his engine, which is of a ſimple and cheap conſtruction, the following deſcription, and figure referred to, are extracted from the Tranſactions of the Society of Arts for 1787.

The engine is fixed on a wood frame, which is ſupported with four legs, and on this frame is a box for containing the ſtraw, four feet ſix inches long, and about ten inches broad; at one end is fixed acroſs the box two rollers inlaid with iron, in a diagonal line about an eighth of an inch above the ſurface; on the ends of theſe rollers are fixed two ſtrong braſs wheels, which takes one into the other. On one of theſe wheels is a contrect wheel, whoſe teeth take in a worm on a large arbour; on the end of this arbour is fixed a wooden wheel, two feet five inches diameter and three inches thick; on the inſide-part of this wheel is fixed a knife, and every revolution of the wheel the knife paſſes before the end of the box and cuts the chaff, which is brought forward between the rollers, which are about two inches and a half aſunder; the ſtraw is brought on by the worm taking one tooth of the wheel every round of the knife; the ſtraw being ſo hard preſſed between the rollers, the knife cuts off the chaff with ſo great eaſe, that twenty-two buſhels can be cut within the hour, and makes no more noiſe than is cauſed by the knife paſſing through the chaff.

Plate CXXXVI. *A* is the box into which the ſtraw is put. *B*, the upper roller, with its diagonal projecting ribs of iron, the whole moving by the revolution of the braſs wheel *C* on the axis of which it is fixed. *D*, a braſs wheel, having upon it a face wheel, whoſe teeth take into the endleſs ſcrew on the arbour *E*, while the teeth on the edge of this wheel enter between thoſe on the edge of the wheel *C*. On the axis of the wheel *D* is a roller, with iron ribs ſimilar to *B*, but hid within the box. *E*, the arbour, one of the ends of which being made ſquare and paſſing through a mortiſe in the centre of the wooden wheel *F*, is faſtened by a ſtrong ſcrew and nut; the other end of this arbour moves round in a hole within the wooden block *G*. *H*, the knife, made faſt by ſcrews to the wooden wheel *F*, and kept at the diſtance of nearly three quarters of an inch from it by means of a ſtrip of wood of that thickneſs, of the form of the blade, and reaching to within an inch of the edge. *I*, the handle mortiſed into the outſide of the wooden wheel *F*.

CHAFFER, in zoology, a ſpecies of beetle. See Scarabæus.

CHAFFERCONNERS, in commerce, printed linens manufactured in the Great Mogul's dominions. They are imported by the way of Surat; and are of the number of thoſe linens prohibited in France.

CHAFFERY, in the iron-works, the name of one of the two principal forges. The other is called the *finery*. When the iron has been brought at the finery into what is called an ancony, or ſquare maſs, hammered into a bar in its middle, but with its two ends rough, the buſineſs to be done at the chaffery is the reducing the whole to the ſame ſhape, by hammering down theſe rough ends to the ſhape of the middle part.

CHAFFINCH, in ornithology, the Engliſh name of a ſpecies of Fringilla.

CHAGRE, a fort of America in the province of Darien at the mouth of a river of the ſame name. It has been taken ſeveral times by the buccaneers, and laſt of all by Admiral Vernon in 1740. W. Long. 82. 7. N. Lat. 9. 50.

CHAIN, (*Catena*) a ſeries of ſeveral rings, or links, fitted into one another.

There are chains of divers matters, ſizes, forms, and for divers uſes.—Ports, rivers, ſtreets, &c. are cloſed with iron chains: rebellious cities are puniſhed by taking away their chains and barriers.

The arms of the kingdom of Navarre are, *Chains, Or, in a field Gules*. The occaſion hereof is referred to the kings of Spain leagued againſt the Moors; who having gained a celebrated victory againſt them in 1212, in the diſtribution of the ſpoils the magnificent tent of Miralmumin fell to the king of Navarre, as being the firſt that broke and forced the chains thereof.

A gold Chain, is one of the ornaments or badges of the dignity of the chief magiſtrates of a city, as the mayor of London, the provoſt and bailies of Edinburgh, &c.—Something like this obtained among the ancient Gauls: the principal ornament of their perſons in power and authority was a gold chain, which they wore on all occaſions; and even in battle, to diſtinguiſh them from the common ſoldiers.

Chain alſo denotes a kind of ſtring, of twiſted wire; ſerving to hang watches, tweezer-caſes, and other valuable toys upon. The invention of this piece of curious work is owing to the Engliſh; whence, in foreign countries, it is denominated the *Engliſh chain*. Theſe chains are uſually either of ſilver or gold, ſome of gilt copper; the thread or wire of each kind to be very fine.—For the fabric, or making of theſe chains: a part of the wire is folded into little links of an oval form; the longeſt diameter about three lines; the ſhorteſt one. Theſe, after they have been exactly ſoldered, are again folded into two; and then bound together or interwove, by means of ſeveral other little threads of the ſame thickneſs; ſome whereof, which paſs from one end to the other, imitate the warp of a ſtuff; and the others, which paſs tranſverſe, the woof. There are at leaſt four thouſand little links in a chain of four pendants; which are by this means bound ſo equally, and withal ſo firmly together, that the eye is deceived, and takes the whole to conſiſt of one entire piece.

Chain is alſo a kind of meaſure in France, in the trade of wood for fuel. There are chains for wood by tale, for wood by the rope, for faggots, for cleft wood, and for round ſticks. There are alſo chains for meaſuring the ſheaves of all ſorts of corn, particularly with regard to the payment of tithes; for meaſuring pottles of hay, and for meaſuring horſes. All theſe are divided into feet, inches, hands, &c. according to the uſe they are deſigned for.

Chain, in ſurveying, is a meaſure, conſiſting of a certain number of links of iron wire, uſually a hundred; ſerving to take the dimenſions of fields, &c.

This is what Merſenne takes to be the arvipendium of the ancients.

The chain is of various dimenſions, as the length or number of links varies: that commonly uſed in meaſuring land, called Gunter's chain, is in length four poles or perches: or ſixty-ſix feet, or a hundred links; each link being ſeven inches $\frac{92}{100}$. Whence it is eaſy to reduce any number of thoſe links to feet, or any number of feet to links.

This chain is entirely adapted to Engliſh meaſures; and its chief convenience is in finding readily the numbers contained in a given field. Where the proportions of ſquare feet and acres differ, the chain, to have the ſame advantages as Gunter's chain, muſt alſo be varied. Thus in Scotland, the chain ought to be of 74 feet, or 24 Scotch ells, if no regard be had to the difference between the Scotch and Engliſh foot; but if regard be had to this difference, the Scotch chain ought to conſiſt of $74\frac{2}{5}$ Engliſh feet, or 74 feet 4 inches and $\frac{4}{5}$ of an inch. This chain being divided into an hundred links, each of theſe will be $8\frac{928}{1000}$ inches.

That ordinarily uſed for large diſtances, is in length a hundred feet; each link one foot. For ſmall parcels, as gardens, &c. is ſometimes uſed a ſmall chain of one pole, or ſixteen feet and a half length; each link one inch $\frac{98}{100}$.

Some in lieu of chains uſe ropes; but theſe are liable to ſeveral irregularities; both from the different degrees of moiſture, and of the force which ſtretches them. Schwenterus, in his Practical Geometry, tells us, he has obſerved a rope ſixteen feet long, reduced to fifteen in an hour's time, by the mere falling of a hoar froſt. To obviate theſe inconveniences, Wolfius directs, that the little ſtrands whereof the rope conſiſts be twiſted contrary ways, and the rope dipped in boiling hot oil; and when dry, drawn through melted wax. A rope thus prepared, will not get or loſe any thing in length, even though kept under water all day.

Chain-Pump. See Pump.

Chain-Shot, two bullets with a chain between them. They are uſed at ſea to ſhoot down yards or maſts, and to cut the ſhrouds or rigging of a ſhip.

Top-Chain, on board a ſhip, a chain to ſling the ſail-yards in time of battle, in order to prevent them from falling down when the ropes by which they are hung happen to be ſhot away or rendered incapable of ſervice.

Plate CXXXVI. *Chain-Wales*, or *Channels*, of a ſhip, *porteboiſſoirs*, are broad and thick planks projecting horizontally from the ſhip's outſide, abreaſt of and ſomewhat behind the maſts. They are formed to extend the ſhrouds from each other, and from the axis or middle line of the ſhip, ſo as to give a greater ſecurity and ſupport to the maſts, as well as to prevent the ſhrouds from damaging the gunwale, or being hurt by rubbing againſt it. Every maſt has its chain-wales, which are either built above or below the ſecond deck-ports in a ſhip of the line: they are ſtrongly connected to the ſide by knees, bolts, and ſtandards, beſides being confined thereto by the chains whoſe upper ends paſs through notches on the outer edge of the chain-wales, ſo as to unite with the ſhrouds above.

Chains, in ſhip-building, are ſtrong links or plates of iron, the lower ends of which are bolted through the ſhip-ſide to the timbers.

Hanging in Chains, a kind of puniſhment inflicted on murderers. By ſtat. 25. Geo. II. c. 37. the judge ſhall direct ſuch to be executed on the next day but one, unleſs Sunday intervene; and their bodies to be delivered to the ſurgeons to be diſſected and anatomized: and he may direct them afterwards to be hung in chains. During the interval between ſentence and execution, the priſoner ſhall be kept alone, and ſuſtained only with bread and water. The judge, however, hath power to reſpite the execution, and relax the other reſtraints of the act.

Chain-Iſland, an iſland lately diſcovered by captain Wallis in the South-ſea. It ſeemed to be about five miles long and as much broad, lying in the direction of north-weſt and ſouth-eaſt. It appeared to be a double range of woody iſlands joined together by reefs, ſo as to compoſe one iſland of an oval figure, with a lake in the middle. The trees are large; and from the ſmoke that iſſued from the woods, it appeared to be inhabited. W. Long. 145. 54. S. Lat. 17. 23.

CHAJOTLI, or Chayoti, a Mexican fruit of a round ſhape, and ſimilar in the huſk with which it is covered to the cheſnut, but four or five times larger, and of a much deeper green colour. Its kernel is of a greeniſh white, and has a large ſtone in the middle, which is white, and like it in ſubſtance. It is boiled, and the ſtone eat with it. This fruit is produced by a twining perennial plant, the root of which is alſo good to eat. See Plate CXXXVIII.

CHAIR, (*Cathedra*) was anciently uſed for the pulpit, or ſuggeſtum, whence the prieſt ſpoke to the people.

It is ſtill applied to the place whence profeſſors and regents in univerſities deliver their lectures, and teach the ſciences to their pupils: thus, we ſay, the profeſſor's chair, the doctor's chair, &c.

Curule Chair. was an ivory ſeat placed on a car, wherein were ſeated the prime magiſtrates of Rome, and thoſe to whom the honour of a triumph had been granted.

Sedan Chair, a vehicle ſupported by poles, wherein perſons are carried; borne by two men. There are two hundred chairs allowed by act of parliament in London; and no perſon is obliged to pay for a hackney-chair more than the rate allowed by the act for a hackney-coach driven two-third parts of the ſaid diſtance. 9 Ann. c. 23. § 8. Their number is ſince increaſed, by 10 Ann. c. 19. and 12 Geo. I. c. 12. to four hundred. See *Hackney-Coaches*.

Chair is alſo applied by the Romaniſts to certain feaſts, held anciently in commemoration of the tranſlation of the ſee, or ſeat of the vicarage of Chriſt, by St Peter.

The perforated chair, wherein the new-elected pope is placed, F. Mabillon obſerves, is to be ſeen at Rome: but the origin thereof he does not attribute, as is commonly done, to the adventure of Pope Joan; but ſays there is a myſtery in it; and it is intended, to explain to the pope thoſe words of ſcripture, that *God draws the poor from out of the duſt and mire*.

CHAIRMAN, the president, or ſpeaker of an aſſembly,

aſſembly, company, &c. We ſay, the chairman of a committee, &c.

CHAISE, a ſort of light open chariot, or calaſh. Aurelius Victor relates, that Trajan firſt introduced the uſe of poſt-chaſes: but the invention is generally aſcribed to Auguſtus; and was probably only improved by Trajan, and ſucceeding emperors.

CHALAZA, among naturaliſts, a white knotty ſort of ſtring at each end of an egg, formed of a plexus of the fibres of the membranes, whereby the yolk and white are connected together. See EGG.

CHALCAS, in botany: A genus of the monogynia order, belonging to the pentandria claſs of plants. The calyx is quinquepartite; the corolla campanulated, with the petals heeled; the ſtigma round-headed and warty.

CHALCEDON, or CALCEDON, anciently known by the names of *Proceraſtis* and *Colbuſa;* a city of Bithynia, ſituated at the mouth of the Euxine, on the north extremity of the Thracian Boſphorus, over againſt Byzantium. Pliny, Strabo, and Tacitus, call it *The City of the Blind;* alluding to the anſwer which the Pythian Apollo gave to the founders of Byzantium, who, conſulting the oracle relative to a place where to build a city, were directed to chooſe that ſpot which lay oppoſite "to the habitation of the blind;" that is, as was then underſtood, to Chalcedon: the Chalcedonians well deſerving that epithet for having built their city in a barren and ſandy ſoil, without ſeeing that advantageous and pleaſant ſpot on the oppoſite ſhore, which the Byzantines afterwards choſe.—Chalcedon, in the Chriſtian times, become famous on account of the council which was held there againſt Eutyches. The emperor Valens cauſed the walls of this city to be levelled with the ground for ſiding with Procopius, and the materials to be conveyed to Conſtantinople, where they were employed in building the famous Valentinian aqueduct. Chalcedon is at preſent a poor place, known to the Greeks by its ancient name, and to the Turks by that of *Cadiaci*, or "the judges town."

CHALCEDONY, in natural hiſtory, a genus of the ſemipellucid gems. They are of an even and regular, not tabulated ſtructure; of a ſemi-opaque cryſtalline baſis; and variegated with different colours, but thoſe ever diſpoſed in form of miſts or clouds, and, if nicely examined, found to be owing to an admixture of various coloured earths, but imperfectly blended in the maſs, and often viſible in diſtinct moleculæ.—It has been doubted by ſome whether the ancients were at all acquainted with the ſtone we call *chalcedony;* they having deſcribed a Chalcedonian carbuncle and emerald, neither of which can at all agree with the characters of our ſtone; but we are to conſider that they have alſo deſcribed a Chalcedonian jaſper which ſeems to have been the very ſame ſtone as they deſcribe by the word *turbida*, which extremely well agrees with our chalcedony.

There are four known ſpecies of the chalcedony. 1. A bluiſh white one. This is the moſt common of all, and is found in the ſhape of flints and pebbles, in maſſes of two or three inches or more in diameter. It is of a whitiſh colour, with a faint cloud of blue diffuſed all over it, but always in the greateſt degree near the ſurface. This is a little leſs hard than the oriental onyx. The oriental chalcedonies are the only ones of any value; they are found in vaſt abundance on the ſhores of rivers in all parts of the Eaſt-Indies, and frequently come over among the ballaſt of the Eaſt-India ſhips. They are common in Sileſia and Bohemia, and other parts of Europe alſo; but with us are leſs hard, more opaque, and of very little value. 2. The dull milky-veined chalcedony. This is a ſtone of little value, and is ſometimes met with among the lapidaries, who miſtake it for a kind of nephritic ſtone. It is of a ſomewhat yellowiſh white or cream colour, with a few milk-white veins. This is principally found in New-Spain. 3. The third is a browniſh, black, dull, and cloudy one, known to the ancients by the name of ſmoky jaſper, or jaſpis capnitis. This is the leaſt beautiful ſtone of all the claſs: it is of a pale browniſh white, clouded all over with a blackiſh miſt, as the common chalcedony is with a blue. It is common both in the Eaſt and Weſt-Indies, and in Germany; but is very little valued, and is ſeldom worked into any thing better than the handles of knives. 4. The yellow and red chalcedony is greatly ſuperior to all the reſt in beauty; and is in great repute in Italy, though very little known among us. It is naturally compoſed of an admixture of red and yellow only, on a clouded cryſtalline baſis; but is ſometimes found blended with the matter of common chalcedony, and then is mixed with blue. It is all over of the miſty hue of the common chalcedony. This is found only in the Eaſt-Indies, and there not plentifully. The Italians make it into beads, and call theſe *caſſidonies;* but they are not determinate in the uſe of the word, but call beads of ſeveral of the agates by the ſame name.—All the chalcedonies readily give fire with ſteel, and make no efferveſcence with aquafortis.

CHALCIDENE, or CHALCIDICE, (anc. geog.) an inland country of Syria, having Antiochis or Seleucia to the weſt, Cyrrheſtica to the north, to the ſouth Apamene and Cœleſyria, and to the eaſt Chalybonitis; being ſo called from its principal city Chalcis. This province, one of the moſt fruitful in Syria, was ſeized by Ptolemy the ſon of Mennæus during the troubles of Syria, and by him made a ſeparate kingdom. Ptolemy himſelf is ſtyled by Joſephus and Hegeſippus only Prince of Chalcis, but his ſon Lyſanias is honoured both by Joſephus and Dio with the title of King. Upon the death of Antiochus Dionyſius king of Syria, Ptolemy attempted to make himſelf maſter of Damaſcus and all Cœleſyria; but the inhabitants, having an utter averſion to him on account of his cruelty and wickedneſs, choſe rather to ſubmit to Aretas king of Arabia, by whom Antiochus and his whole army had been cut off. He oppoſed Pompey on his entering Syria; but was by him defeated, taken priſoner, and ſentenced to death; which, however, he eſcaped by paying a thouſand talents, and was left alſo in the poſſeſſion of his kingdom. After Ariſtobulus king of Judæa had been poiſoned by the friends of Pompey, and Alexander his ſon beheaded at Antioch, he ſent Philippion his ſon to Aſcalon, whither the widow of Ariſtobulus had retired with her other children, to bring them all to Chalcis; propoſing, as he was in love with one of the daughters named Alexandria, to maintain them in his own kingdom in a manner ſuitable to their rank: but Philippion likewiſe being in love with Alexandria, married her on the way; for which preſumption Ptolemy put him to death on his return, and then took her to wife. On account of this affinity, he ſupported to the utmoſt of his power Antigonus the younger ſon of Ariſtobulus who took the field at the head of a conſiderable army, but on his entering Judæa was entirely defeated by Herod. Ptolemy ſoon after died, and was ſucceeded by his ſon Lyſanias; who, eſpouſing the cauſe of the Aſmonæan family with great warmth, promiſed to Barzapharnes who command the Parthian troops in Syria, and to Pacorus the king's ſon, a thouſand talents and five hundered women, provided they ſhould put Antigonus in poſſeſſion of the kingdom of Judæa, and depoſe Hyrcanus. He was not long after put to death by Marc Antony, at the inſtigation of Cleopatra; who, in order to have his dominions, accuſed him falſely of having entered into an alliance with the Parthians.

CHALCIDIC, CHALCIDICUM, or CHALCEDONIUM, in the ancient architecture, a large magnificent hall belonging to a tribunal or court of juſtice.—Feſtus ſays, it took its name from the city of Chalcis; but he does not give the reaſon. Philander will have it to be the court or tribunal where affairs of money and coinage were regulated; ſo called from χαλκος *braſs*, and δικη *juſtice*. Others ſay the money was ſtruck in it; and derive the word from χαλκος, and οικος, *houſe*. In Vitruvius, it is uſed for the auditory of a baſilica; in other of the ancient writers for a hall or apartment where the heathen imagined their gods to eat.

CHALCIDICE, (anc. geog.) an eaſtern diſtrict of Macedonia, ſtretching northwards between the Sinus Toronæus and Singiticus. Formerly a part of Thrace, but invaded by Philip of Macedon. Named from the city Chalcis near Olynthus.

CHALCIDIUS, a famous platonic philoſopher in the third century, who wrote a commentary, which is eſteemed, on the Timæus of Plato. This work has been tranſlated from the Greek into Latin.

CHALCIS, a city of Chalcidice. See CHALCIDICE. (anc. geog.)—Another of Ætolia, near the mouth of the river Evenus, on the Ionian Sea, at the foot of a cognominal mountain; and therefore called by ſome *Hypochalcis*.—Another of Eubœa (Strabo), on the Euripus, the country of Lycophron the poet, one of the ſeven which formed the conſtellation Pleiades. Now *Negroponte*. E. Long. 24. 30. Lat. 38. 30.—A fourth, the capital of Chalcidene in Syria; diſtinguiſhed by the ſurnames *ad Belum*, a mountain or a river; and *ad Libanum*, from its ſituation (Pliny).

CHALCITIS, one of the diviſions or diſtricts of Meſopotamia, to the ſouth of Anthemuſia, the moſt northern diſtrict, next to Armenia, and ſituated between Edeſſa and Carræ. *Chalcitis* (Pliny), an iſland oppoſite to Chalcedon.

CHALCONDYLAS, (Demetrius) a learned Greek, born at Conſtantinople, left that city after its being taken by the Turks, and afterwards taught Greek in ſeveral cities in Italy. He compoſed a Greek grammar; and died at Milan in 1513.

CHALCONDYLAS, (Laonicus) a famous Greek hiſtorian of the 15th century, was born at Athens; and wrote an excellent hiſtory of the Turks, from Ottoman, who reigned about the year 1300, to Mahomet II. in 1463.

CHALDEA, (anc. geog) taken in a larger ſenſe, included Babylonia; as in the prophecies of Jeremiah and Ezekiel. In a reſtricted ſenſe, it denoted a province of Babylonia, towards Arabia Deſerta; called in Scripture *The land of the Chaldeans*. Named from Chaſed the fourth ſon of Nahor. See BABYLONIA.

CHALDEE LANGUAGE, that ſpoken by the Chaldeans or people of Chaldea. It is a dialect of the HEBREW.

CHALDEE Paraphraſe, in the rabbinical ſtyle, is called TARGUM. There are three Chaldee paraphraſes in Walton's Polyglot; *viz.* that of Onkelos, that of Jonathan ſon of Uziel, and that of Jeruſalem.

CHALDRON, a dry Engliſh meaſure, conſiſting of thirty ſix buſhels, heaped up according to the ſealed buſhel kept at Guildhall, London; but on ſhipboard, twenty-one chaldrons of coals are allowed to the ſcore. The chaldron ſhould weigh two thouſand pounds.

CHALICE, the cup or veſſel uſed to adminiſter the wine in the ſacrament, and by the Roman Catholics in the maſs.

The uſe of the chalice, or communicating in both kinds, is by the church of Rome denied to the laity, who communicate only in one kind, the clergy alone being allowed the privilege of communicating in both kinds.

CHALK, *Creta*, is a white earth found plentifully in Britain, France, Norway, and other parts of Europe, ſaid to have been anciently dug chiefly in the iſland of Crete, and thence to have received its name of *Creta*. They have a very eaſy way of digging chalk in the county of Kent in England. It is there found on the ſides of hills; and the workmen undermine it ſo far as appears proper; then digging a trench at the top as far diſtant from the edge as the undermining goes at bottom, they fill this with water, which ſoaks through in the ſpace of a night, upon which the whole flake falls down at once. In other parts of the kingdom, chalk generally lies deeper, and they are forced to dig for it at conſiderable depths, and draw it up in buckets.

Chalk is of two kinds; hard, dry, and firm, or ſoft and unctuous; both of which are adapted to various purpoſes. The hard and dry kind is much the propereſt for burning into lime; but the ſoft and unctuous chalk is beſt for uſing as a manure for lands. Chalk whether burnt into lime or not, is in ſome caſes an excellent manure. Its mode of operating on the ſoil is explained under the article AGRICULTURE, n° 20, 25, &c.

Pure chalk melts eaſily with alkali and flint into a tranſparent colourleſs glaſs. With alkaline ſalts it melts ſomewhat more difficultly, and with borax ſomewhat more eaſily, than with flint or ſand. It requires about half its weight of borax, and its whole weight of alkali, to fuſe it. Sal mirabile, and ſandiver, which do not vitrify at all with the cyrſtalline earths, form with half their weight of chalk, the firſt a yellowiſh black, the latter a greeniſh, glaſs. Nitre, on the other hand, one of the moſt active fluxes for flint, does not perfectly vitrify with chalk. This earth notably promotes the vitrification of flint; a mixture of the two requiring leſs alkali than either of them ſeparately. If glaſs made from flint and alkali is further

ther ſaturated with the flint, ſo as to be incapable of bearing any further addition of that earth without becoming opaque and milky, it will ſtill in a ſtrong fire take up a conſiderable proportion, one-third or one-fourth of its weight, of chalk, without injury to its tranſparency; hence chalk is ſometimes made uſe of in compoſitions for glaſs, as a part of the ſalt may then be ſpared. Chalk likewiſe has a great effect in melting the ſtony matters intermixed with metallic ores, and hence might be of uſe in ſmelting ores; as indeed limeſtone is uſed for that purpoſe. But it is remarkable, that chalk, when deprived of its fixed air, and converted into limeſtone, loſes much of its diſpoſition to vitrify. It is then found to melt very difficultly and imperfectly, and to render the glaſs opaque and milky.

Chalk readily imbibes water; and hence maſſes of it are employed for drying precipitates, lakes, earthy powders that have been levigated with water, and other moiſt preparations. Its œconomical uſes in cleaning and poliſhing metalline or glaſs utenſils are well known. In this caſe it is powdered and waſhed from any gritty matter it may contain, and is then called *whiting*.—In medicine it is one of the moſt uſeful abſorbents, and is to be looked upon ſimply as ſuch. The aſtringent virtues which ſome have attributed to it have no foundation, unleſs in as far as the earth is ſaturated with an acid, with which it compoſes a ſaline concrete manifeſtly ſub-aſtringent. For the further properties of chalk, ſee CHEMISTRY, *Index*.

Black-CHALK, a name given by painters to a ſpecies of earth with which they draw on blue paper, &c. It is found in pieces from two to ten feet long, and from four inches to twenty in breadth, generally flat, but ſomewhat riſing in the middle, and thinner towards the edges, commonly lying in large quantities together. While in the earth, it is moiſt and flaky: but being dried, it becomes conſiderably hard and very light; but always breaks in ſome particular direction; and if attentively examined when freſh broken, appears of a ſtriated texture. To the touch it is ſoft and ſmooth, ſtains very freely, and by virtue of its ſmoothneſs makes very neat marks. It is eaſily reduced into an impalpable ſoft powder without any diminution of its blackneſs. In this ſtate it mixes eaſily with oil into a ſmooth paſte: and being diffuſed through water, it ſlowly ſettles into a black ſlimy or muddy form; properties which make its uſe very convenient to the painters both in oil and water colours. It appears to be an earth quite different from common chalk, and rather of the ſlaty bituminous kind. In the fire it becomes white with a reddiſh caſt, and very friable, retaining its flaky ſtructure, and looking much like the white flaky maſſes which ſome ſorts of pit-coal leave in burning. Neither the chalk nor theſe aſhes are at all affected by acids.

The colour-ſhops are ſupplied with this earth from Italy or Germany; though ſome parts of England afford ſubſtances nearly, if not entirely, of the ſame quality, and which are found to be equally ſerviceable both for marking and as black paints. Such particularly is the black earth called *killow*, ſaid by Dr Merret in his *Pinax Rerum Britannicarum* to be found in Lancaſhire; and by Mr Da Coſta, in his hiſtory of foſſils, to be plentiful near the top of Cay-Avon, an high hill in Merionethſhire.

Red-CHALK, an earth much uſed by painters and artificers, and common in the colour-ſhops. It is properly an indurated clayey ochre; and is dug in Germany, Italy, Spain, and France, but in greateſt quantity in Flanders. It is of a fine, even, and firm texture; very heavy, and very hard; of a pale red on the outſide, but of a deep duſky chocolate colour within. It adheres firmly to the tongue, is perfectly inſipid to the taſte, and makes no efferveſcence with acids.

CHALK-*Land*. Barley and wheat will ſucceed very well on the better ſort of chalky land, and oats generally do well on any kind of it. The natural produce of this ſort of land in weeds, is that ſort of ſmall vetch called the *tine-tare*, with poppies, may-weed, &c. Sainfoin and hop-clover will generally ſucceed tolerably well on theſe lands; and where they are of the better ſort, the great clover will do. The beſt manure is dung, old rags, and the ſheep-dung left after folding them.

CHALK-*Stones*, in medicine, ſignify the concretions of calcareous matter in the hands and feet of people violently afflicted with the gout. Leeuwenhoek has been at the pains of examining theſe by the microſcope. He divides them into three parts. The firſt is compoſed of various ſmall parcels of matter looking like white grains of ſand; this is harder and drier, and alſo whiter than the reſt. When examined with large magnifiers, theſe are found to be compoſed of oblong particles laid cloſely and evenly together: though the whole ſmall ſtones are opapue, theſe component parts of them are pellucid, and reſemble pieces of horſe-hair cut ſhort, only that they are ſomewhat pointed at both ends. Theſe are ſo extremely thin, that Mr Leeuwenhoek computes that 1000 of them placed together would not amount to the ſize of one hair of our heads. The whole ſtones in this harder part of the chalk are not compoſed of theſe particles, but there are confuſedly thrown in among them ſome broken parts of other ſubſtances, and in a few places ſome globules of blood and ſmall remains of other juices. The ſecond kind of chalky matter is leſs hard and leſs white than the former, and is compoſed of fragments or irregular parts of thoſe oblong bodies which compoſe the firſt or hardeſt kind, and theſe are mixed among tough and clear matter, interſperſed with the ſmall broken globules of blood diſcoverable in the former, but in much greater quantity. The third kind appears red to the naked eye; and, when examined with glaſſes, is found to be a more tough and clammy white matter, in which a great number of globules of blood are interſperſed; theſe give it the red appearance it has.

CHALLENGE, a cartel or invitation to a duel or other combat*. A challenge either by word or letter, or to be the bearer of ſuch a challenge, is puniſhable by fine and impriſonment on indictment or information.

CHALLENGE, among hunters. When hounds or beagles, at firſt finding the ſcent of their game, preſently open and cry, they are ſaid to challenge.

CHALLENGE, in the law of England, is an exception made to jurors†; and is either in civil or criminal caſes.

---

* See *Duel*.

† See the art. *Trial*.

I. In *civil* caſes challenges are of two ſorts; challenges to the *array*, and challenges to the *poll*.

1. Challenges to the array are at once an exception to the whole panel, in which the jury are arrayed, or ſet in order by the ſheriff in his return; and they may be made upon account of partiality or ſome default in the ſheriff or his under officer who arrayed the panel. Alſo, though there be no perſonal objection againſt the ſheriff, yet if he arrays the panel at the nomination, or under the direction of either party, this is good cauſe of challenge to the array. Formerly, if a lord of parliament had a cauſe to be tried, and no knight was returned upon the jury, it was a cauſe of challenge to the array: alſo by the policy of the ancient law, the jury was to come *de vicineto*, from the neighbourhood of the vill or place where the cauſe of action was laid in the declaration: and therefore ſome of the jury were obliged to be returned from the hundred in which ſuch vill lay, and, if none were returned, the array might be challenged from defect of hundreders. For, living in the neighbourhood, theſe were ſuppoſed to know beforehand the characters of the parties and witneſſes; and therefore they better knew what credit to give to the facts alleged in evidence. But this convenience was overbalanced by another very natural and almoſt unavoidable inconvenience; that jurors coming out of the immediate neighbourhood, would be apt to intermix their prejudices and partialities in the trial of right. And this the law was ſo ſenſible of, that it for a long time has been gradually relinquiſhing this practice; the number of neceſſary hundreders in the whole panel, which in the reign of Edward III. were conſtantly ſix, being in the time of Forteſcue reduced to four; afterwards by ſtatute 27 Eliz. c. 6. to two; and at length, by ſtatute 4 and 5 Anne, c. 16. it was entirely aboliſhed upon all civil actions, except upon penal ſtatutes; and upon thoſe alſo by the 24 Geo. II. c. 18. the jury being now only to come *de corpore comitatus*, from the body of the county at large, and not *de vicineto*, or from the particular neighbourhood. The array by the ancient law may alſo be challenged, if an alien be party to the ſuit, and, upon a rule obtained by his motion to the court for a jury *de medietate linguæ*, ſuch a one be not returned by the ſheriff purſuant to the ſtatute 28 Edward III. c. 13. enforced by 18 Hen. VI. c. 29. which enacts, that where either party is an alien born, the jury ſhall be one-half denizens and the other aliens (if ſo many be forthcoming in the place), for the more impartial trial: A privilege indulged to ſtrangers in no other country in the world; but which is as ancient in England as the time of King Ethelred, in whoſe ſtatute *de monticolis. Walliæ* (then aliens to the crown of England), c. 3. it is ordained, that "duodeni legales homines, quorum ſex Walli et ſex Angli erunt, Anglis et Wallis jus dicunto."

2. Challenges to the polls, *in capita*, are exceptions to particular jurors; and ſeem to anſwer the *recuſatio judicis* in the civil and canon laws; by the conſtitutions of which, a judge might be refuſed upon any ſuſpicion of partiality. By the laws of England alſo, in the times of Bracton and Fleta, a judge might be refuſed for good cauſe; but now the law is otherwiſe, and it is held that judges or juſtices cannot be challenged. For the law will not ſuppoſe a poſſibility of bias or favour in a judge who is already ſworn to adminiſter impartial juſtice, and whoſe authority greatly depends on that preſumption and idea. And, ſhould the fact at any time prove flagrantly ſuch, as the delicacy of the law will not preſume beforehand, there is no doubt but that ſuch miſbehaviour would draw down a heavy cenſure from thoſe to whom the judge is accountable for his conduct. But challenges to the polls of the jury (who are judges of fact) are reduced to four heads by Sir Edward Coke: *propter honoris reſpectum*; *propter defectum*; *propter affectum*; and *propter delictum*. 1. *Propter honoris reſpectum*; as, if a lord of parliament be impanelled on a jury, he may be challenged by either party, or he may challenge himſelf. 2. *Propter defectum*; as, if a juryman be an alien born, this is defect of birth; if he be a ſlave or bondman, this is defect of liberty, and he cannot be a *liber et legalis homo*. Under the word *homo* alſo, though a name common to both ſexes, the female is however excluded, *propter defectum ſexus*; except when a widow feigns herſelf with child in order to exclude the next heir, and a ſuppoſititious birth is ſuſpected to be intended; then, upon the writ *de ventre inſpiciendo*, a jury of women is to be impanelled to try the queſtion whether with child or not. But the principal deficiency is defect of eſtate ſufficient to qualify him to be a juror, which depends upon a variety of ſtatutes*. 3. Jurors may be challenged *propter affectum*, for ſuſpicion of bias or partiality. This may be either a principal challenge, or to the favour. A *principal* challenge is ſuch, where the cauſe aſſigned carries with it, *prima facie*, evident marks of ſuſpicion either of malice or favour: as, that a juror is of kin to either party within the ninth degree; that he has an intereſt in the cauſe; that there is an action depending between him and the party; that he has taken money for his verdict, &c. which, if true, cannot be over-ruled, for jurors muſt be *omne exceptione majores*. Challenges *to the favour*, are where the party hath no principal challenge; but objects only ſome probable circumſtances of ſuſpicion, as acquaintance, and the like; the validity of which muſt be left to the determination of *triors*, whoſe office is to decide whether the juror be favourable or unfavourable. 4. Challenges *propter delictum*, are for ſome crime or miſdemeanour that affects the juror's credit, and renders him infamous: As for a conviction of treaſon, felony, perjury, or conſpiracy: or if, for ſome infamous offence, he hath received judgment of the pillory or the like.

II. In *criminal* caſes, challenges may be made either on the part of the king, or on that of the priſoner; and either to the whole array, or to the ſeparate polls, for the very ſame reaſons that they may be in civil cauſes. For it is here at leaſt as neceſſary as there, that the ſheriff or returning officer be totally indifferent; that, where an alien is indicted, the jury ſhould be *de midietate*, or half foreigners, if ſo many are found in the place (which does not indeed hold in treaſons, aliens being very improper judges of the breach of allegiance; nor yet in the caſe of Egyptians under the ſtatute 22 Hen. VIII. c. 10.); that on every panel there ſhould be a competent number of hundreders; and that the particular jurors ſhould be *omne exceptione majores*, not liable to objections either *propter honoris reſpectum*,

*See *Blackſtone's Com.* III. 362.

ſpectum, propter defectum, propter affectum, or *propter delictum.*

Challenges on any of the foregoing accounts are ſtyled challenges *for cauſe*; which may be without ſtint in both civil and criminal trials. But in criminal caſes, or at leaſt in capital ones, there is, *in favorem vitæ*, allowed to the priſoner an arbitrary and capricious ſpecies of challenge to a certain number of jurors, without ſhowing any cauſe at all; which is called a peremptory challenge: a proviſion full of that tenderneſs and humanity to priſoners for which our laws are famous. This is grounded on two reaſons: 1. As every one muſt be ſenſible what ſudden impreſſions and unaccountable prejudices we are apt to conceive upon the bare looks and geſtures of another; and how neceſſary it is, that a priſoner, when put to defend his life, ſhould have a good opinion of his jury, the want of which might totally diſconcert him; the law wills not that he ſhould be tried by any one man againſt whom he has conceived a prejudice even without being able to aſſign a reaſon for ſuch his diſlike. 2. Becauſe upon challenges for cauſe ſhown, if the reaſon aſſigned prove inſufficient to ſet aſide the juror, perhaps the bare queſtioning his indifference may ſometimes provoke a reſentment; to prevent all ill conſequences from which, the priſoner is ſtill at liberty, if he pleaſes, peremptorily to ſet him aſide.

This privilege of peremptory challenges, though granted to the priſoner, is denied to the king by the ſtatute 33 Edward I. ſtat. 4. which enacts, that the king ſhall challenge no jurors without aſſigning a cauſe certain to be tried and approved by the court. However, it is held that the king need not aſſign his cauſe of challenge till all the panel is gone through, and unleſs there cannot be a full jury without the perſons ſo challenged. And then, and not ſooner the king's counſel muſt ſhow the cauſe: otherwiſe the juror ſhall be ſworn.

The peremptory challenges of the priſoner muſt, however, have ſome reaſonable boundary; otherwiſe he might never be tried. This reaſonable boundary is ſettled by the common law to the number of 35; that is, one under the number of three full juries. For the law judges, that 35 are fully ſufficient to allow the moſt timorous man to challenge through mere caprice; and that he who peremptorily challenges a greater number, or three full juries, has no intention to be tried at all. And therefore it deals with one who peremptorily challenges above 35, and will not retract his challenge, as with one who ſtands mute or refuſes his trial; by ſentencing him to the *peine forte et dure* in felony, and by attainting him in treaſon. And ſo the law ſtands at this day with regard to treaſon of any kind. But by ſtatute 22 Hen. VIII. c. 14. (which, with regard to felonies, ſtands unrepealed), no perſon arraigned for felony can be admitted to make more than 20 peremptory challenges.

CHALLON-SUR-SAONE, an ancient town of France, in Burgundy, and capital of the Challonnois, with a citadel and biſhop's ſee. It is ſeated on the river Saone, in E. Long. 5. 7. N. Lat. 46. 47.

CHALLONS-Sur-Marne, a large epiſcopal town of France, in Champagne. It carries on a conſiderable trade in ſhalloons, and other woollen ſtuffs. It is ſeated between two fine meadows on the rivers Marne, Mau, and Nau, in E. Long. 4. 37. N. Lat 48. 57.

CHALONER, (Sir Thomas) a ſtateſman, ſoldier, and poet, deſcended from a good family in Denbigh in Wales, was born at London about the year 1515. Having been educated in both univerſities, but chiefly at Cambridge, he was introduced at the court of Henry VIII, who ſent him abroad in the retinue of Sir Henry Knevet ambaſſador to Charles V. and he had the honour to attend that monarch on his fatal expedition againſt Algiers in 1541. Soon after the fleet left that place, he was ſhipwrecked on the coaſt of Barbary in a very dark night: and having exhauſted his ſtrength by ſwimming, he chanced to ſtrike his head againſt a cable, which he had the preſence of mind to catch hold of with his teeth; and, with the loſs of ſeveral of them, was drawn up by it into the ſhip to which he belonged. Mr Chaloner returned ſoon after to England, and was appointed firſt clerk of the council, which office he held during the reſt of that reign. On the acceſſion of Edward VI. he became a favourite of the Duke of Somerſet, whom he attended to Scotland, and was knighted by that nobleman after the battle of Muſſelburgh, in 1547. The protector's fall put a ſtop to Sir Thomas Chaloner's expectations, and involved him in difficulties. During the reign of queen Mary, being a determined proteſtant, he was in ſome danger; but having many powerful friends, he had the good fortune to eſcape. On the acceſſion of queen Elizabeth, he appeared again at court; and was ſo immediately diſtinguiſhed by her Majeſty, that ſhe appointed him ambaſſador to the emperor Ferdinand I. being the firſt ambaſſador ſhe nominated. His commiſſion was of great importance; and the queen was ſo well ſatisfied with his conduct, that, ſoon after his return, ſhe ſent him in the ſame capacity to Spain: but Sir Thomas was by no means ſatisfied with this inſtance of her majeſty's confidence: the courts of England and Spain being at this time extremely diſſatisfied with each other, he foreſaw that his ſituation would be very diſagreeable; and ſo it proved; but Elizabeth muſt be obeyed. He embarked for Spain in 1561, and returned to London in 1564, in conſequence of a requeſt to his ſovereign, in an elegy written in imitation of Ovid. After his return, he reſided in a houſe built by himſelf in Clerkenwell-cloſe, where he died in the year 1565, and was buried in St Paul's. Sir William Cecil aſſiſted as chief mourner at his funeral.

So various were the talents of Sir Thomas Chaloner, that he excelled in every thing to which he applied himſelf. He made a conſiderable figure as a poet. His poetical works were publiſhed by William Malim, maſter of St Paul's ſchool, in 1579. His capital work was that "Of reſtoring the Engliſh republic, in ten books," which he wrote when he was ambaſſador in Spain. It is remarkable, that this great man, who knew how to tranſact as well as to write upon the moſt important affairs of ſtates and kingdoms, could deſcend to compoſe a *dictionary for children*, and to tranſlate from the Latin a book *Of the office of Servants*, merely for the utility of the ſubjects.

CHALONER, (Sir Thomas) the younger, though inconſiderable as an author, deſerves to be recorded as a ſkilful naturaliſt, in an age wherein natural hiſtory was very

very little underſtood in this or any other country; and particularly as the founder of the alum-works in Yorkſhire, which have ſince proved ſo exceedingly advantageous to the commerce of Britain. He was the only ſon of Sir Thomas Chaloner mentioned in the laſt article, and was born in the year 1559. Being very young at the time of his father's death, the lord treaſurer Burleigh taking charge of his education, ſent him to St Paul's ſchool, and afterwards to Magdalen college in Oxford, where, like his father, he diſcovered extraordinary talents for Latin and Engliſh poetry. About the year 1580, he made the tour of Europe, and returned to England before 1584; for, in that year, we find him a frequent attendant in the court of queen Elizabeth. About this time he married the daughter of Sir William Fleetwood, recorder of London. In 1591 he was knighted; and, ſome time after, diſcovered the alum-mines on his eſtate at Giſborough, near the river Tees in Yorkſhire (A).

Towards the latter end of the queen's reign, Sir Thomas viſited Scotland; and returning to England in the retinue of king James I. found ſuch favour in the ſight of his majeſty, that he was immediately appointed governor to prince Henry, whom he conſtantly attended, and, when his royal pupil viſited Oxford, was honoured with the degree of maſter of arts. How he was employed after the death of the prince is not known. Some years before that event, he married a ſecond wife, the daughter of Mr William Blount of London, by whom he had ſome children. He died in the year 1615, and was buried at Chiſwick in Middleſex. His eldeſt ſon William was created a baronet in the 18th of James *anno* 1620. The title was extinct in 1681. He wrote, 1. Dedication to Lord Burleigh of his father's poetical works, dated 1579. 2. The virtue of nitre, wherein is declared the ſundry cures by the ſame effected. Lond. 1584, 4to.

CHALYBEAT, in medicine, an appellation given to any liquid, as wine or water, impregnated with particles of iron or ſteel. See MINERAL WATERS.

CHALYBES, (anc. geog.) an ancient people of the Hither Aſia. Their ſituation is differently aſſigned; Strabo placing them in Paphlagonia, to the eaſt of Synope; Apollonius Rhodus and Stephanus, on the eaſt of the Thermodon, in Pontus; called *Halizones* by Homer. They either gave their name to, or took it from, their iron manufactures, (Xenophon, Val. Flaccus), their only ſupport, their ſoil being barren and ungrateful, (Dionyſius Periegetes).

CHAM, or KHAN, the title given to the ſovereign princes of Tartary.

The word, in the Perſian, ſignifies *mighty lord*; in the Scalvonic, *emperor*. Sperlingius, in his Diſſertation on the Daniſh term of *Majeſty, koning, king*, thinks the Tartarian *cham* may be well derived from it; adding, that in the north they ſay *kan, konnen, konge, konning*, &c. The term *cham* is alſo applied, among the Perſians, to the great lords of the court, and the governors of provinces.

CHAM, in geography, a town of the Bavarian palatinate, ſituated on a river of the ſame name, about 25 miles north-eaſt of Ratiſbon; E. Long. 13. N. Lat. 49. 15.

CHAMA, in zoology, a genus of ſhell-fiſh belonging to the order of vermes teſtaceæ. The ſhell is thick, and has two valves; it is an animal of the oyſter kind. Linnæus enumerates 14 ſpecies, principally diſtinguiſhed by the figure of their ſhells.

CHAMADE, in war, a certain beat of a drum, or ſound of a trumpet, which is given the enemy as a ſignal to inform them of ſome propoſition to be made to the commander, either to capitulate, to have leave to bury their dead, make a truce, or the like.—Menage derives the word from the Italian *chiamata*, of *clamare* to "cry."

CHAMÆDRYS, in botany. See VERONICA.

CHAMÆLEON, in zoology, the trivial name of a ſpecies of LACERTA.

CHAMÆPITYS, in botany. See TEUCRIUM.

CHAMÆROPS, in botany: a genus of the natural order of palmæ. The hermaphrodite calyx is tripartite; the corolla tripetalous; there are ſix ſtamina, three piſtils, and three monoſpermous plums. The male, in a diſtinct plant, the ſame as the hermaphrodite. There are two ſpecies, the moſt remarkable of which is the glabra, a native of the Weſt-Indies, and warm parts of America, alſo of the correſponding latitudes of Aſia and Africa. It never riſes with a tall ſtem; but when the plants are old, their leaves are five or ſix feet long, and upwards of two feet broad; theſe ſpread open like a fan, having many foldings, and at the top are deeply divided like the fingers of a hand. This plant the Americans call *thatch*, from the uſe to which the leaves are applied.—Under the name of palmetto, however, Mr Adanſon deſcribes a ſpecies of palm which grows naturally at Senegal, whoſe trunk riſes from 50 to 60 feet in height: from the upper end of the trunk iſſues a bundle of leaves, which, in turning off, form a round head; each leaf repreſents a fan of five or ſix feet in expanſion, ſupported by a tail of the ſame length. Of theſe trees, ſome produce male flowers, which are conſequently barren; other are female, and loaded with fruit, which ſucceed each other uninterruptedly almoſt the whole year round. The fruit of the large palmettos, Mr Adanſon affirms to be of the bigneſs of an ordinary melon, but rounder: it is inveloped in two ſkins as tough as leather, and as thick as ſtrong parchment; within the fruit is yellowiſh, and full of filaments faſtened to three large kernels in the middle. The negroes are very fond of this fruit, which,

---

(A) Sir Thomas, during his reſidence in Italy, being particularly fond of natural hiſtory, ſpent ſome time at Puzzoli, where he was very attentive to the art of producing alum. This attention proved infinitely ſerviceable to his country, though of no great benefit to himſelf or his family, his attempt being attended with much difficulty and expence. It was begun about the year 1600, in the reign of queen Elizabeth; but was not brought to any degree of perfection till ſome time in the reign of Charles I. by the aſſiſtance of one Ruſſel a Walloon, and two other workmen brought from the alum-works at Rochelle. By one of the arbitrary acts of Charles, it was then deemed a mine-royal, and granted to Sir Paul Pindar. The long parliament adjudged it a monopoly, and juſtly reſtored it to the original proprietors.

which, when baked under the aſhes, is ſaid to taſte like a quince.

The little palmetto may be eaſily raiſed in Britain from ſeeds brought from America; but, as the plants are tender, they muſt be conſtantly kept in a bark-ſtove.

CHAMANIM, in the Jewiſh antiquities, is the Hebrew name for that which the Greeks call *Pyreia* or *Pyrateria*; and St Jerom in Leviticus has tranſlated *Simulachra*, in Iſaiah, *delubra*. Theſe chamanim were, according to Rabbi Solomon, idols expoſed to the ſun upon the tops of houſes. Abenezra ſays they were portable chapels or temples made in the form of chariots, in honour of the Sun. What the Greeks call Pyreia, were temples conſecrated to the ſun and fire, wherein a perpetual fire was kept up. They were built upon eminences; and were large incloſures without covering, where the ſun was worſhipped. The Gaebres, or worſhippers of fire, in Perſia and the Eaſt-Indies, have ſtill theſe Pyreia. The word *chamanim* is derived from *Chaman*, which ſignifies to warm, or burn.

CHAMARIM, a word which occurs in ſeveral places of the Hebrew bible, and is generally tranſlated the *the prieſts of the idols*, or the *prieſts clothed in black*, becauſe *chamar* ſignifies "black," or "blackneſs." St Jerom, in the ſecond book of Kings, renders it *aruſpices*. In Hoſea and Zephania, he tranſlates it *æditui* or church-wardens. But the beſt commentators are of opinion, that by this word we are to underſtand the prieſts of the falſe gods, and in particular the worſhippers of fire; becauſe they were, as they ſay, dreſſed in black; or perhaps the Hebrews gave them this name in deriſion, becauſe, as they were continually employed in taking care about the fuel, and keeping up the fire, they were always as black as ſmiths or colliers. We find prieſts, among thoſe of Iſis, called *melanephori*, that is to ſay, that wear black; but whether this may be by reaſon of their dreſſing in black, or whether it were becauſe they wore a certain ſhining black veil in the proceſſions of this goddeſs, is not certain. *Camar*, in Arabic, ſignifies the "moon." Iſis is the ſame deity. Grotius thinks the Roman prieſts, called *camilli*, came from the Hebrew *chamarim*. Thoſe among the heathens who ſacrificed to the infernal gods were dreſſed in black.

CHAMBER, in building, a member of a lodging, or piece of an apartment, ordinarily intended for ſleeping in; and called by the Latins *cubiculum*. The word comes from the Latin *camera*; and that, according to *Nicod*, from the Greek καμαρα, *vault* or *curve*; the term *chamber* being originally confined to places arched over.

A complete apartment is to conſiſt of a hall, antichamber, *chamber*, and cabinet.

Privy-CHAMBER, in England. Gentlemen of the privy-chamber are ſervants of the king, who are to wait and attend on him and the queen at court, in their diverſions, &c. Their number is forty-eight, under the lord-chamberlain, twelve of whom are in quarterly waiting, and two of theſe lie in the privy-chamber.

In the abſence of the lord-chamberlain, or vice-chamberlain, they execute the king's orders: at coronations, two of them perſonate the dukes of Aquitain and Normandy; and ſix of them, appointed by the lord-chamberlain, attend ambaſſadors from crowned heads to their audiences, and in public entries. The gentlemen of the privy chamber were inſtituted by Henry VII.

CHAMBER, in policy, the place where certain aſſemblies are held, alſo the aſſemblies themſelves. Of theſe ſome are eſtabliſhed for the adminiſtration of juſtice, others for commercial affairs.

Of the firſt kind are, 1. Star-chamber, ſo called, becauſe the roof was painted with ſtars; the authority, power, and juriſdiction of which, are abſolutely aboliſhed by the ſtatute 17 Car. I. 2. Imperial chamber of Spire, the ſupreme court of judicatory in the empire, erected by Maximilian I. This chamber has a right of judging by appeal; and is the laſt reſort of all civil affairs of the ſtates and ſubjects of the empire, in the ſame manner as the aulic council of Vienna. Nevertheleſs it is reſtrained in ſeveral caſes: it takes no notice of matrimonial cauſes, theſe being left to the pope; nor of criminal cauſes, which either belong to particular princes or towns in their reſpective territories, or are cognizable by all the ſtates of the empire in a diet. By the treaty of Oſnaburg, in 1648, fifty aſſeſſors were appointed for this chamber, whereof 24 were to be Proteſtants, and 26 Catholics; beſides five preſidents, two of them Proteſtants, and the reſt Catholics. 3. Chamber of accounts, a ſovereign court in France, where accounts are rendered of all the king's revenues, inventories, and avowals thereof regiſtered; oaths of fidelity taken, and other things relating to the finances tranſacted. There are nine in France, that of Paris is the chief; it regiſters proclamations, treaties of peace, naturalizations, titles of nobility, &c. All the members wear long black gowns of velvet, of ſattin, or damaſk, according to their places. 4. Eccleſiaſtical chambers in France, which judge by appeal of differences about collecting the tythes. 5. Chamber of audience, or grand chamber, a juriſdiction in each parliament of France, the counſellors of which are called *jugeurs*, or judges, as thoſe of the chamber of inqueſts are called *raporteurs*, reporters of proceſſes by writing. 6. Chamber of the edict, or miparty, a court eſtabliſhed by virtue of the edict of pacification in favour of thoſe of the reformed religion. This chamber is now ſuppreſſed. 7. Apoſtolical chamber of Rome, that wherein affairs relating to the revenues of the church and the pope are tranſacted. This council conſiſts of the cardinal-camerlingo, the governor of the rota, a treaſurer, an auditor, a preſident, one advocate-general, a ſolicitor-general, a commiſſary, and 12 clerks. 8. Chamber of London, an apartment in Guildhall, where the city money is depoſited.

Of the laſt ſort are, the chambers of commerce; the chambers of aſſurance; and the royal or ſyndical chamber of bookſellers in France.

1. The chamber of commerce is an aſſembly of merchants and traders, where the affairs relating to trade are treated of. There are ſeveral eſtabliſhed in moſt of the chief cities of France; and in Britain there have lately been chambers of this kind erected, particularly in London, Edinburgh, and Glaſgow.—2. Chamber of aſſurance in France, denotes a ſociety of merchants and others for carrying on the buſineſs of inſuring: but in Holland, it ſignifies a court of juſtice, where cauſes relating to inſurance are tried.

3. Chamber of bookſellers in Paris, an aſſembly conſiſting of a ſyndic and aſſiſtants, elected by four delegates from the printers, and twelve from the bookſellers, to viſit the books imported from abroad, and to ſearch the houſes and ſellers of marble paper, printſellers, and dealers in printed paper for hangings, who are prohibited from keeping any letters proper for printing books. In the viſitation of books, which ought to be performed by three perſons at leaſt from among the ſyndic and aſſiſtants, all libels againſt the honour of God and the welfare of the ſtate, and all books printed either within or without the kingdom in breach of their regulations and privileges, are ſtopt, even with the merchandiſes that may happen to be in the bales with ſuch libels or other prohibited books. The days appointed for this chamber to meet, are Tueſdays and Fridays, at two o'clock in the afternoon.

CHAMBER, in military affairs. 1. Powder-chamber, or bomb-chamber; a place ſunk under ground for holding the powder, or bombs, where they may be out of danger, and ſecured from the rain. 2. Chamber of a mine; the place, moſt commonly of a cubical form, where the powder is confined. 3. Chamber of a mortar; that part of the chaſe, much narrower than the reſt of the cylinder, where the powder lies. It is of different forms; ſometimes like a reverſed cone; ſometimes globular, with a neck for its communication with the cylinder, whence it is called a bottled chamber; but moſt commonly cylindrical, that being the form which is found by experience to carry the ball to the greateſt diſtance.

CHAMBERLAIN, an officer charged with the management and direction of a chamber. See CHAMBER, *in policy*.

There are almoſt as many kinds of chamberlains as chambers, the principal whereof are as follows.

Lord CHAMBERLAIN of Great-Britain, the ſixth great officer of the crown; to whom belongs livery and lodging in the king's court; and there are certain fees due to him from each archbiſhop or biſhop when they perform their homage to the king, and from all peers at their creation, or doing their homage. At the coronation of every king, he is to have forty ells of crimſon velvet for his own robes. This officer on the coronation-day, is to bring the king his ſhirt, coif, and wearing clothes; and after the king is dreſſed, he claims his bed, and all the furniture of his chamber, for his fees: he alſo carries, at the coronation, the coif, gloves, and linen, to be uſed by the king on that occaſion, alſo the ſword and ſcabbard, the gold to be offered by the king, and the robes-royal and crown: he dreſſes and undreſſes the king on that day, waits on him before and after dinner, &c. To this officer belongs the care of providing all things in the houſe of lords, in the time of parliament; to him alſo belongs the government of the palace of Weſtminſter: he diſpoſes likewiſe of the ſword of ſtate, to be carried before the king, to what lord he pleaſes.

The great chamberlain of Scotland was ranked by King Malcom as the third great officer of the crown, and was called *Camerarius Domini Regis*. Before there was a treaſurer appointed, it was his duty to collect the revenue of the crown, and he diſburſed the money neceſſary for the king's expences, and the maintenance of the king's houſehold. From the time that a treaſurer was appointed, his province was limited to the boroughs throughout the kingdom, where he was a ſort of juſtice-general, as he had a power for judging of all crimes committed within the borough, and of the crime of foreſtalling. He was to hold chamberlain-ayres every year. He was ſupreme judge; nor could any of his decrees be queſtioned by any inferior judicatory. His ſentences were put in execution by the magiſtrates of the boroughs. He alſo regulated the prices of proviſions within the borough, and the fees of the workmen in the mint-houſe. His ſalary was only L. 200 a-year. The ſmallneſs of his ſalary, and his great powers, had no doubt been the cauſes of much oppreſſion in this officer, and the chamberlain-ayre was called rather a legal robbery than a court of juſtice; and when the combined lords ſeized King James VI. Auguſt 24, 1582, and carried him to Ruthven Caſtle, they iſſued a proclamation in the king's name, diſcharging the chamberlain-ayres to be kept. The chamberlain had great fees ariſing from the profits of eſcheats, fines, tolls, and cuſtoms. This office was granted heritably to the family of Stuart, duke of Lenox; and when their male line failed, king Charles II. conferred it in like manner upon his natural ſon, whom he created duke of Monmouth, and on his forfeiture it went to the duke of Lenox; but that family ſurrendered the office to the crown in 1703.

Lord CHAMBERLAIN of the Houſehold, an officer who has the overſight and direction of all officers belonging to the king's chambers, except the precinct of the king's bed-chamber.

He has the overſight of the officers of the wardrobe at all his majeſty's houſes, and of the removing wardrobes, or of beds, tents, revels, muſic, comedians, hunting, meſſengers, &c. retained in the king's ſervice. He moreover has the overſight and direction of the ſerjeant at arms, of all phyſicians, apothecaries, ſurgeons, barbers, the king's chaplains, &c. and adminiſters the oath to all officers above ſtairs.

Other chamberlains are thoſe of the king's court of exchequer, of North-Wales, of Cheſter, of the city of London, &c. in which caſes this officer is generally the receiver of all rents and revenues belonging to the place whereof he is chamberlain.

In the exchequer there are two chamberlains, who keep a controlment of the pells of receipts and exitus, and have certain keys of the treaſury, records, &c.

CHAMBERLAIN of London keeps the city money, which is laid up in the chamber of London: He alſo preſides over the affairs of maſters and apprentices, and makes free of the city, &c.

His office laſts only a year; but the cuſtom uſually obtains to re-chuſe the ſame perſon, unleſs charged with any miſdemeanour in his office.

CHAMBERLAYNE, (Edward) deſcended from an ancient family, was born in Glouceſterſhire 1616, and made the tour of Europe during the diſtractions of the civil war. After the reſtoration he went as ſecretary with the earl of Carliſle, who carried the order of the Garter to the king of Sweden; was appointed tutor to the duke of Grafton, natural ſon of Charles II. and was afterwards pitched on to inſtruct prince George of Denmark in the Engliſh tongue. He died in 1703, and was buried in a vault in Chelſea church.

church-yard: his monumental inſcription mentions ſix books of his writing; and that he was deſirous of doing ſervice to poſterity, that he ordered ſome copies of his books to be covered with wax, and buried with him. That work by which he is beſt known, is his *Angliæ Notitiæ*, or *the preſent ſtate of England*, which has been often ſince printed.

CHAMBERLAYNE, (John) ſon to the author of “*The Preſent State of England*,” and continuator of that uſeful work, was admitted into Trinity College, Oxford, 1685; but it doth not appear that he took any degree. Beſide the *Continuation* juſt mentioned, he was author of “Diſſertations hiſtorical, critical, theological, and moral, on the moſt memorable events of the Old and New Teſtaments, with Chronological Tables;” one vol. folio; and tranſlated a variety of works from the French, Dutch, and other languages. He likewiſe was F. R. S. and communicated ſome pieces, inſerted in the Philoſophical Tranſactions. It was ſaid of him that he underſtood ſixteen languages; but it is certain that he was maſter of the Greek, Latin, French, High and Low Dutch, Portugueſe, and Italian. Though he was qualified for employment, he had none but that of Gentleman-Uſher to George Prince of Denmark. After a uſeful and well-ſpent life, he died in the year 1724. He was a very pious and good man, and earneſt in promoting the advancement of religion, and the intereſt of true Chriſtianity; for which purpoſe he kept a large correſpondence abroad.

CHAMBERRY, a conſiderable and populous town of Italy, in Savoy, with a caſtle. It is capital of the duchy, and well built, but has no fortifications. It is watered by ſeven ſtreams, which have their ſources in St Martin's-hill, and run through ſeveral of the ſtreets. There are piazzas under moſt part of the houſes, where people may walk dry in the worſt weather. It hath large and handſome ſuburbs; and in the centre of the town is the royal palace. The parliament meet here, which is compoſed of four preſidents, and a pretty large number of ſenators, being the ſupreme tribunal of the whole duchy. The principal church is St Leger, and the Jeſuits college is the moſt magnificent of all the monaſteries. E. Long. 5. 50. N. Lat. 45. 35.

CHAMBERS, (David) a Scots hiſtorian, prieſt, and lawyer, was born in the ſhire of Roſs, about the year 1530, and educated in the univerſity of Aberdeen. From thence he went to France and Italy, where he continued ſome time, particularly at Boulogne, where, in 1556, he was a pupil of Marianus Sozenus.

After his return to Scotland, he was appointed, by queen Mary, parſon of Suddy and chancellor of Roſs. He was ſoon after employed in digeſting the laws of Scotland, and was principally concerned in publiſhing the acts of parliament of that kingdom by authority in 1566. He was alſo appointed one of the lords of ſeſſion, and continued her majeſty's faithful ſervant till her declining fortune obliged her adherents to ſeek for refuge in other kingdoms. Chambers went firſt to Spain, where he was graciouſly received by king Philip; and thence travelled to Paris, where he was no leſs kindly received by Charles IX. of that kingdom, to whom, in 1572, he preſented his hiſtory of Scotland, *&c.* He died at Paris in the year 1592, much regretted (ſays Mackenzie) by all who knew him. His writings were chiefly calculated to aſſiſt his royal miſtreſs, and to extol the wiſdom of the Scots nation.

CHAMBERS, (Ephraim) author of the ſcientific Dictionary which goes under his name, was born at Milton, in the county of Weſtmoreland. His parents were diſſenters of the Preſbyterian perſuaſion; and his education no other than that common one which is intended to qualify a youth for trade and commerce. When he became of a proper age, he was put apprentice to Mr Senex the globe-maker, a buſineſs which is connected with literature, and eſpecially with aſtronomy and geography. It was during Mr Chambers's reſidence with this ſkilful mechanic, that he contracted that taſte for ſcience and learning which accompanied him through life, and directed all his purſuits. It was even at this time that he formed the deſign of his grand work, the “Cyclopædia;” and ſome of the firſt articles of it were written behind the counter. Having conceived the idea of ſo great an undertaking, he juſtly concluded that the execution of it would not conſiſt with the avocations of trade; and therefore he quitted Mr Senex, and took chambers at Gray's-Inn, where he chiefly reſided during the reſt of his days. The firſt edition of the *Cyclopædia*, which was the reſult of many years intenſe application, appeared in 1728, in two vols. fol. It was publiſhed by ſubſcription, the price being 4l. 4s. and the liſt of ſubſcribers was very reſpectable. The dedication, which was to the king, is dated October 15, 1727. The reputation that Mr Chambers acquired by his execution of this undertaking, procured him the honour of being elected F. R. S. Nov. 6, 1729. In leſs than ten years time a ſecond edition became neceſſary; which accordingly was printed, with corrections and additions, in 1738; and was followed by a third the very next year.

Although the Cyclopædia was the grand buſineſs of Mr Chambers's life, and may be regarded as almoſt the ſole foundation of his fame, his attention was not wholly confined to this undertaking. He was concerned in a periodical publication intitled, “The Literary Magazine,” which was begun in 1735. In this work he wrote a variety of articles, and particularly a review of Morgan's “Moral Philoſopher.” He was engaged, likewiſe, in conjunction with Mr John Martyn, F. R. S. and profeſſor of botany at Cambridge, in preparing for the preſs a tranſlation and abridgement of the “Philoſophical Hiſtory and Memoirs of the Royal Academy of Sciences at Paris, or an Abridgment of all the Papers relating to Natural Philoſophy which have been publiſhed by the Members of that illuſtrious Society.” This undertaking, when completed was compriſed in five volumes 8vo. which did not appear till 1742, ſome time after our author's deceaſe, when they were publiſhed in the joint names of Mr Martyn and Mr Chambers. Mr Martyn, in a ſubſequent publication, hath paſſed a ſevere cenſure, upon the ſhare which his fellow-labourer had in the abridgement of the Pariſian papers. The only work beſides, that we find aſcribed to Mr Chambers, is a tranſlation of the *Jeſuit's Perſpective*, from the French; which was printed in 4to, and hath gone through ſeveral editions. Mr Chambers's cloſe and unremitting attention to his ſtudies at length impaired his health, and obliged him occaſionally to take a lodging at Canonbury-houſe, Iſlington. This not having greatly contributed to his recovery, he made an excurſion to the ſouth of France, but did not reap that benefit from it which he had himſelf hoped, and his friends wiſhed. Returning to England, he died at Canonbury-houſe, and was buried at Weſtminſter; where the following inſcription, written by himſelf, is placed on the north ſide of the cloyſters of the Abbey:

Multis pervulgatus,
Paucis notus;
Qui vitam, inter lucem & umbram,
Nec eruditus, nec idiota,
Literis deditus, tranſegit; ſed ut homo
Qui humani nihil a ſe alienum putat.
Vita ſimul, & laboribus functus,
Hic requieſcere voluit,
Ephraim Chambers, R. S. S.
Obiit XV Maii, MDCCXL.

After the author's death, two more editions of his Cyclopædia were publiſhed. The proprietors afterwards procured a ſupplement to be compiled, which extended to two volumes more: And in the year 1778 began to be publiſhed in weekly numbers, an edition of both, improved, and incorporated into one alphabet, by Dr Rees, which has been lately completed in four volumes folio, and forms a very valuable work.

CHAMBRE, (Martin Cureau de la) phyſician in ordinary to the French king, was diſtinguiſhed by his knowledge in medicine, philoſophy, and polite learning. He was born at Mons; and was received into the French academy in 1635, and afterwards into the academy of ſciences. He wrote a great number of works, the principal of which are, 1. The characters of the paſſions. 2. The art of knowing men. 3. On the knowledge of beaſts, &c. He died at Paris in 1669.

CHAMELEON. See Lacerta.

CHAMFERING, in architecture, a phraſe uſed for cutting any thing aſlope on the under ſide.

CHAMIER, (Daniel) an eminent proteſtant divine born in Dauphine. He was many years preacher at Montellimart; from whence he went in 1612 to Montaubon, to be profeſſor of divinity in that city, and was killed by a cannon-ball during the ſiege in 1621. The moſt conſiderable of his works is his *Panſtratia Catholica*, or "Wars of the Lord," in four volumes folio; in which he treats very learnedly of the controverſies between the Proteſtants and Roman Catholics.

CHAMOIS, or Chamois-goat, in zoology. See Capra.

CHAMOMILE. See Anthemis.

CHAMOS, or Chemosh, the idol or god of the Moabites.

The name of *chamos* comes from a root which, in Arabic, ſignifies to *make haſte*; for which reaſon many believe chamos to be the ſun, whoſe precipitate courſe might well procure it the name of ſwift or ſpeedy. Others have confounded chamos with the god *Hammon*, adored not only in Libya and Egypt, but alſo in Arabia, Ethiophia, and the Indies. Macrobius ſhows that Hammon was the ſun; and the horns, with which he was repreſented, denoted his rays. Calmet is of opinion, that the god Hamonus, and Apollo Chomeus, mentioned by Strabo and Ammianus Marcellinus, was the very ſame as chamos or the ſun. Theſe deities were worſhipped in many of the eaſtern provinces. Some who go upon the reſemblance of the Hebrew term *chamos*, to that of the Greek *comos*, have believed chamos to ſignify the god Bacchus the god of drunkenneſs, according to the ſignification of the Greek *comos*. St Jerom, and with him moſt other interpreters, take Chamos and Peor for the ſame deity. But it ſeems that Baal-Peor was the ſame as Tammuz or Adonis; ſo that Chamos muſt be the god whom the heathens call the Sun.

CHAMOUNI, one of the elevated valleys of the Alps ſituated at the foot of Mount Blanc. See Alps and Blanc.

The firſt ſtrangers whom a curioſity to viſit the glaciers drew to Chamouni (M. Saſſure obſerves), certainly conſidered this valley as a den of robbers; for they came armed cap-a-pee, attended with a troop of domeſtics armed in the ſame manner: they would not venture into any houſe; they lived in tents which they had brought along with them; fires were kept burning, and centinels on guard the whole night over. It was in the year 1741 that the celebrated traveller Pocock, and another Engliſh gentleman called Wyndham, undertook this intereſting journey. It is remembered by the old men of Chamouni, and they ſtill laugh at the fears of the travellers, and at their unneceſſary precautions. For 20 or 25 years after this period, the journey was made but ſeldom, and then chiefly by Engliſhmen, who lodged with the curate: for when I was there in 1760, and even for four or five year afterwards, there was no habitable houſe except one or two miſerable inns, like thoſe in villages that are little frequented. But now that this expedition has gradually become ſo faſhionable, three large and good inns, which have been ſucceſſively built, are hardly ſufficient to contain the travellers that come during the ſummer from all quarters.

This concourſe of ſtrangers, and the money they leave behind them at Chamouni, have ſomewhat affected the ancient ſimplicity of the inhabitants, and even the purity of their manners. Nobody, however, has any thing to fear from them: the moſt inviolable fidelity is obſerved with reſpect to travellers; they are only expoſed to a few importunate ſolicitations, and ſome ſmall artifices, dictated by the extreme eagerneſs with which the inhabitants offer their ſervices as guides.

The hope of obtaining this employment brings together round a traveller, almoſt all the men in every village through which he paſſes, and makes him believe that there are a great many in the valley; but there are very few at Chamouni in ſummer. Curioſity, or the hope of making money, draws many to Paris and into Germany: beſides, as the ſhepherds of Chamouni have the reputation of excelling in the making of cheeſe, they are in great requeſt in the Tarentaiſe, in the valley of Aoſte, and even at greater diſtances; and they receive there, for four or five months in ſummer, very conſiderable wages. Thus the labours of the field devolve almoſt entirely on the women, even ſuch as in other countries fall ſolely on the men; as mowing, cutting of wood and threſhing: even the animals of the ſame ſex are not ſpared, for the cows there are yoked in the plough.

The only labours that belong excluſively to the men are the ſeeking for rock cryſtal, and the chaſe. Happily they are now leſs employed than formerly in the firſt of theſe occupations. I ſay happily, for many of them periſhed in this purſuit. The hope of enriching themſelves quickly by the diſcovery of a cavern filled with fine cryſtals, was ſo powerful a motive, that they expoſed themſelves in the ſearch to the moſt alarming dangers; and hardly a year paſſed without ſome of them periſhing in the ſnows, or among the precipices.

The principal indication of the grottos, or cryſtal ovens, as they are here called, are veins of quartz, which appear on the outſide of the rocks of granite, or of the laminated rock. Theſe white veins are ſeen at a diſtance, and often at great heights, on vertical and inacceſſible places. The adventurers endeavour to arrive at theſe, either by fabricating a road acroſs the rocks, or by letting themſelves down from above ſuſpended by ropes. When they reach the place, they gently ſtrike the rock; and if the ſtone returns a hollow ſound, they endeavour to open it with a hammer, or to blow it up with powder. This is the principal method of ſearching: but young people, and even children, often go in queſt of theſe cryſtals over the glaciers, where the rocks have lately fallen down. But whether they conſider theſe mountains as nearly exhauſted, or that the quantity of cryſtal found at Madagaſcar has too much lowered the price of this foſſil, there are now but few people that go in ſearch of it, and perhaps there is not a ſingle perſon at Chamouni that makes it his only occupation. They go however occaſionally, as to a party of pleaſure.

But the chaſe of the Chamois goat, as dangerous, and perhaps more ſo than the ſeeking for cryſtal, ſtill occupies many inhabitants of the mountains, and carries off, in the flower of their age, many men whoſe lives are moſt valuable to their families. And when we are informed how this chaſe is carried on, we will be aſtoniſhed that a courſe of life, at once ſo laborious and perilous, ſhould have irreſiſtible attractions for thoſe who have been accuſtomed to it.

The Chamois hunter generally ſets out in the night, that he may reach by break of day the moſt elevated paſtures where the goats come to feed, before they arrive. As ſoon as he diſcovers the place where he hopes to find them, he ſurveys it with his glaſs. If he finds none of them there, he proceeds always aſcending: whenever he deſcries any, he endeavours to get above them, either by ſtealing along ſome gully, or getting behind ſome rock or eminence. When he is near enough to diſtinguiſh their horns, which is the mark by which he judges of the diſtance, he reſts his piece on a rock, takes his aim with great compoſure, and rarely miſſes. This piece is a rifle-barrelled carabine, into which the ball is thruſt, and theſe carabines often contain two charges, though they have but one barrel; the charges are put one above another, and are fired in ſucceſſion. If he has wounded the chamois, he runs to his prey, and for ſecurity he hamſtrings it; then he conſiders his way home: if the road is difficult, he ſkins the chamois, and leaves the carcaſe; but, if it is practicable, he throws the animal on his ſhoulders, and bears him to his village, though at a great diſtance, and often over frightful precipices: he feeds his family with the fleſh, which is excellent, eſpecially when the creature is young, and he dries the ſkins for ſale.

But if, as is the moſt common caſe, the vigilant chamois perceives the approach of the hunter, he immediately takes flight among the glaciers, through the ſnows, and over the moſt precipitous rocks. It is particularly difficult to get near theſe animals when there are ſeveral together; for then one of them, while the reſt are feeding, ſtands as a centinel on the point of ſome rock that commands a view of the avenues leading to the paſture; and as ſoon as he perceives any object of alarm, he utters a ſort of hiſs, at which the others inſtantly gather round him to judge for themſelves of the nature of the danger: if it is a wild beaſt, or a hunter, the moſt experienced puts himſelf at the head of the flock; and away they fly, ranged in a line, to the moſt inacceſſible retreats.

It is here that the fatigues of the hunter begin; inſtigated by his paſſion for the chaſe, he is inſenſible to danger; he paſſes over ſnows, without thinking of the horrid precipices they conceal; he intangles himſelf among the moſt dangerous paths, and bounds from rock to rock, without knowing how he is to return. Night often ſurpriſes him in the midſt of his purſuit; but he does not for that reaſon abandon it; he hopes that the ſame cauſe will arreſt the flight of the chamois, and that he will next morning overtake them. Thus he paſſes the night, not at the foot of a tree, like the hunter of the plain; not in a grotto, ſoftly reclined on a bed of moſs, but at the foot of a rock, and often on the bare points of ſhattered fragments, without the ſmalleſt ſhelter. There, all alone, without fire, without light, he draws from his bag a bit of cheeſe, with a morſel of oaten bread, which make his common food: bread ſo dry, that he is ſometimes obliged to break it between two ſtones, or with the hatchet he carries with him to cut out ſteps in the ice. Having thus made his ſolitary and frugal repaſt, he puts a ſtone below his head for a pillow, and goes to ſleep, dreaming on the rout which the chamois may have taken. But ſoon he is awakened by the freſhneſs of the morning; he gets up, benumbed with cold; ſurveys the precipices which he muſt traverſe in order to overtake his game; drinks a little brandy, of which he is always provided with a ſmall portion, and ſets out to encounter new dangers. Hunters ſometimes remain in theſe ſolitudes for ſeveral days together, during which time their families, their unhappy wives in particular, experience a ſtate of the moſt dreadful anxiety: they dare not go to reſt for fear of ſeeing their huſbands appear to them in a dream; for it is a received opinion in the country, that when a man has periſhed, either in the ſnow, or on ſome unknown rock, he appears by night to the perſon he held moſt dear, deſcribes the place that proved fatal to him, and requeſts the performance of the laſt duties to his corpſe.

Voyage dans les Alpes, par M. Saſſure, tem. iii.

“ After this picture of the life which the chamois hunters lead, could one imagine that this chaſe would be the object of a paſſion abſolutely unſurmountable? I knew a well-made, handſome man, who had juſt married a beautiful woman:—‘ My grandfather, ſaid he to me, loſt his life in the chaſe; ſo did my father; and I am perſuaded, that I too ſhall die in the ſame manner: this bag which I carry with me when I hunt I call my grave-cloaths, for I am ſure I will have no other; yet if you ſhould offer to make my fortune on condition of abandoning the chaſe of the chamois, I could not conſent. I made ſome excurſions on the Alps with this man: his ſtrength and addreſs were aſtoniſhing: but his temerity was greater than his ſtrength; and I have heard, that, two years afterwards, he miſſed a ſtep on the brink of a precipice, and met with the fate he had expected.

“ The few who have grown old in this employment bear upon their faces the marks of the life they have led. A ſavage look, ſomething in it haggard and wild, makes them be known in the midſt of a crowd, even when they are not in their hunting dreſs. And undoubtedly it is this ill look which makes ſome ſuperſtitious peaſants believe that they are ſorcerers, that they have dealings with the devil in their ſolitudes, and that it is he who throws them down the rocks. What then can be the paſſionate inducement to this courſe of life? It is not avarice, at leaſt it is not an avarice conſiſtent with reaſon: the moſt beautiful chamois is never worth more to the perſon that kills it than a dozen of francs, even including the value of its fleſh; and now that the number is ſo much diminiſhed, the time loſt before one can be taken is much more than its value. But it is the very dangers that attend the purſuit, thoſe alternations of hope and fear, the continual agitation and exerciſe which theſe emotions produce in the mind, that inſtigate the hunter: they animate him as they do the gamſter, the warrior, the ſailor, and even to a certain degree, the naturaliſt of the Alps; whoſe life, in ſome meaſure, pretty much reſembles that of the hunter whoſe manners we have deſcribed.”

But there is another kind of hunting, which is neither dangerous nor laborious, nor fatal to any one but to the poor animals that are the objects of it.—Theſe are the marmots, animals that inhabit the high mountains; where in ſummer they ſcoop out holes, which they line with hay, and retire to at the beginning of autumn: here they grow torpid with the cold, and remain in a ſort of lethargy, till the warmth of the ſpring returns to quicken their languid blood, and to recal them to life. When it is ſuppoſed that they have retired to their winter abode, and before the ſnow has covered the high paſtures where their holes are made, people go to unharbour them. They are found from 10 to 12 in the ſame hole, heaped upon one another, and buried in the hay. Their ſleep is ſo profound, that the hunter often puts them into his bag, and carries them home without their awaking. The fleſh of the young is good, though it taſtes of oil, and ſmells ſomewhat of muſk; the fat is uſed in the cure of rheumatiſms and pains, being rubbed on the parts affected; but the ſkin is of little value, and is ſold for no more than five or ſix ſols. Notwithſtanding the little benefit they reap from it, the people of Chamouni go in queſt of this animal with great eagerneſs, and its numbers accordingly diminiſh very ſenſibly.

It has been ſaid, that marmots, in order to tranſport the hay into their holes, uſe one of their number laid on his back as a cart; but this is fabulous, for they are ſeen carrying the hay in their mouths. Nor is it for food that they gather it, but for a bed, and in order to ſhut out the cold, and to guard the avenues of their retreat from enemies. When they are taken in autumn, their bowels are quite empty, and even as clean as if they had been waſhed with water; which proves that their torpidity is preceded by a faſt, and even by an evacuation: a wiſe contrivance of Nature for preventing their accumulated fæces from growing putrid, or too dry, in the long lethargy they are expoſed to. They alſo continue a few days after their revival without eating, probably to allow the circulation and digeſtive power to recover their activity. At firſt, leaving their holes, they appear ſtupid and dazzled with the light: they are at this time killed with ſticks, as they do not endeavour to fly, and their bowels are then alſo quite empty. They are not very lean when they awake, but grow more ſo for a few days after they firſt come abroad. Their blood is never congealed, however profound their ſleep may be; for at the time that it is deepeſt, if they are bled, the blood flows as if they were awake.

In theſe countries the period is ſo ſhort between the diſſolution of the ſnow and its return, that grain has hardly time to come to maturity. Mr Saſſure mentions a very uſeful and ingenious practice, invented by mountaineers of the Argentiere, for enlarging this period. “I obſerved (ſays he), in the middle of the valley, ſeveral large ſpaces where the ſurface of the ſnow exhibited a ſingular appearance, ſomewhat reſembling a piece of white cloth ſpotted with black. While I was endeavouring to divine the cauſe of this phenomenon, I diſcovered ſeveral women walking with meaſured pace, and ſowing ſomething in handfuls that was black; and which being ſcattered, regularly diverging, on the ſurface of the ſnow, formed that ſpotted appearance that I had been admiring. I could not conceive what ſeed ſhould be ſown on ſnow ſix feet deep; but my guide, aſtoniſhed at my ignorance, informed me, that it was black earth ſpread upon the ſnow to accelerate its melting; and thus to anticipate, by a fortnight or three weeks, the time of labouring the fields and ſowing. I was ſtruck with the elegant ſimplicity of a practice ſo uſeful, the effects of which I already ſaw very evidently in places which had not been thus treated above three days.

“ As to the inhabitants of Chamouni, the men, like thoſe of moſt high valleys, are neither well-made nor tall: but they are nervous and ſtrong, as are alſo the women. They do not attain to a great age; men of 80 are very rare. Inflammatory diſeaſes are the moſt fatal to them; proceeding, no doubt, from obſtructed perſpiration, to which the inconſtant temperature of the climate expoſes them.

“ They are in general honeſt, faithful, and diligent in the practice of religious duties. It would, for inſtance, be in vain to perſuade them to go any where on a holiday before hearing maſs. They are economical, but charitable. There are among them neither hoſpitals nor foundations for the poor; but orphans and old people, who have no means of ſubſiſtence, are entertained by every inhabitant of a pariſh in his turn. If a man is prevented by age or infirmities from taking charge of his affairs, his neighbours join among themſelves and do it for him.

“ Their mind is active and lively, their temper gay, with an inclination to raillery: they obſerve, with ſingular acuteneſs, the ridiculous in ſtrangers, and turn it into a fund of very facetious merriment among themſelves; yet they are capable of ſerious thinking: many of them have attacked me on religious and metaphyſical ſubjects; not as profeſſing a different faith from theirs, but on general queſtions, which ſhowed they had ideas independent of thoſe they were taught."

CHAMPAGNE, a conſiderable province of France, about 162 miles in length, and 112 in breadth, bounded on the north by Hainhalt and Luxemburg, on the eaſt by Lorrain and the Franche-Comté, on the ſouth by Burgundy, and on the weſt by the iſle of France and Soiſſonnois. It has a great number of rivers, the principal of which are the Meuſe, the Seine, the Marne, the Aube, and the Aine. Its principal trade conſiſts in excellent wine, all ſorts of corn, linen cloth, woollen ſtuffs, cattle, and ſheep. It is alſo divided into the higher and lower, and Troys is the capital town. Its ſub-diviſions are Champagne Proper, and Rhemois, the Retelois, the Pertois, the Vallage, Baſigni, the Senonois, and the Brie Champenois.

Champagne Proper, is one of the eight parts of Champagne, which comprehends the towns of Troys, Chalons, St Menehold, Eperney, and Vertus.

CHAMPAIN, or *Point Champain*, in heraldry, a mark of diſhonour in the coat of arms of him who kills a priſoner of war after he has cried quarter.

CHAMPERTRY, in law, a ſpecies of MAINTENANCE, and puniſhed in the ſame manner; being a bargain with the plaintiff or defendant *campum partire*, "to divide the land," or other matter ſued for between them, if they prevail at law; whereupon the champertror is to carry on the party's ſuit at his own expence. Thus *Champart*, in the French law, ſignifies a ſimilar diviſion of profits, being a part of the crop annually due to the landlord by bargain or cuſtom. In our ſenſe of the word, it ſignifies the purchaſing of a ſuit, or right of ſuing; a practice ſo much abhorred by our law, that it is one main reaſon why a *choſe* in action, or thing of which one hath the right but not the poſſeſſion, is not aſſignable in common law; becauſe no man ſhould purchaſe any pretence to ſue in another's right. Theſe peſts of civil ſociety, that are perpetually endeavouring to diſturb the repoſe of their neighbours, and officiouſly interfering in other mens quarrels, even at the hazard of their own fortunes, were ſeverely animadverted on by the Roman law; and were puniſhed by the forfeiture of a third part of their goods and perpetual infamy. Hitherto alſo muſt be referred the proviſion of the ſtatue 32 Henry VIII. c. 9. that no one ſhall ſell or purchaſe any pretended right or title to land, unleſs the vender hath received the profits thereof for one whole year before ſuch grant, or hath been in actual poſſeſſion of the land, or of the reverſion or remainder; on pain that both purchaſer and vender ſhall each forfeit the value of ſuch land to the king and the proſecutor.

CHAMPION, a perſon who undertakes a combat in the place or quarrel of another; and ſometimes the word is uſed for him who fights in his own cauſe.

It appears that champions, in the juſt ſenſe of the word, were perſons who fought inſtead of thoſe that, by cuſtom, were obliged to accept the duel, but had a juſt excuſe for diſpenſing with it, as being too old, infirm, or being eccleſiaſtics, and the like. Such cauſes as could not be decided by the courſe of common law, were often tried by ſingle combat; and he who had the good fortune to conquer, was always reputed to have juſtice on his ſide. See the article BATTEL.

Champion of the King, (campio regis), is an ancient officer, whoſe office is, at the coronation of Britiſh kings, when the king is at dinner, to ride armed *cap-a-pee*, into Weſtminſter-Hall, and by the proclamation of an herald make a challenge, "That if any man ſhall deny the king's title to the crown, he is there ready to defend it in ſingle combat, *&c.*" which being done, the king drinks to him, and ſends him a gilt cup with a cover full of wine, which the champion drinks, and hath the cup for his fee. This office, at the coronation of king Richard II. when Baldwin Freville exhibited his petition for it, was adjudged from him to his competitor Sir John Dymocke (both claiming from Marmion), and hath continued ever ſince in the family of the Dymockes; who hold the manor of Sinvelſby in Lincolnſhire, hereditary from the Marmions by grand ſerjeantry, *viz.* that the lord thereof ſhall be the king's champion as aforeſaid. Accordingly Sir Edward Dymocke performed this office at the coronation of king Charles II. a perſon of the name of Dymocke performed at the coronation of his preſent majeſty George the third.

CHAMPLAIN, (Samuel de) a celebrated French navigator, the founder of the colony of New France, or Canada. He built Quebec; and was the firſt governor of the colony in 1603. Died after 1649. See QUEBEC.

CHANANAEI, (anc. geog.) the name of the ancient inhabitants of Canaan in general, deſcendants of Canaan; but peculiarly appropriated to ſome one branch; though uncertain which branch or ſon of Canaan it was, or how it happened that they preferred the common gentilitious name to one more appropriated as deſcendants of one of the ſons of Canaan: unleſs from their courſe of life, as being in the mercantile way, the import of the name *Canaan*; and for which their ſituation was greatly adapted, they living on the ſea and about Jordan, and thus occupying the greater part of the Land of Promiſe.

CHANCE, a term we apply to events, to denote that they happen without any neceſſary or foreknown cauſe. See CAUSE.

Our aim is, to aſcribe thoſe things to *chance*, which are not neceſſarily produced as the natural effects of any proper cauſe: but our ignorance and precipitancy lead us to attribute effects to *chance*, which have a neceſſary and determinate cauſe.

When we ſay a thing happens *by chance*, we really mean no more than that its cauſe is unknown to us: not, as ſome vainly imagine, that *chance* itſelf can be the cauſe of any thing.

The caſe of the painter, who, unable to expreſs the foam at the mouth of a horſe he had painted, threw his ſponge in deſpair at the piece, and, *by chance*, did that which he could not before do by deſign, is an eminent inſtance of the force of *chance*: yet, it is obvious, all we here mean by *chance*, is, that the painter was not aware of the effect; or that he did not throw the ſponge with ſuch a view: not but that he actually did every thing neceſſary to produce the effect; inſomuch, that, conſidering the direction wherein he threw his ſponge, together with its form, ſpecific gravity, the colours wherewith it was ſmeared, and the diſtance of the hand from the piece, it was impoſſible, on the preſent ſyſtem of things, the effect ſhould not follow.

Chance is frequently perſonified, and erected into a chimerical being, whom we conceive as acting arbitrarily, and producing all the effects whoſe real cauſes do not appear to us: in which ſenſe the word coincides with the *τυχη*, *fortuna*, of the ancients.

CHANCE is alſo uſed for the manner of deciding things, the conduct or direction whereof is left at large, and not reducible to any determinate rules or meaſures; or where there is no ground for preference: as at cards, dice, lotteries, &c.

For the Laws of CHANCE, *or the proportion of Hazard in Gaming*, ſee GAME.

The ancient *ſortilege*, or *chance*, M. Placette obſerves, was inſtituted by God himſelf; and in the Old Teſtament we find ſeveral ſtanding laws and expreſs commands which preſcribed its uſe on certain occaſions: hence the Scripture ſays, "The *lot*, or *chance*, fell on Matthias," when it was in queſtion who ſhould fill Judas's place in the apoſtolate.

Hence alſo aroſe the *ſortes ſanctorum*; or method of determining things, among the ancient Chriſtians, by opening ſome of the ſacred books, and pitching on the firſt verſe they caſt their eye on, as a ſure prognoſtic of what was to befal them. The *ſortes Homericæ, Virgilianæ, Præneſtinæ*, &c. uſed by the heathens, were with the ſame view, and in the ſame manner. See SORTES.

St Auguſtin ſeems to approve of this method of determining things future, and owns that he had practiſed it himſelf; grounded on this ſuppoſition, that God preſides over *chance*; and on Prov. xvi. 33.

Many among the modern divines hold *chance* to be conducted in a particular manner by Providence; and eſteem it an extraordinary way which God uſes to declare his will, and a kind of immediate revelation.

CHANCE-Medley, in law, is where one is doing a lawful act, and a perſon is killed by chance thereby; for if the act be unlawful, it is felony. If a perſon caſt, not intending harm, a ſtone, which happens to hit one, whereof he dies; or ſhoots an arrow in an highway, and another that paſſeth by is killed therewith; or if a workman, in throwing down rubbiſh from a houſe after warning to take care, kills a perſon; or a ſchoolmaſter in correcting his ſcholar, a maſter his ſervant, or an officer in whipping a criminal in a reaſonable manner, happens to occaſion his death; it is chance-medley and miſadventure. But if a man throw ſtones in a highway where perſons uſually paſs; or ſhoot an arrow, &c. in a market-place among a great many people; or if a workman caſt down rubbiſh from a houſe in cities and towns where people are continually paſſing; or a ſchoolmaſter, &c. correct his ſervant or ſcholar, &c. exceeding the bounds of moderation; it is manſlaughter: and if with an improper inſtrument of correction, as with a ſword or iron bar, or by kicking, ſtamping, &c. in a cruel manner, it is murder. If a man whips his horſe in a ſtreet to make him gallop, and the horſe runs over a child and kills it, it is manſlaughter: but if another whips the horſe, it is manſlaughter in him, and chance-medley in the rider. And if two are fighting, and a third perſon coming to part them is killed by one of them without any evil intent, yet this is murder in him, and not manſlaughter by chance-medley or miſadventure. In chance-medley, the offender forfeits his goods; but hath a pardon of courſe.

CHANCEL, is properly that part of the choir of a church, between the altar or communion-table and the baluſtrade or rail that incloſes it, where the miniſter is placed at the celebration of the communion. The word comes from the Latin *cancellus*, which in the lower Latin is uſed in the ſame ſenſe, from *cancelli*, "lattices or croſs bars," wherewith the chancels were anciently encompaſſed, as they now are with rails. The right of a ſeat and a ſepulchre in the chancels is one of the privileges of founders.

CHANCELLOR, was at firſt only a chief notary or ſcribe under the emperors; and was called *cancellarius*, becauſe he ſat behind a lattice (in Latin *cancellus*) to avoid being crowded by the people: though ſome derive the word from *cancellare*, "to cancel" (See CHANCERY). This office was afterwards inveſted with ſeveral judicial powers, and a general ſuperintendency over the reſt of the officers of the prince. From the Roman empire it paſſed to the Roman church, ever emulous of imperial ſtate: and hence every biſhop has to this day his chancellor, the principal judge of his conſiſtory. And when the modern kingdoms of Europe were eſtabliſhed upon the ruins of the empire, almoſt every ſtate preſerved its chancellor with different juriſdictions and dignities, according to their different conſtitutions. But in all of them he ſeems to have had the ſuperviſion of all charters, letters, and ſuch other public inſtruments of the crown as were authenticated in the moſt ſolemn manner: and therefore, when ſeals came in uſe, he had always the cuſtody of the king's great ſeal.

Lord High CHANCELLOR *of Great Britain*, or *Lord Keeper of the Great Seal*, is the higheſt honour of the long robe, being created by the mere delivery of the king's great ſeal into his cuſtody; whereby he becomes, without writ or patent, an officer of the greateſt weight and power of any now ſubſiſting in that kingdom. He is a privy counſellor by his office; and, according to Lord Chancellor Elleſmere, prolocutor of the houſe of lords by preſcription. To him belongs the appointment of all the juſtices of the peace throughout the kingdom. Being in former times commonly an eccleſiaſtic (for none elſe were then capable of an office ſo converſant in writing), and preſiding over the royal chapel, he became keeper of the king's conſcience; viſitor, in right of the king, of all hoſpitals and colleges of the king's foundation; and patron of all the king's livings under the value of L. 20 *per annum* in the king's books. He is the general guardian of all infants, ideots, and lunatics; and has the general ſuperintendance of all charitable uſes in the kingdom. And all this over and above the vaſt extenſive juriſdiction which he exerciſes in his judicial capacity in the court of chancery. He takes precedence of every temporal lord except the royal family, and of all others except the archbiſhop of Canterbury. See CHANCERY.

CHANCELLOR, in Scotland, was the chief in matters of juſtice. In the laws of King Malcolm II. he is placed before all other officers; and from theſe it appears that he had the principal direction of the chancery, or Chancellary as it is called, which is his proper office. He had the cuſtody of the king's ſeal; and he was the king's moſt intimate counſellor, as appears by an old law cited by Sir James Balfour: "The chancellar ſall at al tymes aſſiſt the king, in giving him counſall mair ſecretly nor the reſt of the nobility, to qhuais ordinances all officiaris, als well of the realme as the kingis hous, ſould anſwer and obey. The chancellar ſall be ludgit neir unto the kingis grace, for keiping of his bodie, and the ſeill; and that he may be readie baith day and nicht at the kingis command." By having the cuſtody of the great ſeal, he had an opportunity of examining the king's grants and other deeds which were to paſs under it, and to cancel them if they appeared againſt law, and were obtained ſurreptitiouſly or by falſe ſuggeſtions.

King James VI. ordained the chancellor to have the firſt place and rank in the nation, *ratione officii*; by virtue whereof he preſided in the parliament, and in all courts of judicature. After the reſtoration of King Charles II. by a particular declaratory law, parliament firſt, the lord chancellor was declared, by virtue and right of his office, preſident in all the meetings of parliament, or other public judicatures of the kingdom. Although this act was made to declare the chancellor preſident of the exchequer as well as other courts, yet in 1663 the king declared the treaſurer to be preſident of that court.

The office of lord chancellor of Scotland was aboliſhed by the Union, their being no farther uſe for the judicial part of this office; and, to anſwer all the other parts of the chancellor's office, a lord keeper of the great ſeal was erected, with a ſalary of L. 3000 a-year.

CHANCELLOR *of a Cathedral*, an officer that hears leſſons and lectures read in the church, either by himſelf or his vicar; to correct and ſet right the reader when he reads amiſs; to inſpect ſchools; to hear cauſes; apply the ſeal; write and diſpatch the letters of the chapter; keep the books; take care that there be frequent preachings, both in the church and out of it, and aſſign the office of preaching to whom he pleaſes.

CHANCELLOR *of the Duchy of Lancaſter*, an officer appointed chiefly to determine controverſies between the king and his tenants of the duchy-land, and otherwiſe to direct all the king's affairs belonging to that court. See *DUCHY-Court*.

CHANCELLOR *of the Exchequer*, an officer who preſides in that court, and takes care of the intereſt of the crown. He is always in commiſſion with the lord-treaſurer, for the letting of crown-lands, &c. and has power, with others, to compound for forfeitures of lands upon penal ſtatutes. He has alſo great authority in managing the royal revenues, and in matters relating to the firſt-fruits.

CHANCELLOR *of the Order of the Garter, and other Military Orders*, is an officer who ſeals the commiſſions and mandates of the chapter and aſſembly of the knights, keeps the regiſter of their proceedings, and delivers acts thereof under the ſeal of their order.

CHANCELLOR *of an Univerſity*, is he who ſeals the diplomas, or letters of degrees, proviſion, &c. given in the univerſity.

The chancellor of Oxford is uſually one of the prime nobility, choſen by the ſtudents themſelves in convocation. He is their chief magiſtrate; his office is, *durante vita*, to govern the univerſity, preſerve and defend its rights and privileges, convoke aſſemblies, and do juſtice among the members under his juriſdiction.

Under the chancellor is the vice-chancellor, who is choſen annually, being nominated by the chancellor, and elected by the univerſity in convocation. He is always the head of ſome college, and in holy orders. His proper office is to execute the chancellor's power, to govern the univerſity according to her ſtatutes, to ſee that officers and ſtudents do their duty, that courts be duly called, &c. When he enters upon his office, he chooſes four pro-vice-chancellors out of the heads of the colleges, to execute his power in his abſence.

The chancellor of Cambridge is alſo uſually one of the prime nobility, and in moſt reſpects the ſame as that in Oxford; only he does not hold his office *durante vita*, but may be elected every three years. Under the chancellor there is a commiſſary, who holds a court of record for all privileged perſons and ſcholars under the degree of maſter of arts, where all cauſes are tried and determined by the civil and ſtatute law, and by the cuſtom of the univerſity.

The vice-chancellor of Cambridge is choſen annually by the ſenate, out of two perſons nominated by the heads of the ſeveral colleges and halls.

CHANCELLOR's Court. See *UNIVERSITY Courts*.

CHANCERON, in natural hiſtory, a name given by the French writers to the ſmall caterpillar that eats the corn, and does vaſt miſchief in their granaries. See the article *CORN-Butterfly*.

CHANCERY, the higheſt court of juſtice in Britain next to the parliament, and of very ancient inſtitution. It has its name chancery (*cancellaria*) from the judge who preſides here, the lord chancellor, or *cancellarius*; who, according to Sir Edward Coke, is ſo termed *a cancellando*, from cancelling the king's letters patent when granted contrary to law, which is the higheſt point of his juriſdiction. In chancery there are two diſtinct tribunals: the one ordinary, being a court of common law; the other extraordinary, being a court of equity.

Blackſt. Comment.

1. The *ordinary* legal court holds pleas of recognizances acknowledged in the chancery, writs of *ſcire facias*, for repeal of letters patent, writs of partition, &c. and alſo of all perſonal actions by or againſt any officer of the court. Sometimes a *ſuperſedeas*, or writ of privilege, hath been here granted to diſcharge a perſon out of priſon; one from hence may have a *habeas corpus* prohibition, &c. in the vacation: and here a *ſubpœna* may be had to force witneſſes to appear in other courts, when they have no power to call them. But, in proſecuting cauſes, if the parties deſcend to iſſue, this court cannot try it by jury; but the lord chancellor delivers the record into the king's bench to be tried there; and after trial had, it is to be remanded into the chancery, and there judgment given: tho' if there be a demurrer in law, it ſhall be argued in this court.

In this court is alſo kept the *officina juſtitiæ*; out of which all original writs that paſs under the great ſeal, all commiſſions of charitable uſes, ſewers, bankruptcy, idiocy,

idiocy, lunacy, and the like, do iſſue; and for which it is always open to the ſubject, who may there at any time demand and have, *ex debito juſtitiæ*, any writ that his occaſions may call for. Theſe writs, relating to the buſineſs of the ſubject, and the returns of them, were, according to the ſimplicity of ancient times, originally kept in a hamper, *in hanaperio*; and the others (relating to ſuch matters wherein the crown is mediately or immediately concerned) where preſerved in a little ſack or bag, *in parva baga*: and hence hath ariſen the diſtinction of the *hanaper* office, and the *petty-bag* office, which both belong to the common law-court in chancery.

2. The *extraordinary* court, or court of equity, proceeds by the rules of equity and conſcience; and moderates the rigour of the common law, conſidering the *intention* rather than the *words* of the law. It gives relief for and againſt infants notwithſtanding their minority, and for and againſt married women notwithſtanding their coverture. All frauds and deceits for which there is no redreſs at common law; all breaches of truſt and confidence; and accidents, as to relieve obligors, mortgagers, &c. againſt penalties and forfeitures, where the intent was to pay the debt, are here remedied: for in chancery, a forfeiture, &c. ſhall not bind, where a thing may be done after or compenſation made for it. Alſo this court will give relief againſt the extremity of unreaſonable engagements entered into without conſideration; oblige creditors that are unreaſonable to compound with an unfortunate debtor; and make executors, &c. give ſecurity and pay intereſt for money that is to lie long in their hands. This court may confirm title to lands, though one hath loſt his writings; and render conveyances, defective through miſtake, &c. good and perfect. In chancery, copy-holders may be relieved againſt the ill uſage of their lords; incloſures of lands that are common be decreed; and this court may decree money or lands given to charitable uſes, oblige men to account with each other, &c. But in all caſes where the plaintiff can have his remedy at law, he ought not to be relieved in chancery; and a thing which may be tried by a jury is not triable in this court.

The proceedings in chancery are, firſt to file the bill of complaint, ſigned by ſome counſel, ſetting forth the fraud or injury done, or wrong ſuſtained, and praying relief: after the bill is filed, proceſs of *ſubpœna* iſſues to compel the defendant to appear; and when the defendant appears, he puts in his anſwer to the bill of complaint, if there be no cauſe for the plea to the juriſdiction of the court, in diſability of the perſon, or in bar, &c. Then the plaintiff brings his replication, unleſs he files exceptions againſt the anſwer as inſufficient, referring it to a maſter to report whether it be ſufficient or not; to which report exceptions may alſo be made. The anſwer, replication, rejoinder, &c. being ſettled, and the parties come to iſſue, witneſſes are to be examined upon interrogatories, either in court, or by commiſſion in the country, wherein the parties uſually join; and when the plaintiff and defendant have examined their witneſſes, publication is to be made of the depoſitions, and the cauſe is to be ſet down for hearing; after which follows the decree. But it is now uſual to appeal to the houſe of lords; which appeals are to be ſigned by two noted counſel, and exhibited by way of petition; the petition or appeal is lodged with the clerk of the houſe of lords, and read in the houſe, whereon the appellee is ordered to put in his anſwer, and a day fixed for hearing the cauſe; and after counſel heard, and evidence given on both ſides, the lords will affirm or reverſe the decree of the chancery, and finally determine the cauſe by a majority of votes, &c.

CHANDELIER, in fortification, a kind of moveable parapet, conſiſting of a wooden frame, made of two upright ſtakes, about ſix feet high, with croſs planks between them; ſerving to ſupport faſcines to cover the pioneers.

CHANDERNAGORE, a French ſettlement in the kingdom of Bengal in the Eaſt-Indies. It lies on the river Ganges, two leagues and a half above Calcutta. The diſtrict is hardly a league in circumference, and has the diſadvantage of being ſomewhat expoſed on the weſtern ſide; but its habour is excellent, and the air is as pure as it can be on the banks of the Ganges. Whenever any building is undertaken that requires ſtrength, it muſt here, as well as in all other parts of Bengal, be built upon piles; it being impoſſible to dig three or four feet without coming at water.

CHANDLER, (Mary) diſtinguiſhed by her talent for poetry, was the daughter of a diſſenting miniſter at Bath; and was born at Malmſbury in Wiltſhire, in 1687. She was bred a milliner; but from her childhood had a turn for poetry, and in her riper years applied herſelf to the ſtudy of the poets. Her poems, for which ſhe was complimented by Mr Pope, breathe the ſpirit of piety and philoſophy. She had the misfortune to be deformed, which determined her to live ſingle; though ſhe had great ſweetneſs of countenance, and was ſolicited to marry. She died in 1745, aged 58.

CHANDLER, (Dr Samuel) a learned and reſpectable diſſenting miniſter, deſcended from anceſtors heartily engaged in the cauſe of religious liberty, and ſufferers for the ſake of conſcience and nonconformity; was born at Hungerford in Berks, where his father was a miniſter of conſiderable worth and abilities. Being by his literary turn deſtined to the miniſtry, he was at firſt placed at an academy at Bridgewater, and from thence removed to Glouceſter under Mr Samuel Jones. Among the pupils of Mr Jones were Mr Joſeph Butler, afterwards biſhop of Durham, and Mr Thomas Secker, afterwards archbiſhop of Canterbury. With theſe eminent perſons he contracted a friendſhip that continued to the end of their lives, notwithſtanding the different views by which their conduct was afterwards directed, and the different ſituations in which they were placed.

Mr Chandler having finiſhed his academical ſtudies, began to preach about July 1714; and being ſoon diſtinguiſhed by his talents in the pulpit, he was choſen in 1716 miniſter of the Preſbyterian congregation at Peckham near London, in which ſtation he continued ſome years. Here he entered in the matrimonial ſtate, and began to have an increaſing family, when, by the fatal South-ſea ſcheme of 1720, he unfortunately loſt the whole fortune which he had received with his wife. His circumſtances being thereby embarraſſed, and his income as a miniſter being inadequate to his expences, he engaged in the trade of a bookſeller, and kept a ſhop in the Poultry, London, for about two or three

Chandler.

years, ſtill continuing to diſcharge the duties of the paſtoral office. He alſo officiated as joint preacher with the learned Dr Lardner of a winter weekly evening lecture at the meeting-houſe in the Old Jewry, London: in which meeting he was eſtabliſhed aſſiſtant preacher about the year 1725, and then as the paſtor. Here he miniſtered to the religious improvement of a very reſpectable congregation for 40 years with the greateſt applauſe; and with what diligence and application he improved the vacancies of time from his paſtoral duties, for improving himſelf and benefiting the world, will appear from his many writings on a variety of important ſubjects. While he was thus laudably employed, not only the univerſities of Edinburgh and Aberdeen gave him, without any application, teſtimonies of their eſteem in diplomas, conferring on him the degree of D. D. but he alſo received offers of preferment from ſome of the governors of the eſtabliſhed church, which he nobly declined. He had likewiſe the honour of being afterwards elected F. R. and A. SS.

On the death of George II. in 1760, Dr Chandler publiſhed a ſermon on that event, in which he compared that prince to King David. This gave riſe to a pamphlet, which was printed in the year 1761, intitled "The Hiſtory of the Man after God's own Heart;" wherein the author ventured to exhibit King David as an example of perfidy, luſt, and cruelty, fit only to be ranked with a Nero or a Caligula; and complained of the inſult that had been offered to the memory of the late Britiſh monarch by Dr Chandler's parallel between him and the king of Iſrael. This attack occaſioned Dr Chandler to publiſh in the following year "A Review of the Hiſtory of the Man after God's own Heart; in which the Falſehoods and Miſrepreſentations of the Hiſtorian are expoſed and corrected." He alſo prepared for the preſs a more elaborate work, which was afterwards publiſhed in two volumes 8vo, under the following title: "A Critical Hiſtory of the Life of David: in which the principal Events are ranged in Order of time; the chief Objections of Mr Bayle and others againſt the Character of this Prince, and the Scripture Account of him, and the Occurrences of his Reign, are examined and refuted; and the Pſalms which refer to him explained." As this was the laſt, it was likewiſe one of the beſt, of Dr Chandler's productions. The greateſt part of this work was printed off at the time of our author's death, which happened May 8th 1766, aged 73. During the laſt year of his life, he was viſited with frequent returns of a very painful diſorder, which he endured with great reſignation and Chriſtian fortitude. He was interred in the burying-ground at Bunhill-fields on the 16th of the month; and his funeral was very honourably attended by miniſters and other gentlemen. He expreſsly deſired, by his laſt will, that no delineation of his character might be given in his funeral ſermon, which was preached by Dr Amory. He had ſeveral children; two ſons and a daughter who died before him, and three daughters who ſurvived him; two of whom are yet living, and both married, one of them to the Rev. Dr Harwood.

Dr Chandler was a man of very extenſive learning and eminent abilities; his apprehenſion was quick and his judgment penetrating; he had a warm and vigorous imagination; he was a very inſtructive and animated preacher; and his talents in the pulpit and as a writer procured him very great and general eſteem, not only among the diſſenters, but among large numbers of the eſtabliſhed church. He was principally inſtrumental in the eſtabliſhment of the fund for relieving the widows and orphans of poor Proteſtant diſſenting miniſters: the plan of it was firſt formed by him; and it was by his intereſt and application to his friends that many of the ſubſcriptions for its ſupport were procured.

Chandler, Chang-tong.

In 1768, four volumes of our author's ſermons were publiſhed by Dr Amory, according to his own directions in his laſt will; to which was prefixed a neat engraving of him, from an excellent portrait by Mr Chamberlin. He alſo expreſſed a deſire to have ſome of his principal pieces reprinted in four volumes 8vo: propoſals were accordingly publiſhed for that purpoſe, but did not meet with ſufficient encouragement. But in 1777, another work of our author was publiſhed in one volume 4to, under the following title: "A Paraphraſe and Notes on the Epiſtles of St Paul to the Galatians and Epheſians, with doctrinal and practical Obſervations: together with a critical and practical Commentary on the two Epiſtles of St Paul to the Theſſalonians." Dr Chandler alſo left, in his interleaved Bible, a large number of critical notes, chiefly in Latin, which are now the property of Dr Hippis, Mr Farmer, Dr Price, and Dr Savage, and which have been intended to be publiſhed; but the deſign has not yet been executed. A complete liſt of Dr Chandler's works is given in the Biographia Britannica, vol. III. p. 435.

CHANG-TONG, a province of China, bounded on the eaſt by Petcheli and part of Honan, on the ſouth by Kiang-nan, on the eaſt by the ſea, and on the north by the ſea and part of Petcheli. The country is well watered by lakes, ſtreams, and rivers; but is nevertheleſs liable to ſuffer from drought, as rain falls here but ſeldom. The locuſts alſo ſometimes make great devaſtation. However, it abounds greatly in game; and there is perhaps no country where quails, partridges, and pheaſants, are ſold cheaper, the inhabitants of this province being reckoned the keeneſt ſportſmen in the empire. The province is greatly enriched by the river Yun, called the *Grand Imperial Canal*, through which all the barks bound to Pekin muſt paſs in their way thither. The duties on this canal alone amount to more than L. 450,000 annually. The canal itſelf is greatly admired by European travellers on account of its ſtrong and long dikes, the banks decorated with cut ſtone, the ingenious mechaniſm of its locks, and the great number of natural obſtacles which have been overcome in the execution of the work.—The province produces ſilk of the ordinary kind; and, beſides this, another from a ſort of inſect reſembling our caterpillar. It is coarſer than the ordinary ſilk, but much ſtronger and more durable; ſo that the ſtuffs made from it have a very extenſive ſale throughout the empire.

Chang-tong is remarkable for being the birth-place of the celebrated philoſopher and lawgiver Confucius. His native city is called *Kio-feou*, where there are ſeveral monuments erected in honour of this great man. The province is divided into ſix diſtricts, which contain ſix cities of the firſt claſs, and 114 of the ſecond and third. Along the coaſt, alſo, are 15 or 16 villages of cofiderable importance on account of their commerce; there are likewiſe a number of ſmall iſlands, moſt of which have harbours very convenient for the Chineſe junks which paſs from thence to Corea or Lea-tong. The moſt remarkable cities are, 1. Tſi-nan-fou, the capital, which ſtands ſouth of the river Tſingho or Tſi. It is large and populous; but chiefly celebrated for having been the reſidence of a long ſeries of kings, whoſe tombs, riſing on the neighbouring mountains, afford a beautiful proſpect. 2. Yen-tcheu-fou, the ſecond city of the province, ſituated between two rivers, and in a mild and temperate climate. Great quantities of gold are ſaid to have been formerly collected in its neighbourhood. 3. Lin-tcin-tcheu, ſituated on the great canal, is much frequented by ſhips, and may be called a general magazine for every kind of merchandiſe. Here is an octagonal tower, divided into eight ſtories, the walls of which are covered on the outſide with porcelain loaded with various figures neatly executed, and encruſted on the inſide with variouſly coloured marble. A ſtaircaſe, conſtructed in the wall, conducts to all the ſtories, from which there are paſſages that lead into magnificent galleries ornamented with gilt balluſtrades. All the cornices and projections of the tower are furniſhed with little bells; which, ſays Mr Groſier, when agitated by the wind, form a very agreeable harmony. In the higheſt ſtory is an idol of gilt copper, to which the tower is dedicated. In the neighbourhood are ſome other temples, the architecture of which is exceedingly beautiful.

CHANGER, in England, an officer belonging to the king's mint, who changes money for gold or ſilver bullion. See MINT.

Money-CHANGER, is a banker who deals in the exchange, receipt, and payment, of moneys. See BANKER.

CHANGES, in arithmetic, &c. the permutations or variations of any number of quantities; with regard to their poſition, order, &c. See COMBINATION.

To find all the poſſible CHANGES *of any Number of Quantities, or how oft their Order may be varied.*] Suppoſe two quantities *a* and *b*. Since they may be either wrote *a b* or *b a*, it is evident their *changes* are $2=2.1$. Suppoſe three quantities *a b c*: their *changes* will be as in the margin; as is evident by combining *c* firſt with *a b*, then with *b a*; and hence the number of *changes* ariſes $3.\ 2.\ 1=6$. If the quantities be 4, each may be combined four ways with each order of the other three; whence the number of changes ariſes $6.\ 4=4.\ 3.\ 2.\ 1.=24$. Whereof, if the number of quantities be ſuppoſed n, the number of *changes* will be $n.n-1.n-2.n-3.n-4.$&c. If the ſame quantity occur twice, the *changes* of two will be found *b b*; of three, *b a b*, *a b b*, *b b c*; of four, *c b a b*, *b c a b*, *b a b c*. And thus the number of *changes* in the firſt caſe will be $1=(2.\ 1):2.\ 1$; in the ſecond, $3=(3.\ 2.\ 1):2.\ 1$: in the third, $12=(4.\ 3.\ 2.\ 1):2.\ 1$.

c a b
a c b
a b c
——
c b a
b c a
b a c

If a fifth letter be added, in each ſeries of four quantities, it will beget five *changes*, whence the number of all the *changes* will be $60=(5.\ 4.\ 3.\ 2.)\ 1,:2.\ 1.$ Hence if the number of quantities be n, the number of *changes* will be $(n.n-1.n-2.n-3.n-4.\ \text{\&c.}):2.\ 1.$ From theſe ſpecial formulæ may be collected a general one, viz. if n be the number of quantities, and m the number which ſhows how oft the ſame quantity occurs; we ſhall have $(n.n-1.n-2.n-3.n-4.n-5.n-6.n-7.n-8.n-9.\ \text{\&c.}:m-1.m-2.m-3.m-4.\ \text{\&c.})$ the ſeries being to be continued, till the continual ſubtraction of unity from n and m leave 0. After the ſame manner we may proceed further, till putting n for the number of quantities, and l, m, r, &c. for the number that ſhows how oft any of them is repeated, we arrive at an univerſal form. $(n.n-1.n-2.n-3.n-4.n-5.n-6.n-7.n-8.\ \text{\&c.}):(l.l-1.l-2.l-3.l-4.l-5.\ \text{\&c.}\ m.m-1.m-2.m-3.\ \text{\&c.}\ r.r-1.r-2.r-3.r-4.r-5.\ \text{\&c.}$

Suppoſe, for inſtance, $n=6$, $l=3$, $r=0$. The number of *changes* will be $(6.\ 5.\ 4.\ 3.\ 2.\ 1.):(3.\ 2.\ 1.\ 3.\ 2.\ 1.)=(6.\ 5.\ 4.):(3.\ 2=2.\ 5.\ 2=20)$.

Hence, ſuppoſe thirteen perſons at a table, if it be required how oft they may *change* places; we ſhall find the number $13.\ 12.\ 11.\ 10.\ 9.\ 8.\ 7.\ 6.\ 5.\ 4.\ 3.\ 2.\ 1.=6227020800$.

In this manner may all the poſſible anagrams of any word be found in all languages, and that without any ſtudy: ſuppoſe *v. g.* it were required to find the anagrams of the word *amor*, the number of *changes* will be

a

The anagrams therefore of the word *amor*, in the Latin tongue, are *roma*, *mora*, *maro*, *ramo*, *armo*. See ANAGRAM.

Whether this new method of anagramatizing be like to prove of much ſervice to that art, is left to the poets.

CHANNA, in zoology, the name of a fiſh caught in great plenty in the Mediterranean, and brought to market in Italy and elſewhere, among the ſea-perch, which it ſo nearly reſembles, that it would not be diſtinguiſhable from it, but that the ſea-perch is bigger, and has only broad tranſverſe lines on its back, whereas the channa has them both tranſverſe and longitudinal. It has a very wide mouth, and its lower jaw is longer than its upper; ſo that its mouth naturally falls open. Its eyes are ſmall, and its teeth very ſharp: its back is of a blackiſh red: it has ſeveral longitudinal lines of a reddiſh hue, and its tail is marked with reddiſh ſpots. There is an obſervation, that in all the fiſh of this kind which have been examined by naturaliſts, there have been found none but females. This is as old as the days of Ariſtotle. Whether this be true in fact, would require many obſervations. If it ſhould prove ſo, the whole ſeems to end in this, that the channa is no diſtinct ſpecies, but only the female of ſome other fiſh. There is another fiſh not unlike this, called *cannadella*, or rather *channadella*, which at Marſeilles is known by the name of *charina*.

CHANNEL, in geography, an arm of the ſea, or a narrow ſea between two continents, or between a continent and an iſland. Such are the Britiſh channel, St George's channel, the channel of Conſtantinople, &c.

Channel of a Ship. See *Chain-Wales.*

CHAN-SI, a province of China, and one of the ſmalleſt in the empire, is bounded on the eaſt by Pet-cheli, on the ſouth by Honan, on the weſt by Chen-ſi, and on the north by the great wall. The climate is healthful and agreeable, and the ſoil generally fertile, though the country is full of mountains. Some of the laſt are rough, wild, and uninhabited; but others are cultivated with the greateſt care from top to bottom, and cut into terraces, forming a very agreeable proſpect; while ſome have on their tops vaſt plains no leſs fertile than the richeſt low-lands. Theſe mountains abound with coal, which the inhabitants pound and make into cakes with water; a kind of fuel which, though not very inflammable, affords a ſtrong and laſting fuel when once kindled. It is principally uſed for heating their ſtoves, which are conſtructed with brick as in Germany; but the inhabitants of this province give them the form of ſmall beds, and ſleep upon them. The beſt grapes to be met with in this part of Aſia grow in the province of Chan-ſi; ſo that good wine might be made, but the people chooſe rather to dry and ſell them to the neighbouring provinces. The country abounds with muſk, prophyry, marble, lapis lazuli, and jaſper of various colours; and iron mines as well as ſalt-pits and cryſtal are very common. Here are five cities of the firſt claſs, and eighty-five of the ſecond and third: the moſt remarkable are, 1. Tai-youen-fou the capital, an ancient city about three leagues in circumference, but much decayed in conſequence of being no longer the reſidence of the princes of the blood as it was formerly. Nothing now remains of the palaces of thoſe prince's but a few ruins: but their tombs are ſtill to be ſeen on a neighbouring mountain. The burying-place is magnificently ornamented; and all the tombs are of marble or cut ſtone, having near them triumphal arches, ſtatues of heroes, figures of lions and different animals, eſpecially horſes, and which are diſpoſed in very elegant order. An awful and melancholy gloom is preſerved around theſe tombs by groves of aged cypreſſes, which have never felt the ſtroke of an axe, placed chequer-wiſe. The principal articles of trade here are, hard-ware, ſtuffs of different kinds, particularly carpets in imitation of thoſe of Turkey. 2. Ngan-y is ſituated near a lake as ſalt as the ocean, from which a great quantity of ſalt is extracted. 3. Fuen-tcheou-fou, an ancient and commercial city, built on the banks of the river Fuenho: it has baths and ſprings almoſt boiling hot, which by drawing hither a great number of ſtrangers, add greatly to its opulence. 4. Tai-tong-fou; ſituated near the wall, is a place of great ſtrength, and important by reaſon of its ſituation, as being the only one expoſed to the incurſions of the Tartars. Its territories abound with lapis lazuli, medicinal herbs, and a particular kind of jaſper called *yieche*, which is as white and beautiful as agate; marble and prophyry are alſo common; and a great revenue is produced from the ſkins which are dreſſed here.

CHANT, *(cantus)*, is uſed for the vocal muſic of churches.

In church hiſtory we meet with divers kinds of *chant* or *ſong*. The firſt is the *Ambroſian*, eſtabliſhed by St Ambroſe. The ſecond, the *Gregorian chant*, introduced by Pope Gregory the great, who eſtabliſhed ſchools of chantors, and corrected the church-ſong. This is ſtill retained in the church under the name of *plain ſong*: at firſt it was called the *Roman ſong*. The *plain* or *Gregorian chant*, is where the choir and people ſing in uniſon, or all together in the ſame manner.

CHANTILLY, a village in France, about ſeven leagues from Paris, where there is a magnificent palace and fine foreſt belonging to the duke of Bourbon.

CHANTOR, a ſinger of a choir in a cathedral. The words is almoſt grown obſolete, *choriſter* or *ſinging-man* being commonly uſed inſtead of it. All great chaptors have chantors and chaplains to aſſiſt the canons, and officiate in their abſence.

Chantor is uſed by way excellence for the precentor maſter of the choir, which is one of the firſt dignities of the chapter. At St David's in Wales, where there is no dean, he is next in dignity to the biſhop. The ancients called the chantor *primicerius cantorum*. To him belonged the direction of the deacons and other inferior officers.

Chantors, in the temple of Jeruſalem, were a number of Levites employed in ſinging the praiſes of God, and playing upon inſtruments before his altar. They had no habits diſtinct from the reſt of the people; yet in the ceremony of removing the ark to Solomon's temple, the chantors appeared dreſſed in tunics of byſſus or fine linen. 2 Chron. v. 12.

CHANTRY, or Chauntry, was anciently a church or chapel endowed with lands, or other yearly revenue, for the maintenance of one or more prieſts, daily ſaying or ſinging maſs for the ſouls of the donors, and ſuch others as they appointed. Hence *chauntry-rents* are rents paid to the crown by the tenants or purchaſers of *chauntry lands*.

CHAOLOGY the hiſtory or deſcription of the choas. See Chaos.

Orpheus, in his chaology, ſets forth the different alterations, ſecretions, and divers forms which matter went through till it became inhabitable, which amounts to the ſame with what we otherwiſe call *coſmogony*. Dr Burnet, in his theory of the earth repreſents the chaos as it was at firſt, entire, undivided, and univerſally rude and deformed; or the *tohu bohu*: then ſhews how it came to be divided into its reſpective regions; how the homogeneous matter gathered itſelf apart from all of a contrary principle; and laſtly, how it hardened and became a ſolid habitable globe. See Earth.

CHAOS, that confuſion in which matter lay when newly produced out of nothing at the beginning of the world, before God, by his almighty word, had put it into the order and condition wherein it was after the ſix days creation. See Earth.

Chaos is repreſented by the ancients as the firſt principle, ovum, or ſeed of nature and the world. All the ſophiſts, ſages, naturaliſts, philoſophers, theologues, and poets, held that chaos was the eldeſt and firſt principle, το αρχαιον χαος. The Barbarians, Phœnicians, Egyptians, Perſians, &c. all refer the origin of the world to a rude, mixed, confuſed maſs of matter. The Greeks, Orpheus, Heſiod, Menander, Ariſtophanes, Euripides, and the writers of the Cyclic Poems, all ſpeak of the firſt chaos: the Ionic and Platonic Philoſophers build the world out of it. The Stoics hold, that as the world was firſt made of a chaos, it ſhall at laſt be reduced to a chaos; and that its periods and revolutions in the mean time are only tranſitions from one chaos to another. Laſtly, the Latins as Ennius, Varro, Ovid, Lucretius, Statius, &c. are all of the ſame opinion. Nor is there any ſect or nation whatever, that does not derive their *διακοσμησις*, *the ſtructure of the world*, from chaos.

The opinion firſt aroſe among the Barbarians, whence it ſpread to the Greeks, and from the Greeks to the Romans and other nations. Dr Burnet obſerves, that beſides Ariſtotle and a few other pſeudo-Pythagoreans, nobody ever aſſerted that our world was always from eternity of the ſame nature, form and ſtructure, as at preſent; but that it had been the ſtanding opinion of the wiſe men of all ages, that what we now call the *terreſtrial globe*, was originally an unformed, indigeſted maſs of heterogeneous matter, called *chaos*; and no more than the rudiments and materials of the preſent world.

It does not appear who firſt broached the notion of a chaos. Moſes, the eldeſt of all writers, drives the origin of this world from a confuſion of matter, dark, void, deep, without form, which he calls *tohu bohu*; which is preciſely the chaos of the Greek and Barbarian philoſophers. Moſes goes no further than the chaos; nor tells us whence it took its origin, or whence its confuſed ſtate; and where Moſes ſtops, there, preciſely, do all the reſt. Dr Burnet endeavours to ſhow, that as the ancient philoſophers, &c. who wrote of the coſmogony, acknowledged a chaos for the principle of their world; ſo the divines, or writers of the theogony, derive the origin or generation of their fabled gods from the ſame principle.

Mr Whiſton ſuppoſes the ancient chaos, the origin of our earth, to have been the atmoſphere of a comet; which, though new, yet, all things conſidered, is not the moſt improbable aſſertion. He endeavours to make it out by many arguments, drawn from the agreement which appears to be between them. So that, according to him, every planet is a comet, formed into a regular and laſting conſtitution, and placed at a proper diſtance from the ſun, revolving in a nearly circular orbit: and a comet is a planet either beginning to be deſtroyed or re-made; that is, a chaos or planet unformed or in its primæval ſtate, and placed as yet in an orbit very eccentrical.

Chaos, in the phraſe of Paracelſus, imports the air. It has alſo ſome other ſignifications amongſt the alchemiſts.

Chaos, in zoology, a genus of inſects belonging to the order of vermes zoophyta. The body has no ſhell or covering, and is capable of reviving after being dead to appearance for a long time: it has no joints or external organs of ſenſation. There are five ſpecies, moſtly obtained by infuſion of different vegetables in water, and only diſcoverable by the microſcope. See Animalcule.

CHAPEAU, in heraldry, an ancient cap of dignity worn by dukes, being ſcarlet-coloured velvet on the outſide, and lined with a fur. It is frequently borne above an helmet inſtead of a wreath, under gentlemens creſts.

CHAPEL, a place of divine worſhip, ſo called. The word is derived from the Latin *capella*. In former times when the kings of France were engaged in war they always carried St Martin's hat into the field, which was kept in a tent as a precious relic: from whence the place was called *capella*; and the prieſt, who had the cuſtody of the tent, *capellani*. Afterwards the word *capella* became applied to private oratories.

In Britain there are ſeveral ſorts of chapels. 1. Parochial chapels: theſe differ from pariſh-churches only in name; they are generally ſmall, and the inhabitants within the diſtrict few. If there be a preſentation *ad eccleſiam*, inſtead of *capellam*, and an admiſſion and inſtitution upon it, it is no longer a chapel, but a church. 2. Chapels, which adjoin to, and are part of the church; ſuch were formerly built by honourable perſons, as burying-places for themſelves and their families. 3. Chapels of eaſe; theſe are uſually built in very large pariſhes, where all the people cannot conveniently repair to the mother-church. 4. Free chapels; ſuch as were founded by kings of England. They are free from all epiſcopal juriſdiction, and only to be viſited by the founder and his ſucceſſors; which is done by the lord chancellor; yet the king may licenſe any ſubject to build and endow a chapel, and by letters patent exempt it from the viſitation of the ordinary. 5. Chapels in the univerſities, belonging to particular colleges. 6. Domeſtic chapels, built by noblemen or gentlemen for the private ſervice of God in their families. See Chaplain.

Chapel is alſo a name given to a printer's workhouſe; becauſe, according to ſome authors, printing was firſt actually performed in chapels or churches, or, according to others, becauſe Caxton, an early printer, exerciſed the art in one of the chapels in Weſtminſter Abby. In this ſenſe they ſay, *the orders* or *laws of the chapel*, *the ſecrets of the chapel*, &c.

Knights of the Chapel, called alſo *Poor knights of Windſor*, were inſtitued by Henry VIII. in his teſtament. Their number was at firſt thirteen, but has been ſince augmented to twenty-ſix. They aſſiſt in the funeral ſervices of the kings of England: they are ſubject to the office of the canons of Windſor, and live on penſions aſſigned them by the order of the garter. They bear a blue or red cloak, with the arms of St George on the left ſhoulder.

CHAPELAIN, (James) an eminent French poet born at Paris in 1595, and often mentioned in the works of Balzac, Menage, and other learned men. He wrote ſeveral works, and at length diſtinguiſhed himſelf by a heroic poem called *La Pucelle, ou France Delivrée*, which employed him ſeveral years; and which, raiſing the expectation of the public, was as much decried by ſome as extolled by others. He was one of the king's counſellors; and died in 1674, very rich, but was very covetous and ſordid.

CHAPELET, in the manege, a couple of ſtirrup-leathers, mounted each of them with a ſtirrup, and joined at top in a ſort of leather buckle, called the *head of the chapelets*, by which they are made faſt to the pummel of the ſaddle, after being adjuſted to the rider's length and bore. They are uſed both to avoid the trouble of taking up or letting down the ſtirrups every time that the gentleman mounts on a different horſe and

and ſaddle, and to ſupply the place of the academy ſaddles, which have no ſtirrups to them.

CHAPELLE, (Claudius Emanuel Luillier) the natural ſon of Francis Lullier, took the name of *Chapelle* from a village between Paris and St Denys, where he was born. He diſtinguiſhed himſelf by writing ſmall pieces of poetry, in which he diſcovered great delicacy, an eaſy turn, and an admirable facility of expreſſion. He was the friend of Gaſſendi and Moliere; and died in 1686.

CHAPERON, **CHAPERONNE**, or **CHAPEROON**, properly ſignifies a ſort of hood or covering of the head anciently worn both by men and women, the nobles and the populace, and afterwards appropriated to the doctors, and licentiates in colleges, &c. Hence the name paſſed to certain little ſhields, and other funeral devices, placed on the foreheads of the horſes that drew the hearſes in pompous funerals, and which are ſtill called *chaperoons*, or *ſhafferoons*; becauſe ſuch devices were originally faſtened on the *chaperonnes*, or hoods, worn by thoſe horſes with their other coverings of ſtate.

CHAPERON *of a bit-mouth*, in the manege, is only uſed for ſcatch-mouths, and all others that are not cannon-mouths, ſignifying the end of the bit that joins to the branch juſt by the banquet. In ſcatch-mouths the chaperon is round, but in others it is oval: and the ſame part that in ſcatch and other mouths is called *chaperon*, is in cannon-mouths called *fronceau*.

CHAPITERS, in architecture, the ſame with CAPITALS.

CHAPITERS, in law, formerly ſignified a ſummary of ſuch matters as were inquired of, or preſented before juſtices in eyre, juſtices of aſſize, or of the peace in their ſeſſions.

Chapiters, at this time, denote ſuch articles as are delivered by the mouth of the juſtice in his charge to the inqueſt.

CHAPLAIN properly ſignifies a perſon provided with a chapel; or who diſcharges the duty thereof.

CHAPLAIN is alſo uſed for an eccleſiaſtical perſon, in the houſe of a prince, or a perſon of quality, who officiates in their chapels, &c.

In England there are 48 chaplains to the king, who wait four each month, preach in the chapel, read the ſervice to the family, and to the king in his private oratory, and ſay grace in the abſence of the clerk of the cloſet. While in waiting they have a table, and attendance, but no ſalary. In Scotland the king has ſix chaplains, with a ſalary of L. 50 each, three of them having in addition the deanery of the chapel-royal divided between them, making up above L. 100 to each. Their only duty at preſent is to ſay prayers at the election of peers for Scotland to ſit in parliament.——According to a ſtatute of Henry VIII. the perſons veſted with a power of retaining chaplains, together with the number each is allowed to qualify, is as follows: An archbiſhop, eight; a duke or biſhop, ſix; marquis or earl, five; viſcount, four; baron, knight of the garter, or lord chancellor three; a ducheſs, marchioneſs, counteſs, baroneſs, the treaſurer and comptroller of the king's houſe, clerk of the cloſet, the king's ſecretary, dean of the chapel, almoner, and maſter of the rolls, each of them two; chief juſtice of the kings bench, and warden of the cinque-parts, each one. All theſe chaplains may purchaſe a licence or diſpenſation, and take two benefices with cure of ſouls. A chaplain muſt be retained by letters teſtimonial under hand and ſeal; for it is not ſufficient that he ſerve as chaplain in the family.

The firſt chaplains are ſaid to have been thoſe inſtituted by the ancient kings of France, for preſerving the chape, or cape, with the other relics of St Martin, which the kings kept in their palace, and carried out with them to the war. The firſt chaplain is ſaid to have been Gul. de Meſmes, chaplain to St Louis.

CHAPLAIN *in the order of Malta*, is uſed for the ſecond rank, or claſs, in that order; otherwiſe called *diaco*.

The knights make the firſt claſs, and the chaplains the ſecond.

CHAPLAINS *of the Pope*, are the auditors, or judges of cauſes in the ſacred palace; ſo called, becauſe the pope anciently gave audience in his chapel, for the deciſion of caſes ſent from the ſeveral parts of Chriſtendom. He hither ſummoned as aſſeſſors the moſt learned lawyers of his time; and they hence acquired the appellation of *capellani*, chaplains. It is from the decrees formerly given by theſe, that the body of decretals is compoſed: their number pope Sixtus IV. reduced to twelve.

Some ſay, the ſhrines of relics were covered with a kind of tent, cape, or *capella*, i. e. little cape; and that hence the prieſts that had the care of them, were called chaplains. In time theſe relics where repoſited in a little church, either contiguous to a larger, or ſeparate from it; and the ſame name, *capella*, which was given to the cover, was alſo given to the place where it was lodged: and hence the prieſt who ſuperintended it came to be called chaplain.

CHAPLET, an ancient ornament for the head, like a garland or wreath; but this word is frequently uſed to ſignify the circle of a crown. There are inſtances of its being borne in a coat of arms, as well as for creſts; the paternal arms for Laſcelles are argent, three chaplets, gules.

CHAPLET alſo denotes a ſtring of beads uſed by the Roman Catholics, to count the number of their prayers. The invention of it is aſcribed to Peter the hermit, who probably learned it of the Turks, as they owe it to the Eaſt-Indians.

Chaplets are ſometimes called *pater-noſters*; and are made of coral, of diamonds, of wood, *&c.* The common chaplet contains fifty ave-marias, and five pater-noſters. There is alſo a chaplet of our Saviour, conſiſting of 33 beads, in honour of his 33 years living on earth, inſtituted by father Michael the Camaldulian.

The Orientals have a kind of chaplets which they call *chains*, and which they uſe in their prayers, rehearſing one of the perfections of God on each link or head. The great Mogul is ſaid to have 18 of theſe chains, all precious ſtones; ſome diamonds, others rubies, pearls, &c. The Turks have likewiſe chaplets, which they bear in the hand, or hang it at the girdle; but father Dandini obſerves, they differ from thoſe uſed by the Romaniſts, in that they are all of the ſame bigneſs, and have not that diſtinction into decads; though they conſiſt of ſix decads, or 60 beads. He adds, that the muſſulmans run over the chaplet almoſt in an inſtant, the prayers being extremely ſhort, as containing only theſe words, "praiſe to God," or "glory to God," for each bead. Beſides the common chaplet they have likewiſe a larger one conſiſting of 100 beads, where there is ſome diſtinction, as being divided by little threads into three parts; on one of which they repeat 30 times *ſoubhan Allah*, i. e "God is worthy to be praiſed;" on another, *ellamb Allah*, "glory be to God;" and on the third, *Allah echer*, "God is great." Theſe thrice thirty times making only 90; to complete the number 100, they add other prayers for the beginning of the chaplet.—He adds, that the Mahometan chaplet appears to have had its riſe from the *mea beracoth*, or "hundred benedictions; which the Jews are obliged to repeat daily, and which we find in their prayer-books; the Jews and Mahometans having this in common, that they ſcarce do any thing without pronouncing ſome laud or benediction.

Menage derives the word *chaplet* from *chapeau*, "hat." The modern Latins call it *chapellina*, the Italians more frequently *corona*.

Chaplet, or *Chapelet*, in architecture, a little moulding, cut, or carved into round beads, pearls, olives, or the like.

CHAPMAN, (George) born in 1557, a man highly eſteemed in his time for his dramatic and poetic works. He wrote 17 plays; tranſlated Homer and ſome other ancient poets; and was thought no mean genius. He died in 1634; and he was buried in St Gile's in the fields, where his friend Inigo Jones erected a monument to him.

CHAPPE', in heraldry, the dividing an eſcutheon by lines drawn from the centre of the upper edge to the angles below, into three parts, the ſections on the ſides being of different metal or colour from the reſt.

CHAPPEL in frith, a market-town of Derbyſhire, about 26 miles north-weſt of Derby; W. Long. 1. 50. N. Lat. 53. 22.

Chappel, (William) a learned and pious biſhop of Cork, Cloyne, and Roſs, in Ireland, born in Nottinghamſhire in 1582. When the troubles began under Charles I. he was proſecuted by the puritan party in parliament, and retired to Derby, where he devoted himſelf to ſtudy until his death in 1649. He wrote *Methodus Concionandi*, i. e. "the method of preaching:" and he is one of thoſe to whom the *Whole Duty of Man* has been attributed. He left behind him alſo his own life written by himſelf in Latin, which has been twice printed.

CHAPTER, in eccleſiaſtical polity, a ſociety or community of clergymen belonging to the cathedrals and collegiate churches.

It was in the eighth century that the body of canons began to be called a chapter. The chapter of the canons of a cathedral were a ſtanding council to the biſhop, and, during the vacancy of the ſee, had the juriſdiction of the dioceſe. In the earlier ages, the biſhop was head of the chapter; afterwards abbots and other dignitaries, as deans, provoſts, treaſurers, &c. were preferred to this diſtinction. The deans and chapters had the privilege of chooſing the biſhops in England; but Henry VIII. got this power veſted in the crown: and as the ſame prince expelled the monks from the cathedrals, and placed ſecular canons in their room, thoſe he thus regulated were called deans and chapters of the new foundation; ſuch are Canterbury, Wincheſter, Ely, Carliſle, &c. See Dean.

Chapter, in matters in literature, a diviſion in a book for keeping the ſubject treated of more clear and diſtinct.

CHAR, in ichthyology, a ſpecies of Salmo.

CHARA, in botany: A genus of the monandria order, belonging to the monœcia claſs of plants. There is neither male calyx nor corolla; and the anthera is placed under the germen. The female calyx is tetraphyllous; no corolla; the ſtigma quinquefid, with one roundiſh ſeed.

CHARABON, a ſea-port town on the northern coaſt of the iſland of Java in the Eaſt-Indies; E. Long. 10. 8. S. Lat. 6.

CHARACENE, the moſt ſouthern part of Suſiana, a province of Perſia, lying on the Perſian gulph, between the Tigris and the Eulæus. It was ſo named from the city of Chorax, called firſt Alexandria, from its founder Alexander the Great; afterwards Antiochia, from Antiochus V. king of Syria, who repaired and beautified it; and laſtly, Chorax Spaſinæ, or Paſinæ, that is the Mole of the Spaſines, an Arabian king of that name having ſecured it againſt the overflowing of the Tigris, by a high bank or mole extending three miles, which ſerved as a fence to all that country. Dionyſius Periegetes, and Iſidorus, author of the Parthicæ Manſiones, were both natives of this city. The ſmall diſtrict of Characene was ſeized by Paſines, the ſon of Sogodonacus, king of the neighbouring Arabs, during the troubles of Syria, and erected into a kingdom. Lucian calls him Hyſpaſines, and adds, that he ruled over the Characeni and the neighbouring people: he died in the 85th year of his age. The other kings of this country we find mentioned by the ancients are, Teræus, who died in the 92d year of his age, and after him Artabazus the ſeventh, as Lucian informs us, who was driven from the throne by his own ſubjects, but reſtored by the Parthians. And this is all we find in the ancients relating to the kings of Characene.

CHARACTER, in a general ſenſe, ſignifies a mark or figure, drawn on paper, metal, ſtone, or other matter, with a pen, graver, chiſſel, or other inſtrument, to ſignify or denote any thing. The word is Greek, χαρακτηρ, formed from the verb, χαρασσειν, *inſculpere*, "to ingrave, impreſs," *&c.*

The various kinds of characters may be reduced to three heads, viz. *Literal Characters*, *Numeral Characters*, and *Abbreviations*.

I. *Literal Character*, is a letter of the alphabet, ſerving to indicate ſome articulate ſound, expreſſive of ſome idea or conception of the mind. See Alphabet.

1. Theſe may be divided, with regard to their nature and uſe, into *Nominal Characters*, or thoſe we properly call *letters*; which ſerve to expreſs the names of things: See Letter. *Real Characters*; thoſe that inſtead of names expreſs things and ideas: See Idea, &c. *Emblematical* or *Symbolical Characters*: which have this in common with real ones, that they expreſs the things themſelves; but have this further, that they in ſome meaſure perſonate them, and exibit their form: ſuch are the hieroglyphics of the ancient Egyptians. See Hieroglyphic, Symbol, &c.

2. *Literal Characters* may be again divided, with regard

regard to their invention and uſe, into *particular* and *general* or *univerſal*.

Particular CHARACTERS, are thoſe peculiar to this or that nation. Such are the Roman, Italic, Greek, Hebrew, Arabic, Gothic, Chineſe, &c. *characters*. See HEBREW, GOTHIC, CHINESE, *&c.*

Univerſal CHARACTERS, are alſo *real characters*, and make what ſome authors call a *Philoſophical Language*.

That diverſity of *characters* uſed by the ſeveral nations to expreſs the ſame idea, is found the chief obſtacle to the advancement of learning: to remove this, ſeveral authors have taken occaſion to propoſe plans of *characters* that ſhould be univerſal, and which each people ſhould read in their own language. The *character* here is to be real, not nominal: to expreſs things and notions; not as the common ones, letters or ſounds: yet to be mute like letters, and arbitrary; not emblematical like hieroglyphics.

Thus, every nation ſhould retain its own language, yet every one underſtand that of each other, without learning it; only by ſeeing a real or univerſal *character*, which ſhould ſignify the ſame things to all people, by what ſounds ſoever each expreſs it in their particular idiom. For inſtance, by ſeeing the *character* deſtined to ſignify *to drink*, an Engliſhman ſhould read *to drink*; a Frenchman, *boire*; a Latin, *bibere*; a Greek, πινειν; a Jew, שמה; a German *trincken*; and ſo of the reſt: in the ſame manner as ſeeing a horſe, each people expreſſes it after their own manner; but all mean the ſame animal.

This real *character* is no chimera; the Chineſe and Japoneſe have already ſomething like it. They have a common *character* which each of thoſe nations underſtand alike in their ſeveral languages; though they pronounce them with ſuch different ſounds, that they do not underſtand one another in ſpeaking.

The firſt and moſt conſiderable attempts for a *real character*, or philoſophical language, in Europe, are thoſe of biſhop Wilkins and Dalgarme: but theſe, with how much art ſoever they were contrived, have yet proved ineffectual.

M. Leibnitz had ſome thoughts the ſame way; he thinks thoſe great men did not hit the right method. It was probable, indeed, that by their means, people, who do not underſtand one another, might eaſily have a commerce together; but they have not hit on true *real characters*.

According to him, the *characters* ſhould reſemble thoſe uſed in Algebra: which, in effect, are very ſimple, yet very expreſſive, without any thing ſuperfluous or equivocal; and contain all the varieties required.

The *real character* of biſhop Wilkins has its juſt applauſe: Dr Hook recommends it on his own knowledge and experience as a moſt excellent ſcheme; and to engage the world to the ſtudy thereof, publiſhes ſome fine inventions of his own therein.

M. Leibnitz tells us, he had under conſideration an *alphabet of human thoughts*; in order to a new philoſophical language, on his own ſcheme: but his death prevented its being brought to maturity.

M. Lodwic, in the Engliſh *philoſophical tranſactions*, gives us a plan of *an univerſal alphabet* or *character* of another kind: this was to contain an enumeration of all ſuch ſingle ſounds, or letters, as are uſed in any language; by means whereof, people ſhould be enabled to pronounce truly and readily any language; to deſcribe the pronunciation of any language that ſhall be pronounced in their hearing, ſo as others accuſtomed to this language, though they had never heard the language pronounced, ſhall at firſt be able truly to pronounce it: and, laſtly, this *character* to ſerve as a ſtandard to perpetuate the ſounds of any language. In the Journal Literaire, *an.* 1720, we have a very ingenious project for an univerſal *character*. The author, after obviating the objections that might be made againſt the feaſibleneſs of ſuch ſchemes in the general, propoſes his own: his *characters* are to be the common Arabic, or numeral figures. The combinations of theſe nine are ſufficient to expreſs diſtinctly an incredible quantity of numbers, much more than we ſhall need terms to ſignify our actions, goods, evils, duties, paſſions, &c. Thus is all the trouble of framing and learning any new *character* at once ſaved; the Arabic figures having already all the univerſality required.

The advantages are immenſe. For, 1*mo*, We have here a ſtable, faithful interpreter; never to be corrupted or changed, as the popular languages continually are. 2*do*, Whereas the difficulty of pronouncing a foreign language is ſuch as uſually gives the learner the greateſt trouble, and there are even ſome ſounds which foreigners never attain to; in the *character* here propoſed, this difficulty has no place: every nation is to pronounce them according to the particular pronunciation that already obtains among them. All the difficulty is, the accuſtoming the pen and the eye to affix certain notions to *characters* that do not, at firſt ſight, exhibit them. But this trouble is no more than we find in the ſtudy of any language whatever.

The inflections of words are here to be expreſſed by the common letters. For inſtance the ſame *character* ſhall expreſs a *filly* or a *colt*, a *horſe* or a *mare*, an *old horſe* or an *old mare*, as accompanied with this or that diſtinctive letter, which ſhall ſhow the ſex, youth, maturity, or old age: a letter alſo to expreſs the bigneſs or ſize of things; thus *v. g.* a man with this or that letter, to ſignify a *great man*, or a *little man*, &c.

The uſe of theſe letters belongs to the grammar; which, once well underſtood, would abridge the vocabulary exceedingly. An advantage of this grammar is, that it would only have one declenſion and one conjugation: thoſe numerous anomalies of grammarians are exceeding troubleſome; and ariſe hence, that the common languages are governed by the populace, who never reaſon on what is beſt: but in the character here propoſed, men of ſenſe having the introduction of it, would have a new ground whereon to build regularly.

But the difficulty is not in inventing the moſt ſimple, eaſy, and commodious *character*, but in engaging the ſeveral nations to uſe it; there being nothing they agree leſs in, than the underſtanding and purſuing their common intereſt.

3. Literal characters may again be divided, with reſpect to the nations among whom they have been invented, into Greek characters, Roman characters, Hebrew characters, &c. The Latin character now uſed through all Europe, was formed from the Greek, as the Greek was from the Phœnician; and the Phœnician,

Characters. as well as the Chaldee, Syriac, and Arabic characters, were formed from the ancient Hebrew, which ſubſiſted till the Babyloniſh captivity; for after that event the character of the Aſſyrians, which is the ſquare Hebrew now in uſe, prevailed, the ancient being only found on ſome Hebrew medals, commonly called Samaritan medals. It was in 1091, that the Gothic characters, invented by Ulfilas, were aboliſhed, and the Latin ones eſtabliſhed in their room.

Medalliſts obſerve, that the Greek character, conſiſting only of majuſcule letters, has preſerved its uniformity on all medals, as low as the time of Gallienus; from which time it appears ſomewhat weaker and rounder: from the time of Conſtantine to Michael we find only Latin characters: after Michael, the Greek characters recommence; but from that time they began to alter with the language, which was a mixture of Greek and Latin. The Latin medals preſerve both their character and language as low as the tranſlation of the ſeat of the empire to Conſtantinople: towards the time of Decius the character began to loſe its roundneſs and beauty; ſome time after, it retrieved, and ſubſiſted tolerably till the time of Juſtin, when it degenerated gradually into the Gothic. The rounder, then, and better formed a character is upon a medal, the fairer pretence it has to antiquity.

II. *Numeral* CHARACTERS, are characters uſed to expreſs numbers, are either letters or figures.

The Arabic character, called alſo the common one, becauſe it is uſed almoſt throughout Europe in all ſorts of calculations, conſiſts of theſe ten digits, 1, 2, 3, 4, 5, 6, 7, 8, 9, 0.

The Roman numeral character conſiſts of ſeven majuſcule letters of the Roman alphabet, *viz.* I, V, X, L, C, D, M. The I denotes one, V five, X ten, L fifty, C, a hundred, D, five hundred, and M a thouſand. The I repeated twice makes two, II; thrice, three, III: four is expreſſed thus IV, as I before V or X takes an unit from the number expreſſed by theſe letters. To expreſs ſix, an I is added to a V, VI; for ſeven, two, VII; and for eight, three, VIII. nine is expreſſed by an I before X, thus IX. The ſame remark may be made of the X before L or C, except that the diminution is by tens; thus XL denotes forty, XC ninety, and LX ſixty. The C before D or M diminiſhes each by a hundred. The number five hundred is ſometimes expreſſed by an I before a C inverted thus, IↃ; and inſtead of M, which ſignifies a thouſand, an I is ſometimes uſed between two C's, the one direct, and the other inverted, thus CIↃ. The addition of C and Ↄ before or after raiſes CIↃ by tens, thus, CCIↃↃ expreſſes ten thouſand, CCCIↃↃↃ, a hundred thouſand. The Romans alſo expreſſed any number of thouſands by a-line drawn over any numeral leſs than a thouſand; thus $\overline{\mathrm{V}}$ denotes five thouſand, $\overline{\mathrm{LX}}$, ſixty thouſand: ſo likewiſe $\overline{\mathrm{M}}$ is one million, $\overline{\mathrm{MM}}$ is two millions, &c.

The Grecks had three ways of expreſſing numbers: 1. Every letter, according to its place in the alphabet, denoted a number, from α, one, to ω, twenty-four. 2. The alphabet was divided into eight units, α one, β two, three, *&c.;* into γ eight tens, ι ten, κ twenty, λ thirty, *&c.;* and eight hundreds, ρ one hundred, σ two hundred, τ three hundred, *&c.* 3. I ſtood for one, Π five, Δ ten, H a hundred, X a thouſand, M ten thouſand; and when the letter Π incloſed any of theſe, except I, it ſhowed the incloſed letter to be five times its value: as $\overline{|\Delta|}$ fifty, $\overline{|\mathrm{H}|}$ five hundred, $\overline{|\mathrm{X}|}$ five thouſand, $\overline{|\mathrm{M}|}$ fifty thouſand. Characters.

The French CHARACTER uſed in the chamber of accounts, and by perſons concerned in the management of the revenue, is, properly ſpeaking, nothing elſe than the Roman numerals, in letters that are not majuſcule: thus, inſtead of expreſſing fifty-ſix by LVI, they denote it by ſmaller characters lvj.

III. CHARACTERS of Abbreviations, &c. in ſeveral of the arts, are ſymbols contrived for the more conciſe and immediate conveyance of the knowledge of things. For the

CHARACTERS uſed in Algebra. See ALGEBRA, Introduction.

CHARACTERS uſed in Aſtronomy, viz.

Of the Planets. See Plate LXII. fig. 19.

Of the Signs. Plate LXXVI. fig. 158. & LXXXV. fig. 204.

Of the Aſpects.

☌ or S Conjunction
SS Semiſextile
⚹ Sextile
Q Quintile
□ Quartile

D. M. Diis manibus.
J. H. S. Jeſus.
X. P. a character found in the catacombs, about the meaning of which authors are not agreed.

CHARACTERS uſed in Muſic, and of Muſical Notes with their proportions, are as follow.

𝆷 character of a large 8
𝆶 a long 4
𝅜 a breve 2
𝅝 a ſemibreve 1
𝅗𝅥 a minim $\frac{1}{2}$
♩ crotchet $\frac{1}{4}$
♪ quaver $\frac{1}{8}$
𝅘𝅥𝅯 ſemiquaver $\frac{1}{16}$
𝅘𝅥𝅰 demiſemiquaver $\frac{1}{32}$

※ character of a ſharp note: this character at the beginning of a line or ſpace, denotes that all the notes in that line are to be taken a ſemitone higher than in the natural ſeries; and the ſame affects all the octaves above and below, though not marked: but when prefixed to any particular note it ſhows that note alone to be taken a ſemitone higher than it would be without ſuch character.

♭ or *b*, character of a flat note: this is the contrary to the other above; that is, a ſemitone lower.

♮ character of a natural note: when in a line or ſeries of artificial notes, marked at the beginning *b* or ※, the natural note happens to be required, it is denoted by this character

𝄞 character of a treble cliff.

𝄡 character of the mean cliff.

𝄢 baſs cliff.

$\frac{2}{4}$, or $\frac{4}{8}$ characters of common duple time, ſignifying the meaſure of two crotchets to be equal to two notes, of which four make a ſemibreve.

C ₵ ⦶, characters that diſtinguiſh the movements of common time, the firſt implying ſlow, the ſecond quick, and the third very quick.

$\frac{1}{2}$, $\frac{2}{3}$, $\frac{3}{4}$, $\frac{3}{8}$, $\frac{3}{16}$, characters of ſimple triple time, the meaſure of which is equal to three ſemibreves, or to three minims.

$\frac{4}{6}$, $\frac{6}{8}$, or $\frac{6}{16}$, characters of a mixed triple time, where the meaſure is equal to ſix crotchets, or ſix quavers.

$\frac{9}{4}$, or $\frac{9}{8}$, or $\frac{9}{16}$, or $\frac{9}{1}$, or $\frac{9}{2}$, characters of compound triple time.

$\frac{4}{12}$, $\frac{8}{12}$, $\frac{12}{16}$, or $\frac{1}{12}$, or $\frac{2}{12}$, characters of that ſpecies of triple time called the meaſure of twelve times.

CHARACTER, in human life, that which is peculiar in the manners of any perſon, and diſtinguiſhes him from all others.

Good CHARACTER is particularly applied to that conduct which is regulated by virtue and religion; in an inferior but very common ſenſe, it is underſtood of mere honeſty of dealing between man and man The importance of a good character in the commerce of life ſeems to be univerſally acknowledged.—To thoſe who are to make their own way either to wealth or honours, a good character is uſually no leſs neceſſary than addreſs and abilities. To tranſcribe the obſervation of an elegant moraliſt: Though human nature is degenerate, and corrupts itſelf ſtill more by its own inventions; yet it uſually retains to the laſt an eſteem for excellence. But even if we are arrived at ſuch an extreme degree of depravity as to have loſt our native reverence for virtue; yet a regard to our own intereſt and ſafety, which we ſeldom loſe, will lead us to apply for aid, in all important tranſactions, to men whoſe integrity is unimpeached. When we chooſe an aſſiſtant, a partner, a ſervant, or firſt enquiry is concerning his character. When we have occaſion for a counſellor or attorney, a phyſician or apothecary, whatever we may be ourſelves, we always chooſe to truſt our property and perſons to men of the beſt character. When we fix on the tradeſmen who are to ſupply us with neceſſaries, we are not determined by the ſign of the lamb, or the wolf, or the fox; nor by a ſhop fitted up in the moſt elegant taſte, but by the faireſt reputation. Look into a daily newſpaper, and you will ſee, from the higheſt to the loweſt rank, how important the characters of the employed appear to the employers. After the advertiſement has enumerated the qualities required in the perſon wanted, there conſtantly follows, that none need apply who cannot bring an undeniable character. Offer yourſelf as a candidate for a ſeat in the legiſlature, be promoted to honour and emolument, or in any reſpect attract the attention of mankind upon yourſelf, and, if you are vulnerable in your character, you will be deeply wounded. This is a general teſtimony in favour of honeſty, which no writings and no practices can poſſibly refute.

Young men, therefore, whoſe characters are yet unfixed, and who, conſequently, may render them juſt ſuch as they wiſh, ought to pay great attention to the firſt ſteps which they take on entrance into life. They are uſually careleſs and inattentive to this object. They purſue their own plans with ardour, and neglect the opinions which others entertain of them. By ſome thoughtleſs action or expreſſion, they ſuffer a mark to be impreſſed upon them, which ſcarcely any ſubſequent merit can entirely eraſe. Every man will find ſome perſons,

ſons, who, though they are not profeſſed enemies, yet view him with an envious or a jealous eye, and who will gladly revive any tale to which truth has given the ſlighteſt foundation.

In this turbulent and confuſed ſcene, where our words and actions are often miſunderſtood, and oftener miſrepreſented, it is indeed difficult even for innocence and integrity to avoid reproach, abuſe, contempt, and hatred. Theſe not only hurt our intereſt and impede our advancement in life, but ſorely afflict the feelings of a tender and delicate mind. It is then the part of wiſdom firſt to do every thing in our power to preſerve an irreproachable character, and then to let our happineſs depend chiefly on the approbation of our own conſciences, and on the advancement of our intereſt in a world where liars ſhall not be believed, and where ſlanderers ſhall receive countenance from none but him who, in Greek, is called, by way of eminence, *Diabolus*, or the calumniator.

CHARACTER, in poetry, particularly the epopee and drama, is the reſult of the manners or peculiarities by which each perſon is diſtinguiſhed from others.

The poetical character, ſays Mr Boſſu, is not properly any particular virtue or quality, but a compoſition of ſeveral which are mixed together, in a different degree, according to the neceſſity of the fable and the unity of the action: there muſt be one, however, to reign over all the reſt; and this muſt be found, in ſome degree, in every part. The firſt quality in Achilles, is wrath; in Ulyſſes, diſſimulation; and in Æneas, mildneſs: but as theſe characters cannot be alone, they muſt be accompanied with others to embelliſh them, as far as they are capable, either by hiding their defects, as in the anger of Achilles, which is palliated by extraordinay valour; or by making them centre in ſome ſolid virtue, as in Ulyſſes, whoſe diſſimulation makes a part of his prudence; and in Æneas, whoſe mildneſs is employed in a ſubmiſſion to the will of the gods. In the making up of which union, it is to be obſerved, the poets have joined together ſuch qualities as are by nature the moſt compatible; valour with anger, piety with mildneſs, and prudence with diſſimulation. The fable required prudence in Ulyſſes, and piety in Æneas; in this, therefore, the poets were not left to their choice: but Homer might have made Achilles a coward without abating any thing from the juſtneſs of his fable: ſo that it was the neceſſity of adorning his character that obliged him to make him valiant: the character, then, of a hero in the epic poem, is compounded of three ſorts of qualities; the firſt eſſential to the fable; the ſecond, embelliſhments of the firſt; and valour, which ſuſtains the other two, makes the third.

Unity of character is as neceſſary as the unity of the fable. For this purpoſe a perſon ſhould be the ſame from the beginning to the end: not that he is always to betray the ſame ſentiments, or one paſſion; but that he ſhould never ſpeak nor act inconſiſtently with his fundamental character. For inſtance, the weak may ſometimes ſally into a warmth, and the breaſt of the paſſionate be calm, a change which often introduces in the drama a very affecting variety; but if the natural diſpoſition of the former was to be repreſented as boiſterous, and that of the latter mild and ſoft, they would both act out of character, and contradict their perſons.

True characters are ſuch as we truly and really ſee in men, or may exiſt without any contradiction to nature: no man queſtions but there have been men as generous and as good as Æneas, as paſſionate and as violent as Achilles, as prudent and wiſe as Ulyſſes, as impious and atheiſtical as Mezentius, and as amorous and paſſionate as Dido; all theſe characters, therefore, are true, and nothing but juſt imitations of nature. On the contrary, a character is falſe when an author ſo feigns it, that one can ſee nothing like it in the order of nature wherein he deſigns it ſhall ſtand: theſe characters ſhould be wholly excluded from a poem, becauſe tranſgreſſing the bounds of probability and reaſon, they meet with no belief from the readers; they are fictions of the poet's brain, not imitations of nature; and yet all poetry conſiſts in an imitation of nature.

CHARACTER is alſo uſed for certain viſible qualities, which claim reſpect or reverence to thoſe veſted therewith.—The majeſty of kings gives them a character which procures reſpect from the people. A biſhop ſhould ſuſtain his character by learning and ſolid piety, rather than by worldly luſtre, &c. The law of nations ſecures the character of an ambaſſador from all inſults.

CHARACTER, among naturaliſts, is ſynonymous with the definition of the genera of animals, plants, &c.

CHARACTERISTIC, in the general, is that which characteriſes a thing or perſon, i. e. conſtitutes its character, whereby it is diſtinguiſhed. See CHARACTER.

CHARACTERISTIC, is peculiarly uſed in grammar, for the principal letter of a word: which is preſerved in moſt of its tenſes and moods, its derivatives and compounds.

CHARACTERISTIC of a Logarithm, is its index or exponent. See LOGARITHM.

CHARACTERISTIC Triangle of a Curve, in the higher geometry, is a rectilinear right-angled triangle, whoſe hypothenuſe makes a part of the curve, not ſenſibly different from a right-line. It is ſo called, becauſe curve lines are uſed to be diſtinguiſhed hereby. See CURVE.

CHARADE, the name of a new ſpecies of compoſition or literary amuſement. It owes its name to the idler who invented it. Its ſubject muſt be a word of two ſyllables, each forming a diſtinct word; and theſe two ſyllables are to be concealed in an enigmatical deſcription, firſt ſeparately, and then together. The exerciſe of charades, if not greatly inſtructive, is at leaſt innocent and amuſing. At all events, as it has made its way into every faſhionable circle, and has employed even Garrick, it will ſcarcely be deemed unworthy of attention. The ſillineſſes indeed of moſt that have appeared in the papers under this title, are not only deſtitute of all pleaſantry in the ſtating, but are formed in general of words utterly unfit for the purpoſe. They have therefore been treated with the contempt they deſerved. In trifles of this nature, inaccuracy is without excuſe. The following examples therefore are at leaſt free from this blemiſh.

I.

My *firſt*, however here abuſed,
Deſigns the ſex alone;
In Cambria, ſuch is cuſtom's pow'r,
'Tis Jenkin, John, or Joan.

Charade, Charadrius.

My *ſecond* oft is loudly call'd,
When men prepare to liſt it:
Its name delights the female ear;
Its force, may none reſiſt it!
It binds the weak, it binds the ſtrong,
The wealthy and the poor;
Still 'tis to joy a paſſport deem'd,
For ſullied fame a cure.
It may inſure an age of bliſs,
Yet miſ'ries oft attend it;
To fingers, ears, and noſes too,
Its various lords commend it.
My *whole* may chance to make one drink,
Though vended in a fiſh-ſhop;
'Tis now the monarch of the ſeas,
And has been an archbiſhop. *Her-ring.*

II.

My *firſt*, when a Frenchman is learning Engliſh, ſerves him to ſwear by. My *ſecond*, is either hay or corn. My *whole* is the delight of the preſent age, and will be the admiration of poſterity. *Gar-rick.*

III.

My *firſt*, is plowed for various reaſons, and grain is freqently buried in it to little purpoſe. My *ſecond*, is neither riches nor honours; yet the former would generally be given for it, and the latter is often taſteleſs without it. My *whole* applies equally to ſpring, ſummer, atumn, and winter; and both fiſh and fleſh, praiſe and cenſure, mirth and melancholly, are the better for being in it. *Sea-ſon.*

IV.

My *firſt*, with the moſt rooted antipathy to a Frenchman, prides himſelf, whenever they meet, upon ſticking cloſe to his jacket. My *ſecond* has many virtues, nor is it its leaſt that it gives name to my firſt. My *whole*, may I never catch! *Tar-tar.*

V

My *firſt* is one of England's prime boaſts; it rejoices the ear of a horſe, and anguiſhes the toe of a man. My *ſecond*, when brick is good; when ſtone, better; when *wooden*, beſt of all. My *whole* is famous alike for rottenneſs and tin. *Corn-wall.*

VI.

My *firſt* is is called bad or good,
May pleaſure or offend ye;
My *ſecond*, in a thirſty mood,
May very much befriend ye.
My *whole*, tho' ſtyled a "cruel word,"
May yet appear a kind one;
It often may with joy be heard,
With tears may often blind one. *Fare-well.*

VII.

My *firſt* is equally friendly to the thief and the lover, the toper, and the ſtudent. My *ſecond* is light's oppoſite: yet they are frequently ſeen hand in hand; and their union, if judicious, gives much pleaſure. My *whole*, is tempting to the touch, grateful to the ſight, fatal to the taſte. *Night-ſhade.*

CHARADRIUS, in ornithology, a genus belonging to the order of grallæ. The beak is cylindrical and blunt; the noſtrils are linear; and the feet have three toes.

1. The Hiaticula, or Sea-lark of Ray, has a black breaſt; a white ſtreak along the front; the top of the head is brown; and the legs and beak are reddiſh. It is found on the ſhores of Europe and America. They frequent our ſhores in the ſummer, but are not numerous. They lay four eggs, of a dull whitiſh colour, ſparingly ſprinkled with black: at the approach of winter they diſappear.

Charadrius.

2. The Alexandrinus, or Alexandrian Dotterel, is of a browniſh colour, with the forehead, collar, and belly white; the prime tail-feathers on both ſides are white; and the legs are black. It is about the ſize of a lark, and lives upon inſects.

3. The Vociferous, or Noiſy Plover of Cateſby, has black ſtreaks on the breaſt, neck, forehead, and cheeks; and the feet are yellow. It is a native of North-America.

4. The Egyptius, has a black ſtreak on the breaſt, white eye-brows, the prime tail-feathers ſtreaked with black at the points, and bluiſh legs. It is found in the plains of Egypt, and feeds on inſects.

5. The Morinellus has an iron-coloured breaſt, a ſmall white ſtreak on the breaſt and eye-brows, and black legs. It is the Dotterel of Ray, and a native of Europe. They are found in Cambridgeſhire, Lincolnſhire, and Derbyſhire: on Lincoln-heath, and on the moors of Derbyſhire, they are migratory; appearing there in ſmall flocks of eight or ten only in the latter end of April, and ſtay there all May and part of June, during which time they are very fat, and much eſteemed for their delicate flavour. In the months of April and September, they are taken on the Wiltſhire and Berkſhire downs; they are alſo found in the beginning of the former month on the ſea ſide at Meales in Lancaſhire, and continue there about three weeks, attending the barley fallows: from thence they remove northward to a place called *Leyton Haws*, and ſtay there about a fortnight; but where they breed, or where they reſide during the winter, we have not been able to diſcover. They are reckoned very fooliſh birds, ſo that a dull fellow is proverbially ſtyled a *dotterel*. They were alſo believed to mimic the action of the fowler, ſtretching out a wing when he ſtretches out an arm, &c. continuing their imitation, regardleſs of the net that is ſpreading for them.

6. The Apricarius has a black belly; the body is brown, and variegated with white and yellow ſpots; and the legs are aſh-coloured. It is the ſpotted Plover of Edwards, and a native of Canada.

7. The Pluvialis is black above, with green ſpots, white underneath, and the feet are aſh-coloured. It is the green plover of Ray, and is a native of Europe. They lay four eggs, ſharply pointed at the leſſer end, of a dirty white colour, and irregularly marked, eſpecially at the thicker end, with blotches and ſpots. It breeds on ſeveral unfrequented mountains of Scotland; and is very common on theſe of the iſle of Rum, and others of the loftier Hebrides. They make a ſhrill whiſtling noiſe; and may be enticed within a ſhot by a ſkilful imitator of the note.

8. The Torquatus has a black breaſt, and a white front; the top of the head and the collar is black; and the beak and feet are bluiſh. It is a native of St Domingo.

9. The Calidris has black feet, and a black bill; the rump is greyiſh; and the body is pure white below. It frequents the ſhores of Europe.

10. The Oedicnemus or Stone-curlew of Ray, is of a grey colour, with two of the prime wing-feathers black, but white in the middle: it has a ſharp bill, and

and aſh-coloured feet; and is about the ſize of a crow. In Hampſhire, Norfolk, and on Lincoln-heath, it is called the ſtone-curlew, from a ſimilarity of colours to the curlew. It breeds in ſome places in rabbit-burrows; alſo among ſtones on the bare ground, laying two eggs of a copper-colour ſpotted with a darker red. The young run ſoon after they are hatched. Theſe birds feed in the night on worms and caterpillars: they will alſo eat toads, and will catch mice. They inhabit fallow lands and downs; affect dry places, never being ſeen near any waters. When they fly, they extend their legs ſtraight out behind: are very ſhy birds; run far before they take to wing; and often ſquat: are generally ſeen ſingle; and are eſteemed very delicate food.—Haſſelquiſt informs us, that this bird is alſo met with in Lower Egypt, in the Acacia groves, near the villages Abuſir and Sackhara, near the ſepulchres of the ancient Egyptians, and in the deſarts. The Arabians call it Kervan. It has a ſhrill voice, ſomewhat reſembling that of the black woodpecker, which it raiſes and lowers ſucceſſively, uttering agreeable notes. The Turks and Egyptians value it much, if they can get it alive; and keep it in a cage for the ſake of its ſinging. Its fleſh is hard, and of a very good taſte, inclined to aromatic. It is a very voracious bird, catching and devouring rats and mice, which abound in Egypt. It ſeldom drinks; and when taken young, and kept in a cage in Egypt, they give it no water for ſeveral months, but feed it with freſh meat macerated in water, which it devours very greedily. It is found in deſarts, and is therefore accuſtomed to be without water.

11. The Himantopus is white below, with a black back, and a long black bill; the feet are red, and very long. It is the autumnal dotterel of the Engliſh authors, and frequents the ſea ſhores of Europe. It is alſo found in the lakes of Egypt in the month of October.

12. The Spinoſus, armed Dotterel, or Lapwing, has black breaſt, legs, and wings; it has a creſt on the hinder part of the head. It is of the ſize of a pigeon; the French call it *dominicanus*, from the reſemblance it has to the dreſs of a Dominican monk. It is a native of Egypt.

13. The New-Zealand plover, has the forepart of the head, taking in the eye, chin, and throat, black, paſſing backward in a collar at the hind-head; all the back part of the head, behind the eye, greeniſh aſh-colour; theſe two colours divided by white: the plumage on the upper parts of the body is the ſame colour as the back of the head: the quills and tail are duſky: the laſt order of coverts is white for ſome part of their length, forming a bar on the wing: the under parts of the body are white; and the legs red. It inhabits Queen Charlotte's ſound; where it is known by the name of *Doodooroa-attoo*. See Plate CXXII. There are 12 or 13 more ſpecies.

CHARAG, the tribute which Chriſtians and Jews pay to the grand ſignior.

It conſiſts of ten, twelve, or fifteen franks *per annum*, according to the eſtate of the party. Men begin to pay it at nine or at ſixteen years old; women are diſpenſed with, as alſo prieſts, rabbins, and religious.

CHARAIMS, a ſect of the Jews in Egypt. They live by themſelves, and have a ſeparate ſynagogue; and as the other Jews are remarkable for their eyes, ſo are thoſe for their large noſes, which run through all the families of this ſect. Theſe are the ancient Eſſenes. They ſtrictly obſerve the five books of Moſes, according to the letter; and receive no written traditions. It is ſaid that the other Jews would join the *Charaims*; but thoſe not having obſerved the exact rules of the law with regard to divorces, theſe think they live in adultery.

CHARANTIA, in botany. See MOMORDICA.

CHARBON, in the manege, that little black ſpot or mark which remains after a large ſpot in the cavity of the corner teeth of a horſe: about the ſeventh or eighth year, when the cavity fills up, the tooth being ſmooth and equal, it is ſaid to be raſed.

CHARCAS, the ſouthern diviſion of Peru in South America, remarkable for the ſilver mines of Potoſi.

CHARCOAL, a ſort of artificial coal, or fuel, conſiſting of wood half burnt; chiefly uſed where a clear ſtrong fire, without ſmoke, is required; the humidity of the wood being here moſtly diſſipated, and exhaled in the fire wherein it is prepared.

The microſcope diſcovers a ſurpriſing number of pores in charcoal: they are diſpoſed in order, and traverſe it lengthwiſe; ſo that there is no piece of charcoal, how long ſoever, but may be eaſily blown through. If a piece be broken pretty ſhort, it may be ſeen through with a microſcope. In a range the 18th part of an inch long, Dr Hook reckoned 150 pores; whence he concludes, that in a charcoal of an inch diameter, there are no leſs than 5,724,000 pores. It is to this prodigious number of pores, that the blackneſs of charcoal is owing; for the rays of light ſtriking on the charcoal, are received and abſorbed in its pores, inſtead of being reflected; whence the body muſt of neceſſity appear black, blackneſs in a body being no more than a want of reflection. Charcoal was anciently uſed to diſtinguiſh the bounds of eſtates and inheritances; as being incorruptible, when let very deep within ground. In effect, it preſerves itſelf ſo long, that there are many pieces found entire in the ancient tombs of the northern nations. M. Dodart ſays, there is charcoal made of corn, probably as old as the days of Cæſar: he adds, that it has kept ſo well, that the wheat may be ſtill diſtinguiſhed from the rye; which he looks on as proof of its incorruptibility.

The operation of charring wood, is performed in the following manner: The wood intended for this purpoſe is cut into proper lengths, and piled up in heaps near the place where the charcoal is intended to be made: when a ſufficient quantity of wood is thus prepared, they begin conſtructing their ſtacks, for which there are three methods. The firſt is this: They level a proper ſpot of ground, of about twelve or fifteen feet in diameter, near the piles of wood; in the centre of this area a large billet of wood, ſplit acroſs at one end and pointed at the other, is fixed with its pointed extremity in the earth, and two pieces of wood inſerted through the clefts of the other end, forming four right angles; againſt theſe croſs pieces four other billets of wood are placed, one end on the ground, and the other leaning againſt the angles. This being finiſhed, a number of large and ſtraight billets

billets are laid on the ground to form a floor, each being as it were the radius of the circular area; on this floor a proper quantity of bruſh or ſmall wood is ſtrewed, in order to fill up the interſtices, when the floor will be complete; and in order to keep the billets in the ſame order and poſition in which they were firſt arranged, pegs or ſtumps are driven into the ground in the circumference of the circle, about a foot diſtant from one another: upon this floor a ſtage is built with billets ſet upon one end, but ſomething inclining towards the central billet; and on the tops of theſe another floor is laid in a horizontal direction, but of ſhorter billets, as the whole is, when finiſhed, to form a cone.

The ſecond method of building the ſtacks for making charcoal is performed in this manner: A long pole is erected in the centre of the area above deſcribed, and ſeveral ſmall billets ranged round the pole on their ends: the interſtices between theſe billets and the pole is filled with dry bruſh-wood, then a floor is laid, on that a ſtage in a reclining poſition, and on that a ſecond floor, *&c.* in the ſame manner as deſcribed above; but in the lower floor there is a billet larger and longer than the reſt, extending from the central pole to ſome diſtance beyond the circumference of the circle.

The third method is this: A chimney, or aperture of a ſquare form, is built with billets in the centre, from the bottom to the top; and round theſe, floors and inclined ſtages are erected, in the ſame manner as in the ſtacks above deſcribed, except that the baſe of this inſtead of being circular like the others, is ſquare; and the whole ſtack, when completed, forms a pyramid.

The ſtack of either form being thus finiſhed, is coated over with turf, and the ſurface plaſtered with a mixture of earth and charcoal-duſt well tempered together.

The next operation is the ſetting the ſtack on fire. In order to this, if it be formed according to the firſt conſtruction, the central billet in the upper ſtage is drawn out, and ſome pieces of very dry and combuſtible wood are placed in the void ſpace, called, by workmen, the chimney, and fire ſet to theſe pieces. If the ſtack be built according to the ſecond conſtruction, the central pole is drawn out, together with the large horizontal billet above deſcribed; and the void ſpace occupied by the latter being filled with pieces of very dry combuſtible wood, the fire is applied to it at the baſe of the ſtack. With regard to the third conſtruction, the ſquare aperture or chimney is filled with ſmall pieces of very dry wood, and the fire applied to it at the top or apex of the pyramidal ſtack. When the ſtack is ſet on fire, either at the top or bottom, the greateſt attention is neceſſary in the workman; for in the proper management of the fire the chief difficulty attending the art of making good charcoal conſiſts. In order to this, care is taken, as ſoon as the flame begins to iſſue ſome height above the chimney, that the aperture be covered with a piece of turf, but not ſo cloſe as to hinder the ſmoke from paſſing out: and whenever the ſmoke appears to iſſue very thick from any part of the pile, the aperture muſt be covered with a mixture of earth and charcoal duſt. At the ſame time, as it is neceſſary that every part of the ſtack ſhould be equally burnt, it will be requiſite for the workman to open vents in one part and ſhut them in another. In this manner the fire muſt be kept up till the charcoal be ſufficiently burnt, which will happen in about two days and a half, if the wood be dry; but if green the operation will not be finiſhed in leſs than three days. When the charcoal is thought to be ſufficiently burnt, which is eaſily known from the appearance of the ſmoke, and the flames no longer iſſuing with impetuoſity through the vents; all the apertures are to be cloſed up very carefully with a mixture of earth and charcoal-duſt, which by excluding all acceſs of the external air, prevents the coals from being any further conſumed, and the fire goes out of itſelf. In this condition it is ſuffered to remain, till the whole is ſufficiently cooled; when the cover is removed and the charcoal is taken away. If the whole proceſs is ſkilfully managed, the coals will exactly retain the figure of the pieces of wood: ſome are ſaid to have been ſo dexterous as to char an arrow without altering even the figure of the feather.

There are conſiderable differences in the coals of different vegetables, in regard to their habitude to fire: the very light coals of linen, cotton, ſome fungi, *&c.* readily catch fire from a ſpark, and ſoon burn out; the more denſe ones of woods and roots are ſet on fire more difficultly, and burn more ſlowly: the coals of the black berry-bearing alder, of the hazel, the willow, and the lime-tree, are ſaid to anſwer beſt for the making of gunpowder and other pyrotechnical compoſitions, perhaps from their being eaſily inflammable: for the reduction of metallic calces thoſe of the heavier woods, as the oak and the beech, are preferable, theſe ſeeming to contain a larger proportion of the phlogiſtic principle, and that perhaps, in a more fixed ſtate: conſidered as common fuel, thoſe of the heavy woods give the greateſt heat, and require the moſt plentiful ſupply of air to keep them burning; thoſe of the light woods preſerve a glowing heat, without much draught of air, till the coals themſelves are conſumed; the bark commonly crackles and flies about in burning, which the coal of the wood itſelf very ſeldom does.

Mathematical inſtrument makers, engravers, *&c.* find charcoal of great uſe to poliſh their braſs and copper-plates after they have been rubbed clean with powdered pumice-ſtone. Plates of horn are poliſhable in the ſame way, and a gloſs may be afterwards given with tripoli.

The coals of different ſubſtances are alſo uſed as pigments; hence the bone-black, ivory-black, *&c.* of the ſhops. Moſt of the paints of this kind, beſides their incorruptibility, have the advantage of a full colour, and work freely in all the forms in which powdery pigments are applied; provided they have been carefully prepared, by thoroughly burning the ſubject in a cloſe veſſel, and afterwards grinding the coal into a powder of due fineneſs. Pieces of charcoal are uſed alſo in their entire ſtate for tracing the outlines of drawing *&c.*; in which intention they have an excellence, that their mark is eaſily wiped out. For theſe purpoſes, either the finer pieces of common charcoal are picked out and cut to a proper ſhape; or the pencils are formed of wood, and afterwards burnt into charcoal in a proper veſſel well covered. The artiſts commonly make choice of the ſmaller branches of the tree freed from the bark and pith; and the willow and

Philoſoph. Commerce of Arts.

vine are preferred to all others. This choice is confirmed by the experiments of Dr Lewis who has found that the wood of the trunks of trees produces charcoal of a harder nature than their ſmall twigs or branches; and the hard woods, ſuch as box and guaiacum, produced coals very ſenſibly harder than the ſofter woods. Willow he prefers to all others. The ſhells and ſtones of fruits yielded coals ſo hard that they would ſcarce mark on paper at all; while the coals of the kernels of fruits were quite ſoft and mellow. The ſeveral coals produced by the doctor's experiments were levigated into fine powder, mixed both with gum-water and oil, and applied as paints both thin and thick, and diluted with different degrees of white. All of them, when laid on thick, appeared of a ſtrong full black, nor could it be judged that one was of a finer colour than another; diluted with white, or when ſpread thin, they had all ſomewhat of a bluiſh caſt.

Horns and the bones both of fiſhes and land-animals, gave coals rather gloſſier and deeper-coloured than vegetables; and which, in general were very hard, ſo as difficultly, or not at all, to ſtain paper. Here alſo the hardneſs of the coal ſeemed to depend on that of the ſubject from whence it was prepared; for ſilk, woollen, leather, blood, and the fleſhy parts of animals, yielded ſoft coals, ſome of theſe differed from others very ſenſibly in colour: that of ivory is ſuperior to all the reſt, and indiſputably the fineſt of all the charcoal blacks. The animal coals had much leſs of the bluiſh caſt in them than the vegetable, many of them inclining rather to a brown. Charred pit-coal, on the other hand, ſeemed to have this blueneſs in a greater degree.

Charcoal is not ſoluble in any of the acids; but may be diſſolved in conſiderable quantities by a ſolution of *hepar ſulphuris*, to which it communicates a green colour. Melted with colourleſs fruits or glaſſes, it gives a pale yellow, dark yellow, reddiſh, browniſh, or blackiſh colour, acccording as the inflammable matter is in greater or leſs proportion; the phlogiſton, or inflammable matter of the the coal ſeeming to be the direct tinging ſubſtance. When the phlogiſtic matter is thus diffuſed through glaſs, it is no more affected by continued ſtrong fire than charcoal is when excluded from the air.

The vapour of burning charcoal is found to be highly noxious, being no other than *fixed air*. How this affects the animal ſyſtem is explained under the article BLOOD.

From ſome late experiments it appears, that charcoal poſſeſſes many extraordinary properties altogether unſuſpected by former chemiſts. It has particularly a great attraction for what is called the *phlogiſton*, or rather for any kind of oily matter with which other ſubſtances may be ſullied; ſo that it now promiſes to be very uſeful in the arts in various ways never thought of before. M. Lowits has found that it is uſeful in preparing cryſtals of tartar of a very white colour; and that the marine and nitrous acids are decompoſed by being diſtilled upon it: the red juices of vegetable fruits are diſcoloured, without loſing any of their acidity; brown rancid oils are rendered ſweet and clear by agitating them for ſome days with charcoal in powder; it changes the ſmell of putrid vegetables to that of a pure volatile alkali, and it produces the ſame effect on freſh meat. On boiling coals in powder with honey, the pure ſaccharine parts of the latter are ſaid to be ſeparated, and the honey to become a well-taſted ſugar; the purification of real ſugar is alſo ſaid to be facilitated by the ſame method. Thus alſo the mother-water of the Pruſſian alkali and of the tartareous acid are made to cryſtallize eaſily; terra foliata tartari may be made white without calcination, by previouſly diſtilling the vinegar from coals. Vinegar concentrated by freezing, and diſtilled from a large proportion of powdered coal, is extremely ſtrong, pure, and fragrant. Corn ſpirit merely ſhaken with coal loſes its bad flavour; and if honey is added, it becomes a ſweet and pleaſant liquor. Even when ardent ſpirits are impregnated with any vegetable oils, the flavour is deſtroyed in this way: and if the ſpirit be diſtilled the reſiduum is ſaid not to be brown; ſo that if the diſtillation is carried too far, no inconvenience enſues. With Peruvian bark, a clear decoction was formed, and the reſiduum was a ſalt, in taſte like digeſtive ſalt. Theſe effects were produced by every kind of coal, whether foſſil or charred vegetable ſubſtances.

Charcoal has lately been ſeparated from the pureſt ſpirit of wine in the proceſs for making ether*; and by M. Lavoiſier is ſuppoſed to be one of the conſtituent parts or elements of that very volatile liquid. But the moſt extraordinary modern diſcovery concerning this ſubſtance is that of Dr Prieſtley, who has found that ſeveral of the metals may be converted into charcoal by paſſing the ſteam of ſpirit of wine over them when red-hot; and this, by way of diſtinction, he calls the *charcoal of metals*.

This ſurpriſing diſcovery was made accidentally, while the Doctor was repeating the experiments by which Mr Lavoiſier imagined water might be converted into air. Having tranſmitted the ſteam of water thro' a copper tube, on which it had no effect, he was willing to try the effects of that of other fluids; and for this purpoſe made choice of ſpirit of wine, having before procured inflammable air by ſending the ſame ſteam through a red-hot tobacco-pipe. No ſooner had the vapour of this fluid, however, touched the red-hot copper, than he was aſtoniſhed at the rapid production of air from it, which reſembled the blowing of a pair of bellows; and before four ounces of the ſpirit were expended, the tube was found to be perforated in two or three places. In a moment afterwards it was ſo far deſtroyed, that it fell to pieces on attempting to remove it from the fire; the inſide being filled with a black matter reſembling lamp-black. Having now recourſe to earthen tubes, the Doctor found that, by melting copper and other metals in them, and tranſmitting the vapour of ſpirit of wine in contact with them while in a ſtate of ignition, different ſubſtances were formed according to the metals employed. On ſending three ounce-meaſures of ſpirit of wine over two ounces of copper, the metal loſt 28 grains of its weight, and 446 grains of charcoal were procured, chiefly in the form of powder, though ſome of it was in large flakes ſeveral inches long; having ſeparated at once from the ſurface of the melted metal. Theſe pieces were almoſt quite black, and bore handling without any danger of being broken. In another experiment, 508 grains of charcoal were obtained from 19 grains of copper; but here the metal had been previouſly re-

---

* See *Chemiſtry*, Index.

duced to thin plates, and they were not all converted into charcoal, being ſomething harder, and therefore partially metallic in the middle.

Silver was found to be affected very much as copper had been; but the larger maſſes of charcoal procured from this metal were much whiter than thoſe from copper. Only a ſmall quantity of charcoal could be procured from lead. Three ounce-meaſures of ſpirit of wine and near four ounces of lead, gave only a ſmall quantity of whitiſh powdery ſubſtance, though 58 grains of the lead were miſſing; but the inſide of the glaſs-tube through which the air was tranſmitted became very black. The like quantity of ſpirit of wine ſent over 360 grains of melted tin, and produced 26 grains of black duſt, the metal not being diminiſhed quite four grains. The vapour of two ounce-meaſures of ſpirit of wine, ſent over 960 grains of iron-ſhavings, diminiſhed the metal only two grains; but no charcoal could be collected, though the air was loaded with black particles. The iron had acquired a dark blue colour. Gold was not ſenſibly changed or diminiſhed in weight; and it not only remained unalterable by the proceſs itſelf, but effectually protected a tenth-part of its weight of copper from the action of the ſteam.

Spirit of turpentine was found to anſwer for the production of this charcoal, as well as ſpirit of wine; 120 grains of the former being obtained from five of copper by means of the turpentine, notwithſtanding a very denſe black ſmoke which iſſued from the end of the tube during the whole time of the operation. The Doctor obſerves, indeed, that in all thoſe experiments, where the heat is very great, the minute diviſion and volatility of this charcoal is very extraordinary. Seeing it iſſue from the end of a tube in a denſe black cloud, he endeavoured to collect it in a large glaſs receiver; but after having given the glaſs a very thin black coating, not diſtinguiſhable in appearance from ſoot, it iſſued from the orifice like denſe ſmoke, and appeared to be altogether incoercible, even when ſeveral adopters were connected with the receiver, and a tube, from whence it finally iſſued, plunged deep into water.

It is obſerved, that charcoal of wood, when freſh made, has a ſtrong attraction for air, and will continue to abſorb it for a conſiderable time; a property which it has in common with ſeveral other ſubſtances. Dr Prieſtley made ſome experiments to aſcertain the quantity abſorbed. For this purpoſe, he left in an open diſh, on the fourth of September, ſome charcoal freſh made from dry oak, and weighing 364 grains. Two or three days after it weighed 390 grains; on the 24th of October, 419; and on the 26th of April following it weighed 421 grains. By diſtillation in an earthen retort it yielded a quantity of air conſiderably phlogiſticated, and then weighed 312 grains, but the retort appeared to have been cracked. On expoſing it again to the open air for a whole year, it weighed 371 grains. In another experiment, a quantity of charcoal which had yielded by a ſtrong heat 336 ounce-meaſures of air, and weighed immediately afterwards 756 grains, increaſed in three days to 817; and on expelling the air from it was reduced to 711 grains. In all theſe experiments the air was worſe than that of the atmoſphere, and a part was fixed air.

It has been generally ſuppoſed by chemiſts, that charcoal was indeſtructible by any other means than burning in an open fire, though of late it is found totally diſſipable and convertible into inflammable air, by the heat of a burning lens *in vacuo*, at leaſt with the aſſiſtance of a ſmall quantity of water. By burning in dephlogiſticated air, it is found to convert almoſt the whole of it into fixed air. See AEROLOGY, n° 110—113, 129, 131. From the experiments there related, it is now evident, that charcoal as ſuch, and without any decompoſition, is an ingredient in both thoſe aerial fluids, and is indeed the phlogiſton of Stahl ſo long ſought in vain. This diſcovery, however, has not by any means put an end to the diſputes betwixt the *Phlogiſtians* and *Antiphlogiſtians*, though it certainly ought to have done ſo, and muſt aſſuredly do ſo in a ſhort time. The experiments of Dr Prieſtley are not doubted; and charcoal, the gravitating matter of light inflammable air, and *phlogiſton*, are allowed to be the ſame by the Antiphlogiſtians as well as by the oppoſite party. "The preſent controverſy (ſays Mr Higgins) among the philoſophers depends upon the following queſtions: 1. Whether water be or be not compoſed of dephlogiſticated and light inflammable air? 2. Whether or no the condenſation of dephlogiſticated air, or its union to different bodies, does not depend upon one principle, common to all combuſtible bodies? or, in other words, whether or no all bodies which burn or calcine, ſuch as ſulphur, phoſphorus, charcoal, oils, metals, phlogiſticated air, &c. contain the matter of light inflammable air as one of their conſtituent principles? One ſhould ſuppoſe, if theſe ſubſtances were compoſed of two principles, namely a peculiar baſis, and the matter of light inflammable air or phlogiſton, that it would be poſſible to reſolve them into theſe principles; more eſpecially when we conſider the great attraction of the matter of light inflammable air to fire; but the maintainers of phlogiſton have not as yet been able to do this," &c.

Higgins's Comparative View, Pref. p. 5.

The limits of this work will not allow us to enter on a full diſcuſſion of this controverſy, nor can we pretend to be able to ſettle the diſputes on the ſubject. It nevertheleſs ſeems ſomewhat unnatural to call iron, lead, copper, ſulphur, phoſphorus, &c. ſimple and unchangeable bodies, or if we pleaſe *elements*; as thus the number of elementary bodies might be increaſed without number, and *water*, which has generally been reckoned a ſimple one, ſuppoſed to be almoſt the only compound body in nature. It is alſo certain, that Dr Prieſtley has made ſome very ſtriking and apparently deciſive experiments on the ſubject of metals, to which no proper reply has ever been made. In order to ſee the force of theſe experiments, however, we muſt ſtill obſerve, that, according to the Phlogiſtians, the calces of metals are reduced, on the addition of charcoal, not only by emitting the dephlogiſticated air which adheres to them when in the form of calces, but by the admiſſion of a quantity of the charcoal itſelf into their ſubſtance. This the Antiphlogiſtians deny; and though they admit the neceſſity of charcoal in the operation, yet they affirm that it acts only by attracting the dephlogiſticated air contained in the calx, with which it forms fixed air; and hence they muſt ſay, that in all metallic reductions a quantity of fixed air is produced, equivalent not only to the weight of the charcoal employed, but alſo to that of the dephlogiſticated air contained in the calx. The deciſive experiment therefore would be, to expel from a metallic calx all the air it contained, to weigh it exactly in that ſtate, and then obſerve whether it gained any thing in weight by being reduced to a metal. This, however, has not been done; and the Antiphlogiſtians complain that their adverſaries have not been able to produce a pure metallic calx free from all kind of aerial vapour. But though it is not pretended that any ſuch calx has yet been produced, if the Phlogiſtians can ſhow the poſſibility of reducing a calx without the production of fixed air, it would ſeem to be equally deſtructive of the antiphlogiſtic doctrine. This appears to have been done by Dr Prieſtley in the experiments above alluded to; and it is even doubtful whether he did not obtain the ſo much deſired calx, viz. one perfectly free from air altogether. "I put (ſays he) upon a piece of broken crucible, which could yield no air, a quantity of minium, *out of which all air* had been extracted; and placing it upon a convenient ſtand, introduced it into a large receiver filled with inflammable air confined by water. As ſoon as the minium was dry, by means of the heat thrown upon it, I obſerved that it became black, and then ran in the form of perfect lead, at the ſame time that the air diminiſhed at a great rate the water aſcending within the receiver. Before this firſt experiment was concluded, I perceived, that if the phlogiſton in inflammable air had any baſe, it muſt be very inconſiderable; for the proceſs went on till there was no more room to operate without endangering the receiver; and examining the air that remained, I found that it could not be diſtinguiſhed from that in which I began the experiment, which was air extracted from iron by oil of vitriol.

"I afterwards carefully expelled, from a quantity of minium, all the phlogiſton, and every thing elſe that could have aſſumed the form of air, by giving it a red heat when mixed with ſpirit of nitre; and immediately uſing it in the manner mentioned above, I reduced 101 ounce-meaſures of inflammable air to two. To judge of its degree of inflammability, I preſented the flame of a ſmall candle to the mouth of a vial filled with it, and obſerved, that it made 13 ſeparate exploſions, though weak ones (ſtopping the mouth of the phial with my finger after each exploſion); when freſh made inflammable air, in the ſame circumſtances, made only 14 exploſions, though ſtronger ones. In this experiment, however, I overlooked one obvious conſideration, viz. that water, or any thing ſoluble in water, might be the baſis of inflammable air. All that could be abſolutely inferred from the experiment was, that this baſis could not be any thing that was capable of ſubſiſting in the form of air. It will be ſeen, that I afterwards made the experiment with air confined by mercury."

In this experiment it is to be regretted that the Doctor did not inform us whether the weight of his calces was on the whole increaſed or diminiſhed by the operation. As it ſtands, though ſufficient to overthrow the doctrine of the Antiphlogiſtians, it is not altogether ſufficient to eſtabliſh that of their adverſaries. Mr Higgins, however, though he does not reply to this experiment, gives an account of another from Dr Higgins, which he conſiders as abſolutely deciſive againſt the phlogiſtians. "Dr Higgins (ſays he) introduced ſome pieces of well-burned charcoal into a deep crucible, and covered them over an inch deep with powdered charcoal. Having luted on a cover, he expoſed them for two hours to heat ſufficient to melt ſilver; he then placed the crucible in ſuch a manner that the powder might remain red hot for ſome time after the pieces next the bottom had cooled. This he had done, as the charcoal muſt imbibe ſomething on cooling, both to ſupply it with inflammable air, and to prevent a communication with the external air, which the charcoal would otherwiſe have imbibed.

"One hundred and twenty grains of this charcoal quickly powdered, were well mixed with 7680 grains of litharge, which had been previouſly fuſed to ſeparate any uncalcined lead it might contain. The mixture was charged into a coated retort juſt large enough to contain it; ſo that the common air muſt have been nearly ſecluded. Being then placed in a reverberating furnace, and heat duly applied, it yielded by eſtimation, after cooling to the mean temperature of the atmoſphere, 384 grains of fixable air, at the rate of 0.57 grains to a cubic inch, 8.704 of phlogiſticated air, and 0.911 grains of dephlogiſticated air, beſides 49 grains of water. On breaking the retort, 3888 grains of revived lead were found, beſides ſome vitrified litharge; but not an atom of charcoal was left, nor was there a particle of inflammable air produced. Now, let my reader conſider the weight that 3888 grains of lead acquire by its converſion to litharge, and the quantity of inflammable air that 120 grains of charcoal will afford (which, according to Dr Prieſtley, is about 360 ounce-meaſures), and he will find, making allowance for the phlogiſticated air, that theſe nearly correſpond with the proportion of heavy inflammable air and dephlogiſticated air neceſſary to the formation of fixable air by the electric ſpark. Hence we may conclude, that not a particle of charcoal entered into the conſtitution of the revived lead, but muſt have been wholly converted into fixable air."

To this experiment, however, the Phlogiſtians will reply, that ſo far from being deciſive on the ſubject, no concluſion whatever can be drawn from it, on account of its *enormous* inaccuracy. The quantity of matter put into the retort was 7680+120, or 7800 grains, and the whole produce was 3888+384+8.704 +0.911+49=4330.615 grains: a deficiency therefore of no leſs than 3469.385 grains is to be accounted for; and of this we hear not one word; ſo that we are at liberty to ſuppoſe that the vitrified litharge had perforated the retort in ſuch a manner as to admit the fixed and phlogiſticated air from without, as Dr Prieſtley found earthen retorts pervious to air from without; and this, though coated, might by a corroſion of the glaſs (if it was a glaſs one) be reduced to a ſimilar ſituation.

We do not mean that this ſhould be reckoned a formal anſwer to Dr Higgins's experiment; all we intend here, is to ſtate the arguments fairly on both ſides, ſo that the reader who has not an opportunity of making experiments himſelf, may be able to judge on which ſide the truth lies. Dr Prieſtley informs us, that in his experiment, the calx of lead abſorbed a quantity of inflammable air without the extrication of fixed air, or any thing elſe that could be perceived. Whether or not have we reaſon to conclude from thence, that the gravitating, ſolid, or coally, part of the inflammable air was received into the calx, and became part of the revived metal? In Dr Higgins's experiment a quantity of elaſtic fluid was produced, and a quantity of lead revived; but we neither know how much of the calx went to this lead, how much the litharge had originally attracted from the air, nor whether the elaſtic fluids were certainly produced; or indeed whether any of them, the ſmall quantity of dephlogiſticated air alone excepted, came from the materials or not. From ſuch a ſtate of the caſe, then, have we reaſon to "conclude, that not a particle of charcoal entered into the conſtitution of the lead?"

Higgins's Comparative View, p.49.

We ſhall next conſider an experiment made by Mr Higgins himſelf, and which he likewiſe conſiders as deciſive againſt the Phlogiſtians. "I introduced (ſays he) ſome iron nails, free from ruſt, into ſtrong volatile vitriolic acid; when it ſtood for a few minutes, it acquired a milky appearance, and the ſolution went on without ebullition or extrication of air. On ſtanding for a few hours, the ſolution acquired a darkiſh colour, and a black powder was precipitated. This powder, when collected and waſhed, put on red hot iron, burned partly like ſulphur and partly like charcoal duſt, and the incombuſtible reſiduum was of a purpliſh colour. The filtered ſolution was perfectly neutraliſed, and free from the leaſt ſulphureous pungency. Its taſte was ſtrongly chalybeate, but not ſo diſagreeable as that of the ſolution of iron in the perfect vitriolic acid, or in any of the mineral acids. Nitrous acid dropped into the ſolution inſtantly produced a cloudineſs, which immediately diſappeared without ebullition, though volatile ſulphureous acid was extricated in its utmoſt degree of pungency. The vitriolic, marine, and acetous acids, decompoſed this ſolution, but cauſed no turbidneſs, nor was any inflammable air produced.

In order to know whether the ſulphur was diſengaged from the volatile ſulphureous acid or the iron, I poured marine acid on the ſame nails, when light inflammable air and hepatic air were copiouſly produced, and likewiſe ſulphur was produced in its crude ſtate. When I uſed vitriolic or the nitrous acid, no ſulphur was produced. I tried different nails, and likewiſe iron-filings, with the ſame reſult. Theſe facts convinced me that the ſulphur came from the iron; but that all ſorts of iron contain ſulphur is what I cannot pretend to know, as I have not tried ſteel, or varieties enough of malleable iron. However, I have ſtrong reaſons to ſuſpect, that ſulpur has more to do in the different properties of iron than we are aware of. That iron ſhould contain ſulphur, notwithſtanding the different proceſſes it muſt neceſſarily undergo before it acquires malleability, conſidering the volatility of ſulphur, points out the force of their attraction to one another; and the ſeparation of this again by volatile ſulphureous acid, ſhows likewiſe the greater attraction of iron to ſulphur and dephlogiſticated air jointly. That volatile ſulphureous acid ſhould diſſolve iron without the extrication of inflammable air or phlogiſton, is a very ſtrong inſtance of the fallacy of the phlogiſtic doctrine. A ſmall quantity of inflammable air is produced, but it is ſo trifling comparatively to what ſhould be produced from the quantity of iron diſſolved, that it is hardly worth noticing; and in my opinion proceeds from a portion of perfect vitriolic acid, which is generally inſeparable from the volatile acid. If volatile vitriolic acid were a compound of phlogiſton, a certain baſis, and dephlogiſticated air, a greater quantity of inflammable air ſhould have been diſengaged during the ſolution of iron in this acid than when the perfect vitriolic acid is uſed. Let us even ſuppoſe volatile ſulphureous acid to be compoſed of the baſis of ſulphur, phlogiſton, and dephlogiſticated air, which is the opinion of all the phlogiſtians, though they differ with reſpect to the modification of theſe three principles; and likewiſe iron to be compoſed of a certain baſis and phlogiſton; I would aſk the Phlogiſtians, What becomes of the phlogiſton of the iron during its ſolution?"

But however much Mr Higgins may be convinced, from this experiment, of the fallacy of the phlogiſtic doctrine, his adverſaries inſtead of being ſilenced, will urge his own experiment againſt himſelf. He owns, that during the ſolution ſomething was ſeparated of a black colour, and which burned like charcoal duſt. Unleſs therefore Mr Higgins ſhall prove the contrary, they will ſay that this was the real *phlogiſton* or *charcoal* which entered into the ſubſtance of the metal; and that it appeared in its native form, becauſe the volatile vitriolic acid had not ſpecific or latent heat ſufficient to convert it into inflammable air. At any rate, it was incumbent on Mr Higgins to have accounted for the coally part of his reſiduum as well as the ſulphureous one; yet he has been at conſiderable pains to deduce the latter from the iron, without ſpeaking a word about the former. Indeed whether he deduced this from the iron or the vitriolic acid, it will make equally againſt him; for his principles do not allow that the volatile vitriolic acid contains any charcoal. That the latter really does ſo, however, appears from an experiment of Dr Prieſtley, in which he reduced a calx of lead by means of vitriolic acid air, the ſame with the vitriolic or volatile ſulphureous acid. It is true, that only a ſmall quantity of metal was then procured; but however ſmall this was, the Antiphlogiſtians do not pretend that metals can be reduced to their metallic ſtate in any quantity, except by the mediation of charcoal.

Thus it appears, that with regard to metals the diſpute is as yet far enough from being decided in favour of the Antiphlogiſtians. Their cauſe is equally doubtful with regard to ſulphur and phoſphorus, both of which Dr Prieſtley has produced by heating vitriolic and phoſphoric acid in inflammable air. Indeed, by ſome experiments on ſulphur, the matter ſeems to be decided againſt them. "Perhaps (ſays Dr Prieſtley) as deciſive a proof as any, of the real production of fixed air from phlogiſton and dephlogiſticated air, may be drawn from the experiments in which I always found a quantity of it when I burned ſulphur in dephlogiſticated air. In one of theſe experiments to which I gave more particular attention, ſix ounce-meaſures and an half of the dephlogiſticated air were reduced to about two ounce-meaſures, and one-fifth of this was fixed air." Now, though the Doctor inferred from this, that fixed air was compoſed of phlogiſton and dephlogiſticated air, on the ſuppoſition of ſulphur containing phlogiſton; yet admitting from other proofs, that fixed air is compoſed of theſe two principles, the expeririment unanſwerably proves, that ſulphur contains phlogiſton or charcoal, though indeed in a very ſmall quantity; but if the ſulphur contained none at all, and the dephlogiſticated air as little, as the Antiphlogiſtians would have it, how is it poſſible that a compound, of which phlogiſton makes a part, ſhould reſult from an union of the two*? Another experiment equally deciſive, even with regard to metals, is that quoted from Dr Prieſtley in the place juſt referred to (A), where he obtained pure fixed air from a mixture of red precipitate and iron-filings. Now, according to the antiphlogiſtic doctrine, neither of theſe materials contained an atom of charcoal or phlogiſton; whence then came the phlogiſton in the fixed air which iſſued from the mixture?

* See *Aerology*, n° 111.

Thus the Antiphlogiſtians ſeem to be unanſwerably refuted with regard to ſulphur and metallic ſubſtances; for if the two experiments juſt related be accurate, it is impoſſible to invalidate them by any argumentation whatever. Their laſt reſource therefore is the decompoſition of water: and even here it is evident they have little reaſon to boaſt. On this ſubject, however, we are ſorry to obſerve, that the opinions have been ſo many, ſo various, and ſo fluctuating, that it is not only impoſſible to ſay what are the prevailing ones, but even difficult to aſcertain what are the ſentiments of any individual on the ſubject. Under the article AEROLOGY, n° 81. we have quoted Dr Prieſtley as favouring the doctrine of the decompoſition of water; and in Mr Higgins's work we find him quoted as oppoſing it. "Dr Prieſtley (ſays he) ſuppoſes that the water produced by the condenſation of inflammable and dephlogiſticated air, is only what was ſuſpended and attached to them in their elaſtic ſtate, and that their reſpective gravitating particles form a different compound, namely, the nitrous acid. To aſcertain this, he confined his mixture of airs with dry fixed alkali over mercury, in order to abſtract from it as much water as poſſible. Having thus prepared his mixture of airs, he found, after exploding them, that the product of water fell far ſhort of the weight of both airs, and he obſerved a denſe vapour after every exploſion, which ſoon condenſed, and adhered in a ſolid ſtate to the ſides of the veſſel, which he found afterwards to be the nitrous acid." To this Mr Higgins anſwers, that the airs ought to have been accurately weighed after abſtracting the water from them, when (he ſuppoſes) the weight of water produced would have equalled them. This indeed ought to have been done; but Mr Higgins, or ſome Antiphlogiſtian, ought to have done ſo before he decided poſitively in favour of the oppoſite doctrine. At any rate, it cannot be pretended, that in any experiment, let the circumſtances of it be what they would, the quantity of water produced ever equalled that of the two airs. It is evident, therefore, that till this ſhall ſome how or other be cleared up, the matter muſt remain uncertain. That the pureſt water we can obtain always contains phlogiſton, is what no Phlogiſtian denies; that it eſſentially belongs to it is doubtful, though indeed it muſt be probable, that it does ſo until experiments ſhow the contrary. Mr Cavendiſh ſuppoſes that *dephlogiſticated* air and *dephlogiſticated water* may be the ſame; and indeed this would ſeem to be almoſt certain, were it not for a circumſtance taken notice of by Mr Higgins, viz. that in the firing of iron in dephlogiſticated air the latter appears to be totally abſorbed; though it is certain, that a quantity of undecompoſed water enters into its compoſition.

Comparative View, p. 3.

How far this circumſtance throws any obſcurity on the matter the reader muſt determine. For a more full inveſtigation of the ſubject, however, we muſt refer to the article WATER; and in the mean time ſhall diſmiſs the article with a few obſervations on the compoſition of charcoal.

From the days of Stahl till very lately, the component parts of this ſubſtance have been reckoned a certain kind of earth combined with what was called phlogiſton. The late experiments of Dr Prieſtley have ſhown, that this doctrine is erroneous, and that charcoal is wholly diſſipable into vapour. "On the whole (ſays the tranſlator of Wiegleb's Chemiſtry), charcoal appears from the experiments of Lavoiſier and Barthollet, to be an oil deprived of its inflammable gas. But coal of wood (or common charcoal) likewiſe contains fixed alkali, which the ſoot (or the coal of oil) does not, but inſtead of this exhibits volatile alkali. The fixed alkali of the former proceeds from the plant itſelf, and this, in the caſe of ſoot, is joined with inflammable gas, and forms volatile alkali, the earthy part being left behind, as happens when this latter is prepared from fixed alkali. Genuine charcoal, therefore, conſiſts of this vegetable principle, united with a little fixed alkali and part of the phlogiſton that conſtituted the oil of the plant of which it is made: for ſome of this principle is carried off, together with the *hydrophloge* (B), in the form of inflammable gas, if diſtilled in cloſe veſſels; but if burned in the open air, the hyrophloge unites with the pure part of the air, and forms water. From theſe conſiderations, as well as from the experiments and obſervations of M. Berthollet, in the Mem. de l'Acad. des Sciences pour 1786, p. 33. *et ſeq.* it appears, that common charcoal conſiſts of the vegetable principle, ſome phlogiſton, fixed alkali, and no inflammable gas."

On all this, however, we muſt obſerve, that it is entirely diſproved by the experiments of Dr Prieſtley, ſo often quoted, in which it was totally diſſipated into inflammable air*. On this occaſion indeed he acknowledges, that ſome very minute particles of aſhes were obſerved, which could not have amounted to a ſingle grain from many pounds of wood. Even theſe, according to what he obſerves in the ſame place, may be ſuppoſed to have come from the ſmall quantity of air in the receiver; and it is to be wiſhed that the Doctor would repeat the experiment in one of thoſe perfect vacuums through which the electric fluid cannot be made to paſs. From undoubted experiments, however, it appears, that charcoal cannot be decompoſed by mere heat; as *in vacuo* it is diſſipated into inflammable air; and

* See *Aerology*, n° 129, 130.

(A) See *Encycl.* Vol. I. p. 169. col. 1. where, in lines 18, 19, from the top, read *precipitate* for *charcoal.*

(B) A word uſed by Mr Wiegleb, as far as we can comprehend the author's meaning, for one of the component parts of water. See his General Syſtem of Chemiſtry, tranſlated by Hopſon, p. 39.

and this, on preſenting a proper ſubſtance to attract the ſolid part again diſcovers itſelf, by its blackneſs, to be real charcoal. As little does it appear deſtructible by burning in the open air; for though ſome aſhes are left, it appears probable that thoſe differ from the coal itſelf in nothing but having a quantity of air attached to them. By far the greateſt part of it, even in the common way of burning, is converted into fixed air; and from that it may again be ſeparated by taking the electric ſpark in that fluid, when it is reſolved into very pure dephlogiſticated and inflammable air. The ſame ſeparation may be effected by merely heating iron in fixed air; in which caſe the dephlogiſticated part will unite to the iron, and the coaly part, together with part of the phlogiſton of the metal, be converted into inflammable air. From all theſe, and other conſiderations, a ſuſpicion is induced, that the matter of charcoal is not different from the element of earth itſelf; and that, according to the different modifications of this ſubſtance, it either appears as coal, aſhes, earth of various kinds, or even metals. This receives ſome confirmation from the following experiments of Mr Watt, related in the 74th volume of the Philoſophical Tranſactions: “ I diſſolved (ſays he) magneſia alba, calcareous earth, and minium, in nitrous acid dephlogiſticated by boiling, and diluted with proper proportions of water. I made uſe of glaſs-retorts coated with clay; and I received the air in glaſs-veſſels, whoſe mouths were immerſed in a glazed earthen baſon containing the ſmalleſt quantity of water that could be uſed for the purpoſe. As ſoon as the retort was heated a little above the degree of boiling water, the ſolutions began to diſtil watery vapours containing nitrous acid. Soon after theſe vapours ceaſed, yellow fumes, and, in ſome of the caſes, dark red fumes, began to appear in the neck of the retort; and, at the ſame time, there was a production of dephlogiſticated air, which was greater in quantity from ſome of theſe mixtures than from others, but continued in all of them until the ſubſtances were reduced to dryneſs. I found in the receiving water, &c. very near the whole of the nitrous acid uſed for their ſolution, but highly phlogiſticated, ſo as to emit nitrous air by the application of heat; and there is reaſon to believe, that with more precaution the whole might have been obtained. As the quantity of dephlogiſticated air produced by theſe proceſſes did not form a ſufficient part of the whole weight to enable me to judge whether any of the real acid entered into the compoſition of the air I obtained, I ceaſed to purſue them further, having learned from them the fact, that however much the acid and the earths were dephlogiſticated before the ſolution, the acid always became highly phlogiſticated in the proceſs.

“ In order to examine whether this phlogiſton was furniſhed by the earths, ſome dephlogiſticated nitrous acid was diſtilled from minium till no more air or acid came over. More of the ſame acid was added to the minium as ſoon as it was cold, and the diſtillation repeated, which produced the ſame appearances of red fumes and dephlogiſticated air. This operation was repeated a third time on the ſame minium, without any ſenſible variation in the phænomena. The proceſs ſhould have been ſtill farther repeated, but the retort broke about the end of the third diſtillation; the quantity of minium uſed was 120 grains, and the quantity of nitrous acid added each time was 240 grains, of ſuch ſtrength that it could diſſolve half its weight of mercury by means of heat. It appears from this experiment, that unleſs minium be ſuppoſed principally to conſiſt of phlogiſton, the ſource of the phlogiſton thus obtained, was either the nitrous acid itſelf, or the water with which it was diluted; or elſe that it came through the retort with the light; for the retort was in this caſe red hot before any air was produced. Yet this latter concluſion does not appear very ſatisfactory, when it is conſidered, that in the proceſs wherein the earth made uſe of was magneſia, the retort was not red hot, or very obſcurely ſo, in any part of the proceſs, and by no means luminous when the yellow and red fumes firſt made their appearance.”

To theſe experiments, however, the Antiphlogiſtians will no doubt reply, that there was no phlogiſton in the caſe, and that the nitrous acid was only decompoſed; and indeed the deciſive experiment here would be, the entire diſſipation of a quantity of earth into ſome kind of air, as may be done with charcoal; but to do this in the way of diſtillation muſt be attended with incredible labour, though, as finally deciding this point, it ſeems to be well worth purſuing.

A pretty ſtrong proof of the identity of metallic calces with charcoal, is their converſion into it in the manner already related. Experiments, however, are yet wanting on the ſubject; though it ſeems probable from what Dr Prieſtley has already done, that they may thus be entirely diſſipated into air as well as common charcoal.

CHARDIN, (Sir John) a celebrated traveller, was born at Paris, 1643. His father, who was a jeweller, had him educated in the Proteſtant religion; after which he travelled into Perſia and India. He traded in jewels, and died at London in 1713. The account he wrote of his travels is much eſteemed.

CHARENTON, the name of two towns of France, the one upon the Marmaude in the Bourbonnois; the other in the iſle of France, near the confluence of the Marne with the Seine.

CHARES the Lydian, a celebrated ſtatuary, was the diſciple of Lyſippus; and made the famous Coloſſus of the ſun in the city of Rhodes. Flouriſhed 288 years before Chriſt.

CHARGE, in gunnery, the quantity of powder and ball wherewith a gun is loaded for execution.

The rules for charging large pieces in war are, That the piece be firſt cleaned or ſcoured withinſide: that the proper quantity of powder be next driven in and rammed down; care, however, being taken, that the powder, in ramming, be not bruiſed, becauſe that weakens its effect: that a little quantity of paper, hay, lint, or the like, be rammed over it; and that the ball or ſhot be intruded. If the ball be red hot, a tompion, or trencher of green wood, is to be driven in before it. The common allowance for a charge of powder of a piece of ordnance is half the weight of the ball. In the Britiſh Navy, the allowance for 32 pounders is but ſeven-ſixteenths of the weight of the bullet. But a late author is of opinion, that if the powder in all ſhip-cannon whatever was reduced to one-third weight of the ball, or even leſs, it would be of conſiderable advantage, not only by ſaving ammunition, but by keeping

Robin's Propoſal for increaſing the Strength of the Navy.

ing the guns cooler and quieter, and at the ſame time more effectually injuring the veſſels of the enemy. With the preſent allowance of powder the guns are heated, and their tackle and furniture ſtrained; and this only to render the bullets leſs efficacious: for a bullet which can but juſt paſs through a piece of timber, and loſes almoſt all its motion thereby, has a much better chance of rending and fracturing it, than if it paſſes through with a much greater velocity.

Charge, in heraldry, is applied to the figures repreſented on the eſcutcheon, by which the bearers are diſtinguiſhed from one another; and it is to be obſerved, that too many charges are not ſo honorable as fewer.

Charge of Lead, denotes a quantity of 36 pigs. See Pig.

To Charge in the military language, is to attack the enemy either with horſe or foot.

Charge, in law, denotes the inſtructions given to the grand jury, with reſpect to the articles of their inquiry, by the judge who preſides on the bench.

Charge, in law, alſo ſignifies a thing done that bindeth him that doeth it; and diſcharge is the removal of that charge. Lands may be charged in various ways; as by grant of rent out of it, by ſtatutes, judgments, conditions, warranties, &c.

Charge of horning, in Scots law. See Horning.

Charge to enter Heir, in Scots law, a writing paſſing under the ſignet, obtained at the inſtance of a creditor, either againſt the heir of his debtor, for fixing upon him the debt as repreſenting the debtor, which is called a general charge; or, againſt the debtor himſelf or his heir, for the purpoſe of veſting him in the right of any heritable ſubject to which he has made up no title, in order that the creditor may attach that ſubject for payment of his debt, in the ſame manner as if his debtor or his heir were legally veſted in it by ſervice or otherwiſe. This laſt kind is called a *ſpecial charge*.

Charge, or rather *Overcharge*, in painting is an exaggerated repreſentation of any perſon; wherein the likeneſs is preſerved, but at the ſame time ridiculed.

Few painters have the genius neceſſary to ſucceed in theſe charges: the method is, to ſelect and heighten ſomething already amiſs in the face, whether by way of defect, or redundancy; thus *v. g.* if Nature have given a man a noſe a little larger than ordinary, the painter falls in with her, and makes the noſe extravagantly long: or if the noſe be naturally too ſhort, in the painting it will be a mere ſtump; and thus of the other parts.

CHARGED, in heraldry, a ſhield carrying ſome impreſs or figure, is ſaid to be charged therewith; ſo alſo, when one bearing, or charge has another figure added upon it, it is properly ſaid to be charged.

Charged, in electrical experiments, is when a vial, pane of glaſs, or other electric ſubſtance, properly coated on both ſides, has a quantity of electricity communicated to it; in which caſe the one ſide is always electrified poſitively, and the other negatively.

CHARIOT, a half coach, having only a ſeat behind, with a ſtool before. See Coach.

The chariots of the ancients, chiefly uſed in war, were called by the ſeveral names *bigæ*, *trigæ*, &c. according to the number of horſes applied to draw them. Every chariot carried two men, who were probably the warrior and the charioteer; and we read of ſeveral men of note and valour employed in driving the chariot. When the warriors came to encounter in cloſe fight; they alighted out of the chariot, and fought on foot; but when they were weary, which often happened by reaſon of their armour, they retired into their chariot, and thence annoyed their enemies with darts and miſſive weapons. Theſe chariots were made ſo ſtrong, that they laſted for ſeveral generations.

Beſides this ſort, we find frequent mention of the *currus falcati*, or thoſe charriots armed with hooks, or ſcythes, with which whole ranks of ſoldiers were cut off together, if they had not the art of avoiding the danger; theſe were not only uſed by the Perſians, Syrians, Egyptians, *&c.* but we find them among the ancient Britons; and notwithſtanding the imperfect ſtate of ſome of the moſt neceſſary arts among that nation before the invaſion of the Romans, it is certain that they had war-chariots in great abundance. By the Greek and Roman hiſtorians, theſe chariots are deſcribed by the ſix following names; *viz* Benna, Petoritum, Currus or Carrus Covinus, Eſſedum, and Rheda The benna ſeems to have been a chariot deſigned rather for travelling than war. It contained two perſons, who were called *combennones*, from their ſitting together in the ſame machine. The petoritum ſeems to have been a larger kind of chariot than the benna; and is thought to have derived its name from the Britiſh word *pedwar*, ſignifying *four;* this kind of carriage having four wheels. The carrus or currus was the common cart or waggon. This kind of chariot was uſed by the ancient Britons, in times of peace, for the purpoſes of agriculture and merchandiſe; and in times of war, for carrying their baggage, and wives and children, who commonly followed the armies of all the Celtic nations. The covinus was a war-chariot, and a very terrible inſtrument of deſtruction; being armed with ſharp ſcythes and hooks for cutting and tearing all who were ſo unhappy as to come within its reach. This kind of chariot was made very ſlight, and had few or no men in it beſides the charioteer; being deſigned to drive with great force and rapidity, and to do execution chiefly with its hooks and ſcythes. The eſſedum and rheda were alſo war-chariots, probably of a large ſize, and ſtronger made than the covinus, deſigned for containing a charioteer for driving it, and one or two warriors for fighting. The far greateſt number of the Britiſh war-chariots ſeem to have been of this kind. Theſe chariots, as already obſerved, were to be found in great numbers among the Britons; inſomuch that Cæſar relates that Caſſibelanus, after diſmiſſing all his other forces, retained no fewer than 4000 of theſe war-chariots about his perſon. The ſame author relates, that, by continual experience, they had at laſt arrived at ſuch perfection, in the management of their chariots, that "in the moſt ſteep and difficult places they could ſtop their horſes upon full ſtretch, turn them which way they pleaſed, run along the pole, reſt on the harneſs, and throw themſelves back into their chariots, with incredible dexterity."

Chariots, in the heathen mythology, were ſometimes conſecrated to the ſun; and the ſcripture obſerves, that Joſiah burnt thoſe which had been offered to the ſun by the king's predeceſſors. This ſuperſtitious

tious cuſtom was an imitation of the heathens, and principally of the Perſians, who had horſes and chariots conſecrated in honour of the ſun. Herodotus, Xenophon, and Quintus Curtius, ſpeak of white chariots crowned, which were conſecrated to the ſun, among the Perſians, which in their ceremonies were drawn by white horſes conſecrated to the ſame luminary.

Triumphal Chariot, was one of the principal ornaments of the Roman celebration of a victory.

The Roman triumphal chariot was generally made of ivory, round like a tower, or rather of a cylindrical figure; it was ſometimes gilt at the top, and ornamented with crowns, and to repreſent a victory more naturally, they uſed to ſtain it with blood. It was uſually drawn by four white horſes; but oftentimes by lions, elephants, tygers, bears, leopards, dogs, &c.

CHARISIA, in the heathen theology, a wake, or night-feſtival, inſtituted in honour of the graces. It continued the whole night, moſt of which time was ſpent in dancing; after which, cakes made of yellow flour mixed with honey, and other ſweetmeats, were diſtributed among the aſſiſtants.—Chariſia is alſo ſometimes uſed to ſignify the ſweetmeats uſed on ſuch occaſions.

CHARISIUS, in the heathen theology, a ſurname given to Jupiter. The word is derived from χαρις, *gratia*, "grace" or "favour;" he being the God by whoſe influence men obtain the favour and affection of one another. On which account the Greeks uſed at their meals to make a libation of a cup to Jupiter Chariſius.

CHARISTIA, a feſtival of the ancient Romans, celebrated in the month of February, wherein the relations by blood and marriage met, in order to preſerve a good correſpondence; and that if there happened to be any difference among them, it might be the more eaſily accommodated, by the good humour and mirth of the entertainment. *Ovid. Faſt.* i. 617.

CHARISTICARY, commendatory, or donatory, a perſon to whom is given the enjoyment of the revenues of a monaſtery, hoſpital, or benefice.

The chariſticaries among the Greeks, were a kind of donatories, or commendatories, who enjoyed all the revenues of hoſpitals and monaſteries, without giving an account thereof to any perſon—The original of this abuſe is referred to the Iconoclaſtæ, particularly Conſtantine, Copronymus, the avowed enemy of the monks, whoſe monaſteries he gave away to ſtrangers. In after times, the emperors and patriarchs gave many to people of quality, not by way of gift, to reap any temporal advantage from them; but to repair, beautify, and patronize them. At length avarice crept in, and thoſe in good condition were given away, eſpecially ſuch as were rich; and at laſt they were all given away, rich and poor, thoſe of men and of women, and that to laymen and married men.

CHARITY, among divines, one of the three grand theological virtues, conſiſting in the love of God and of our neighbour, or the habit and diſpoſition of loving God with all our heart, and our neighbour as ourſelves.

CHARITY is alſo uſed for the effect of a moral virtue, which conſiſts in ſupplying the neceſſities of others, whether with money, counſel, aſſiſtance, or the like.

As pecuniary relief is generally the moſt efficacious, and at the ſame time that from which we are moſt apt to excuſe ourſelves, this branch of the duty merits particular illuſtration; and a better cannot be offered than what is contained in the following extracts (if we may be permitted to make them) from the elegant *Moral Syſtem* of Archdeacon *Paley*.

Whether pity be an inſtinct or a habit, it is in fact a property of our nature, which God appointed: and the final cauſe for which it was appointed, is to afford to the miſerable, in the compaſſion of their fellow creatures, a remedy for thoſe inequalities and diſtreſſes which God foreſaw that many muſt be expoſed to, under every general rule for the diſtribution of property.

The Chriſtian ſcriptures are more copious and explicit upon this duty than almoſt any other. The deſcription which Chriſt has left us of the proceedings of the laſt day, eſtabliſhes the obligation of bounty beyond controverſy. When the Son of Man ſhall come in his glory, and all the holy angels with him, then ſhall he ſit upon the throne of his glory, and before him ſhall be gathered all nations; and he ſhall ſeparate them one from another. Then ſhall the king ſay unto them on his right hand, Come ye bleſſed of my father, inherit the kingdom prepared for you from the foundation of the world: For I was an hungered, and ye gave me meat; I was thirſty, and ye gave me drink; I was a ſtranger, and ye took me in; naked, and ye clothed me; I was ſick, and ye viſited me; I was in priſon, and ye came unto me. And inaſmuch as ye have done it to one of the leaſt of theſe my brethren, ye have done it unto me." It is not neceſſary to underſtand this paſſage as a literal account of what will actually paſs on that day. Suppoſing it only a ſcenical deſcription of the rules and principles by which the Supreme Arbiter of our deſtiny will regulate his deciſions, it conveys the ſame leſſon to us; it equally demonſtrates of how great value and importance theſe duties in the ſight of God are, and what ſtreſs will be laid upon them. The apoſtles alſo deſcribe this virtue as propitiating the divine favour in an eminent degree. And theſe recommendations have produced their effect. It does not appear that, before the times of Chriſtianity, an infirmary, hoſpital, or public charity of any kind, exiſted in the world; whereas moſt countries in Chriſtendom have long abounded with theſe inſtitutions. To which may be added, that a ſpirit of private liberality ſeems to flouriſh amidſt the decay of many other virtues: not to mention the legal proviſion for the poor, which obtains in ſome countries, and which was unknown and unthought of by the moſt poliſhed nations of antiquity.

St Paul adds upon the ſubject an excellent direction; and which is practicable by all who have any thing to give. "Upon the firſt day of the week (or any other ſtated time) let every one of you lay by in ſtore, as God hath proſpered him." By which the apoſtle may be underſtood to recommend what is the very thing wanting with moſt men, *the being charitable upon a plan*; that is, from a deliberate compariſon of our fortunes with the reaſonable expences and expectations of our families, to compute what we can ſpare, and to lay by ſo much for charitable purpoſes, in ſome mode or other. The mode will be a conſideration afterwards.

The effect, which Chriſtianity produced upon ſome of its converts, was ſuch as might be looked for from a divine religion coming with full force and miraculous evidence upon the conſciences of mankind. It overwhelmed all worldly conſiderations in the expectation of a more important exiſtence. “And the multitude of them that believed were of one heart and of one ſoul; neither ſaid any of them that aught of the things which he poſſeſſed, was his own; but they had all things in common.—Neither was there any among them that lacked; for as many as were poſſeſſors of lands or houſes ſold them, and brought the prices of the things that were ſold, and laid them down at the apoſtle's feet; and diſtribution was made unto every man, according as he had need.” Acts iv. 32.

Nevertheleſs, this community of goods, however it manifeſted the ſincere zeal of the primitive Chriſtians, is no precedent for our imitation. It was confined to the church at Jeruſalem; continued not long there; was never enjoined upon any (Acts v. 4.); and, although it might ſuit with the particular circumſtances of a ſmall and ſelect ſociety, is altogether impracticable in a large and mixed community.

The conduct of the apoſtles upon the occaſion deſerves to be noticed. Their followers laid down their fortunes at their feet: but ſo far were they from taking advantage of this unlimited confidence to enrich themſelves or eſtabliſh their authority, that they ſoon after got rid of this buſineſs as inconſiſtent with the main object of their miſſion, and transferred the cuſtody and management of the public funds to deacons, elected to that office by the people at large. (Acts vi.)

There are three kinds of charity, our author obſerves, which prefer a claim to attention.

1. The firſt, and apparently one of the beſt, is to give ſtated and conſiderable ſums, by way of penſion or annuity to individuals or families, with whoſe behaviour and diſtreſs we ourſelves are acquainted. In ſpeaking of conſiderable ſums, it is meant only, that five pounds, or any other ſum, given at once, or divided amongſt five or fewer families, will do more good than the ſame ſum diſtributed amongſt a greater number in ſhillings or half crowns; and that, becauſe it is more likely to be properly applied by the perſons who receive it. A poor fellow, who can find no better uſe for a ſhilling than to drink his benefactor's health, and purchaſe half an hour's recreation for himſelf, would hardly break into a guinea for any ſuch purpoſe, or be ſo improvident as not to lay it by for an occaſion of importance, for his rent, his clothing, fuel, or ſtock of winter's proviſion. It is a ſtill greater recommendation of this kind of charity, that penſions and annuities, which are paid regularly, and can be expected at the time, are the only way by which we can prevent one part of a poor man's ſufferings, the dread of want.

2. But as this kind of charity ſuppoſes that proper objects of ſuch expenſive benefactions fall within our private knowledge and obſervation, which does not happen to all, a ſecond method of doing good, which is in every one's power who has the money to ſpare, is by ſubſcription to public charities. Public charities admit of this argument in their favour, that your money goes farther towards attaining the end for which it is given, than it can do by any private and ſeparate beneficence. A guinea, for example, contributed to an infirmary, becomes the means of providing one patient, at leaſt, with a phyſician, ſurgeon, apothecary; with medicine, diet, lodging, and ſuitable attendance; which is not the tenth part of what the ſame aſſiſtance, if it could be procured at all, would coſt to a ſick perſon or family in any other ſituation.

3. The laſt, and, compared with the former, the loweſt exertion of benevolence, is the relief of beggars. Nevertheleſs, the indiſcriminate rejection of all who implore our alms in this way, is by no means approved. Some may periſh by ſuch a conduct. Men are ſometimes overtaken by diſtreſs, for which all other relief would come too late. Beſides which, reſolutions of this kind compel us to offer ſuch violence to our humanity, as may go near, in a little while, to ſuffocate the principle itſelf; which is a very ſerious conſideration. A good man, if he do not ſurrender himſelf to his feelings without reſerve, will at leaſt lend an ear to importunities which come accompanied with outward atteſtations of diſtreſs; and after a patient hearing of the complaint, will direct himſelf by the circumſtances and credibility of the account that he receives.

There are other ſpecies of charity well contrived to make the money expended *go far;* ſuch as keeping down the price of fuel or proviſion in caſe of a monopoly or temporary ſcarcity, by purchaſing the articles at the beſt market, and retailing them at prime coſt, or at a ſmall loſs; or the adding a bounty to a particular ſpecies of labour, when the price is accidentally depreſſed.

The proprietors of large eſtates have it in their power to facilitate the maintenance, and thereby encourage the eſtabliſhment of families (which is one of the nobleſt purpoſes to which the rich and great can convert their endeavours), by building cottages, ſplitting farms, erecting manufactures, cultivating waſtes, embanking the ſea, draining marſhes, and other expedients, which the ſituation of each eſtate points out. If the profits of theſe undertakings do not repay the expence, let the authors of them place the difference to the account of charity. It is true of almoſt all ſuch projects, that the public is a gainer by them, whatever the owner be. And where the loſs can be ſpared, this conſideration is ſufficient.

It is become a queſtion of ſome importance, Under what circumſtances works of charity ought to be done in private, and when they may be made public without detracting from the merit of the action; if indeed they ever may, the Author of our religion having delivered a rule upon this ſubject, which ſeems to enjoin univerſal ſecrecy. “When thou doeſt alms, let not thy left hand know what thy right hand doth; that thy alms may be in ſecret, and thy Father which ſeeth in ſecret, himſelf ſhall reward thee openly.” (Matth. vi. 3, 4.) From the preamble to this prohibition, it is plain that our Saviour's ſole deſign was to forbid *oſtentation,* and all publiſhing of good works which proceeds from that motive. Take heed that ye do not your alms before men, *to be ſeen of them;* otherwiſe ye have no reward of your Father, which is in heaven: therefore, when thou doeſt thy alms, do not ſound a trumpet before thee, as the hypocrites do in the ſynagogues and in the ſtreets, *that they may have glory of men.*

men. Verily I ſay unto thee, they have their reward," v. 2. There are motives for the doing our alms in public beſide thoſe of oſtentation; with which therefore our Saviour's rule has no concern; ſuch as to teſtify our approbation of ſome particular ſpecies of charity, and to recommend it to others; to take off the prejudice which the want, or, which is the ſame thing, the ſuppreſſion of our name in the liſt of contributors, might excite againſt the charity or againſt ourſelves. And, ſo long as theſe motives are free from any mixture of vanity, they are in no danger of invading our Savour's prohibition: they rather ſeem to comply with another direction which he has left us: "Let your light ſo ſhine before men, that they may ſee your good works, and glorify your father which is in heaven." If it be neceſſary to propoſe a preciſe diſtinction upon the ſubject, there can be none better than the following: When our bounty is beyond our fortune or ſtation, that is, when it is more than could be expected from us, our charity ſhould be private, if privacy be practicable; when it is not more than might be expected, it may be public: for we cannot hope to influence others to the imitation of extraordinary generoſity, and therefore want, in the former caſe, the only juſtifiable reaſon for making it public.

The pretences by which men excuſe themſelves from giving to the poor, are various; as,

1. "That they have nothing to ſpare;" i. e. nothing, for which they have not ſome other uſe; nothing which their plan of expence, together with the ſavings they have reſolved to lay by, will not exhauſt: never reflecting whether it be in their power, or that it is their duty, to retrench their expences, and contract their plan, "that they may have to give to them that need;" or rather that this ought to have been part of their plan originally.

2. "That they have families of their own, and that charity begins at home." A father is no doubt bound to adjuſt his œconomy with a view to the reaſonable demands of his family upon his fortune; and until a ſufficiency for theſe is acquired, or in due time probably will be acquired (for in human affairs probability is enough), he is juſtified in declining *expenſive* liberality; for to take from thoſe who want, in order to give to thoſe who want, adds nothing to the ſtock of public happineſs. Thus far, therefore, and no farther, the plea in queſtion, is an excuſe for parſimony, and an anſwer to thoſe who ſolicit our bounty.

3. "That charity does not conſiſt in giving money, but in benevolence, philanthropy, love to all mankind, goodneſs of heart," *&c.* Hear St James: "If a brother or ſiſter be naked, and deſtitute of daily food, and one of you ſay unto them, depart in peace, be ye warmed and filled, notwithſtanding *ye give them not thoſe things which are needful to the body*, what doth it profit?" (James ii. 15, 16.)

4. "That giving to the poor is not mentioned in St Paul's deſcription of charity, in the 13th chapter of his firſt epiſtle to the Corinthians." This is not a deſcription of charity, but of good nature; and it is not neceſſary that every duty be mentioned in every place.

5. "That they pay the poor-rates." They might as well allege that they pay their debts; for the poor have the ſame righ to that proportion of a man's property, which the laws aſſign them, that the man himſelf has to the remainder.

6. "That they employ many poor perſons:"—for their own ſake, not the poor's—otherwiſe it is a good plea.

7. "That the poor do not ſuffer ſo much as we imagine; that education and habit have reconciled them to the evils of their condition, and make them eaſy under it." Habit can never reconcile human nature to the extremities of cold, hunger, and thirſt, any more than it can reconcile the hand to the touch of a red-hot iron: beſides, the queſtion is not, how unhappy any one is, but how much more happy we can make him.

8. "That theſe people, give them what you will, will never thank you, or think of you for it." In the firſt place, this is not true: in the ſecond place, it was not for the ſake of their thanks that you relieved them.

9. That we are ſo liable to be impoſed upon." If a due enquiry be made, our motive and merit is the ſame: beſide that, the diſtreſs is generally real, whatever has been the cauſe of it.

10. "That they ſhould apply to their pariſhes." This is not always practicable: to which we may add, that there are many requiſites to a comfortable ſubſiſtence, which pariſh-relief does not always ſupply; and that there are ſome who would ſuffer almoſt as much from receiving pariſh-relief as by the want of it: and laſtly, that there are many modes of charity, to which this anſwer does not relate at all.

11. "That giving money encourages idleneſs and vagrancy." This is true only of injudicious and indiſcriminate generoſity.

12. "That we have too many objects of charity at home to beſtow any thing upon ſtrangers; ſo that there are other charities which are more uſeful, or ſtand in greater need." The value of this excuſe depends entirely upon the *fact*, whether we actually relieve thoſe neighbouring objects, and contribute to thoſe other charities.

Beſides all theſe excuſes, pride, or prudery, or delicacy, or love of eaſe, keep one half of the world out of the way of obſerving what the other half ſuffer.

CHARITY Schools, are ſchools erected and maintained in various pariſhes by the voluntary contributions of the inhabitants, for teaching poor children to read, write, and other neceſſary parts of education. See SCHOOL.

Brothers of CHARITY, a ſort of religious hoſpitallers, founded about the year 1297, ſince denominated *Billetins*. They took the third order of St Francis, and the ſcapulary, making three uſual vows, but without begging.

Brothers of CHARITY, alſo denote an order of hoſpitallers ſtill ſubſiſting in Romiſh countries, whoſe buſineſs is to attend the ſick poor, and miniſter to them both ſpiritual and temporal ſuccour.

They are all laymen, except a few prieſts, for adminiſtering the ſacraments to the ſick in their hoſpitals. The brothers of charity uſually cultivate botany, pharmacy, ſurgery, and chemiſtry, which they practiſe with ſucceſs.

They were firſt founded at Granada, by St John de

Dieu; and a ſecond eſtabliſhment was made at Madrid in the year 1553: the order was confirmed by Gregory XIII. in 1572: Gregory XIV. forbad them to take holy orders; but by leave of Paul V. in 1609, a few of the brothers might be admitted to orders. In 1619 they were exempted from the juriſdiction of the biſhop. Thoſe of Spain are ſeparated from the reſt; and they, as well as the brothers of France, Germany, Poland, and Italy, have their diſtinct generals, who reſide at Rome. They were firſt introduced into France by Mary of Medicis in 1601, and have ſince built a fine hoſpital in the Fauxbourg St Germain.

Charity of St Hippolitus, a religious congregation founded about the end of the 14th century, by one Bernardin Alvarez, a Mexican, in honour of St Hippolitus the martyr, patron of the city of Mexico; and approved by Pope Gregory XIII.

Charity of our Lady, in church-hiſtory, a religious order in France, which though charity was the principal motive of their union, grew in length of time ſo diſorderly and irregular, that their order dwindled, and at laſt became extinct.

There is ſtill at Paris a religions order of women, called *nuns hoſpitallers of the charity of our lady*. The religious of this hoſpital are by vow obliged to adminiſter to the neceſſities of the poor and the ſick, but thoſe only women.

CHARLATAN, or Charletan, ſignifies an empiric or quack, who retails his medicines on a public ſtage, and draws people about him with his buffooneries, feats of activity, &c. The word according to Calepine, comes from the Italian *ceretano*; of *Cæretum*, a town near Spoletto in Italy, where theſe impoſtors are ſaid to have firſt riſen. Menage derives it from *ciarlatano*, and that from *circulatorius*, of *circulator*, a quack.

CHARLEMAGNE, or Charles the I. king of France by ſucceſſion, and emperor of the weſt by conqueſt in 800, (which laid the foundation of the dynaſty of the weſtern Franks, who ruled the empire 472 years till the time of Radolphus Auſpurgenſis, the founder of the houſe of Auſtria). Charlemagne was as illuſtrious in the cabinet as in the field; and though he could not write his name, was the patron of men of letters, the reſtorer of learning, and a wiſe legiſlator: he wanted only the virtue of humanity to render him the moſt accompliſhed of men; but when we read of his beheading 4500 Saxons, ſolely for their loyalty to their prince, in oppoſing his conqueſts, we cannot think he merits the extravagant encomiums beſtowed on him by ſome hiſtorians. He died in 814, in the 74th year of his age, and 47th of his reign.

France had nine ſovereigns of his name, of whom Charles V. merited the title of *the wiſe* (crowned in 1364, died in 1380): and charles VIII. ſignalized himſelf in the field by rapid victories in Italy; crowned 1483, died in 1498. The reſt do not deſerve particular mention in this place. See *(Hiſtory of)* France.

CHARLEMONT, a town of the province of Namur in the Auſtrian Netherlands, about 18 miles ſouth of Namur. E. Long. 4. 40. N. Lat. 50. 10.

Charlemont is alſo the name of a town of Ireland, ſituated on the river Blackwater, in the county of Armagh, and province of Ulſter, about ſix miles ſouth-eaſt of Dungannon. W. Long. 6. 50. N. Lat. 50. 16.

CHARLEROY, a ſtrong town in the province of Namur, in the Auſtrian Netherlands, ſituated on the river Sambre, about 19 miles weſt of Namur. E. Long. 4. 20. N. Lat. 50. 30.

CHARLES Martel, a renowned conqueror in the early annals of France. He depoſed and reſtored Chilperic king of France; and had the entire government of the kingdom, once with the title of *mayor of the palace* and afterwards as *duke of France*; but he would not accept the crown. He died, regretted, in 741.

Charles le Gros, emperor of the weſt in 881, king of Italy and Suabia, memorable for his reverſe of fortune, being dethroned at a diet held near Mentz, by the French, the Italians, and the Germans, in 887: after which he was obliged to ſubſiſt on the bounty of the archbiſhop of Mentz. He died in 888.

Charles V. (emperor and king of Spain), was ſon of Philip I. archduke of Auſtria, and of Jane queen of Caſtile. He was born at Ghent, February 24, 1500. and ſucceeded to the crown of Spain in 1517. Two years afterwards he was choſen emperor at Francfort after the death of Maximilian his grandfather. He was a great warrior and politician; and his ambition was not ſatisfied with the many kingdoms and provinces he poſſeſſed; for he is ſuppoſed, with reaſon, to have aſpired at univerſal empire. He is ſaid to have fought 60 battles in moſt of which he was victorious. He took the king of France (Francis I.) priſoner, and ſold him his liberty on very hard terms; yet afterwards, when the people of Ghent revolted, he aſked leave to paſs through his dominions; and though the generous king thus had him in his power, and had an opportunity of revenging his ill-treatment, yet he received and attended him with all pomp and magnificence. He ſacked Rome, and took the Pope priſoner; and the cruelties which his army exerciſed there are ſaid to have exceeded thoſe of the northern barbarians. Yet the pious emperor went into mourning on account of this conqueſt: forbad the ringing of bells; commanded proceſſions to be made, and prayers to be offered up for the deliverance of the Pope his priſoner; yet did not inflict the leaſt puniſhment on thoſe who treated the holy father and the holy ſee with ſuch inhumanity. He is accuſed by ſome Romiſh writers of favouring the Lutheran principles, which he might eaſily have extirpated. But the truth is, he found his account in the diviſions which that ſect occaſioned; and he for ever made his advantage of them, ſometimes againſt the Pope, ſometimes againſt France, and at other times againſt the empire itſelf. He was a great traveller, and made 50 different journeys into Germany, Spain, Italy, Flanders, France, England, and Africa. Though he had been ſucceſsful in many unjuſt enterpriſes, yet his laſt attempt on Metz, which he beſieged with an army of 100,000 men, was very juſt and very unſucceſsful.

Vexed at the reverſe of fortune which ſeemed to attend his latter days, and oppreſſed by ſickneſs, which unfitted him any longer from holding the reigns of government with ſteadineſs, or to guide them with addreſs,

dreſs, he reſigned his dominions to his brother Ferdinand and his ſon Philip; and retreated to the monaſtery of St Juſtus near Placentia in Eſtramadura.

When Charles entered this retreat, he formed ſuch a plan of life for himſelf as would have ſuited a private gentleman of moderate fortune. His table was neat, but plain; his domeſtics few; his intercourſe with them familiar; all the cumberſome and ceremonious forms of attendance on his perſon were entirely aboliſhed, as deſtructive of that ſocial eaſe and tranquillity which he courted in order to ſooth the remainder of his days. As the mildneſs of the climate, together with his deliverance from the burdens and cares of government procured him at firſt a conſiderable remiſſion from the acute pains of the gout, with which he had been long tormented, he enjoyed perhaps more complete ſatisfaction in this humble ſolitude than all his grandeur had ever yielded him. The ambitious thoughts and projects which had ſo long engroſſed and diſquieted him, were quite effaced from his mind. Far from taking any part in the political tranſactions of the princes of Europe, he reſtrained his curioſity even from an enquiry concerning them; and he ſeemed to view the buſy ſcene which he had abandoned with all the contempt and indifference ariſing from his thorough experience of its vanity, as well as from the pleaſing reflection of having diſentangled himſelf from its cares.

Other amuſements, and other objects, now occupied him. Sometimes he cultivated the plants in his garden with his own hand; ſometimes he rode out to the neighbouring wood on a little horſe, the only one that he kept, attended by a ſingle ſervant on foot. When his infirmities confined him to his apartment, which often happened, and deprived him of theſe more active recreations, he either admitted a few gentlemen who reſided near the monaſtery to viſit him, and entertained them familiarly at his table; or he employed himſelf in ſtudying mechanical principles, and in forming curious works of mechaniſm, of which he had always been remarkably fond, and to which his genius was peculiarly turned. With this view he had engaged Turriano, one of the moſt ingenious artiſts of that age, to accompany him in his retreat. He laboured together with him in framing models of the moſt uſeful machines, as well as in making experiments with regard to their reſpective powers; and it was not ſeldom that the ideas of the monarch aſſiſted or perfected the inventions of the artiſt. He relieved his mind at intervals with ſlighter and more fantaſtic works of mechaniſm, in faſhioning puppets, which, by the ſtructure of internal ſprings, mimicked the geſtures and actions of men, to the no ſmall aſtoniſhment of the ignorant monks, who, beholding movements which they could not comprehend, ſometimes diſtruſted their own ſenſes, and ſometimes ſuſpected Charles and Turriano of being in compact with inviſible powers. He was particularly curious with regard to the conſtruction of clocks and watches; and having found, after repeated trials, that he could not bring any two of them to go exactly alike, he reflected, it is ſaid, with a mixture of ſurpriſe as well as regret on his own folly, in having beſtowed ſo much time and labour in the more vain attempt of bringing mankind to a preciſe uniformity of ſentiment concerning the intricate and myſterious doctrines of religion.

But in what manner ſoever Charles diſpoſed of the reſt of his time, he conſtantly reſerved a conſiderable portion of it for religious exerciſes. He regularly attended divine ſervice in the chapel of the monaſtery every morning and evening; he took great pleaſure in reading books of devotion, particularly the works of St Auguſtine and St Bernard; and converſed much with his confeſſor, and the prior of the monaſtery, on pious ſubjects. Thus did Charles paſs the firſt year of his retreat in a manner not unbecoming a man perfectly diſengaged from the affairs of this preſent life, and ſtanding on the confines of a future world, either in innocent amuſements which ſoothed his pains, and relieved a mind worn out with exceſſive application to buſineſs; or in devout occupations, which he deemed neceſſary in preparing for another ſtate.

But, about ſix months before his death, the gout, after a longer intermiſſion than uſual, returned with a proportional increaſe of violence. His ſhattered conſtitution had not ſtrength enough remaining to withſtand ſuch a ſhock. It enfeebled his mind as much as his body; and from this period we hardly diſcern any traces of that ſound and maſculine underſtanding which diſtinguiſhed Charles among his cotemporaries. An illiberal and timid ſuperſtition depreſſed his ſpirit. He had no reliſh for amuſements of any kind. He endeavoured to conform, in his manner of living, to all the rigour of monaſtic auſterity. He deſired no other ſociety than that of monks, and was almoſt continually employed in chanting with them the hymns of the miſſal. As an expiation for his ſins, he gave himſelf the diſcipline in ſecret with ſuch ſeverity, that the whip of cords which he employed as the inſtrument of his puniſhment, was found, after his deceaſe, tinged with his blood. Nor was he ſatisfied with theſe acts of mortification, which, however ſevere, were not unexampled. The timorous and diſtruſtful ſolicitude which always accompanies ſuperſtition, ſtill continued to diſquiet him, and depreciating all that he had done, prompted him to aim at ſomething extraordinary, at ſome new and ſingular act of piety, that would diſplay his zeal, and merit the favour of heaven. The act on which he fixed was as wild and uncommon as any that ſuperſtition ever ſuggeſted to a diſordered fancy. He reſolved to celebrate his own obſequies before his death. He ordered his tomb to be erected in the chapel of the monaſtery. His domeſtics marched thither in funeral proceſſion, with black tapers in their hands. He himſelf followed in his ſhroud. He was laid in his coffin with much ſolemnity: The ſervice for the dead was chanted; and Charles joined in the prayers which were offered up for the reſt of his ſoul, mingled his tears with thoſe which his attendants ſhed, as if they had been celebrating a real funeral. The ceremony cloſed with ſprinkling holy water on the coffin in the uſual form, and, all the aſſiſtants retiring, the doors of the chapel were ſhut. Then Charles roſe out of the coffin, and withdrew to his apartment, full of thoſe awful ſentiments which ſuch a ſingular ſolemnity was calculated to inſpire. But either the fatiguing length of the ceremony, or the impreſſion which this image of death left on his mind, affected him ſo much, that next day he was ſeized with a fever. His feeble frame could not long reſiſt its violence; and he expired on the 21ſt of September, after a life of 58 years ſix months and 21 days.

CHARLES I. } Kings of Britain. See BRITAIN,
CHARLES II. } n° 49,——254.

CHARLES XII. king of Sweden, was born in 1682. By his father's will, the adminiſtration was lodged in the hands of the queen-dowager Eleonora with five ſenators till the young prince was 18: but he was declared major at 15, by the ſtates convened at Stockholm. The beginning of his adminiſtration raiſed no favourable ideas of him, as he was thought both by Swedes and foreigners to be a perſon of mean capacity. But the difficulties that gathered round him ſoon afforded him an opportunity to diſplay his real character. Three powerful princes, Frederic king of Denmark, Auguſtus king of Poland and elector of Saxony, and Peter the Great czar of Muſcovy, preſuming on his youth, conſpired his ruin almoſt at the ſame inſtant. Their meaſures alarming the council, they were for diverting the ſtorm by negociations; but Charles, with a grave reſolution that aſtoniſhed them, ſaid, "I am reſolved never to enter upon an unjuſt war, nor to put an end to a juſt one but by the deſtruction of my enemies. My reſolution is fixed: I will attack the firſt who ſhall declare againſt me; and when I have conquered him, I may hope to ſtrike a terror into the reſt." The old counſellors received his orders with admiration; and were ſtill more ſurpriſed when they ſaw him on a ſudden renounce all the enjoyments of a court, reduce his table to the utmoſt frugality, dreſs like a common ſoldier, and, full of the ideas of Alexander and Cæſar, propoſe thoſe two conquerors for his models in every thing but their vices. The king of Denmark began by ravaging the territories of the duke of Holſtein. Upon this Charles carried the war into the heart of Denmark; and made ſuch a progreſs, that the king of Denmark thought it beſt to accept of peace, which was concluded in 1700. He next reſolved to advance againſt the king of Poland, who had blocked up Riga. He had no ſooner given orders for his troops to go into winter-quarters, than he received advice that Narva, where count Horne was governor, was beſieged by an army of 100,000 Muſcovites. This made him alter his meaſures, and move toward the Czar; and at Narva he gained a ſurpriſing victory, which coſt him not above 2000 men killed and wounded. The Muſcovites were forced to retire from the provinces they had invaded. He purſued his conqueſts, till he penetrated as far as where the diet of Poland was ſitting; when he made them declare the throne of Poland vacant, and elect Staniſlaus their king: then making himſelf maſter of Saxony, he obliged Auguſtus himſelf to renounce the crown of Poland, and acknowledge Staniſlaus by a letter of congratulation on his acceſſion. All Europe was ſurpriſed with the expeditious finiſhing of this great negociation, but more at the diſintereſtedneſs of the king of Sweden, who ſatisfied himſelf with the bare reputation of this victory, without demanding an inch of ground for enlarging his dominions. After thus reducing the king of Denmark to peace, placing a new king on the throne of Poland, having humbled the emperor of Germany, and protected the Lutheran religion, Charles prepared to penetrate into Muſcovy in order to dethrone the Czar. He quickly obliged the Muſcovites to abandon Poland, purſued them into their own country, and won ſeveral battles over them. The Czar diſpoſed to peace, ventured to make ſome propoſals: Charles only anſwered, "I will treat with the Czar at Moſcow." When this haughty anſwer was brought to Peter, he ſaid, "My brother Charles ſtill affects to act the Alexander, but I flatter myſelf he will not in me find a Darius." The event juſtified him: for the Muſcovites, already beaten into diſcipline, and under a prince of ſuch talents as Peter, entirely deſtroyed the Swediſh army at the memorable battle of Pultowa, July 8, 1709; on which deciſive day, Charles loſt the fruits of nine years labour, and of almoſt 100 battles! The king, with a ſmall troop, purſued by the Muſcovites, paſſed the Boriſthenes to Oczakow in the Turkiſh territories: and from thence through deſart countries, arrived at Bender; where the Sultan, when informed of his arrival, ſent orders for accommodating him in the beſt manner, and appointed him a guard. Near Bender Charles built a houſe, and intrenched himſelf; and had with him 1800 men, who were all clothed and fed, with their horſes, at the expence of the Grand Signior. Here he formed a deſign of turning the Ottoman arms upon his enemies; and is ſaid to have had a promiſe from the Vizir of being ſent into Muſcovy with 200,000 men. While he remained here, he inſenſibly acquired a taſte for books: he read the tragedies of Corneille and Racine, with the works of Deſpreaux, whoſe ſatires he reliſhed, but did not much admire his other works. When he read that paſſage in which the author repreſents Alexander as a fool and a madman, he tore out the leaf. He would ſometimes play at cheſs: but when he recovered of his wounds, he renewed his fatigues in exerciſing his men; he tired three horſes a day; and thoſe who courted his favour were all day in their boots. To diſpoſe the Ottoman Porte to this war, he detached about 800 Poles and Coſaques of his retinue, with orders to paſs the Neiſter, that runs by Bender, and to obſerve what paſſed on the frontiers of Poland. The Muſcovite troops, diſperſed in thoſe quarters, fell immediately upon this little company, and purſued them even to the territories of the Grand Signior. This was what the king expected. His miniſters at the Porte excited the Turks to vengeance; but the Czar's money removed all difficulties, and Charles found himſelf in a manner priſoner among the Tartars. He imagined the Sultan was ignorant of the intrigues of his Grand Vizir. Poniatoſky undertook to make his complaints to the Grand Signior. The Sultan, in anſwer, ſome days after, ſent Charles five Arabian horſes, one of which was covered with a ſaddle and houſing of great riches; with an obliging letter, but conceived in ſuch general terms, as gave reaſon to ſuſpect that the miniſter had done nothing without the Sultan's conſent: Charles therefore refuſed them. Poniatoſky had the courage to form a deſign of depoſing the Grand Vizir;

who accordingly was deprived of his dignity and wealth, and baniſhed. The ſeal of the empire was given to Numan Cuproughly; who perſuaded his maſter, that the law forbid him to invade the Czar, who had done him no injury; but to ſuccour the king of Sweden as an unfortunate prince in his dominions. He ſent his majeſty 800 purſes, every one of which amounted to 500 crowns, and adviſed him to return peaceably to his own dominions. Charles rejected this advice, threatening to hang up the baſhaws, and ſhave the beards of any Janiſaries who brought him ſuch meſſages; and ſent word that he ſhould depend upon the Grand Signior's promiſe, and hoped to re-enter Poland as a conqueror with an army of Turks. After various intrigues at the Porte, an order was ſent to attack this *head of iron*, as he was called, and to take him either alive or dead. He ſtood a ſiege in his houſe, with forty domeſtics, againſt the Turkiſh army; killed no leſs than 20 Janiſaries with his own hand; and performed prodigies of valour on a very unneceſſary and unwarrantable occaſion. But the houſe being ſet on fire, and himſelf wounded, he was at laſt taken priſoner, and ſent to Adrianople; where the Grand Signior gave him audience, and promiſed to make good all the damages he had ſuſtained. At laſt, after a ſtay of about five years, he left Turkey; and, having diſguiſed himſelf, traverſed Wallachia, Tranſylvania, Hungary, and Germany, attended only by one perſon: and in 16 days riding, during which time he never went to bed, came to Stralſund at midnight, November 21, 1714. His boots were cut from his ſwollen legs, and he was put to bed; where, when he had ſlept ſome hours, the firſt thing he did was to review his troops, and examine the ſtate of the fortifications. He ſent out orders that very day, to renew the war with more vigour than ever. But affairs were now much changed: Auguſtus had recovered the throne of Poland; Sweden had loſt many of its provinces, and was without money, trade, credit, or troops. The kings of Denmark and Pruſſia ſeized the iſland of Rugen; and beſieged him in Stralſund, which ſurrendered; but Charles eſcaped to Carlſcroon. When his country was threatened with invaſion by ſo many princes, he, to the ſurpriſe of all Europe, marched into Norway with 20,000 men. A very few Danes might have ſtopped the Swediſh army; but ſuch a quick invaſion they could not foreſee. Europe was yet more at a loſs to find the Czar ſo quiet, and not making a deſcent upon Sweden, as he had before agreed with his allies. This inaction was the conſequence of one of the greateſt deſigns, and at the ſame time the moſt difficult of any that were ever formed by the imagination of man. In ſhort, a ſcheme was ſet on foot for a reconciliation with the Czar; for replacing Staniſlaus on the throne of Poland; and ſetting James the ſecond's ſon upon that of England, beſide reſtoring the duke of Holſtein to his dominions. Charles was pleaſed with theſe grand ideas, though without building much upon them, and gave his miniſter leave to act at large. In the mean time, Charles was going to make a ſecond attempt upon Norway in 1718; and he flattered himſelf with being maſter of that kingdom in ſix months: but while he was examining the works at Fredericſhall, a place of great ſtrength and importance, which is reckoned to be the key of that kingdom, he was killed by a ſhot from the enemy, as has been generally believed; though it has been alſo reported that he fell by the treachery of one of his own officers, who had been bribed for that purpoſe.

This prince experienced the extremes of proſperity and of adverſity, without being ſoftened by the one, or diſturbed for a moment at the other: but was a man rather extroardinary than great, and fitter to be admired than imitated. He was honoured by the Turks for his rigid abſtinence from wine, and his regularity in attending public devotion.

As to his perſon, he was tall and of a noble mien, had a fine open forehead, large blue eyes, flaxen hair, fair complexion, an handſome noſe, but little beard, and a laugh not agreeable. His manners were harſh and auſtere, not to ſay ſavage; and as to his religion, he was indifferent towards all, though exteriorly a Lutheran, and a ſtrong believer in predeſtination. A few anecdotes will illuſtrate his character. No dangers, however great, made the leaſt impreſſion upon him. When a horſe or two were killed under him at the battle of Narva in 1700, he leaped nimbly upon freſh ones, ſaying, “theſe people find me exerciſe.” One day, when he was dictating letters to a ſecretary, a bomb fell through the roof into the next room of the houſe, where they were ſitting. The ſecretary, terrified leaſt the houſe ſhould come down upon them, let his pen drop out of his hand; “What is the matter,” ſays the king calmly. The ſecretary could only reply, “Ah, Sir, the bomb.” “The bomb (ſays the king)! what has the bomb to do with what I am dictating to you? Go on.”

He preſerved more humanity than is uſually found among conquerors. Once, in the middle of an action, finding a young Swediſh officer wounded and unable to march, he obliged the officer to take his horſe, and continued to command his infantry on foot. The princeſs Lubomirſki, who was very much in the intereſt and good graces of Auguſtus, falling by accident into the hands of one of his officers, he ordered her to be ſet at liberty; ſaying, “that he did not make war with women.” One day, near Leipſic, a peaſant threw himſelf at his feet, with a complaint againſt a grenadier, that he had robbed him of certain eatables provided for himſelf and his family. “Is it true, (ſaid Charles ſternly), that you have robbed this man?” The ſoldier replied, “Sir, I have not done near ſo much harm to this man as your majeſty has done to his maſter; for you have taken from Auguſtus a kingdom, whereas I have only taken from this poor ſcoundrel a dinner.” Charles made the peaſant amends, and pardoned the ſoldier for his firmneſs: “However, my friend (ſays he to him), you will do well to recollect, that if I took a kingdom from Auguſtus, I did not take it for myſelf.”

Though Charles lived hardily himſelf, a ſoldier did not fear to remonſtrate to him againſt ſome bread, which was very black and mouldy, and which yet was the only proviſion the troops had. Charles called for a piece of it, and calmly eat it up; ſaying, “that it was indeed not good, but that it might be eaten.” From the danger he was in in Poland, when he beat

the

the Saxon troops in 1702, a comedy was exhibited at Marienburg, where the combat was repreſented to the diſadvantage of the Swedes. "Oh, (ſays Charles, hearing of it), I am far from envying them in this pleaſure. Let them beat me upon the theatres as long as they will, provided I do but beat them in the field." He wrote ſome obſervations on war, and on his own campaigns from 1700 to 1709; but the MS. was loſt at the unfortunate battle of Pultowa.

CHARLES's-cape, a promontory of Virginia, in North-America, forming the northern head-land of the ſtrait that enters the bay of Cheaſepeak.

Charles's-Fort, a fortreſs in the county of Cork, and province of Munſter, in Ireland, ſituated at the mouth of Kinſale harbour. W. Long. 8. 20. and N. Lat. 51. 21.

Morſe's Geography.

CHARLESTON, the capital of the ſtate of South-Carolina, is the only conſiderable town in that ſtate. It is ſituated on the tongue of land which is formed by the the confluence of Aſhley and Cooper rivers, which are large and navigable. Theſe rivers mingle their waters immediately below the town, and form a ſpacious and convenient harbour, which communicates with the ocean at Sullivan's iſland, ſeven miles ſouth-eaſt of the town. In theſe rivers the tide riſes, in common, about five feet. The continued agitation which this occaſions in the waters which almoſt ſurround Charleſton, and the refreſhing ſea breezes which are regularly felt, render Charleſton more healthy than any part of the low country in the ſouthern ſtates. On this account it is the reſort of great numbers of gentlemen, invalids from the Weſt-India iſlands, and of the rich planters from the country, who come here to ſpend the *ſickly months*, as they are called, in queſt of health and of the ſocial enjoyments which the city affords. And in no part of America are the ſocial bleſſings enjoyed more rationally and liberally than in Charleſton. Unaffected hoſpitality—affability—eaſe in manners and addreſs—and a diſpoſition to make their gueſts welcome, eaſy and pleaſed with themſelves, are characteriſtics of the reſpectable people in Charleſton.

The land on which the town is built is flat and low, and the water brackiſh and unwholeſome. The inhabitants are obliged to raiſe banks of earth as barriers to defend themſelves againſt the higher floods of the ſea. The ſtreets from eaſt to weſt extend from river to river, and running in a ſtraight line, not only open beautiful proſpects each way, but afford excellent opportunities, by means of ſubterranean drains, for removing all nuiſances and keeping the city clean and healthy. Theſe ſtreets are interſected by others, nearly at right angles, and throw the town into a number of ſquares, with dwelling houſes in front, and office houſes and little gardens behind. Some of the ſtreets are conveniently wide, but moſt of them are much too narrow, eſpecially for ſo populous a city, in ſo warm a climate. From their confined ſituation, they have been found extremely inconvenient in caſe of fires, the deſtructive effects of which have been frequently felt in this city. The houſes, which have been lately built, are brick, with tiled roofs. Some of the buildings in Charleſton are elegant, and moſt of them are neat, airy, and well furniſhed. The public buildings are an exchange, ſtate-houſe, armoury, poor-houſe, two large churches for Epiſcopalians, two for Congregationaliſts or Independents, one for Scotch Preſbyterians, two for the Baptiſts, one for the German Lutherans, one for the Methodiſts, one for French Proteſtants—beſides a meeting houſe for Quakers, and two Jewiſh ſynagogues, one for the Portugueſe, the other for the German Jews. There are upwards of a thouſand Roman Catholics in Charleſton, but they have no public building for worſhip.

In 1787, there were 1,600 houſes in this city, and 9,600 white inhabitants, and 5,400 negroes: and what evinces the healthineſs of the place, upwards of 200 of the white inhabitants were above ſixty years of age.

Charleſton was incorporated in 1783, and divided into 13 wards, who chooſe as many wardens, who, from among themſelves, elect an intendant of the city. The intendant and wardens form the city council, who have power to make and enforce bye-laws for the regulation of the city. W. Long. 79. 0. and N. Lat. 32. 30.

Charles's-Wain, in aſtronomy, ſeven ſtars in the conſtellation called *urſa major*, or the Great Bear.

CHARLETON, an iſland at the bottom of Hudſon's-bay, in North-America, ſubject to Great-Britain. W. Long. 80. 0. and N. Lat. 52. 30.

Charleton, (Walter) a learned Engliſh phyſician born in 1619, was phyſician in ordinary to Charles I. and Charles II. one of the firſt members of the royal ſociety, and preſident of the college of phyſicians. He wrote on various ſubjects; but at laſt his narrow circumſtances obliged him to retire to the iſland of Jerſey, where he died in 1707.

CHARLOCK, the Engliſh name of the Raphanus; it is a very troubleſome weed among corn, being more frequent than almoſt any other. There are two principal kinds of it; the one with a yellow flower, the other with a white. Some fields are particularly ſubject to be over-run with it, eſpecially thoſe which have been manured with cow-dung alone, that being a manure very favourable to the growth of it. The farmers in ſome places are ſo ſenſible of this, that they always mix horſe-dung with their cow-dung, when they uſe it for arable land. When barley, as is often the caſe, is infeſted with this weed to ſuch a degree as to endanger the crop, it is a very good method to mow down the charlock in May, when it is in flower, cutting it ſo low as juſt to take off the tops of the leaves of barley with it: by this means the barley will get up above the weed: and people have got four quarters of grain from an acre of ſuch land as would have ſcarce yielded any thing without this expedient. Where any land is particularly ſubject to this weed, the beſt method is to ſow it with graſs ſeed, and make a paſture of it; for then the plant will not be troubleſome, it never growing where there is a coat of graſs upon the ground.

Queen CHARLOTTE's Island, an iſland in the South Sea, firſt diſcovered by captain Wallis in the Dolphin, in 1767, who took poſſeſſion of it in the name of King George III. Here is good water, and plenty of cocoa-nuts, palm-nuts, and ſcurvy-graſs. The inhabitants are of a middle ſtature, and dark complexion, with long hair hanging over their ſhoulders; the

the men are well made, and the women handſome; their cloathing is a kind of coarſe cloth, or matting, which they faſten about their middle.

Queen Charlotte's *Iſlands*, a cluſter of South-ſea iſlands diſcovered in 1767 by captain Carteret. He counted ſeven, and there were ſuppoſed to be many more. The inhabitants of theſe iſlands are deſcribed as extremely nimble and vigorous, and almoſt as well qualified to live in the water as upon land: they are very warlike; and, on a quarrel with ſome of captain Carteret's people, they attacked them with great reſolution; mortally wounded the maſter and three of the ſailors; were not at all intimidated by the fire-arms; and at laſt, notwithſtanding the averſion of captain Carteret to ſhed blood, he was obliged to ſecure the watering places by firing grape-ſhot into the woods, which deſtroyed many of the inhabitants. Theſe iſlands lie in S. Lat. 11°. E. Long. 164°. They are ſuppoſed to be the Santa Cruz of Mandana, who died there in 1595.

CHARM, a term derived from the Latin *carmen*, a "verſe;" and uſed to denote a magic power, or ſpell, by which, with the aſſiſtance of the devil, ſorcerers and witches, were ſuppoſed to do wonderful things, far ſurpaſſing the power of nature.

CHARNEL, or Charnel-house, a kind of portico or gallery, uſually in or near a church-yard, over which were anciently laid the bones of the dead, after the fleſh was wholly conſumed. Charnel-houſes are now uſually adjoining to the church.

CHARON, in fabulous hiſtory, the ſon of Erebus and Nox, whoſe office was to ferry the ſouls of the deceaſed over the waters of Acheron, for which each ſoul was to pay a piece of money. For this reaſon the Pagans had a cuſtom of putting a piece of money into the mouth of the dead, in order that they might have ſomething to pay Charon for their paſſage.

CHARONDAS, a celebrated legiſlator of the Thurians, and a native of Catanea in Sicily, flouriſhed 446 before Chriſt. He forbad any perſon's appearing armed in the public aſſemblies of the nation; but one day going thither in haſte, without thinking of his ſword, he was no ſooner made to obſerve his miſtake than he ran it through his body.

CHAROST, a town of France, in Berry, with the title of a duchy. It is ſeated on the river Arnon, E. Long. 2. 15. N. Lat. 46. 56.

CHAROUX, a town of France, in the Bourbonnois, ſeated on an eminence, near the river Sioulle. It has two pariſhes, which are in different dioceſes. E. Long. 3. 15. N. Lat. 46. 10.

CHARPENTIER, (Francis) dean of the French academy, was born in 1620. His early capacity inclined his friends to educate him for the bar: but he was much more delighted with the ſtudy of languages and antiquity than of the law; and preferred repoſe to tumult. M. Colbert made uſe of him in eſtabliſhing his new academy of medals and inſcriptions; and no perſon of that learned ſociety contributed more than himſelf towards that noble ſeries of medals which were ſtruck on the conſiderable events that diſtinguiſhed the reign of Louis XIV. He publiſhed ſeveral works, which were all well received; and died in 1702.

CHARR, in ichthyology. See Salmo.

CHARRON, (Peter) the author of a book intitled *Of Wiſdom*, which gained him great reputation, was born at Paris in the year 1541. After being advocate in the parliament of Paris for five or ſix years, he applied himſelf to divinity; and became ſo great a preacher, that the biſhops of ſeveral dioceſes offered him the higheſt dignities in their gift. He died at Paris, ſuddenly in the ſtreet, November 16, 1603.

CHART, or Sea-chart, an hydrographical map, or a projection of ſome part of the earth's ſuperficies *in plano*, for the uſe of navigators.

Charts differ very conſiderably from geographical or land-maps, which are of no uſe in navigation. Nor are ſea-charts all of the ſame kind, ſome being what we call plane-charts others, mercator-charts, and others globular-charts.

Plane-Chart, is a repreſentation of ſome part of the ſuperficies of the terraqueous globe, in which the meridians are ſuppoſed parallel to each other, the parallels of latitude at equal diſtances, and conſequently the degrees of latitude and longitude every where equal to each other. See *Plane-Chart*.

Mercator's-Chart, is that where the meridians are ſtraight lines, parallel to each other, and equidiſtant; the parallels are alſo ſtraight lines, and parallel to each other: but the diſtance between them increaſes from the equinoctial towards either pole, in the ratio of the ſecant of the latitude to the radius. See Navigation.

Globular-Chart, a meridional projection, wherein the diſtance of the eye from the plane of the meridian, upon which the projection is made, is ſuppoſed to be equal to the ſine of the angle 45°. This projection comes the neareſt of all to the nature of the globe, becauſe the meridians therein are placed at equal diſtances; the parallels alſo are nearly equidiſtant, and conſequently the ſeveral parts of the earth have their proper proportion of magnitude, diſtance, and ſituation, nearly the ſame as on the globe itſelf. See *Globular Projection*.

Hydrographic Charts, ſheets of large paper, whereon ſeveral parts of the land and ſea are deſcribed, with their reſpective coaſts, harbours, ſounds, flats, rocks, ſhelves, ſands, &c. together with the longitude and latitude of each place, and the points of the compaſs. See *Mercator's-Chart*.

Selenographic-Charts, particular deſcriptions of the ſpots, appearances, and maculæ of the moon. See Astronomy, n° 63. and 140.

Topographic-Charts, draughts of ſome ſmall parts of the earth only, or of ſome particular places, without regard to its relative ſituation, as London, York, &c.

CHARTA, or Carta, primarily ſignifies a ſort of paper made of the plant *papyrus* or *biblus*. See Paper and Charter.

Charta-Emporetica, in pharmacy, &c. a kind of paper made very ſoft and porous, uſed to filter withal. See Filtration, &c.

Charta is alſo uſed in ancient cuſtoms for a charter, or deed in writing. See Charter.

Magna Charta, the great charter of the liberties of Britain, and the baſis of their laws and privileges.

Charta.

This charter may be ſaid to derive its origin from king Edward the Confeſſor, who granted ſeveral privileges to the church and ſtate by charter: theſe liberties and privileges were alſo granted and confirmed by king Henry I. by a celebrated great charter now loſt; but which was confirmed or re-enacted by king Henry II. and king John. Henry III. the ſucceſſor of this laſt prince, after having cauſed 12 men make inquiry into the liberties of England in the reign of Henry I. granted a new charter; which was the ſame as the preſent magna charta. This he ſeveral times confirmed, and as often broke; till, in the 37th year of his reign, he went to Weſtminſter-hall, and there, in preſence of the nobility and biſhops, who held lighted candles in their hands, magna charta was read, the king all the time holding his hand to his breaſt, and at laſt ſolemnly ſwearing faithfully and inviolably to obſerve all the things therein contained, &c. Then the biſhops extinguiſhing the candles, and throwing them on the ground, they all cried out, "Thus let him be extinguiſhed, and ſtink in hell, who violates this charter." It is obſerved, that, notwithſtanding the ſolemnity of this confirmation, king Henry, the very next year, again invaded the rights of his people, till the barons entered into a war againſt him; when, after various ſucceſs, he confirmed this charter, and the charter of the foreſt, in the 52d year of his reign.

This charter confirmed many liberties of the church, and redreſſed many grievances incident to feodal tenures, of no ſmall moment at the time; tho' now, unleſs conſidered attentively and with this retroſpect, they ſeem but of trifling concern. But, beſides theſe feodal proviſions, care was alſo taken therein to protect the ſubject againſt other oppreſſions, then frequently ariſing from unreaſonable amercements, from illegal diſtreſſes, or other proceſs for debts or ſervices due to the crown, and from the tyrannical abuſe of the prerogative of purveyance and pre-emption. It fixed the forfeiture of lands for felony in the ſame manner as it ſtill remains; prohibited for the future the grants of excluſive fiſheries; and the erection of new bridges ſo as to oppreſs the neighbourhood. With reſpect to private rights, it eſtabliſhed the teſtamentary power of the ſubject over part of his perſonal eſtate, the reſt being diſtributed among his wife and children; it laid down the law of dower, as it hath continued ever ſince; and prohibited the appeals of women, unleſs after the death of their huſbands. In matters of public police and national concern, it enjoined an uniformity of weights and meaſures; gave new encouragements to commerce, by the protection of merchant-ſtrangers; and forbad the alienation of lands in mortmain. With regard to the adminiſtration of juſtice: beſides prohibiting all denials or delays of it, it fixed the court of common-pleas at Weſtminſter, that the ſuitors might no longer be harraſſed with following the king's perſon in all his progreſſes; and at the ſame time brought the trial of iſſues home to the very doors of the freeholders, by directing aſſizes to be taken in the proper counties, and eſtabliſhing annual circuits: it alſo corrected ſome abuſes then incident to the trials by wager of law and of battle; directed the regular awarding of inqueſts for life or member; prohibited the king's inferior miniſters from holding pleas of the crown, or trying any criminal charge, whereby many forfeitures might otherwiſe have unjuſtly accrued to the exchequer; and regulated the time and place of holding the inferior tribunals of juſtice, the county-court, ſheriff's torn, and court leet. It confirmed and eſtabliſhed the liberties of the city of London, and all other cities, boroughs, towns, and ports of the kingdom. And laſtly (which alone would have merited the title that it bears, of the *great charter*), it protected every individual of the nation in the free enjoyment of his life, his liberty, and his property, unleſs declared to be forfeited by the judgment of his peers, or the law of the land.

This excellent charter, ſo equitable, and beneficial to the ſubject, is the moſt ancient written law in the kingdom. By the 25th Edward I. it is ordained, that it ſhall be taken as the common law; and by the 43d Edward III. all ſtatutes made againſt it are declared to be void.

Charter, Charter-party.

CHARTER, in law, a written inſtrument, or evidence of things acted between one perſon and another. The word charter comes from the Latin *charta*, anciently uſed for a public and authentic act, a donation, contract, or the like; from the Greek χαρτης, "thick paper" or "paſteboard," whereon public acts were wont to be written. Britton divides charters into thoſe of the king, and thoſe of private perſons. 1. Charters of the king, are thoſe whereby the king paſſeth any grant to any perſon or body politic, as a *charter of exemption* of privilege, &c.; *charter of pardon*, whereby a man is forgiven a felony, or other offence committed againſt the king's crown and dignity; *charter of the foreſt*, wherein the laws of the foreſt are compriſed, ſuch as the charter of Canutus, &c. 2. Charters of private perſons, are deeds and inſtruments for the conveyance of lands, &c. And the purchaſer of lands ſhall have all the charters, deeds, and evidences, as incident to the ſame, and for the maintenance of his title.

Charter-Governments in America. See Colony.

Charter-Land, ſuch land as a perſon holds by charter; that is, by evidence in writing, otherwiſe called freehold.

CHARTERPARTY, in commerce, denotes the inſtrument of freightage, or articles of agreement for the hire of a veſſel. See Freight, &c.

The charterparty is to be in writing; and to be ſigned both by the proprietor or the maſter of the ſhip, and the merchant who freights it. It is to contain the name and the burden of the veſſel; the names of the maſter and the freighter; the price or rate of freight; and the time of loading and unloading; and the other conditions agreed on. It is properly a deed, or policy, whereby the maſter or proprietor of the veſſel engages to furniſh immediately a tight ſound veſſel, well equipped, caulked, and ſtopped, provided with anchors, ſails, cordage, and all other furniture to make the voyage required, as equipage, hands, victuals, and other munitions; in conſideration of a certain ſum to be paid by the merchant for the freight. Laſtly, the ſhip with all its furniture, and the cargo, are reſpectively ſubjected to the conditions of the *charterparty*. The *charterparty* differs from a *bill of lading*, in that the firſt is for the entire freight or lading, and that both for going and returning; whereas the latter is only for a part of the freight, or at moſt only for the voyage one way.

The preſent Boyer ſays, the word comes from hence, that *per medium charta incidebatur, et ſic fiebat charta partita*; becauſe, in the time when notaries were leſs common, there was only one inſtrument made for both parties: this they cut in two, and gave each his proportion; joining them together at their return, to know if each had done his part. This he obſerves to have ſeen practiſed in his time; agreeable to the method of the Romans, who, in their ſtipulations, uſed to break a ſtaff, each party retaining a moiety thereof as a mark.

CHARTOPHYLAX, the name of an officer of the church of Conſtantinople, who attends at the door of the rails when the ſacrament is adminiſtered, and gives notice to the prieſts to come to the holy table. He repreſents the patriarch upon the bench, tries all eccleſiaſtical cauſes, keeps all the marriage regiſters, aſſiſts at the conſecration of biſhops, and preſents the biſhop elect at the ſolemnity, and likewiſe all other ſubordinate clergy. This office reſembles in ſome ſhape that of the *bibliothecarius* at Rome.

CHARTRES, a large city of France, in the province of Orleanois, ſituated on the river Eure, in E. Long. 1. 32. N. Lat. 48. 47. It is a biſhop's ſee.

CHARTREUSE, or CHARTREUSE-GRAND, a celebrated monaſtery, the capital of all the convents of the Carthuſian monks, ſituated on a ſteep rock in the middle of a large foreſt of fir-trees, about ſeven miles north-eaſt of Grenoble, in the province of Dauphine in France: E. Long. 5. 5. N. Lat. 45. 20. See CARTHUSIANS.

From this mother-convent, all the others of the ſame order take their name; among which was the Chartreuſe of London, corruptly called the charterhouſe, now converted into an hoſpital, and endowed with a revenue of 600l. *per ann.*

Here are maintained 80 decayed gentlemen, not under 50 years of age: alſo forty boys are educated and fitted either for the univerſity or trades. Thoſe ſent to the univerſity, have an exhibition of 20l. a year for eight years; and have an immediate title to nine church-livings in the gift of the governors of the hoſpital, who are ſixteen in number, all perſons of the firſt diſtinction, and take their turns in the nomination of penſioners and ſcholars.

CHARTULARY, CHARTULARIUS, a title given to an ancient officer in the Latin church, who had the care of charters and papers relating to public affairs. The chartulary preſided in eccleſiaſtical judgments, in lieu of the pope. In the Greek church the chartulary was called *chartophylax*; but his office was there much more conſiderable; and ſome even diſtinguiſh the chartulary from the chartophylax in the Greek church. See CHARTOPHYLAX.

CHARYBDIS, (anc. geog.) a whirlpool in the ſtraits of Meſſina, according to the poets; near Sicily, and oppoſite to Scylla, a rock on the coaſt of Italy. Thucydides makes it to be only a ſtrong flux and reflux in the ſtrait, or a violent reciprocation of the tide, eſpecially if the wind ſets ſouth. But on diving into the Charybdis, there are found vaſt gulphs and whirlpools below, which produce all the commotion on the ſurface of the water.

Charybdis is uſed by Horace to denote a rapacious proſtitute.

CHASE, or CHACE, in law, is uſed for a driving of cattle to or from any place; as to a diſtreſs, or fort-let, *&c.*

CHASE, or *Chace*, is alſo a place of retreat for deer and wild beaſts; of a middle kind between a foreſt and a park, being uſually leſs than a foreſt, and not poſſeſſed of ſo many privileges; but wanting, *v. g.* courts of attachment, ſwainmote, and juſtice-ſeat.* Yet it is of a large extent, and ſtocked both with a greater diverſity of wild beaſts or game, and more keepers than a park. Crompton obſerves, that a foreſt cannot be in the hands of a ſubject, but it forthwith loſes its name, and becomes a *chaſe*; in regard all thoſe courts loſe their nature when they come into the hands of a ſubject; and that none but a king can make a lord chief juſtice in eyre of the foreſt. See JUSTICE *in Eyre*.

* See *Foreſt*.

“When our barons began to form a power, they claimed a vaſt, but more limited, tract for a diverſion that the Engliſh were always fond of. They were very jealous of any encroachments on their reſpective bounds, which were often the cauſe of deadly feuds: ſuch a one gave cauſe to the fatal day of *Chevy-chace*; a fact which, though recorded only in a ballad, may, from what we know of the manners of the times, be founded on truth: not that it was attended with all the circumſtances which the author of that natural but heroic compoſition hath given it; for, on that day, neither a *Percy* nor a *Douglas* fell: here the poet ſeems to have claimed his privilege, and mixed with this fray ſome of the events of the battle of *Otterbourne*.”

Britiſh Zool. i. 42.

CHASE, in the ſea-language, is to purſue a ſhip; which is alſo called *giving chaſe*.

Stern CHASE, is when the chaſer follows the chaſed aſtern directly upon the ſame point of the compaſs.

To lie with a ſhip's fore-foot in a CHASE, is to ſail and meet with her by the neareſt diſtance; and ſo to croſs her in her way, or to come acroſs her fore-foot.

A ſhip is ſaid to have a *good chaſe*, when ſhe is ſo built foreward on, or a-ſtern, that ſhe can carry many guns to ſhoot forwards or backwards; according to which ſhe is ſaid to have a *good foreward*, or *good ſtern chaſe*.

CHASE-Guns, are ſuch whoſe ports are either in the head (and then they are uſed in chaſing of others); or in the ſtern, which are only uſeful when they are purſued or chaſed by any other ſhip.

CHASE of a Gun, is the whole bore or length of a piece taken within-ſide.

Wild-gooſe CHACE, a term uſed to expreſs a ſort of racing on horſeback uſed formerly, which reſembled the flying of wild-geeſe; thoſe birds generally going in a train one after another, not in confuſed flocks as other birds do. In this ſort of race the two horſes, after running twelve ſcore yards, had liberty, which horſe ſoever could take the leading, to ride what ground the jockey pleaſed, the hindmoſt horſe being bound to follow him within a certain diſtance agreed on by the articles, or elſe to be whipped in by the tryers and judges who rode by; and whichever horſe could diſtance the other, won the race. This ſort of racing was not long in common uſe; for it was found inhuman, and deſtructive to good horſes, when two ſuch were matched together. For in this caſe neither was able to diſtance the other till they were both ready to ſink under their riders; and often two very good horſes were both ſpoiled, and the wagers forced to be drawn at laſt. The miſchief of this ſort of racing ſoon brought in the method now in uſe, of running only for a certain quantity of ground, and determining the plate or wager by the coming in firſt at the poſt.

CHASING of Gold, Silver, &c. See ENCHASING.

CHASTE-TREE. See Vitex.

CHASTITY; purity of the body, or freedom from obſcenity.—The Roman law juſtifies homicide in defence of the chaſtity either of one's ſelf or relations; and ſo alſo, according to Selden, ſtood the law in the Jewiſh republic. Our law likewiſe juſtifies a woman for killing a man who attempts to raviſh her. So the huſband or father may juſtify killing a man who attempts a rape upon his wife or daughter; but not if he takes them in adultery by conſent: for the one is forcible and felonious, but not the other.

Chaſtity is a virtue univerſally celebrated. There is indeed no charm in the female ſex that can ſupply its place. Without it, beauty is unlovely, and rank is contemptible; good breeding degenerates into wantonneſs, and wit into impudence. Out of the numerous inſtances of eminent chaſtity recorded by authors, the two following are ſelected on account of the leſſon afforded by the different modes of conduct which they exhibit.

Lucretia was a lady of great beauty and noble extraction: ſhe married Collatinus, a relation of Tarquinius Superbus, king of Rome. During the ſiege of Ardea, which laſted much longer than was expected, the young princes paſſed their time in entertainments and diverſions. One day as they were at ſupper,* at Sextus Tarquin's the king's eldeſt ſon, with Collatinus, Lucretia's huſband, the converſation turned to the merit of their wives: every one gave his own the preference. "What ſignify ſo many words?" ſays Collatinus; "you may in a few hours, if you pleaſe, be convinced by your own eyes, how much my Lucretia excels the reſt. We are young: let us mount our horſes, and go and ſurpriſe them. Nothing can better decide our diſpute than the ſtate we ſhall find them in at a time when moſt certainly they will not expect us." They were a little warmed with wine: "Come on, let us go," they all cried together. They quickly galloped to Rome, which was about twenty miles from Ardea, where they find the princeſſes, wives of the young Tarquins, ſurrounded with company, and every circumſtance of the higheſt mirth and pleaſure. From thence they rode to Collatia, where they ſaw Lucretia in a very different ſituation. With her maids about her, ſhe was at work in the inner part of her houſe, talking on the dangers to which her huſband was expoſed. The victory was adjudged to her unanimouſly. She received her gueſts with all poſſible politeneſs and civility. Lucretia's virtue, which ſhould have commanded reſpect, was the very thing which kindled in the breaſt of Sextus Tarquin a ſtrong and deteſtable paſſion. Within a few days he returned to Collatia; and upon the plauſible excuſe he made for his viſit, he was received with all the politeneſs due to a near relation, and the eldeſt ſon of a king. Watching the fitteſt opportunity, he declares the paſſion ſhe had excited at his laſt viſit, and employed the moſt tender entreaties, and all the artifices poſſible, to touch a woman's heart; but all to no purpoſe. He then endeavoured to extort her compliance by the moſt terrible threatenings. It was in vain. She ſtill perſiſted in her reſolution; nor could ſhe be moved, even by the fear of death. But when the monſter told her that he would firſt diſpatch her, and then having murdered a ſlave, would lay him by her ſide, after which he would ſpread a report, that having caught them in the act of adultery, he had puniſhed them as they deſerved; this ſeemed to ſhake her reſolution. She heſitated, not knowing which of theſe dreadful alternatives to take, whether, by conſenting, to diſhonour the bed of her huſband, whom ſhe tenderly loved; or, by refuſing, to die under the odious character of having proſtituted her perſon to the luſt of a ſlave. He ſaw the ſtruggle of her ſoul; and ſeized the unlucky moment, obtained an inglorious conqueſt. Thus Lucretia's virtue, which had been proof againſt the fear of death, could not hold out againſt the fear of infamy. The young prince, having gratified his paſſion, returned home as in triumph. On the morrow, Lucretia, overwhelmed with grief and deſpair, ſent early in the morning to deſire her father and her huſband to come to her, and bring with them each a truſty friend, aſſuring them there was no time to loſe. They came with all ſpeed, the one accompanied with Valerius (ſo famous after under the name of Publicola), and the other with Brutus. The moment ſhe ſaw them come, ſhe could not command her tears; and when her huſband aſked her if all was well? "By no means," ſaid ſhe, "it cannot be well with a woman after ſhe has loſt her honour. Yes, Collatinus, thy bed has been defiled by a ſtranger: but my body only is polluted; my mind is innocent, as my death ſhall witneſs. Promiſe me only not to ſuffer the adulterer to go unpuniſhed: it is Sextus Tarquinius, who laſt night, treacherous gueſt, or rather cruel foe, offered me violence, and reaped a joy fatal to me; but, if you are men, it will be ſtill more fatal to him." All promiſed to revenge her; and, at the ſame time, tried to comfort her with repreſenting, "That the mind only ſins, not the body; and where the conſent is wanting, there can be no guilt." "What Sextus deſerves," replies Lucretia, "I leave you to judge; but for me, though I declare myſelf innocent of the crime, I exempt not myſelf from puniſhment. No immodeſt woman ſhall plead Lucretia's example to outlive her diſhonour." Thus ſaying, ſhe plunged into her breaſt a dagger ſhe had concealed under her robe, and expired at their feet. Lucretia's tragical death has been praiſed and extolled by Pagan writers, as the higheſt and moſt noble act of heroiſm. The goſpel thinks not ſo: it is murder, even according to Lucretia's own principles, ſince ſhe puniſhed with death an innocent perſon, at leaſt acknowledged as ſuch by herſelf. She was ignorant that our life is not in our own power, but in his diſpoſal from whom we receive it. St Auſtin, who carefully examines, in his book *De Civitate Dei*, what we are to think of Lucretia's death, conſiders it not as a courageous action, flowing from

* *Liv.* l. i. c. 56—60. *Dionyſ.* l. iv. p. 261—277. *Flor.* l. iii. 9.

a true love of chaſtity, but as an infirmity of a woman too ſenſible of worldly fame and glory; and who, from a dread of appearing in the eyes of men an accomplice of the violence ſhe abhorred, and of a crime to which ſhe was entirely a ſtranger, commits a real crime upon herſelf voluntarily and deſignedly. But what cannot be ſufficienly admired in this Roman lady is her abhorrence of adultery, which ſhe ſeems to hold ſo deteſtable as not to bear the thoughts of it. In this ſenſe, ſhe is a noble example for all her ſex.

Chiomara, the wife of Ortiagon, a Gauliſh prince, was equally admirable for her beauty and chaſtity. During the war between the Romans and the Gauls, A. R. 563, the latter were totally defeated on Mount Olympus. Chiomara, among many other ladies, was taken priſoner, and committed to the care of a centurion, no leſs paſſionate for money than women. He, at firſt, endeavoured to gain her conſent to his infamous deſires; but not being able to prevail upon her, and ſubvert her conſtancy, he thought he might employ force with a woman whom misfortune had reduced to ſlavery. Afterwards, to make her amends for that treatment, he offered to reſtore her liberty; but not without ranſom. He agreed with her for a certain ſum, and to conceal this deſign from the other Romans, he permitted her to ſend any of the priſoners ſhe ſhould choſe to her relations, and aſſigned a place near the river where the lady ſhould be exchanged for gold. By accident there was one of her own ſlaves amongſt the priſoners. Upon him ſhe fixed; and the centurion ſoon after carried her beyond the advanced poſts, under cover of a dark night. The next evening two of the relations of the princeſs came to the place appointed, whether the centurion alſo carried his captive. When they had delivered him the Attic talent they had brought, which was the ſum they had agreed on, the lady, in her own language, ordered thoſe who came to receive her to draw their ſwords and kill the centurion, who was then amuſing himſelf with weighing the gold. Then, charmed with having revenged the injury done her chaſtity, ſhe took the head of the officer, which ſhe had cut off with her own hands, and hiding it under her robe, went to her huſband Ortiagon, who had returned home after the defeat of his troops. As ſoon as ſhe came into his preſence, ſhe threw the centurion's head at his feet. He was ſtrangely ſurpriſed at ſuch a ſight; and aſked her whoſe head it was, and what had induced her to do an act ſo uncommon to her ſex? With a face covered with a ſudden bluſh, and at the ſame time expreſſing her fierce indignation, ſhe declared the outrage which had been done her, and the revenge ſhe had taken for it. During the reſt of her life, ſhe ſtedfaſtly retained the ſame attachment for the purity of manners which conſtitutes the principal glory of the ſex, and nobly ſuſtained the honour of ſo glorious, bold, and heroic an action.—This lady was much more prudent than Lucretia, in revenging her injured honour by the death of her raviſher, rather than by her own. Plutarch relates this fact, in his treatiſe upon the virtue and great actions of women; and it is from him we have the name of this, which is well worthy of being tranſmitted to poſterity.

The above virtue in men is termed *continence*. See CONTINENCE.

CHATEAU-BRIANT, a town of France in Brittany, with an old caſtle. W. Long. 1. 20. N. Lat. 47. 40.

CHATEAU-Chinon, a town of France in Nivernois, and capital of Morvant, with a conſiderable manufacture of cloth. E. Long. 3. 48. N. Lat. 47. 2.

CHATEAU-Dauphin, a very ſtrong caſtle of Piedmont in Italy, and in the marquiſate of Saluces, belonging to the king of Sardinia. It was taken by the combined army of France and Spain in 1744, and was reſtored by the treaty of Aix-la-Chapelle.

CHATEAU-du-Loir, a town of France in the Maine, famous for ſuſtaining a ſiege of ſeven years againſt the Count of Mans. It is ſeated on the river Loir, in E. Long. 0. 25. N. Lat. 47. 40.

CHATEAU-Dun, an ancient town of France, and capital of the Dunois, with a caſtle and rich monaſtery; ſeated on an eminence near the river Loir, in E. Long 1. 26. N. Lat. 48. 4.

CHATEAU-Neuf, the name of ſeveral towns of France, *viz.* one in Perche; another in Angumois, on the river Charente, near Anguoſeline; a third in Berry, ſeated on the river Cher; and ſeveral other ſmall places.

CHATEAU-Portien, a town of France, in Champagne, and in a diſtrict called Portien, with a caſtle built on a rock, near the river Aine. E. Long. 4. 23. N. Lat. 49. 35.

CHATEAU-Renaud, a town of France, in the Gatenois, where clothes are made for the army, and where there is a trade in ſaffron. E. Long. 2. 25. N. Lat. 48. 0. This is alſo the name of a town of Touraine, in France, with the title of a marquiſate. E. Long. 2. 41. N. Lat. 47. 22.

CHATEAU-Roux, a town of France, in Berry, with the title of a duchy. It has a cloth-manufacture, and is ſeated in a very large pleaſant plain on the river Indre. in E. Long. 1. 47. N. Lat. 46. 49.

CHATEAU-Thierra, a town of France, in Champagne, with the title of a duchy, and a handſome caſtle on an eminence, ſeated on the river Maine, in E. Long. 3. 23. N. Lat. 49. 12.

CHATEAU-Vilain, a town of France, in Champagne, with a caſtle, and the title of a duchy; ſeated on the river Anjou. E. Long. 2. 59. N. Lat. 48. 0.

CHATEL, or CHATE, a town of Lorrain, in the Voſque, ſeated on the river Moſelle, eight miles from Mirecourt.

CHATEL-Aillon, a maritime town of France, in Saintonge, five miles from Rochelle; formerly very conſiderable, but is now greatly decayed.

CHATEL-Chalon, a town of France, in Franche Compte, remarkable for its abbey of benedictine nuns. E. Long. 5. 25. N. Lat. 46. 50.

CHATELET, a town of the Netherlands, in Namur, ſeated on the Sambre, in the biſhopric of Leige. E. Long. 4. 28. N. Lat. 50. 25.

CHATELET, the name of certain courts of juſtice eſtabliſhed in ſeveral cities in France. The grand chatelet at Paris is the place where the preſidial or ordinary court of juſtice of the provoſt of Paris is kept; conſiſting of a preſidial, a civil chamber, a criminal chamber, and a chamber of policy. The little chatelet is an old fort, now ſerving as a priſon.

CHATELLERAULT, a town of France, in Poitou, ton, with the title of a duchy; ſeated in a fertile and pleaſant country, on the river Vienne, over which there is a handſome ſtone-bridge. E. Long. 0. 40. N. Lat. 46. 34.

CHATHAM, a town of Kent, in England, adjoining to Rocheſter, and ſeated on the river Medway. It is the principal ſtation of the royal navy; and the yards and magazines are furniſhed with all kinds of naval ſtores, as well as materials for building and rigging the largeſt men of war. The entrance into the river Medway is defended by Sheerneſs and other forts; notwithſtanding which, the Dutch fleet burnt ſeveral ſhips of war here in the reign of Charles II. after the peace of Breda had been agreed upon. In the year 1757, by direction of the Duke of Cumberland, ſeveral additional fortifications were begun at Chatham; ſo that now the ſhips are in no danger of an inſult either by land or water. It has a church, a chapel of eaſe, and a ſhip uſed as a church for the ſailors. It has likewiſe about 500 houſes, moſtly low, and built with brick; the ſtreets are narrow, and paved; and it contains about 3000 inhabitants. The principal employment of the labouring hands is ſhip-building in the king's yard and private docks. This town gave title of Earl to that great ſtateſman William Pitt in the reigns of George II. and III. E. Long. 0. 40. N. Lat. 51. 20.

CHATIGAN, a town of Aſia, in the kingdom of Bengal, on the moſt eaſterly branch of the river Ganges. It is but a poor place, though it was the firſt the Portugueſe ſettled at in theſe parts, and who ſtill keep a ſort of poſſeſſion. It has but a few cotton manufactures; but affords the beſt timber for building of any place about it. The inhabitants are ſo ſuſpicious of each other, that they always go armed with a ſword, piſtol, and blunderbuſs, not excepting the prieſts. It is ſubject to the great Mogul. E. Long. 91. 10. N. Lat. 23. 0.

CHATILLON-SUR-SEINE, a town of France, in Burgundy, divided into two by the river Seine. It is 32 miles from Langres, and 40 from Dijon; and has iron works in its neigbourhood. E. Long. 4. 33. N. Lat. 47. 45.

CHATRE, a town of France, in Berry, ſeated on the river Indres, 37 miles from Bourges. It carries on a conſiderable trade in cattle. E. Long. 1. 55. N. Lat. 46. 35.

CHATTELS, a Norman term, under which were anciently comprehended all moveable goods; thoſe immoveable being termed *fief*, or *fee*.

CHATTELS, in the modern ſenſe of the word, are all ſorts of goods, moveable or immoveable, except ſuch as are in the nature of freehold.

CHATTERER, in ornithology. See AMPELIS.

CHATTERTON, (Thomas) a late unfortunate poet, whoſe fate and performances have excited in no ſmall degree the public attention, as well as given riſe to much literary controverſy. He was born at Briſtol, Nov. 20, 1752; and educated at a charity-ſchool on St Auguſtin's Back, where nothing more was taught than reading, writing, and accounts. At 14 years of age, he was articled clerk to an attorney at Briſtol, with whom he continued about three years; yet, though his education was thus confined, he diſcovered an early turn towards poetry and Engliſh antiquities, and particularly towards heraldry. How ſoon he began to be an author is not known. In the Town and Country Magazine for March 1769, are two letters, probably from him, as they are dated from Briſtol, and ſubſcribed with his uſually ſignature, D. B. that is, *Dunhelmus Briſtolienſis*. The former contains ſhort extracts from two MSS. "written 300 years ago by one Rowley a monk," concerning dreſs in the age of Henry II.; the latter, "Ethelgar, a Saxon poem," in bombaſt proſe. In the ſame magazine for May 1769, are three communications from Briſtol, with the ſame ſignature D. B. one of them intitled "Obſervations upon Saxon Heraldry,' with drawings of Saxon Atchievements;" and in the ſubſequent months of 1769 and 1770, there are ſeveral other pieces in the ſame magazine, which are undoubtedly of his compoſition.

In April 1770, he left Briſtol, diſguſted with his profeſſion, and irreconcileable to the line of life in which he was placed; and going to London in hopes of advancing his fortune by his pen, he ſunk at once from the ſublimity of his views to an abſolute dependence on the patronage of bookſellers. Things, however, ſeem ſoon to have brightened up a little with him; for, May 14, he writes to his mother, in high ſpirits, upon the change of his ſituation, with the following ſarcaſtic reflection upon his former patrons at Briſtol. "As to Mr ——, Mr ——, Mr ——, &c. &c. they rate literary lumber ſo low, that I believe an author, in their eſtimation, muſt be poor indeed, but here matters are otherwiſe. Had Rowley been a Londoner inſtead of a Briſtowyan, I could have lived by copying his works." In a letter to his ſiſter, May 30, he informs her that he is to be employed in writing a voluminous Hiſtory of London, to appear in numbers the beginning of next winter. Meanwhile, he had written ſomething in praiſe of Beckford, then lord mayor, which had procured him the honour of being preſented to his lordſhip; and, in the letter juſt mentioned, he gives the following account of his reception, with certain obſervations upon political writing. "The lord mayor received me as politely as a citizen could: but the devil of the matter is, there is no money to be got on this ſide of the queſtion.—However, he is a poor author who cannot write on both ſides.—Eſſays on the patriotic ſide will fetch no more than what the copy is ſold for. As the patriots themſelves are ſearching for places, they have no gratuity to ſpare.—On the other hand, unpopular eſſays will not even be accepted, and you muſt pay to have them printed: but then you ſeldom loſe by it, as courtiers are ſo ſenſible of their deficiency in merit, that they generouſly reward all who know how to daub them with the appearance of it."

He continued to write inceſſantly in various periodical publications. July 11th, he tells his ſiſter that he had pieces laſt month in ſeveral magazines; in The Goſpel Magazine, The Town and country, The Court and City, The London, The Political Regiſter, &c. But all theſe exertions of his genius brought in ſo little profit, that he was ſoon reduced to the extremeſt indigence; ſo that at laſt, oppreſſed with poverty and alſo diſeaſe, in a fit of deſpair he put an end to his exiſtence, Aug. 1770, with a doſe of poiſon. This unfortunate perſon, though certainly a moſt extraordinary genius, ſeems yet to have been a moſt ungracious compoſition. He was violent and impetuous to a ſtrange degree. From the firſt of the above-cited letters, he ſeems to have had a portion of ill-humour and ſpleen more than enough for a lad of 17; and the editor of his Miſcellanies records, “that he poſſeſſed all the vices and irregularities of youth, and that his profligacy was at leaſt as conſpicuous as his abilities.”

In 1777 were publiſhed, in one volume 8vo, “Poems, ſuppoſed to have been written at Briſtol, by Thomas Rowley and others, in the 15th century: the greateſt part now firſt publiſhed from the moſt authentic copies, with an engraved ſpecimen of one of the MSS. To which are added, a Preface, an introductory Account of the ſeveral Pieces, and a Gloſſary.” And, in 1778, were publiſhed, in one volume 8vo, “Miſcellanies in Proſe and Verſe, by Thomas Chatterton, the ſuppoſed author of the Poems publiſhed under the names of Rowley, &c.”

Of Rowely's Poems, we have the following account in the preface, given in the words of Mr George Catcot of Briſtol, to whom, it is ſaid, the public is indebted for them. “The firſt diſcovery of certain MSS. having been depoſited in Redclift church above three centuries ago, was made in the year 1768, at the time of opening the new bridge at Briſtol; and was owing to a publication in Farley's Weekly Journal, Oct. 1ſt, containing an account of the ceremonies obſerved at the opening of the old bridge, taken, as it was ſaid, from a very ancient MS. This excited the curioſity of ſome perſons to enquire after the original. The printer, Mr Farley, could give no account of it, or of the perſon who brought the copy; but after much inquiry it was diſcovered, that this perſon was a youth between 15 and 16 years of age, whoſe name was Thomas Chatterton, and whoſe family had been ſextons of Redclift church for near 150 years. His father, who was now dead, had alſo been maſter of the free-ſchool in Pile-ſtreet. The young man was at firſt very unwilling to diſcover from whence he had the original: but, after many promiſes made to him, was at laſt prevailed on to acknowledge that he had received this, together with many other MSS. from his father, who had found them in a large cheſt in an upper room over the chapel, on the north ſide of Redclift church.” It is added, that ſoon after this Mr Catcot commenced an acquaintance with Chatterton, and partly as preſents, partly as purchaſes, procured from him copies of many of his MSS. in proſe and verſe; as other copies were diſpoſed of in like manner to others. It is concluded, however, that whatever may have been Chatterton's part in this very extraordinary tranſaction, whether he was the author, or only (as he conſtantly aſſerted) the copier of all theſe productions, he appears to have kept the ſecret entirely himſelf, and not to have put it in any one's power to bear certain teſtimony either of his fraud or of his veracity.

This affair, however, hath ſince become the foundation of a mighty controverſy among the critics, which hath yet ſcarcely ſubſided. The poems in queſtion, publiſhed in 1777, were republiſhed in 1778, with an “Appendix, containing ſome obſervations upon their language; tending to prove that they were written, not by any ancient author, but entirely by Chatterton.” Mr Warton, in the third volume of his Hiſtory of Engliſh poetry, hath eſpouſed the ſame ſide of the queſtion. Mr Walpole alſo obliged the world with a Letter on Chatterton, from his preſs at ſtrawberry-hill. On the other hand have appeared, “Obſervations” upon theſe poems, “in which their authenticity is aſcertained,” by Jacob Bryant, Eſq. 1781, 2 vols 8vo; and another edition of the “Poems, with a comment, in which their Antiquity is conſidered and defended, by Jeremiah Milles, D. D. Dean of Exeter, 1782,” 4to. In anſwer to theſe two works, we have had three pamphlets: 1. “Curſory Obſervations on the Poems, and Remarks on the Commentaries of Mr Bryant and Dr Milles; with a ſalutary propoſal addreſſed to the friends of thoſe gentlemen.” 2. “An Archæological Epiſtle to Dean Milles, editor of a ſuperb edition of Rowley's Poems, &c.” 3. “An Inquiry into the Authenticity of the Poems attributed to Thomas Rowley, in which the Arguments of the Dean of Exeter and Mr Bryant are examined, by Thomas Warton; and other pieces in the public prints and magazines: All preparatory to the complete ſettlement of the buſineſs in “A Vindication of the Appendix to the Poems called Rowley's, in reply to the Anſwers of the Dean of Exeter, by Jacob Bryant, Eſq; and a third Anonymous Writer; with ſome further Obſervations upon thoſe Poems, and an Examination of the Evidence which has been produced in ſupport of their Authenticity. By Thomas Tyrwhitt, 1782,” 8vo.

CHAUCER, (Sir Geofrey) an eminent Engliſh poet in the 14th century, born at London in 1328. After he left the univerſity, he travelled into Holland, France, and other countries. Upon his return he entered himſelf in the Inner-temple, where he ſtudied the municipal laws of England. His firſt ſtation at court was page to Edward III. and he had a penſion granted him by that prince till he could otherwiſe provide for him. Soon after we find him gentleman of the king's privy chamber; next year, ſhield-bearer to the king. Eſteemed and honoured, he ſpent his younger days in a conſtant attendance at court, or for the moſt part living near it, in a ſquare ſtone-houſe near the park-gate at Woodſtock, ſtill called *Chaucer's Houſe*.

Soon after, having got the Duke of Lancaſter for his patron, Chaucer began every day to riſe in greatneſs. In 1373, he was ſent, with other perſons, to the republic of Genoa to hire ſhips for the king's navy (their want of ſhipping in thoſe times being uſually ſupplied by ſuch means); and the king was ſo well ſatisfied with his negociation, that, on his return, he obtained a grant of a pitcher of wine daily in the port of London, to be delivered by the butler of England; and ſoon after was made comptroller of the cuſtoms for wool, wool-fells, and hides; an office which he diſcharged with great diligence and integrity. At this period, Chaucer's income was about L. 1000 a-year; a ſum which in thoſe days might well enable him to live, as he ſays he did, with dignity in office, and hoſpitality among his friends. It was in this meridian blaze of proſperity, in perfect health of body and peace of mind, that he wrote his moſt humorous poems. His ſatires againſt the prieſts were probably written to oblige his patron the Duke of Lancaſter, who favoured the cauſe of Wickliff, and endeavoured to expoſe the clergy to the indignation of the people. In the laſt year of Edward III. our poet was employed in a commiſſion to treat with the French ; and in the beginning of King Richard's reign, he was in ſome degree of favour at court.

The Duke of Lancaſter at laſt finding his views checked, began to abandon Wickliff's party : upon which Chaucer likewiſe, how much ſoever he had eſpouſed that divine's opinions, thought it prudent to conceal them more than he had done. With the Duke's intereſt that of Chaucer entirely ſunk ; and the former paſſing over ſea, his friends felt all the malice of the oppoſite party. Theſe misfortunes occaſioned his writing that excellent treatiſe *The Teſtament of Love*, in imitation of Boethius on the conſolation of philoſophy. Being much reduced he retired to Woodſtock, to comfort himſelf with ſtudy, which produced his admirable treatiſe of the *Aſtrolabe*.

The Duke of Lancaſter at laſt ſurmounting his troubles, married Lady Catherine Swynford, ſiſter to Chaucer's wife ; ſo that Thomas Chaucer, our poet's ſon, became allied to moſt of the nobility, and to ſeveral of the king's of England. Now the ſun began to ſhine upon Chaucer with an evening ray ; for by the influence of the Duke's marriage, he again grew to a conſiderable ſhare of wealth. But being now 70, he retired to Dunnington-caſtle near Newbury. He had not enjoyed this retirement long before Henry IV. ſon of the Duke of Lancaſter, aſſumed the crown, and in the firſt year of his reign gave our poet marks of his favour. But however pleaſing the change of affairs might be to him at firſt, he afterwards found no ſmall inconveniences from it. The meaſures and grants of the late king were annulled ; and Chaucer, in order to procure freſh grants of his penſions, left his retirement, and applied to court, where, though he gained a confirmation of ſome grants, yet the fatigue of attendence, and his great age, prevented him from enjoying them. He fell ſick at London ; and ended his days in the 72d year of his age, leaving the world as though he deſpiſed it, as appears from his ſong of *Flie from the Preſe*. The year before his death he had the happineſs, if at his time of life it might be ſo called, to ſee the ſon of his brother-in-law (Hen. IV.) ſeated on the throne. He was interred in Weſtminſter abbey ; and in 1556, Mr Nicholas Bingham, a gentleman of Oxford, at his own charge, erected a handſome monument for him there. Caxton firſt printed the Canterbury Tales ; but his works were firſt collected and publiſhed in one volume folio, by William Thynne, London, 1542. They were afterwards reprinted in 1561, 1598, 1602. Oxford, 1721.

Chaucer was not only the firſt, but one of the beſt poets which Britain ever produced. He was equally great in every ſpecies of poetry which he attempted ; and his poems in general poſſeſs every kind of excellence, even to a modern reader, except melody and accuracy of meaſure ; defects which are to be attributed to the imperfect ſtate of the Engliſh language, and the infancy of the art in that kingdom at the time when he wrote. "As he is the father of Engliſh poetry (ſays Mr Dryden), ſo I hold him in the ſame degree of veneration as the Grecians held Homer, or the Romans Virgil. He is a perpetual fountain of good ſenſe, learned in all ſciences, and therefore ſpeaks properly on all ſubjects. As he knew what to ſay, ſo he knows alſo when to leave off ; a continence which is practiſed by few writers, and ſcarcely by any of the ancients, except Virgil and Horace." This character Chaucer certainly deſerved. He had read a great deal ; and was a man of the world, and of ſound judgment. He was the firſt Engliſh poet who wrote *poetically*, as Dr Johnſon obſerves in his preface to his Dictionary, and (he might have added) who wrote like a gentleman. He had alſo the merit of improving the language conſiderably, by the introduction and naturalization of words from the Provençal, at that time the moſt poliſhed dialect in Europe.

CHAUCIS, (anc. geog.) the country of the Chauci, a people of Germany : divided into the *Minores*, now *Eaſt Frieſeland* and the county of *Oldenburg* ; and into the *Majores*, now the duchy of *Bremen* and a part of *Lunenburg*.

CHAUD-MEDLEY, in law, is of much the ſame import with *CHANCE-Medley*. The former in its etymology ſignifies an affray in the heat of blood or paſſion ; the latter, a caſual affray. The latter is in common ſpeech too often erroneouſly applied to any manner of homicide by miſadventure ; whereas it appears by the ſtat. 24 Hen. VIII. c. 5. and ancient books (Staundf. P. C. 16.), that it is properly applied to ſuch killing as happens in ſelf-defence upon ſudden encounter.

CHAL, a town of the Eaſt Indies, on the coaſt of Malabar, in the province of Blagana, and kingdom of Viſapour. Its river affords a good harbour for ſmall veſſels. The town is fortified, and ſo is the iſland on the ſouth ſide of the harbour. It had formerly a good trade, but is now miſerably poor. It was taken by the Portugueſe in 1507, to whom it ſtill belongs. It is 15 miles ſouth of Bombay, and five miles from the ſea. E. Long. 72. 45. N. Lat. 18. 30.

CHAULIEU, (William Amfry de) abbé d'Amale, one of the moſt polite and ingenious of the French poets, was born in 1639, and died at the age of 84. The moſt complete edition of his poems is that printed in 2 vols 8vo in 1733.

CHAUMONT, a town of France, in Champagne, and in the diſtrict of Baſſigni, of which it is the capital. It is ſeated on a mountain near the river Marne. E. Long. 5. 15. N. Lat. 48. 6.

CHAUNE, a town of France, in Picardy, and in the diſtrict of Sanſterre, with the title of a duchy. E. Long. 2. 55. N. Lat. 49. 45.

CHAUNTRY See CHANTRY.

CHAUNY, a town of France, in Picardy, ſeated on the river Oiſe, in Chantry. E. Long. 3. 17. N. Lat. 49. 37.

CHAUVIN, (Stephen) a celebrated miniſter of the reformed religion, born at Niſmes, left France at the revocation of the edict of Nantz, and retired to Rotterdam, where he began a new *Journal des Sçavans* ; and afterwards removing to Berlin, continued it there three years. At this laſt place, he was made profeſſor of philoſophy, and diſcharged that office with much honour and reputation. His principal work is a philoſophical dictionary, in Latin, which he publiſhed at Rotterdam in 1692 ; and gave a new edition of it much augmented, at Lewarden, in 1713, folio. He died in 1725, aged 85.

CHAVEZ, a ſtrong town of Tralos-Montes in Portugal, is ſeated at the foot of a mountain on the river Tamega. It has two ſuburbs, and as many forts ;

one of which looks like a citadel. Between the town and ſuburb of Magdalena, is an old Roman ſtone-bridge about 92 geometrical paces long. W. Long. 7. 1. N. L. 41. 45.

CHAZELLES, (John Matthew) a celebrated French mathematician and engineer, was born at Lyons in 1657. M. du Hamel, with whom he got acquainted, finding his genius incline towards aſtronomy, preſented him to M. Caſſini, who employed him in his obſervatory. In 1684, the Duke of Mortemar made uſe of Chazelles to teach him mathematics; and, the year after, procured him the preferment of hydrography profeſſor for the galleys of Marſeilles, where he ſet up a ſchool for young pilots deſigned to ſerve aboard the galleys. In 1686, the galleys made four little campaigns, or rather four courſes, purely for exerciſe, Chazelles went on board every time with them; kept his ſchool upon the ſea, and ſhowed the practice of what he taught. In the year 1687 and 1688, he made two other ſea-campaigns, in which he drew a great many plans of ports, roads, towns, and forts, which were lodged with the miniſters of ſtate. At the beginning of the war, which ended with the peace of Ryſwick, ſome marine officers, and Chazelles among the reſt, fancied the galleys might be ſo contrived as to live upon the ocean; that they might ſerve to tow the men of war when the wind failed or proved contrary, and alſo help to ſecure the coaſt of France upon the ocean. Chazelles was ſent to the weſt coaſts in July 1689, to examine the practicableneſs of this ſcheme; and in 1690, fifteen galleys new built ſet ſail from Rochefort, and cruiſed as far as Torbay in England, and proved ſerviceable at the deſcent upon Tinmouth. After this, he digeſted into order the obſervations he had made on the coaſts of the ocean; and drew diſtinct maps with a portulan to them, *viz.* a large deſcription of every haven, of the depth, the tides, the dangers and advantages diſcovered, &c. Theſe maps were inſerted in the *Neptune Françoiſe*, publiſhed in 1692, in which year Chazelles was engineer at the deſcent at Oneille. In 1693, Monſieur de Pontchartrain, then ſecretary of ſtate for the marine, and afterwards chancellor of France, reſolved to get the *Neptune Françoiſe* carried on to a ſecond volume, which was alſo to take in the Mediterranean. Chazelles deſired that he might have a year's voyage on this ſea, for making aſtronomical obſervations; and the requeſt being granted, he paſſed by Greece, Egypt, and the other parts of Turkey, with his quadrant and teleſcope in his hand. When he was in Egypt he meaſured the pyramids; and finding the ſides of the largeſt preciſely facing the four cardinal points, naturally concluded this poſition to have been intended, and alſo that the poles of the earth and meridians had not ſince deviated. Chazelles likewiſe made a report of his voyage in the Levant, and gave the academy all the ſatisfaction they wanted concerning the poſition of Alexandria: upon which he was made a member of the academy in 1695. He died in 1710.

CHAZINZARIANS, a ſect of heretics who roſe in Armenia in the ſeventh century. The word is formed of the Armenian *chazus*, "croſs," They are alſo called *ſtaurolatræ*, which in Greek ſignifies the ſame as *Chazinzarians* in Armenian, *viz. adorers of the croſs*; they being charged with paying adoration to the croſs alone. In other reſpects they were Neſtorians; and admitted two perſons in Jeſus Chriſt. Nicephorus aſcribes other ſingularities to them; particularly their holding an annual feaſt in memory of the dog of their falſe prophet Sergius, which they called *artzibartzes*.

CHEASAPEAK BAY, in North America, the entrance between Cape Henry and Cape Charles, running up 300 miles between Virginia and Maryland. It is navigable almoſt all the way for large ſhips, and has ſeveral navigable rivers that fall into it, by means of which ſhips go up to the very doors of the planters, to take in their lading of goods.—Here was a ſea-engagement in 1781 between the Britiſh fleet under Admiral Graves conſiſting of 19 ſhips of the line, and the French fleet of 24 line-of-battle ſhips under the Count de Graſſe, which ended in the Count's keeping poſſeſſion of the Bay, by which Lord Cornwallis and his whole army were made priſoners of war at Yorktown, being inveſted both by ſea and land by very ſuperior numbers.

CHEATS, are deceitful practices in defrauding, or endeavouring to defraud, another of his known right, by means of ſome artful device, contrary to the plain rules of common honeſty: as by playing with falſe dice, or by cauſing an illiterate perſon to execute a deed to his prejudice, by reading it over to him in words different from thoſe in which it was written, &c.—In England if any perſon deceitfully get into his hands or poſſeſſion any money or other things of any other perſon's by colour of any falſe token, &c. being convicted, he ſhall have ſuch puniſhment by impriſonment, ſetting upon the pillory, or by any corporeal pain except pains of death, as ſhall be adjudged by the perſons before whom he ſhall be convicted.—As there are frauds which may be relieved civilly, and not puniſhed criminally; ſo there are other frauds which in a ſpecial caſe may not be helped civilly, and yet ſhall be puniſhed criminally. Thus if a minor goes about the town, and, pretending to be of age, defrauds many perſons by taking credit for a conſiderable quantity of goods, and then inſiſting on his nonage, the perſons injured cannot recover the value of their goods, but they may indict and puniſh him for a common cheat. Perſons convicted of obtaining money or goods by falſe pretences, or of ſending threatening letters in order to extort money or goods, may be puniſhed with fine or impriſonment, or by pillory, whipping, or tranſportation.

CHEBRECHIN, a town of Poland, in the province of Ruſſia and Palatinate of Belſkow. It is ſeated on the declivity of a hill, and the river Wierpi waters its walls, and afterwards falls into the river Bog. The Jews there are very rich. E. Long. 23. 51. N. Lat. 50. 35.

CHECAYA, in Turkiſh affairs, the ſecond officer of the Janiſaries, who commands them under the aga, and is otherwiſe called *protogero*.

There is alſo a checaya of the treaſury, ſtables, kitchen, &c. the word ſignifying as much as lieutenant, or the ſecond in any office.

CHECK, or *Check-Roll*, a roll or book, wherein are contained the names of ſuch perſons as are attendants and in the pay of kings, or other great perſonages, as their houſhold ſervants.

Clerk of the CHECK *in the king's houſehold*, in Britain, has the check and controlment of the yeomen of the guard, and all the uſhers belonging to the royal family, allowing their abſence or defects in attendance, or diminiſhing their wages for the ſame, &c. He alſo, by himſelf or deputy, takes the view of thoſe that are to watch in the court, and has the ſetting of the watch, &c.

Clerk of the CHECK *in the royal dock-yards*, in Britain, an officer who keeps a muſter or regiſter of all the men employed aboard his majeſty's ſhips and veſſels, and alſo all the artificers and others in the ſervice of the navy at the port where he is ſettled.

CHECK, in falconry, a term uſed of a hawk, when ſhe forſakes her proper game, to fly at pyes, crows, rooks, or the like, that croſs her in her flight.

CHECKY, in heraldry, is when the ſhield, or a bordure, &c. is chequered, or divided in chequers or ſquares, in the manner of a cheſs-board.

This is one of the moſt noble and moſt ancient figures uſed in armoury; and a certain author ſaith, that it ought to be given to none but great warriors, in token of their bravery: for the cheſs-board repreſents a field of battle; and the pawns placed on both ſides repreſent the ſoldiers of the two armies, which move, attack, advance, or retire, according to the will of the gameſters, who are generals.

This figure is always compoſed of metal and colour. But ſome authors would have it reckoned among the ſeveral ſorts of furs.

CHEEK, in anatomy, that part of the face ſituated below the eyes on each ſide.

CHEEKS, a general name among mechanics, for almoſt all thoſe pieces of their machines and inſtruments, that are double, and perfectly alike. Thus, the cheeks of a printing-preſs are its two principal pieces: they are placed perpendicular, and parallel to each other; ſerving to ſuſtain the three ſommers, viz. the head, ſhelves, and winter, which bear the ſpindle, and other parts of the machine. See PRINTING-*Preſs*.

The *cheeks of a turner's lathe*, are two long pieces of wood, between which are placed the puppets, which are either pointed or otherwiſe, ſerving to ſupport the work and the mandrils of the workman. Theſe two pieces are placed parallel to the horizon, ſeparated from one another by the thickneſs of the tail of the puppets, and joined with tenons to two other pieces of wood placed perpendicularly, called the *legs of the lathe*.

Cheeks of the glazier's vice, are two pieces of iron joined parallel at top and bottom; in which are the axis, or ſpindles, little wheel, cuſhions, &c. whereof the machine is compoſed.

The cheeks of a mortar, or the *brackets*, in artillery, are made of ſtrong planks of wood, bound with thick plates of iron, and are fixed to the bed by four bolts; they riſe on each ſide of the mortar, and to ſerve to keep her at what elevation is given her, by the help of ſtrong bolts of iron which go through both cheeks, both under and behind the mortar, betwixt which are driven coins of wood; theſe bolts are called the *bracket bolts*, and the bolts which are put one in each end of the bed, are the traverſe-bolts, becauſe with handſpikes the mortar is by theſe traverſed to the right or left.

CHEEKS, in ſhip-building, are two pieces of timber, fitted on each ſide of the maſt at the top, ſerving to ſtrengthen the maſts there. The uppermoſt bail or piece of timber in the beak of a ſhip, is called the *cheek*. The knees which faſten the beak-head to the ſhip, are called *cheeks*; and the ſides of any block, or the ſides of a ſhip's carriage of a gun, are called *cheeks*.

CHEESE, a ſort of food prepared of curdled milk purged from the ſerum or whey, and afterwards dried for uſe.

Cheeſe differs in quality according as it is made from new or ſkimmed milk, from the curd which ſeparates ſpontaneouſly upon ſtanding, or that which is more ſpeedily produced by the addition of runnet. Cream alſo affords a kind of cheeſe, but quite fat and butyraceous, and which does not keep long. Analyzed chemically, cheeſe appears to partake much more of an animal nature than butter, or the milk from which it was made. It is inſoluble in every liquid except ſpirit of nitre, and cauſtic alkaline ley. Shaved thin, and properly treated with hot water, it forms a very ſtrong cement if mixed with quicklime.* When prepared with hot water, it is recommended in the Swediſh memoirs to be uſed by anglers as a bait: it may be made into any form, is not ſoftened by the cold water, and the fiſhes are fond of it. As a food, phyſicians condemn the too free uſe of cheeſe. When new, it is extremely difficult of digeſtion: when old, it becomes acrid and hot; and, from Dr Percival's experiments, is evidently of a ſceptic nature. It is a common opinion that old cheeſe digeſts every thing, yet is left undigeſted itſelf; but this is without any ſolid foundation. Cheeſe made from the milk of ſheep digeſts ſooner than that from the milk of cows, but is leſs nouriſhing; that from the milk of goats digeſts ſooner than either, but is alſo the leaſt nouriſhing. In general, it is a kind of food fit only for the laborious, or thoſe whoſe organs of digeſtion are ſtrong.

Every country has places noted for this commodity: thus Cheſter and Glouceſter cheeſe are famous in England; and the Parmeſan cheeſe is in no leſs repute abroad, eſpecially in France. This ſort of cheeſe is entirely made of ſweet cow-milk: but at Rochefort in Languedoc, they make it of ewe's milk; and in other places it is uſual to add goat or ewe's milk in a certain proportion to that of the cow. There is likewiſe a kind of medicated cheeſe made by intimately mixing the expreſſed juice of certain herbs, as ſage, baum, mint, &c. with the curd before it is faſhioned into a cheeſe.—The Laplanders make a ſort of cheeſe of the milk of their rein-deer; which is not only of great ſervice to them as food, but on many other occaſions. It is a very common thing in theſe climates to have a limb numbed and frozen with the cold: their remedy for this is the heating an iron red hot, and thruſting it through the middle of one of theſe cheeſes; they catch what drops out, and with this anoint the limb, which ſoon recovers. They are ſubject alſo to coughs and diſeaſes of the lungs, and theſe they cure by the ſame ſort of medicine: they boil a large quantity of the cheeſe in the freſh deer's milk, and drink the decoction in large draughts warm ſeveral times a-day. They make a leſs ſtrong decoction of the ſame kind alſo, which they uſe as their common drink, for three or four days together, at ſeveral times of the year. They

* See *Cement*.

do this to prevent the miſchiefs they are liable to from their water, which is otherwiſe their conſtant drink, and is not good.

The hundred weight of cheeſe pays on importation into Britain 1s. $3\frac{4}{10}$d. and draws back on exportation 1s. $1\frac{1}{2}$d. at the rate of 6s. 8d.

Beſt methods of making cheeſe in England. The double Glouceſter is a cheeſe that pleaſes almoſt every palate. The beſt of this kind is made from new, or (as it is called in that and the adjoining counties) *covered milk.* An inferior ſort is made from what is called *half-covered milk;* though when any of theſe cheeſes turn out to be good, people are deceived, and often purchaſe them for the beſt *covered milk cheeſe:* but farmers who are honeſt have them ſtamped with a piece of wood made in the ſhape of a heart, ſo that any perſon may know them.

It will be every farmer's intereſt (if he has a ſufficient number of cows) to make a large cheeſe from one meal's milk. This, when brought in warm, will be eaſily changed or turned with the rennet; but if the morning or night's milk be to be mixed with that which is freſh from the cow, it will be a longer time before it turns, nor will it change ſometimes without being heated over the fire, by which it often gets duſt or ſoot, or ſmoke, which will give the cheeſe a very diſagreeable flavour.

When the milk is turned, the whey ſhould be carefully ſtrained from the curd. The curd ſhould be broken ſmall with the hands; and when it is equally broken, it muſt be put by little at a time into the vat, carefully breaking it as it is put in. The vat ſhould be filled an inch or more above the brim, that when the whey is preſſed out it may not ſhrink below the brim; if it does, the cheeſe will be worth very little. But firſt, before the curd is put in, a cheeſe-cloth or ſtrainer ſhould be laid at the bottom of the vat; and this ſhould be ſo large, that when the vat is filled with the curd, the the ends of the cloth may turn again over the top of it. When this is done, it ſhould be taken to the preſs, and there remain for the ſpace of two hours; when it ſhould be turned and have a clean cloth put under it, and turned over as before. It muſt then be preſſed again, and remain in the preſs ſix or eight hours; when it ſhould again be turned and rubbed on each ſide with ſalt. After this it muſt be preſſed again for the ſpace of 12 or 14 hours more; when, if any of the edges project, they ſhould be pared off: it may then be put on a dry board, where it ſhould be regularly turned every day. It is a good way to have three or four holes bored round the lower part of the vat, that the whey may drain ſo perfectly from the cheeſe as not the leaſt particle of it may remain.

The prevailing opinion of the people of Glouceſterſhire and the neighbouring counties is, that the cheeſes will ſpoil if they do not ſcrape and waſh them when they are found to be mouldy. But others think that ſuffering the mould to remain, mellows them, provided they are turned every day. Thoſe, however, who will have the mould off, ſhould cauſe it to be removed with a clean dry flannel, as the waſhing the cheeſes is only a means of making the mould (which is a ſpecies of fungus rooted in the coat) grow again immediately.

Some people ſcald the curd: but this is a bad and mercenary practice; it robs the cheeſe of its fatneſs, and can only be done with a view to raiſe a greater quantity of whey butter, or to bring the cheeſes forward for ſale, by making them appear older than they really are.

As moſt people like to purchaſe high-coloured cheeſe, it may be right to mix a little annatto with the milk before it is turned. No cheeſe will look yellow without it; and though it does not in the leaſt add to the goodneſs, it is perfectly innocent in its nature and effects.

It is not in the power of any perſon to make good cheeſe with bad rennet; therefore the following receipt ſhould be attended to. Lethe *vell*, *maw*, *rennet-bag* (or by whatever name it is called), be perfectly ſweet; for if it be the leaſt tainted, the cheeſe will never be good. When this is fit for the purpoſe, three pints or two quarts of ſoft water (clean and ſweet) ſhould be mixed with ſalt, wherein ſhould be put ſweet-briar, roſe leaves and flowers, cinnamon, mace, cloves, and, in ſhort, almoſt every ſort of ſpice and aromatic that can be procured; and if theſe are put into two quarts of water, they muſt boil gently till the liquor is reduced to three pints, and care ſhould be taken that this liquor is not ſmoked. It ſhould be ſtrained clean from the ſpices, &c. and when found to be not warmer than milk from the cow, it ſhould be poured upon the vell or maw. A lemon may then be ſliced into it; when it may remain a day or two: After which it ſhould be ſtrained again, and put in a bottle; where, if well corked, it will keep good for twelve months or more. It will ſmell like a perfume; and a ſmall quantity of it will turn the milk, and give the cheeſe a pleaſing flavour. After this, if the vell be ſalted, and dried for a week or two near the fire, it will do for the purpoſe again almoſt as well as before.

Chedder cheeſe is held in high eſteem; but its goodneſs is ſaid to be chiefly owing to the land whereon the cows feed, as the method of making it is the ſame as is purſued throughout Somerſetſhire, and the adjoining counties.

Cheſhire cheeſe is much admired; yet no people take leſs pains with the rennet than the Cheſhire farmers. But their cheeſes are ſo large as often to exceed one hundred pounds weight each; to this (and the age they are kept, the richneſs of the land, and the keeping ſuch a number of cows as to make ſuch a cheeſe without adding a ſecond meal's milk) their excellence may be attributed. Indeed they ſalt the curd (which may make a difference), and keep the cheeſes in a damp place after they are made, and are very careful to turn them daily.

But of all the cheeſe England produces, none is more highly eſteemed than the Stilton, which is called the *Parmeſan* of England, and (except faulty) is never ſold for leſs than 1s. or 1s. 2d. per pound.

The Stilton Cheeſes are uſually made in ſquare vats, and weigh from ſix to twelve pounds each cheeſe. Immediately after they are made, it is neceſſary to put them into ſquare boxes made exactly to fit them; they being ſo extremely rich, that except this precaution be taken they are apt to bulge out and break aſunder. They ſhould be continually and daily turned in theſe boxes, and muſt be kept two years before they are properly mellowed for ſale.

Some make them in a net, ſomewhat like a cabbage net; ſo that they appear, when made, not unlike an a-corn. But theſe are never ſo good as the other, having a thicker coat, and wanting all that rich flavour and mellowneſs which make them ſo pleaſing.

It is proper to mention that the making of theſe cheeſes is not confined to the Stilton farmers, as many others in Huntingdonſhire (not forgetting Rutland and Northamptonſhires) make a ſimilar ſort, ſell them for the ſame price, and give all of them the name of *Stilton Cheeſes*.

Though theſe farmers are remarked for cleanlineſs, they take very little pains with the rennet, as they in general only cut pieces from the vell or maw, which they put into the milk, and move gently about with the hand, by which means it breaks or turns ſo, that they eaſily obtain the curd. But if the method above deſcribed for making rennet were put in practice, they would make their cheeſe ſtill better; at leaſt they would not have ſo many faulty and unſound cheeſes; for notwithſtanding their cheeſes bear ſuch a name and price, they often find them ſo bad as not to be ſaleable; which is probably owing to their being ſo careleſs about the rennet.

It has been alleged, that as good cheeſe might be made in other counties, if people would adhere to the Stilton plan, which is this—They make a cheeſe every morning; and to this meal of new milk they add the cream taken from that which is milked the night before. This, and the age of their cheeſes, have been ſuppoſed the only reaſons why they are preferred to others; for from the niceſt obſervation, it does not appear that their land is in any reſpect ſuperior to that of other counties.

Excellent cream cheeſes are made in Lincolnſhire, by adding the cream of one meal's milk to milk which comes immediately from the cow; theſe are preſſed gently two or three times, turned for a few days, and are then diſpoſed of at the rate of 1s. per pound, to be eaten while new with radiſhes, ſallad, &c.

Many people give ſkimmed milk to pigs, but the whey will do equally as well after cheeſes are made from this milk; ſuch cheeſes will always ſell for at leaſt 2d. per pound, which will amount to a large ſum annually where they make much butter. The peaſants and many of the farmers in the north of England never eat any better cheeſe; and though they appear harder, experience hath proved them to be much eaſier of digeſtion than any new milk cheeſes. A good market may always be found for the ſale of them at Briſtol.

Account of the making of Parmeſan Cheeſe: by Mr Zappa of Milan, in anſwer to queries from Arthur Young, Eſq.

" Are the cows regularly fed in ſtables?"—From the middle of April, or ſooner if poſſible, the cows are ſent to paſture in the meadows till the end of November uſually.

" Or only fed in ſtables in winter?"—When the ſeaſon is paſt, and ſnow comes, they are put into ſtables for the whole winter, and fed with hay.

" Do they remain in the paſture from morning till night? or only in hot weather?"—Between nine and ten in the morning the cows are ſent to water, and then to the paſtures, where they remain four or five hours at moſt, and at three or four o'clock are driven to the ſtables if the ſeaſon is freſh, or under porticos if hot; where, for the night, a convenient quantity of hay is given them.

" In what months are they kept at paſture the whole day?"—Moſtly anſwered already; but it might be ſaid, that no owner will leave his cattle, without great cauſe, in uncovered places at night. It happens only to the ſhepherds from the Alps, when they paſs, becauſe it is impoſſible to find ſtables for all their cattle.

" What is the opinion in the Lodeſan, on the beſt conduct for profit in the management of meadows?"—For a dairy farm of 100 cows, which yields daily a cheeſe weighing 70 to 75 lb. of 28 ounces, are wanted 1000 perticas of land. Of theſe about 800 are ſtanding meadows, the other 200 are in the cultivation for corn and graſs fields in rotation.

" Do you milk the cows morning and evening?"—Thoſe that are in milk are milked morning and evening, with exception of ſuch as are near calving.

" One hundred cows being wanted to make a Lodeſan each day, it is ſuppoſed that it is made with the milk of the evening and the following morning; or of the morning and evening of the ſame day: how is it?"—The 100 cows form a dairy farm of a good large cheeſe; it is reckoned that 80 are in milk, and 20 with calves ſuckling, or near calving. They reckon one with the other about 32 boccalis of 32 oz. of milk. Such is the quantity for a cheeſe about 70 lb. of 28 ounces. They join the evening with the morning milk, becauſe ſo it is freſher than if it was that of the morning and evening of the ſame day. The morning milk would be 24 hours old when the next morning the cheeſe ſhould be made.

" Do they ſkim or not the milk to make butter before they make the cheeſe?"—From the evening milk all the cream poſſible is taken away for butter, maſcarponi (cream-cheeſe), &c. The milk of the morning ought to be ſkimmed ſlightly; but every one ſkims as much cream as he can. The butter is ſold on the ſpot immediately at 24 ſous; the cheeſe at about 28 ſous. The butter loſes nothing in weight; the cheeſe loſes one-third of it, is ſubject to heat, and requires expences of ſervice, attention, warehouſes, &c. before it is ſold; and a man in two hours makes 45 to 50 lb. of butter that is ſold directly. However, it is not poſſible to leave much cream in the milk to make Lodeſan cheeſe, called *grained cheeſe*; becauſe if it is too rich, it does not laſt long, and it is neceſſary to conſume it while young and ſound.

" Is Parmeſan or Lodeſan cheeſe made every day in the year or not?"—With 100 cows it is. In winter, however, the milk being leſs in quantity, the cheeſe is of leſſer weight, but certainly more delicate.

" After gathering or uniting the milk, either ſkimmed or not, what is exactly the whole operation?"—The morning of the 3d of March 1786, I have ſeen the whole operation, having gone on purpoſe to the ſpot to ſee the whole work from beginning to end. At 16 Italian hours, or ten in the morning, according to the northern way to account hours, the ſkimming of that morning's milk, gathered only two hours before, was finiſhed. I did, meanwhile, examine the boiler or pot. At the top it was eight feet (Engliſh) diameter, or thereabout; and about five feet three inches deep, made

made like a bell, and narrowing towards the bottom to about two one-half feet. They joined the cream produced that morning with the other produced by the milk of the evening before. That produced by this laſt milk was double in quantity to that of the morning milk, becauſe it had the whole night to unite, and that of the morning had only two hours to do it, in which it could not ſeparate much. Of the cream ſome was deſtined to make maſcarponies (cream-cheeſe), and they put the reſt into the machine for making butter. Out of the milk of the evening before and of that morning that was all put together after ſkimming, they took and put into the boiler 272 boccali, and they put under it two faggots of wood; which being burnt, were ſufficient to give the milk a warmth a little ſuperior to lukewarm. Then the boiler being withdrawn from the fire, the foreman put into it the rennet, which they prepare in ſmall balls of one ounce each, turning the ball in his hand always kept in the milk entirely covered; and after it was perfectly diſſolved, he covered the boiler to keep the milk defended, that it might not ſuffer from the coldneſs of the ſeaſon, in particular as it was a windy day. I went then to look on the man that was making maſcarponies, &c. and then we went twice to examine if the milk was ſufficiently coagulated. At the 18 hours, according to the Italian clocks, or noon, the true manufactory of cheeſe began. The milk was coagulated in a manner to be taken from the boiler in pieces from the ſurface. The foreman, with a ſtick that had 18 points, or rather nine ſmall pieces of wood fixed by their middle in the end of it, and forming nine points in each ſide, began to break exactly all the coagulated milk, and did continue to do ſo for more than half an hour, from time to time examining it to ſee its ſtate. He ordered to renew the fire, and four faggots of willow branches were uſed all at once: he turned the boiler that the fire might act; and then the underman began to work in the milk with a ſtick like the above, but with only four ſmaller ſticks at the top, forming eight points, four at each ſide, a ſpan long each point. In a quarter of an hour the foreman mixed in the boiler the proper quantity of ſaffron, and the milk was all in knobs, and finer grained than before, by the effect of turning and breaking the coagulation, or curd, continually. Every moment the fire was renewed or fed; but with a faggot only at a time, to continue it regular. The milk was never heated much, nor does it hinder to keep the hand in it to know the fineneſs of the grain, which refines continually by the ſtick-work of the underman. It is of the greateſt conſequence to mind when the grain begins to take a conſiſtence. When it comes to this ſtate, the boiler is turned from the fire, and the underman immediately takes out the whey, putting it into proper receivers. In that manner the grain ſubſides to the bottom of the boiler; and leaving only in it whey enough to keep the grain covered a little, the foreman extending himſelf as much as he can over and in the boiler, unites with his hands the grained milk, making like a body of paſte of it. Then a large piece of linen is run by him under that paſte, while another man keeps the four corners of it, and the whey is directly put again into the boiler, by which is facilitated the means of raiſing that paſte that is taken out of the boiler, and put for one quarter of an hour into the receiver where the whey was put before, in the ſame linen it was taken from the boiler; which boiler is turned again directly on the fire, to extract the maſcarpa (whey-cheeſe); and is a ſecond product, eaten by poor people. After the paſte remained for a quarter of an hour in that receiver, it was taken out and turned into the wooden form called *faſſera*, without any thing elſe made than the rotundity, having neither top or bottom. Immediately after having turned it into that round wooden form, they put a piece of wood like a cheeſe on it, putting and increaſing gradually weights on it, which ſerve to force out the remnant of whey; and in the evening the cheeſe ſo formed is carried into the warehouſe, where, after 24 hours, they begin to give the ſalt. It remains in that warehouſe for 15 or 20 days; but in ſummer only from 8 to 12 days. Meanwhile the air and ſalt form the cruſt to it; and then it is carried into another warehouſe for a different ſervice. In the ſecond warehouſe they turn every day all the cheeſes that are not older than ſix months; and afterwards it is enough if they are only turned every 48 or 60 hours, keeping them clean, in particular of that bloom which is inevitable to them, and which, if neglected, turns muſty, and cauſes the cheeſe to acquire a bad ſmell. The Lodeſan, becauſe it is a province watered, has a great deal of meadows, and abounds with cows, its product being moſtly in cheeſe, butter, &c. However, the province of Pavia makes a great deal of that cheeſe; and we Milaneſe do likewiſe the ſame from the ſide of Porte Toſa, Romana, Ticineſe, and Vercillina, becauſe we have fine meadows and dairy farms.

Cheese-Rennet. See Gallium and Runnet.

CHEGOE, or Nigua, the Indian name of an inſect common in Mexico, and alſo found in other hot countries where it is called *pique*, is an exceeding ſmall animal, not very unlike a flea, and is bred in the duſt. It fixes upon the feet, and breaking inſenſibly the cuticle, it neſtles betwixt that and the true ſkin, which alſo, unleſs it is immediately taken out, it breaks, and pierces at laſt to the fleſh, multiplying with a rapidity almoſt incredible. It is ſeldom diſcovered until it pierces the true ſkin, when it cauſes an intolerable itching. Theſe inſects, with their aſtoniſhing multiplication, would ſoon diſpeople thoſe countries, were it leſs eaſy to avoid them, or were the inhabitants leſs dexterous in getting them out before they begin to ſpread. On the other hand, nature, in order to leſſen the evil, has not only denied them wings, but even that conformation of the legs and thoſe ſtrong muſcles which are given to the flea for leaping. The poor, however, who are in ſome meaſure doomed to live in the duſt, and to a habitual neglect of their perſons, ſuffer theſe inſects ſometimes to multiply ſo far as to make large holes in their fleſh, and even to occaſion dangerous wounds.

CHEIRANTHUS, stock-gilliflower, or *Wall-flower*: A genus of the 39th natural order, *Siliquoſæ*; and belonging to the tetradynamia claſs of plants. The germen is marked with a glandulous denticle on each ſide; the calyx is cloſe, with two of its leaves gibbous at the baſe; the ſeeds plane. The ſpecies are 13; but the following three are moſt worthy of notice. 1. The cheiri, or common wall-flower, with ligneous, long, tough roots; an upright, woody, abiding ſtalk, divided into many erect angular branches, forming a buſhy head from one to two feet high, cloſely garniſhed with ſpear-ſhaped, acute, ſmooth leaves, and all the branches terminating in long erect ſpikes of numerous flowers, which in different varieties are yellow, bloody, white, *&c.* 2. The incanus, or hoary cheiranthus, with ligneous, long, naked, white roots; and upright, ſtrong, woody, abiding ſtem, from one to three feet high, branchy at top, adorned with long, ſpear-ſhaped, obtuſe, hoary leaves; and the top of the ſtalk and all the branches terminated by erect ſpikes of flowers from one to two or three feet long, of different colours in different varieties. 3. The annuus, or ten-weeks-ſtock, with an upright, woody, ſmooth ſtalk, divided into a branchy head, 12 or 15 inches high, garniſhed with ſpear-ſhaped, blunt, hoary leaves, a little indented, and all the branches terminated by long erect ſpikes of numerous flowers of different colours in different varieties.—The two firſt ſorts are very hardy evergreen biennials or perennials; but the laſt is an annual plant, ſo muſt be continued by ſeed ſown every year; and even the two firſt, notwithſtanding their being perennial, degenerate ſo much in their flowers after the firſt year, that it will be proper alſo to raiſe an annual ſupply of them. The ſeeds are to be ſaved only from the plants with ſingle flowers; for the double ones bring no ſeeds to perfection. The ſeeds are to be choſen from ſuch flowers as have five, ſix, or more petals, or from ſuch as grow near to the double ones. They may be ſown in the full ground in the ſpring, and may be afterwards tranſplanted. When fine doubles of the two firſt kinds are obtained, they may be multiplied by ſlips from the old plants.

CHEKAO, in natural hiſtory, the name of an earth found in many parts of the Eaſt Indies, and ſometimes uſed by the Chineſe in their porcelain manufactures. It is a hard and ſtony earth; and the manner of uſing it is this: they firſt calcine it in an open furnace, and then beat it to a fine powder. This powder they mix with large quantities of water: then ſtirring the whole together, they let the coarſer part ſubſide; and pouring off the reſt yet thick as cream, they leave it to ſettle, and uſe the matter which is found at the bottom in form of a ſoft paſte, and will retain that humidity a long time. This ſupplies the place of the earth called *hoache*, in the making of that elegant ſort of china-ware which is all white, and has flowers which ſeem formed by a mere vapour within its ſurface. The manner of their uſing it is this: they firſt make the veſſel of the common matter of the manufacture; when this is almoſt dry, they paint upon it the flowers, or whatever other figures they pleaſe, with a pencil dipt in this preparation of the chekao; when this is thoroughly dry, they cover the whole veſſel with the varniſh in the common way, and bake it as uſual. The conſequence is, that the whole is white: but the body of the veſſel, the figures, and the varniſh, being three different ſubſtances, each has its own particular white; and the flowers being painted in the fineſt white of all, are diſtinctly ſeen through the varniſh upon the veſſel, and ſeem as if traced by a vapour only. The hoache does this as well as the chekao; and has beſides this the quality of ſerving for making the porcelain ware either alone, or in the place of kaolin: the chekao has not this property, nor any other ſubſtance beſides this hoache, which appears to be the ſame with the ſteaties or ſoap-rock.

CHEKE, (Sir John) a celebrated ſtateſman, grammarian, and divine, of an ancient family in the iſle of Wight, was born at Cambridge in the year 1514, and educated at St John's college in that univerſity; where, after taking his degrees in arts, he was firſt choſen Greek lecturer, and in 1540 profeſſor of that language, with a ſtipend of 40l. a-year. In this ſtation he was principally inſtrumental in reforming the pronunciation of the Greek language, which, having been much neglected, was imperfectly underſtood. About the year 1543 he was incorporated maſter of arts at Oxford, where, we are told, he had ſtudied for ſome time. In the following year he was ſent to the court of king Henry VIII. and appointed tutor for the Latin language, jointly with Sir Anthony Cooke, to prince Edward, about which time he was made canon of the college newly founded in Oxford; wherefore he muſt have now been in orders. On the acceſſion of his royal pupil to the crown, Mr Cheke was firſt rewarded with a penſion of 100 merks, and afterwards obtained ſeveral conſiderable grants from the crown. In 1550 he was made chief gentleman of the privy-chamber, and was knighted the following year; in 1552, chamberlain of the exchequer for life; in 1553, clerk of the council; and ſoon after ſecretary of ſtate and privy-councillor. But theſe honours were of ſhort duration. Having concurred in the meaſures of the duke of Northumberland for ſettling the crown on the unfortunate Jane Grey, and acted as her ſecretary during the nine days of her reign, on the acceſſion of queen Mary, Sir John Cheke was ſent to the tower, and ſtript of the greateſt part of his poſſeſſions. In September 1554 he obtained his liberty, and a licence from her majeſty to travel abroad. He went firſt to Baſil, thence to Italy, and afterwards returned to Straſburg, where he was reduced to the neceſſity of reading Greek lectures for ſubſiſtence. In 1556 he ſet out in an evil hour to meet his wife at Bruſſels: but, before he reached that city, he was ſeized by order of king Philip II. hoodwinked, and thrown into a waggon; and thus ignominiouſly conducted to a ſhip, which brought him to the tower of London. He ſoon found that religion was the cauſe of his impriſonment; for he was immediately viſited by two Romiſh prieſts, who piouſly endeavoured to convert him, but without ſucceſs. However, he was at laſt viſited by Fleckenham; who told him from the queen, that he muſt either comply or burn. This powerful argument had the deſired effect; and Sir John Cheke accordingly complied in form, and his lands, upon certain conditions, were reſtored: but his remorſe ſoon put an end to his life. He died in September 1557, at the houſe of his friend Mr Peter Oſborne in Wood-ſtreet, London, and was buried in St Alban's church. He left three ſons, the eldeſt of whom, Henry, was knighted by queen Elizabeth. He wrote 1. A Latin tranſlation of two of St Chryſoſtom's homilies. Lond. 1543, 4to. 2. The Hurt of Sedition. Lond. 1549, 1576, 1641. 3. Latin Tranſlation of the Engliſh Communion Service. Printed among Bucer's opuſcula. 4. De pronunciatione Græcæ. Baſil, 1555, 8vo. 5. Several letters publiſhed in his life by Strype; and a great number of other books.

CHE-KYANG, or TCHE-KIANG, a maritime province of China, and one of the moſt conſiderable in the empire; is bounded on the ſouth by Fo-kien; on the north and weſt by Kiang-nan and Kiangſi; and on on the eaſt by the ſea. The air is pure and healthful, and the ſoil fertile, being watered by a number of rivers and canals, as well as ſprings and lakes. The chief produce is ſilk; a vaſt quantity of which is cultivated here, and for which the whole country is covered with mulberry trees. Theſe are purpoſely checked in their growth by the natives, experience having taught them, that the leaves of the ſmalleſt trees produce the beſt ſilk. The ſtuffs made in this province, which are embroidered with gold and ſilver, are reckoned the beſt in the empire: and notwithſtanding a vaſt exportation to the Japan and Philippine iſlands, as well as to every part of China, and to Europe, ſuch an abundance is left in the province, that a complete ſuit of ſilk may be bought here as cheap as one of the coarſeſt woollen in France.

This province is alſo remarkable for a particular ſpecies of muſhrooms, which is exported to every part of the empire. They are pickled, and then dried; when they will keep good for a whole year. When uſed they muſt be ſoaked in water, which renders them as freſh as at firſt. Here alſo the tallow tree is met with; and the province affords excellent hams, and thoſe ſmall gold-fiſhes with which the ponds are uſually ſtocked.

Che-kyang contains 11 cities of the firſt claſs, 72 of the third, and 18 fortreſſes, which, in Europe, would be accounted large cities. The principal of theſe are, 1. Hang-tcheou-fou, the metropolis, accounted by the Chineſe to be the paradiſe of the earth. It is four leagues in circumference, excluſive of the ſuburbs; and the number of its inhabitants are computed at more than a million, and 10,000 workmen are ſuppoſed to be employed within its walls in manufacturing of ſilk. Its principal beauty is a ſmall lake, cloſe to the walls on the weſtern ſide, the water of which is pure and limpid, and the banks almoſt every where covered with flowers. Its banks are likewiſe adorned with halls and open galleries ſupported by pillars, and paved with large flag-ſtones for the convenience of thoſe who are fond of walking; and the lake itſelf is interſected with cauſeways caſed with cut-ſtone, openings covered with bridges being left in them for the paſſage of boats. In the middle are two iſlands with a temple and ſeveral pleaſure-houſes, and the emperor has a ſmall palace in the neighbourhood. The city is garriſoned by 3000 Chineſe and as many Tartars, and has under its juriſdiction ſeven cities of the third claſs. 2. Hou-tcheou-fou is alſo ſituated on a lake, and manufactures an incredible quantity of ſilk, inſomuch, that the tribute of a city under its juriſdiction amounts to more than 500,000 ounces of ſilver. 3. Ning-po-fou, by Europeans called Liampo, is an excellent port, oppoſite to Japan. Eighteen or twenty leagues from it is an iſland called Tcheou-chan, where the Engliſh firſt landed on their arrival at China. 4. Ning-po is remarkable for the ſilk manufactured there, which is much eſteemed in foreign countries, eſpecially Japan, where it is exchanged for gold, ſilver, and copper. 5. Chao-hing-fou, ſituated in an extenſive and fertile plain, is remarkable for a tomb about half a league diſtant, which is ſaid to be that of *Yu*. The people of this province are ſaid to be the moſt verſed in chicanery of any in China. 6. Tchu-tcheou-fou, remarkable for having in its neighbourhood pines of an extraordinary ſize, capable of containing 40 men in their trunks. The inhabitants are ingenious, polite, and courteous to ſtrangers, but very ſuperſtitious.

CHELIDONIAS, according to Pliny, an anniverſary wind, blowing at the appearance of the ſwallows; otherwiſe the Favonius, or Zephyrus.

CHELIDONIUM, Celandine, and Horned or prickly poppy: A genus of the monogynia order, belonging to the pentandria claſs of plants; and in the natural method ranking under the 27th order, *Rhœadeæ*. The corolla is tetrapetalous, the calyx diphyllous, the ſiliqua unilocular and linear. There are ſix ſpecies; none of which are remarkable for their beauty; but one of them, *viz.* the majus, is an article in the materia medica. It grows on old walls, among rubbiſh, and in waſte ſhady places. The herb is of a bluiſh green colour; the root of a deep red; and both contain a gold-coloured juice: their ſmell is diſagreeable, the taſte ſomewhat bitteriſh, very acrid, burning and biting the mouth; the root is the moſt acrid. The juice takes off warts; cures tetters, ring-worms, and the itch; and, diluted with milk, it conſumes opaque white ſpots on the eye.—Horſes, cows, goats, and ſwine, refuſe to eat the herb.

CHELIDONIUS lapis, in natural hiſtory, a ſtone ſaid by the ancients to be found in the ſtomachs of young ſwallows, and greatly cried up for its virtues in the falling-ſickneſs; but, from their deſcription, it appears to be only a ſpecies of lycodontes, or bufonitæ. See Lycodontes, and Bufonitæ.

CHELM, a town of Poland, capital of a palatinate of the ſame name. It is ſituated in the province of Red Ruſſia. E. Long. 23. 30. N. Lat. 51. 25.

CHELMSFORD, the county town of Eſſex, ſituated on the river Chelmer, in E. Long. 0. 30. N. Lat. 51. 40. It ſends two members to parliament.

CHELONE, in botany: A genus of the angioſpermia order, belonging to the didynamia claſs of plants; and in the natural method ranking under the 40th order, *Perſonatæ*. The calyx is quinquepartite; the rudiment of a fifth filament among the higheſt ſtamina, the capſule bilocular. There are three ſpecies, *viz.* the Glabra, the Hirſuta, and the Penſtemon. They are natives of North America; and are herbaceous flowery perennials, with upright ſtalks two feet high, decorated with ſpear-ſhaped leaves, and beautiful ſpikes of monopetalous, ringent flowers, red, roſe-coloured, blue, and purple. They flower from September to November, and are ſometimes ſucceeded by ripe ſeeds in Britain. They are very hardy plants, and may be propagated by ſeeds ſown in any ſoil or ſituation; but the two firſt multiply ſo faſt by their creeping roots, that the ſeeds are ſeldom regarded.

CHELSEA, a fine village ſituated on the northern bank of the river Thames, a mile weſtward of Weſtminſter, remarkable for a magnificent hoſpital of invalids and old decrepit ſoldiers; and a pleaſure-houſe, called Ranelagh, to which a great deal of fine company reſort in ſummer; and a noble botanic garden belonging to the company of apothecaries. The royal hoſpital of invalids was begun by Charles II. carried on by James II. and finiſhed by king William. It conſiſts of a vaſt range of buildings, that form three large ſquares, in which there is an uncommon air of neatneſs and elegance obſerved. It is under the direction of commiſſioners, who conſiſt generally of the

offi-

officers of ſtate and of war. There is a governor with 500 l. ſalary, a lieutenant governor with 400 l. and a major, with 250l. beſides inferior officers, ſerjeants, corporals and drums, with about 400 men, who all do garriſon duty; and there are above 10,000 out penſioners who receive an annuity of 7l. 12s. 6d. each; all which expence is defrayed by a poundage deducted from the army, deficiences being made good by parliament.—The botanic garden is very extenſive, enriched with a vaſt variety of domeſtic and exotic plants, the original ſtock of which was given to the apothecaries of London by Sir Hans Sloane.—At Ranelagh Garden and amphitheatre the entertainment is a fine band of muſic, with an organ and ſome of the beſt voices, and the regale is tea and coffee.

CHELTENHAM, or CHILTENHAM, a market town of Glouceſterſhire, ſeven miles north-eaſt of Glouceſter. W. Long. 2. 10. N. Lat. 51. 50. It is chiefly remarkable for its mineral waters, of the ſame kind with thoſe of Scarborough. See SCARBOROUGH.

CHEMISE, in fortification, the wall with which a baſtion, or any other bulwark of earth, is lined for its greater ſupport and ſtrength: or it is the ſolidity of the wall from the talus to the ſtone-row.

Fire-CHEMISE, a piece of linen cloth, ſteeped in a compoſition of oil of petrol, camphor, and other combuſtible matters, uſed at ſea, to ſet fire to an enemy's veſſel.

CHEMISTRY

1 Definition.

MAY be defined, The ſtudy of ſuch phenomena or properties of bodies as are diſcovered by variouſly mixing them together, and by expoſing them to different degrees of heat, alone, or in mixture, with a view to the enlargement of our knowledge in nature, and to the improvement of the uſeful arts: or, It is the ſtudy of the effects of heat and mixture upon all bodies, whether natural or artificial, with a view to the improvement of arts and natural knowledge.

2 Antiquity.

The ſcience of chemiſtry is undoubtedly of very high antiquity; and, like moſt other ſciences, its origin cannot be traced. In ſcripture, Tubal Cain, the 8th from Adam, is mentioned as the father or inſtructor of every artificer in braſs or iron. This, however, does not conſtitute him a chemiſt, any more than a founder or blackſmith among us has a right to that title. The name of chemiſt could only belong to him, whoever he was, who firſt diſcovered the method of extracting metals from their ores; and this perſon muſt neceſſarily have lived before Tubal Cain, as every blackſmith or founder muſt have metals ready prepared to his hand. Nevertheleſs, as Tubal Cain lived before the flood, and the ſcience of chemiſtry muſt have exiſted before his time, ſome have conjectured, that the metallurgic part, on account of its extreme uſefulneſs to mankind, was revealed to Adam by God himſelf.

3 Science founded.

Be this as it will, *Siphoas*, an Egyptian, is conſidered by the chemiſts as the founder of their ſcience. He was known by the Greeks under the name of *Hermes*, or *Mercurius Triſmegiſtus*; and is ſuppoſed to have lived more than 1900 years before the Chriſtian æra. A numerous liſt of this philoſopher's works is given by Clemens Alexandrinus; but none of them are now to be found, nor do any of them appear to have been written profeſſedly on chemiſtry.

Two illuſtrious Egyptians, of the name of Hermes, are recorded by ancient authors. The elder ſuppoſed to be the ſame with *Mizraim*, the grandſon of Noah, the *Hermes* of the Greeks, and *Mercury* of the Romans. The younger Hermes lived a thouſand years afterwards; and is ſuppoſed to have reſtored the ſciences after they had fallen into oblivion, in conſequence of an inundation of the Nile. No leſs than 36,000 books are ſaid to have been written under the name of Hermes; but, according to Jamblichus, a cuſtom prevailed of inſcribing all books of ſcience with the name of Hermes. Some authors deny the exiſtence of Hermes, and maintain that his hiſtory is allegorical.

4 Moſes ſuppoſed to be ſkilled in chemiſtry:

As the ſcience of chemiſtry is ſuppoſed to have been well known to the Egyptians, Moſes, who was ſkilled in their wiſdom, is thence ranked among the number of chemiſts; a proof of whoſe ſkill in this ſcience is thought to be, his diſſolving the golden calf made by the Iſraelites, ſo as to render it potable.

Of all the Greeks who travelled into Egypt in order to acquire knowledge, Democritus alone was admitted into their myſteries. The Egyptian prieſts are ſaid to have taught him many chemical operations; among which were the art of ſoftening ivory, of vitrifying flints, and of imitating precious ſtones. Dr Black, however, is of opinion, that Democritus knew nothing more of theſe arts than that of making a coarſe kind of glaſs, as no mention is particularly made of his imitating any other precious ſtone than the emerald, whoſe colour is green; and the coarſer the glaſs the greener it is.

After the time of Democritus, we may know that conſiderable improvements were made in chemiſtry, as phyſicians began to make uſe of metallic preparations, as ceruſe, verdegris, litharge, &c. Dioſcorides deſcribes the diſtillation of mercury from cinnabar by means of an *embic*, from which, by adding the Arabic *Al*, comes the term *Alembic*. The art of diſtillation, however, at that time was in a very rude ſtate; the operation being performed chiefly by ſeparating the air, and more ſubtle part of tar, from the reſt of the matter. This was done by putting the matter to be diſtilled into a veſſel, the mouth of which was covered with a wet cloth; and by this the ſteams of aſcending vapour were condenſed, which were afterwards procured by wringing out the cloth. No other diſtillation, beſides this kind, is mentioned by Galen, Oribaſius, Ælian, or Paulus Ægineta.

5 Derivation of the word Alembic.

6 Original method of diſtilling.

The preciſe time is not known when the three mineral acids were firſt diſcovered; though, as no mention is made of them by Geber, Avicenna, or Roger Bacon, it is probable that they were not known in the 12th century.

tury. Raymond Lully gives ſome hints of his being acquainted with the marine acid; whence it is probable, that it was diſcovered towards the end of the 13th, or beginning of the 14th century.

7 Pliny's account of the origin of glaſs-making.

Several chemical facts are related by Pliny, particularly the making of glaſs, which he aſcribes to the following accident. "Some merchants in the Levant, who had nitre on board their ſhip, having occaſion to land, lighted a fire on the ſand in order to prepare their food. To ſupport their veſſels they took ſome of the lumps of nitre with which their ſhip was loaded: and the fire acting on theſe, melted part of them along with the ſand, and thus formed the tranſparent ſubſtance called glaſs, to the great ſurpriſe of the beholders." But it is probable, that the art of glaſs-making was known long before; and it is by no means likely that it took its riſe from ſuch an accident.

8 Alchemy firſt mentioned by Firmicus Maternus.

9 Origin of the fable the Argonauts.

10 Alchemy firſt ſuppoſed to be derived from the Arabians.

The next traces we find of chemiſtry are to be extracted from the extravagant purſuits of the *Alchemiſts*, who imagined it poſſible to convert the baſer metals into gold or ſilver. The firſt mention we find of this ſtudy is by Julius Firmicus Maternus, who lived in the beginning of the fourth century, and ſpeaks of it as a well known purſuit in his time. Æneas Blaſius, who lived in the fifth century, likewiſe ſpeaks of it; and Suidas explains the term by telling us, that it is the art of making gold and ſilver. He tells us, that Diocleſian, when perſecuting the Chriſtians, forbad all chemical operations, leſt his ſubjects ſhould diſcover the art of making gold, and thus be induced to rebel againſt him. He ſuppoſes alſo, that the Argonautic expedition was only an attempt to procure a ſkin or parchment, on which was written the *recipe* for making gold. It is a common practice, however, in ſome places where gold is waſhed down in ſmall particles by brooks and rivulets from the mountains, to ſuſpend in the water the ſkins of animals having wool or hair upon them, in order to detain the heavier particles which contain the gold; and this probably gave riſe to the fable of the golden fleece. Suidas, however, who lived as late as the tenth century, deſerves very little credit, eſpecially as alchemy is not mentioned by any ancient author.—The Arabian phyſicians afford the moſt clear and diſtinct evidence concerning alchemy. Avicenna, who lived in the tenth century, is ſaid by a diſciple of his to have wrote upon alchemy; he mentions alſo roſe-water, and ſome other chemical preparations; and in the 12th century we find phyſicians adviſed to cultivate an acquaintance with the chemiſts; and another of the Arabian writers ſay, that the method of preparing roſe-water, &c. was then well known.—From this evidence of the exiſtence of alchemy among the Arabians, with the prefatory article *Al*, to denote the greatneſs of the ſcience, it has been conjectured, that the doctrine of the tranſmutation of metals firſt took its riſe among the Arabians, and was introduced into Europe by means of the Cruſades, and by the rapid conqueſts of the Arabians themſelves in Europe as well as in Aſia and Africa. Europe at that time had been in a ſtate of the greateſt barbarity from the incurſions of the northern nations; but the Arabians contributed to revive ſome of the ſciences, and introduced alchemy among the reſt, which continued till the middle of the 17th century; at which time the extravagance of its profeſſors roſe to the greateſt height.

11 No credit due to the doctrine of tranſmutation.

12 Quickſilver produced from lead.

Though the pretenſions of the alchemiſts are now univerſally refuted, yet from ſome of the diſcoveries which have been made in chemiſtry, we are even yet in danger of giving ſome credit to the poſſibility of the proceſs of tranſmutation. When we conſider that the metals are bodies compounded of parts which we can take away and reſtore, and that they are cloſely allied to one another in their external appearance, we may be inclined to think favourably even of the projects of the alchemiſts. The very ſeparation of the metals from their ores, the depriving them of their ductility and malleability, and the reſtoration of theſe properties to them at pleaſure, will appear very ſurpriſing to thoſe who are unacquainted with chemiſtry. There are alſo proceſſes of the more difficult kind, by which quickſilver may be produced from metals that are commonly ſolid, as from lead. Some of theſe we find in Boerhaave, Boyle, &c. authors of the greateſt credit, who both ſpeak of the operation and product as realities of which they were convinced by their own experience. Theſe have been urged, not without ſome plauſibility, in favour of the tranſmutation of the imperfect metals into gold; and hence the deluſions of alchemy were not confined to the vain, the ignorant, and the ambitious part of mankind; but many ingenious and learned men, who took pleaſure in the ſtudy of nature, have been ſeduced into this unhappy purſuit. This happened chiefly in Germany, where the variety of mines naturally turned the thoughts of chemiſts principally towards the metals, though the numerous failures of thoſe who had attempted this art ought to have taught them better.

About the beginning of the 16th century, the pretenders to alchemy were very numerous, and a multitude of knaves, who had beggared themſelves in the attempt, now went abont to enſnare others, performing legerdemain tricks, and cauſing people believe that they could actually make gold and ſilver. A number of the tricks they made uſe of are to be met with in Lemery. Many books, with the ſame deſign of impoſing upon mankind, were written upon the ſubject of alchemy. They aſſumed fictitious names of the greateſt antiquity, and contained rules for preparing the philoſopher's ſtone; a ſmall quantity of which thrown into a baſe metal ſhould convert the whole into gold. They are wrote in a myſterious ſtyle, without any diſtinct meaning; and though ſometimes proceſſes are clearly enough deſcribed, they are found to be falſe and deceitful upon trial, the products not anſwering the pretenſions of the authors. Their excuſe was, that it was vain to expect plain accounts of theſe matters, or that the books on theſe ſubjects ſhould be written diſtinctly and clearly; that the value of gold was in proportion to its ſcarcity, and that it might be employed to bad purpoſes: they wrote only for the laborious and judicious chemiſts, who would underſtand them provided they made themſelves acquainted with the metals by ſtudy and experience. But in fact, no diſtinct meaning has ever been obtained, and the books have only ſerved to delude and betray a great number of others into the loſs of their *lives*.

But though the alchemiſts failed in the execution of their

13 Chemiſtry derived ſome advantages from the labours of the alchemiſts.

their grand project, we muſt ſtill own ourſelves indebted to them for many diſcoveries brought to light during the time they vainly ſpent their labour in the expectation of making gold. Some of theſe are the methods of preparing ſpirit of wine, aquafortis, volatile alkali, vitriolic acid, and gun powder. Medicine too was indebted to them for ſeveral valuable remedies; whence alſo it appears that many, who had waſted their time in the vain purſuit of the philoſopher's ſtone, thought of trying ſome of their moſt elaborate preparations in the cure of diſeaſes; and meeting with ſome ſucceſs, they preſumed that diſeaſes were only to be cured by the aſſiſtance of chemiſtry; and that the moſt elaborate of all its preparations, the philoſophers ſtone, would cure all diſeaſes. Some cures they performed did indeed awaken the attention of phyſicians; and they introduced the uſe of opium, which had formerly been accounted poiſonous. They ſucceeded alſo in the cure of the venereal diſeaſe, which had lately made its appearance, and baffled the regular phyſicians; but the chemiſts, by giving mercury, put a ſtop to its ravages, and, thus introduced this valuable article into the materia medica.

14 Account of Paracelſus.

The moſt famous of the chemical profeſſors was Paracelſus, well known for his arrogance, abſurdity, and profligacy. He was bred to the ſtudy of medicine; but becoming acquainted with the alchemiſts, travelled about in the character of a phyſician, and was at great pains to collect powerful medicines from all quarters. Theſe he uſed with great freedom and boldneſs. His ſucceſs in ſome caſes operated ſo upon the natural arrogance and ſelf-ſufficiency of his diſpoſition, that he formed a deſign of overturning the whole ſyſtem of medicine, and ſupplying a new one from chemiſtry: and indeed he found but very weak adverſaries in the ſubtle theories of Galen with the refinements of the Arabian phyſicians, which only prevailed in his time; and he no doubt had ſome ſhare in baniſhing that veneration which had been ſo long entertained for theſe celebrated perſonages.

15 Hiſtory of chemiſtry ſince the time of Paracelſus.

16 The ſcience ſtudied by Lord Verulam;

From the time of Paracelſus, chemiſtry began every where to aſſume a new face. In Great Britain, Lord Verulam amuſed himſelf at his leiſure hours with forming plans for promoting the ſciences in general, eſpecially thoſe which related to the ſtudy of nature. He ſoon found that chemiſtry might turn out one of the moſt uſeful and comprehenſive branches of natural philoſophy, and pointed out the means of its improvement. A number of experiments were propoſed by him: but he obſerved, that the views of chemiſts were as yet only adapted to explain their particular operations on metals; and he obſerved, that, inſtead of the abſtruſe and barren philoſophy of the times, it was neceſſary to make a very large collection of facts, and to compare them with each other very maturely and cautiouſly, inorder to diſcover the common cauſes and circumſtances of connection upon which they all depend. He did not, however, make any conſiderable diſcoveries, and his works are tedious and diſagreeable to the reader.

17 And by Mr Boyle.

A ſuperior genius to Lord Verulam was Mr Boyle, who was born the very day that the former died. His circumſtances were opulent, his manners agreeable; he was endowed by nature with a goodneſs of heart; and his inclination led him entirely to the ſtudy of nature, which he was beſt pleaſed with cultivating in the way of experiment. He conſidered the weight, ſpring, and qualities of the air; and wrote on hydroſtatics and other ſubjects; and was poſſeſſed of that happy penetration and ingenuity ſo well ſuited to the making of experiments in philoſophy, which ſerves to deduce the moſt uſeful truths from the moſt ſimple and ſeemingly inſignificant facts. As chemiſtry was his favourite ſcience, he ſpared no pains to procure from chemiſts of greateſt note the knowledge of curious experiments, and entertained a number of operators conſtantly about him. His diſcoveries are related in an eaſy ſtyle; and though rather copious, ſuited to the taſte of the times in which he lived, and free from that abſurd and myſterious air which formerly prevailed in chemical writings: nor does he betray a deſign of concealing any thing except ſome particulars which were communicated to him under the notion of ſecrecy, or the knowledge of which might do more harm than good. It is objected indeed, that he betrays a good deal of credulity with regard to facts which were given on the faith of others, and which may ſeem incredible; but this proceeded from his candour, and his being little diſpoſed to ſuſpect others. He ſhowed the neceſſary connection between philoſophy and the arts; and ſaid, that by attending the ſhop of a workman, he learned more philoſophy than he had done in the ſchools for a long time. Thus his writings ſhowed an univerſal taſte for the ſtudy of nature, which had now made ſome advances in the other parts of the world.

18 Chemiſtry emerges from its obſcurity.

Agricola is one of the firſt and beſt authors on the ſubject of metallurgy. Being born in a village in Miſnia, a country abounding in mines and metallurgic works, he deſcribed them exactly and copiouſly. He was a phyſician, and cotemporary with Paracelſus, but of a character very different. His writings are clear and inſtructive, as thoſe of Paracelſus are obſcure and uſeleſs. Lazarus Erker, Schinder, Schlutter, Henkel, &c. have alſo written on metallurgy, and deſcribed the art of aſſaying metals. Anthony Neri, Dr Merret, and the famous Kunkel (who diſcovered the phoſphorus of urine), have deſcribed very fully the arts of making glaſs, enamels, imitations of precious ſtones, &c.: but their writings, as well as thoſe of ſucceeding chemiſts, are not free from the illuſions of alchemy: ſo true it is, that an obſtinate and inveterate malady never diſappears at once, without leaving traces behind. In a ſhort time, however the alchemical phrenzy was attacked by many powerful antagoniſts, who contributed to reſcue the ſcience of chemiſtry from an evil which at once diſgraced it and retarded its progreſs. Among theſe, the moſt diſtinguiſhed are Kircher a Jeſuit, and Conringius a phyſician, who wrote with much ſucceſs and reputation.

19 Royal Society how founded.

About the year 1650 the Royal Society was formed by a number of gentlemen who were unwilling to engage in the civil wars; and being ſtruck with the extenſive views of Lord Verulam and Mr Boyle, contributed to the expence of coſtly experiments. This example appeared ſo noble, and the deſign ſo good, that it has been followed by all the civilized ſtates of Europe, and has met with the protection of their reſpective ſovereigns; and from theſe chemiſtry has received conſiderable improvements. In France, Geoffroy, Lemery, Reaumur, &c. came to be diſtinguiſhed;

ed; and in Germany Margraaf, Pott, and others, have made a conſiderable figure in thoſe ſocieties. Kunckel, Begar, Stahl, and Hoffman, &c. have done great ſervice to ſociety, by introducing new arts, and the numerous improvements they have made.

20
Of the improvements made by different nations in chemiſtry.

The chemiſts who have made a figure in Germany and France are more in number than thoſe whom Britain has produced. In France, the ſociety was encouraged by the ſovereign; and in it they have diveſted themſelves of that myſterious air which was affected in former ages. In Germany, the richneſs of the country, and the great variety of mines, by turning the attention of chemiſts to the metals, have given that alchymiſtical air to their writings which we obſerve in them. The number of thoſe who have applied themſelves to chemiſtry is very ſmall in England, owing to the great improvements made by Sir Iſaac Newton in the ſciences of aſtronomy and optics; which, by turning the general attention that way, has occaſioned what may be called a neglect of chemiſtry. But if their number be inconſiderable, they are by no means inferior in merit and fame. The name of Boyle has always been held in the higheſt eſteem, as well as that of Hales, for the analyſis he has made of the air. Sir Iſaac Newton alone has done more to the eſtabliſhing a rational chemical theory than ever was done before. Of late, the taſte for the ſtudy has became more general, and many uſeful books have appeared; ſo that it is to be hoped they will ſoon excel in this branch of ſcience, as they have done in all the reſt.

PART I. THEORY OF CHEMISTRY.

21
Perfect Theory, what.

According to the definition we have given of this ſcience, the theory of it ought to conſiſt in a thorough knowledge of all the phenomena which reſult from every poſſible combination of its objects with one another, or from expoſing them in all poſſible ways to thoſe ſubſtances which chemiſts have found to be the moſt active in producing a change. So various, however, and ſo widely extended are the objects of chemiſtry (comprehending all terreſtrial bodies whatever), that a knowledge of this kind is utterly unattainable by man. The utmoſt that can be done in this caſe is, to give ſome account of the phenomena which accompany the mixtures of particular ſubſtances, or the appearances they put on when expoſed to heat; and theſe have been already ſo well aſcertained, that they may now be laid down as rules, whereby we may, with a good deal of certainty, judge of the event of our experiments, even before they are made.

22
Objects of Chemiſtry, what.

Here we muſt obſerve, that though the objects of chemiſtry are as various as there are different ſubſtances in the whole ſyſtem of nature, yet they cannot all be examined with equal eaſe. Some of theſe ſubſtances act upon others with great violence; and the greater their activity, the more difficultly are they themſelves ſubjected to a chemical examination. Thus, fire, which is the moſt active body in nature, is ſo little the ſubject of examination, that it hath hitherto baffled the ingenuity of the greateſt philoſophers to underſtand its compoſition. This ſubſtance, therefore, though it be the principal, if not the only *agent* in chemiſtry, is not properly an *object* of it, becauſe it cannot be made a ſubject of any chemical operation.

23
Suppoſition of elements the origin of alchemy.

It hath been cuſtomary to conſider all bodies as compoſed of certain permanent and unchangeable parts called *elements*; and that the end of chemiſtry was to reſolve bodies into theſe elements, and to recompoſe them again by a proper mixture of the elements when ſo ſeparated. Upon this ſuppoſition the alchemiſts went; who, ſuppoſing that all bodies were compoſed of ſalt, ſulphur, and mercury, endeavoured to find out the proportions in which theſe exiſted in gold, and then to form that metal by combining them in a ſimilar manner. Had they taken care to aſcertain the real exiſtence of their elements, and, by mixing them together, compoſed any one metal whatever, though but a grain of lead, the leaſt valuable of them all; their pretenſions would have been very rational and well founded; but as they never aſcertained the exiſtence of ſuch elementary bodies, it is no wonder that their labours were never attended with ſucceſs.

24
Mr Boyle's opinion.

Another ſet of elements which were as generally received, and indeed continue to be ſo in ſome meaſure to this day, are fire, air, earth, and water.—This doctrine of elements was ſtrenuouſly oppoſed by Mr Boyle; who endeavoured to prove, that fire was not an element *per ſe*, but generated merely from the motion of the particles of terreſtrial bodies among one another; that air was generally produced from the ſubſtance of ſolid bodies; and that water, by a great number of diſtillations, was converted into earth. His arguments, however, concerning fire were not at all concluſive; nor does the expulſion of air from fixed bodies prove that any of their ſolid parts were employed in the compoſition of that air; as later diſcoveries have ſhown that air may be abſorbed from the external atmoſphere, and fixed in a great number of ſolid ſubſtances. His aſſertion concerning water deſerves much conſideration, and the experiment is well worth repeating; but it does not appear that he, or any other perſon, ought to have relied upon the experiment which was intended to prove this tranſmutation. The fact was this. Having deſigned to try the poſſibility of reducing water to earth by repeated diſtillations, he diſtilled an ounce of water three times over himſelf, and found a ſmall quantity of earth always remaining. He then gave it to another, who diſtilled it 197 times. The amount of earth from the whole diſtillations was ſix drams, or $\frac{3}{4}$ths of the quantity of water employed; and this earth was fixed, white, and inſoluble in water.—Here it is evident, that great ſuſpicions muſt lie againſt the fidelity of the unknown operator, who no doubt would be wearied out with ſuch a number of diſtillations. The affair might appear trivial to him; and as he would perhaps know to which ſide Mr Boyle's opinion inclined, he might favour it, by mixing ſome white earth with the water. Had the experiment been tried by Mr Boyle's own hand, his known character would have put the matter beyond a doubt.

The decompoſition of water, however, in another way, by the combination of one part of it with the phlogiſtic, and another with the earthy part of a metal, is now well aſcertained, and the experiments which led to the diſcovery are treated of under the articles AEROLOGY and WATER.

25 Exiſtence of elements diſputed.

Even the exiſtence of earth as an element appears as dubious as that of the others; for it is certain that there is no ſpecies of earth whatever, from which we can produce two diſſimilar bodies, by adding their other component parts.—Thus, the earth of alum has all the characters of ſimplicity which we can deſire in any terreſtrial ſubſtance. It is white, inſipid, inodorous, and perfectly fixed in the fire; nevertheleſs, it ſeems to be only an element of that particular body called *alum*; for though alum is compoſed of a pure earth and vitriolic acid joined together, and Epſom ſalt and ſelenite are both compoſed of a pure earth combined with the ſame acid; yet by adding oil of vitriol to the earth of alum, in any poſſible way, we ſhall never be able to form either Epſom ſalt or ſelenite. In like manner, though all the imperfect metals are compoſed of inflammable matter joined with an earthy baſis; yet by adding to earth of alum any proportion we pleaſe of inflammable matter, we ſhall never produce a metal; and what is ſtill more mortifying, we can never make the earthy baſis of one metallic ſubſtance produce any other metal than that which it originally compoſed.

26 Elements neceſſarily inviſible.

A little conſideration upon the ſubject of elements will convince us, not only that no ſuch bodies have ever yet been diſcovered, but that they never will; and for this plain reaſon, that they muſt be in their own nature inviſible.—The component parts of any ſubſtance may with propriety enough be called the elements of that ſubſtance, as long as we propoſe carrying the decompoſition no farther; but theſe elements have not the leaſt property reſembling any ſubſtance which they compoſe. Thus, it is found that the compound ſalt called *ſal ammoniac*, is formed by the union of an acid and an alkali: we may therefore properly enough call theſe two the elements of ſal ammoniac; but, taken ſeparately, they have not the leaſt reſemblance to the compound, which is formed out of them. Both the acid and alkali are by themſelves ſo volatile as to be capable of diſſipation into an inviſible vapour by the heat of one's hand; whereas, when joined together, they are ſo fixed as almoſt to endure a red heat without going off. If, again, we were to ſeek for the elements of the acid and alkali, we muſt not expect to find them have any properties reſembling either an acid or an alkali, but others quite different. Any common element of all bodies muſt therefore be a ſubſtance which has no property ſimilar to any other in the whole ſyſtem of nature, and conſequently muſt be imperceptible.

27 Suppoſition concerning phlogiſton.

To the abovementioned four elements, viz. fire, air, earth, and water, a kind of *fifth* element has generally been added, but not uſually diſtinguiſhed by that name, though it has apparently an equal, if not a greater, right to the title of an *element* than any of the others. This ſubſtance is called the *phlogiſton*, or inflammable principle; on which the ignition of all bodies depends. The exiſtence of this element was firſt aſſerted by Stahl, and from him the opinion has been derived to other chemiſts: but of late a new doctrine was broached by M. Lavoiſier, who denies the exiſtence of phlogiſton altogether. Though none of theſe ſubſtances therefore are properly the objects of chemiſtry, yet as they have ſo much ingroſſed the attention of modern chemiſts, we ſhall here give an account of the moſt remarkable theories that have appeared concerning them.

Of the Element of Fire.

Sect. I. *Of the Element of Fire.*

28 Two general theories of heat.

The opinions concerning the element of fire may be divided into two general claſſes; the one conſidering it as an effect, the other as a cauſe. The former is maintained by Lord Bacon, Mr Boyle, and Sir Iſaac Newton; whoſe reſpectable names for a long time gave ſuch a ſanction to this theory, that it was generally looked upon as an eſtabliſhed truth. Some learned men, however, among whom was the great Dr Boerhaave, always diſſented, and inſiſted that fire was a fluid univerſally diffuſed, and equally preſent in the frozen regions of Nova Zembla as in a glaſs-houſe furnace, only that in the latter its motion made it conſpicuous; and by ſetting it in motion in the coldeſt parts of the world, its previous exiſtence there would be equally demonſtrable as in the furnace abovementioned.

29 Lord Bacon's definition of heat.

Lord Bacon defines heat, which he uſes as a ſynonymous term with fire, to be an expanſive undulatory motion in the particles of a body, whereby they tend with ſome rapidity towards the circumference, and alſo a little upwards. Hence, if in any natural body you can excite a motion whereby it ſhall expand or dilate itſelf, and can repreſs and direct this motion upon itſelf in ſuch a manner that the motion ſhall not proceed uniformly, but obtain in ſome parts and be checked in others, you will generate heat or fire.

30 Mr Boyle's opinion

The ſame opinion is ſupported by Mr Boyle in the following manner: "The production of heat diſcovers nothing, either in the agent or patient, but motion, and its natural effects. When a ſmith briſkly hammers a ſmall piece of iron, the metal thereby becomes exceedingly hot: yet there is nothing to make it ſo, except the motion of the hammer impreſſing a vehement and variouſly determined agitation on the ſmall parts of the iron; which, being a cold body before, grows hot by that ſuperinduced motion of its ſmall parts: firſt, in a more looſe acceptation of the word, with regard to ſome other bodies, in compariſon of which it was cold before; then ſenſibly hot, becauſe the motion in the parts of the iron is greater than that in the parts of our fingers; at the ſame time that the hammer and anvil, by which the percuſſion is communicated, may, on account of their magnitude, remain cold. It is not neceſſary, therefore, that a body ſhould itſelf be hot in order to communicate heat to another."

31 Sentiments of Sir Iſaac Newton.

The arguments made uſe of by Sir Iſaac Newton are not intended poſitively to eſtabliſh any kind of theory relating to fire, but are to be found in a conjecture, publiſhed at the end of his Treatiſe on Optics, concerning the nature of the ſun and ſtars. "Large bodies (he obſerves) preſerve their heat the longeſt, their parts heating one another; and why may not great, denſe, and fixed bodies, when heated beyond a certain degree, emit light ſo copiouſly, as, by the emiſſion and reaction of it, and the reflections and refractions within the pores, to grow continually hotter, till they arrive at ſuch a period of heat as is that of the ſun? Their

parts

parts may be further preſerved from fuming away, not only by their fixity, but by the vaſt weight and denſity of the atmoſphere incumbent on them, ſtrongly compreſſing them, and condenſing the vapours exhaled from them. Thus we ſee, that warm water, in an exhauſted receiver, ſhall boil as vehemently as the hotteſt water expoſed to the air: the weight of the incumbent atmoſphere in this latter caſe keeping down the vapours, and hindering the ebullition till it has received its utmoſt degree of heat. Thus alſo a mixture of tin and lead, put on a red hot iron *in vacuo*, emits a fume and flame: but the ſame mixture in the open air, by reaſon of the incumbent atmoſphere, does not emit the leaſt ſenſible flame." In conſequence of theſe experiments, Sir Iſaac conjectures, that there is no eſſential diſtinction betwixt fire and groſs bodies; but that they may be converted into one another. "Fire (he ſays) is a body heated ſo hot as to emit light copiouſly; for what (ſays he) is a red hot iron but fire?"

32
Fire now generally allowed to be an element *per ſe*.

33
Two other theories inſtituted.

34
In what they differ from the former.

The hypotheſes of theſe great men produced long and violent diſputes, which were never deciſively ſettled: The diſcoveries in electricity, however furniſhed ſuch additional ſtrength to the followers of Dr Boerhaave, that fire is now believed to be an element and fluid diſtinct from all others, by at leaſt as many as eſpouſe the contrary ſyſtem; but the queſtion is not decided, Whether the fire itſelf is to be conſidered as the agent? or, Whether its action is to be derived from the principles of attraction and repulſion, the natural agents ſuppoſed to influence other material ſubſtances? This has produced two other ſyſtems of a kind of mixed nature, in which heat or fire is conſidered as a ſubſtance diſtinct from all others, but which acts in other bodies according to its *quantity*. Theſe ſyſtems have been promulgated by Dr Black of Edinburgh and Dr Irvine of Glaſgow. They differ from the opinions of Mr Boyle, Lord Bacon, and Sir Iſaac Newton, in ſuppoſing heat to be a fluid diſtinct from all other material ſubſtances; and they alſo differ from the hypotheſis of Dr Boerhaave, Lemery, and others, in ſuppoſing different terreſtrial ſubſtances to be hot according to the *quantity* of fluid contained, and not according to the force with which it moves in them.

35
General account of Dr Black's and Dr Irvine's theories.

Dr Black is of opinion that *heat*, which he ſeems to make ſynonymous with fire, exiſts in two different ſtates; in one of which it affects our ſenſes and the thermometer, in the other it does not. The former therefore he calls *ſenſible* heat, the later *latent* heat. On theſe principles he gives the only ſatisfactory explanation of the phenomena of evaporation and fluidity that has yet appeared, as ſhall afterwards be more fully explained. At preſent we ſhall only obſerve, that, according to the theory of Dr Black, heat or fire itſelf ſeems to be the agent; but, according to that of Dr Irvine, as far as we can gather it from the treatiſes of Dr Crawford and others, the principles of attraction and repulſion are the agents by which heat, as well as other bodies, is influenced. Thus, on the principles of Dr Black, we ſay, that water is converted into vapour by a quantity of heat entering into it in a *latent* ſtate, and thereby rendering it ſpecifically lighter than the atmoſphere; according to the principles of Dr Irvine, we ſay, that water is converted into vapour by having its capacity for attracting heat from the atmoſphere increaſed. So that, according to the former, the abſorption of heat is the *cauſe*; according to the latter, the *effect*, of its converſion into vapour.

36
Dr Irvine's theory explained by Dr Crawford.

37
Abſolute heat defined.

83
Relative heat.

Dr Crawford, in his Treatiſe on Heat, publiſhed in 1788, informs us, that *heat*, in the philoſophical ſenſe of the word, has been uſed to expreſs what is frequently called the *element of fire*, in the abſtract, without regard to the peculiar effects which it may produce in relation to other bodies. This, with Dr Irvine, he calls *abſolute* heat; and the external cauſe, as having a relation to the effects it produces, he calls *relative* heat. "From this view of the matter (ſays he), it appears, that *abſolute heat* expreſſes, in the abſtract, that *power* or *element* which, when it is preſent to a *certain* degree, excites in all animals the ſenſation of heat; and *relative* heat expreſſes the ſame power, conſidered as having a relation to the effects by which it is known and meaſured.

39
How divided.

40
Comparative heat defined.

"The effects by which heat is known and meaſured are three; and therefore relative heat may admit of three ſubdiviſions. 1. This principle is known by the peculiar ſenſations which it excites in animals. Conſidered as exciting thoſe ſenſations, it is called *ſenſible* heat. 2. It is known by the effect which it produces upon an inſtrument that has been employed to meaſure it, termed a *thermometer*. This is called the *temperature of heat in bodies*. 3. It has been found by experiment, that in bodies of different kinds the quantities of abſolute heat may be unequal, though the temperatures and weights be the ſame. When the principle of heat is conſidered relatively to the whole quantity of it contained in bodies of different kinds, but which have equal weights and temperatures, I ſhall term it *comparative heat*. If, for example, the temperatures and weights being the ſame, the whole quantity of heat in water be four times as great as that of antimony, the comparative heats of theſe ſubſtances are ſaid to be as four to one."

41
Experiments by which Dr Black was led to the diſcovery of latent heat.

42
A quantity of heat loſt in the melting of ice.

In order to have a proper conception of what is meant by a difference in abſolute heat, when the temperatures are the ſame, it will be neceſſary to relate ſome experiments, by which Dr Black was firſt led to the diſcovery of latent heat. He obſerves, that when two equal maſſes of the ſame matter, heated to different degrees, are mixed together, the heat of the mixture ought to be an arithmetical mean betwixt the two extremes. This, however, only takes place on mixing hot and cold water together; but if inſtead of cold water we take ice, the caſe is remarkably different. Here the temperature of the mixture is much below the arthmetical mean, and a quantity of heat is apparently loſt. Now we know that the temperature of ice newly frozen is generally 32 degrees of Fahrenheit; ſuppoſing therefore the temperature of the water which diſſolves it to be 120, the arithmetical mean is 71; but if the mixture indicates a temperature only of 60°, then we muſt ſuppoſe that the ice contained 11° of heat leſs than was indicated by the thermometer; and conſequently, that water at 32° contains 11° more of abſolute heat than ice at 32°.

43
Great quantity of heat produced by the condenſation of vapour.

The ſame thing is made ſtill more evident from the condenſation of vapour. The fluid of water is not capable of ſuſtaining a great degree of heat; and 212° of Fahrenheit is the utmoſt it can be made to bear, without an extraordinary degree of preſſure, as in Papin's digeſter, or the admixture of ſaline ſubſtances: the temperature of the ſteam emitted by it therefore never can exceed 212°, except in the caſes juſt mentioned; and it is often capable of bearing a great degree of cold without being condenſed. When the condenſation takes place at laſt, however, a very conſiderable degree of heat is always produced; and Dr Black has ſhown, that, in the condenſation of ſteam by the refrigeratory of a common ſtill, as much heat is communicated to the water in the refrigeratory as would be ſufficient to make the water which comes over as hot as red hot-iron, were it all to exiſt in a ſenſible ſtate.

44 Dr Black's method of calculating it.

His method of making the calculation is very eaſy. For, ſuppoſing the refrigeratory to contain 100 pounds of water, and that one pound has been diſtilled; if the water in the refrigeratory has received 10 degrees of heat, we know that the diſtilled pound has parted with 1000. If in paſſing through the worm of the refrigeratory, it has been reduced to the temperature of 50° of Fahrenheit, having been at 212° when it entered it, then it has loſt only 162° of ſenſible heat; all the reſt communicated to the water of the refrigeratory amounting to more than 800°, having been contained in a latent ſtate, and ſuch as could not then affect the thermometer.

45 Mr Watt's experiment on the diſtillation of water *in vacuo*

This experiment was tried by Mr Watt in a manner ſtill more ſtriking, by a diſtillation of water *in vacuo*. Thus the ſteam, freed from the preſſure of the atmoſphere, could not conceive ſuch a degree of ſenſible heat as in the common method of diſtilling. It came over therefore with a very gentle warmth, ſcarce more than what the hand could bear; nevertheleſs it had abſorbed as much heat as though the diſtillation had been performed in the common way; for the refrigeratory had 1000 degrees of heat communicated to it.

46 Difference of abſolute heat in different fluids.

47 Thinneſt fluids contain the greateſt quantity of heat.

The difference of abſolute heat is likewiſe perceptible betwixt any two bodies of different denſity, water and mercury for inſtance: and in comparing theſe, it will always be found that the thinneſt fluids contain the greateſt quantity of abſolute heat; as water more than mercury, ſpirit of wine, more than water, ether more than ſpirit of wine, and air more than any of them. Dr Black having brought equal bulks of mercury and water, the former to a temperature of 50 degrees higher than the latter, found that, on mixture, there was a gain of only 20 degrees above the original; but on reverſing the experiment, and heating the water 50 degrees above the mercury, there was a gain of 30 degrees on the whole.

48 Great difference betwixt the calculations of Drs Cleghorn and Crawford.

“Hence (ſays Dr Cleghorn in his theſis *de Igne*) it appears, that the quantity of heat in water is to that in mercury, when both are of equal temperatures, as 3 to 2.” Dr Crawford, however, tells us, that “the ſame quantity of heat which raiſes a pound of water one degree, will raiſe a pound of mercury 28 degrees; whence it follows, that the comparative heat of water is to that of mercury as 28 to 1: and conſequently, the alterations which are produced in the temperatures of bodies by given quantities of abſolute heat, may properly be applied as a meaſure of their comparative heats; the alterations of temperature and the comparative heats being reciprocally proportional to one another.

49 Crawford's account of ſenſible heat.

“Senſible heat (continues Dr Crawford) depends partly on the ſtate of the temperature, and partly on that of the organ of feeling; and therefore if a variation be produced in the latter, the ſenſible heat will be different, though the temperature continue the ſame. Thus water at the temperature of 62° of Fahrenheit appears cold to a warm hand immerſed in it; but on the contrary, that fluid will appear warm if a hand be applied to it which has a lower degree of heat than 62°. For this reaſon, the thermometer is a much more accurate meaſure of heat than the ſenſes of animals. As long, however, as the organs remain unchanged, the ſenſible heat is in proportion to the temperature; and therefore thoſe terms have generally been conſidered as ſynonymous.

50 Dr Reid's obſervation concerning temperatures.

On this ſubject Dr Reid obſerves, that until the ratio between one temperature and another be aſcertained by experiment and induction, we ought to conſider temperature as a meaſure which admits of degrees, but not of ratios; and conſequently ought not to conclude, that the temperature of one body is double or triple to that of another, unleſs the ratio of different temperatures were determined. Nor ought we to uſe the expreſſions of a *double* or *triple* temperature, thoſe being expreſſions which convey no diſtinct meaning until the ratio of different temperatures be determined.”

51 Difference betwixt the calculations of Drs Crawford and Black.

In making experiments on the comparative quantities of heat in different bodies, our author chooſes rather to uſe equal *weights* than equal *bulks* of the ſubſtances to be compared. Thus he found the comparative heat of water to be to that of mercury as 28 to 1 by weight, and 2 to 1 by bulk; which differs very conſiderably from the concluſion of Dr Black, who makes it only as 3 to 2, as has been already mentioned.

52 Capacities for containing heat explained.

From the differences obſerved in the quantities of abſolute heat contained in different bodies, our author concludes, that “there muſt be certain eſſential differences in the nature of bodies; in conſequence of which, *ſome* have the power of collecting and retaining that element in greater quantity than *others*.” Theſe different powers he calls the *capacities* for containing heat. Thus, if we find by experiment that a pound of water contains four times as much abſolute heat as diaphoretic antimony, when at the ſame temperature, the capacity of water for containing heat is ſaid to be to that of animony as 4 to 1.

53 How the capacity, temperature, and abſolute heat, are to be diſtinguiſhed.

“The temperature, the capacity for containing heat, and the abſolute heat contained, may be diſtinguiſhed from each other in the following manner.

“The capacity for containing heat, and the abſolute heat contained, are diſtinguiſhed as a force diſtinct from the ſubject upon which it operates. When we ſpeak of the capacity, we mean a power inherent in the heated body; when we ſpeak of the abſolute heat, we mean an unknown principle which is retained in the body by the operation of this power; and when we ſpeak of the temperature, we conſider the unknown principle as producing certain effects upon the thermometer.

“The capacity for containing heat may continue unchanged, while the abſolute heat is varied without end. If a pound of ice, for example, be ſuppoſed to retain its ſolid form, the quantity of its abſolute heat will be altered by every increaſe or diminution of its ſenſible heat: but as long as its form continues the ſame, its capacity for receiving heat is not affected by an an alteration of temperature, and would remain unchanged though the body were wholly deprived of its heat."

54
Crawford's opinion concerning heat in the abſtract.

In the courſe of his work, Dr Crawford obſerves, that "he has not entered into the inquiry which has been ſo much agitated among the Engliſh, the French, and the German philoſophers, Whether heat be a *ſubſtance* or a *quality*? In ſome places indeed he has uſed expreſſions which ſeem to favour the former opinion; but his ſole motive for adopting theſe was, becauſe the language ſeemed to be more ſimple and natural, and more conſonant to the facts which had been eſtabliſhed by experiment. At the ſame time, he is perſuaded that it would be a very difficult matter to reconcile many of the phenomena with the ſuppoſition that heat is a *quality*. It is not eaſy to conceive, upon this hypotheſis, how heat can be abſorbed in the proceſſes of fuſion, evaporation, combuſtion; how the quantity of heat in the air can be diminiſhed, and that in the blood increaſed, by reſpiration, though no ſenſible heat or cold be produced.

"Whereas, if we adopt the opinion that heat is a diſtinct ſubſtance, or an element *ſui generis*, the phenomena will be found to admit of a ſimple and obvious interpretation.

55
Fire contained in bodies partly by its attraction to them, and partly by the preſſure of the external fluid.

"Fire will be conſidered as a principle; which is diſtributed in various proportions throughout the different kingdoms of nature. The mode of its union with bodies will reſemble that particular ſpecies of union, wherein the elements are combined by the joint forces of preſſure and attraction. Of this kind is the combination of fixed air and water; for fixed air is retained in water partly by its attraction for that fluid, and partly by the preſſure of the external air; and if either of theſe forces be diminiſhed, a portion of the fixed air eſcapes. In like manner, it may be conceived that elementary fire is retained in bodies, partly by its attraction to theſe bodies, and partly by the action of the ſurrounding heat; and in that caſe a portion of it will be diſengaged, either by diminiſhing the attractive force, or by leſſening the temperature of the circumambient medium. If, however, fire be a ſubſtance which is ſubject to the laws of attraction, the mode of its union with bodies ſeems to be different from that which takes place in chemical combination: for, in chemical combination, the elements acquire new properties, and either wholly or in part loſe thoſe by which they were formerly characterized. But we have no ſufficient evidence for believing that fire, in conſequence of its union with bodies, does, in any inſtance, loſe its diſtinguiſhing properties."

56
Dr Berkenhout's opinion concerning the nature of heat.

Dr Berkenhout, in his firſt Lines of the Theory and Practice of Philoſophical Chemiſtry, informs us, that "heat, or the *matter of heat*, is by Scheele and Bergman ſubſtituted for fire, which they believe to be the action of heat when increaſed to a certain degree. The firſt of theſe celebrated chemiſts believed this *matter of heat* to be a compound of phlogiſton and pure air. He was certainly miſtaken. It ſeems more philoſophical to conſider heat as an *effect*, of which fire is the ſole cauſe.

57
His diviſion of fire into fixed and volatile.

"Heat I conſider not as a diſtinct ſubſtance, but as an effect of fire, fixed or volatile; in both which ſtates fire ſeems to exiſt in all bodies, ſolid and fluid. Fixed fire I believe to be a conſtituent part of all bodies, and their ſpecific heat to depend on the quantity of fixed fire in each. This fixed, this latent fire, cannot be ſeparated from the other conſtituent parts of bodies but by their decompoſition: it then becomes volatile and incoercible. If this hypotheſis be true, fire exiſts, in all natural bodies that contain phlogiſton, in three different ſtates: 1. In that volatile ſtate in which it perpetually fluctuates between one body and another. 2. Combined with an acid, probably in the form of fixed inflammable air or phlogiſton. 3. Uncombined and fixed, as a conſtituent principle, determining the ſpecific heat of bodies.

58
Pure or volatile fire defined.

"Pure (or volatile) fire is diſtinguiſhed by the following properties. 1. It is eſſentially fluid, inviſible, and without weight. 2. It is the immediate cauſe of all fluidity. 3. It penetrates and pervades all bodies on the ſurface of the earth, and as far beneath the ſurface as hath hitherto been explored. Water hath never been found in a congealed ſtate in the deepeſt mines. 4. It has a conſtant tendency to diffuſe itſelf equally through all bodies, howſoever different in point of denſity. A marble ſlab, a plate of iron, a decanter of water, and a lady's muff, at the ſame diſtance from the fire, and other external circumſtances, being equal, poſſeſs an equal degree of heat, which is preciſely that of the atmoſphere in which they ſtand. 5. It is perpetually in motion from one body to another, and from different parts of the ſame body, becauſe external circumſtances are continually varying. 6. In fluctuating from one body to another, it produces a conſtant vibration of their conſtituent parts; for all bodies expand and contract in proportion to the quantity of fire they contain. 7. Accumulated beyond a certain quantity, it effects the diſſolution of bodies, by forcing their conſtituent parts beyond the ſphere of mutual attraction, called the *attraction of coheſion*, which is the cauſe of ſolidity. Hence the ſoveriegn agency of fire in chemical operations."

59
Dr Crawford's definition of fire.

Dr Crawford, beſides the opinions already quoted, tells us, that fire, in the vulgar acceptation of the word, expreſſes a certain degree of heat accompanied with light; and is particularly applied to that heat and light which are produced by the inflammation of combuſtible bodies. But as heat, when accumulated in a ſufficient quantity, is conſtantly accompanied with light; or, in other words, as fire is always produced by the increaſe of heat, philoſophers have generally conſidered theſe phenomena as proceeding from the ſame cauſe: and have therefore uſed the word *fire* to expreſs that unknown principle, which, when it is preſent to a certain degree, excites the ſenſation of heat alone; but, when accumulated to a greater degree, renders itſelf obvious both to the ſight and touch, or produces heat accompanied with light. In this ſenſe, the element of fire ſignifies the ſame thing with *abſolute heat*.

Having premiſed theſe general definitions and remarks, he gives the properties of heat in the following words:

60
Heat has a tendency to diffuſe itſelf equally over bodies.

"I. Heat has a conſtant tendency to diffuſe itſelf over all bodies till they are brought to the ſame temperature. Thus it is found by the thermometer, that if two bodies of different temperatures are mixed together, or placed contiguous, the heat paſſes from the one to the other till their temperatures become equal;

and

and that all inanimate bodies, when heated and placed in a cold medium, continually loſe heat, till in proceſs of time they are brought to the ſtate of the ſurrounding medium.

" From this property of heat it follows, that the various claſſes of bodies throughout the earth, if they were not acted upon by external cauſes, would at length, arrive at a common temperature when the heat would become quieſcent; in like manner as the waters of the ocean, if not prevented by the winds and by the attractions of the ſun and moon, would come to an equilibrium, and would remain in a ſtate of reſt. But as cauſes continually occur in nature to diſturb the balance of heat as well as that of the waters of the ocean, thoſe elements are kept in a conſtant fluctuation.

61
It is contained in conſiderable quantity in all bodies.

" II. Heat is contained in conſiderable quantities in all bodies when at the common temperature of the atmoſphere.

62
Great degree of cold at Glaſgow,

" From the intereſting experiments which were made on cold by Mr Wilſon, we learn, that at Glaſgow, in the winter of the year 1780, the thermometer on the ſurface of ſnow ſunk 25 degrees below the beginning of Fahrenheit's ſcale.

63
In Siberia, and at Hudſon's bay.

" We are told by Dr Pallas, that in the deſerts of Siberia, during a very intenſe froſt, the mercury was found congealed in thermometers expoſed to the atmoſphere, and a quantity of that fluid in an open bowl placed in a ſimilar ſituation, at the ſame time became ſolid. The deciſive experiments of Mr Hutchins at Hudſon's Bay prove, that the freezing point of mercury is very nearly 40° below the *zero* (or 0°) of Fahrenheit. From which it follows, that at the time of Dr Pallas's obſervation, the atmoſphere in Siberia muſt have been cooled to minus 40. By a paper lately tranſmitted to the Royal Society we are informed, that the ſpirit-of-wine thermometer in the open air at Hudſon's Bay fell to — 42 in the winter of 1785; and from the ſame communication we learn, that by a mixture of ſnow and vitriolic acid, the heat was ſo much diminiſhed, that the ſpirit of wine ſunk to — 80, which is 112 below the freezing point of water.

64
Quantity of heat limited in all bodies.

" Hence it is manifeſt, that heat is contained in conſiderable quantities in all bodies when at the common temperature of the atmoſphere. It is plain, however, that the quantity inherent in each individual body is limited. This, I think, muſt be admitted, whatever be the hypotheſis which we adopt concerning the nature of heat; whether we conceive it to be a force or power belonging to bodies, or an elementary principle contained in them. For thoſe who conſider heat as an element, will not ſuppoſe that an unlimited quantity of it can be contained in a finite body; and if heat be conſidered as a force or power, the ſuppoſition that finite bodies are actuated by forces or powers which are infinite is equally inadmiſſible.

65
Bodies univerſally expanded by heat.

" To place this in another light, we know that bodies are univerſally expanded by heat, excepting in a very few inſtances, which do not afford a juſt objection to the general fact; becauſe, in thoſe inſtances, by the action of heat a fluid is extricated that previouſly ſeparated the particles from each other. Since, therefore, heat is found to expand bodies in the temperatures which fall within the reach of our obſervation, we may conclude that the ſame thing takes place in all temperatures."

66
Expanſion of mercury, &c. proportionable to the degrees of heat.

Our author, by a ſet of very accurate and laborious experiments, determines that the expanſions in mercury and ſome other fluids are proportionable to the quantities of heat applied; " from which (ſays he) it is manifeſt, that the quantities of heat in bodies are limited, becauſe an infinite heat would produce an infinite expanſion.

" It is manifeſt, that the number of degrees of ſenſible heat, as meaſured by the thermometer, and eſtimated from the beginning of the ſcale, muſt be the ſame in all bodies which have a common temperature; for by the firſt general fact it is proved, that heat has a conſtant tendency to diffuſe itſelf uniformly over bodies till their temperatures become equal. From which it may be inferred, that if a quantity of heat were added to bodies abſolutely cold, the ſame uniform diffuſion would take place; and that if a thermometer, altogether deprived of its heat, were applied to ſuch bodies, it would be equally expanded by them, the whole of the ſenſible heat which they had acquired being indicated by that expanſion.

67
Homogeneous bodies of the ſame temperature, contain quantities of heat proportionable to thoſe of their matter.

" III. If the parts of the ſame homogeneous ſubſtance have a common temperature, the quantity of abſolute heat will be proportional to the bulk or quantity of matter. Thus the quantity of abſolute heat in two pounds of water is double that which is contained in one pound when at the ſame temperature.

" IV. The dilatations and contractions of the fluid in the mercurial thermometer are nearly proportional to the quantities of abſolute heat which are communicated to the ſame homogeneous bodies, or ſeparated from them, as long as they retain the ſame form. Thus the quantity of heat required to raiſe a body four degrees in temperature by the mercurial thermometer, is nearly double that which is required to raiſe it two degrees, four times that required to raiſe it one degree, and ſo in proportion."

68
Mr Kirwan's opinion concerning fire.

69
Mr Cavendiſh's opinion that it is not a diſtinct ſubſtance.

70
Difficulty in defining the phraſe *quantity of heat*.

Thus we find, that Dr Black, Dr Irvine, Dr Crawford, and Dr Berkenhout, agree in ſpeaking of fire or heat as a fluid ſubſtance diſtinct from all other bodies. Mr Kirwan, in his Treatiſe of Phlogiſton, agrees in the ſame opinion. " Some (ſays he) have thought, that I ſhould have included the matter of heat, or elementary fire, in the definition of inflammable air; but as fire is contained in all corporeal ſubſtances, to mention it is perfectly needleſs, except where bodies differ from each other in the quantity of it they contain." On the other hand, Mr Cavendiſh, Phil. Tranſ. lxxiv. P. 141. tells us, that " he thinks it more likely that there is no ſuch thing as elementary heat:" but, as he gives no reaſon for this opinion, it ſeems probable that the greater part of philoſophers either poſitively believe that heat is an elementary fluid diſtinct from all others, or find themſelves obliged to adopt a language which neceſſarily implies it. The only difficulty which now remains therefore is, to affix a proper idea to the phraſe *quantity of heat*, which we find univerſally made uſe of, without any thing to determine our opinions concerning it.

71
This phraſe cannot be uſed in the common acceptation of the word with regard to fire.

That we cannot ſpeak of a *quantity* of fire or heat in the ſame ſenſe as we ſpeak of a quantity of water or any other fluid is evident, becauſe we can take away the quantity of water which any ſubſtance contains, but cannot do ſo with heat. Nay, in many caſes we are ſure, that a ſubſtance very cold to the touch does yet

yet contain a very conſiderable quantity of heat. The vapour of water, for inſtance, may be made much colder than the uſual temperature of the atmoſphere without being condenſed, when at the ſame time we are certain that it contains a great quantity of heat; and the ſame may be ſaid of water, which, in the act of freezing, throws out a great quantity of heat without becoming colder; and in the act of melting abſorbs as much without becoming warmer. It is not therefore by the mere preſence or abſence of this fluid that we can determine the real quantity of this fluid; nor does it appear that the word *quantity* can be at all accurately applied to the element itſelf, becauſe we have no method of meaſuring it.

72
Dr Cleghorn's opinion.

Dr Cleghorn, in his inaugural diſſertation *De Igne* throws ſome light on this ſubject, by obſerving, that "the thermometer ſhows only the quantity of heat *going out* of a body, not that which is really contained in it:" and he alſo inſiſts, that "we can neither aſſent to the opinion of Dr Boerhaave, who ſuppoſed that heat was diſtributed among bodies in proportion to their bulks; nor to the hypotheſis of others, who imagined that they were heated in proportion to their denſities." But in what proportion, then, are they heated; or how are we to meaſure the *quantity* which they really contain, ſeeing the thermometer informs us only of what they part with?

73
The latent heat of bodies cannot be meaſured.

As this point is by no means aſcertained, we cannot form a direct idea concerning the abſolute quantity of heat contained in any body; and therefore when we ſpeak of quantities of this fluid, we muſt in fact, if we mean any thing, think of the ſenſible quantity flowing out of them; and though we ſhould ſuppoſe the whole of this ſenſible heat to be removed, it would ſtill be impoſſible for us to know how much remained in a latent ſtate, and could not be diſſipated.

74
Dr Cleghorn's hypotheſis concerning fire.

This difficulty will ſtill appear the greater, if with Dr Cleghorn and others we ſuppoſe the fluid of heat to be ſubject to the laws of attraction and repulſion. This gentleman ſuppoſes, that the particles of heat (like the particles of electric fluid according to the Franklinian hypotheſis) are repulſive of one another, but attracted by all other ſubſtances. "If any body (ſays he), heated beyond the common temperature of the air, is expoſed to it, the heat flows out from it into the atmoſphere, and diffuſes itſelf equally all around till the air becomes of the ſame temperature with itſelf. The ſame happens to bodies ſuſpended *in vacuo*. Hence it is juſtly concluded, that there exiſts between the particles of heat a repulſive power, by which they mutually recede from each other. Notwithſtanding this repulſive power, however, the quantities of heat contained in different ſubſtances, even of the ſame temperature, are found to be altogether different; and from Dr Black's experiments it now appears, that the quantity of heat is ſcarce ever the ſame in any two different bodies: and hence we may conclude, that terreſtrial bodies have a power of attracting heat, and that this power is different in different ſubſtances.—From theſe principles it evidently follows, that heat is diſtributed among bodies directly in proportion to their attracting powers, and inverſely according to the repulſive power between the particles of heat themſelves.

75
Equilibrium of heat defined.

Such is the diſtribution of heat among bodies in the neighbourhood of each other; and which is called the *equilibrium of heat*, becauſe the thermometer ſhows no difference of temperature among them. For ſeeing the heat is diſtributed according to the attracting power of each, the thermometer having alſo a proper attraction of its own, can ſhow no difference in the attracting power of each; for which reaſon all bodies in the neighbourhood of each other are ſoon reduced to the ſame temperature."

76
The quantity of heat cannot be determind by this hypotheſis.

If we aſſent to Dr Cleghorn's hypotheſis, the quantity of heat contained in any ſubſtance depends, in the firſt place, on the attracting power of that ſubſtance, which is altogether unknown; and, in the ſecond place, on the repulſive powers of the particles of heat themſelves, which are equally unknown. To determine the *quantity*, therefore, muſt be impoſſible. Neither will the mixture of two different fluids, as in Dr Black's experiments, aſſiſt us in the leaſt; for though water, heated more than mercury, communicates a greater heat to that fluid than the latter does to water; this only ſhows that water more readily parts with ſome part of the heat it contains than mercury does, but has not the leaſt tendency to diſcover the quantity contained in either.

77
Dr Crawford's method of determining the proportional quantities of heat.

Dr Crawford, as we have already ſeen, calls the *degree*, or, if we may vary the phraſe, the *quantity of power* or *element (fluid*, if we may ſubſtitute a ſynonymous word) exiſting or preſent in any body, its *abſolute heat*; and lays down a rule for determining the proportional quantities of heat in different bodies. "It will appear (ſays he) from the experiments afterwards recited, that if a pound of water and a pound of diaphoretic antimony have a common temperature, the quantity of abſolute heat contained in the former is nearly four times that contained in the latter."—The manner in which he illuſtrates this is as follows.

"If four pounds of diaphoretic antimony at 20 be mixed with one pound of ice at 32, the temperature will be nearly 26: the ice will be cooled ſix degrees, and the antimony heated ſix. If we reverſe the experiment, the effect will be the ſame. That is, if we take ſix degrees of heat from four pounds of antimony, and add it to a pound of ice, the latter will be heated ſix degrees. The ſame quantity of heat, therefore, which raiſes a pound of ice ſix degrees, will raiſe four pounds of antimony ſix degrees.

"If this experiment be made at different temperatures, we ſhall have a ſimilar reſult. If, for example, the antimony at 15, or at any given degree below the freezing point, be mixed with the ice at 32, the heat of the mixture will be the arithmetical mean between that of the warmer and colder ſubſtance. And ſince the capacities of bodies are permanent as long as they retain the ſame form, we infer, that the reſult would be the ſame if the antimony were deprived of all its heat, and were mixed with the ice at 32. But it is evident, that in this caſe the ice would communicate to the antimony the half of its abſolute heat. For if 200 below froſt be conceived to be the point of total privation, the antimony will be wholly deprived of its heat when cooled to 200 degrees below 32, and the heat contained in the ice when at 32 will be 200 degrees. If we now ſuppoſe them to be mixed together, the temperature of the mixture will be half the exceſs of the hotter above the colder, or the ice will be cooled 100 degrees and the antimony heated 100. The one half of the heat, therefore, which was contained in the ice previous to the mixture will be communicated to the antimony; from which it is manifeſt, that after the mixture the ice and antimony muſt contain equal quantities of abſolute heat.

"To place this in another light, it has been proved, that the ſame quantity of heat which raiſes a pound of ice ſix degrees will raiſe four pound of antimony ſix degrees. And as the capacities of bodies, while they retain the ſame form, are not altered by a change of temperature; it follows, that the ſame quantity of heat which raiſes the ice 200 degrees, or any given number of degrees, will raiſe the antimony an equal number of degrees.

"A pound of ice, therefore, and four pounds of antimony, when at the ſame temperature, contain equal quantities of abſolute heat. But it appears from the third general fact (n° 67.), that four pounds of antimony contain four times as much abſolute heat as one pound of antimony; and hence the quantity of abſolute heat in a pound of ice is to that in a pound of antimony as four to one."

78 His method inſufficient.

From this quotation it is evident, that, notwithſtanding all the diſtinctions which Dr Crawford has laid down betwixt abſolute heat and temperature, it is only the *quantity* of the latter that can be meaſured; and all that we can ſay concerning the matter is, that when certain bodies are mixed together, ſome of them part with a greater quantity of heat than others; but how much they *contain* muſt remain for ever unknown, unleſs we can fall on ſome method of meaſuring the quantity of heat as we do that of any other fluid.

79 Nicholſon's account of the theories of heat.

Mr Nicholſon, who has collected the principal opinions on the ſubject of heat, ſeems undetermined whether to believe the doctrine of Boyle or of Boerhave on the ſubject. "There are two opinions (ſays he) concerning heat. According to one opinion, heat conſiſts in a vibratory motion of the parts of bodies among each other, whoſe greater or leſs intenſity occaſions the increaſe or diminution of temperature. According to the other opinion, heat is a ſubtile fluid that eaſily pervades the pores of all bodies, cauſing them to expand by means of its elaſticity or otherwiſe. Each of theſe opinions is attended with its peculiar difficulties. The phenomena of heat may be accounted for by either of them, provided certain ſuppoſitions be allowed to each reſpectively; but the want of proof of the truth of ſuch ſuppoſitions renders it very difficult, if not impoſſible, to decide as yet whether heat conſiſts merely in motion or in ſome peculiar matter. The word *quantity*, applied to heat, will therefore denote either motion or matter, according to the opinion made uſe of, and may be uſed indefinitely without determining which.

80 Advantages of the doctrine that heat is cauſed by vibration,

"The chief advantage which the opinion that heat is cauſed by mere vibration poſſeſſes, is its great ſimplicity. It is highly probable, that all heated bodies have an inteſtine motion, or vibration of their parts; and it is certain that percuſſion, friction, and other methods of agitating the minute parts of bodies, will likewiſe increaſe their temperature. Why, then, it is demanded, ſhould we multiply cauſes, by ſuppoſing the exiſtence of an unknown fluid, when the mere vibration of parts which is known to obtain may be applied to explain the phenomena?"

81 Anſwer to Mr Nicholſon's argument.

To this the reply is obvious, that the vibration of parts is an *effect*; for matter will not begin to move of itſelf: and if it is an effect, we muſt ſuppoſe a cauſe for it; which, though we ſhould not call it a fluid, would be equally unknown and inexplicable with that whoſe exiſtence is aſſerted by thoſe who maintain that fire is a fluid *per ſe*. Dr Cleghorn, however, in the diſſertation already quoted, aſſerts, that "heat is occaſioned by a certain fluid, and not by motion alone, as ſome eminent writers have imagined: becauſe, 1. Thoſe who have adopted the hypotheſis of motion could never even prove the exiſtence of that motion for which they contended; and though it ſhould be granted, the phenomena could not be explained by it. 2. If heat depended on motion, it would inſtantaneouſly paſs through an elaſtic body; but we ſee that heat paſſes through bodies ſlowly like a fluid. 3. If heat depended on vibration, it ought to be communicated from a given vibration in proportion to the quantity of matter; which is found not to hold true in fact. On the other hand, there are numberleſs arguments in favour of the opinion that heat proceeds from elementary fire. 1. Mr Locke hath obſerved, that when we perceive a number of qualities always exiſting together, we may gather from thence that there really is ſome ſubſtance which produces theſe qualities. 2. The hypotheſis of elementary fire is ſimple and agreeable to the phenomena. 3. From ſome experiments made by Sir Iſaac Newton, it appears, that bodies acquire heat and cold *in vacuo*, until they become of the ſame temperature with the atmoſphere; ſo that heat exiſts in the abſence of all other matter, and is therefore a ſubſtance by itſelf."

82 Dr Cleghorn's proof that heat is occaſioned by a fluid.

83 Difficulties concerning the nature and properties of Fire.

But though theſe and other arguments ſeem clearly to eſtabliſh the point that fire or heat is a diſtinct fluid, we are ſtill involved in very great difficulties concerning its nature and properties. If it be ſuppoſed a fluid, it is impoſſible to aſſign any limits to its extent; and we muſt of neceſſity likewiſe ſuppoſe that it pervades the whole creation, and conſequently conſtitutes an abſolute plenum, contrary to a fundamental principle of the received ſyſtem of natural philoſophy. But if this is the caſe, it is vain to talk of its being abſorbed, accumulated, collected, or attracted by different bodies, ſince it is already preſent in all points of ſpace; and we can conceive of terreſtrial bodies no otherwiſe than as ſponges thrown into the ocean, each of which will be as full of fluid as it can hold. The different capacities will then be ſimilar to the differences between bits of wood, ſponge, porous ſtones, &c. for containing water; all of which depend entirely on the ſtructure of the bodies themſelves, and which, unleſs we could ſeparate the water by preſſure, or by evaporation, would be for ever unknown. Suppoſing it were impoſſible to collect this water in the manner we ſpeak of, we could only judge of the quantity they contained by the degree to which they ſwelled by being immerſed in it. It is eaſy to ſee, however, that ſuch a method of judging would be very inadequate to the purpoſe, as ſubſtances might contain internal cavities or pores in which water could lodge without augmenting the external bulk. This would ſuggeſt another method of judging of the quantity, namely, the ſpecific gravity;

vity ; and we might reaſonably ſuppoſe, that ſubſtances of the greateſt ſpecific gravity would contain the ſmalleſt quantity of water, though ſtill we could by no means determine what quantity they did contain, unleſs we could lay hold of the element itſelf.

This ſeems to be very much the caſe with elementary fire, if we ſuppoſe it to be a fluid *per ſe*. We judge of its preſence by the degree of expanſion which one heated body communicates to another : but this is only ſimilar to the calculation of the quantity of moiſture a ſponge or any other body contains, by what it communicates to wood when it comes into contact with it ; which never could be ſuppoſed to carry the leaſt pretenſions to accuracy, though we ſhould aſcertain it with all imaginable exactneſs. It is likewiſe probable, that the moſt denſe bodies contain the ſmalleſt quantity of fire, as they generally communicate leſs when heated to an equal temperature than thoſe which are more rare, though we are far from having any perfect knowledge in this reſpect.

84
Difficulty ariſing from the ſuppoſition that heat diffuſes itſelf equally.

But the greateſt difficulty of all will be, on the ſuppoſition that heat is a fluid, and an omnipreſent one (which it muſt be, or there would be ſome places where bodies could not be heated), to anſwer the queſtion, Why are not all bodies of an equal temperature, excepting only the differences ariſing from their ſpecific denſities, which render ſome capable of containing a greater quantity than others ?—The difficulty will not be leſſened, though the omnipreſence of the fluid ſhould be given up, if we ſuppoſe, as is generally done, that heat has a tendency to diffuſe itſelf equably every way. If it has this tendency, what hinders it from doing ſo ? Why doth not the heat from the burning regions of the torrid zone diffuſe itſelf equally all over the globe, and reduce the earth to one common temperature ? This indeed might require time ; but the experience of all ages has ſhown that there is not the leaſt advance towards an equality of temperature. The middle regions of the earth continue as hot, and the polar ones as cold, as we have any reaſon to believe they were at the creation of the world, or as we have any reaſon to believe they will be while the world remains. This indeed is one of the many inſtances of the impropriety of eſtabliſhing general laws from the trifling experiments we are capable of making, and which hold good only on the narrow ſcales on which we can make them, but are utterly inſufficient to ſolve the phenomena of the great ſyſtem of nature, and which can be ſolved only by obſerving other phenomena of the ſame ſyſtem undiſturbed by any manoeuvres of our own.

85
Another from the ſeeming diſappearance of the heat.

86
Dr Crawford's ſolution.

Again, ſuppoſing the objection already made could be got over, and ſatisfactory reaſons ſhould be given why an equilibrium of temperature in the earth and its atmoſphere ſhould never be obtained, it will by no means be eaſy to tell what becomes of the heat which is communicated to the earth at certain times of the year. This difficulty, or ſomething ſimilar, Dr Crawford ſeems to have had in view when treating of the effects of the evolution and abſorption of heat. Thus, ſays he, “ the Deity has guarded againſt ſudden viciſſitudes of heat and cold upon the ſurface of the earth.

“ For if heat were not evolved by the proceſs of congelation, all the waters which were expoſed to the influence of the external air, when its temperature was reduced below 32°, would ſpeedily become ſolid ; and, at the moment of congelation, the progreſs of cooling would be as rapid at it was before the air had arrived at its freezing point.

“ This is manifeſt from what was formerly obſerved reſpecting the congelation of different fluids. It was ſhown, that if the velocities of the ſeparation of heat were equal, the times of the congelation would be in proportion to the quantities of heat which the fluids gave off from an internal ſource in the freezing proceſs. Whence it follows, that if no heat were evolved, the congelation ſhould be inſtantaneous.

“ In the preſent ſtate of things, as ſoon as the atmoſphere is cooled below 32°, the waters begin to freeze, and at the ſame time to evolve heat ; in conſequence of which, whatever may be the degree of cold in the external air, the freezing maſs remains at 32°, until the whole is congealed ; and as the quantity of heat extricated in the freezing of water is conſiderable, the progreſs of congelation in large maſſes is very ſlow.—That the abſorption and extrication of heat in the melting and freezing of bodies has a tendency to retard the progreſs of theſe proceſſes, is remarked by Mr Wilkie in his eſſay on latent Heat.—The ſame doctrine is likewiſe taught by Dr Black in his lectures.

87
Severity of the cold in the northern regions mitigated by the production of ice.

“ In the northern and ſouthern regions, therefore, upon the approach of winter, a quantity of elementary fire is extricated from the waters, proportional to the degree of cold that prevails in the atmoſphere. Thus the ſeverity of the froſt is mitigated, and its progreſs retarded ; and it would ſeem that, during this retardation of the cooling proceſs, the various tribes of animals and vegetables which inhabit the circumpolar regions gradually acquire power of reſiſting its influence.

88
Inundations prevented by the ſlowneſs with which congealed water melts.

“ On the contrary, if, in the melting of ice, a quantity of heat were not abſorbed, and rendered inſenſible, that ſubſtance, when it was expoſed to a medium warmer than 32°, would ſpeedily become fluid, and the proceſs of heating would be as rapid as if no alteration in its form had taken place. If things were thus conſtituted, the vaſt maſſes of ice and ſnow which are collected in the frigid zones would, upon the approach of ſummer, ſuddenly diſſolve, and great inundations would annually overflow the regions near to the poles.

“ But by the operation of the law of the abſorption of heat, when the ice and ſnow upon the return of ſpring have arrived at 32°, they begin to melt, and at the ſame time to imbibe heat : during this proceſs, a large quantity of elementary fire becomes inſenſible ; in conſequence of which the earth is ſlowly heated, and thoſe gradual changes are produced which are eſſential to the preſervation of the animal and vegetable kingdoms.

89
Equal diſtribution of heat promoted by its abſorption and evolution.

“ We may remark, in the laſt place, that this law not only reſiſts ſudden changes of temperature, but that it likewiſe contributes to a more equal diſtribution of the principle of heat throughout the various parts of the earth, in different ſeaſons and climates. Thus the diurnal heats are moderated by the evaporation of the waters on the earth's ſurface, a portion of the fire derived from the ſun being abſorbed and extinguiſhed by the vapours at the moment of their aſcent. On the approach of night the vapours are again condenſed, and falling in the form of dew, communicate to the air and to the earth the fire which they had imbibed during the day.

"It was before ſhown, that, in the regions near to the poles, when the vernal and ſummer heats prevail, proviſion is made for tempering the ſeverity of the winter cold, a quantity of elementary fire, upon the diſſolution of the ice and ſnow, being abſorbed by the waters, and depoſited, as it were, in a great magazine for the purpoſe of mitigating the intenſity of the cold when the froſt returns.

90 Heat of the torrid zone thus mitigated.

"From the experiments of Hales, Halley, and Watſon, it appears, that vaſt quantities of water are continually converted into vapour by the action of the ſolar rays upon the portion of the earth's ſurface which is expoſed to the light; and by the celebrated diſcovery of Dr Black, it is proved, that, in the proceſs of evaporation, much elementary fire is abſorbed. It is manifeſt, that this cauſe will have a powerful influence in mitigating the intenſity of the heat in the torrid zone, and in promoting a more equal diffuſion of it through the earth. For a conſiderable portion of the heat, which is excited by the action of the ſolar rays upon the earth's ſurface within the tropics, is abſorbed by the aqueous vapours, which being collected in the form of clouds, are ſpread like a canopy over the horizon, to defend the ſubjacent regions from the direct rays of the ſun. A great quantity of elementary fire is thus rendered inſenſible in the torrid zone, and is carried by the diſperſion of the vapours to the north and to the ſouth, where it is gradually communicated to the earth when the vapours are condenſed."

91 This ſolution totally inſufficient to remove the difficulty.

That all this takes place, as the Doctor has advanced, cannot be denied; but, by allowing it, the difficulty is not removed in the ſmalleſt degree, as will appear from a due conſideration of the phenomena which he himſelf has mentioned. He owns that the ſun communicates fire to the earth: the queſtion is, What becomes of it, ſeeing the emiſſion is continual? In ſummer, the air, the earth, and the water, are heated to a certain degree. On the ſun's declining ſouthward, the air firſt loſes its heat. Whither does it go? It does not aſcend into the higher regions of the atmoſphere, for theſe are conſtantly found colder than the parts below. It does not deſcend to the earth and water; for theſe give out the quantity they had abſorbed, as Dr Crawford obſerves. Neither does it go laterally to the ſouthern regions; for they are conſtantly very hot, and ought to impart their heat to thoſe farther north, inſtead of receiving any from them. How comes it then, that the atmoſphere ſeems perpetually to receive heat without ever being ſatiated? or if the heat cannot be found going off either upwards, downwards, or ſideways, how are we to account for its diſappearance?

92 Heat moſt probably the action of an omnipreſent fluid.

This queſtion ſeems to be altogether unanſwerable on the ſuppoſition that heat is occaſioned by the mere preſence of a fluid; but if we ſuppoſe it to be only a particular mode of action of an omnipreſent fluid, the whole difficulty vaniſhes at once.—On this ſuppoſition indeed the queſtion will naturally ariſe, Whence does this motion proceed, or by what is its action in general determined? Dr Berkenhout, in enumerating the properties of matter, exempts fire from two of thoſe uſually aſcribed to other material ſubſtances, viz gravitation and the *vis intertiæ*. "According to the philoſophers (ſays he), matter cannot move without being either impelled or attracted. I doubt much whether this be true of fire, and whether, when uncombined, motion be not one of its eſſential properties.—Gravitation ſeems alſo to be no property of fire, which moves with equal facility in all directions, and may be accumulated in hard bodies to any degree without increaſing their weight. Fire, being the cauſe of volatility, ſeems rather to be in conſtant counteraction to gravity."

93 Fire ſeems deſtitute of gravity and *vis inertiæ*.

But however eſſential we may ſuppoſe the motion of fire to be to it, there cannot be any ſelf-exiſtent mobility in its parts, otherwiſe it would ſoon be diffuſed equally throughout the univerſe, and the temperature of the whole reduced to an equilibrium. According to the preſent conſtitution of nature, we ſee that the diſtribution of heat is principally owing to the ſun; and what we call its *quantity*, depends on the poſition of the ſun with regard to terreſtrial objects and the length of time they are expoſed to his rays. Heat is not produced while the rays have a direct paſſage; and therefore fluids through which they paſs eaſily, as air, are not heated by the rays of the ſun. But when the rays are impeded in their courſe, and reflected in conſiderable quantity, a degree of heat takes place, which is always greater or leſs in proportion to the intenſity of the rays.—In the reflecting ſubſtance, the heat will be comparatively greater in proportion to the quantity of rays which are abſorbed or ſtopped in their courſe by it: but in any ſubſtance interpoſed betwixt the ſun and the reflecting body, the heat is proportional to the quantity of rays reflected.—Now it is plain, that when the particles of light fall upon any opaque ſubſtance, and enter its pores, which by their extreme ſubtilty they are well calculated to do, they muſt make an attempt to paſs directly through it in their natural courſe; but as this cannot be done, they will puſh laterally, and in all directions, in conſequence of being perpetually urged by the impulſe of the light coming from the ſun: and thus an action will be propagated in all directions as radii from a centre towards a circumference, which when it takes place in that ſubtile fluid always produces what we call *heat*.

94 Diſtribution of heat owing to the ſun.

95 How heat is produced by the ſun's rays.

96 Proofs of the identity of fire, light, and electricity.

In completing the ſyſtem of nature, we perceive three kinds of fluids of extreme ſubtilty, and very much reſembling one another, viz. fire, light, and electricity. That it ſhould be agreeable to vulgar conceptions to ſuppoſe theſe all to be ultimately the ſame, is not ſurpriſing; and on examining the evidence of their identity, it will certainly be found exceedingly ſtrong. They all agree in the property of exciting the ſenſation of heat in certain circumſtances, and in not doing ſo in others. Fire, we know, in the common acceptation of the word, always does ſo; but when it aſſumes the latent and inviſible ſtate, as in the formation of vapour, it lays aſide this ſeemingly eſſential property, and the vapour is cold to the touch.—Light, when collected in a focus by a burning glaſs, i. e. when its rays converge towards a centre, and diverge or attempt to diverge from one, produces heat alſo: and ſo does the electric fluid; for it has been found that the aura converging from a very large conductor to the point of a needle, is capable of ſetting on fire a ſmall cartridge of gunpowder, or a quantity of tinder ſurrouding it*. There ſeems alſo to be a connection betwixt

---

* See *Electricity*.

Element of Fire.

97 Connection between fire or heat and electricity.

fire and electricity in another way; for in proportion as heat is diminiſhed, or the bodies are cooled, electricity ſucceeds in its place. Thus all electric bodies by heat become conductors of electricity, and cannot be excited or made to ſhow any ſigns of containing that fluid; but as ſoon as the heat is removed, their electric property returns. Water is naturally a conducting ſubſtance: by being frozen its conducting power is leſſened, which ſhows an approach to electricity; and, by being cooled down to 20° below 0 of Fahrenheit, the ice actually becomes electric, and will emit ſparks by friction like glaſs*. The atmoſphere is a natural electric: but by a certain degree of heat it loſes this property, and becomes a conductor; nor is there any doubt that its electric properties are increaſed in proportion to the degree of cold imparted to it. In the winter time, therefore, we muſt conſider the frozen ſurface of the earth, the water, and the atmoſphere of the polar regions, as forming one electrical machine of enormous magnitude; for the natural cold of theſe countries is often ſufficient to cool the water to more than 20° below 0, and conſequently to render it an electric. That this is really the caſe, appears from the exceſſively bright aurora borealis and other electric appearances, far exceeding any thing obſerved in this country. In the ſummer time, however, no ſuch appearances are to be ſeen, nor any thing remarkable except an exceſſive heat from the long continuance of the ſun above the horizon. This quantity of heat then being ſucceeded by a proportionable quantity of electricity in winter, it is impoſſible to avoid concluding that the heat in ſummer becomes electric fluid in winter, which, going off through the celeſtial expanſe, returns again to the grand ſource of light and heat from which it originally came; thus making room for the ſucceeding quantities which are to enliven the earth during the following ſummer.

98 Exceſſive electricity of the polar regions in winter.

99 Heat in ſummer becomes electric fluid in winter.

100 Why thunder and lightning take place in ſummer and not in winter.

Thus the diſappearance of heat in winter, and of electricity in ſummer, in theſe countries, will be very naturally and eaſily accounted for. It is true, that the phenomena of thunder and lightning ſhow the exiſtence of this fluid in vaſt quantities during the ſummer ſeaſon: but theſe phenomena are only partial, and though formidable to us, are trifling in compariſon with the vaſt quantities of electric matter diſcharged by the continual flaſhing of the aurora borealis, not to mention the fire-balls and meteors called *falling ſtars*, which are very often to be ſeen in the northern countries. In the ſummer-time, the air which is an electric, heated by the rays of the ſun, is excited or made to part with the fluid to the vapours contained in it; and it is the unequal or oppoſite electricity of the clouds to one another, or to the earth, which produces the lightning. But in winter, when the air, earth, and vapours, all become electric, they cannot diſcharge ſparks from one to another as before; but the whole, as one connected and vaſt electrified apparatus, diſcharges the matter almoſt in a continued ſtream for many months.

101 Heat, light, cold, and electricity, the effects of one univerſal fluid.

From a conſideration of theſe and other phenomena of nature, as well as of the beſt experiments which have hitherto been made, we muſt conſider fire in the abſtract as an omnipreſent fluid, of ſuch ſubtilty as to prevade all terreſtrial ſubſtances. When by any means it is made to diverge every way as from a centre, there it operates as heat; expands, rarefies, or burns, according to the intenſity of its action. Proceeding in ſtraight and parallel lines, or ſuch as diverge but little, it acts as light, and ſhows none of that power diſcoverable in the former caſe, though this is eaſily diſcoverable by making it converge into a focus. In a quieſcent ſtate, or where the motion is but little, it preſſes on the ſurfaces of bodies, contracts and diminiſhes them every way in bulk, forces out the expanding fluid within their pores, and then acts as cold. In this caſe alſo, being obliged to ſuſtain the vehement action of that part of the fluid which is in motion, it flies with violence to every place where the preſſure is leſſened, and produces all the phenomena of ELECTRICITY.

Nature of Heat.

§ 1. *Of the Nature of Heat.*

102 Particular ſolution of the phenomena of heat.

The manner in which the phenomena of heat may be ſolved, and its nature underſtood, will appear from the following propoſitions.

1. It is in all caſes obſerved, that when light proceeds in conſiderable quantity from a point, diverging as the radii of a circle from its centre, there a conſiderable degree of heat is found to exiſt, if an opaque body, having no great reflective power, is brought near that point.

2. This action of the light, therefore, may be accounted the ultimate cauſe of heat, without having recourſe to any farther ſuppoſitions; becauſe nothing elſe beſides this action is evident to our ſenſes.

3. If the point from which the rays are emitted is placed in a tranſparent medium, ſuch as air or water, that medium, without the preſence of an opaque body, will not be heated.

4. Another cauſe of heat, therefore, is the reſiſtance of the parts of that body on which the light falls, to the action mentioned in Prop. 1. Where this reſiſtance is weak, as in the caſes juſt mentioned, the heat is either nothing, or very little.

5. If a body capable of reflecting light very copiouſly is brought near the lucid point, it will not be heated*.

6. A penetration of the light, therefore, into the ſubſtance of the body, and likewiſe a conſiderable degree of reſiſtance on the part of that body to the action of the light, are the requiſites to produce heat.

7. Thoſe bodies ought to conceive the greateſt degrees of heat into whoſe ſubſtance the light can beſt penetrate, *i. e.* which have the leaſt reflective power, and which moſt ſtrongly reſiſt its action; which is evidently the caſe with black and ſolid ſubſtances.

8. By heat all bodies are expanded in their dimenſions every way, and that in proportion to their bulk and the quantity of heat communicated to them.

9. This expanſion takes place not only by an addition of *ſenſible* heat, but likewiſe of that which is *latent*. Of this laſt we have a remarkable inſtance in the caſe of ſnow mixed with ſpirit of nitre. The ſpirit of nitre contains a certain quantity of latent heat, which cannot be ſeparated from it without effecting a change on the ſpirit itſelf; ſo that, if deprived of this heat, it would no longer be ſpirit of nitre.—Beſides this, it contains a quantity of ſenſible heat, of a great part of which it may be deprived, and yet retain its characteriſtic properties as nitrous acid. When it is poured upon ſnow, the latter is immediately melted by the action of the latent heat in the acid. The ſnow cannot be

---

* See *Electricity*.

* See the article *Burning-Glaſs*.

Nature of Heat.

be melted or converted into water, without imbibing a quantity of latent heat, which it receives immediately from the acid which melts it. But the acid cannot part with the heat without decompoſition; to prevent which, its ſenſible heat occupies the place of that which has entered the ſnow and liquefied it. The mixture then becomes exceedingly cold, and the heat forces into it from all the bodies in the neighbourhood; ſo that, by the time it has recovered that quantity of ſenſible heat which was loſt, or arrived at the temperature of the atmoſphere around it, it will contain a conſiderably larger quantity of heat than it originally did, and is therefore obſerved to be expanded in bulk. Another inſtance of this expanſive power of latent heat is in the caſe of ſteam, which always occupies a much larger ſpace than the ſubſtance from which it was produced; and this whether its temperature is greater or leſs than the ſurrounding atmoſphere.

10. The difference between latent and ſenſible heat, then, as far as we can conceive, is, that the expanſive power of the former is directed only againſt the particles of which the body is compoſed; but that of the latter is directed alſo againſt other bodies. Neither doth there ſeem to be any difference at all between them farther than in quantity. If water, for inſtance, hath but a ſmall quantity of heat, its parts are brought near each other, it contracts in bulk, and feels cold. Still, however, ſome part of the heat is detained among the aqueous particles, which prevents the fluid from congealing into a ſolid maſs. But, by a continuation of the contracting power of the cold, the particles of water are at laſt brought ſo near each other that the internal or *latent* heat is forced out. By this diſcharge a quantity of air is alſo produced, the water is congealed, and the ice occupies a greater ſpace than the water did; but then it is full of air-bubbles, which are evidently the cauſe of its expanſion. The heat then becomes *ſenſible*, or, as it were, lies on the outſide of the matter; and conſequently is eaſily diſſipated into the air, or communicated to other bodies. Another way in which the latent heat may be extricated is by a conſtant addition of ſenſible heat. In this caſe the body is firſt raiſed into vapour, which for ſome time carries off the redundant quantity of heat. But as the quantity of this heat is continually increaſed, the texture of the vapour itſelf is at laſt totally deſtroyed. It becomes too much expanded to contain the heat, which is therefore violently thrown out on all ſides into the atmoſphere, and the body is ſaid to burn, or be on fire. See Combustion, Flame, and Ignition.

11. Hence it follows, that thoſe bodies which have the leaſt ſhare of latent heat, appear to have the greateſt quantity of ſenſible heat; but this is only in appearance, for the great quantity they ſeem to contain is owing really to their inability to contain it. Thus, if we can ſuppoſe a ſubſtance capable of tranſmitting heat through it as faſt as it received it; if ſuch a ſubſtance was ſet over a fire, it would be as hot as the fire itſelf, and yet the moment it was taken off, it would be perfectly cool, on account of its incapacity to detain the heat among the particles of which it was compoſed.

12. The heat, therefore, in all bodies conſiſts in a certain violent action of the elementary fire within them tending from a centre to a circumference, and thus making an effort to ſeparate the particles of the body from each other, and thereby to change its form or mode of exiſtence. When this change is effected, bodies are ſaid to be diſſipated in vapour, calcined, vitrified, or burnt, according to their different natures.

Nature of Heat.

13. Inflammable bodies are ſuch as are eaſily raiſed in vapours; that is, the fire eaſily penetrates their parts, and combines with them in ſuch quantity, that, becoming exceedingly light, they are carried up by the atmoſphere. Every ſucceeding addition of heat to the body increaſes alſo the quantity of latent heat in the vapour, till at laſt, being unable to reſiſt its action, the heat breaks out all at once, the vapour is converted into flame, and is totally decompoſed. See the article Flame, and Prop. 10.

14. Uninflammable bodies are thoſe which have their parts more firmly connected, or otherwiſe diſpoſed in ſuch a manner, that the particles of heat cannot eaſily combine with them or raiſe them into vapour.

15. Heat therefore being only a certain mode of the action of elementary fire, it follows, that the capacity of a body for containing it, is only a certain conſtitution of the body itſelf, or a diſpoſition of its parts, which can allow the elementary fire contained in it to exert its expanſive power upon them without being diſſipated on other bodies. Thoſe ſubſtances which allow the expanſive power of the fire to operate on their own particles are ſaid to contain a great deal of heat; but thoſe which throw it away from themſelves upon other bodies, though they feel very hot, yet philoſophically ſpeaking they contain very little heat.

16. What is called the *quantity* of heat contained in any ſubſtance, if we would ſpeak with the ſtricteſt propriety, is only the apparent force of its action, either upon the parts of the body itſelf, or upon other bodies in its neighbourhood. The expanſive force of the elementary fire contained in any body upon the parts of that body, is the *quantity of latent heat* contained in it; and the expanſive force of the fire exerted upon other bodies which touch or come near it, is the *quantity of ſenſible heat* it contains.

17. If what we call *heat* conſiſts only in a certain action of that fluid called *elementary fire*, namely, its expanſion, or acting from a centre to a circumference, it follows, that if the ſame fluid act in a manner directly oppoſite to the former, or preſs upon the particles of a body as from a circumference to a centre, it will then produce effects directly oppoſite to thoſe of heat, i. e. it will then be abſolute *cold*, and produce all the effects already attributed to Cold. See that article.

18. If heat and cold then are only two different modifications of the ſame fluid, it follows, that if a hot body and a cold one are ſuddenly brought near each other, the heat of the one ought to drive before it a part of the cold contained in the other, *i. e.* the two portions of elementary fire acting in two oppoſite ways, ought in ſome meaſure to operate upon one another as any two different bodies would when driven againſt each other. When a hot and a cold body therefore are brought near each other, that part of the cold body fartheſt from the hot one ought to become colder than before, and that part of the hot body fartheſt from the cold one ought to become hotter than before.

19. For the ſame reaſon, the greateſt degree of cold in any body ought to be no obſtacle, or at leaſt very little, to its conceiving heat, when put in a proper ſituation. Cold air, cold fuel, &c. ought to become as intenſely heated, and nearly as ſoon, as that which is hotter.

The two laſt propoſitions are of great importance. When the firſt of them is thoroughly eſtabliſhed, it will confirm beyond a doubt, that cold is a *poſitive*, as well as heat; and that each of them has a ſeparate and diſtinct power, of which the action of its antagoniſt is the only proper limit; *i. e.* that heat can only limit the power of cold, and *vice verſa*. A ſtrong confirmation of this propoſition is the experiment related by M. Geoffroy; an account of which is given under the article COLD. Another, but not ſo well authenticated, is related under the article CONGELATION. —De Luc's obſervation alſo, mentioned by Dr Cleghorn, affords a pretty ſtrong proof of it; for if the lower parts of the atmoſphere are cooled by the paſſage of the ſun's rays at ſome diſtance above, and it hath been already ſhown that they do not *attract* the heat from the lower parts, it follows, that they muſt *expel* part of the cold from the upper regions.—The other propoſition, when fully eſtabliſhed, will prove, that heat and cold are really convertible into one another; which indeed ſeems not improbable, as we ſee that fires will burn with the greateſt fierceneſs during the time of intenſe froſts, when the coldeſt air is admitted to them; and even in thoſe diſmal regions of Siberia, when the intenſe cold of the atmoſphere is ſufficient to congeal quickſilver, it cannot be doubted that fires will burn as well as in this country; which could not happen if heat was a fluid *per ſe*, and capable of being carried off, or abſolutely diminiſhed in quantity, either in any part of the atmoſphere itſelf, or in ſuch terreſtrial bodies as are uſed for fuel.

§ 2. *Of the general Effects of Heat.*

HAVING ſaid thus much concerning the nature of heat in general, we come now to a particular explanation of its ſeveral effects, which indeed conſtitute the whole of the active part of chemiſtry.—Theſe are,

103 Inſtruments for meaſuring the expanſions of bodies.

I. *Expanſion*, or increaſe of bulk in every direction. This is a neceſſary conſequence of the endeavour which the fluid makes to eſcape in all directions, when made to converge into a focus. The degree of expanſion is unequal in different bodies, but in the ſame body is always proportionable to the degree of heat applied. There are two different inſtruments in uſe for aſcertaining the degrees of expanſion; and as we have already ſhown, that the degree of heat can only be known by the expanſion, theſe effects of heat upon the inſtrument are uſually taken for the degrees of heat themſelves. Theſe inſtruments are called the THERMOMETER and PYROMETER. The former is compoſed of a glaſs tube, with a globe or rather oval tube at one end, and exactly cloſed at the other: it is moſt uſually filled with mercury or ſpirit of wine; but mercury is generally preferred on account of its expanſions being more equable than thoſe of any other fluid. It has the diſadvantage, however, of being ſubject to congelation; which is not the caſe with ſpirit of wine, when very highly rectified. Spirit-of-wine thermometers, therefore ought not to be entirely diſuſed, but ſeem rather a neceſſary part of the chemical apparatus, as well as thoſe made of mercury.

104 Wedgewood's improvement of the thermometer.

As no thermometer made with any fluid can meaſure either the degrees of heat about the point at which it boils, or the degree of cold below which it congeals, inſtruments have been contrived by which the expanſion of ſolid bodies, though much leſs than what is occaſioned by an equal degree of heat in a fluid, may become viſible. Theſe were uſually called *Pyrometers*; but Mr Wedgewood has lately contrived a method of connecting the two together, in which the higheſt degree of heat, exceeding even that of a glaſs-houſe furnace, may be meaſured as accurately as the more moderate degrees by the common mercurial thermometer. See THERMOMETER.

105 Inſtances of bodies expanding by cold.

106 Prodigious force exerted by water in freezing.

Expanſion in ſome caſes does not appear to be the effect of heat, of which we have two remarkable inſtances, viz. of iron, which always expands in cooling after it has been melted; and of water, which expands with prodigious force in the act of freezing. The power with which iron expands in the act of paſſing from a fluid to a ſolid ſtate, has never been meaſured, nor indeed does it ſeem eaſy to do ſo; but that of freezing water has been accurately computed. This was done by the Florentine Academicians, who having filled an hollow braſs ball of an inch diameter, with water, expoſed it to a mixture of ſnow and ſalt, in order to congeal the water, and try whether its force was ſufficient to burſt the ball or not. The ball, being made very ſtrong, reſiſted the expanding force of the water twice, even though a conſiderable part of its thickneſs had been pared off when it was perceived too ſtrong at firſt. At the third time it burſt; and by a calculation founded on the thickneſs of the globe and the tenacity of the metal, it was found that the expanſive power of a ſpherule of water only one inch in diameter, was ſufficient to overcome a reſiſtance of more than 27,000 pounds, or 13 tons and an half.

107 Uſed as an argument for the exiſtence of cold as a poſitive ſubſtance.

108 Explained by Dr Black's theory of latent heat.

109 The expanſion produced by the extrication of air-bubbles.

A power of expanſion ſo prodigious, little leſs than double that of the moſt powerful ſteam-engines, and exerted in ſo ſmall a body, ſeemingly by the force of cold, was thought to be a very powerful argument in favour of thoſe who ſuppoſe cold to be a poſitive ſubſtance as well as heat; and indeed contributed not a little to embarraſs the oppoſite party. Dr Black's diſcovery of latent heat, however, has now afforded a very eaſy and natural explication of this phenomenon. He has ſhown, that, in the act of congelation, water is not cooled more than it was before, but rather grows warmer: that as much heat is diſcharged, and paſſes from a latent to a ſenſible ſtate, as, had it been applied to water in its fluid ſtate, would have heated it to 135°. In this proceſs the expanſion is occaſioned by a great number of minute bubbles ſuddenly produced. Theſe were formerly ſuppoſed to be formed of *cold* in the abſtract; and to be ſo ſubtile, that, inſinuating themſelves into the ſubſtances of the fluid, they augmented its bulk, at the ſame time that, by impeding the motion of its particles upon each other, they changed it from a fluid to a ſolid. Dr Black, however, has demonſtrated, that theſe are only air extricated during the congelation; and to the extrication of this air he very juſtly attributes the prodigious expanſive force exerted by freezing water. The

110 This air extricated by part of the heat contained in the water.

only queſtion, therefore, which now remains is, By what means this air comes to be extricated, and to take up more room than it naturally does in the fluid? To this we can ſcarce give any other anſwer, than that part of the heat which is diſcharged from the freezing water combines with the air in its unelaſtic ſtate, and, by reſtoring its elaſticity, gives it that extraordinary force, as we ſee alſo in the caſe of air ſuddenly extricated in the exploſion of gunpowder. Thus expanſion, even in the caſe of freezing, is properly an effect of heat; and muſt therefore be conſidered as a phenomenon uniformly and certainly attending the action of heat, and in all caſes to be aſcribed to it.

111 Capacity of a body for containing heat, the ſame with the action of heat upon that body.

112 Impoſſibility of determining the quantity of heat any body contains.

The only way in which the element or fluid of fire can be ſuppoſed to act, and the way in which we can have a rational idea of its being able to produce both heat and cold according to the diverſity of its action, has been already explained ſo fully, that it is needleſs at preſent to enter into any further diſcuſſion of the ſubject. It will eaſily appear, that the *capacity* for containing heat is nothing different from the action of heat upon that body in expanding, and at laſt altering its form in ſuch a manner, as either to be able to inſinuate itſelf among the particles in much greater quantity than before, ſtill retaining its internal action, though the external one becomes imperceptible; or ſcattering them in ſuch a manner, that it breaks forth in great quantity in its peculiar appearances of fire and light; in the former caſe producing vapour or ſmoke, and in the latter flame, as ſhall afterwards be more fully explained. It muſt likewiſe appear, that to determine the quantity of heat in any body is altogether impoſſible: and with regard to the loweſt degree of heat, or total expulſion of that fluid, ſo far from being able to determine what it is, the probability muſt be, that nature does not admit of any ſuch thing; for if heat conſiſts in the expanſive action of a certain fluid, and cold in its oppoſite or contractile action, there is very little reaſon to ſuppoſe that the conſtitution of nature will allow any one of theſe actions intirely to ceaſe, as it does not appear by what means it could again be renewed. Cold, as we have already ſeen, always tends to produce electricity; and the connexion betwixt that and fire is ſo ſtrong, that we cannot ſuppoſe the former to be carried to any great extreme without producing the latter. Whatever we may therefore ſuppoſe concerning the capacities of different bodies for containing heat, or concerning the point of total privation of heat, muſt be altogether void of foundation. A rule, however, has been given by Mr Kirwan for finding the point of total privation, which, together with its demonſtration, we ſhall ſubjoin; and as it is neceſſary for the better underſtanding of this, to call to remembrance what has been ſaid concerning the difference between the temperatures and ſpecific heats of bodies, we ſhall inſert an epitome of the doctrine from Mr Nicholſon.

113 Mr Nicholſon's account of the capacities of bodies for containing heat, &c.

“If two equal bodies of different kinds and temperatures be brought into contact, the common temperature will ſeldom, if ever, be the mean betwixt the two original temperatures; that is to ſay, the ſurplus of heat in the hotter body will be unequally divided between them, and the proportions of this ſurplus retained by each body will expreſs their reſpective diſpoſitions, affinities, or capacities for heat.—If, therefore, a given ſubſtance, as for example fluid water, be taken as the ſtandard of compariſon, and its capacity for heat be called one, or unity, the reſpective capacities of their bodies may be determined by experiment, and expreſſed in numbers in the ſame manner as ſpecific gravities uſually are. And becauſe it is eſtabliſhed as well from reaſon as experiment, that the ſame capacity for heat obtains in all temperatures of a given body, ſo long as its ſtate of ſolidity, fluidity, or vapour is not changed, it will follow, that the whole quantities of heat in equal bodies of a given temperature will be as thoſe capacities. And as the reſpective quantities of matter, in bodies of equal volume, give the proportions of their ſpecific gravities, ſo the reſpective quantities of heat in bodies of equal weight and temperature give the proportions of their ſpecific heats.

“A greater capacity for heat, or greater ſpecific heat, in a given body, anſwers the ſame purpoſe with reſpect to temperature as an increaſe of the maſs; or the quantity of heat required to be added or ſubducted, in order to bring a body to a given temperature, will be as its capacity or ſpecific heat.

“The capacities not only differ in various bodies, but alſo in the ſame body, according as it is either in a ſolid, fluid, or vaporous ſtate. All the experiments hitherto made conſpire to ſhow, that the capacity, and conſequently the ſpecific heat, is greateſt in the vaporous, leſs in the fluid, and leaſt in the ſolid ſtate.

“The quantity of heat that conſtitutes the difference between the ſeveral ſtates, may be found in degrees of the thermometer. Thus if equal quantities of water at 162° and ice at 32° of temperature be mixed, the ice melts, and the common temperature becomes 32°; or otherwiſe, if equal quantities of frozen or fluid water, both at 32°, be placed in a like ſituation to acquire heat from a fire, the water will become heated to 162°, while the ice melts without acquiring any increaſe of temperature. In either caſe the ice acquires 130° of heat, which produces no other effect than rendering it fluid. Fluid water, therefore, contains not only as much more heat than ice, as is indicated by the thermometer, but alſo 130°, that is in ſome manner or other employed in giving it fluidity. And as fluid water cannot become ice without parting with 130° of heat beſides what it had above 32° in its temperature; ſo alſo ſteam cannot become condenſed into water without imparting much more heat to the matters it is cooled by, than water at the ſame temperature would have done.

“The heat employed in maintaining the fluid or vaporous form of a body, has been called latent heat, becauſe it does not affect the thermometer.

114 Mr Kirwan's theorem for finding the point of total privation of heat.

“From the conſideration of the ſpecific heats of the ſame body in the two ſtates of fluidity and ſolidity, and the difference between thoſe ſpecific heats, is deduced a method of finding the number of degrees which denote the temperature of any body immediately after congelation, reckoned from the natural zero, or abſolute privation of heat. The rule is; multiply the degrees of heat required to reduce any ſolid to a fluid ſtate, by the number expreſſing the ſpecific heat of the fluid: divide this product by the difference between the numbers expreſſing the ſpecific heat of the body in each ſtate: the quotient will be the number

of

General Effects of Heat.

of degrees of temperature, reckoned from an abſolute privation of heat.

"This theorem is Mr Kirwan's, and may be proved thus. Let s repreſent the required temperature of the body juſt congealed, $l =$ the number of degrees that expreſs the heat required to reduce it to fluidity, $n =$ the ſpecific heat of the ſolid, and $m =$ the ſpecific heat of the fluid. Then $s+l : s :: m : n$. Whence $s = \frac{ln}{m-n} =$ the temperature from the natural zero in thermometrical degrees of the fluid. But becauſe the actual fall of the thermometer is to be produced by cooling the ſolid, we muſt pay attention to its capacity. The quantity of heat required to produce a given change of temperature in a body is as its capacity; and conſequently the changes of temperature, when the quantity of heat is given, will be inverſely as the capacities: therefore, $n : m :: \frac{ln}{m-n} : \frac{ln}{m-n} = s$. which is the rule abovementioned.

"If the data l, m, and n, be accurately obtained by experiment, in any one inſtance, and the difference between the zero of Fahrenheit's ſcale and the natural zero be thence found in degrees of that ſcale, this difference will ſerve to reduce all temperatures to the numeration which commences at the natural *o*. So that s being known in all caſes, if any two of the quantities l, m, or n, be given in any body, the other may be likewiſe had. For $l = \frac{sm-sn}{m}$; and $m = \frac{sn}{s-l}$ and $n = \frac{sm-lm}{s}$.

"To give an example of this curious rule, let it be required to determine how many degrees of refrigeration would abſolutely deprive ice of all its heat? The degrees of heat neceſſary to melt ice are 130; and the ſpecific heats of ice and water are as 9 to 10. The number 130 multiplied by 10, produces 1300, and divided by the difference between 9 and 10 quotes 1300: therefore if ice were cooled 1300 degrees below 32°, or to—1268 of Fahrenheit's ſcale, it would retain no more heat."

115 Fluidity to be aſcribed to the abſorption of heat.

II. *Fluidity* is another effect of heat, and is capable of taking place in all bodies hitherto known, when the fire is carried to a certain pitch. Theories have been invented, by which fluidity was aſcribed to the ſmoothneſs and round figure of the particles whereof bodies were compoſed, and ſolidity to an angular or irregular figure. It has alſo been aſcribed to a ſtronger degree of attraction between the parts of ſolids than of fluids. Dr Black, however, has ſhown, that in the caſe of melting ice, we are certainly to aſcribe the acquired fluidity of the water to the abſorption of heat. This was determined by a deciſive experiment, in which he expoſed a Florence-flaſk full of water to the atmoſphere in a warm room, when he found that the heat in the air evidently left it, to flow into the ice in the bottle, and reduced it to fluidity. The air thus deprived of its heat, he felt ſenſibly deſcending like a cold blaſt from the bottle, and continuing to do ſo as long as any of the ice remained unthawed; yet after it was all melted, the temperature of the fluid was no more than 32°. Different degrees of heat are requiſite for converting different ſolids into fluids, for which ſee the *Table of Degrees of* HEAT.

General Effect of Heat.

116 Senſible heat produced by the converſion of a fluid into a ſolid.

This theory receives an additional confirmation from the quantity of heat which is always known to be produced by the converſion of a fluid into a ſolid. And that this is really the caſe appears, 1. From what happens in the congelation of waters, it appears that ice is formed very ſlowly, and with ſeveral circumſtances which ſupport the theory.—Thus, if we ſuppoſe equal quantities of water to the air, which is perhaps 10 below froſt, and add to one of theſe a ſmall quantity of ſalt or ſpirit of wine, and obſerve the cooling of each, we ſhall find them both grow gradually colder, until they arrive at the temperature of froſt: after which the water containing the ſalt will continue to grow colder, until it has arrived at the temperature of the air, at the ſame time that only a ſmall quantity of the other water is converted into ice. Yet were the common opinion juſt, it ought all to have been congealed by this time; inſtead of which, it is ſcarce grown a degree colder during the whole time. Its remaining at the ſame temperature for ſo long a time, ſhows that it has been communicating heat to the atmoſphere; for it is impoſſible that any body can remain in contact with another that is colder, without communicating heat to it. Whence then comes this heat? There muſt be ſome ſource adding to the ſenſible heat of the water, ſo as to keep its temperature to the freezing point: and this ſource of heat muſt be very conſiderable; for it will continue to act for a very long time before the water is changed into ice; during all which time, even to the laſt drop, the water is not a degree colder than 32° of Fahrenheit's thermometer. This, therefore, is the *latent heat* of the water, which had formerly entered into it during its tranſition from ice to a fluid ſtate.

117 Argument in ſupport of the theory from water remaining fluid tho' cooled below 32°.

A ſtill ſtronger argument is derived from the following experiment; which evinces that the fluidity of water really depends upon its latent heat, and that the ſenſible heat is only a mean or condition to its containing the latent heat. This experiment conſiſts in expoſing water contained in a covered beer-glaſs to the air of a cold froſty night; and when the atmoſphere is at the temperature of perhaps 10° or 12° below froſt, the water will acquire that temperature without freezing: ſo that the fluidity of the water does not altogether depend on the quantity of ſenſible heat contained in it. The congelation, however, may be brought on by touching it with a bit of ice, with the extremity of a wire, by a ſhock upon the board, or otherwiſe diſturbing it; and we then find the temperature ſuddenly raiſed up to 32°. This ſhows plainly, that the water has a diſpoſition to retain the quantity of latent heat, upon which its fluidity muſt immediately and neceſſarily depend; and it retains it with a certain degree of force, ſo as to keep the water fluid in a temperature below that in which it uſually parts with the latent heat and congeals. By diſturbing it, however, we inſtantly bring on the congelation, which cannot take place without an extrication of the latent heat; which then, being changed into the ordinary or moveable heat, raiſes the thermometer as uſual. The quantity of heat diſcharged from the firſt ſmall portion of ice formed in the water is ſufficient to prevent any more latent heat from ſeparating, and conſequently from any more ice being produced till more of the ſenſible heat is abſtracted.

This doctrine extends not only to ſuch bodies as are actually converted from a ſolid to a fluid, or from a fluid to a ſolid ſtate, but to ſuch as are in a kind of middle ſtate betwixt ſolidity and fluidity; for every degree of ſoftneſs depends on a certain degree of heat contained in the body. Thus, for inſtance, melted wax, allowed to cool ſlowly, ſoon becomes opaque and conſiſtent; but it muſt be colder ſtill before it attains its utmoſt degree of hardneſs. There is therefore a certain degree of heat below which every body is ſolid, and above which every one is fluid; the former being called the *congealing*, and the latter the *melting*, point of bodies.

118 Heat the cauſe of the ſoftneſs of bodies approaching to fluidity.

119 Abſorption of heat the univerſal cauſe of fluidity.

By making experiments upon different ſubſtances, the Doctor was convinced that latent heat is the univerſal cauſe of fluidity; and the doctrine holds good in all the experiments that have hitherto been made upon ſpermaceti, bees-wax, and ſome of the metals. If they are melted, allowed to cool ſlowly, and a thermometer be immerſed into them, we find, that as long as they continue fluid, their ſenſible heat diminiſhes very faſt; but as ſoon as they begin to grow ſolid, the ſenſible heat continues greater than that of the air to which they are expoſed; and during all this time it is communicating heat to the air, without having its ſenſible heat diminiſhed; for the latent heat within the fluid gradually receives a ſenſible form, and keeps up the temperature, proving a ſource of ſenſible heat, which is communicated to the neighbouring bodies as well as the ſurrounding air. The ſoftneſs and ductility of bodies depend on this alſo.

120 Vapour formed by the abſorption of latent heat.

III. *Evaporation.* A third effect of the action of heat is that of converting bodies into vapour, by which they are rendered ſpecifically lighter than the ſurrounding atmoſphere, and enabled to riſe in it. To account for this, many theories have been invented; but that of Dr Black, who accounts for it, as well as fluidity from the abſorption of latent heat, is now univerſally received. The circumſtances by which he proves and illuſtrates his doctrine are the following:

121 Experiments by Dr Black on the converſion of water into vapour.

1. When we attend to the phenomena of boiling water, in a tea kettle for inſtance, it may, when firſt put upon the fire, be about the temperature of 48° or 50°. In a quarter of an hour it will become heated to 212°. It then begins to boil, and has gained 162° of vapour in that time. Now, if the converſion of it into vapour depended on the quantity of ſenſible heat introduced, we may aſk how long it will be neceſſary to raiſe it all in vapour? Surely another quarter of an hour ſhould be ſufficient; but this is far from being the caſe. Dr Black made ſome experiments upon this ſubject in conjunction with another gentleman. Having the opportunity of what is called a kitchen-table or a thick plate of caſt iron, one end of which was made ſenſibly red-hot, they ſet upon this ſome iron veſſels with circular flat bottoms, of about four inches diameter, and which contained a quantity of water. The temperature of the water was noted, as alſo when it began to boil; and when the whole of it was boiled away, it was found, that when ſet on the table its temperature had been 54°; in four minutes it began to boil, and in that ſpace of time received 158° degrees of heat. Had the evaporation, therefore, depended merely on the quantity of ſenſible heat introduced, it ought to have been diſſipated entirely in a ſingle minute more. It was, however, 18 minutes in diſſipating; and therefore had received 807 degrees of heat before it was all evaporated. All this time, therefore, while the water continued to boil, it was receiving a great quantity of heat, which muſt have been flowing equally faſt out of it; for the veſſel was no hotter, and the iron plate continued equally hot, the whole time. The veſſels were of different ſhapes, ſome of them cylindrical, ſome conical, others widening upwards; one of the deſigns of the experiment being to ſhow how far the evaporation was retarded by the particular form of the veſſels. By ſuſpending a thermometer in the mouth of one of the evaporating veſſels, the heat of the ſteam was found to be exactly 212°; ſo that as the great quantity of heat abſorbed was found neither to have remained in the water, nor to have been carried away by the ſteam in a ſenſible manner, we have nothing left to ſuppoſe, but that it flew off as one of the component parts of the ſteam in a latent ſtate.

2. In an experiment to ſhow the fixedneſs of the boiling point of water, Dr Black incloſed ſome of that fluid in a ſtrong vial having a thermometer in it, and ſtopped cloſe with a cork. By the application of heat he hoped now to be able to raiſe the thermometer ſome degrees above the boiling point, which would be the natural conſequence of the confinement of the ſteam. When this was done, he pulled out the cork, and ſuppoſed that the water would now all fly out in vapour: but in this he was totally diſappointed; a ſudden and very tumultuous boiling enſued, which threw out ſome of the water; but though ſome quantity of ſteam likewiſe iſſued, the quantity of water was not conſiderably diminiſhed. The vial had been heated to 20° above the boiling point, but almoſt inſtantly cooled down to 212°, when the cork was taken out.

3. Mr Watt, in making ſome experiments on the force of ſteam, had occaſion to uſe Papin's digeſter, with a pipe proceeding from its ſide; the orifice of which was ſhut with a valve preſſed down by one end of a lever. Thus he heated ſteam to 400° of Fahrenheit; after which, having ſuddenly ſtruck off the lever, a quantity of ſteam flew out with conſiderable noiſe, and with ſuch violence as to make an impreſſion on the ceiling of the room; but this noiſe gradually diminiſhed, and after ten minutes it ceaſed entirely; and upon opening the machine, he found the greateſt part of the water ſtill remaining.

122 Boiling point of water *in vacuo* determined by Mr Boyle.

4. The change of ſenſible into latent heat in the formation of vapour, appears ſtill more evident in the boiling of water *in vacuo*. Mr Boyle took a quantity of water which had been previouſly boiled to purge it of its air, and put it whilſt hot under the receiver of an air-pump. In conſequence of this it began again to boil, and continued boiling till it was only lukewarm, and it ſoon arrived at this temperature; ſo that in this caſe alſo the heat had diſappeared during the converſion of the fluid into vapour. Others have repeated the experiment, as Boerhaave, Muſchenbroek; and Robinſon, who lectures on chemiſtry in Glaſgow, ſays that the heat diminiſhes very faſt till it comes to 90° or 95°, which ſeems to be the boiling point of water *in vacuo*. As a conſiderable part of the heat thus diſappears, and is to be diſcovered neither in the water nor in the vapour, we muſt conclude that it enters the latter as part of its compoſition.

123 And by Mr Robinſon of Glaſgow.

5. Thus alſo we may underſtand ſome curious experiments made by Dr Cullen upon ether and other volatile

124 Dr Cullen's experiments on cold produced by evaporation.

latile fluids. He employed ſome perſons to make experiments upon the cold produced by evaporation; and willing to repeat them himſelf *in vacuo*, he put ſome of the moſt volatile liquors under the receiver of an air-pump. One of theſe was ether. It was contained in a glaſs, in which there was alſo placed ſome water. When the air was extracted, the ether began to boil, and to be converted into vapour, till it became ſo very cold that it froze the water contained in the veſſel, though the temperature of the room was about 50°. Here therefore there was a quantity of heat which diſappeared all of a ſudden; which it is plain could not be owing to its having any communication with that of the atmoſphere or other cold bodies, as they could not render it colder than they were themſelves. Ether therefore is to be conſidered as a fluid ſo volatile, that were it not for the preſſure of the atmoſphere it would be perpetually in the ſtate of vapour.

125 Heat expelled in great quantity by the condenſation of vapour.

6. That this heat which enters into the vapour is not deſtroyed, but remains in a latent ſtate, is eaſily proved; for we find that a great quantity of heat is expelled from vapour when it is condenſed again to form the body it compoſed originally. This is eaſily aſcertained by obſerving the quantity of heat communicated to the water in the refrigeratory of a ſtill by any given quantity of liquid which comes over. Thus, if the refrigeratory contain 100 pounds of water, and the diſtillation be continued till only one pound has come over, ſuppoſing the water in the refrigeratory to have received 8° of heat; it is plain, that if the whole of the quantity thus received could be thrown into one pound of water, the latter would be heated to 800°; which is ſufficient to make an equal ſpace of iron red-hot. But that this quantity of heat is received by the water in the refrigeratory has appeared from ſeveral experiments, which ſhow that water, by being converted into vapour, abſorbs between 800° and 900° of heat.

126 Mr Watt's experiments on the evaporation of fluids *in vacuo*.

On this principle we may explain ſome curious experiments made by Mr Watt with regard to the evaporation of fluids *in vacuo*. That gentleman had formed a deſign of converting water into ſteam with leſs expence of fuel, which he imagined might be done by removing the preſſure of the air from the water, which he thought would thus require a much ſmaller quantity of fuel to convert it into vapour. Dr Black, however, perceiving that only the ſmall quantity of ſenſible heat the ſteam poſſeſſed could thus be carried off, informed him beforehand that his project would not be found attended with the advantages he imagined. The experiment, however, was made in the following manner: A ſtill was procured of tinned iron, the body of which reſembled that of a retort, with a veſſel ſerving as a condenſer; the whole apparatus being cloſe, excepting a little hole in the extremity of the condenſing veſſel. He firſt exhauſted this veſſel of air by holding the condenſer over the retort, in which ſome boiling water was contained, until it was entirely converted into ſteam. He then ſuddenly ſtopped the little hole, and removed the veſſels from the fire; when, after they were cooled, there was a pretty perfect vacuum formed by the condenſation of the ſteam. The retort was then put on the fire, and turned ſo that the pipe and condenſing veſſel ſhould hang downward; and plunging them into cold water, heat was applied to the ſtill till the water boiled, as could be known by the noiſe. It was kept boiling, till a quantity of ſteam was puſhed over and condenſed with a very gentle heat, the ſtill feeling little warmer than his hand. After a certain quantity had been diſtilled, the apparatus was removed, and he had noted the heat of the water in the refrigeratory; but though the ſteam all along came over with ſo gentle a heat, he found the quantity communicated to the water in the refrigeratory to be ſurpriſingly great, not leſs than 1000°; ſo that it would have been more than ſufficient to heat the quantity of liquor which came over red-hot.

127 Ignition a conſtant and ſteady effect of heat.

128 All ignited bodies equally hot.

IV. *Ignition*, or the cauſing bodies to ſhine or emit light in the dark. This may be conſidered as a ſpecies of inflammation, and ſhall therefore be explained under that head: here we ſhall only obſerve, that ignition is a more ſteady and conſtant effect of heat than either the production of fluidity or vapour; and appears not only to be the ſame degree with regard to any particular body, but the ſame with regard to all kinds of matter. Dr Martin imagines, that a red-hot piece of iron is hotter than a red-hot piece of ſtone; but if you put into a crucible an hundred different kinds of matter, as metals, glaſs, &c. that are capable of bearing a red heat, they will all begin to appear luminous about the ſame time, and their brightneſs will increaſe equally as their heat increaſes. But it is difficult to know at what point this begins, as we have no way of aſcertaining the beginning or loweſt degree of ignition but by the effect it produces on our ſight, and we cannot be ſure that we perceive the loweſt degree of light; for we know that other animals ſee objects with ſuch light as appears perfect darkneſs to us. Sir Iſaac Newton's method of determining this has been already mentioned.

129 Metals may become vaſtly hotter after they are brought into fuſion.

Dr Boerhaave entertained a notion, that ſome metals, after being once brought into a ſtate of fuſion, could be made no hotter; and propoſes the poſſibility of this as a queſtion, "Whether the heat of metals can be increaſed after they are melted?" There is not, however, the leaſt doubt but that their heat may be vaſtly increaſed after they are melted; and we know certainly that ſuch as are of eaſy fuſion may be heated to a vaſtly greater degree after being melted; and why may not thoſe requiring ſtronger heats be the ſame? We are ſure that this is the caſe with ſilver, which, after being melted, may be brought to ſuch a heat as to become too dazzling for the eye to bear it. If Boerhaave's opinion were juſt, it would be impoſſible to caſt any metal into moulds, becauſe it muſt loſe a little heat in being removed from the fire and in entering the mould; nor would they receive a proper impreſſion if they did not contain a greater quantity of heat than was neceſſary for their fuſion.

130 Ignition an univerſal effect of fire.

131 Water may be made ſufficiently hot to melt lead.

Ignition appears to be univerſal; and all bodies capable of ſupporting it without being converted into an elaſtic vapour that cannot be confined, are affected the ſame way. Water, which in its ordinary ſtate ſeems very little capable of enduring this heat, may be confined in ſtrong veſſels ſo as to become capable of melting lead, which is more than half way betwixt a red heat and that of boiling water. Experiments with the eolipile ſhow alſo that it can be made red-hot; for when the ſteam paſſes through burning fuel, it cannot

not miſs of being made red hot. Dr Black has alſo frequently ſeen the vapour of water heated by throwing it into the aſh-pit of a furnace, ſo as to produce a very large and tranſparent flame in riſing up through the vent. There is reaſon therefore to conclude, that ignition is one of the more general effects of heat, only that ſome bodies are incapable of it until they be reduced to a ſtate of vapour.

132 Difference betwixt ignition and inflammation.

V. The laſt of the effects of heat here to be taken notice of is *inflammation*. It differs from ignition in this, that the bodies ſubject to the latter gradually grow cooler as ſoon as they are taken out of the fire, without undergoing any conſiderable change; while thoſe ſubject to inflammation become continually hotter and hotter, communicating a vaſt quantity of heat to others, and undergoing a kind of decompoſition themſelves, inſomuch, that by this means they have been thought to be reduced to their conſtituent principles or elements.

133 Inflammation decompounds but does not deſtroy bodies.

Some ſubſtances indeed ſeem to be an exception to this, as in the open air they burn totally away, without leaving any reſiduum or producing any ſoot. Theſe are ſpirit of wine, ſulphur, and eſpecially inflammable air; which laſt, by a proper mixture with dephlogiſticated air, may be ſo totally conſumed, that ſcarce a fiftieth part of the two will remain. On a careful examination of theſe ſubſtances, however, we find that there is by no means a total conſumption, or indeed, properly ſpeaking, any conſumption at all, at leaſt if we meaſure the quantity of matter by the weight of the ſubſtance employed.

134 Spirit of wine yields a great quantity of water by being burned.

Thus, if we are at pains to collect the vapour of burning ſpirit of wine, we will find, that an aqueous dew is collected, which ſometimes equals the ſpirit of wine itſelf in weight. With regard to ſulphur, the caſe is ſtill more evident; for the vapour of this, when collected, not only equals but greatly exceeds the weight of the ſulphur employed; and on burning dephlogiſticated and inflammable air together, as much water is found to be produced as nearly equals the weight of both airs.

135 Water produced by the deflagration of dephlogiſticated and inflammable air.

In like manner, when we collect the aſhes, water, ſoot, and oil, procured by burning any of the common inflammable ſubſtances, we will find, that they in general exceed the weight of the matter employed. The great waſte of bodies by fire, therefore, is owing to the diſſipation of the volatile principles they contain, which are carried off and rendered inviſible by being mixed with the atmoſphere.

136 Of the exiſtence of phlogiſton.

The proceſs of inflammation has long been explained from the preſence of a ſubſtance called *Phlogiſton* in thoſe bodies which are ſubject to it, and which is ſuppoſed to be the ſame in all bodies belonging to this claſs; the differences between them ariſing from the principles with which it is combined.

137 Denied by M. Lavoiſier.

This doctrine, which was firſt introduced by Stahl, has given occaſion to ſuch various and diſcordant theories, that the exiſtence of phlogiſton has been lately denied altogether by M. Lavoiſier, who brought in a new method of ſolving the phenomena of fire, heat, and ignition, without any aſſiſtance from this principle.

138 Arguments againſt it drawn from the increaſed weight of metals by calcination.

The foundation of M. Lavoiſier's doctrine is the increaſe of weight in metals by calcination. This increaſe he finds to be preciſely, or very nearly ſo, proportionable to the decreaſe of weight in the air in which they are calcined. His theory, therefore, is, that in the act of calcination, the pure part of the air, which he calls the *acidifying* or *oxygenous* principle, unites with the metal, and converts it into a calx.

139 His theory of inflammation.

In like manner, in ſubſtances truly inflammable, the heat and flame are ſuppoſed to proceed from the union of the pure air, or the oxygenous principle, with the ſubſtance, and converting it into thoſe principles which are found to remain after inflammation. Thus the increaſed weight of the ſubſtance is eaſily accounted for; while the inflammation, in his opinion, is nothing more than a combination of the inflammable body itſelf with pure air, which has an attraction for it: and in confirmation of that it is urged, that when combuſtion is performed in empyreal or dephlogiſticated air, the whole of the latter is abſorbed; but in common atmoſpherical air only one-fourth, being the quantity of pure air contained in it.

140 Arguments for the non-exiſtence of phlogiſton, from the reduction of the calces of perfect metals without addition.

Other arguments in favour of this opinion are, that the calces of the perfect metals may be reduced without addition by the mere emiſſion of the oxygenous principle, (dephlogiſticated air); by an union with which they aſſume the form of a calx. Thus he evades a very ſtrong argument uſed by the oppoſite party; who adduced, as a proof of the exiſtence of phlogiſton, the uſe of charcoal in the reduction of metals to their proper form.

141 Diſpute betwixt Lavoiſier and Prieſtley.

A diſpute indeed took place betwixt M. Lavoiſier and Dr Prieſtley concerning the reduction of the whole of a mercurial calx formed by an union with the nitrous acid without addition; the Doctor maintaining that the whole could not be reduced by mere heat, but that a very perceptible quantity was always loſt: but on a thorough examination of the ſubject, the truth ſeemed rather to lie on M. Lavoiſier's ſide. See AEROLOGY.

142 Dr Lubbock's theory.

Another theory, ſomewhat ſimilar to that of Lavoiſier's, has been publiſhed by Dr Lubbock, in an Inaugural Diſſertation in 1784. In this he ſuppoſes two kinds of matter to exiſt in the univerſe; one he calls the *principium proprium*, the other the *principium ſorbile*; and it is this latter, which, according to our author, is the principle of mutability, or which by being united in various proportions with the other, forms bodies of all the different kinds we ſee in nature. It is this principle, therefore, which he ſuppoſes to be abſorbed in the calcination of metals, and not empyreal air, as M. Lavoiſier ſuppoſes; and he contends, that this ſame principle extends throughout the whole ſyſtem of nature, even to the utmoſt celeſtial bounds.

143 Diſputes concerning phlogiſton now entirely decided.

It would exceed the limits of this treatiſe to give an account of the various theories which have been invented, and the arguments uſed for and againſt them; nor indeed is there any occaſion for doing ſo, as late experiments have reduced the diſpute into a much narrower compaſs than before, and furniſhed the moſt deciſive arguments in favour of the exiſtence of phlogiſton.

144 Objections againſt the exiſtence of phlogiſton from its inviſibility and ſuppoſed want of gravity.

The greateſt objection to the belief of this principle was, that it could neither be ſeen nor felt by our ſenſes directly, nor diſcover itſelf indirectly by the weight it communicated to the bodies with which it was united; on the contrary, the latter always became lighter in proportion to the quantity they contained: ſo that it was imagined, inſtead of being poſſeſſed of any ſpecific gravity of its own, to be a principle of poſitive levity, ſuch as that of heat or light may be reaſonably ſuppoſed. This objection, however, is now intirely removed; and phlogiſton in the abſtract is found to be no ſubtile principle capable of eluding our reſearches, but one very common, and eaſily met with, being no other than common charcoal.

145
Common charcoal and phlogiſton the ſame.

In the laſt edition of this work, under the article PHLOGISTON, it was ſhown, that inflammable air, deprived of its elaſticity, and combined with metallic ſubſtances, is really their phlogiſton; and that in the inflammable bodies commonly uſed, what we call their phlogiſton, is really their oil; and that which exiſts in charcoal, and cannot be driven off by diſtillation, is part of the empyreumatic or burnt oil of the ſubject which adheres ſo obſtinately. A ſimilar doctrine ſoon after appeared in the Philoſophical Tranſactions for 1782, and the identity of phlogiſton and inflammable air was clearly proved by Mr Kirwan.

146
Deciſive proofs of this identity given by Dr Prieſtley.

Still, however, it was inſiſted by the French philoſophers and others, that no *facts* had been adduced againſt M. Lavoiſier, nor any deciſive proofs appeared of the exiſtence of phlogiſton as a ſubſtance *per ſe*. Facts of this kind, however, have now been diſcovered by Dr Prieſtley, and are related under the articles AEROLOGY, CHARCOAL, PHLOGISTON, &c.

147
Spirit of wine and metals convertible into charcoal.

It is ſufficient at preſent to mention, that he has been able to convert the pureſt ſpirit of wine, and one of the hardeſt metals, viz. copper, as well as ſeveral others, into a ſubſtance entirely reſembling charcoal; that by means of the heat of a burning glaſs in vacuo, he has diſſipated this metallic charcoal, as well as the common kind, *entirely* into inflammable air, with the aſſiſtance only of a little water, which ſeems neceſſary to make it aſſume the aerial form, and perhaps is the true ſolvent of it; and by a combination with the element of heat, with the aid of the charcoal, is enabled to reſiſt condenſation in the common way.*

148
Charcoal entirely diſſipated by heat into inflammable air.

This inflammable air, when abſorbed by metallic calces, again reduces them to their metallic form: ſo that here is one fact by which the phlogiſton not only appears to our ſenſes, but we are able to aſcertain its quantity with the utmoſt preciſion.

149
Metallic calces reduced by inflammable air.

Nor can it here be any objection, that the reduced metal is lighter than the calx; for this only proves that the metallic earth, while a calx, is united to a heavy ingredient (the baſis of dephlogiſticated air), and in the latter to a light one, viz. charcoal, the baſis of inflammable air.

150
Why metals are lighter in their metallic than in their calcined ſtate.

Another caſe in which the exiſtence of phlogiſton is made equally evident to our ſenſes, and where no ſuch objection can occur, is related under the article AEROLOGY, n° 112.

151
Dephlogiſticated air converted into aerial acid by charcoal.

It is there ſhown, that “by the loſs of one grain of charcoal of copper (formed by the union of ſpirit of wine with the metal), and which like common charcoal was conſumed without having any reſiduum, he reduced four ounce-meaſures of dephlogiſticated air till only one-ninth remained unabſorbed by water; and, again, with the loſs of one grain and a half of charcoal, ſix and an half meaſures of dephlogiſticated air were reduced till five and an half meaſures were pure fixed air.”—Here, then, is an abſolute and undeniable evidence, that fixed air is compoſed of dephlogiſticated air, and charcoal or phlogiſton, and elementary fire. There were no other ingredients preſent, and the charcoal muſt either have been annihilated or diſpoſed of in the manner juſt mentioned: but the ſuperior weight of the fixed air evidently ſhows that ſome ingredient had been added to the dephlogiſticated air; and which increaſe was more than we can ſuppoſe to ariſe from the condenſation of the dephlogiſticated air during the operation, for this ſometimes amounted to no more than one-thirtieth part.

152
Objections drawn from the total combuſtion of dephlogiſticated air in ſome caſes.

The ſtrongeſt objection which can be made againſt the doctrine of phlogiſton may be drawn from the total conſumption of pure air in certain caſes of combuſtion, for inſtance, in that of phoſphorus, inflammable air, and iron. It muſt be obſerved, however, that in no caſe whatever is the air totally conſumed; and in that of inflammable air water is produced by the union of the baſis of the latter, that is charcoal, with the baſis of dephlogiſticated air, the oxygenous principle of M. Lavoiſier, and which appears to be one of the component parts of WATER. In the caſe of phoſphorus, the latter is converted into an acid; and in all probability a quantity of water is alſo produced, by which part of it is converted into cryſtalline flowers.

153
Little phlogiſton expelled from iron by being burnt in dephlogiſticated air.

The caſe of the iron, therefore, alone remains to be conſidered. Dr Prieſtley's experiments on this ſubject are related at length under the article AEROLOGY, n° 67 *et ſeq.* In them the iron burnt briſkly in dephlogiſticated air, which, according to the common theory, ſhould have indicated the expulſion of a great quantity of phlogiſton; yet the whole reſiduum, of which the fixed air, produced by the ſuppoſed union of the phlogiſton or principle of inflammability, was only a part, ſcarce amounted ſometimes to one-fourteenth of the air originally employed.

154
The objection inconcluſive.

The argument, however, inſtead of contradicting the exiſtence of phlogiſton, only ſhows, that in ſome caſes the diſſipation of a very ſmall quantity of phlogiſton is neceſſary to inflammation; or that the aerial principle may combine with the iron in its metallic ſtate.

155
Iron is not reduced to a calx by burning in dephlogiſticated air.

In this caſe only a very little quantity of the phlogiſton of the iron was diſſipated; for it was not reduced to a calx, but to that kind of ſcoriæ which flies off in ſcales by beating the metal when red-hot with an hammer. A deciſive proof of this was had by uniting iron thus combined with the baſis of dephlogiſticated air with inflammable air.

156
Water produced in the reduction of it by inflammable air.

By this the metal was indeed reduced to perfect iron again; but water was produced at the ſame time from the union of the baſis of the two airs, that of the inflammable air being capable of furniſhing a ſuperfluous quantity, which united with the other into the form of a fluid.

157
Heat produced in the combuſtion of inflammable bodies derived from the air.

The exiſtence of phlogiſton being thus proved, and its nature aſcertained, we may now proceed to determine the queſtion, Whether the great quantity of heat produced by the combuſtion of inflammable bodies proceeds from the bodies themſelves, or from the air which muſt be admitted to them in order to make them burn? That the heat in this caſe proceeds from the atmoſphere is evident; becauſe in all caſes of combuſtion there is a certain diminution undoubtedly takes place by means of the converſion of the dephlogiſticated part of the atmoſphere into fixed air. It is proved, under the article *ELASTIC Vapours*, that elementary fire is the univerſal cauſe of elaſticity in fluids. By uniting a certain quantity of it with any ſubſtance, the latter at length aſſumes an aerial or vaporous form; and it is this vapour alone which is inflammable*. Different vapours no doubt contain different quantities of theſe ingredients; but in all caſes the baſis of the dephlogiſticated part of the atmoſphere

---

* See *Elaſtic Vapour.*

* See the article *Flame.*

muſt unite with the phlogiſton of the inflammable body, or with ſomething elſe, ſo that a decompoſition may enſue: and it is this decompoſition which produces the heat and light; for then the fire contained in the atmoſphere having no longer any thing to abſorb it, muſt appear in its proper form.

158 Too much phlogiſton prevents the heat from being intenſe.

But in thoſe caſes where there is a great quantity of phlogiſton, and conſequently much fixed air produced, the latter abſorbs ſo much heat in a latent ſtate, that the quantity communicated to ſurrounding bodies muſt be greatly diminiſhed; and if an exceſs of this ingredient, not only fixed air, but the phlogiſticated kind and groſs ſmoke be alſo produced, this diminiſhes the heat ſtill farther by the great abſorption, and will even deſtroy it altogether. The remedy for this is either to diminiſh the quantity of phlogiſton, or to augment the quantity of air; which, by furniſhing a greater quantity of dephlogiſticated baſis, affords an opportunity for the evolution of a greater quantity of heat.

159 Too great a quantity of air has the ſame effect.

On the other hand, when the quantity of air is too great, the phlogiſtic matter cannot combine with the baſis of the pure air in ſufficient quantity to effect a decompoſition; and therefore the heat is abſorbed in a latent ſtate, and the fire goes out.

From this theory, which is farther illuſtrated under the articles FIRE, FLAME, HEAT, PHLOGISTON, &c. we may not only have a rational idea of the manner in which inflammation is generally accompliſhed, but ſee why a fire may be put out both by too great a quantity of fuel, and by too great a quantity of air.

160 Why the ſolar heat and that of electricity are ſo intenſe.

We may alſo ſee why the ſolar beams and electric fluid, which contain no phlogiſtic matter, excite a much more powerful heat than any we can raiſe in our hotteſt furnaces. The difference between ignition and inflammation will now likewiſe appear; ſuch bodies as are capable only of ignition containing little or no phlogiſton, but inflammable bodies a great deal.

161 Table of the various degrees of heat.

The following table ſhows the moſt remarkable degrees of heat from the congelation of mercury to that of Mr Wedgewood's hotteſt furnace.

Mercury freezes at - -	40
Weak ſpirit of wine - -	32
Brandy at - - -	10
Cold produced by ſnow and ſalt mixed	0
Strong wine freezes at -	20
Vinegar freezes at - -	27
Water freezes at - -	32
Temperature of ſpring and autumn	50
Ordinary ſummer weather -	65
Sultry heat - - -	75
Heat of human blood -	97 to 100
Feveriſh heat - - -	108
Bees wax melts - - -	142
Serum coagulates - - -	156
Spirit of wine boils - -	174
Water boils - - -	212
Tin melts - - -	408
Biſmuth melts - -	460
Oil of vitriol boils - -	550
Oil of turpentine boils -	561
Lead melts - -	585
Quickſilver and linſeed-oil boil -	600
Iron begins to ſhine in the dark -	635
Iron ſhines briſkly in the dark -	750
Iron ſhines in the twilight -	884
Iron red-hot from a common fire	1050
Red heat fully viſible in day light according to Mr Wedgewood -	1077
Heat by which his enamel colours are burnt on - - -	1857
Braſs melts - - -	3807
Swediſh copper melts - -	4587
Fine ſilver melts - -	4717
Fine gold melts - -	5237
Leaſt welding heat of iron -	12777
Greateſt ditto - -	13427
Greateſt heat of a common ſmith's forge - - -	17327
Caſt iron melts - -	17977
Greateſt heat of Wedgewood's ſmall air-furnace - - -	21877
Extremity of the ſcale of his thermometer - - -	32277

SECT. II. *Of the Doctrine of Elective Attraction, and of the different Objects of Chemiſtry.*

162 Chemical attraction.

BEFORE we proceed to give a general theory of the changes which happen upon the mixtures of different bodies together, or expoſing them ſingly to heat, we muſt obſerve, that all depend on certain qualities in bodies, by which ſome of them are apt to join together, and to remain united while they have an opportunity. The cauſe of theſe qualities is totally unknown; and therefore philoſophers, after the example of Sir Iſaac Newton, have expreſſed the apparent effect of this unknown cauſe by the word *attraction*. From them the word has been adopted by the chemiſts, and is now generally uſed in ſpeaking of the phenomena which are obſerved in the mixture of different ſubſtances; but to diſtinguiſh it from other kinds, it is uſually called *Elective*.

This attraction is not equally ſtrong between all ſubſtances; in conſequence of which, if any body is compounded of two others, and another is preſented to it which has a greater attraction for one of the component parts than they have for one another, the ſubſtance will be *decompounded*. A new compound is then formed by the union of that third ſubſtance with one of the component parts or *elements* (if we pleaſe to call them ſo) of the firſt. If the attraction between the body ſuperadded and either of the component parts of the other is not ſo ſtrong as that between themſelves, no decompoſition will enſue; or if the third ſubſtance is attracted by both the others, a new compoſition will take place by the union of all the three.

163 Objects of chemiſtry how claſſed.

The objects of chemiſtry, as we have already obſerved, are ſo various, that an enumeration of them all is impoſſible. To eaſe the mind, therefore, when ſpeaking of them, and render more uſeful any thing that is ſaid or wrote on chemiſtry, it is neceſſary to divide them into different claſſes, comprehending in each claſs thoſe bodies which have the greateſt reſemblance to one another, and to which one common rule applies pretty generally.—The diviſion formerly uſed, was that of vegetables, animals, and minerals; but this has been thought improper, as there are many ſubſtances in each of thoſe kingdoms which differ very widely from one another, and which are by no means ſubject to the ſame laws. The moſt approved method,

thod, at preſent, of arranging the objects of chemiſtry, is into ſalts, earths, metals, inflammable ſubſtances, waters, animal and vegetable ſubſtances.

Sect. III. *Salts.*

164
Salts.

Salts are either *fuſible*, that is, capable of abiding the fire, and melting in a ſtrong heat, without being diſſipated; or *volatile*, that is, being diſperſed in vapour with a ſmall heat. Their other properties are, that they are ſoluble in water: not inflammable, unleſs by certain additions; and give a ſenſation of taſte when applied to the tongue.

The moſt general characteriſtic of ſalts is, that they are all ſoluble in water, though ſome of them with much more difficulty than others. Moſt of them have likewiſe the property of forming themſelves, in certain circumſtances, into ſolid tranſparent maſſes of regular figures, different according to the different ſalt made uſe of, and which are termed *cryſtals* of that ſalt. In this ſtate they always contain a quantity of water; and therefore the utmoſt degree of purity in which a ſalt can be procured, is when it has been well cryſtallized, and the cryſtals are freed of their ſuperfluous moiſture by a gentle heat. They generally appear then in the form of a white powder.

165
Phenomena attending their ſolution.

In the ſolution of ſalts in water, the firſt thing obſervable is, that the water parts with the air contained in it; which immediately riſes to the top in the form of bubbles. This, however, is moſt remarkable when the ſalt is in the dry form we have juſt now mentioned, becauſe there is always a quantity of air entangled among the interſtices of the powder, which riſes along with the reſt; and this diſcharge of air is ſometimes ſo great, as to be miſtaken for an effervescence. From this, however, it is eſſentially different. See Effervescence.

Another thing obſervable in the ſolution of ſalts is, that a conſiderable change happens in the temperature of the water in which they are diſſolved; the mixture becoming either a good deal warmer or colder than either the ſalt or the water were before. In general, however, there is an increaſe of cold, and ſcarce any ſalt produces heat, except when it has been made very dry, and deprived of that moiſture which it naturally requires; and thus the heating of ſalts by being mixed with water may be explained on the ſame principle with the heat produced by quicklime. See Quicklime.

After ſalt has been diſſolved in a certain quantity by water, no more of that ſalt will be taken up unleſs the water is heated; and as long as the heat continues to increaſe, the ſalt will be diſſolved. When the water boils, at which time it has attained its greateſt heat, and will take up no more ſalt, it is then ſaid to be *ſaturated* with that ſalt. This, however, does not prevent it from taking up a certain quantity of another ſalt, and after that perhaps of a third, or fourth, without letting go any of the firſt which it had diſſolved. How far this property of water extends, has not yet been aſcertained by experiments.

To the above rule there is only one exception known as yet; namely, common ſea-ſalt: for water diſſolves it in the very ſame quantity when cold as when boiling hot. It has been ſaid by ſome, that all deliqueſcent ſalts, or thoſe which grow moiſt on being expoſed to the air, had the ſame property: but this is found to be a miſtake.

166
Mixture and ſeparation of ſalts.

This property of ſolubility, which all the ſalts poſſeſs in common, renders them eaſily miſcible together; and the property by which moſt of them ſhoot into cryſtals, renders thoſe eaſily ſeparable again which have no particular attraction for one another. This is likewiſe rendered ſtill more eaſy by their requiring different proportions of water, and different degrees of heat, to ſuſpend them; for by this they cryſtallize at different times, and we have not the trouble of picking the cryſtals of one out among thoſe of the other.

167
Hypotheſis concerning the ſolution of ſalts.

The manner in which the ſolution of ſalts in water is effected, is equally unaccountable with moſt of the other operations of nature. Sir Iſaac Newton ſuppoſed that the particles of water got between thoſe of the ſalt, and arranged them all at an equal diſtance from one another: and from this he alſo accounts for the regular figures they aſſume on paſſing into a cryſtalline form; becauſe, having been once arranged in an orderly manner, they could not come together in diſorder, unleſs ſomething was to diſturb the water in which they were ſuſpended; and if any ſuch diſturbance is given, we find the cryſtals are by no means ſo regular as otherwiſe they would have proved. Others have thought that theſe figures depend on a certain *polarity* in the very ſmall particles into which the ſalt is reſolved when in a ſtate of ſolution. Theſe things, however, are merely conjectural; neither is it a matter of any conſequence to a chemiſt whether they are right or wrong.

168
Salts deſtructible by repeated ſolutions.

Though ſolution is that operation which ſalts undergo the moſt eaſily, and which ſhould ſeem to affect them the leaſt of any, a repetition of it proves nevertheleſs very injurious to them, eſpecially if it is followed by quick evaporation; and the ſalt, inſtead of being cryſtallized, is dried with a pretty ſtrong heat. Newman relates, that a pound of ſea-ſalt was reduced, by 13 ſolutions and exſiccations, to half an ounce; and even that was moſtly earth. Where ſolution is required, therefore, it ought always to be done in cloſe veſſels, in which alſo the ſubſequent evaporation ſhould be performed, (ſee Evaporation); and in all caſes where cryſtallization is practicable, it ought to be preferred to violent exſiccation.

169
Acids.

The two great diviſions of ſalts are into acids and alkalies. The former of theſe are known by their peculiar taſte, which is called *acid* or *ſour*. They are not found in a ſolid form; neither are any of them, except the acids of vitriol, of tartar, of phoſphorus, and of borax, capable of being reduced to ſolidity. The others, when highly concentrated, that is, brought to the utmoſt degree of ſtrength of which they are capable, always become an inviſible vapour, permanently elaſtic, until it comes in contact with water, or ſome other ſubſtance with which they are capable of uniting. For ſuch acids the name of *ſalts* ſeems leſs proper, as we can ſcarcely ſay that a *vapour*, which is already much more fluid than water, can be *diſſolved* in that element.

The acids are divided into the mineral, the vegetable, and the animal; expreſſing their different origin, or where they are moſt commonly to be found. The mineral acids are commonly reckoned three; the

vi-

vitriolic, the nitrous, and the marine. To this the acid of borax ought to be added; but its weakneſs makes it much leſs taken notice of as an acid than the others. A Swediſh chemiſt, however, Mr Scheele, hath lately added ſeveral others, which are afterwards taken notice of.

The vegetable kingdom affords only two diſtinct ſpecies of acids, at leaſt without the aſſiſtance of ſome chemical operation. The one appears fluid, and when concentrated to the utmoſt degree becomes an inviſible vapour. This is produced from fermented liquors, under the name of *vinegar*. An acid ſimilar to this, and which is thought not to be eſſentially different from it, is extracted from moſt vegetables by diſtillation with a ſtrong fire. The other is likewiſe a conſequence of fermentation; and cruſts on the bottom and ſides of caſks in which wine is put to depurate itſelf. In its crude ſtate it is called *tartar*; and when afterwards purified, is called the *cream*, or cryſtals, of tartar. As for the various acids produced in the different chemical proceſſes to be afterwards related, we forbear to mention them at preſent, it being juſtly ſuſpected that ſome of them are artificial.

The animal acids, which have hitherto been diſcovered, are only two; the acid of ants, and that of urine, which is alſo the acid of phoſphorus. The firſt of theſe is volatile; and conſequently muſt be ſuppoſed a vapour when in its ſtrongeſt ſtate: the other is exceedingly fixed; and will rather melt into glaſs than riſe in vapours. Beſides theſe, it is ſaid an acid is contained in blood, in waſps, bees, &c.: but no experiments have as yet been made on theſe to determine this matter with any degree of preciſion.

170 Alkalies.

The alkalies are of two kinds; fixed and volatile. The fixed kind are ſubdivided into two; the vegetable, and mineral or foſſil alkali. The vegetable is ſo called, becauſe it is procured from the aſhes of burnt vegetables; the foſſile, becauſe it is found native in ſome places of the earth, and is the baſis of ſea-ſalt, which in ſome places is dug out of mines in vaſt quantity. They are called *fixed*, becauſe they endure a very intenſe degree of heat without being diſſipated in vapour, ſo as even to form a part of the compoſition of glaſs. The volatile alkali is generally obtained by diſtillation from animal ſubſtances. In its pure ſtate this alkali is perfectly inviſible; but affects the ſenſe of ſmelling to ſuch a degree, as not to be approached with ſafety.

171 Different action of alkalies and acids.

The acids and alkalies are generally thought to be entirely oppoſite in their natures to one another. Some, however, imagine them to be extremely ſimilar, and to be as it were parts of one ſubſtance violently taken from each other. Certain it is, that when ſeparated, they appear as oppoſite to one another as heat and cold. Their oppoſite action indeed very much reſembles that of heat and cold, even when applied to the tongue; for the alkali has a hot, bitter, burning taſte, while the acid, if not conſiderably concentrated, always gives a ſenſation of coldneſs. In their action too upon animal ſubſtances, the alkali diſſolves, and reduces the part to a mucilage; while the acid, if not very much concentrated, tends to preſerve it uncorrupted.

172 Neutral ſalts.

If an alkaline ſalt, and moderately ſtrong acid in a liquid ſtate, be mixed together, they will immediately unite; and, provided the alkali has not been deprived of its fixed air, their union will be attended with a very conſiderable efferveſcence: (ſee Aerology.) If the alkali has been deprived of air, no efferveſcence will enſue, but they will quietly mix together; but if a due proportion of each has been added, the liquor will neither have the properties of an acid nor an alkali, but will be what is called *neutral*. The bringing the liquor into this ſtate, is called *ſaturating* the acid or alkali, or combining them to the point of ſaturation.

If the liquor after ſuch a ſaturation be gently evaporated, a ſaline maſs will be left, which is neither an acid nor an alkali, but a new compound formed by the union of the two, and which is called a *perfect neutral ſalt*. The epithet *perfect* is given it, to make a diſtinction between the ſalts formed by the union of an acid and an alkali, and thoſe formed by the union of acids, with earthy or metallic ſubſtances; for theſe will likewiſe unite with acids, and ſome of the compounds will cryſtallize into regular figures; but, becauſe of their weaker union with theſe ſubſtances, the ſalts reſulting from combinations of this kind are called *imperfect*.

173 Vegetable colours changed by acids and alkalies.

All acids, the volatile ſulphureous one excepted, change the blue infuſions of vegetables, ſuch as violets, to a red; and alkalies, as well as ſome of the imperfect neutrals, change them to green. This is the niceſt teſt of an acid or alkali abounding in any ſubſtance, and ſeems the moſt proper method of determining whether a ſolution intended to be neutral really is ſo or not.

174 Differences in the degrees of attraction between acids and alkalies

Though between every acid and alkali there is a very ſtrong attraction, yet this is far from being the ſame in all; neither is it the ſame between the ſame acid and alkali in different circumſtances of the acid. When the acids are in a liquid ſtate, and as free as poſſible of inflammable matter, between which and the nitrous and vitriolic acids there is a very ſtrong attraction, the vitriolic will expel any of the reſt from an alkaline baſis, and take its place. Thus, if you combine the acid of ſea-ſalt, or marine acid, to the point of ſaturation, with the foſſil alkali, a neutral ſalt will be formed, which has every property of common ſalt: but, if you pour on a certain proportion of the vitriolic acid, the acid of ſea-ſalt will immediately be expelled; and the liquor, upon being evaporated, will contain not the neutral ſalt formed by an union of the marine acid with the alkali, but another conſiſting of the vitriolic acid joined with that alkali, and which has quite different properties from the former.

When the acids and alkalies are applied to one another in a liquid ſtate, the vitriolic acid always ſhows itſelf to be the moſt powerful; but when applied in a ſolid form, and urged with a violent heat, the caſe is very much altered. Thus, the acid of borax, commonly called *ſal ſedativus*, is ſo weak as to be diſengaged from its baſis by every acid applied in a liquid form, that of tartar alone excepted; but if even the vitriolic acid combined with an alkali be mixed with this weak acid, then exſiccated, and at laſt urged with a vehement fire, the vitriolic acid will be diſengaged from its baſis, and riſe in vapours, leaving the weaker acid in poſſeſſion of the alkali. The ſame thing happens on adding the phoſphorine or urinous acid,

acid, or the acid of arſenic, &c. to combinations of the vitriolic or other acids with alkaline ſalts.—When the acids are in a liquid ſtate, therefore the moſt powerful is the vitriolic; next the nitrous; then the marine; then vinegar; acid of ants; and laſtly the ſal ſedativus and tartar, which ſeem to be nearly equal in this reſpect.—If they are applied in a ſolid form, the moſt powerful are the ſal ſedativus and phoſphorine acid; then the vitriolic, nitrous, marine, and vegetable acids.

When they are reduced to vapour, the caſe is exceedingly different; for then the marine acid appears to be the moſt powerful, and the vitriolic the leaſt ſo of any. It is impoſſible, however, to preſerve the vitriolic acid in the form of vapour, without combining it with a certain quantity of inflammable matter, which muſt neceſſarily deſtroy its ſtrength. Dr Prieſtley found, that the marine acid, when reduced to vapour, was capable of diſuniting the nitrous acid from a fixed alkali.

Though the vitriolic acid ſometimes aſſumes a ſolid form, it is by no means eaſy to reduce it to this ſtate by mere concentration, without the aſſiſtance of nitrous acid. Baldaſart, however, pretends that he diſcovered, in the neighbourhood of a volcano, a pure and icy oil of vitriol, from which nothing could be precipitated by alkaline ſalts; though there is certainly very great reaſon to doubt the accuracy of this obſervation. Of late the nitrous acid has alſo been found capable of aſſuming a ſolid form. This was firſt obſerved by M. Bernhard in diſtilling a very large quantity of the acid. At that time he perceived a white ſalt adhering to the inſide of the receiver, which on examination proved to be the acid of nitre in a concrete form; being extremely corroſive, emitting red vapours copiouſly on being expoſed to the air, and at length totally evaporating in it. Its ſpecific gravity, however, was far inferior to that of the glacial oil of vitriol.

175
Acids unite with phlogiſton.

The acids have the property of uniting themſelves to many other ſubſtances beſides fixed alkalies, and forming neutral compounds with them. Of theſe the chief is the principle of inflammability or phlogiſton. In the vitriolic, nitrous, and phoſphorine acids, the attraction for this principle is very ſtrong; ſo great, that the two former will even leave a fixed alkali to unite with it. In the marine acid it is leſs perceptible; in the liquid vegetable or animal acid ſtill leſs; and in the acid of tartar, and ſal ſedativus, not at all.

176
With metals and earth.

Beſides this, all acids will diſſolve metallic and earthy ſubſtances: with theſe, however, they do not in general unite ſo firmly with alkaline ſalts; nor do they unite ſo ſtrongly with metals as with earths.

177
Elective attractions.

In general, therefore, we may expect, that after having diſſolved a metal in any acid whatever, if we add an earthy ſubſtance to that ſolution, the acid will quit the metal, which it had before diſſolved, to unite with the earth. In this caſe the ſolution will not be clear as before, but will remain muddy, and a quantity of powder will fall to the bottom. This powder is the metalline ſubſtance itſelf, but deprived of one of its component parts; and in this caſe it is ſaid to *precipitate* in the form of a *calx*.

If to this new ſolution of the earthy ſubſtance in an acid liquor, a volatile alkaline ſalt, not deprived of its fixed air, is added, the acid will quit the earth, and unite wit hthe alkaline ſalt. The earth thus diſengaged will again *precipitate*, and lie at the bottom in fine powder, while the volatile alkali and acid remain combined together, and the liquor again becomes clear.

The attraction between volatile alkalies and acids is conſiderably leſs than between fixed alkalies and the ſame acids. If, therefore, a fixed alkali be now added to the liquor, the volatile alkali will be ſeparated, and the acid will unite with the fixed alkali. The volatile alkali indeed, being perfectly ſoluble in water, cannot precipitate, but will diſcover its ſeparation by the pungent ſmell of the mixture; and upon evaporating the liquor, the volatile alkali will be diſſipated, and a ſaline maſs, conſiſting of the acid and fixed alkali, will remain.

178
Detonation of nitre.

Laſtly, If the acid employed was the nitrous, which has a ſtrong attraction for the principle of inflammability, if the ſaline maſs be mixed with a proper quantity of inflammable matter, and expoſed to a ſtrong heat, the acid will leave the alkali with vaſt rapidity, combine with the inflammable matter, and be deſtroyed in flame in a moment, leaving the alkali quite pure.

179
Exceptions to the above rules.

Though the abovementioned effects generally happen, yet we are not to expect that they will invariably prove the ſame whatever acid is made uſe of; or even that they will be the ſame in all poſſible variety of circumſtances in which the ſame acid can be uſed.—The acid of tartar is one exception, where the general rule is in a manner reverſed; for this acid will quit a fixed alkali for an earth, eſpecially if calcined, and even for iron. If lead, mercury or ſilver, are diſſolved in the nitrous acid, and a ſmall quantity of the marine acid is added, it will ſeparate the ſtronger nitrous acid, and fall to the bottom with the metals in form of a white powder.—The vitriolic acid, by itſelf, has a greater attraction for earthy ſubſtances than for metals; and greater ſtill for fixed alkaline ſalts than for either of theſe: but if quickſilver is diſſolved in the nitrous acid, and this ſolution is poured into a combination of vitriolic acid with fixed alkali, the vitriolic acid will quit the alkali to unite with the quickſilver. Yet quickſilver by itſelf cannot eaſily be united with this acid. The reaſon of all theſe anomalies, however, is fully explained in the following ſection.

§ 1. *Of the Operations of Solution and Precipitation.*

The chemical ſolution of ſolid bodies in acid or other menſtrua, is a phenomenon which, though our familiarity with it has now taken off our ſurpriſe, muſt undoubtedly have occaſioned the greateſt admiration and aſtoniſhment in thoſe who firſt obſerved it. It would far exceed the limits of this treatiſe to ſpeak particularly of all the various circumſtances attending the ſolution of different ſubſtances in every poſſible menſtruum. The following are the moſt remarkable, collected from Mr Bergman's Diſſertion on Metallic Precipitates.

180
Phenomena attending the ſolution of a metal.

1. On putting a ſmall piece of metal into any acid, it is diſſolved ſometimes with violence, ſometimes gently, according to the nature of the menſtruum and of the metal to be diſſolved.

2. The nitrous acid is the moſt powerful in its action

tion upon metallic ſubſtances, when unaſſiſted by heat. So great indeed is the violence with which this acid ſometimes acts, that the metal, inſtead of being diſſolved, ſeparates inſtantaneouſly from it in the form of a calx or powder ſcarce ſoluble in any menſtruum, at the ſame time that the heat, efferveſcence, and noxious vapours iſſuing from the mixture, render it abſolutely neceſſary to moderate the action of the menſtruum, either by dilution or cold, or both. In other caſes, however, as when put to gold or platina, the nitrous acid has no effect until it be united with the marine, when the mixture acts upon thoſe metals, which neither of the acids ſingly would touch.

181 Nitrous acid the moſt violent in its operation.

182 Vitriolic acid acts more weakly.

3. The action of the vitriolic acid, though in the higeſt degree of concentration, is more weak. It does not readily attack ſilver or mercury unleſs aſſiſted by a boiling heat, nor will even that be ſufficient to make it act upon gold or platina.

183 Marine acid generally more weak than either, except when dephlogiſticated.

4. The action of marine acid, unleſs on ſome particular ſubſtances, is ſtill more weak; but when dephlogiſticated, or deprived of part of the phlogiſton eſſential to its conſtitution as an acid, it acts much more powerfully, and diſſolves all the metals completely.

184 The reſt of the acids much weaker ſtill.

5. The other acids, as thoſe of fluor, borax, with ſuch as are obtained from the animal and vegetable kingdoms, are much inferior in their powers as ſolvents, unleſs in very few inſtances.

185 Different degrees of ſolubility in metals.

6. Metals vary very much in their degrees of ſolubility; ſome yielding to almoſt every menſtruum, and others, as has been already obſerved, being ſcarce acted upon by the moſt powerful.

186 Solution ſometimes promoted by abſtracting a certain proportion of phlogiſton.

187 But is totally prevented by taking away too much: exemplified in manganeſe.

7. Zinc and iron are of the former kind, and gold and ſilver of the latter, eluding the marine; and gold, unleſs in one particular caſe, viz. when aſſiſted by heat in a cloſe veſſel, the action of the nitrious acid alſo. Theſe metals, however, which in their perfect ſtate reſiſt the action of the moſt powerful menſtrua, may be diſſolved much more readily when deprived of a certain quantity of their inflammable principle. But though the ſeparation of this principle in ſome degree renders metals more ſoluble, the abſtraction of too much of it, particularly in the caſe of iron and tin, renders theſe metals almoſt entirely inſoluble. Manganeſe is the moſt remarkable inſtance of this power of the phlogiſtic principle, in depriving metals of their ſolubility by its abſence, or reſtoring it to them by its preſence; for this ſubſtance, when reduced to blackneſs, cannot be diſſolved by any acid without the addition of ſome inflammable matter; but when by the addition of phlogiſton it has become white, may be diſſolved in any acid.

188 Solution of metals attended with an efferveſcence.

8. The diſſolution of metals by acids, even to their very laſt particle, is attended by a viſible efferveſcence: this is more perceptible according to the quickneſs of the ſolution; but more obſcure, and ſcarcely to be ſeen at all, when the ſolution proceeds ſlowly.

189 Various kinds of elaſtic fluids extricated.

9. The elaſtic fluids extricated by theſe ſolutions are various, according to the nature of the acid and of the metal employed. With the nitrous, the fluid produced is commonly that called *nitrous air*; with vitriolic and marine acids the produce is ſometimes inflammable air, ſometimes otherwiſe, acccording to the nature of the metal acted upon.

10. Heat in a greater or ſmaller degree is always produced during the diſſolution of metals; and the degree of it is in proportion to the quantity of the matter and the quickneſs of the ſolution; and hence, in ſmall quantities of metal, and when the ſolution proceeds very ſlowly, the temperature of the maſs is ſcarcely altered.

190 Heat produced during the diſſolution of metals.

191 Little air can be obtained from metals when calcined.

11. The calces of metals either yield no air at all, or only the aerial acid, unleſs when urged by a violent heat almoſt to ignition; when, by means of vitriolic or nitrous acid, they yield a quantity of pure air, after other elaſtic fluids, ſuch as vitriolic, nitrous, or phlogiſticated air. None of the dephlogiſticated air is uſually produced by the marine acid in conjunction with metallic calces.

192 Various colours of metallic calces.

12. The ſolutions of ſome metals are coloured, others are not. The colour of the former is only that which is proper to the calx, but rendered more vivid by the moiſture. Thus ſolutions of gold and platina are yellow; thoſe of copper, blue or green; ſolutions of nickel of a bright green; but thoſe of cobalt are red, although the calx is black. We may obſerve that even this red colour may be heightened to blackneſs. Iron moderately calcined is green; but this rarely continues upon further dephlogiſtication. The white calces of ſilver, lead, tin, biſmuth, arſenic, antimony, and manganeſe, are diſſolved without colour; but ſolutions of lead, tin, and antimony, are ſomewhat yellow, unleſs ſufficiently diluted. Mercury, however, forms a ſingular exception to this rule; for the orange-coloured calx of this metal forms a colourleſs ſolution. The metals yielding coloured ſolutions are gold, platina, copper, iron, tin, nickel, and cobalt; the reſt, if properly depurated, give no tinge. A ſolution of ſilver is ſometimes of a blue or green colour at firſt, although there be no copper preſent; the vitriolic acid becomes blue with copper; the nitrous may be made either blue or green at pleaſure; the marine varies according to the quantity of water with which it is diluted. Manganeſe, when too much dephlogiſticated, renders both the vitriolic and marine acids purple.

193 Bergman's account of the cauſe of chemical ſolution.

194 Solution impeded by too great a quantity of phlogiſton.

159 Sulphur dephlogiſticated by nitrous acid.

With regard to the cauſe of chemical ſolutions, our author obſerves, that though attraction muſt be looked upon as the fundamental cauſe, yet we may alſo lay it down as a maxim, that no metal can be taken up by an acid, and at the ſame time preſerve the whole quantity of phlogiſton which was neceſſary to it in its metallic ſtate. A certain proportion of the principle of inflammability therefore may be conſidered as an obſtacle which muſt be removed before a ſolution can take place. Thus, of all the acids, the nitrous attracts phlogiſton the moſt powerfully, and ſeparates it even from the vitriolic. A proof of this may be had by boiling ſulphur ſlowly in concentrated nitrous acid. At length all its phlogiſton may be ſeparated, and the vitriolic acid will remain, deprived of its principle of inflammability. The extraordinary ſolvent powers of this acid, therefore, is conformed to the peculiarity of its nature in this reſpect. For this menſtruum diſſolves metals for ſolution with the greateſt eaſe, moſt commonly without any aſſiſtance from external heat; which in ſome inſtances would be hurtful, by ſeparating too much of phlogiſton, as appears in the caſe of iron, tin, and antimony; all of which may be ſo far dephlogiſticated by the nitrous acid, as to be rendered extremely difficult of ſolution: for this reaſon it is very often neceſſary, as has already been obſerved, to temper the

196 Calces of ſome metals prepared by nitrous acid almoſt inſoluble ever afterwards.

activity of this menſtruum by water.

197 Why the vitriolic acid cannot act on lead, ſilver, &c. without a boiling heat.

The vitriolic acid requires a boiling heat before it can act upon ſilver or mercury. The reaſon of this is, that by means of the heat, the watery part of the menſtruum is diminiſhed, its power is thereby increaſed, and the connection of the metallic earths with the inflammable principle diminiſhed.

198 Why marine acid acts on ſome metals and not on others.

Marine acid, which contains phlogiſton as one of its conſtituent principles, muſt neceſſarily have little or no effect on thoſe metals which retain their principle of inflammability very obſtinately. But its watery part being diminiſhed by boiling, it aſſumes an aerial form, and powerfully attracts a larger quantity of phlogiſton than before; ſo that in a vaporous ſtate it will diſſolve metals, particularly ſilver and mercury, which in its liquid form it would ſcarce be brought to touch. When dephlogiſticated as much as poſſible, it attracts phlogiſton with prodigious avidity, diſſolving all metals by its attraction for their phlogiſton, and, uniting the inflammable principle to itſelf, reſumes the ordinary form of marine acid. When dephlogiſticated by means of nitrous acid in aqua regis, it diſſolves gold and platina. On the ſame principles may we account for its inferiority in power to the other acids.

199 Why ſome metals are more ſoluble than others.

It has already been obſerved that the metals differ much in their degrees of ſolubility, which is owing to the various, degrees of force with which they retain their phlogiſton. Thoſe called perfect metals effectually reſiſt calcination in the dry way. In this operation, the fire on the one hand, the great cauſe of the volatility of bodies, ſtrenuouſly endeavours to expel the phlogiſton; on the other hand, the baſis of the dephlogiſticated part of the atmoſphere (the acidifying principle of M. Lavoiſier, and the *principium ſorbile* of Dr Lubbock) attracts the calx ſtrongly. Experience, however, ſhows, that theſe two forces united, cannot decompoſe gold, ſilver, or platina to any conſiderable degree. All the other metals yield to theſe forces when united, but not ſingly. Iron and zinc retain their inflammable principle ſo ſlightly, that any acid immediately acts upon them; but if the other metals be properly prepared for ſolution by being calcined to a certain degree, the acid will immediately take them up. Any further privation, however, would be injurious, and precipitate what was before diſſolved.

200 Why nitrous acid precipitates a ſolution of tin or antimony.

Thus the nitrous acid, when added to a ſolution of tin or antimony in marine acid, by its extraordinary attraction for phlogiſton carries off ſuch a quantity of it, that the calces of the metals are immediately precipitated.

201 Different kinds of air produced during the diſſolution of metals.

The various elaſtic fluids which reſemble air, and which are produced in plenty during the diſſolution of metals, may be reduced to the following, *viz.* thoſe extricated by the vitriolic, nitrous, and marine acids, fluor acid, vinegar, alkaline ſalts, and hepar ſulphuris.

202 Pure vitriolic acid cannot be reduced into an aerial form but by a combination with phlogiſton.

Pure vitriolic acid expoſed to a violent heat, is indeed reſolved into vapours, but of ſuch a nature, that when the heat is gone, they condenſe again into an acid liquor of the ſame nature as before. But if any ſubſtance be added which contains phlogiſton in a ſeparable ſtate, an elaſtic fluid is produced by means of fire, which is ſcarcely condenſible by the moſt extreme cold, unleſs it comes in contact with water. This is called the volatile ſulphureous acid, or vitriolic acid air, which may be totally abſorbed by water. In this caſe the bond of union betwixt it and the phlogiſton is ſo weak, that the latter ſoon flies off totally, and common vitriolic acid is regenerated.

203 Nitrous acid more obviouſly changed.

The nitrous acid undergoes a ſimilar change in a more obvious manner. Let a piece of ſilver, for inſtance be put into a dilute nitrous acid, and the ſurface of the metal will inſtantly be covered with innumerable bubbles, which ariſing to the top of the liquor, there burſt; and if collected, are found to be nitrous air.

204 Why nitrous air does not unite with water.

The nitrous acid ſaturates itſelf with phlogiſton more completely than the vitriolic; therefore the elaſtic fluid produced, or nitrous air, does not unite with water, and ſcarce retains any veſtige of an acid nature. The vitriolic acid, however, differs from the nitrous in this reſpect, that the phlogiſton is abſorbed by the latter even beyond the point neceſſary to obliterate its acid nature. In proof of this, our author adduces the decompoſition of hepatic by means of nitrous air.

205 Phenomena exhibited by the marine acid.

The marine acid exhibits different phenomena. It naturally contains phlogiſton, and therefore can by its means be reſolved into a kind of air ſomewhat ſimilar to that produced by the vitriolic acid when artificially united to the ſame principle, and which has the ſame property, *viz.* that of remaining permanently elaſtic as long as it is kept from the contact of water. But as the acid we ſpeak of naturally contains phlogiſton, there is no neceſſity of adding more to produce this effect. In the mean time, the marine as well as nitrous air, when in its expanded ſtate, attracts phlogiſton, and that with wonderful avidity.

206 Of the dephlogiſticated marine acid.

When the marine acid is dephlogiſticated, it yields another elaſtic fluid of a reddiſh brown colour, having an odour like that of warm aqua regia. This does not unite with water, or only in very ſmall quantity: and by the addition of a proper proportion of phlogiſton may be reduced again to common marine acid. It is ſaid that the marine acid may be dephlogiſticated by lead as well as by manganeſe, the nitrous acid, and arſenic.

207 Of the fluor acid.

The fluor acid abounds with phlogiſton, and therefore may, without any adventitious matter, be reduced to an elaſtic fluid. This air is eaſily diſtinguiſhed from all others by its corroſion of glaſs whilſt hot.

208 Why vinegar may be reduced into air without addition.

Vinegar alſo contains phlogiſton; and for that reaſon, when well dephlegmated, may be reduced without addition into a permanently elaſtic fluid, called acetous air.

209 Heat and not phlogiſton the principle of elaſticity.

All theſe fluids ſeem to be nothing elſe, according to Mr Bergman, than the acids themſelves expanded by phlogiſton. "Perhaps (ſays he) the matter of heat alſo enters their compoſition." The experiments lately made on theſe ſubjects, however, have put it beyond all doubt, that the expanſive principle is not phlogiſton but heat; nevertheleſs, it ſeems highly probable, that theſe elaſtic fluids do really conſiſt of the acid united to phlogiſton, and expanded by heat. This is alſo the caſe with the cauſtic volatile alkali, now called alkaline air.

210 Sulphur exiſts in hepatic air.

In the hepatic air, it has been ſhown by Mr Bergman, that ſulphur exiſts which contains phlogiſton; and there is little reaſon to doubt that the expanſive power here is the ſame as in other caſes. See Hepatic Air.

The heat generated during the ſolution of metals is by Mr Bergman ſuppoſed to be owing to the matter

211
Heat in ſolution moſt probably proceeds from the ſolvent liquor.

of heat which had been fixed in the metals; but it may with much more reaſon be ſuppoſed to proceed from the acid. Dr Black has demonſtrated, that heat is univerſally the principle of fluidity; and all fluids, whether acid or not, are found to contain a great quantity of it. It is not probable that ſolids, even the moſt inflammable, contain an equal quantity; for it is always obſerved, that bodies in becoming fluid abſorb heat, and throw it out again on becoming ſolid. Acids in all probability contain a much greater quantity than what is neceſſary to their fluidity; for we ſee that the nitrous acid, when poured upon ſnow, parts with as much heat as is neceſſary to diſſolve the ſnow, at the ſame time that it ſtill retains its fluidity. The caſe is not ſo with common ſalt, which is a ſolid: for though, in a mixture of ſalt and ſnow, the latter abſorbs as much heat from the ſalt as is neceſſary for its own liquefaction; yet the ſalt could not be held in ſolution by a liquid of this temperature, were it not that an additional quantity is perpetually abſorbed from the adjacent bodies, particularly the atmoſphere. But were it poſſible to prevent this adventitious increaſe of heat, there is not the leaſt reaſon to believe that the ſalt would be diſſolved; for the ſtrongeſt brine, when reduced to the temperature of 0 of Fahrenheit, is decompoſed, the ſalt falling to the bottom in powder, and the water being converted into ice. Add to this alſo, that the cold produced by ſpirit of nitre and ſnow is much more intenſe than that produced by common ſalt and ſnow; which undoubtedly ſhows, that a ſolid does not readily part with as much heat as a fluid, and conſequently cannot be ſuppoſed to contain as much. The ſolution of metals in acids alſo demonſtrates, that the ſolid ſubſtance has not parted with heat, but abſorbed it; for as ſoon as the ſolution becomes ſolid again, *i. e.* when it cryſtallizes, the temperature becomes higher than before.

212
Solid bodies do not part with ſo much heat as fluids.

213
Why little or no elaſtic fluid is obtained from metallic calces.

The calces of metals have not that quantity of phlogiſton that is neceſſary for their metallic ſtate, but yet are not entirely deſtitute of it; therefore, in their ſolution, ſcarce any elaſtic fluid is generated, unleſs the fire be continued after exſiccation. Such as contain aerial acid, diſcharge it immediately in the ſame form as they had received it. It is remarkable, that Dr Prieſtley mentions a calx of lead, which, with the acid of phoſphorous, produced an inflammable air. By means of the nitrous acid and evaporation to dryneſs, a pure air is produced. Sometimes a ſmall portion of vitriolic acid air is obtained by means of a proper degree of fire from vitriolic acid, but a far greater quantity of pure air.

214
Metallic ſolutions contain a calx of the metal with various degrees of phlogiſton.

The ſolutions made by the menſtrua abovementioned, contain a metallic calx intimately united with the acid, the quantity of phlogiſton left being various according to the difference of the menſtrua and of the temperature; but the performance of the operation either with or without intenſe heat, frequently occaſions a remarkable difference. That metals are leſs calcined by the marine than by the nitrous acid, appears from pouring concentrated nitrous acid on tin or antimony; but the difference, if it actually does take place, is leſs viſible in other metals.

215
Reaſons for believing that metals are calcined by phlogiſton.

Some modern chemiſts have denied this calcination of metals by ſolution. They have inſiſted, that the perfect metals ought to be excepted, as they do not yield to the moſt intenſe fire. On this ſubject, however, it may be obſerved, 1. That during their ſolution nitrous air is always generated, and that of a very perfect kind, which cannot happen without phlogiſton; but in this caſe there is nothing preſent which can yield phlogiſton except the metals. Therefore, 2. The metals, when precipitated from their menſtrua by fixed alkalis, both with reſpect to their external appearance and internal properties, appear to be calcined. Thus the precipitate of gold refuſes to unite with mercury, and may be diſſolved by marine acid and other ſimple menſtrua, and that without the production of any elaſtic fluid. 3. Glaſs may be ſtained by theſe calces; but no metal in its perfect ſtate can be taken up by glaſs.

216
Why the calces of the perfect metals may be reduced without addition.

The common objection is, that the calces of the perfect metals may be reduced by heat alone without the addition of charcoal. Many theories have been invented to ſolve this phenomenon. Some have ſuppoſed, that the matter of heat and light are the ſame with the phlogiſton, and that thus the calces are reduced in the ſame manner as by charcoal or other ſubſtances uſually termed *phlogiſtic*. But in this caſe we ought to find the calces of the imperfect metals alſo reduced by a long continuance of heat, as well as the more perfect; which, however, has never yet been known to take place. Some, among whoſe number is Dr Lewis, have imagined, that the poroſity of the veſſels, particularly thoſe made of earthen ware, may be ſuch as to admit the paſſage of phlogiſtic vapours through them; and he inſtances the revival of globules of lead in the middle of pieces of glaſs upwards of an inch in thickneſs, and that where there was not the leaſt appearance of a crack. But from an experiment of Mr Kirwan's to be afterwards related, it is much more probable that the reduction is effected by means of the phlogiſton contained in one part of the calx attracted by another; by which means the latter is reduced to a perfect metal, while the former becomes ſomewhat more dephlogiſticated. In conſequence of this it appears, that the calx of the perfect metals is never totally reduced: for if the operation be performed in a glaſs retort, the bottom of it is always ſtained; which indicates the exiſtence of a calx, in however little quantity.

217
Difficulty concerning the amalgamation of ſilver ſolved by Bergman.

The following fact, Mr Bergman ſays, has been propoſed to him as an inextricable dilemma. "Silver cannot amalgamate with mercury except when in its metallic ſtate, yet both ſalited and nitrated ſilver are taken up by mercury; it is therefore not calcined by the acids, but adheres to them in its metallic form." This, however, may be eaſily ſolved in the following manner. It is well known that the calx of copper, diſſolved in the vitriolic acid, is precipitated in its metallic form on the addition of iron, and that by means of a double elective attraction; for the iron, diſſolving in the acid, would form an inflammable air by its phlogiſton, were not the copper preſent which takes it up, and thereby becomes inſoluble as long as it retains it; but mercury has a ſtronger attraction for acids than ſilver: if therefore ſalited or nitrated ſilver be triturated with mercury, the ſilver muſt be precipitated in a metallic ſtate, and the mercury be calcined by being diſſolved. This alſo takes place, provided there be moiſture ſufficient to ſuffer the elective attractions to operate. The ſuperabundant mercury greedily takes up the comminuted ſilver precipitate; and the *arbores Dianæ* are nothing more than ſuch an amalgam cryſtallized. But although the acids cannot take up any metal while it retains its full proportion of phlogiſton, various metallic ſalts are able to effect that ſolution. Thus nitrated or ſalited mercury, boiled in water together with the crude metal, can take up a certain portion of it without dephlogiſtication; and the latter of theſe ſalts, even in the *via ſicca*, becomes a mercurius dulcis, which contains at the ſame time a crude and a calcined mercury.

218 Phlogiſton the cauſe of colour in metallic ſolutions.

Perfect ſolutions ſhould in general be tranſparent; but ſome, as has been already mentioned, are diſtinguiſhed by a peculiar colour. That phlogiſton is the chief cauſe of colour appears from hence, that the black clax of mangancſe tinges vitriolic acid of a red colour; but on the addition of ſugar the tinge is entirely deſtroyed. Nitrous acid is rendered blue by copper; but when the metal is added in conſiderable quantity, it becomes of a very deep green. The marine acid, which dephlogiſticates the copper leſs, is yet made green; but by dephlegmation may be ſo condenſed as to become brown. Mr Bergman has ſometimes ſeen a ſolution of ſilver green, without the preſence of the ſmalleſt particle of copper. This depends on the abſorption of nitrous air: for let ſmoking nitrous acid be diluted, on the addition of a certain quantity of water it will be of a deep green; by a greater, blue; and upon a ſtill greater, becomes limpid. By means of the water, the nitrous air is extended to a greater ſpace; and this attenuation gradually increaſed varies the colours. Hence we ſee why nitrous acid is made green by a large quantity of copper.

219 Attraction of phlogiſton the cauſe of cauſticity.

Metals dephlogiſticated by acid ſolvents powerfully attract phlogiſton; nay, nitrated ſilver and mercury, and ſalited antimony, corrode animal ſubſtances, in order, as our author ſuppoſes, to extract it. "This metallic cauſticity (ſays he), which is only to be moderated by phlogiſton, ought to be carefully diſtinguiſhed from the acid cauſticity, which is repreſſed by alkalies, and the alkaline, which is mitigated by acids. Colours vary according to the quantity of phlogiſton preſent; and ſome experiments ſhow, that by a ſufficient quantity all colour is entirely deſtroyed.

220 Phenomena attending the precipitation of metals by alkaline ſalts.

All metals may be precipitated by alkaline ſalts; which, by their ſuperior power of attraction, ſeparate them from their menſtrua; but their difference with regard to their nature and preparation alters the nature of the precipitate. With the cauſtic fixed alkali the calces fall almoſt entirely pure, but loaded with water. The weight is found to be increaſed by the water, and perhaps (ſays Mr Bergman) by the matter of heat; but yet leſs than by the aerial acid. With the aerated fixed alkali, by means of a double decompoſition, the aerial acid unites to moſt calces. The volatile alkali, which naturally contains phlogiſton, ſometimes phlogiſticates the precipitate. It throws down a black or white precipitate of mercury; nay, it makes the orange coloured precipitate white. Gold receives its fulminating quality from this precipitant, as is afterwards to be explained. The alkali, which is commonly called *phlogiſticated*, generally precipitates metals with an increaſe of weight.

221 Precipitates occaſioned by acids, and why;

The acids frequently occaſion precipitates, and that for various reaſons. By means of elective attraction, mercury, ſilver, and lead, are taken from the nitrous acid by the addition of the marine or vitriolic. Theſe acids form with the metals new compounds which are difficult of ſolution in water; they are therefore precipitated in greater or leſſer quantity according to circumſtances. The nitrous acid is capable of decompounding ſalited tin and antimony by dephlogiſticating the calx of the metals too much; for when theſe are too much calcined, they cannot be diſſolved in any menſtruum, as has been already obſerved.

222 By the perfect neutral ſalts;

Metallic ſolutions are ſometimes diſturbed by the neutral ſalts formed by an union of alkalies with acids. Thoſe which contain the vitriolic or marine acids decompoſe ſolutions of ſilver, mercury, or lead, in nitrous acid, and precipitate the metals. By forming a triple combination, the vegetable as well as the volatile alkali, though ſaturated with vitriolic, nitrous, or marine acid, precipitate platina from aqua regia; but when the baſis is mineral alkali, the ſalt has no power of this kind.

223 By a triple combination.

224 Some metallic ſalts decompoſe others.

Some metallic ſalts can decompoſe others, and precipitate their baſes; which may happen whether the acid be different in the two ſalts or not. Solution of gold affords an example of each of theſe caſes. This is precipitated by martial vitriol; the reaſon of which will appear from conſidering the nature of the precipitate: for this, when well waſhed and dried, not only ſhows many ſhining gold-coloured particles, but alſo unites with mercury by trituration, diſſolves in aqua regia, but not in marine acid alone, together with other circumſtances which evince a complete reſuſcitation of the gold. Martial vitrol, in its ordinary ſtate, contains phlogiſton, but very looſely adhering; ſo that the clax of gold may eaſily take it from the ſolution to ſupply the loſs it had ſuſtained during the ſolution. That this is the true foundation of the proceſs, appears alſo from the following circumſtances, that the weight of the gold is exactly recovered, and that dephlogiſticated vitriol will not precipitate this metal. The reaſon that the ſurrounding aqua regia leaves this precipitate untouched is, that the menſtruum is diluted and weakened by a large quantity of water; for upon boiling it gently, ſo as to expel part of the water, the menſtruum recovers its ſolvent power, and takes up the precipitate again.

225 Why ſolution of gold is precipitated by green vitriol;

226 But not by this ſalt when dephlogiſticated.

227 Why ſolution of gold is precipitated by ſolution of tin.

It is ſomewhat more difficult to explain the reaſon why the ſolution of gold in aqua regia ſhould be precipitated by a ſolution of tin in the ſame menſtruum. Here Mr Bergman firſt ſuppoſed that the the tin had attracted a ſuperabundance of acid, and taken it from the gold; which being therefore deſtitute of its proper quantity, muſt fall to the bottom: but on employing a ſolution containing a ſuperabundant aqua regia, the ſame precipitation took place. The cauſe is therefore not in the menſtruum. On examining the precipitate itſelf, we find nothing like the metallic ſplendor of gold, but that it entirely reſembles a calx. It is eaſily found by its weight, indeed, that it cannot conſiſt entirely of gold; and in fact chemical examination ſhows that it conſiſts partly of tin. It cannot be diſſolved by the marine acid alone, but is eaſily taken up by the addition of a little nitrous acid. It ſcarcely unites with mercury by trituration. Theſe properties ſeem to indicate, that the gold has ſo far received phlogiſton

228 This precipitate conſiſts partly of tin.

giſton as to reſiſt the marine acid until it receive the aſſiſtance of the nitrous; but its earthy appearance, and difficulty of uniting with mercury, evince that it is not in its complete metallic form. The following therefore, according to our author, ſeems to be the moſt eaſy and rational explanation. The ſolution of tin neceſſary for this operation muſt retain as much phlogiſton as it poſſibly can, in a conſiſtence with ſolubility. This is dropped into a ſolution of gold very much diluted; by which means the phlogiſton remaining in the tin is more looſened, and of conſequence more eaſily attracted by the gold calx, which is thereby brought to a ſtate approximating to completion, ſo that it can no longer be retained by the menſtruum; and the ſame happens to the tin, by means of the dephlogiſtication; they muſt both therefore fall to the bottom mixed intimately with one another. It is probable, ſays he, that in this caſe it is the tin which prevents the matter from uniting with mercury.

229 Precipitation of metals by one another, owing to a double elective attraction.

The metals precipitate one another after a certain order, which is the ſame in all acid menſtrua. This precipitation is occaſioned by a double elective attraction; for the metal to be precipitated exiſts in the ſolution in a calcined ſtate; but being reduced by the phlogiſton of the precipitant falls to the bottom, while at the ſame time the precipitant becomes ſoluble by calcination: but if the precipitant has been calcined ſo that a part of it being inſoluble is mixed with the precipitate, the metallic ſplendor is wanting, and it puts on an earthy appearance. A pure precipitate is of the ſame weight with the metal before ſolution. The mixed precipitates are leſs frequently met with, yet gold precipitated by tin exhibits one of that kind.

230 Variations in the order in which the metals precipitate one another.

Though the order in which the metals precipitate one another is conſtant and never inverted, yet there are many anomalous circumſtances which occur in the matter. Thus zinc conſtantly prevails over iron; iron over lead; lead over tin; tin over copper; copper over ſilver; ſilver over mercury, *&c.* yet it ſometimes happens, that a metal which, according to the general rule, precipitates another in its metallic ſtate from one menſtruum, precipitates it from another in form of a calx, and not at all from a third. Thus zinc precipitates iron from marine acid in its metallic ſtate, but from the nitrous only in form of a clax. Tin is precipated by lead from the marine acid in its metallic ſtate, but is not thrown down from the nitrous acid; and from the acetous is precipitated even by iron and zinc in form of a clax; ſolution of lead in vinegar is not precipitated by iron.

231 Mineral alkali why preferred as a precipitant by Mr Bergman.

232 How he prepared his cauſtic alkali.

233 Various precipitates of gold.

In Mr Bergman's experiments on this ſubject he employed the mineral alkali, as the degree of its ſaturation with fixed air was more conſtant. When he had occaſion for a cauſtic alkali, he prepared it by a ſmall quantity of burned lime kept in a cloſe bottle; and the goodneſs of it was proved by its occaſioning no precipitation in lime water. Phlogiſticated alkali, or that by which Pruſſian blue is prepared, was alſo made uſe of. With theſe he made the following obſervations. Gold diſſolved in aqua regia is precipitated by cauſtic alkali almoſt black; by the aerated, yellow, as well as by the phlogiſticated, unleſs ſome iron be preſent, which frequently happens; but the whole of the gold is ſcarce ever precipitated, ſo that the weight cannot be aſcertained.

234 Mineral alkalies precipitate platina imperfectly.

Neither the cauſtic nor aerated mineral alkali precipitate one half of platina diſſolved in aqua regia; the precipitate is of an orange colour, which on dying becomes brown. An over-proportion of alkali rediſſolves the precipitate, and the liquor becomes more dark; nay, the precipitation is ſo imperfect, that the matter ſeems to be diſſolved even by neutral ſalts. The phlogiſticated alkali does not precipitate the depurated ſolution, nor even make it turbid, but heightens the colour in the ſame manner as an exceſs of alkali.

235 Precipitates of ſilver.

Solution of ſilver in nitrous acid lets fall a white precipitate by the aerated alkali; brown by the cauſtic, and of an obſcure yellow. By the nitrous and marine acids it lets fall a white precipitate, which with the former conſiſts of more diſtinct particles, which grow black more ſlowly with the light of the ſun.

236 Of mercury.

Salited mercury lets fall a red precipitate, or rather one of a ferruginous colour, by aerated alkali; but of a more yellowiſh or orange colour by the cauſtic. Nitrated mercury prepared without heat, yields a ferruginous precipitate with mineral alkali; a black with cauſtic: and when prepared with heat, it yields to cauſtic alkali an orange or reddiſh yellow precipitate. By phlogiſticated alkali it is precipitated from all acids of a white colour; but turns of a browniſh yellow when dry. Salited mercury is very ſparingly precipitated by this alkali. The precipitate by phlogiſticated alkali is again diſſolved, if too much of the precipitant be made uſe of.—Corroſive ſublimate muſt be very cautiouſly precipitated by cauſtic, as well as aerated fixed alkali; for the part ſeparated may again be diſſolved by a large quantity of water. When too much alkali is uſed, a new compound ariſes of a peculiar nature.

237 Precipitates of lead.

Solution of lead in ſpirit of nitre is precipitated down white by aerated, cauſtic, or phlogiſticated alkali. By uſing too much alkali, the precipitate by the phlogiſticated kind is diſſolved with a browniſh yellow colour. Vitriol of lead and ſolution of lead in marine acid are precipitated white.

238 Of copper;

Blue ſolution of copper in ſpirit of nitre is precipitated of a bright green by aerated fixed alkali; by the cauſtic of a greyiſh brown, which grows reddiſh by age. By phlogiſticated alkali copper is precipitated of a greeniſh colour, which grows afterwards of a browniſh red, and upon exſiccation almoſt black. The aerial acid takes up a ſmall quantity of copper during the precipitation, which is again depoſited by the heat of boiling.

239 Of iron;

Aerated fixed alkali precipitates iron of a green colour from vitriolic and marine acid; but the precipitate becomes of a browniſh yellow, eſpecially on exſiccation; with the cauſtic alkali it approaches more to black. In the precipitation ſome part is held in ſolution by the aerial acid, when the mild alkali is uſed. With phlogiſticated alkali a Pruſſian blue is formed.

240 Of tin;

Tin is precipitated of a white colour by every alkaline ſalt, even by the phlogiſticated kind; but at length ſome blue particles appear in the mixture: ſo that the whole, when collected and dried, appears of a light blue colour. That theſe blue particles are occaſioned by iron appears by calcination; for they become

ferru-

ferruginous, and obey the magnet. Our author has always found a proportion of iron in tin.

241 Precipitates of biſmuth;

Biſmuth is thrown down of a fine white by water and alkalies, particularly the former; phlogiſticated alkali throws down a yellow powder, which being mixed with blue particles occaſioned by iron, at length appears green. This yellow ſediment eaſily diſſolves in nitrous acid.

242 Of nickel;

Nickel is precipitated of a whitiſh green by fixed alkalies; by the phlogiſticated alkali of a yellow; and by exſiccation it is condenſed into a dark brown maſs.

243 Of arſenic;

Arſenic diſſolved in acids, which prevent too great dephlogiſtication, may, to a certain degree, be precipitated white by the fixed alkali, even when phlogiſticated, but the ſediment is found ſoluble in water; yet nitrous acid, either alone, or joined with the marine, generally dephlogiſticates the arſenical acid, which thereby becomes unfit for ſeparation. Arſenic diſſolved in marine acid, with the aſſiſtance of a little nitrous acid, depoſited a white ſediment on the addition of a large quantity of phlogiſticated alkali. The ſediment was mixed with Pruſſian blue. This was diſſolved in water, and freed by frequent filtration from the blue particles; and at length, on evaporating to dryneſs, yielded a ſemipellucid maſs.

244 Of cobalt;

Cobalt diſſolved in acids is thrown down by fixed alkali, whether aerated or cauſtic, of a reddiſh blue, which grows darker on exſiccation, eſpecially when the former alkali has been uſed. Phlogiſticated alkali throws down a powder of almoſt the ſame colour, which, upon exſiccation, becomes of a reddiſh brown.

245 Of zinc;

Zinc is precipitated white by aerated and cauſtic fixed alkalies, as alſo by the phlogiſticated alkali; but this laſt becomes of a citron colour on exſiccation: a ſmall portion of aerial acid may eaſily eſcape during the precipitation.

246 Of antimony;

Antimony is precipitated white by alkalies. When the phlogiſticated alkali is uſed, ſome blue particles are almoſt always precipitated at the ſame time, though the regulus had been prepared without any iron. This operation ſhould be cautiouſly conducted, leſt ſome part be taken up by the alkaline ſalt.

247 Of manganeſe.

Manganeſe procured by reduction from common magneſia nigra, generally renders menſtrua brown, and with aerated alkali yields a yellowiſh brown ſediment; with the cauſtic, one ſtill darker; with the phlogiſticated, firſt a blue, then a white, powder is ſeparated, the mixture of which renders the maſs a black green. To obtain a pure and white calx of manganeſe, we muſt diſſolve in pure vinegar the precipitate thrown down by cauſtic alkali; for there ſtill remains a quantity of iron which is taken up by the aerial acid. This acetous ſolution contains little or nothing of iron. That metal may alſo at firſt be ſeparated by a ſmall quantity of volatile alkali.

The common ſolution of the regulus is not perfectly precipitated by the aerated alkali; and upon evaporating the remaining liquor ſpontaneouſly to dryneſs, grains of a metallic ſplendor, and not unlike copper, are depoſited on the glaſs. The nitrous acid attracts theſe readily, though they are only partially diſſolved by it; but on the addition of zinc, nothing falls beſides the manganeſe, though at firſt it is a little reddiſh. With phlogiſticated alkali, we obtain a yellow precipitate like pure manganeſe, provided the ſolution has depoſited the iron when too much dephlogiſticated by age. But the new ſolution yields a precipitate almoſt like that which is obtained from common regulus. The yellow ſediment may be diſſolved in water.

248 On the cauſe of ſuch great variations in the weight of precipitates.

The following is Mr Bergman's table of the quantities of precipitate of different metals, thrown down from various menſtrua by the different alkalies. "On comparing the weights (ſays he), a queſtion occurs concerning the cauſe of ſuch enormous differences; and it is plain, that this cauſe muſt be ſought for in the precipitates themſelves.—The fixed alkali ſaturated with aerial acid, when added to the ſolution, is taken up by the more powerful menſtruum; and the weaker is of courſe expelled, and is abſorbed by the calx as it falls, in greater or leſſer quantity according to circumſtances. That this is actually the caſe is eaſily demonſtrated:—Let a bottle containing a quantity of nitrous acid be accurately weighed. Let there be put into it, for inſtance, 132 parts of lead precipitated by aerated alkali; and not only an efferveſcence will be obſerved, which continues until the very laſt particle is diſſolved, but when the ſolution is finiſhed, a deficiency of weight is diſcovered, which amounts nearly to 21, and which is undoubtedly owing to the extrication of aerial acid. But 132—21=111; a weight which ſtill conſiderably exceeds that of the metal. Upon diſtillation nearly eight of water are diſcovered. There yet remain therefore three, which by violent heat are increaſed by ſeven; for 132 of the calx well calcined yield 110. The whole increment of weight then does not depend on the water and aerial acid. The ſame thing is evinced by conſidering the precipitate of lead by the cauſtic alkali; in which caſe there can be no aerial acid, nor does any efferveſcence accompany the ſolution. If we ſuppoſe the quantity of water equal in both caſes, yet even on this ſuppoſition the whole exceſs of weight is not accounted for; for 116—8=108. It is therefore probable, that the matter of heat is attached to the calx (A).—In proof of this opinion, and that cauſtic alkalies contain the matter of heat, our author adduces ſeveral arguments, of which the following is the ſtrongeſt.—"Let the heat occaſioned by the mixture of any acid and cauſtic alkali be determined by a thermometer; let then an equal portion of the ſame menſtruum be ſaturated with a metal; afterwards, on the addition of an equal quantity of cauſtic alkali, it will be found, either that no heat is generated, or a degree very much leſs than before.—Some of the matter of heat therefore is taken up and fixed, which alſo generally makes the colours of the precipitates more obſcure; and in diſtillation with ſal-ammoniac, communicates to the volatile alkali the quantity that had been taken away."

249 Argument in favour of the weight of precipitates being augmented by the matter of heat.

250 Inſufficient

In this inſtance alſo, however, our author ſeems to have been deceived. It has already been obſerved, that in all ſolutions generating heat, it moſt probably comes from the fluid. Acids contain a quantity ſufficient

---

(A) This increaſe of weight is with more probability to be aſcribed to a remainder of the acid.

ficient not only for their own fluidity, but for rendering ſolid bodies fluid alſo. After they have diſſolved the metal, however, this ſuperfluous quantity is employed; and when the cauſtic alkali is added, if in a ſolid form, it is again employed in giving fluidity to the alkali; or if the alkali be already diſſolved, the increaſed quantity of fluid makes the heat extricated leſs perceptible.

251 A quantity of the menſtruum retained by ſome precipitates.

252 Difference in the precipitates of mercury.

"What has been ſaid of lead (continues our author), is alſo true of the other metals, a few excepted, which ſeem to take up little or no aerial acid; ſuch are tin, antimony, gold and platina.—But ſome precipitates retain alſo a quantity of the menſtruum. Thus, corroſive mercury, precipitated by aerated alkali, retains a portion of marine acid, which cannot be waſhed off by water; but, by cauſtic alkali, the precipitate may be obtained, either free of the acid altogether, or in a great meaſure. In this caſe, as in many others, the aerial acid ſeems to generate a triple ſalt, ſcarce at all ſoluble. The preſence of the marine acid is eaſily diſcovered by ſolution of ſilver in nitrous acid, if the menſtruum has been pure. Hence we obſerve another difference in mercury precipitated from marine acid, according as we employ the aerated or cauſtic alkali; the latter, well waſhed, and put into volatile alkali, is ſcarcely changed in colour; but the former inſtantly grows white, generating a ſpecies of ſal-alembroth, but containing ſo little marine acid as not to be eaſily ſoluble in water. The calces which retain any of their former menſtruum, generally give over on diſtillation a ſmall portion of ſublimate. The mercurial calx juſt mentioned, expoſed to a ſufficient degree of heat, is partly reduced to crude mercury, partly to mercurius dulcis, by means of its remaining marine acid. This mercurius dulcis did not exiſt in the precipitate; for in that caſe it would be eaſily diſcovered by acids in which it is not ſoluble, and would grow black with cauſtic alkali, neither of which take place, ſo that it muſt be generated during the diſtillation."

253 Advantages to be derived from the examination of metallic precipitates.

254 Platina is not compoſed partly of iron;

255 Nor regulus of nickel;

256 Cobalt or manganeſe

257 Quantity of precipitate obtained from manganeſe by phlogiſticated alkali.

Mr Bergman concludes his diſſertation, with an enumeration of the advantages reſulting from the careful examination of metallic precipitates.—Theſe are 1. That thus the theory of the operation will be more perfectly underſtood. 2. We may diſcover the more uſeful and remarkable properties. 3. A foundation is thereby laid for eſſaying in the moiſt way, from the bare knowledge of the weights. "It may be objected (ſays he), that the doctrine of the weights is very fallacious; that they vary in different precipitates; that by imperfect precipitation ſomething remains in the liquor; and that ſometimes extraneous matters remain in them. All this is true; but if the mode of operation be the ſame, the reſults of the experiments will be equally conſtant. Thus, let us ſuppoſe that a certain quantity of metal *a*, precipitated in a certain manner, makes a weight *b*; if that ſame manner be exactly employed, we may fairly conclude, that a quantity of precipitate *nb*, occurring in any caſe, is correſpondent to a quantity of perfect metal *na*; though, in the fundamental experiment, the precipitation is either incomplete, or ſome extraneous matter may be preſent. 4. The nature of metals is thus illuſtrated. Platina, nickel, cobalt, and manganeſe, are ſuppoſed by ſome to derive their origin from a mixture of other metals. But if iron neceſſarily enters into the compoſition of platina, when the latter is diſſolved in aqua regia, it ought to yield a Pruſſian blue on the addition of phlogiſticated alkali; which indeed is the caſe when common platina is employed, but not with that which is well depurated. In like manner, if iron, adhering very obſtinately to nickel, formed a great part of the latter, the precipitates obtained from it by alkalies could not differ from martial precipitates ſo much as they do in colour, weight, and other properties. The ſame holds true of cobalt and manganeſe. The regulus obtained from the latter contains about 0.08 of iron, which affects the mixture in the following manner. An hundred pounds diſſolved in an acid menſtruum, yields, by treatment with phlogiſticated alkali, a powder conſiſting partly of blue, partly of browniſh yellow particles, equal in weight to 150 pounds; but eight pounds of iron yield 48 of Pruſſian blue, nearly ⅓ of the whole maſs of precipitate: whence it follows, that 100 parts of pure manganeſe yield to phlogiſticated alkali ſcarcely 111; *i. e.* nearly ſix times leſs than an equal weight of iron.

258 Metals contain different quantities of phlogiſton.

"Laſtly, by this method of examining precipitates, it may perhaps be poſſible to determine the unequal quantities of phlogiſton in different metals; for a given weight of precipitating metal does not yield an equal quantity of precipitate: thus, for inſtance, copper is able to precipitate from nitrous acid four times its weight of ſilver."

260
Kirwan's definition of chemical attraction.

Mr Kirwan has made a great number of experiments on the attractive powers of the mineral acids to various ſubſtances, and greatly illuſtrated the operations of both ſolution and precipitation. Chemical attraction, he obſerves, "is that power by which the inviſible particles of different bodies intermix and unite with each other ſo intimately, as to be inſeparable by mere mechanical means." Thus it differs from the attraction of coheſion, as well as from that of magnetiſm and electricity, as not acting with the indifference obſerved to take place in theſe powers, but cauſing a body already united to another to quit that and unite with a third; whence it is called *elective* attraction. Hence attraction of coheſion often takes place betwixt bodies that have no chemical attraction for each other; as for inſtance, biſmuth and regulus of cobalt, which cannot be made to unite together by fuſion, though they cohere with each other ſo ſtrongly, that they cannot be ſeparated but by the blow of a hammer.

261
Difference betwixt chemical attraction and that of coheſion.

262
Geoffroy's rule for determining the degree of chemical attraction.

To determine the degrees of attraction betwixt different ſubſtances, M. Geoffroy laid it down as a general rule, that when two ſubſtances are united, and either quits the other to unite with a third, that which thus unites to the third muſt be ſaid to have a greater affinity to it than to the ſubſtance it has quitted. In many caſes, however, the ſeemingly ſingle decompoſition is in truth a double one. Thus, when the vitriolic acid expels the air from a fixed alkali, it does not neceſſarily follow, that the acid is more attracted by the alkali than the fixed air; for here though the latter reſigns its place to the acid, yet the acid gives out its fire to the air; whence a decompoſition might take place, even though the attractive powers of both the vitriolic and aerial acid to the alkali were equal.

263
Chemical decompoſitions, tho' ſeemingly ſingle are often double.

264
Force of the attractive powers to be determined by numbers.

To attain to any certainty in this matter, therefore, it is neceſſary to determine the quantity and force of each of the attractive powers, and denote it by numbers. The neceſſity of this has been obſerved by Mr Morveau and Mr Wenzel, who have both propoſed methods for anſwering the purpoſe; but Mr Kirwan has ſhowed that both are defective: and he tells us, that the diſcovery of the quantity of real acid in each of the mineral acid liquors, with the proportion of real acid taken up by a given quantity of each baſis at the point of ſaturation, led him unexpectedly to what ſeems the true method of inveſtigating the quantity of attraction which each acid bears to the ſeveral baſes to which it is capable of uniting: "for it was impoſſible (ſays he) not to perceive, 1. That the quantity of real acid neceſſary to ſaturate a given weight of each baſis is inverſely as the affinity of each baſis to ſuch acid. 2. That the quantity of each baſis requiſite to ſaturate a given quantity of each acid is directly as the affinity of ſuch acid to each baſis. Thus 100 grains of each of the acids require for their ſaturation a greater quantity of fixed alkali than of calcareous earths, more of this earth than of volatile alkali, more of this alkali than of magneſia, and more of magneſia than of earth of alum.

265
True method of inveſtigating the quantity of attraction each of the acids has for its different baſes.

"If an acid be united to leſs of any baſis than is requiſite for its ſaturation, its affinity to the deficient part of its baſis is as the ratio which that deficient part bears to the whole of what the acid can ſaturate. Thus, if 100 grains of vitriolic acid, which can ſaturate 110 of calcareous earth, be united only to 55, its affinity to the deficient 55 parts ſhould be eſtimated one half of its whole affinity; but its affinity to the retained part is as its whole affinity."

266
Method of explaining the decompoſitions effected by acids alone.

To explain the decompoſitions in which theſe acids are concerned, we muſt conſider, firſt, the powers which reſiſt any decompoſition, and tend to keep the bodies in their preſent ſtate; and, ſecondly, the powers which tend to effect a decompoſition and new union; the former our author calls *quieſcent affinities*, the latter *divellent*. A decompoſition will therefore always take place when the ſum of the divellent affinities is greater than the quieſcent; and, on the contrary, no decompoſition will happen when the ſum of the quieſcent affinities is greater than that of the divellent. All we have to do therefore is to compare the ſums of each of theſe powers. The method our author takes to compare the affinities together is by the following table; in which the quantity of alkali, earth, &c. ſaturated by 100 grains of each of the mineral acids, is ſtated.

267
Quieſcent and divellent affinities.

268
Quantity of acid taken up by various baſes.

	Veg. fixed alkali.	Mineral alkali.	Calcar. earth.	Vol. alk.	Magneſia.	Earth of alum.
Vitriolic acid	215	165	110	90	80	75
Nitrous acid	215	165	96	87	75	65
Marine acid	215	158	89	79	71	55

Theſe numbers he conſiders as adequate expreſſions of the quanity of each of the affinities. Thus the affinity of the vitriolic acid to fixed vegetable alkali is to the affinity with which it adheres to calcareous earth as 215 to 110; and to that which the nitrous acid bears to calcareous earth as 215 to 96, &c. Hence we ſum up the powers of affinity betwixt any number of different ſubſtances, and account for their decompoſitions, as in the following example of the double decompoſition, which takes place when a ſolution of vitriolated tartar and ſolution of lime or chalk in nitrous acid are mixed together.

269
Expreſſive of the quantity of attraction they have for each of theſe baſes.

270
Decompoſition of vitriolated tartar by ſolution of calcareous earth explained.

Quieſcent Affinities.		*Divellent Affinities.*	
Vitriolic acid to vegetable fixed alkali,	215	Vitriolic acid to calcareous earth,	110
Nitrous acid to calcareous earth,	96	Nitrous acid to vegetable alkali,	215
Sum of quieſcent affinities	311	Sum of divellent affinities	325

Hence we ſee that a double decompoſition muſt enſue. The ſame will be produced, if inſtead of vitriolated tartar we make uſe of Glauber's ſalt; for the ſum of the

the quieſcent affinities is 261, of the divellent 275; with vitriolic ammoniac the ſum of the quieſcent is 186, of the divellent 195, &c. In mixing vitriolated tartar with ſolution of magneſia in nitrous or marine acids, a double decompoſition takes place though inviſibly, as the vitriolic Epſom ſalt is very ſoluble in water, and therefore cannot be precipitated like ſelenite. In the former caſe the ſum of the quieſcent powers is 290, of the divellent 295; in the ſecond 286 and 295.

271 Coincidence of the above table with experience.

Other decompoſitions take place in the ſame manner; and from all the facts which our author had occaſion to obſerve, he concludes, that the quantity of each affinity, as determined in the above table, coincides exactly with experience; and that theſe decompoſitions are perfectly conſiſtent with the ſuperior affinity which has been hitherto obſerved in the vitriolic and nitrous acids with fixed alkalies over the calcareous earths; nor do they infringe in the leaſt the known laws of affinity, as has been inſinuated by ſome chemiſts.

272 Miſtake of Dr Crell corrected.

One fact only, mentioned in Dr Crell's Journal, ſeems to be repugnant to what is here advanced; and that is, that if ſolutions of one part of alum and two of common ſalt be mixed together, evaporated, and ſet to cryſtallize, a Glauber's ſalt will be formed; though, in this caſe, the ſum of the quieſcent affinities is 233, and that of the divellent only 223. Mr Kirwan repeated this experiment without ſucceſs; and Dr Crell himſelf owns that it will not ſucceed but in the moſt intenſe cold. If it does ſucceed at all, he ſays the decompoſition muſt ariſe from a large exceſs of acid in the alum, which acted upon and decompoſed the common ſalt: and this explanation is confirmed by the ſmall proportion of Glauber's ſalt ſaid to be obtained by this proceſs; for from 30lb. of common ſalt and 16 of alum, only 15lb. of Glauber's ſalt were produced; whereas, if the whole of the alum had been decompoſed, there ſhould have been formed, according to Mr Kirwan's computation of the quantity of acid in the different ſalts, 29½lb, or, according to Mr Bergman's, 22lb. of Glauber's ſalt.

273 Formation of triple and quadruple ſalts.

In ſome caſes, the neutral ſalts have a power of uniting, without any decompoſition, or with only a very ſmall one, to a third ſubſtance; thus forming triple ſalts, and ſometimes quadruple; which often cauſes anomalies that have not yet been ſufficiently inveſtigated. Volatile alkalies in particular are poſſeſſed of the power of uniting with neutral ſalts in this manner. Hence they ſeem to precipitate magneſia from Epſom ſalt, even when perfectly cauſtic; but this is owing to their combination with that ſalt, and forming a triple one, which is inſoluble in water.

274 Volatile alkalies particularly form ſalts of this kind.

275 Vitriolic ſalts decompoſed by the nitrous and marine acids.

It ſeems extraordinary that, according to Mr Kirwan's table, the three mineral acids ſhould have the ſame affinity to vegetable fixed alkalies, when it is well known that the vitriolic will expel either of the other two from an alkaline baſis. In explication of this, Mr Kirwan obſerves, that nitre is decompoſed by the marine acid; and that Glauber's ſalt and vitriolic ammoniac are decompoſed by that of nitre; and that theſe ſalts, as well as cubic nitre and nitrous ammoniac, are decompoſed by the marine acid.

276 Theſe decompoſitions ſuppoſed to ariſe from compound forces.

Mr Kirwan is of opinion, that theſe decompoſitions are the effect of a double affinity, or at leaſt of compound forces. He ſuſpected that they aroſe from the different capacities of the acids for elementary fire; and to determine this matter, he made the following experiments, in which the decompoſitions were not diſcovered by cryſtallization, but by teſts.

277 Experiments to determine this by the various degrees of heat excited by mixtures.

1. Having procured a quantity of each of the three mineral acids containing the ſame proportion of real acid, and reduced them to the temperature of 68° of Fahrenheit, 100 grains of vitriolic acid, containing 26.6 of real acid, was projected upon 480 grains of oil of tartar at the ſame temperature, by which the thermometer was raiſed to 138°.

2. An hundred grains of ſpirit of nitre, containing alſo 26.6, projected on 480 grains of oil of tartar, produced only 120° of heat.

3. An hundred grains of ſpirit of ſalt, the ſpecific gravity of which was 1220, and which contained the uſual proportion of real acid, raiſed the thermometer from 69 to 129.

278 Vitriolic acid contains more fire than the nitrous and marine.

"Hence (ſays he) it follows, that the vitriolic acid contains more ſpecific fire, or at leaſt gives out more by uniting with fixed alkalies, than either the nitrous or marine; and therefore when the vitriolic acid comes in contact with either nitre or ſalt of Sylvius, its fire paſſes into theſe acids, which are thereby rarefied to a great degree, and are thus expelled from their alkaline baſis, which is then ſeized on by the vitriolic."—On this, however, it is obvious to remark, that, according to Mr Kirwan's explanation, the marine acid, as giving out more ſpecific heat, ought to expel the nitrous from an alkaline baſis; which, however, is not the caſe. Something elſe, therefore, beſides the mere quantity of ſpecific heat, muſt here be taken into conſideration. Mr Kirwan, however, goes on to prove the truth of his theory by the following experiments.

279 Difficulty in the theory.

280 On the expulſion of the nitrous acid by the vitriolic diluted.

4. To 400 grains of vitriolic acid, whoſe ſpecific gravity was 1.362, ſixty grains of nitre were added; on which the thermometer fell from 68° to 60°. During the time of this deſcent, the nitrous acid was not expelled; for ſome filings of copper, put into the mixture, were not acted upon in the leaſt; but in five minutes afterwards they viſibly effervesced, which ſhowed that the nitrous acid began to be expelled; for the vitriolic acid does not act upon copper but by a boiling heat.

281 By the ſame acid concentrated.

5. Sixty grains of nitre were put to 400 of oil of vitriol, whoſe ſpecific gravity was 1.870; the thermometer inſtantly roſe from 68° to 105°, and the nitrous acid was expelled in a viſible fume.—"Theſe experiments (ſays Mr Kirwan) prove, 1. That neutral ſalts are not decompoſed by mere ſolution in an acid different from their own. 2. That the nitrous acid, being converted into vapour, had imbibed a large quantity of fire. But as the vitriolic acid, in both theſe experiments, was uſed in much larger quantity than was neceſſary to ſaturate the alkali of the nitre, ſixty grains of the latter were put into 64 of the abovementioned dilute ſpirit of vitriol, which contained the ſame quantity of real vitriolic acid that the 60 grains of nitre did of the nitrous; with the addition of 40 grains of water and a few copper-filings. In leſs than two hours the copper was acted upon, and conſequently the nitrous acid was expelled.

282 With a ſmall quantity of diluted vitriolic acid.

283 On the expulſion of marine acid by the concentrated vitriolic.

6. To 400 grains of oil of vitriol, of the ſpecific gravity of 1.870, 100 grains of common ſalt were added. An effervescence immediately enſued, and

and the marine acid roſe in white vapours. A thermometer held in the liquor roſe only 4 degrees, but in the froth it aſcended to 10°, and fell again upon being replaced in the liquor. Hence Mr Kirwan concludes, that the vitriolic acid gives out its fire to the marine; and that this latter received more than it could abſorb even in the ſtate of vapour, and therefore communicated heat to the contiguous liquor. It appears to him alſo, that the nitrous and marine acids receive fire from the vitriolic, and are thrown into a vaporous ſtate, or at leaſt rarefied to ſuch a degree as to be expelled from their alkaline baſis, though their affinity with that baſis may be equally ſtrong with the vitriolic.

284 Both the nitrous and marine acids receive fire from the vitriolic during their expulſion.

285 On the decompoſition of vitriolated tartar by nitrous acid.

7. To aſcertain the manner in which vitriolated tartar and Glauber's ſalt are decompoſed by ſpirit of nitre, 60 grains of powdered tartar of vitriol were put into 400 of nitrous acid, whoſe ſpecific gravity was 1.355, and which contained about 105 grains of real acid. The thermometer was not affected by the mixture; but in 24 hours the vitriolic acid was in part diſengaged, as appeared by the acid mixture acting upon regulus of antimony, which neither pure vitriolic nor pure nitrous acid will do by themſelves. On putting the ſame quantity of vitriolated tartar into 400 grains of ſpirit of nitre whoſe ſpecific gravity was 1.478°, the thermometer roſe from 67° to 79°: the vitriolated tartar was quickly diſſolved, and the regulus of antimony ſhowed that the vitriolic acid, was diſengaged. Hence it appeared that the nitrous acid, having the ſame affinity with the baſis of vitriolated tartar as the vitriolic, but giving out, during the ſolution, more fire than was neceſſary to perform the ſolution, the vitriolic, receiving this fire, was diſengaged: for as it cannot unite to alkalies without giving out fire; ſo when it receives back that fire, it muſt quit them. The reaſon why the nitrous acid, which ſpecifically contains leſs fire than the vitriolic, gives out ſo much is, that its quantity in both theſe experiments is far greater than that of the vitriolic; it being in the firſt as 105 to 17, and in the laſt as 158 to 17.

286 Acids unite to alkalies by giving out fire, and quit them by receiving it.

287 Vitriolated tartar cannot be decompoſed by diluted nitrous acid.

8. To 60 grains of ſpirit of nitre, whoſe ſpecific gravity was 1.355, Mr Kirwan added 1000 grains of water; and into this dilute acid put 60 grains of vitriolated tartar, containing exactly the ſame quantity of real acid that the 60 grains of nitrous acid did. In eight days the vitriolated tartar was almoſt entirely diſſolved, and without any ſign of its decompoſition; and no nitre was found upon evaporating the liquor. Hence he concludes, that the nitrous acid can never decompoſe vitriolated tartar, without the aſſiſtance of heat, but when its quantity is ſo great that it contains conſiderably more fire, and by the act of ſolution is determined to give out this fire. This ſalt is alſo decompoſed, in ſimilar circumſtances, by the marine acid; though ſtill more ſlowly and with more difficulty than by the nitrous, as appears by the following experiments.

288 Decompoſition of vitriolated tartar by marine acid.

9. Into 400 grains of ſpirit of ſalt, whoſe ſpecific gravity was 1.220, were put 60 grains of vitriolated tartar. The thermometer was not affected in the leaſt, and the ſalt diſſolved very ſlowly. Some pulverized biſmuth was added to try whether the vitriolic acid was diſengaged; and in 12 hours part of it was diſſolved, ſo that it could not be precipitated by water. This ſhowed, that part of the vitriolic acid was diſlodged; for this ſemi-metal cannot be kept in ſolution when much diluted with water, excepting by a mixture of marine and vitriolic acids.

289 Requiſites for the ſucceſs of this experiment.

In this experiment the quantity of marine acid was much greater than that of the vitriolic; and therefore it was capable of diſlodging it. This circumſtance alone, however, is not ſufficient; the acid muſt be diſpoſed to give out by ſolution that quantity of fire which it is neceſſary the vitriolic ſhould receive in order to its quitting the baſis to which it is united; and therefore when Mr Cornette added two ounces of ſpirit of ſalt to half an ounce of vitriolated tartar already diſſolved, in water, no decompoſition took place. The reaſon of this was, that as the vitriolated tartar was already diſſolved, no cold nor heat was generated by the mixture; and therefore the ſpirit of ſalt could not give out any fire. Glauber's ſalt is more eaſily decompoſed by marine acid then vitriolated tartar, on account of its being more eaſily ſoluble in ſpirit of ſalt; and likewiſe becauſe its alkaline baſis takes up an equal quantity of both acids: conſequently the marine gives out more fire in uniting to the baſis of Glauber's ſalt than on being united to that of vitriolated tartar. Vitriolic ammoniac is alſo decompoſed by means of marine acid; but in all theſe caſes, the quantity of marine acid muſt greatly exceed that of the vitriolic contained in the ſalt to be decompoſed; and it muſt be remarked, that according to the obſervations of Mr Bergman, the decompoſition of Glauber's ſalt or vitriolic ammoniac by this acid is never complete.

290 Vitriolated tartar diſſolved in water cannot be decompoſed by marine acid, and why.

291 Decompoſition of vitriolic ammoniac and Glauber's ſalt by marine acid never complete.

On the ſame principles the marine acid decompoſes ſalts which have the nitrous acid for their baſis. Mr Cornette found, that cubic nitre was more eaſily decompoſed by it than that which has vegetable alkali for its baſis. Accordingly, during the ſolution of priſmatic nitre, only three degrees of cold were produced; but ſix by the ſolution of cubic nitre; which ſhows that the ſpirit of ſalt gave out more fire in the latter caſe than in the former; and its quantity muſt always be greater than that of the nitrous acid contained in the mineral alkaline baſis; becauſe this baſis requires for its ſaturation more of the marine than of the nitrous acid. The nitrous acid, however, in its turn decompoſes ſalt of Sylvius and common ſalt; but it muſt always be in greater quantity than the marine to produce that effect.

292 Nitrous ſalts decompoſed by marine acid.

293 Marine ſalts decompoſed by the nitrous acid.

10. Sixty grains of common ſalt being added to 400 of colourleſs ſpirit of nitre, whoſe ſpecific gravity was 1.478, the mixture quickly efferveſced and grew red, yet the thermometer roſe but two degrees; which ſhowed that the marine acid had abſorbed the greater part of the firſt given out by that of nitre; the decompoſition was likewiſe haſtened by the ſuperior affinity of the nitrous acid to the alkaline baſis of the ſea-ſalt: hence the decompoſition of ſea-ſalt by means of nitre takes place without any ſolution; but ſpirit of ſalt will not decompoſe cubic nitre until it has firſt diſſolved it. This mutual expulſion of the nitrous and marine acids by each other, is the reaſon why aqua-regia may be made by adding nitre or nitrous ammoniac to ſpirit of ſalt, as well as by adding common ſalt or ſal ammoniac to ſpirit of nitre.

Selenite cannot be decompoſed either by nitrous or

294 Selenites cannot be decompoſed by marine acid.

295 Why the vitriolic acid aſſumes on evaporation the baſes it had loſt.

marine acid ; becauſe it cannot be diſſolved in either without the aſſiſtance of foreign heat. It muſt likewiſe be obſerved, that in all decompoſitions of this kind, when the liquor has been evaporated to a certain degree, the vitriolic acid expels in its turn the nitrous or marine acid to which it had already yielded its baſis. The reaſon of this is, that the free part of the weaker acids being evaporated, the neutral ſalts begin to cryſtallize, and then giving out heat, the vitriolic abſorbs it ; and thus reacting upon them expels them from the alkali or earth to which they are united.

296 Difficulties in determining the attractive powers of the acids to metals.

Mr Kirwan found much more difficulty in determining the attractive powers of the different acids to the metals than to alkaline ſalts or earths. Some of the difficulties met with in this caſe aroſe from the nature of metallic ſubſtances themſelves. Their calces when formed by fire always contain a quantity of air, which cannot be extracted from them without great difficulty, and is very ſoon re-abſorbed ; and if formed by ſolution, they as conſtantly retain a part of their ſolvent or precipitant ; ſo that the preciſe weight of the metalline part can ſcarce be diſcovered. Our author, therefore, and becauſe metallic calces are generally inſoluble in acids, choſe to have the metals in their perfect ſtate : and even here they muſt loſe a part of their phlogiſton before they can be diſſolved in acids, and a conſiderable part remains in the ſolution of the acid and calx ; which laſt quantity he endeavoured to determine.

297 Metallic ſalts inſoluble in water without an exceſs of acids.

A new difficulty now occurred, ariſing from the impoſſibility of finding the real quantity of acid neceſſary to ſaturate the metal, for all metallic ſolutions contain an exceſs of acid : the reaſon of which is, that the ſalts formed by a due proportion of acid and calx are inſoluble in water without a further quantity of acid ; and in ſome caſes this quantity, and even its proportion to the aqueous part of the liquor, muſt be very conſiderable, as in ſolutions of biſmuth. It was in vain attempted to deprive thoſe ſolutions of their exceſs of acid by means of cauſtic alkalies and lime-water ; for when deprived of only part of it, many of the metals were precipitated, and all of them would be ſo if deprived of the whole. As the ſolution of ſilver, however, can be very much ſaturated, Mr Kirwan began with it and found that 657 grains of this ſolution contained 100 grains of ſilver, and 31.38 grains of real acid, after making the proper allowance for the quantity diſſipated in nitrous air. Nine grains of this ſolution tinged an equal quantity of ſolution of litmus as red as $\frac{8}{10}$ of a grain of real acid of ſpirit of nitre would have done; whence our author concluded that 9 grains of his ſolution of ſilver contained an exceſs of $\frac{8}{10}$ of a grain of real ſilver : according to which calculation, the whole quantity ought to have contained 5.6 grains ; which deducted from 31.38, leaves 25.78 grains for the quantity of acid ſaturated by 100 grains of ſilver.

As the vitriolic ſolutions of tin, biſmuth, regulus of antimony, nickel, and regulus of arſenic, contain a large exceſs of acid, Mr Kirwan ſaturated part of it with cauſtic volatile alkali before he tried them with the infuſion of litmus ; and the ſame method was uſed with ſolutions of iron, lead, tin, and regulus of antimony in the nitrous and marine acids. The proportion of vitriolic and marine acid taken up by lead, ſilver, and mercury, were determined by computing the quantity of real acid neceſſary to precipitate theſe metals from their ſolutions in the nitrous acid ; which ſeemed to be the moſt exact method of determining this point. The reſult of all the experiments was, that 100 grains of each of theſe acids take up at the point of ſaturation of each metallic ſubſtance, dephlogiſticated ſuch a degree as is neceſſary for its ſolution in each acid, the quantities marked in the following table.

298 Quantities of the different metals taken up by acid:

100 grains of	Iron.	Copper.	Tin.	Lead.	Silver.	Merc.	Zinc.	Biſmuth.	Nickel.	Cobalt.	Reg. of ant.	Reg. of arſen.
Vitriolic acid	270	260	138	412	390	432	318	250 310	320	360	200	260
Nitrous acid	255	255	120	365	375	416	304	290	300	350	194	220
Marine acid	265	265	130	400	420	438	312	250 320	275 310	370	198	290

299 Metals have a greater affinity with acids than alkalies.

300 Why alkalies precipitate the metals.

Though from this table, compared with the former, we might ſuppoſe that metals, having a greater attraction for acids than alkalies, could not be precipitated by them, yet Mr Kirwan obſerves, that the common tables, which poſtpone metallic ſubſtances to alkaline ſalts, are in reality juſt, though there can ſcarce be any room to doubt that almoſt all metallic ſubſtances have a greater affinity with acids than alkalies have. The common tables, he ſays, are tables of precipitation rather than of affinity, as far as they relate to metallic ſubſtances. Theſe precipitations, however, are conſtantly the reſult of a double affinity and decompoſition ; the precipitating metal yielding its phlogiſton to the precipitated one, while the precipitated metal yields its acid to the other. Thus, though copper in its metallic form precipitates ſilver and mercury from the nitrous acid, yet the calx will precipitate neither.

301 Nitrous acid attracts ſilver more than fixed alkali.

The ſuperior attraction the nitrous acid has to ſilver rather than fixed alkali, appears from the following experiment. If a ſolution of ſilver in nitrous acid be poured into a mixed ſolution of alkali and ſea-ſalt, the ſilver will be precipitated by the ſea-ſalt into a luna cornea, and not by the looſe alkali contained in the liquor. “ Now (ſays Mr Kirwan), if the nitrous acid had a greater affinity to the free alkali than to the ſilver, it is evident that the ſilver would be precipitated pure, and not in the ſtate of luna cornea ; but from its being precipitated in this ſtate, it is plain, that the precipitation was not accompliſhed by a ſingle but by a double affinity. Hence alſo the marine acid appears to have a greater attraction to ſilver than the nitrous has to fixed alkalies.’ The reſult is ſimilar when we make uſe of ſolutions of lead or mercury in the nitrous acid. Mr Bayen has alſo ſhown, that vitriol of lead and corroſive ſublimate mercury cannot be deprived of more than half their acid, even by cauſtic fixed alkalies.

With

302
Sea-ſalt decompoſed in various ways by means of lead.

With regard to lead, if perfectly dry ſalt be projected on this metal heated to ignition, the common ſalt will be decompoſed, and plumbum corneum formed. Nor can we attribute this to the volatilization of the alkali by heat; for the alkali is as fixed as the lead, and muſt therefore be cauſed by the ſuperior attraction which the calx of this metal, even when dephlogiſticated, has for the marine acid. Mr Scheele informs us, that if a ſolution of common ſalt be digeſted with litharge, the common ſalt will be decompoſed, and a cauſtic alkali produced. It may alſo be decompoſed ſimply by letting its ſolution paſs ſlowly through a funnel filled with litharge; and the ſame thing happens to a ſolution of calcareous earth in marine acid; which ſhows that the decompoſition takes place merely by the ſuperior degree of attraction betwixt the acid and metallic calx (A).

303
Acids attract metallic earth more ſtrongly than volatile alkali.

304
Why the metallic earths ſeldom decompoſe ſalts having an earth or alkali for their baſis.

305
Decompoſition of vitriolated tartar by ſolution of ſilver explained;

That acids have a greater attraction for metallic earths than volatile alkalies, is ſtill more evident. Luna cornea is ſoluble in volatile alkalies; but if this ſolution be triturated with four times its weight of quickſilver, a *mercurius dulcis*, and not ſal ammoniac, is formed. The reaſon why alkalies and earths precipitate all metallic ſolutions is, that the metals are held in ſolution by an exceſs of acid. Even if the alkaline and earthy ſubſtance did no more than abſorb this exceſs of acid, a precipitation muſt neceſſarily enſue; but they not only take up this ſuperabundant acid, but alſo the greater part of that which is neceſſary to ſaturate the metallic earth. This they are enabled to do by means of a double affinity; for during the ſolution of metals, only a ſmall part of the phlogiſton, comparatively ſpeaking, eſcapes, the remainder being retained by the compound of acid and calx. When therefore an alkali or earth is added to ſuch a ſolution, the phlogiſton quits the acid, and joins with the calx, while the greater part of the acid reunites to the precipitate. Notwithſtanding this great affinity, however, of metallic earths to acids, there are but few inſtances of their decompoſing thoſe ſalts which have an alkali, or an earth for their baſis, by reaſon of the inability of the acids, while combined with theſe baſes, and thereby deprived of a great part of their ſpecific fire, to volatilize the phlogiſton combined with the metallic earths, which muſt neceſſarily be expelled before an acid can combine with them: and as to the metallic calces, they are generally combined with fixed air, which muſt alſo be partly expelled; but ammoniacal ſalts (containing much more fire, for they abſorb it during their formation) for that reaſon act much more powerfully on metals. Allowing then the affinities of the mineral acids with metallic ſubſtances to be as above, all double decompoſitions, in which only ſalts containing theſe acids united to alkaline, terrene, or metallic baſes, are concerned, admit of an eaſy explanation; nay, ſays Mr Kirwan, I am bold to ſay, they cannot otherwiſe be explained. Thus, if a ſolution of tartar vitriolate, and of ſilver in the nitrous acid, be mixed in proper proportion, nitre and vitriol of ſilver will be formed; and this latter for the moſt part precipitated.

Quieſcent Affinities		*Divellent Affinities.*	
Nitrous acid to ſilver,	375	Nitrous acid to vegetable alkali,	215
Vitriolic acid to vegetable alkali,	215	Vitriolic acid to ſilver,	390
	590		605

306
And of Glauber's ſalt, vitriolic ammoniac, &c.

Thus alſo, if, inſtead of a ſolution of tartar vitriolate, that of Glauber's ſalt, or of vitriolic ſal ammoniac, ſelenite, Epſom ſalt, or alum, be uſed, the balance is conſtantly in favour of the divellent powers; and a precipitation is the conſequence, though but ſlight when ſelenite or alum are uſed.

307
In what caſes ſolution of ſilver is precipitated by other metals.

Solution of ſilver is alſo precipitated by the vitriolic ſolutions of iron, copper, tin, and probably by many other ſolutions of metals in the vitriolic acid: for this reaſon, among others undoubtedly, that they contain an exceſs of acid: but if a ſaturated ſolution of ſilver be mixed with a very ſaturated ſolution of lead or mercury in the vitriolic acid, the ſilver will not be precipitated; and in both caſes the balance is in favour of the quieſcent affinities.

308
Conſtantly decompoſed by marine ſalts;

309
As alſo ſolution of lead.

All the marine neutral ſalts, whether the baſis be alkaline, terrene, or metallic, decompoſe the nitrous ſolution of ſilver; and theſe decompoſitions are conſtantly indicated by the balance of affinities already deſcribed. The ſame thing alſo takes place with ſolution of ſilver in the vitriolic acid, as is indicated alſo by the ſame table. The nitrous ſolution of lead is alſo decompoſed, and the metal for the moſt part precipitated, unleſs the ſolution be very dilute in the form of vitriol of lead, by all the neutral ſalts containing either the vitriolic or marine acid, excepting only the combination of ſilver with marine acid, which precipitates it in no other way than by its exceſs of acid.

310
Solution of lead in marine acid decompoſed by vitriolic ſalts;

Solution of lead in marine acid is decompoſed by all the neutral ſalts containing the vitriolic acid, excepting only ſelenite and ſolution of nickel in oil of vitriol. Theſe can only precipitate it by virtue of an exceſs of acid.

311
Alſo nitrous ſolution of mercury;

Nitrous ſolution of mercury is decompoſed by all the neutral ſalts containing the vitriolic acid, except vitriol of lead, which only decompoſes it by an exceſs of acid.

312
And by the ſalts containing marine acid.

All the ſalts containing marine acid decompoſe the nitrous ſolution of mercury, excepting the combinations of marine acid with ſilver and lead, which decompoſe it by exceſs of acid.

313
Vitriol of mercury decompoſed by marine acid.

314
Why luna cornea cannot be reduced without loſs by alkaline ſalts.

Theſe ſalts alſo decompoſe vitriol of mercury, tho' a precipitation does not always appear, owing, as Mr Kirwan ſuppoſes, to the facility with which a ſmall quantity of the marine ſalt of mercury is ſoluble in an exceſs of acid. Marine ſalt of ſilver, however, decompoſes vitriol of mercury only through its exceſs of acid. Hence we ſee why luna cornea can never be reduced by fixed alkalies without loſs; and were it not that the action of the alkali is aſſiſted by heat, it never could be reduced by them at all.

When oil of vitriol is mixed with a ſolution of corroſive ſublimate, a precipitate falls: but this, as Mr Bergman remarks, does not proceed from a decompoſition

---

(A) Theſe experiments have been repeated by many other chemiſts without ſucceſs; and Mr Wiegleb informs, that none of thoſe who have attempted to decompoſe ſea-ſalt by means of lead, ever found their methods anſwer the purpoſe.

ſition of the mercurial ſalt, but from an abſtraction of the water neceſſary to keep the ſublimate diſſolved.

315
Precipitation of corroſive mercury by oil of vitriol explained.

316
Table of the affinities to the different metals explained.

In the foregoing table two different affinities are aſſigned to the vitriolic acid with regard to biſmuth and nickel; one ſhowing the affinity which theſe acids bear to the metals when dephlogiſticated only by ſolution in the acids; the other that which the acids bear to them when more dephlogiſticated, as when they are diſſolved in the nitrous acid. On the other hand, all the acids have leſs affinity with the calces of iron, zinc, tin, and antimony, when they are dephlogiſticated to a certain degree; but our author found himſelf unable to give any certain criteria of this dephlogiſtication.

317
Of the quantity of phlogiſton contained in the different metals.

318
Method of calculating this quantity exemplified in regulus of arſenic.

The moſt difficult point to be ſettled was the precipitation of metals by each other from the mineral acids. To determine this it was neceſſary to find the quantity of phlogiſton in each of them, not only in their natural ſtate, but according to their various degrees of dephlogiſtication by each of the acids. The ſubſtance he choſe for determining the abſolute quantity of phlogiſton in a metallic ſubſtance was regulus of arſenic. An hundred grains of this ſemimetal diſſolved in dilute nitrous acid yielded 102.4 cubic inches of nitrous air; which, according to his calculations on that ſubject, contain 6.86 grains of phlogiſton: and hence he concluded that 100 grains of regulus of arſenic contain 6.86 grains of phlogiſton. From this experiment, three times repeated with the ſame ſucceſs, our author proceeded to form, by calculation, a table of the abſolute quantity of phlogiſton contained in metals, the relative quantity having been computed by Mr Bergman and his calculations adopted by our author. Theſe quantities are as follow.

319
Table of the quantities of phlogiſton in different metals.

		Relative Quantity.	Abſolute Quantity
100 grains	Gold	394	24.82
	Copper	312	19.65
	Cobalt	270	17.01
	Iron	233	14.67
	Zinc	182	11.46
	Nickel	156	9.82
	Regulus of antimony	120	7.56
	Tin	114	7.18
	Regulus of arſenic	109	6.86
	Silver	100	6.30
	Mercury	74	4.56
	Biſmuth	57	3.59
	Lead	43	2.70

320
Experiments explaining the reduction of ſilver *per ſe*.

This point he likewiſe endeavoured to aſcertain by other experiments. As ſilver loſes a certain quantity of phlogiſton, which eſcapes and ſeparates from it during its ſolution in nitrous acid, he concluded, that if the ſolution was expoſed to nothing from which it could reobtain phlogiſton, and this was diſtilled to dryneſs, and entirely ſeparated from the acid, as much ſilver ſhould remain unreduced as correſponded with the quantity of phlogiſton loſt by it; and if this quantity correſponded with that in the above table, he then had good reaſon to conclude that the table was juſt.

For this purpoſe 120 grains of ſtandard ſilver were diſſolved in dephlogiſticated nitrous acid diluted with water, and he obtained from it 24 cubic inches of nitrous air. This ſolution was gently evaporated to dryneſs; and he found that, during the evaporation, about a quarter of a grain of the ſilver had been volatilized. The dry reſiduum was then diſtilled, and kept an hour in a coated green-glaſs retort heated almoſt to a white heat. Abundance of nitrous acid paſſed off during the operation, and a green and white ſublimate roſe into the neck of the retort, ſome of it even paſſing over into the receiver. On breaking the retort, the inſide was penetrated with a yellow and red tinge, and partly covered over with an exceedingly fine ſilver powder, which could ſcarcely be ſcraped off. The remainder of the ſilver was white, and perfectly free from acid, but not melted into a button. On being collected, it weighed 94 grains; conſequently 26 grains had been loſt either by ſublimation or vitrification; but of theſe 26 grains 9 were copper; for 100 grains of ſtandard ſilver contain $7\frac{1}{4}$ of copper, therefore only 17 grains of pure ſilver remained unreduced, being either volatilized or vitrified. The whole quantity of pure ſilver in 120 grains of ſtandard ſilver amounts to 111 grains; then if 111 grains of pure ſilver loſe 17 by being deprived of its phlogiſton, 100 grains of the ſame ſhould loſe 15.3; and by the above table 15.3 grains of ſilver ſhould contain 0.945 of a grain of phlogiſton. Now, 100 grains of pure ſilver afford 14 cubic inches of nitrous air, which, according to our author's calculation, contain 0.938 of a grain of phlogiſton; and this differs from 0.945 only by .007 of a grain. "In this experiment (ſays Mr Kirwan) only as much of the ſilver ſublimed as could not regain phlogiſton; the remainder regained it from the nitrous air abſorbed by the ſolution, and by that which remained in the acid and calx. If this were not ſo, I do not ſee why the whole of the ſilver would not ſublime."

321
Quantity of pure metal contained in ſtandard ſilver.

322
Examination of Dr Prieſtley's experiment concerning the revival of mercury.

Dr Prieſtley having ſeveral times diſſolved mercury in the nitrous acid, and revivified it by diſtilling over that acid, conſtantly found a conſiderable portion of it unreduced. To try whether that proportion correſponded with his calculation, Mr Kirwan examined Dr Prieſtley's experiment, *viz.* that having diſſolved 17 penny-weights 13 grains (321 grains) of mercury in nitrous acid, 36 grains remained unreduced. According to Mr Kirwan's calculation 56 grains ſhould have remained unreduced; for 100 grains of mercury afford 12 cubic inches of nitrous air; of conſequence 321 grains ſhould afford 38.52, which contain 2.58 of phlogiſton: and if, as according to the table, 4.56 grains of phlogiſtion be neceſſary to metallize 100 grains of mercury, 2.58 grains will be neceſſary to metallize 56 grains of the ſame metal; and our author is ſatisfied from his own trials, that more than 50 grains would have remained unreduced, if dephlogiſticated nitrous acid had been uſed in diſſolving the mercury, and the ſolution performed with heat and a ſtrong acid: but that which the Doctor uſed was of the ſmoking kind, and conſequently contained a conſiderable quantity of phlogiſton already, which undoubtedly contributed to revive more of the metal than would otherwiſe have been done. It is true, Dr Prieſtley afterwards revived a great part of what had originally remained unreduced; but this happened after it had been ſome time expoſed to the free air, from which the calces of metals always attract phlogiſton; as is evident in luna cornea, which blackens on being expoſed to the air.

323
Why ſo much of the metal was revived in the Doctor's experiments.

By another experiment of Dr Prieſtley's, it was found

324 Of the revival of lead from minium by inflammable air.

325 Mr Kirwan's remarks on the experiments of Dr Prieſtley.

found, that nearly five pennyweights of minium, from whence all its air was extracted, that is, about 118 grains, abſorbed 40 ounce-meaſures, or 75.8 cubic inches of inflammable air, containing 2.65 grains of phlogiſton, by which they were reduced. An hundred grains of minium, therefore, require for their reduction nearly 2.25 grains of phlogiſton. In another experiment made with more care, he found, that 480 grains of minium abſorbed 108 ounce-meaſures of inflammable air; ſo that, according to this, 100 grains of minium require for their reduction 1.49 grains of phlogiſton; and in two ſucceeding experiments he found the quantity ſtill leſs. On this Mr Kirwan remarks, 1. That the whole of the minium was not dephlogiſticated; for it is never equally calcined, and beſides much of it muſt have been reduced during the expulſion of its air. 2. The quantity of phlogiſton in the inflammable air may have been greater, as this varies with its temperature and the weight of the atmoſphere: ſo that on the whole theſe experiments confirm the reſults expreſſed in the table.

326 Of the attraction of metallic calces to phlogiſton.

327 Of finding the ſpecific gravity of the different metallic calces.

328 Whence their various degrees of affinity to phlogiſton may be determined.

Mr Kirwan next proceeds to conſider the attraction of metallic calces to phlogiſton. Inflammable air, when condenſed into a ſolid ſubſtance, he ſuppoſes not only equal, but much ſuperior, to any metallic calx in ſpecific gravity; and therefore, if we could find the ſpecific gravity of any calx free both from phlogiſton and fixed air, we would thus know the denſity which phlogiſton acquires by its union with ſuch calx. It has, however, hitherto proved impoſſible to procure calces in ſuch a ſtate; as, during their dephlogiſtication, they combine with fixed air or ſome particles of the menſtruum, whence their abſolute weight is increaſed, and their ſpecific gravity diminiſhed. Hence it appears, that the ſpecific gravity of the calces differs much leſs from that of their reſpective metals, than the ſpecific gravity which the phlogiſton acquires by its union with thoſe calces from that which it poſſeſſes in its uncombined ſtate. Hence, inſtead of deducing the quantity of affinity betwixt phlogiſton and metallic calces from the following propoſition, that "the affinity of metallic calces to phlogiſton is in a compound ratio of its quantity and denſity in each metal," he is obliged to deduce it from this other, that "the affinity of metallic calces to phlogiſton is directly as the ſpecific gravity of the reſpective metals, and inverſely as the quantity of calx contained in a given weight of theſe metals." This latter propoſition is an approximation to the former, founded on this truth, that "the larger the quantity of phlogiſton in any metal is, the ſmaller is the quantity of calx in a given weight of that metal;" and, that "the denſity which the phlogiſton acquires is as the ſpecific gravity of the metal." This latter propoſition, however, is not ſtrictly true, for this denſity is much greater; but its defect is only ſenſible with regard to thoſe metals which contain a conſiderable quantity of phlogiſton, as gold, copper, cobalt, and iron. With regard to the reſt, it is of no importance. The ſpecific gravity of the different metals, then, being as repreſented in the firſt column of the following table, the affinity of their calces to phlogiſton will be as in the ſecond; and the third expreſſes the affinities in numbers homogeneous with thoſe which expreſs the affinities of acids with their baſis.

330 Table of the proportional affinities of metallic calces to phlogiſton.

	Specific Gravity.	Proportionable Affinities.	Real Affinities of Calx to Phlogiſt.
Gold	19	0.25	1041
Mercury	14	0.147	612
Silver	11.091	0.118	491
Lead	11.33	0.116	483
Copper	8.8	0.109	454
Biſmuth	9.6	0.099	412
Cobalt	7.7	0.092	383
Iron	7.7	0.090	375
Regulus of Arſenic	8.31	0.089	370
Zinc	7.24	0.0812	338
Tin	7	0.075	312
Regulus of Antimony	6.86	0.074	308

331 Why lead is uſeful in cupellation.

From this table we may ſee why lead is uſeful in cupellation; namely, becauſe it has a greater affinity with phlogiſton than the calces of any of the other imperfect metals; conſequently after it has loſt its own phlogiſton, it attracts that of the other metals with which it is mixed, and thus promotes their calcination and vitrification.

332 Quantity of phlogiſton loſt by metals during calcination.

The third point neceſſary for the explanation of the phenomena attending the ſolution of metals, and their precipitation by each other, is to determine the proportion of phlogiſton which they loſe by ſolution in each of the acids, and the affinity which their calces bear to the part ſo loſt. Though our author was not able to determine this by any direct experiment, yet from various conſiderations he was led to believe that it was as follows:

Quantity of Phlogiſton ſeparated

	From Iron,	Copper,	Tin,	Lead,	Silver,	Mercury,	Zinc,	Biſmuth,	Cobalt,	Nickel,	Reg. of Ant.	Reg. of Arſ.
By the vitriolic acid	$\frac{2}{3}$	$\frac{8}{10}$	$\frac{7}{10}$	$\frac{98}{100}$	Entire	$\frac{87}{100}$	$\frac{85}{100}$	$\frac{85}{100}$	$\frac{93}{100}$	Entire	$\frac{97}{100}$	$\frac{86}{100}$
By nitrous acid	$\frac{1}{3}$	$\frac{81}{100}$	$\frac{7}{10}$	$\frac{88}{100}$	Entire	$\frac{9}{10}$	$\frac{99}{100}$	$\frac{97}{100}$	Entire	Entire	Entire	$\frac{99}{100}$
By marine acid	$\frac{42}{100}$	$\frac{57}{100}$	$\frac{3}{10}$	$\frac{6}{10}$	——	——	$\frac{6}{10}$	$\frac{7}{10}$	$\frac{94}{100}$	$\frac{8}{10}$	$\frac{84}{100}$	$\frac{6}{10}$

329 Of the affinity of calces to the deficient part of their phlogiſton.

The affinity of the calces to the deficient part of their phlogiſton may now be eaſily calculated; for they may be conſidered as acids, whoſe affinity to the deficient part of their baſis is as the ratio which that part bears to the whole. Thus the affinity of iron, thoroughly deprived of its phlogiſton, being 375, as it loſes two-thirds of its phlogiſton by ſolution in the vitriolic acid, the affinity of iron to theſe is two-thirds of its whole affinity; that is, two-thirds of 375, or 250.

333 Uſe of theſe calculations and tables for knowing *à priori* the phenomena of precipitation.

Thus we may eaſily conſtruct a table of the affinities of the phlogiſton of different metals for their calces; and from this and that formerly given, by which the affinities of the acids to the metallic calces was expreſſed, we may gueſs what will happen on putting one metal in the ſolution of another. Thus if a piece of copper be put into a ſaturated ſolution of ſilver, the ſilver will be precipitated; for the balance is in favour of the divellent powers, as appears from the following calculation.

Quieſcent

Quieſcent Affinities.		*Divellent Affinities.*	
Nitrous acid to ſilver	375	Nitrous acid to copper	255
Calx of copper to phlogiſton	363	Calx of ſilver to phlogiſton	491
Sum of the quieſcent affinities	738	Sum of the divellent	746

334 Of the exceſs of acid in ſolutions proper for making theſe experiments.

In making theſe experiments the ſolutions muſt be nearly, though not entirely, ſaturated. If much ſuperfluous acid be left, a large quantity of the added metal will be diſſolved, before any precipitation can be made to appear; and when the ſolution is perfectly ſaturated, the attraction of the calces for one another begins to appear; a power which ſometimes takes place, and which has not yet been fully inveſtigated.

335 Why the metals are more dephlogiſticated by mutual precipitation than by direct ſolution.

336 Why copper is diſſolved by ſolution of ſilver, mercury, or iron.

In this way the precipitating metals are more dephlogiſticated than by direct ſolution in their reſpective menſtrua; and are even diſſolved by menſtrua which would not otherwiſe affect them. The reaſon of this is, that their phlogiſton is acted upon by two powers inſtead of one: and hence, though copper be directly ſoluble in the vitriolic acid only when in its concentrated ſtate, and heated to a great degree; yet if a piece of copper be put into a ſolution of ſilver, mercury, or even iron, though dilute and cold, and expoſed to the air, it will be diſſolved; a circumſtance which has juſtly excited the admiration of ſeveral eminent chemiſts, and which is inexplicable on any other principles than thoſe juſt now laid down. From this circumſtance we may ſee the reaſon why vitriol of copper, when formed by nature, always contains iron.

Mr Kirwan now proceeds to conſider the ſolutions of metallic ſubſtances in all the different acids.

337 Iron and zinc the only metals diſſolved by vitriolic acid.

Vitriolic acid, he obſerves, diſſolves only iron and zinc of all the metallic ſubſtances, becauſe its affinity to their calces is greater than that which they bear to the phlogiſton they muſt loſe before they can unite with it.

338 Nitrous acid diſſolves all metals, though it has leſs affinity with them than the vitriolic or marine.

339 Why it cannot diſſolve them when much concentrated.

Nitrous acid has leſs affinity with all metallic ſubſtances than either the vitriolic or marine; yet it diſſolves them all, gold, ſilver, and platina excepted, though it has even leſs affinity with them than they have with that portion of phlogiſton which muſt be loſt before they can diſſolve in any acid. The reaſon of this is, that it unites with phlogiſton, unleſs when in too diluted a ſtate; and the heat produced by its union with phlogiſton is ſufficient to promote the ſolution of the metal. On the other hand, when very concentrated, it cannot diſſolve them: becauſe the acid does not then contain fire enough to throw the phlogiſton into an aerial form, and reduce the ſolid to a liquid.

340 In what caſes the marine acid can diſſolve metals, and when it cannot.

The marine acid dephlogiſticates metals leſs powerfully than any other. It can make no ſolution, or at leaſt can operate but very ſlowly, without heat, in thoſe caſes where the metallic calx has a ſtronger affinity with that portion of the phlogiſton which muſt be loſt, than the acid: nor can it operate briſkly even where the attraction is ſtronger, provided, the quantity of acid be ſmall; becauſe ſuch a little quantity of acid does not contain fire enough to volatilize the phlogiſton: and hence heat is neceſſary to aſſiſt the marine acid in diſſolving lead. When dephlogiſticated, it acts more powerfully.

341 Why copper and iron precipitate one another.

It has been obſerved, that copper and iron mutually precipitate one another. If a piece of copper be put into a ſaturated ſolution of iron freſh made, no precipitation will enſue for 12 hours, or even longer, if the liquor be kept cloſe from the air; but if the liquor be expoſed to the open air, the addition of volatile alkali will ſhow, in 24 hours, that ſome of the copper has been diſſolved, or ſooner, if heat be applied, and a calx of iron is precipitated. The reaſon of this will be underſtood from the following ſtate of the affinities.

Quieſcent.		Divellent.	
Vitriolic acid to calx of iron	270	Vitriolic acid to copper	260
Copper to its phlogiſton	360	Calx of iron to phlogiſton	250
	360		510

In this caſe no decompoſition can take place, becauſe the ſum of the divellent affinities is leſs than that of the quieſcent; but in the ſecond, when much of the phlogiſton of the iron has eſcaped, the affinity of the calx of iron to the acid is greatly diminiſhed, at the ſame time that the affinity of the calx to phlogiſton is augmented. The ſtate of the affinities may therefore be ſuppoſed as follows.

Quieſcent.		*Divellent.*	
Vitriolic acid to calx of iron	240	Vitriolic acid to copper	260
Copper to its phlogiſton	360	Calx of iron to phlogiſton	370
	600		630

342 Increaſe of the attraction of calx of iron to phlogiſton demonſtrated.

The increaſe of affinity of the calx of iron to phlogiſton is not a mere ſuppoſition; for if we put ſome freſh iron to a ſolution of the metal ſo far dephlogiſticated as to refuſe to cryſtallize, ſo much of the phlogiſton will be regained that the impoveriſhed ſolution will now yield cryſtals. The reaſon why the increaſed quantity of phlogiſton does not enable the acid to react upon the metal is, becauſe it is neither ſufficiently large, nor attracted with a ſufficient degree of force, to which the acceſs of air and heat employed contribute conſiderably. The diminution of attraction in calces of iron for acids is evident, not only from this but many other experiments; and particularly from the neceſſity of adding more acid to a turbid ſolution of iron in order to re-eſtabliſh its tranſparency.

343 Calces of copper precipitate dephlogiſticated ſolutions of iron.

A dephlogiſticated ſolution of iron is alſo precipitated by the calces of copper. The ſame thing happens to a ſolution of iron in nitrous acid; only as the acid predominates greatly in this ſolution, ſome of the copper is diſſolved before any of the iron is precipitated. Copper precipitates nothing from ſolution of iron in the marine acid, though expoſed to the open air for 24 hours.

344 Martial vitriol procured by precipitation of copper leſs fit for dyeing than the common.

Solution of copper in the vitriolic acid is inſtantly precipitated by iron; the reaſon of which is plain from the common table of affinities: and hence the foundation of the method of extracting copper, by means of iron, from ſome mineral waters. The precipitated ſolution affords a vitriol of iron, but of a paler kind than that commonly met with, and leſs fit for dyeing, as being more dephlogiſticated: the reaſon of which is, that copper contains more phlogiſton than iron: old iron is alſo uſed which has partly loſt its phlogiſton.

giſton. Hence the iron is more dephlogiſticated by precipitating copper than by mere diſſolution in the vitriolic acid; and hence caſt iron, according to the obſervations of Mr Schlutter, will ſcarcely precipitate a ſolution of copper; becauſe it contains leſs phlogiſton than bar-iron, as Mr Bergman has informed us.

345. Solution of copper ſcarcely decompoſed by caſt iron.

346. Why a ſaturated ſolution of ſilver can ſcarce be precipitated by iron.

Mr Kirwan always found ſilver eaſily precipitated by means of iron from its ſolution in nitrous acid; though Bergman had obſerved that a ſaturated ſolution of ſilver could not be thus precipitated without great difficulty, even though the ſolution were diluted and and an exceſs of acid added to it. What precipitation took place could only be accompliſhed by ſome kinds of iron. The reaſon of this Mr Kirwan ſuppoſes to be, that the ſolution, even after it is ſaturated, takes up ſome of the ſilver in its metallic form; which Mr Scheele has alſo obſerved to take place in quickſilver. The laſt portions of both theſe metals when diſſolved in ſtrong nitrous acid, afford no air, and conſequently are not dephlogiſticated. This compound of calx, therefore, and of ſilver in its metallic ſtate, it may reaſonably be ſuppoſed cannot be precipitated by iron, as the ſilver in its metallic form prevents the calx from coming into contact with the iron, and extracting the phlogiſton from it; and for the ſame reaſon iron has been obſerved not to precipitate a ſolution of mercury in the nitrous acid.

347. Of the precipitation of zinc and iron by one another.

Zinc cannot precipitate iron, as Mr Bergman has ſhown, until the ſolution of the latter loſes part of its phlogiſton. Hence we may underſtand why Newmann denied that iron can be precipitated by means of zinc. Mr Kirwan, however, has found, that zinc does not precipitate iron from the nitrous acid; but on the contrary, that iron precipitates zinc. In a ſhort time the acid rediſſolves the zinc and lets fall the iron, owing to the calx of iron being too much dephlogiſticated. Iron, however, will not precipitate zinc either from the vitriolic or marine acids. Moſt of the metallic ſubſtances precipitated by iron from the nitrous acid are in ſome meaſure rediſſolved ſhortly after; becauſe the nitrous acid ſoon dephlogiſticates the iron too much, then lets it fall, reacts on the other metals, and diſſolves them.

348. Why copper ſometimes cannot precipitate ſilver.

Dr Lewis obſerves, that ſilver is ſometimes not precipitated by copper from the nitrous acid; which happens either when the acid is ſuperſaturated with ſilver by taking up ſome in its metallic form, or when the ſilver is not much dephlogiſticated. In this caſe, the remedy is to heat the ſolution and add a little more acid, which dephlogiſticates it further; but the nitrous acid always retains a little ſilver.

349. Blue vitriol cannot be formed by boiling a ſolution of alum with copper filings.

It has commonly been related by chemical authors, that blue vitriol will be formed by adding filings of copper to a boiling ſolution of alum. Mr Kirwan, however, has ſhowed this to be an error; for after boiling a ſolution of alum for 20 hours with copper filings, not a particle of the metal was diſſolved; the liquor ſtanding even the teſt of the volatile alkali. The alum indeed was precipitated from the liquor, but ſtill retained its ſaline form; ſo that the precipitation was occaſioned only by the diſſipation of the ſuperfluous acid.

350. Why tin cannot be precipitated in its metallic form.

No metal is capable of precipitating tin in its metallic form; the reaſon of which, according to Mr Kirwan, is, becauſe the precipitation is not the effect of a double affinity, but of the ſingle greater affinity of its menſtruum to every other metallic earth. Metals precipitated from the nitrous acid by tin are afterwards rediſſolved, becauſe the acid ſoon quits the tin by reaſon of its becoming too much dephlogiſticated.

351. Why metals precipitated by tin are afterwards rediſſolved.

352. Precipitations by lead.

Lead precipitates metallic ſolutions in the vitriolic and marine acids but ſlowly, becauſe the firſt portions of lead taken up form ſalts very difficult of ſolution, which cover its ſurface, and protect it from the further action of the acid; at the ſame time it contains ſo little phlogiſton, that a great quantity of it muſt be diſſolved before it will diſſolve other metals. A ſolution of lead very much ſaturated cannot be precipitated by iron but with difficulty, if at all. Mr Kirwan conjectures that this may ariſe from ſome of the lead alſo being taken up in its metallic form, as is the caſe with mercury and ſilver. Iron will not precipitate lead from marine acid; for though a precipitate appears the acid is ſtill adhering to the metal. On the contrary, iron is precipitated from its ſolution in this acid by lead, though very ſlowly.

353. Precipitations of mercury by copper.

Mercury is quickly precipitated from the vitriolic acid by copper, though the difference between the ſum of the quieſcent and divellent affinities is but very ſmall. The precipitation, however, takes place, becauſe the calx of mercury has a ſtrong attraction for phlogiſton; and a very ſmall portion of what is contained in copper is ſufficient to revive it.

354. It cannot be precipitated by ſilver from vitriolic acid.

Silver, however, is not able to precipitate mercury from the vitriolic acid, unleſs it contains copper; in which caſe a precipitation will enſue: but on diſtilling ſilver and turpeth mineral, the mercury will paſs over in its metallic form; which ſhows that the affinity of the calx of mercury to phlogiſton is increaſed by heat, though the difference betwixt the divellent and quieſcent powers is very ſmall.

355. Why mercury and ſilver precipitate one another from the nitrous acid.

Mercury appeared to be precipitated by ſilver from the nitrous acid, though very ſlowly; but when the ſolution was made without heat, it was not at all precipitated. On the other hand, mercury precipitates ſilver from this acid, not by virtue of the ſuperiority of the uſual divellent powers, but by reaſon of the attraction of mercury and ſilver for each other; for they form partly an amalgam and partly a vegetation, ſcarcely any thing of either remaining in the ſolution.

356. Corroſive ſublimate cannot be precipitated by ſilver; but luna cornea may be decompoſed by mercury, and ſublimate by ſilver, in the dry way.

Silver does not precipitate mercury from the ſolution of corroſive ſublimate; but, on the contrary, mercury precipitates ſilver from the marine acid: and if a ſolution of *luna cornea* in volatile alkali be triturated with mercury, calomel will be formed; yet on diſtilling calomel and ſilver together, the mercury will paſs in its metallic form, and luna cornea will be formed. The ſame thing happens on diſtilling ſilver and corroſive ſublimate, the affinity of calx of mercury to phlogiſton increaſing with heat.

357. Precipitations of biſmuth.

Biſmuth precipitates nothing from vitriol of copper in 16 hours; nor does copper from vitriol of biſmuth. The two metallic ſubſtances, however, alternately precipitate one another from the nitrous acid, which proceed from their different degrees of dephlogiſtication.

358. Nickel precipitated by zinc.

Nickel will ſcarcely precipitate any metal except it be reduced to powder. A black powder is precipitated by means of zinc from the ſolution of nickel in in the vitriolic and nitrous acids, which has been ſhown by Bergman to conſiſt of arſenic, nickel, and a little of the zinc itſelf. The latter, however, precipitates nickel from the marine acid.

359 Iron and nickel will ſcarcely precipitate one another.

The ſolutions of iron and nickel in the vitriolic acid mutually act upon theſe metals; but neither of them will precipitate the other in 24 hours, though on remaining longer at reſt iron ſeems to have the advantage. Iron, however, evidently precipitates nickel from the nitrous acid; and though nickel ſeems to precipitate iron, yet this ariſes only from the gradual dephlogiſtication of the iron.

360 Precipitation of copper, lead, and biſmuth by nickel.

Copper is precipitated in its metalic form from the vitriolic, nitrous, and marine acids, by nickel. The vitriolic and nitrous ſolutions of lead ſeem to act upon it without any decompoſition, the calces uniting to each other. Lead ſeems for ſome time to be acted upon in the ſame manner by the vitriolic and nitrous ſolutions of nickel, but at laſt nickel ſeems to have the advantage; but a black precipitate appears which ever of them is put into the ſolution of the other. However, nickel readily precipitates vitriolic and nitrous ſolutions of biſmuth; but in the marine acid both theſe ſemimetals are ſoluble in the ſolutions of each other: yet nickel precipitates biſmuth very ſlowly, and only in part; while biſmuth precipitates a red powder, ſuppoſed by Mr Kirwan to be ochre, from the ſolution of nickel.

361 Zinc cannot precipitate cobalt.

Cobalt is not precipitated by zinc either from the vitriolic or nitrous acids, though it ſeems to have ſome effect upon it when diſſolved in that of ſea-ſalt.

362 Cobalt precipitated by iron.

363 Nickel precipitates ſome heterogeneous matter from it.

364 ſolutions of cobalt let fall a white powder on the addition of biſmuth or copper.

Iron precipitates cobalt from all the three acids, yet much of the ſemimetal is retained in the vitriolic and nitrous ſolutions of it, particularly the latter; which, after letting fall the cobalt, takes it up again, and lets fall a dephlogiſticated calx of iron. Nickel alſo, though it does not precipitate cobalt itſelf, as appears by the remaining redneſs of the ſolution, yet conſtantly precipitates ſome heterogeneous matter from it. Solution of cobalt in the marine acid becomes colourleſs by the addition of nickel. Biſmuth is ſoluble in the vitriolic and nitrous ſolutions of cobalt, and throws down a ſmall white precipitate, but does not affect the metallic part. Nor can we attribute theſe ſolutions in vitriolic acid to any exceſs in that acid, as they are dilute and made without heat. Copper alſo precipitates from the ſolution of cobalt a white powder ſuppoſed to be arſenic.

365 Precipitations of and by regulus of antimony.

The regulus of antimony has no effect on ſolution of copper in vitriolic acid, nor is precipitated by it from the ſame acid; but it diſſolves ſlowly in vitriol of antimony. With ſolution of vitriol of lead it becomes red in 16 hours, but is ſcarcely precipitated by lead from the vitriolic acid. Powdered regulus alſo precipitates vitriol of mercury very ſlightly. Biſmuth neither precipitates nor is precipitated by the regulus in 24 hours from the vitriolic acid. Tin precipitates the regulus from the nitrous acid; but if regulus be put into a ſolution of tin in the ſame acid, neither of the metals will be found in the liquid in 16 hours, either by reaſon of the dephlogiſtication or of the union of the calces to each other.

366 A triple ſalt formed by iron, regulus of antimony, and marine acid.

Iron does not precipitate regulus of antimony entirely from the marine acid; but ſeems to form a triple ſalt, conſiſting of the acid and both calces. The regulus may alſo be diſſolved by marine ſalt of iron.

367 Another formed by regulus of antimony, marine acid, and copper.

Copper does not precipitate regulus of antimony from marine acid in 16 hours; and if the regulus be put into marine ſalt of copper, it will be diſſolved, and volatile alkalies will not give a blue, but a yellowiſh white precipitate; ſo that here alſo a triple ſalt is formed.

368 Precipitations of and by arſenic.

Solution of arſenic in vitriolic acid acts upon iron, lead, copper, nickel, and zinc; but ſcarce give any precipitate: neither is arſenic precipitated by iron from the nitrous acid, though it is by copper, and even ſilver gives a ſlight white precipitate. Regulus of arſenic, however, precipitates ſilver completely in 16 hours: whence the former precipitate ſeems to be a triple ſalt. Mercury alſo ſlightly precipitates arſenic from the nitrous acid, and ſeems to unite with it, though it is itſelf precipitated by regulus of arſenic in 24 hours.

369 Regulus of arſenic precipitated by biſmuth from the nitrous acid;

Biſmuth ſlightly precipitates arſenic from ſpirit of nitre, but regulus of arſenic forms a copious precipitate in the nitrous ſolution of biſmuth; ſo that Mr Kirwan is of opinion that the calces unite. It is not precipitated from this acid by nickel, but the calces unite. Though regulus of arſenic produces a copious precipitate in the ſolution of nickel in nitrous acid, yet the liquor remains green; ſo that the nickel is certainly not precipitated. The white precipitate in this caſe ſeems to be arſenic ſlightly dephlogiſticated. Regulus of arſenic alſo produces a white precipitate in the nitrous ſolution of cobalt, but the liquor ſtill continues red.

370 And by copper from the marine acid.

Regulus of arſenic is precipitated from the marine acid by copper; but the precipitate does not ſtrike a blue colour with volatile alkali, becauſe the metal unites with the arſenic. The arſenic is alſo precipitated by iron. Tin is ſoluble in marine ſolution of arſenic, but Mr Kirwan could not obſerve any precipitation; nor does regulus of arſenic precipitate tin. Neither biſmuth nor regulus of arſenic precipitate each other from marine acid in 16 hours. Regulus of antimony is alſo acted upon by the marine ſolution of arſenic, though it cauſes no precipitate, nor does the regulus of arſenic precipitate it.

§ 2. *Of the Quantities of Acid, Alkali, &c. contained in different Salts, with the Specific Gravity of the Ingredients.*

It is a problem by which the attention of the beſt modern chemiſts has been engaged, to determine the quantity of acid exiſting in a dry ſtate in the various compound ſalts, reſulting from the union of acid with alkaline, earthy, and metallic ſubſtances. In this way Mr Kirwan has greatly excelled all others, and determined the matter with an accuracy and preciſion altogether unlooked for. His deciſions are founded on the following principles.

371 Specific gravity of bodies how found.

1. That the ſpecific gravity of bodies is their weight divided by an equal bulk of rain or diſtilled water; the latter being the ſtandard with which every other body is compared.

2. That if bodies ſpecifically heavier than water be weighed in air and in water, they loſe in water part of the weight which they were found to have in air; and

and that the weight ſo loſt is juſt the ſame as that of an equal bulk of water; and conſequently, that their ſpecific gravity is equal to their weight in air, or abſolute weight divided by their loſs of weight in water.

3. That if a ſolid, ſpecifically heavier than a liquid, be weighed firſt in air and then in that liquid, the weight it loſes is equal to the weight of an equal volume of that liquid; and conſequently, if ſuch ſolid be weighed firſt in air, then in water, and afterwards in any other liquid, the ſpecific gravity will be as the weight loſt in it by ſuch ſolid, divided by the loſs of weight of the ſame ſolid in water. This method of finding the ſpecific gravity of liquids, our author found more exact than that by the aerometer, or the compariſons of the weights of equal meaſures of ſuch liquids and water, both of which are ſubject to ſeveral inaccuracies.

372 To find the weight of an equal bulk of water where the ſpecific gravity is known.

4. That where the ſpecific gravity of bodies is already known, we may find the weight of an equal bulk of water; it being as the quotient of their abſolute weight divided by their ſpecific gravities: and this he calls their loſs of weight in water.

Thus where the ſpecific gravity and abſolute weight of the ingredients of any compound are known, the ſpecific gravity of ſuch compound may eaſily be calculated; as it ought to be intermediate betwixt that of the lighter and that of the heavier, according to their ſeveral proportions: and this Mr Kirwan calls the *mathematical* ſpecific gravity.

373 Mathematical ſpecific gravity explained.

But in fact the ſpecific gravity of compounds, found by actual experiment, ſeldom agrees with that found by calculation; but is often greater, without any diminution of the lighter ingredient.

374 Increaſed denſity of mixtures accounted for.

This increaſe of denſity, then, Mr Kirwan ſuppoſes to ariſe from a cloſer union of the component parts to each other than either had ſeparately with its own integrant parts; and this more intimate union muſt, he thinks, proceed from the attraction of theſe parts to each other: for which reaſon he ſuppoſed, that this attraction might be eſtimated by the increaſe of denſity or ſpecific gravity, and was proportionable to it; but ſoon found that he was miſtaken in this point.

575 Weights of different kinds of air

With regard to the abſolute weights of ſeveral ſorts of air, our author adheres to the computations of Mr Fontana, at whoſe experiments he was preſent; the thermometer being at 55°, and the barometer at 29½ inches, or nearly ſo. Theſe weights were as follow:

Cubic inch of common air,	-	0.385
fixed air,	-	0.570
marine acid air,		0.654
nitrous air,	-	0.399
vitriolic acid air,		0.778
alkaline air,	-	0.2
inflammable air,		0.03

376 Method of finding the quantity of pure acid contained in ſpirit of ſalt.

Mr Kirwan begins his inveſtigations with the marine acid; endeavouring firſt to find the exact quantity of pure acid it contains at any given ſpecific gravity, and then by means of it determining the weight of acid contained in all other acids. For if a given quantity of pure fixed alkali were ſaturated, firſt by a certain quantity of ſpirit of ſalt, and then by determined quantities of the other acids, he concluded, that each of theſe quantities of acid liquor muſt contain the ſame quantity of acid; and this being known, the remainder, being the aqueous part, muſt alſo be known. This concluſion, however, reſted entirely on the ſuppoſition that the ſame quantity of all the acids was requiſite for the ſaturation of a given quantity of fixed alkali; for if ſuch given quantity of fixed alkali might be ſaturated by a ſmaller quantity of one acid than of another, the concluſion fell to the ground. The weight of the neutral ſalts produced might indeed determine this point in ſome meaſure; but ſtill a ſource of inaccuracy remained; to obviate which he uſed the following expedient. 1. He ſuppoſed the quantities of nitrous and vitriolic acids neceſſary to ſaturate a given quantity of fixed alkali exactly the ſame as that of marine acid, whoſe quantity he had determined; and to prove the truth of this ſuppoſition, he obſerved the ſpecific gravity of the ſpirit of nitre and oil of vitriol he employed, and in which he ſuppoſed, from the trial with alkalies, a certain proportion of acid and water. He then added to theſe more acid and water, and calculated what the ſpecific gravity ſhould be on the above ſuppoſition; and finding the reſult agreeable with the ſuppoſition, he concluded the latter to be exact. The following experiments were made on the marine acid.

377 Method of finding the ſpecific gravity of ſpirit of ſalt.

Two bottles were filled nearly to the top with diſtilled water, of which they contained in all 1399.9 grains, and ſucceſſively introduced into two cylinders filled with marine air; and the proceſs was renewed, until the water had imbibed, in 18 days, about 794 cubic inches of the marine air. The thermometer did not riſe all this time above 55°; nor ſink, unleſs perhaps at night, above 50°; the barometer ſtanding between 29 and 30 inches. This dilute ſpirit of ſalt then weighed 1920 grains; that is, 520.1 more than before; the weight of the quantity of marine air abſorbed. The ſpecific gravity of the liquor was found to be 1.225. Its loſs of weight in water (that is, the weight of an equal bulk of water) ſhould then be 1567.346 nearly; but it contained only, as we have ſeen, 1399.9 grains of water: ſubtracting this therefore from 1567.346, the remainder (that is, 167.446) muſt be the loſs of 520.1 grains of marine acid; and conſequently the ſpecific gravity of the pure marine acid, in ſuch a condenſed ſtate as when it is united to water, muſt be $\frac{520.1}{167.446}$, or 3.100.

Still, however, it might be ſuſpected, that the denſity of this ſpirit did not entirely proceed from the mere denſity of the marine acid, but in part alſo from the attraction of this acid to water; and though the length of time requiſite to make the water imbibe this quantity of marine acid air, naturally led to the ſuppoſition that the attraction was not very conſiderable, yet the following experiment was more ſatisfactory. He expoſed 1440 grains of this ſpirit of ſalt to marine acid air for five days, the thermometer being at 50°, or below; and then found that it weighed 1562 grains, and conſequently had imbibed 122 grains more. Its ſpecific gravity was then 1.253, which was preciſely what it ſhould have been by calculation.

378 To find the proportion of pure air in other acid liquors.

Being now ſatisfied that the proportion of acid in ſpirit of ſalt was diſcovered, our author determined to find it in other acids alſo. For this purpoſe he took 180 grains of very ſtrong oil of tartar *per deliquium*, and found that it was ſaturated by 180 grains of ſpirit of ſalt, whoſe ſpecific gravity was 1.225; and by calculation it appeared, that 180 grains of this ſpirit contained 48.7 grains of acid, and 131.3 of water. Hence he drew up a table of the ſpecific gravities of acid liquors containing 48.7 grains of pure acid, with different proportions of water, from 50 to 410 parts; the liquor with the firſt proportion having a ſpecific gravity of 1.497, and the latter weighing only 1.074. Mr Baume had determined the ſpecific gravity of the ſtrongeſt ſpirit of ſalt made in the common manner to 1.187, and Bergman 1.190; but we are told in the Paris Memoirs for 1700, that Mr Homberg had produced a ſpirit whoſe ſpecific gravity was 1.300; and that made by Dr Prieſtley, by ſaturating water with marine acid air, muſt have been about 1.500. The ſpirit of ſalt, therefore, whoſe ſpecific gravity is 1.261, has but little attraction for water, and therefore attracts none from the air; for which reaſon alſo it does not heat the ball of a thermometer, as the vitriolic and nitrous acids do; though Mr Cavallo found that this alſo had ſome effect upon the thermometer. Common ſpirit of ſalt, Mr Kirwan informs us, is always adulterated with vitriolic acid, and therefore unfit for theſe trials.

379
Quantities of acid, water, and alkali in digeſtive ſalt.

Mr Kirwan now ſet about inveſtigating the quantity of acid, water, and fixed alkali, in digeſtive ſalt, or a combination of the marine acid with vegetable alkali. For this purpoſe he took 100 grains of a ſolution of tolerably pure vegetable alkali, that had been three times calcined to whiteneſs, the ſpecific gravity of which was 1.097; diluting alſo the ſpirit of ſalt with different portions of water; the ſpecific gravity of one ſort being 1.015, and of another 1.098. He then found that the above quantity of ſolution of the vegetable alkali required for its ſaturation 27 grains of that ſpirit of ſalt whoſe ſpecific gravity was 1.098, and 23.35 grains of that whoſe ſpecific gravity was 1.115. Now, 27 grains of ſpirit of ſalt, whoſe ſpecific gravity is 1.098, contain 3.55 grains of marine acid, as appears by calculation. The principles on which calculations of this kind are founded, our author gives in the words of Mr Cotes.

380
How to find the ſpecific gravities of the different ingredients.

“ The data requiſite are the ſpecific gravities of the mixture and of the two ingredients. Then, as the difference of the ſpecific gravities of the mixture and the lighter ingredient is to the difference of the ſpecific gravities of the mixture and the heavier ingredient; ſo is the magnitude of the heavier to the magnitude of the lighter ingredient. Then, as the magnitude of the heavier, multiplied into its ſpecific gravity, is to the magnitude of the lighter multiplied into its ſpecific gravity; ſo is the weight of the heavier to the weight of the lighter. Then, as the ſum of theſe weights is to the weight of either ingredient; ſo is the weight given to the weight of the ingredient ſought.” Thus, in the preſent caſe, 1.098—1.000=.098 is the magnitude of the heavier ingredient, viz. the marine acid, and .098×3.100=0.3038 the weight of the marine acid; and on the other hand, 3.100—1.098=2.002, the magnitude of the water; and 2.002×1.000=2.002 its weight; the ſum of theſe weights is 2.3058: then if 2.3058 parts of ſpirit of ſalt contain 0.3038 parts acid, 27 grains of this ſpirit of ſalt will contain 3.55 acid. In the ſame manner it will be found, that 23.35 grains of ſpirit of ſalt, whoſe ſpecific gravity is 1.115, contains 3.55 grains acid.

Our author deſcribes very particularly his method of making the ſaturation of the alkali with the acid; which, as it is always difficult to hit with preciſion, we ſhall here tranſcribe. “ It was performed by putting the glaſs cylinder which contained the alkaline ſolution on the ſcale of a very ſenſible balance, and at the ſame time weighing the acid liquor in another pair of ſcales; when the loſs of weight indicated the eſcape of nearly equal quantities of fixed air contained in the ſolution. Then the acid was gradually added by dipping a glaſs rod in it, to the top of which a ſmall drop of acid adhered. With this the ſolution was ſtirred, and very ſmall drops taken up and laid upon bits of paper ſtained blue with radiſh juice. As ſoon as the paper was in the leaſt reddened, the operation was completed; ſo that there was always a very ſmall exceſs of acid, for which half a grain was conſtantly allowed; but no allowance was made for the fixed air, which always remains in the ſolution. But as on this account only a ſmall quantity of the alkaline ſolution was uſed, this proportion of fixed air muſt have been inconſiderable. If one ounce of the ſolution had been employed, this inappretiable portion of fixed air, would be ſufficient to cauſe a ſenſible error; for the quantity of fixed air loſt by the difference betwixt the weight added to the 100 grains and the actual weight of the compound was judged of; and when this difference amounted to 2.2 grains, the whole of the fixed air was judged to be expelled: and it was found to be ſo; as 100 grains of the alkaline ſolution, being evaporated to dryneſs, in the heat of 300°, left a reſiduum which amounted to 10½ grains, which contained 2.2 grains of fixed air.”

381
Mr Kirwan's method of ſaturating the acid and alkali with accuracy.

382
Quantity of mild and cauſtic vegetable alkali ſaturated by a given weight of marine acid.

The reſult of this experiment was, that 8.3 grains of pure vegetable alkali, freed from fixed air and water, or 10.5 of mild fixed alkali, were ſaturated by 3.55 grains of pure marine acid; and conſequently the reſulting neutral ſalt ſhould, if it contained no water, weigh 11.85 grains: but the ſalts reſulting from this union (the ſolution being evaporated to perfect dryneſs in a heat of 160 degrees, kept up for four hours) weighed at a medium 12.66 grains. Of this 11.85 grains were acid and alkali; therefore the remainder, *viz.* 0.81 grains, were water. An hundred grains of perfectly dry digeſtive ſalt contain 28 grains acid, 6.55 of water, and 65.4 of fixed alkali.

In his experiments on the nitrous acid, Mr Kirwan made uſe only of the dephlogiſticated kind, which appears pure and colourleſs as water. “ This pure acid (ſays he) cannot be made to exiſt in the form of air, as Dr Prieſtley has ſhown; for when it is deprived of water and phlogiſton, and furniſhed with a due proportion of elementary fire, it ceaſes to have the properties of an acid, and becomes dephlogiſticated air. Its proportion therefore could not be determined in ſpirit of nitre as the marine acid had been in ſpirit of ſalt in the laſt experiment.”—To determine the matter, the following experiments were made.

383
Nitrous acid, when pure, cannot be made to exiſt in an aerial form.

384
How to determine the quantity of pure acid contained in ſpirit of nitre.

1. To 1963.25 grains of dephlogiſticated ſpirit of nitre, whoſe ſpecific gravity was 1.419, he gradually added 179.5 grains of diſtilled water; and when it cooled, the ſpecific gravity of the mixture was found to be 1.389.

2. To 1984.5 of this 178.75 grains of water were then added, and the ſpecific gravity of the mixture found to be 1.362.

3. An hundred grains of a ſolution of fixed vegetable

table

table alkali, whoſe ſpecific gravity was 1.097, the ſame that had been formerly uſed in the experiments with ſpirit of ſalt, was found to be ſaturated by 11 grains of the ſpirit of nitre, whoſe ſpecific gravity was 1.419, by 12 of that whoſe ſpecific gravity was 1.389, and by 13.08 of that whoſe ſpecific gravity was 1.362. Theſe quantities were the medium of five experiments; and it was found neceſſary to dilute the acid with a ſmall quantity of water. When this was neglected, part of the acid was phlogiſticated, and flew off with the fixed air. Ten minutes were alſo allowed after each affuſion for the matters to unite; a precaution which was likewiſe found to be abſolutely neceſſary.

385
Proportion of acid in ſpirit of nitre to that in ſpirit of ſalt.

386
To find the ſpecific gravity of the pure nitrous acid.

387
How to determine the accrued denſity on mixing ſpirit of nitre with water.

Upon the ſuppoſition, therefore, that a given quantity of vegetable fixed alkali is ſaturated by the ſame weight of both acids, we ſee that 11 grains of ſpirit of nitre, whoſe ſpecific gravity is 1.419, contain the ſame quantity of acid with 27 grains of ſpirit of ſalt, whoſe ſpecific gravity is 1.098, or 3.55 grains. The remainder of 11 grains, or 7.45 grains, is therefore mere water; and of conſequence, if the denſity of the acid and water had not been increaſed by their union, the ſpecific gravity of the pure nitrous acid ſhould be 11.8729. But the ſpecific gravity of the nitrous, as well as of the vitriolic acid, is augmented by its union with water; and therefore the loſs of its weight in water is not exactly, as it would appear by calculation from the above premiſes, according to the rules already laid down. To determine therefore the real ſpecific gravity of the acid in its natural ſtate, the quantity of *accrued* denſity muſt be found, and ſubtracted from the ſpecific gravity of the ſpirit of nitre, whoſe true mathematical ſpecific gravity will then appear. This our author endeavoured to effect by mixing different portions of ſpirit of nitre and water, remarking the degree of diminution they ſuſtained by ſuch union; but was never able to attain a ſufficient degree of exactneſs in the experiment. He had recourſe therefore to the following method, as affording more ſatisfaction, though not altogether accurate. Twelve grains of the ſpirit of nitre, whoſe ſpecific gravity by obſervation was 1.389, contained, as our author ſuppoſed from the former experiment, 3.55 grains of real acid, and 8.45 of water: then if the ſpecific gravity of the pure nitrous acid were 11.872, that of this compound acid and water ſhould be 1.371; for the loſs of 3.55 ſhould be 0.299, and the loſs of the water 8.45, the ſum of the loſſes 8.749. Now, $\frac{12}{8.749}=1.371$: but the ſpecific gravity, as already mentioned, was 1.389: therefore the accrued denſity was at leaſt 0.18. the difference betwixt 1.389 and 1.371. This calculation indeed is not altogether exact: but our author concludes, that 0.18 is certainly a near approximation to the degree of denſity that accrues to 3.55 grains of acid by their union to 7.45 grains of water: therefore, ſubtracting this from 1.419, we have nearly the mathematical ſpecific gravity of that proportion of acid and water, namely, 1.401.

388
To determine the mathematical ſpecific gravity of this acid

Again, ſince 11 grains of this ſpirit of nitre contain 3.55 grains acid, and 7.45 of water, its loſs of weight ſhould be $\frac{11}{1.401}=7.855$; and ſubtracting the loſs of the aqueous part from this, the remainder 0.45 is the loſs of the 3.55 grains acid; and conſequently the true ſpecific gravity of the pure and mere nitrous acid is $\frac{3.55}{0.405}=8.7654$. This being ſettled, the mathematical ſpecific gravity and true increaſe of denſity of the above mixtures will be found. Thus the mathematical ſpecific gravity of 12 grains of that ſpirit of nitre, whoſe ſpecific gravity, by obſervation, was 1.389, muſt be 1.355; ſuppoſing it to contain 3.55 grains acid and 8.45 of water. For the loſs of 3.55 grains acid is $\frac{3.55}{8.763}=0.405$, and the loſs of water 8.45; the ſum of theſe loſſes is 8.855. Then $\frac{12}{8.855}=1.355$; and conſequently the accrued denſity is 1.389—1.355=.034. In the ſame manner it will be found that the mathematical ſpecific gravity of 13.08 grains of that ſpirit of nitre, whoſe ſpecific gravity by obſervation was 1.362, muſt be 1.315; and conſequently its accrued denſity .047.

389
Experiment to determine the quantity of real acid in ſpirit of nitre.

The whole of this, however, ſtill reſts on the ſuppoſition that each of theſe portions of ſpirit of nitre contain 3.55 grains of acid. To verify this ſuppoſition, our author examined the mathematical ſpecific gravities of the firſt mixture he had made of ſpirit of nitre and water in large quantities; for if the mathematical ſpecific gravities of theſe agreed exactly with thoſe of the quantities he had ſuppoſed in ſmaller portions of each, he could not but conclude that the ſuppoſitions of ſuch proportions of acid and water, as he had determined in each, were juſt.

390
Table of ſpecific gravities for ſpirit of nitre, how conſtructed.

This being determined by proper calculations, Mr Kirwan next proceeded to conſtruct another table of ſpecific gravities, continuing his mixtures, till the mathematical ſpecific gravities found by obſervation nearly coincided with thoſe made by calculation. In this table the ſpirit of nitre was mixed with water in various proportions, but after a different manner from that obſerved with the ſpirit of ſalt. Nine grains of the ſpirit containing 3.55 grains of pure acid were mixed with 5.45 of water; the accrued denſity of the mixture was found to be nothing, the mathematical ſpecific gravity 1.537, and the ſpecific gravity by obſervation was found the ſame. When 10 grains of ſpirit were mixed with 6.45 of water, the accrued denſity was 0.009, the mathematical ſpecific gravity 1.458, and the ſpecific gravity by obſervation 1.467. In this manner he proceeded until 38.90 grains of water were mixed with 42.45 of ſpirit. In this caſe the accrued denſity was found to be 0.002, the mathematical ſpecific gravity 1.080, and the ſpecific gravity by obſervation 1.082.

The intermediate ſpecific gravities, in a table of this kind, may be found by taking an arithmetical mean betwixt the ſpecific gravities, by obſervation, betwixt which the deſired ſpecific gravity lies, and noting how much it exceeds or falls ſhort of ſuch arithmetical mean; and then taking alſo an arithmetical mean betwixt the mathematical ſpecific gravities betwixt which that ſought for muſt lie, and a proportionate exceſs or defect.

The ſpecific gravity of the ſtrongeſt ſpirit of nitre yet made, is, according to Mr Baume, 1.500, and according to Mr Bergman 1.586.

Our author next proceeded to examine the proportion

391 Quantity of acid, water, and alkali in nitre determined.

tion of acid, water, and fixed alkali in nitre, in a manner ſimilar to what he had already done with digeſtive ſalt; and found that 100 grains of perfectly dry nitre contained 28.48 grains of acid, 5.2 of water, and 66.32 of fixed alkali.

392 Homberg's experiments compared with thoſe of Mr Kirwan.

Some experiments of the ſame kind had been made by M. Homberg; the reſults of which our author compared with thoſe of his own. The ſpecific gravity of the ſpirit of nitre which M. Homberg made uſe of was 1.349; and of this, he ſays, one ounce two drachms and 36 grains, or 621 troy grains, are required to ſaturate one French ounce (472.5 troy) of dry ſalt of tartar. According to Mr Kirwan's computation, however, 613 grains are ſufficient; for the ſpecific gravity lies between the ſpecific gravities by obſervation 1.362 and 1.337, and is nearly an arithmetical mean between them. The correſponding mathematical ſpecific gravity lies between the quantities marked in Mr Kirwan's table 1.315 and 1.286, being nearly 1.300. Now the proportion of acid and water in this is 2.629 of acid and 7.465 of water; for 8.765—1.300=7.465 of water, and 8.765×.300=2.629 of acid; and the ſum of both is 10.044. Now, ſince 10.5 grains of mild vegetable alkali require 3.53 grains of acid for their ſaturation, 472.5 will require 159.7; therefore if 10.044 grains of nitre contain 2.629 grains acid, the quantity of this ſpirit of nitre requiſite to give 159.7 will be 613.2 nearly, and thus the difference with M. Homberg is only about eight grains.

393 Different reſults of Homberg and Kirwan's experiments accounted for.

M. Homberg ſays he found his ſalt, when evaporated to dryneſs, to weigh 186 grains more than before, but by Mr Kirwan's experiment, it ſhould weigh but 92.8 grains more than at firſt; the cauſe of which difference will be mentioned in treating of vitriolated tartar, as it cannot be entirely attributed to the difference of evaporation.

He alſo aſſerts, that one ounce (472.5 Troy grains) of this ſpirit of nitre contains 141 grains of Troy of real acid. According to Mr Kirwan's computation, however, it contains only 123.08 grains of real acid. But this difference evidently proceeds from his neglecting the quantity of water that certainly enters into the compoſition of nitre; for he proceeds on this analogy, 621 : 186.6 :: 472.5 : 141.

394 Mr Kirwan's experiments confirmed by one of Fontana.

Our author obſerves, that the proportion of fixed alkali aſſigned by him to nitre is fully confirmed by an experiment of Mr Fontana's inſerted in Rozier's Journal for 1778. He decompoſed two ounces of nitre by diſtilling it with a ſtrong heat for 18 hours. After the diſtillation there remained in the retort a ſubſtance purely alkaline, amounting to 10 French drachms and 22 grains. Now two French ounces contain 945 grains Troy, and the alkaline matter 607 grains of the ſame kind: according to Mr Kirwan's computation the two ounces of nitre ought to contain 625 grains of alkali. Such a ſmall difference he ſuppoſes to proceed from the loſs in transferring from one veſſel to another, weighing, filtering, evaporating, *&c.* Mr Kirwan alſo ſhows in a very particular manner the agreement of his calculations with the experiments of M. Lavoiſier on mercury diſſolved in ſpirit of nitre; but our limits will not allow us to inſert an account of them.

When finding the quantity of pure acid contained in oil of vitriol, our author made uſe of ſuch as was not dephlogiſticated; but, though pale, yet a little inclining to red. It contained ſome whitiſh matter, as he preceived by its growing milky on the affuſion of pure diſtilled water; but he imagines it was as pure as the kind uſed in all experiments.

395 Experiments on oil of vitriol.

To 2519.75 grains of this oil of vitriol, whoſe ſpecific gravity was 1.819, he gradually added 180 grains of diſtilled water, and ſix hours after found its ſpecific gravity to be 1.771.—To this mixture he again added 178.75 grains of water, and found its ſpecific gravity, when cooled to the temperature of the atmoſphere, to be 1.719, at which time it was milky. The ſame quantity of the oil of tartar abovementioned was then ſaturated with each of theſe kinds of oil of vitriol in the manner already deſcribed. The ſaturation was effected (taking a medium of five experiments) by 6.5 grains of that whoſe ſpecific gravity was 1.819, by 6.96 grains of that whoſe ſpecific gravity was 1.771, and by 7.41 of that whoſe ſpecific gravity was 1.719.

396 Dilution of oil of vitriol why neceſſary in theſe experiments.

It was found neceſſary to add a certain proportion of water to each of theſe ſorts of oil of vitriol; for when they were not diluted, part of the acid was phlogiſticated, and went off with the fixed air; but knowing the quantity of water that was added, it was eaſy to find by the rule of proportion the quantity of each ſort of vitriol that was taken up by the alkali. Hence it was ſuppoſed, that each of theſe quantities of oil of vitriol of different denſities contained 3.55 grains of acid; as they ſaturated the ſame quantity of vegetable fixed alkali with 11 grains of ſpirit of nitre, which contained that quantity of acid.

397 To find the ſpecific gravity of pure vitriolic acid.

It was next attempted to find the ſpecific gravity of the pure vitriolic acid in a manner ſimilar to that by which the gravity of the nitrous acid was found; as it cannot be had in the ſhape of air, unleſs when united with ſuch a quantity of phlogiſton as quite alters its properties. The loſs of 6.5 grains of oil of vitriol, whoſe ſpecific gravity is 1.819, is $\frac{6.5}{1.819} = 3.572$; but as theſe 6.5 grains contained, beſides 3.55 of acid, 2.95 of water, the loſs of this muſt be ſubtracted from the entire loſs; and then the remainder, or 0.622, is the loſs of the pure acid part in that ſtate or denſity to which it is reduced by its union with water. The ſpecific gravity, therefore, of the pure vitriolic acid, in this ſtate of denſity, is $\frac{3.55}{0.622} = 5.707$. But to find its natural ſpecific gravity, we muſt find how much its denſity is increaſed by its union with this quantity of water: and in order to obſerve this, he proceeded as before with the nitrous acid. 6.96 grains of oil of vitriol, whoſe ſpecific gravity was 1.771, contained 3.55 of acid and 3.41 of water; then its ſpecific gravity by calculation ſhould be 1.726; for the loſs of 3.55 grains of acid is $\frac{3.55}{5.707} = 0.622$; the loſs of 3.41 grains of water is 3.41; the ſum of the loſſes 4.032: then $\frac{6.96}{4.032} = 17.16$; therefore the accrued denſity is 1.771—1.726=0.45. Taking this therefore from 1.819, its mathematical ſpecific gravity will be 1.774. Then the loſs of 6.5 grains of oil of vitriol, whoſe ſpecific gravity by obſervation is 1.819, will be found to be $\frac{6.5}{1.774} = 4.663$; but of this, 2.95 grains are the loſs

of

of the water it contains, and the remainder 0.714 are the loſs of the mere acid part. Then $\frac{3.55}{0.714}$ is nearly the true ſpecific gravity of the pure vitriolic acid. The ſpecific gravity of the moſt concentrated oil of vitriol yet made, is, according to M. Baume and Bergman, 2.125.

398 Quantity of acid, alkali, and water, in vitriolated tartar determined

Mr Kirwan now conſtructed a table of the ſpecific gravities of vitriolic acids, of different ſtrengths, in a manner ſimilar to thoſe conſtructed for ſpirit of ſalt and ſpirit of nitre; but for which, as well as the others, we muſt refer to Phil. Tranſ. vol. 71. He then proceeded to find the proportion of acid, water, and fixed alkali, in vitriolated tartar as he had before done in ſal digeſtivus and nitre.—He found the ſalts reſulting from the ſaturation of the ſame oil of tartar, with portions of oil of vitriol, of different ſpecific gravities, to weigh at a medium 12,45 grains. Of this weight only 11.85 grains were alkali and acid. The remainder, therefore, was water, *viz* 0.6 of a grain. Conſequently 100 grains of perfectly dry tartar vitriolate contain 21.58 grains acid, 4.82 of water, and 66.67 of fixed vegetable alkali.—In drying this ſalt, a heat of 240 degrees was made uſe of, to expel the adhering acid more thoroughly. It was kept in this heat for a quarter of an hour.

399 Difference with Mr Homberg accounted for.

According to Mr Homberg, one French ounce, or 472.5 grains troy, of dry ſalt of tartar, required 297.5 grains troy, of oil of vitriol, whoſe ſpecific gravity was 1.674, to ſaturate it: but by Mr Kirwan's calculation, this quantity of fixed alkali would require 325 grains; a difference which, conſidering the different methods they made uſe of for determining the ſpecific gravities (Homberg's method by menſuration, giving it always leſs than Mr Kirwan's) the different deſiccation of their alkalies, &c. may be accounted inconſiderable.

The ſalt produced, according to Mr Homberg, weighed 182 grains troy above the original weight of the fixed alkali; but by Kirwan's experiment, it ſhould weigh but 87.7 grains more. "It is hard to ſay (adds Mr Kirwan) how Mr Homberg could find this great exceſs of weight, both in nitre and tartar vitriolate; unleſs he meant by the weight of the ſalt of tartar the weight of the mere alkaline part diſtinct from the fixed air it contained: and indeed one would be tempted to think he did make the diſtinction; for in that caſe the exceſs of weight would be nearly ſuch as he determined it."

From Mr Homberg's calculations, he inferred that one ounce (472.5 grains) of oil of vitriol contains 291.7 grains of acid. Mr Kirwan computes the acid only at 213.3 grains; but Homberg made no allowance for the water contained in tartar-vitriolate; and imagined the whole increaſe of weight proceeded from the acid that is united in it to the fixed alkali. Now the aqueous part in 560 grains of tartar vitriolate amounts to 36 grains; the remaining difference may be attributed to the different degrees of deſiccation, &c.

400 Specific gravity of the acetous acid.

On the acetous acid Mr Kirwan did not make any experiment; but by calculating from thoſe of Homberg, he finds that the ſpecific gravity of the pure acetous acid, free from ſuperfluous water, ſhould be 2.30. "It is probable (ſays Mr Kirwan), that its affinity to water is not ſtrong enough to cauſe any irregular increaſe in its denſity; at leaſt what can be expreſſed by three decimals: and hence its proportion of acid and water may always be calculated from its ſpecific quantity and abſolute weight."

401 Specific gravity of ſtrong vinegar.

An hundred parts of foliated tartar, or, as it ſhould rather be called, acetous tartar, contain, when well dried, 32 of fixed alkali, 19 of acid, and 49 parts of water.—The ſpecific gravity of the ſtrongeſt concentrated vinegar yet made is 1.069.—It is more difficult to find the point of ſaturation with the vegetable than with the mineral acids, becauſe they contain a mucilage that prevents their immediate union with alkalies; and hence they are commonly uſed in too great quantity: they ſhould be uſed moderately hot, and ſufficient time allowed them to unite.

402 Vegetable fixed alkali takes up an equal quantity of all the mineral acids.

From all the experiments above related, Mr Kirwan concludes, 1. That the fixed vegetable alkali takes up an equal quantity of the three mineral acids, and probably of all pure acids; for we have ſeen that 8.3 grains of pure vegetable alkali, that is, free from fixed air, take up 3.55 grains of each of theſe acids; and conſequently 100 parts of cauſtic fixed alkali would require 42.4 parts of acid to ſaturate them. But Mr Bergman has found that 100 parts of cauſtic fixed vegetable alkali take up 47 parts of the aerial acid; which, conſidering that his alkali might contain ſome water, differs but little from that already given. It ſhould ſeem, therefore, that alkalies have a certain determined capacity of uniting to acids, that is, to a given weight of acids; and that this capacity is equally ſatiated by a given weight of any pure acid indiſcriminately. This weight is about 2.35 of the vegetable alkali.

403 Quantity of the alkali neceſſary to ſaturate the acids.

2. That the three mineral acids, and probably all pure acids, take up 2.253 times their own weight of pure vegetable alkali, that is, are ſaturated by that quantity.

404 Increaſe of denſity in compound ſubſtances.

405 Why decompoſitions are ſometimes incomplete, and otherwiſe.

406 Why the laſt portions of a ſubſtance obſtinately adhere to that with which it was united.

407 Acids can never totally dephlogiſticate metallic earths.

3. That the denſity accruing to compound ſubſtances, from the union of their compound parts, and exceeding its mathematical ratio, increaſes from a *minimum*, when the quantity of one of them is very ſmall in proportion to that of the other; to a *maximum*, when their qualities differ leſs: but that the attraction, on the contrary, of that part which is in the ſmalleſt quantity to that which is in the greater, is at its maximum when the accrued denſity is at its minimum; but not reciprocally: and hence the point of ſaturation is probably the maximum of denſity and the minimum of ſenſible attraction of one of the parts. Hence no decompoſition operated by means of a ſubſtance that has a greater affinity with one part of a compound than with the other, and than theſe parts have with each other, can be complete, unleſs the minimum affinity of this third ſubſtance be greater than the maximum affinity of the parts already united. Hence alſo few decompoſitions are complete, unleſs a double affinity intervenes; and hence the laſt portions of the ſeparated ſubſtance adhere ſo obſtinately to that with which it was firſt united, as all chemiſts have obſerved.—Thus, though acids have a greater affinity to phlogiſton than the earths of the different metals have to it, yet they can never totally dephlogiſticate theſe earths but only to a certain degree; ſo, though atmoſpheric air, and particularly dephlogiſticated air, attracts phlogiſton more ſtrongly than the nitrous acid does, yet not even dephlogiſticated air can deprive the nitrous acid totally of its phlogiſton; as is evident from the

408 Why precipitates of mercury and alum retain part of the acid.

the red colour of the nitrous acid, when nitrous air and dephlogiſticated air are mixed together. Hence mercury precipitated from its ſolution in any acid, even by fixed alkalies, conſtantly retains a portion of the acid to which it was originally united, as Mr Bayen has ſhown. Thus alſo the earth of alum, when precipitated in like manner from its ſolution, retains part of the acid; and thus ſeveral anomalous decompoſitions may be explained.

409 Alkalies phlogiſticate concentrated acids.

4. That concentrated acids are in ſome meaſure phlogiſticated, and evaporate by union with fixed alkalies.

410 How to determine the quantity of pure acid in any ſubſtance.

5. That, knowing the quantity of fixed alkali in oil of tartar, we may determine the quantity of real pure acid in any other acid ſubſtance that is difficultly decompoſed; as the ſedative acid, and thoſe in vegetables and animals. For 10.5 grains of the mild alkali will always be ſaturated by 3.55 grains of real acid; and reciprocally, the quantity of acid in any acid liquor being known, the quantity of real alkali in any vegetable alkaline liquor may be found.

411 Specific gravity of fixed air determined.

Having thus determined the quantity of acid contained in the liquids of that kind uſually employed in chemiſtry, as well as the ſpecific gravities of the acids themſelves, Mr Kirwan became deſirous of inveſtigating the gravity of fixed and volatile alkalies. But as theſe ſubſtances are not eaſily preſerved from uniting themſelves with fixed air, he was led to conſider the gravity of this in its fixed ſtate, as an element neceſſary for the calculation of the quantities of the alkalies.

412 Specific gravity of fixed vegetable alkali inveſtigated.

To find the ſpecific gravity of the fixed vegetable alkali, our author proceeded in a manner ſimilar to that already deſcribed, excepting that he weighed it in ether inſtead of ſpirit of wine. The reſults of his experiments are.

413 Quantity of earth contained in it.

1. That 100 grains of this alkali contain about 6.7 grains of earth; which, according to Mr Bergman, is ſiliceous. It paſſes the filter along with it when the alkali is not ſaturated with fixed air; ſo that it ſeems to be held in ſolution in the ſame manner as in the *liquor ſilicum.*

414 Quantity of fixed air in oil of tartar and dry vegetable fixed alkali.

415 Mr Watſon's account of the ſpecific gravity of ſalt of tartar, &c.

2. The quantity of fixed air in oil of tartar and dry vegetable fixed alkali is various at various times, and in various parcels of the ſame ſalt; but in the purer alkalies it may be reckoned at a medium 21 grains in 100; and hence the quantity of this alkali may very nearly be gueſſed at in any ſolution, by adding a known weight of any dilute acid to a given weight of ſuch a ſolution, and then weighing it again; for as 21 is to 100, ſo is the weight loſt to the weight of mild alkali in ſuch ſolution. The ſpecific gravity of mild and perfectly dry vegetable fixed alkali, four times calcined, free from ſiliceous earth, and containing 21 *per cent.* of fixed air, was found to be 5.0527. When it contains more fixed air the gravity is probably higher, except when it is not perfectly dry; and hence the ſpecific gravity of this alkali, when cauſtic, was ſuppoſed by Mr Kirwan to be 4.234. For this reaſon the fixed alkalies, when united to aerial acid, are ſpecifically heavier than when united either to the vitriolic or nitrous. Thus Mr R. Watſon, in the Philoſophical Tranſactions for 1770, informs us, that he found the ſpecific gravity of dry ſalt of tartar, including the ſiliceous earth it naturally contains, to be 2.761; whereas the ſpecific gravity of vitriolated tartar was only 2.636, and that of nitre 1.933. The reaſon why nitre is ſo much lighter than tartar vitriolate is, that it contains much more water, and the union of the acid with the water is leſs intimate.

416 Why nitre is ſo much lighter than vitriolated tartar.

417 Quantity of fixed air in pure vegetable alkalies determined by Mr Cavendiſh.

Impure vegetable fixed alkalies, ſuch as pearl-aſh, potaſhes, &c. contain more fixed air than the purer kind. According to Mr Cavendiſh, pearl-aſh contains 28.4 or 20.7 *per cent.* of fixed air. Hence in lyes made from theſe ſalts, of equal ſpecific gravities with thoſe of a purer alkali, the quantity of ſaline matter will probably be in the ratio of 28.4 or 28.7 to 21; but this additional weight is only fixed air. Much alſo depends on their age; the oldeſt containing moſt fixed air. Our author alſo gives a table of the ſpecific gravities of different ſolutions of vegetable fixed alkali, in a manner ſimilar to what he had done before with the acids. He begins with 64.92 grains of a ſolution containing 26.25 grains of ſalt, and 38.67 of water. The accrued denſity he finds to be .050, the mathematical ſpecific gravity 1.445, and the ſpecific gravity by obſervation 1.495. By continually diluting the ſolution containing the ſame quantity of ſalt, he brings the abſolute weight of it at laſt to 341.94 grains, of which 317.49 are water; the accrued denſity 0.01, the mathematical ſpecific gravity 1.061, and the ſpecific gravity by obſervation 1.062.

418 Quantity of acid taken up by mild fixed alkali exactly determined.

419 Of the quantity of ingredients in vitriolated tartar;

420 In nitre;

421 In digeſtive ſalt.

In a ſubſequent paper on this ſubject, Philoſophical Tranſactions, vol. 72, p. 179, our author corrects a ſmall miſtake concerning the quantity of acid taken up by 10.5 grains of mild vegetable alkali. In his former computations he had made no allowance for the ſmall quantity of earth contained in this quantity of alkali; which, though inconſiderable in it, becomes of conſequence where the quantities are large. The error, however, occaſioned by this omiſſion, is ſenſible in his calculations concerning the quantities of acid alkali, &c. contained in the neutral ſalts, as well as in that concerning the vegetable alkali. When the correction is properly made, he ſays, it will be found that 100 grains of ſuch alkali, free from earth, water, and fixed air, take up 46.77 of the mineral acids, that is, of the mere acid part; and 100 grains of common mild vegetable alkali take up 36.23 grains of real acid. An hundred grains of perfectly dry tartar vitriolate contain 30.21 of real acid, 64.61 of fixed alkali, and 5.18 of water. Cryſtallized tartar vitriolate loſes only one *per cent.* of water in a heat in which its acid is not ſeparated in any degree; and therefore contains 6.18 of water. An hundred grains of nitre, perfectly dry, contain 30.86 of acid, 66 of alkali, and 3.14 of water; but in cryſtallized nitre the proportion of water is ſomewhat greater; for 100 grains of thoſe cryſtals being expoſed to a heat of 180° for two hours, loſt three grains of their weight without exhaling any acid ſmell; but when expoſed to a heat of 200 degrees, the ſmell of the nitrous acid is diſtinctly perceived. Hence 100 grains of cryſtallized nitre contain 29.89 of mere acid, 63.97 of alkali, and 6.14 of water. An hundred grains of digeſtive ſalt perfectly dry, contain 29.68 of marine acid, 63.47 of alkali, and 6.85 of water. One hundred grains of cryſtallized digeſtive ſalt loſe but one grain of their weight before the ſmell of the marine acid is perceived; and hence they contain 7.85 grains of water.

Another miſtake, more difficult to be corrected, was his ſuppoſing the mixtures of oil of vitriol and water, and ſpirit of nitre and water, had attained their maximum of denſity when they had cooled to the temperature of the atmoſphere; which at the time he made the experiment was between 50° and 60° of Fahrenheit.

422 Time required by mixtures of mineral acids and water to acquire their utmoſt denſity.

The mixture with oil of vitriol had been ſuffered to ſtand ſix hours; but when the acid was ſo much diluted as to occaſion little or no heat, it was allowed to ſtand only for a very little time. Several months afterwards, however, many of theſe mixtures were found much denſer than when he firſt examined them; and it was diſcovered, that at leaſt twelve hours reſt was neceſſary before concentrated oil of vitriol, to which even twice its weight of water is added, can attain its utmoſt denſity; and ſtill more when a ſmaller proportion of water is uſed. Thus when he made the mixture of 2519.75 grains of oil of vitriol, whoſe ſpecific gravity was 1.819, with 180 of water, he found its denſity ſix hours after 1.771, but after 24 hours it was 1.798: and hence, according to the methods of calculating already laid down, the accrued denſity was at leaſt .064 inſtead of .045. But by uſing oil of vitriol ſtill more concentrated, whoſe ſpecific gravity was 1.8846, he was enabled to make a ſtill nearer approximation; and found, that the accrued denſity of oil of vitriol, whoſe ſpecific gravity is 1.819, amounts to 0.104, and conſequently its mathematical ſpecific gravity is 1.715. Six grains and a half of this oil of vitriol contained, as has been already obſerved, 3.55 of mere acid, and the remainder was water. The weight of an equal bulk of water is 3.79 grains; and ſubtracting from this the weight of the water that enters into the compoſition of the oil of vitriol, it will be found, that the weight of a bulk of water equal to the acid part is 0.84; and conſequently the ſpecific gravity of the mere acid part is 4.226. Thus, by conſtantly allowing the mixtures to reſt at leaſt 12 hours, until the oil of vitriol was diluted with four times its weight of water, and then only ſix hours before the denſity of the mixtures was examined, he conſtructed another table, in which 1000 grains of liquor contained 612.05 of pure acid, 387.95 of water, the accrued denſity being .07, and the mathematical ſpecific gravity 1.877. Increaſing the quantity of water till the acid weighed 7000 grains, and the water 6387.95, he found the accrued denſity .059, and the mathematical ſpecific gravity 1.069. By a ſimilar correction of his experiments on the acid of nitre, he found its denſity to be 5.530; a ſimilar table was conſtructed for it, for which we refer our readers to the 72d volume of the Philoſophical Tranſactions.

423 Alteration of the denſity of acids by various degrees of heat.

Theſe experiments were made when the thermometer ſtood between 50° and 60° of Fahrenheit; but, as it might be ſuſpected that the denſity of acids is conſiderably altered at different degrees of temperature, he endeavoured to find the quantity of this alteration in the following manner: To calculate what this denſity would be at 55°, he took ſome dephlogiſticated ſpirit of nitre, and examined its ſpecific gravity at different degrees of heat; which was found to be as follows,

Degrees of heat.	Specific gravity.
30	1.4653
46	1.4587
86	1.4302
120	1.4123

The total expanſion of this ſpirit of nitre, therefore, from 30 to 120 degrees, that is, by 90° of heat, was 0.0527; for 1.4650=4123+.0527. By which we ſee, that the dilatations are nearly proportional to the degrees of heat: for beginning with the firſt dilatation from 30 to 46 degrees, that is, by 16 degrees of heat, we find that the difference between the calculated and obſerved dilatations is only $\frac{30}{1000}$; a difference of no conſequence in the preſent caſe, and which might ariſe from the immerſion of the cold glaſs-ball filled with mercury in the liquor. In the next caſe the difference is ſtill leſs, amounting only to $\frac{21}{10000}$.

With another, and ſomewhat ſtronger ſpirit of nitre, the ſpecific gravities were as follow:

Degrees of heat.	Specific gravity.
34	1.4750
49	1.4653
150	1.3792

Here alſo the expanſions were nearly proportional to the degrees of heat; for 116° of heat, the difference between 34 and 150, produce an expanſion of 0.0958; and 15° of heat, the difference between 34 and 49, produce an expanſion of 0.0097; and by calculation 0.0123: which laſt differs from the truth only by $\frac{21}{10000}$.

484 Strong ſpirit of nitre more expanded by heat than weak, and why.

From this experiment we ſee, that the ſtronger the ſpirit of nitre is, the more it is expanded by the ſame degree of heat; for if the ſpirit of nitre of the laſt experiment were explained in the ſame proportion as in the former, its dilatation, by 116 degrees of heat, ſhould be 0.0679; whereas it was found to be 0.0958.

As the dilatation of the ſpirit of nitre is far greater than that of water by the ſame degree of heat, and as it conſiſts only of acid and water; it clearly follows, that its ſuperior dilatability muſt be owing to the acid part: and hence the more acid that is contained in any quantity of ſpirit of nitre, the greater is its dilatability. We might therefore ſuppoſe, that the dilatation of nitre was intermediate betwixt the quantity of water it contains and that of the acid. But there exiſts another power alſo which prevents this ſimple reſult, *viz.* the attraction of the acid and water to each other, which makes them occupy leſs ſpace than the ſum of their joint volumes; and by this condenſation our author explains his phraſe of *accrued denſity*.

425 Exact quantity of dilatation of ſpirit of nitre.

Taking this into the account, we may conſider the dilatation of the ſpirit of nitre as equal to thoſe of the quantities of water and acid it contains, minus the condenſation they acquire from their mutual attraction; and this rule holds as to all other heterogeneous compounds.

426 Of the quantities of acid and water contained in ſpirit of nitre.

To find the quantities of acid and water in ſpirit of nitre, whoſe ſpecific gravity was found in degrees of temperature different from thoſe for which the table was conſtructed, viz. 54°, 55°, or 56° of Fahrenheit, the ſureſt method is to find how much that ſpirit of nitre is expanded or condenſed by a greater or leſſer degree of heat; and then, by the rule of proportion, find what its denſity would be at 55°. But if this cannot be done, we ſhall approach pretty near the truth if we allow $\frac{10}{1000}$ for every 15° degrees of heat above or below 55° of Fahrenheit, when the ſpecific gravity is between 1.400 and 1.500, and $\frac{8}{1000}$ when the ſpecific gravity is between 1.600 and 1.800.—The dilatations of oil and ſpirit of vitriol were found to be exceedingly irregular, probably by reaſon of a white foreign matter, which is more or leſs ſuſpended or diſſolved in it, according to its greater or leſſer dilution; and

and this matter our author did not ſeparate, as he intended to try the acid in the ſtate in which it is commonly uſed. In general he found that 15° of heat cauſed a difference of above $\frac{8}{1000}$ in its ſpecific gravity, when it exceeds 1.800, and of $\frac{3}{10000}$ when its ſpecific gravity is between 1.400 and 1.300—The dilatations of ſpirit of ſalt are very nearly proportional to the degrees of heat, as appears by the following table.

427
Dilatation of ſpirit of ſalt by various degrees of heat.

Degrees of heat,	Specific gravity.
33	1.1916
54	1.1860
66	1.1820
128	1.1631

Hence $\frac{6}{10000}$ ſhould be added or ſubtracted for every 21° above or below 55°, in order to reduce it to 55°, the degree for which its proportion of acid and water was calculated. The dilatability of this acid is much greater than that of water, and even than that of the nitrous acid of the ſame denſity.

428
Quantity of pure acid taken up by various ſubſtances.

429
Mineral alkali how prepared for theſe experiments.

Our author next proceeds to conſider the quantity of pure acids taken up at the point of ſaturation by the various ſubſtances they unite with.—He begins with the mineral alkali. Having rendered a quantity of this cauſtic in the uſual manner, and evaporating one ounce of the cauſtic ſolution to perfect dryneſs, he found it to contain 20.25 grains of ſolid matter. He was aſſured, that the watery part alone exhaled during evaporation, as the quantity of fixed air contained in it was very ſmall, and to diſſipate this a much greater heat would have been requiſite than that which he uſed. This dry alkali was diſſolved in twice its weight of water; and ſaturating it with dilute vitriolic acid, he found it to contain 2.25 grains of fixed air; that being the weight which the ſaturated ſolution wanted of being equal to the joint weights of water, alkali, and ſpirit of vitriol employed.

430
Quantity of vitriolic acid neceſſary to ſaturate it.

The quantity of mere vitriolic acid neceſſary to ſaturate 100 grains of pure mineral alkali was found to be 60 or 61 grains; the ſaturated ſolution thus formed being evaporated to perfect dryneſs weighed 36.5 grains; but of this weight only 28.38 were alkali and acid; the remainder, that is, 8.12 grains, therefore, were water. Hence 100 grains of Glauber's ſalt, perfectly dried, contained 29.12 of mere vitriolic acid, 48.6 of mere alkali, and 22.28 of water. But Glauber's ſalt cryſtallized contains a much larger proportion of water; for 100 grains of theſe cryſtals heated red hot loſt 55 grains of their weight; and this loſs Mr Kirwan ſuppoſes to ariſe merely from the evaporation of the watery part, and the remaining 45 contained alkali, water, and acid, in the ſame proportion as the 100 grains of Glauber's ſalt perfectly dried abovementioned. Then theſe 45 contained 13.19 grains of vitriolic acid, 21.87 of fixed alkali, and 9.94 of water: conſequently 100 grains of cryſtallized Glauber's ſalt contains 13.19 of vitriolic acid, 21.87 of alkali, and 64.94 of water.

431
Quantity of ingredients in Glauber's ſalt.

432
Quantity of mineral alkali taken up by dephlogiſticated nitrous acid;

On ſaturating the mineral alkali with dephlogiſticated nitrous acid, it was found that 100 grains of the alkali took up 57 of the pure acid in the experiment he moſt depended upon; though in ſome others this quantity varied by a few grains: he concludes, therefore, that the quantity of alkali taken up by this acid is nearly the ſame as that taken up by the vitriolic. Suppoſing this quantity to be 57 grains, then 100 grains of cubic nitre, perfectly dry, contain 30 of acid, 52.18 of alkali, and 17.82 of water: but cubic nitre cryſtallized contains ſomething more water; for 100 grains of theſe cryſtals loſe about four by gentle drying; therefore 100 grains of the cryſtallized ſalt contain 28.8 of acid, 50.09 of alkali, and 21.11 of water.

433
By marine acid.

An hundred grains of mineral alkali require from 63 to 66 or 67 grains of pure marine acid to ſaturate it; but Mr Kirwan ſuppoſes that one reaſon of this variety is, that it is exceeding hard to hit the true point of ſaturation. Allowing 66 grains to be the quantity required, then 100 grains of perfectly dry common ſalt contain nearly 35 grains of real acid, 53 of alkali, and 13 of water; but 100 grains of the cryſtallized ſalt loſe five by evaporation; ſo that 100 grains of theſe cryſtals contain 33.3 of acid, 50 of alkali, and 16.7 of water.

434
Proportion of fixed air, alkali, and water, inveſtigated by this ſaturation.

The proportion of fixed air, alkali, and water, was thus inveſtigated: 200 grains of theſe cryſtals were diſſolved in 240 of water; the ſolution was ſaturated by ſuch a quantity of ſpirit of nitre as contained 40 of pure nitrous acid; whence it was inferred that theſe 200 grains of ſalt of ſoda contained 70 of pure alkaline ſalt. The ſaturated ſolution weighed 40 grains leſs than the ſum of its original weight, and that of the ſpirit of nitre added to it; conſequently it loſt 40 grains of fixed air. The remainder of the original weight of the cryſtals therefore muſt have been water, *viz.* 90 grains. Conſequently 100 grains of theſe cryſtals contained 35 of alkali, 20 of fixed air, and 45 of water. This proportion differs conſiderably from that aſſigned by Mr Bergman and Lavoiſier, which our author imputes to their having made uſe of ſoda recently cryſtallized; but Mr Kirwan's had been made for ſome months, and probably loſt much water and fixed air by evaporation, which altered the proportion of the whole. According to the calculations of Bergman and Lavoiſier, 100 grains of this alkali take up 80 of fixed air. The ſpecific gravity of the cryſtallized mineral alkali, weighed in ether, found to be 1.421.

435
Differences with M. Bergman and Lavoiſier accounted for.

436
Proportions of ingredients in volatile alkalies.

The proportion of the different ingredients in volatile alkalies can only be had from the experiments lately made by Dr Prieſtley concerning alkaline air. He informs us, that $\frac{6}{10}$ of a meaſure of this, and one meaſure of fixed air, ſaturate one another. Then, ſuppoſing the meaſure to contain 100 cubic inches, 185 cubic inches of alkaline air take up 100 of fixed air; but 185 cubic inches of alkaline air weigh at a medium 42.55 grains, and 100 cubic inches of fixed air weigh 57 grains; therefore 100 grains of pure volatile alkali, free from water, take up 134 of fixed air.

On expelling its aerial acid from a quantity of this volatile alkali in a concrete ſtate, and formed by ſublimation, he found, that 53 grains of it were fixed air: according to the preceding calculation, 100 grains of it ſhould contain 39.47 of real alkali, and 7.53 of water, the reſt being fixed air.—On ſaturating a quantity with the vitriolic, nitrous, and marine acids, 100 grains of the mere alkali were found to take up 106 of mere vitriolic acid, 115 of the nitrous, and 130 of the marine acid. The ſpecific gravity of the volatile alkali

alkali weighed in ether (B) was 1.4076. The proportion of water in the different ammoniacal ſalts could not be found on account of their volatility; but was ſuppoſed to be very ſmall, as both volatile alkali and fixed air cryſtallize without the help of water when in an aerial ſtate.

437 Experiments on calcareous earth.

In making experiments on calcareous earth, it was firſt diſſolved in nitrous acid; and after allowing for the loſs of fixed air and water, 100 grains of the pure earth was found to take up 104 of nitrous acid; but only 91 or 92 of mere vitriolic acid were required to precipitate it from the nitrous ſolution.

438 Quantity of marine acid ſaturated by this earth.

Of the marine acid 100 grains of the pure calcareous earth require 112 for their ſolution. The liquor at firſt is colourleſs, but acquires a greeniſh colour by ſtanding.

439 Proportion of ingredients in natural gypſum;

Natural gypſum varies in its proportion of acid, water, and earth; 100 grains of it containing from 32 to 34 of acid and likewiſe of earth, and from 26 to 32 of water. The artificial gypſum contains 32 of earth, 29.44 of acid, and 38.56 of water. When well dried, it loſes about 24 of water; and therefore contains 42 of earth, 39 of acid, and 19 of water, *per* hundred.

440 In nitrous ſelenite;

Nitrous ſelenite (ſolution of calcareous earth in nitrous acid) carefully dried, contains 33.28 of acid, 32 of earth, and 34.72 of water.

441 In marine ſelenite.

The ſame quantity of marine ſelenite (ſolution of calcareous earth in marine acid), well dried, in ſuch a manner as to loſe no part of the acid, contain of the latter 42.56, of earth 38, and of water 19.44.

442 Calcined magneſia will not diſſolve in acids without heat.

Magneſia, when perfectly dry and free from fixed air, cannot be diſſolved in any of the acids without heat. Even the ſtrongeſt nitrous acid did not act upon it in 24 hours in the temperature of the atmoſphere; but in a heat of 180°, the mineral acids, diluted with four, or even ſix, times their quantity of water, had a very ſenſible effect upon it; but the quantity of acid diſſipated by heat rendered it impoſſible to aſcertain how much was neceſſary for ſolution, except by precipitation after it had been diſſolved. For this purpoſe the cauſtic vegetable alkali was employed; by which it appeared that 100 grains of pure magneſia take up 125 of mere vitriolic acid, 132 of the nitrous, and 140 of the marine. All of theſe ſolutions appeared to contain ſomething gelatinous; but none of them reddened vegetable blues; and that in the marine acid became greeniſh on ſtanding for ſome time.

443 Proportion of the ingredients in common Epſom ſalt;
444 In nitrous Epſom.
445 Cannot be found in marine Epſom.

An hundred grains of perfectly dry Epſom ſalt contain 45.67 of mere vitriolic acid, 36.54 of pure earth, and 17.83 of water. Solution of common Epſom ſalt, however, reddens vegetable blues, and therefore contains an exceſs of acid. A like quantity of nitrous Epſom, well dried, contains 35.64 of acid, 27 of pure earth, and 37.36 of water. The ſolution of marine Epſom cannot be tolerably dried without loſing much of its acid together with the water. The ſpecific gravity of this earth is 2.3296.

446 Earth of alum contains a great quantity of fixed air.

Moſt writers on chemiſtry have ſaid that earth of alum contains ſcarce any fixed air; but Mr Kirwan found that it contained no leſs than 26 *per cent.* though it had been previouſly kept red-hot for half an hour. It diſſolved with a moderate efferveſcence in acids until the heat was raiſed to 220°; after which the ſolution was found to have loſt weight in the proportion abovementioned.

447 Quantity of ingredients in alum.
448 This ſalt always contains an exceſs of acid.
449 Proportion of pure earth of alum taken up by nitrous acid;
450 By marine acid.

An hundred grains of this earth, deprived of the fixed air, require 133 of the pure vitriolic acid to diſſolve them. The ſolution was made in a very dilute ſpirit of vitriol, whoſe ſpecific gravity was 1.093, and in which the proportion of acid to the water was nearly as 1 to 14. It contained a ſlight exceſs of acid, turning the vegetable blues to a browniſh red; but it cryſtallized when cold, and the cryſtals were of the form of alum. Our author, therefore, is of opinion, that this is the true proportion of acid and earth to be uſed in the formation of that ſalt, though there was not water enough to form large cryſtals. Perceiving that the liquor contained an exceſs of acid, more earth was added; but thus it was found impoſſible to prevent it from tinging vegetable blues of a red colour until a precipitation was formed: and even when this was the caſe, though one part of the ſalt fell in the form juſt mentioned, yet the reſt would ſtill redden vegetable blues as before; though here our author doubts whether this be a mark of acidity. An hundred grains of alum, when dried, contain 42.74 of acid, 32.14 of earth, and 25.02 of water; but cryſtallized alum loſes 44 *per cent.* by deſiccation: therefore 100 grains of it contain 23.94 of acid, and 58.06 of water. An hundred grains of this pure earth take up, as near as can be judged, 153 of pure nitrous acid. The ſolution ſtill reddened vegetable blues; but after the above quantity of earth was added, an inſoluble ſalt began to precipitate. The ſolution, when cold, became turbid, and could not be rendered quite clear by 500 times its quantity of water. An hundred and ſeventy-three grains of pure marine acid are required for the diſſolution of 100 grains of earth of alum, but the liquor ſtill reddened vegetable blues. After this an inſoluble ſalt was formed; but it is difficult to aſcertain the beginning of its formation preciſely both in this and the preceding caſes. The ſpecific gravity of pure argillaceous earth, containing 25 *per cent.* of fixed air, is 1.9901.

451 Experiments on metals.
452 Beſt method of diſſolving them.

In the experiments made by our author on metals, the acids employed were ſo far dephlogiſticated as to be colourleſs; the metals were for the moſt part reduced to filings, or to fine powder in a mortar. They were added by little and little to their reſpective menſtrua; much more being thus diſſolved than if the whole had been thrown in at once, and the ſolution was performed in glaſs vials with bent tubes.

453 Proportion of iron taken up by the vitriolic acid.

An hundred grains of bar-iron, in the temperature of 56°, require for their ſolution 190 grains of the real acid, whoſe proportion to that of the water, with which it ſhould be diluted, is as 1 to 8, 10, or 12. It would act on iron, though its proportion were greater or leſſer, though not ſo vigorouſly; but by applying a heat of 200° towards the end, 123 grains of

---

(B) The fixed and volatile alkalies were weighed in ether on account of their great ſolubility in water.

of real acid would be ſufficient. The air produced by this ſolution is entirely inflammable, and generally amounts to 115 cubic inches.

454 Quantity of inflammable air produced.

By the aſſiſtance of a ſtrong heat, iron is alſo ſoluble in the concentrated vitriolic acid, though in ſmaller quantity; and inſtead of inflammable air, a large quantity of vitriolic air is produced, and a little ſulphur is ſublimed towards the end.

455 Why vitriolic air is produced by diſſolving iron in concentrated oil of vitriol.

The reaſon of this is, that the concentrated vitriolic acid, containing much leſs ſpecific fire than the dilute kind, cannot expel the phlogiſton in the form of inflammable air (which abſorbs a vaſt quantity of fire), but unites with it when further dephlegmated by heat, and thus forms both vitriolic air and ſulphur. An hundred grains of iron diſſolved without heat afford more than 400 of vitriol; and 100 grains of vitriol, when cryſtallized, contain 25 of iron, 20 of real acid, and 55 of water. When calcined nearly to redneſs, theſe cryſtals loſe about 40 *per cent.* of water.

456 Solution of the calces of iron in vitriolic acid.

The calces of iron are ſoluble in the vitriolic acid according to the quantity of phlogiſton they contain; the more phlogiſticated being more readily ſoluble, and thoſe which are dephlogiſticated leſs ſo. The latter not only require more real acid for their ſolution, but afford only a thick liquor or magma by evaporation, inſtead of cryſtals like the others.

457 That of the dephlogiſticated calces of iron refuſes to cryſtallize.

Hence alſo ſolutions of iron, when newly made, diminiſh, and conſequently phlogiſticate, the ſuperincumbent air by their gradual emiſſion of phlogiſton; at the ſame time that the calx, becoming more and more dephlogiſticated, gradually falls to the bottom, unleſs more acid be added to keep it in ſolution.

458 Proportion of iron diſſolved in nitrous acid.

An hundred grains of iron require for their ſolution in nitrous acid 142 grains of real acid, ſo diluted that its proportion to water ſhould be as 1 to 13 or 14; and when this laſt proportion is uſed, the heat of a candle may be employed for a few ſeconds, and the acceſs of common air prevented. Thus about 18 cubic inches of nitrous air are produced, the reſt being abſorbed by the ſolution, and no red vapours appear. But if the proportion of acid and water be as 1 to 8 or 10, a much greater quantity of metal will be dephlogiſticated by the application of heat, though very little of it be held in ſolution

459 Quantity of nitrous air obtained from this ſolution.

Thus, from 100 grains of iron Mr Kirwan has obtained 83.87 cubic inches of nitrous air; and by diſtilling the ſolution, a ſtill greater quantity may be obtained which had been abſorbed.

460 Why no inflammable air is here produced.

The reaſon that nitrous ſolutions of iron or other metals yield no inflammable air is, becauſe this acid has leſs affinity to water, and more to phlogiſton, than the vitriolic, and likewiſe contains much leſs fire than either that or the marine (ſee n° 278); and therefore unites with phlogiſton, inſtead of barely expelling it.

461 Vitriolic acid acts on iron in a much more dilute ſtate than nitrous.

Hence alſo the vitriolic acid, though united with 30 times its weight of water, will ſtill viſibly act on iron, and ſeparate inflammable air in the temperature of 55°; whereas nitrous acid, diluted with 15 times its weight of water, has no perceptible effect on the metal in that temperature. The calces of iron, if not too much dephlogiſticated, are alſo ſoluble in the nitrous acid.

462 Iron taken up by the marine acid.

Two hundred and fifteen grains of real marine acid are required for the ſolution of 100 grains of iron. When the proportion of water to the acid is as four to one, it efferveſces rather too violently with the metal; and heat is rather prejudicial, as it volatilizes the acid. No marine air flies off; and the quantity of inflammable air is exactly the ſame as with diluted vitriolic acid.

463 Calces of iron precipitated of a reddiſh colour from their ſolution in marine acid.

The calces of iron are alſo ſoluble in marine acid, and may be diſtinguiſhed by their reddiſh colour when precipitated by fixed alkalies, while the precipitates of the metal are greeniſh.

464 Proportion of copper diſſolved by vitriolic acid.

An hundred and eighty-three grains of real vitriolic acid are required to diſſolve an hundred grains of copper; the proportion of acid to that of water being as 1 to 1.5, or at leaſt as 1 to 1.7; and a ſtrong heat muſt alſo be applied. Mr Kirwan ſays he never could diſſolve the whole quantity of copper; but to diſſolve a given quantity of it, a ſtill greater heat muſt be employed in the proportion of 28 to 100; but this reſiduum alſo is ſoluble by adding more acid. Copper dephlogiſticated in this manner is ſoluble by adding warm water to the maſs.

465 Inflammable and vitriolic acid air obtained from ſolution of copper in vitriolic acid.

By treating 128 grains of copper in this manner, we obtain 11 cubic inches of inflammable air and 65 of vitriolic acid air. When inflammable air was obtained, however, our author tells us the acid was a little more aqueous.

466 Why this metal cannot be acted upon by dilute vitriolic acid.

The reaſon why copper cannot be dephlogiſticated by dilute vitriolic acid, or even by the concentrated kind without the aſſiſtance of heat, is its ſtrong attraction to phlogiſton, and the great quantity it contains.

An hundred grains of vitriol of copper contain 27 of metal, 30 of acid, and 43 of water; 28 of which laſt are loſt by evaporation or ſlight calcination. An hundred grains of copper, when diſſolved, afford 373 of blue vitriol.

467 Proportion of ingredients in blue vitriol.

An hundred grains of copper require 130 of pure nitrous acid for their diſſolution. If the acid be ſo far diluted that its proportion of water be as 1 to 14, the aſſiſtance of heat will be neceſſary, but not otherwiſe. This ſolution affords 67½ inches of nitrous air.—The calces of copper are ſoluble in the nitrous acid.

468 Quantity of copper diſſolved by nitrous acid.

A like quantity of this metal requires 1190 grains of real marine acid, as well as the aſſiſtance of a moderate heat, to diſſolve them; the proportion of water being as 4⅓ to 1. By employing a greater heat, more of the acid will be requiſite, as much more will be diſſipated: the concentrated acid acts more vigorouſly.—Calces of copper are likewiſe ſoluble in the marine acid, though leſs eaſily than in the nitrous.

469 In marine acid.

470 Action of the vitriolic acid in tin.

The vitriolic acid diſſolves tin but in ſmall quantity; an hundred grains of the metal requiring for their ſolution 872 of real acid, whoſe proportion to water ſhould not be leſs than 1 to 0.9. A ſtrong heat is alſo required. When the action of the acid has ceaſed, ſome hot water ſhould be added to the turbid ſolution, and the whole again heated. The metal is ſoluble in a more dilute acid, but not in ſuch quantity.—The ſolution abovementioned affords 70 cubic inches of inflammable air.—The calces of tin, excepting that precipitated from marine acid by fixed alkalies, are inſoluble in the vitriolic acid.

471 Inflammable air obtained from the ſolution.

472 Tin diſſolved in nitrous acid.

An hundred grains of tin require 1200 of real nitrous acid; whoſe proportion of water ſhould be at leaſt 25 to 1, and the heat employed not exceeding 60°. The quantity of air afforded by ſuch ſolution is only 10 cubic inches, and it is not nitrous. The ſolution

lution is not permanent; for in a few days it depoſites a whitiſh calx, and in warm weather burſts the vial. The calces of tin are inſoluble in this acid.

473 In marine acid.

Four hundred and thirteen grains of pure marine acid are required to diſſolve 100 grains of tin, the proportion of water being as $4\frac{1}{2}$ to 1. The aſſiſtance of a moderate heat is alſo required. About 90 cubic inches of inflammable, and 10 of marine air, are afforded by the ſolution; but the calces of tin are nearly inſoluble in this acid.

474 Lead with vitriolic acid.

An hundred grains of lead require 600 grains of real vitriolic acid for their ſolution, the proportion being not leſs than 1 of acid to $\frac{7}{10}$ of water; and it will ſtill be better if the quantity of water be leſs: for which reaſon, as in copper, a greater quantity of metal ſhould be employed than what is expected to be diſſolved. A ſtrong heat is alſo requiſite; and hot water ſhould be added to the calcined maſs, though in ſmall quantity, as it occaſions a precipitation.

475 Scarce ſoluble in dilute vitriolic acid.

—This metal is alſo ſoluble, but very ſparingly, in dilute vitriolic acid. Its calces are ſomething more ſoluble. An hundred grains of vitriol of lead, formed by precipitation, contain 73 of lead, 17 of real acid, and 10 of water.

476 With nitrous acid.

With ſpirit of nitre, 78 grains of real acid are required for the ſolution of 100 of lead, with the aſſiſtance of heat towards the end. The proportion of acid to that of water may be about 1 to 11 or 12. This ſolution produces but eight cubic inches of air, which is nitrous. The calces of the metal are ſoluble in this acid; but leſs ſo when much dephlogiſticated. An hundred grains of minium require 81 of real acid. An hundred grains of nitrous ſalt of lead contain about 60 of the metal.

477 With marine acid.

Six hundred grains of the real marine acid are required for the ſolution of 100 grains of lead; the ſpecific gravity of the acid being 1.141, though more would be diſſolved by a ſtronger acid.—The calces of lead are more ſoluble in this acid than the metal itſelf. An hundred grains of minium require 327 of real acid; but white lead is much leſs ſoluble. The ſame quantity of plumbum corneum, formed by precipitation, contain 72 of lead, 18 of marine acid, and 10 of water.

478 Silver with vitriolic acid.

An hundred grains of ſilver require 530 of real vitriolic acid to diſſolve them; the proportion of acid to water being not leſs than as 1 to $\frac{8}{10}$: and when ſuch a concentrated acid is uſed, it acts ſlightly even in the temperature of 60°; but a moderate heat is required in order to procure a copious ſolution. The calces of ſilver formed by precipitation from the nitrous acid with fixed alkalies are ſoluble even in dilute vitriolic acid without the aſſiſtance of heat. An hundred grains of vitriol of ſilver, formed by precipitation, contain 74 grains of metal, about 17 of real acid, and 9 of water.

479 With nitrous acid.

An hundred grains of the pureſt ſilver require for their ſolution 36 of nitrous acid, diluted with water in the proportion of one part of real acid to ſix of water, applying heat only when the ſolution is almoſt ſaturated. If the ſpirit be much more or much leſs dilute, it will not act without the aſſiſtance of heat. The laſt portions of ſilver thus taken up afford no air. Standard ſilver requires about 38 grains of real acid to diſſolve the ſame proportion of it; and the ſolution affords 20 cubic inches of nitrous air; whereas 100 grains of ſilver revived from luna cornea afford about 14.

Mr Kirwan has never been able to diſſolve ſilver in the marine acid, though Mr Bayen ſays he effected the diſſolution of three grains and a half of it by digeſtion ſome ſome days with two ounces of ſtrong ſpirit of ſalt.

480 Of the diſſolution of ſilver in marine acid.

Newman informs us alſo, that leaf-ſilver is corroded by the concentrated marine acid. It is diſſolved, however, by the dephlogiſticated ſpirit of ſalt, as well as by the phlogiſticated acid when reduced to a ſtate of vapour. An hundred grains of luna cornea contain 75 of ſilver, 18 of acid and 7 of water.

481 Beſt kind of aqua regia for diſſolving gold.

Mr Kirwan found that kind of aqua regia to ſucceed beſt in the diſſolution of gold, which was prepared by mixing together three parts of the real marine acid with one of the nitrous acid. Both of them ought alſo to be as concentrated as poſſible; though, when this is the caſe, it is almoſt impoſſible to prevent a great quantity from eſcaping, as a violent effervеſcence takes place for ſome time after the mixture. Aqua regia made with common ſalt or ſal ammoniac and ſpirit of nitre, is much leſs aqueous than that proceeding from an immediate combination of both acids; and hence it is the fitteſt for producing cryſtals of gold. Very little air is produced by the ſolution of this metal, and the operation goes on very ſlow. It is, however, better promoted by allowing it ſufficient time, than by applying heat.

482 Quantity of gold taken up by aqua regia.

An hundred grains of gold require for their ſolution 246 grains of real acid, the two acids being in the proportion abovementioned. Though ſoluble in the dephlogiſticated marine acid, it is only in very ſmall quantity, unleſs the acid be in a ſtate of vapour; for in its liquid ſtate it is too aqueous.

483 Calces of gold ſoluble in the vitriolic and nitrous acids.

In vitriolic and nitrous acids it is inſoluble, tho' the calces are ſomewhat ſoluble in the nitrous, more eaſily in the marine, but ſcarcely at all in the vitriolic acid.

484 Gold cannot, according to Kirwan, be diſſolved in nitrous acid.

Mr Kirwan ſays, that gold in its metallic ſtate may be diffuſed through the concentrated nitrous acid, tho' not diſſolved in it; contrary to the opinion of other chemiſts, who have affirmed that a true diſſolution takes place.

An hundred grains of mercury require for their ſolution 230 grains of real vitriolic acid, whoſe proportion to that of water is as 1 to $\frac{8}{10}$. A ſtrong heat is alſo requiſite, and the air produced is vitriolic. Precipitate *per ſe* is ſtill leſs ſoluble.

485 Mercury with vitriolic acid.

—An hundred grains of vitriol of mercury, produced by precipitation, contain 77 of metal, 19 of acid, and 4 of water.

486 With ſpirit of nitre.

In ſpirit of nitre, 100 grains of mercury are diſſolved by 28 of real acid, whoſe proportion to the water it contains is as 1 to $1\frac{52}{100}$. In this acid the ſolution takes place without heat; but it may alſo be diſſolved in a much more dilute acid, provided heat be applied. About 12 cubic inches of air are produced when heat is not applied; but M. Lavoiſier found the produce much greater. This, ſays Mr Kirwan, was evidently cauſed by his uſing red or yellow ſpirit of nitre, which already contains much phlogiſton. Precipitate *per ſe* is much leſs eaſily diſſolved in the nitrous acid, which Mr Kirwan ſuppoſes to be owing to the attraction of the aerial acid.

2d 486 With marine acid.

The marine acid, in its common phlogiſticated ſtate, does not act on mercury, at leaſt in its uſual ſtate of concentration; though M. Homberg, in the Paris Memoirs for the year 1700, affirms, that he diſſolved it by ſeveral months digeſtion in this acid. When dephlogiſticated, it certainly acts upon it, though very weakly while in a liquid ſtate. Precipitate *per ſe* is alſo ſoluble in the marine acid with the aſſiſtance of heat. An hundred grains of corroſive ſublimate contain 77 of mercury, 16 of real acid, and ſix of water. The like quantity of mercurius dulcis contains 86 of metal and 14 of acid and water.

487 Zinc with vitriolic acid;

Zinc requires for its ſolution an equal quantity of real vitriolic acid, whoſe proportion to that of water may be as 1 to 8, 10, or 12. Heat muſt be applied towards the end, when the ſaturation is almoſt completed. By the help of heat alſo this ſemimetal is ſoluble in the concentrated vitriolic acid, but a ſmall quantity of black powder remains in all caſes undiſſolved. An hundred cubic inches of inflammable air are produced. An hundred grains of vitriol of zinc contain 20 of zinc, 22 of acid, and 58 of water. The calces of zinc, if not exceedingly dephlogiſticated, are alſo ſoluble in this acid.

488 With nitrous acid.

An hundred and twenty-five grains of real nitrous acid, whoſe proportion to water is that of 1 to 12, are required for the ſolution of 100 grains of this ſemimetal, applying heat ſlightly from time to time.

489 Leſs metal diſſolved by concentrated than by diluted nitrous acid.

A concentrated acid diſſolves leſs of the metal, as a great quantitity of the menſtruum eſcapes during the efferveſcence. No nitrous air can be procured, the acid being partly decompoſed during the operation. The calces of zinc, if not too much dephlogiſticated, are likewiſe diſſolved by the nitrous acid.

490 With marine acid.

An hundred grains of zinc, require for their diſſolution 210 grains of real marine acid, the proportion of it to the water being as 1 to 9. If a more concentrated ſpirit of ſalt be made uſe of, a conſiderable part of it will be diſſipated during the efferveſcence, and conſequently more will be required for the ſolution. The calces of zinc are alſo ſoluble in the marine acid.

491 Biſmuth ſcarce ſoluble in vitriolic acid.

Only three grains of biſmuth were diſſolved by 200 of oil of vitriol, whoſe ſpecific gravity was 1.863, though a ſtrong heat was uſed at the ſame time. A greater quantity was indeed ſlightly dephlogiſticated; but when the gravity of the acid was reduced to 1.200, only a ſingle grain of the metal was diſſolved by 400 of it. The calces of this ſemimetal are much more ſoluble. Four cubic inches of vitriolic air were afforded by the ſolution of three grains of biſmuth.

492 Quantity diſſolved in ſpirit of nitre.

In ſpirit of nitre, 100 grains of real acid are only required to diſſolve 100 grains of the metal. The proportion of water to the acid ought to be as 8 or 9 to 1; in which caſe a gentle heat may be applied. The ſolution affords 44 cubic inches of nitrous air. The calces of biſmuth are alſo ſoluble in this acid.—

493 Scarce ſoluble in marine acids.

Only three or four grains of it were diſſolved by 400 of marine acid, whoſe ſpecific gravity was 1.220.

2d 493 Nickel with vitriolic acid;

About four grains of nickel were diſſolved in an hundred of the concentrated vitriolic acid with the aſſiſtance of a ſtrong heat; but its calces are much more ſoluble.—

494 With nitrous acid.

An hundred grains of nickel require for their ſolution 112 of real nitrous acid, whoſe proportion to water is as 1 to 11 or 12. The product of nitrous air is 79 inches. The calces are alſo ſoluble. A moderate heat is neceſſary for the diſſolution of the metal; but a concentrated acid acts ſo rapidly, that much of it is diſſipated.—Only four or five grains of nickel are diſſolved by 200 of ſpirit of ſalt whoſe ſpecific gravity was 1.220. An acid of this degree of ſtrength acts without the aſſiſtance of heat, though a weaker acid requires it, and diſſolves ſtill leſs of the metal. The calces of nickel are alſo ſoluble with difficulty in this acid.

495 With marine acid;

496 Cobalt with vitriolic acid;

Four hundred and fifty grains of real vitriolic acid, whoſe proportion to water is not leſs than 1 to $\frac{7}{10}$, are required for the diſſolution of 100 grains of cobalt, aſſiſted by a heat of 270° at leaſt. A ſolution is obtained by pouring warm water on the dephlogiſticated maſs.—The calces of cobalt, however, are more ſoluble; ſo that even a dilute acid will ſerve.—

497 With ſpirit of nitre;

In ſpirit of nitre, the like quantity of cobalt requires 220 grains of real acid, whoſe proportion to water is as 1 to 4; giving a heat of 180 towards the end.—The calces of the metal are ſoluble in the nitrous acid.—

498 With ſpirit of ſalt;

An hundred grains of ſpirit of ſalt, whoſe ſpecific gravity is 1.178, diſſolves, with the aſſiſtance of heat, two grains and a half of cobalt; and a greater quantity will be diſſolved by an acid more highly concentrated.—The calces of cobalt are more ſoluble.

499 Regulus of antimony with vitriolic acid;

An hundred grains of regulus of antimony require for their ſolution 725 grains of real vitriolic acid, whoſe proportion to water is as 1 to $\frac{7}{10}$, aſſiſted by a heat of 400°. A large quantity of regulus ſhould be put into the acid; and the reſulting ſalt requires much water to diſſolve it, as the concentrated acid lets fall much when water is added to it. A leſs concentrated acid will likewiſe diſſolve this ſemimetal, but in ſmaller quantity. The calces of antimony, even diaphoretic antimony, are ſomewhat more ſoluble.

500 With nitrous acid.

Nine hundred grains of real nitrous acid are required for the ſolution of 100 grains of regulus; the proportion of acid to the water of the ſolvent being as 1 to 12, and aſſiſted by an heat of 110°; but the ſolution becomes turbid in a few days. The calces are much leſs ſoluble in this acid.—

501 Scarce ſoluble in the marine acid.

Only one grain of the regulus is diſſolved by 100 of ſpirit of ſalt, whoſe ſpecific gravity was 1.220, with the aſſiſtance of a ſlight heat; and that which is only 1.178 diſſolves ſtill leſs; but Mr Kirwan is of opinion that the concentrated acid would, in a long time, and by the aſſiſtance of a gentle heat, diſſolve much more. The calces diſſolve more eaſily in the marine acid.

502 Regulus of arſenic with vitriolic acid;

Eighteen grains of regulus of arſenic are diſſolved in a heat of 250° by 200 grains of real vitriolic acid, whoſe ſpecific gravity is 1.871. About ſeven of theſe parts cryſtallize on cooling, and are ſoluble in a large quantity of water. The calces of arſenic are more ſoluble in this acid.—

503 With nitrous acid;

An hundred and forty grains of real nitrous acid are requiſite for the ſolution of 100 grains of regulus of arſenic; the proportion of acid to the water being as 1 to 11. The ſolution affords 102 cubic inches of nitrous air, the barometer being at 30 and the thermometer at 60. Calces of arſenic are likewiſe ſoluble in this acid.

504 With ſpirit of ſalt.

An hundred grains of ſpirit of ſalt, whoſe ſpecific gravity is 1.220, diſſolve a grain and an half of regulus of arſenic; but the marine acid, in its common ſtate, that is, when its gravity is under 1.17, does not at all affect it. The arſenical calces are leſs ſoluble in this than in the vitriolic or nitrous acids.

§ 3. *Of the Quantity of Phlogiſton contained in different Subſtances.*

Having gone through all the various baſes with which acids are uſually combined, and aſcertained the quantity

Quantity of Phlogiſton in different Subſtances.

quantity of different ingredients contained in the compounds reſulting from their union, we ought next to give an account of our author's experiments on phlogiſton; but as his ſentiments on that ſubject are taken notice of elſewhere, we ſhall content ourſelves with briefly mentioning the very ingenious methods by which he diſcovers the quantities of it contained in various kinds of air and in ſulphur.

505 Quantity of phlogiſton contained in nitrous air.

Having proved that inflammable air, in its concrete ſtate, and phlogiſton are the ſame thing, Mr Kirwan proceeds to eſtimate the quantity contained in nitrous air in the following manner.

"An hundred grains of filings of iron, diſſolved in a ſufficient quantity of very dilute vitriolic acid, produced, with the aſſiſtance of heat gradually applied, 155 cubic inches of inflammable air; the barometer being at 29.5, and the thermometer between 50° and 60°. Now, inflammable air and phlogiſton being the ſame thing, this quantity of inflammable air amounts to 5.42 grains of phlogiſton.—Again, 100 grains of iron diſſolved in dephlogiſticated nitrous acid, in a heat gradually applied and raiſed to the utmoſt, afford 83.87 cubic inches of nitrous air. But as this nitrous air contains nearly the whole quantity of phlogiſton which iron will part with (it being more completely dephlogiſticated by this than any other means), it follows, that 83,87 cubic inches of nitrous air contain at leaſt 5.42 grains of phlogiſton. But it may reaſonably be thought, that the whole quantity of phlogiſton which iron will part with is not expelled by the vitriolic acid, but that nitrous acid may expel and take up more of it. To try whether this was really the caſe, a quantity of green vitriol was calcined until its baſis became quite inſipid; after which two cubic inches of nitrous air were extracted from 64 grains of this ochre; and conſequently 100 grains, would yield 3.12 cubic inches of nitrous air. If 83.87 cubic inches of nitrous air contain 5.42 of phlogiſton; then 3.12 cubic inches of this air contain 0.2 of phlogiſton. The nitrous acid, therefore, extracts from 100 grains of iron two-tenths of a grain more phlogiſton than vitriolic acid does. Therefore 83.87 cubic inches of nitrous air, containing nearly the whole phlogiſton of the iron, have 5.62 of this ſubſtance. Hence 100 cubic inches of nitrous air contain 6.7 grains of phlogiſton."

2d 505 Quantity of phlogiſton in fixed air;

With regard to the quantity of phlogiſton in fixed air, after proving at length that it is compoſed of dephlogiſticated air united to the principle of inflammability, Mr Kirwan aſcertains the quantity of the latter in the following manner: "Dr Prieſtley, in the fourth volume of his Obſervations, p. 380, has ſatisfactorily proved, that nitrous air parts with as much phlogiſton to common air, as an equal bulk of inflammable does when fixed in the ſame proportion of common air. Now, when inflammable air unites with common air, its whole weight unites to it, as it contains nothing elſe but pure phlogiſton. Since, therefore, nitrous air phlogiſticates common air to the ſame degree that inflammable air does, it muſt part with a quantity of phlogiſton, equal to the weight of a volume of inflammable air, ſimilar to that of nitrous air. But 100 cubic inches of inflammable air weigh three grains and a half; therefore 100 cubic inches of nitrous air part with 3.5 grains of phlogiſton, when they communicate their phlogiſton to as much common air as will take it up. In this proceſs, however, the nitrous air does not part with the whole of the phlogiſton it contains, as appears by the red colour it conſtantly aſſumes when mixed with common or dephlogiſticated air; which colour belongs to the nitrous acid, combined with the remainder of its phlogiſton, whence the acid produced is always volatile.

Quantity of Phlogiſton in different Subſtances.

"One meaſure of the pureſt dephlogiſticated air and two of nitrous air occupy but $\frac{3}{100}$ of one meaſure, as Dr Prieſtley has obſerved. Suppoſe one meaſure to contain 100 cubic inches, then the whole, very nearly, of the nitrous air will diſappear (its acid uniting to the water over which the mixture is made), and 97 cubic inches of the dephlogiſticated air, which is converted into fixed air by its union with the phlogiſton of the nitrous air; therefore 97 cubic inches of dephlogiſticated air take up all the phlogiſton which 200 cubic inches of nitrous air will part with; and this we have found to be ſeven grains: therefore a weight of fixed air equal to that of 97 cubic inches of dephlogiſticated air, and 7 of phlogiſton, will contain ſeven grains of the latter. Now, 97 cubic inches of dephlogiſticated air weigh 40.74 grains; to which adding 7, we have the whole weight of the fixed air,=47.74 grains,=83.755 cubic inches; and conſequently 100 cubic inches of fixed air contain 8.357 grains of phlogiſton, the remainder being dephlogiſticated air. An hundred grains of fixed air, therefore, contain 14.661 of phlogiſton, and 85.339 of elementary or dephlogiſticated air. Hence alſo 100 cubic inches of dephlogiſticated air are converted into fixed air by 7.2165 grains of phlogiſton, and will be then reduced to the bulk of 86.34 cubic inches.

506 In vitriolic acid air.

To find the quantity of phlogiſton in vitriolic acid air, our author purſued the following method.

1. He found the quantity of nitrous air afforded by a given weight of copper, when diſſolved in the dephlogiſticated nitrous acid, and by that means how much phlogiſton it parts with.

2. He found the quantity of copper which a given quantity of the dephlogiſticated vitriolic acid could diſſolve; and obſerved, that it could not entirely ſaturate itſelf with copper without dephlogiſticating a further quantity which it does not diſſolve.

3. He found how much it dephlogiſticates what it thoroughly diſſolves, and how much it dephlogiſticates what it barely calcines.

4. How much inflammable air a given quantity of copper affords when diſſolved in the vitriolic acid to the greateſt advantage.

5. He deducts from the whole quantity of phlogiſton expelled by the vitriolic acid the quantity of it contained in the inflammable air; the remainder ſhows the quantity of it contained in the vitriolic acid air.

The concluſion deduced from experiments, conducted after this manner is, that 100 cubic inches of vitriolic air contain 6.6 grains of phlogiſton, and 71.2 grains of acid; and 100 cubic inches of this air weighing 77.8 grains, 100 of it muſt contain 8.48 grains phlogiſton, and 91.52 of acid.

507 Quantity of phlogiſton in Sulphur.

To find the quantity of phlogiſton in ſulphur, Mr Kirwan propoſed to eſtimate that of the fixed air produced during its combuſtion. For this purpoſe he firmly tied and cemented to the open top of a glaſs bell a large bladder, deſtined to receive the air expanded by combuſtion, which generally eſcapes when this

Quantity of Phlogiſton in different Subſtances.

508 Proper method of burning ſulphur.

this precaution is not uſed. Under this bell, containing about 3000 cubic inches of air, a candle of ſulphur, weighing 347 grains, was placed; its wick, which was not conſumed, weighing half a grain. It was ſupported by a very thin concave plate of tin, to prevent the ſulphur from running over during the combuſtion; and both were ſupported by an iron wire fixed in a ſhelf in a tub of water. As ſoon as the ſulphur began to burn with a feeble flame, it was covered with the bell, the air being ſqueezed out of the bladder. The inſide of the bell was ſoon filled with white fumes, ſo that the flame could not be ſeen; but in about an hour after all the fumes were thoroughly ſubſided, and the glaſs become cold, as much water entered the bell as was equal to 87.2 cubic inches; which ſpace our author concludes to have been occupied by fixed air, and which muſt have contained 7.287 grains of phlogiſton. The candle of ſulphur being weighed was found to have loſt 20.75 grains; therefore 20.75 grains of ſulphur contain 7.287 of phlogiſton, beſides the quantity of phlogiſton which remained in the vitriolic air. This air muſt have amounted to 20.75—7.287=13.463 grains, which, as already ſhown, contain 1.41 grains of phlogiſton. Therefore the whole quantity of phlogiſton in 20.75 grains of ſulphur is 8.428; of conſequence 100 grains of ſulphur contain 59.39 of vitriolic acid, and 40.61 of phlogiſton.

509 Quantity of phlogiſton in marine acid air.

The quantity of phlogiſton contained in marine acid air was found by the following method.—Eight grains of copper diſſolved in colourleſs ſpirit of ſalt afforded but 4.9 inches of inflammable air; but when the experiment was repeated over mercury, 91.28 cubic inches of air were obtained. Of theſe only 4.9 cubic inches were inflammable; and conſequently the remainder, 86.38 inches, were marine air, weighing 56.49 grains.—Now as ſpirit of ſalt certainly does not dephlogiſticate copper more than the vitriolic acid does, it follows, that theſe 4.9 cubic inches of inflammable air, and 86.38 of marine air, do not contain more phlogiſton than would be ſeparated from the ſame quantity of copper by the vitriolic acid; and ſince 100 grains of copper would yield to the vitriolic acid 4.32 grains of phlogiſton, 8.5 grains of copper would yield 0.367 grains of phlogiſton. This therefore is the whole quantity extracted by the marine acid, and contained in 91.28 cubic inches of air; and, deducting from this the quantity of phlogiſton contained in 4.9 cubic inches of inflammable air=0.171 grains, the remainder, *viz.* 0.367—0.171=0.196, is all the phlogiſton that can be found in 86.38 cubic inches of marine air. Then 100 cubic inches of it contain but 0.227 of a grain of phlogiſton, 65.173 grains being acid.—Hence we ſee why it acts ſo feebly on oils, ſpirit of wine, *&c.* and why it is not diſlodged from any baſis by uniting with phlogiſton, as the vitriolic and nitrous acids are, its affinity to it being inconſiderable.

510 Why marine acid acts ſo weakly.

§ 4. *Remarks on the Doctrines of the Quantity and ſpecific Gravity above delivered.*

2d 510 Mr Keir's objections to Kirwan's doctrines.

To this doctrine of the ſpecific gravity and quantity of acid contained in different ſubſtances, Mr Keir has made ſeveral objections. 1. Mr Kirwan ſuppoſes, that marine acid gas is the pure and ſolid marine acid diveſted of all water and other matter. Its apparent dryneſs in this reſpect, however, is no argument that it really contains no water; for water itſelf, reduced to a ſtate of vapour, poſſeſſes no moiſtening property. There is great reaſon to believe that water is a conſtituent part of ſome gaſes, and it is certain that all of them are capable of holding it in ſolution. As moiſt materials, therefore, are employed in the preparation of marine acid air, there ſeems no reaſon to believe, that in any way in which Mr Kirwan could obtain it, there was reaſon to ſuppoſe it perfectly free of water; in which caſe the denſity of the acid would be greater, and its quantity ſmaller than he ſuppoſes.

Remarks on the former Doctrines.

2. A conſiderable part of the denſity of the acid abſorbed in the experiment, probably aroſe from the condenſation which always accompanies the union of a concentrated acid with water. Mr Kirwan allows this to be the caſe with the nitrous and vitriolic acids, but thinks it too inconſiderable to deſerve notice in the marine. His reaſoning, however, does not appear ſatisfactory, or his experiments on the ſubject concluſive. He obſerves, that the length of time taken up in effecting an union between the marine gas and water, is no argument againſt their attracting one another ſtrongly when once united; and it is certain that part of this acid gas is very quickly abſorbed by water. He alſo finds fault with his accuracy in calculation; and aſſerts, that if matters are fairly ſtated, the real denſity of the marine acid gas will be conſiderably leſs than Mr Kirwan makes it.

3. A great obſtacle even to an approximation towards the real denſity of the acid, ariſes from the condenſation which the water, as well as the acids, muſt ſuffer in the proceſs: and in this caſe, where a general condenſation takes place, he aſks, “How ſhall we determine the part of the condenſation that belongs to the water, and the part that the acid ſuſtains?” This, with other conſiderations, makes Mr Keir “doubt of the poſſibility of ſolving the queſtion concerning the actual denſity of pure and ſolid acids.” The inveſtigation of the queſtion, indeed, he does not conſider as a matter of great conſequence, as every uſeful application may be obtained, by firſt inveſtigating the comparative ſtrengths of different portions of the ſame acid rendered more or leſs dilute; and then by finding out the ſtrength of the vitriolic, nitrous, and marine acids of known denſities, ſo that they may be compared together. “Homberg (ſays he) has the merit of making the firſt eſſay towards this inveſtigation. Bergman and Wenzal have ſupplied the defect of Homberg, by taking into conſideration the gas united with alkaline ſubſtances; and Mr Kirwan, by uſing determinate quantities of acid liquors of known denſities, has conſiderably improved the method of Bergman: and whoever ſucceeds theſe able chemiſts in this inquiry, may avail himſelf greatly of their labours, particularly thoſe of Mr Kirwan.” He concludes with ſtating the reſults of the inquiries made by the chemiſts abovementioned; on which he makes the following remarks.

3d 510 Great differences in the calculations of different authors.

“The diſcordancy of theſe reſults is very ſtriking, and gives but an humiliating repreſentation of the preciſion of our preſent knowledge in chemiſtry. A great part of the difference ariſes undoubtedly from the different views in which theſe authors conſidered the dryneſs or purity of the acids. Mr Kirwan, as we have ſeen, endeavoured to find their denſity and quantity in

Remarks on the former Doctrines.

a ſtate of perfect dryneſs and purity ; which he ſuppoſed to exiſt in the marine acid gas : with which he compared and inferred the denſities and quantities of the nitrous and vitriolic acids, upon the ſuppoſition that equal quantities of theſe ſeveral acids are ſaturated by a given weight of fixed alkali. Beſides the uncertainty of his principles, from which he deduces the denſity and quantity of the marine acid, his applications from thence to deduce the denſities of the pure nitrous vitriolic acids, being founded on the above ſuppoſition, muſt partake of its defects. The alkali which he happened to fix on as the ſtandard by which he compared the ſtrengths of the different acid liquors, in order to determine the quantity of real acid they contained, and thence to determine their denſity in a ſolid ſtate, was the fixed vegetable. Having found that 100 grains of his real marine acid could ſaturate 215 grains of this alkali, he infers, that the ſame proportion is applicable to the other acids : and accordingly we find that 100 grains of each of the pure and real mineral acids are ſaturated by an equal quantity, *viz.* 215 grains of this alkali. But if we examine the other columns of his table, we ſhall at once ſee, that, in other ſubſtances ſoluble by acids, this equality does not exiſt ; and that every ſuch ſubſtance has a ratio peculiar to itſelf, with reſpect to the proportions of theſe acids neceſſary for its ſaturation. It is evident, therefore, that if Mr Kirwan had fixed on the mineral alkali, the volatile alkali, lime, or any other ſubſtance, as a ſtandard, inſtead of vegetable alkali, his determination of the denſities of the real vitriolic and nitrous acids would have been different ; and as no reaſon can be aſſigned why the vegetable alkali or any other ſubſtance ſhould have the prerogative over the reſt, it is obvious that there can be no ſuch general ſtandard, but that each ſubſtance poſſeſſes ſolely the capacity of determining the proportions of the ſeveral acids neceſſary for its ſaturation.

" The other chemiſts were contented to conſider as the pure and dry acid, that which actually remains in the neutral ſalt, after this has been rendered as dry as poſſible by expoſure to a red heat : and having made their alkalies as dry as they could, they ſuppoſed theſe alkalies to retain the ſame weight in the dried neutral ſalt ; and that the augmentation of the weight gained by the alkali during the formation of the neutral ſalt ſhowed the weight of the dry acid. The uncertainty which affects this method ariſes from the different capacities which different neutral ſalts may poſſeſs of retaining more or leſs water, either as a conſtituent part of the dry ſalt, or merely by the ſtrength of adheſion or affinity. Nevertheleſs, this method being founded ſolely on experiment, without any theoretical inductions, ſeems to furniſh ſome approximation, not perhaps of the abſolute quantity of the acids in their drieſt poſſible ſtate, but of the acids as they actually exiſt in theſe ſalts comparatively with each other. Though the diſagreements between Bergman's and Wenzel's reſults are little in compariſon of the difference between them and Kirwan's, yet as their experiments were made nearly in the ſame manner, and upon the ſame grounds, there ſeems to be ſufficient reaſon to wiſh for a careful repetition of their experiments, or of others with the ſame view, and leſs liable to objections.

Remarks on the former Doctrines.

" The only difference in the methods employed by theſe two celebrated chemiſts conſiſted in the mode of ſaturation. Bergman probably uſed the common method, but Wenzel employed a very peculiar one. He added to his alkali a greater quantity of acid than was neceſſary for the ſaturation ; and after the alkali was diſſolved, he added a lump of zinc, or of oyſter-ſhell, in order to ſaturate completely the ſuperfluous acid. By obſerving how much of the zinc or oyſter-ſhell the acid diſſolved, and knowing how much of theſe ſubſtances was ſoluble in his acid by former experiments, he inferred the quantity of acid left for the ſaturation of the alkali. Having thus aſcertained the quantity neceſſary to ſaturate the alkali, he mixed together the proper proportions of theſe, and formed his neutral ſalt by evaporating the mixture and drying the ſalt with a red heat. Perhaps the difference in the reſults obtained by theſe two chemiſts might ariſe from their different modes of ſaturation. The common method of aſcertaining the point of ſaturation by means of litmus or other blue vegetable juices, appears ſufficiently exact, is ſimpler, and therefore preferable to that uſed by Wenzel.

" The ſtandard for comparing the ſtrengths of acids, and likewiſe of alkalies with one another, may be either an acid or an alkaline ſubſtance ; and if we had one of each, the proportion of whoſe quantities requiſite for their mutual ſaturation were well aſcertained, the conveniency in making the experiments would be obvious, and the certainty greater. Alkaline, and the earthy ſubſtances that are ſoluble in acids, are ſeldom pure enough for this purpoſe. They generally contain quantities, which are not conſtant, of fixed air, ſiliceous earth, magneſia, neutral ſalts, and inflammable matter, which render any of thoſe that are commonly met with unfit for the purpoſe without a very ſkilful and careful purification. The chemiſts who have made experiments to determine the proportions of acids and alkalies requiſite for each other's ſaturation, have ſcarcely been explicit enough in explaining the means of purifying the alkalies which they employed : for thoſe in commerce are quite uncertain in ſtrength and purity : and as to the general rules for making allowances for any heterogeneous ſubſtances they may contain, they are quite inapplicable to delicate experiments. No other method ſeems proper for aſcertaining the purity of alkalies but that of cryſtallization : of which both the vegetable and mineral alkalies are ſuſceptible, eſpecially the latter, which on account of its being more eaſily reducible into cryſtals, is therefore preferable. Theſe alkaline cryſtals, however, are not fit to be uſed as a ſtandard, becauſe they either are apt to be ſufficiently dried, or, upon expoſure to air, to loſe a part of the water of their cryſtallization, and to fall into powder. Even if they ſhould be taken, as is poſſible with due care, at the exact ſtate of dry but entire cryſtals, another uncertainty ariſes from a property which ſeems to be common to them all, namely, that of retaining a greater or ſmaller quantity of water, according to the degree of heat in which they were cryſtallized ; the colder the weather the greater quantity of water entering into the compoſition of the cryſtals. It ſeems poſſible, however, to make a pretty accurate ſtandard of mineral alkali in the following manner : Let the alkali be purified by repeated ſolution

4th 510
Mr Keir's method of preparing an alkaline ſtandard.

Remarks on the former Doctrines.

tion and cryſtallization, uſing only ſuch as are formed firſt, and rejecting the remaining liquors. Let the pure cryſtals be expoſed to a dry air until they have completely effloreſced or fallen into a dry white powder; which alteration may be facilitated by bruiſing the cryſtals and changing the ſurface of the powder. Let this powder be then expoſed for a certain and determinate time to a conſtant heat, as that of boiling water for 12 hours; letting the ſurface expoſed be in ſome given proportion, ſuppoſe of a ſquare inch to an ounce of the powder of cryſtals, and let it be ſtirred every two hours. When thus dried, let them be put while hot into a bottle, and well ſtopped. This powder I have found to be an uniform and conſtant ſtandard for aſcertaining the ſtrength of acids; and alſo, by compariſon by means of acids, of other alkaline ſubſtances."

With regard to an acid ſtandard, our author recommends oil of vitriol; which, he ſays, as it comes from the hands of the Britiſh manufacturers, is of the ſpecific gravity of about 1.846, but ſoon becomes weaker, unleſs carefully kept from the external air; and in general he rates it at 1.844. One part of this acid mixed with nine of water, is of a very convenient ſtrength for uſe; and as every ten grains of the mixture contain one of the ſtandard acid, the computations are thus rendered eaſy: and by theſe ſtandards, the ſtrength of all acids, alkalies, and ſubſtances ſoluble in acids, may be meaſured and compared together.

5th 510 His method of finding the ſpecific gravity of different liquors.

To determine the ſpecific gravity of liquors with accuracy, our author recommends the method of weighing them in a phial fitted with a glaſs-ſtopper, which can only enter a certain length into the neck. In this way, he obſerves, no other inconvenience can enſue than the ſlight one, that the glaſs-ſtopper, by very frequent uſe, is apt to wear itſelf and the neck of the phial alſo; ſo that after a great number of experiments, it will at laſt diminiſh, in ſome meaſure, the capacity of the phial itſelf. This, however, is but very trifling, and may be corrected at any time. Mr Keir has beſides found, that after ſome hundreds of experiments, the error amounted only to one quarter of a grain in 101 grains.

"The methods hitherto practiſed (ſays he) for aſcertaining the quantities of acids and alkalies contained in neutral ſalts, ſeem to be liable to ſeveral objections beſides thoſe abovementioned, ariſing from the different proportions of water remaining in a neutral ſalt, after expoſure to a red-heat, which heat is alſo very indefinite. In boiling the ſaturated mixture of acid and alkali to dryneſs, and afterwards in expoſing this ſalt to a red-heat, it has been ſuppoſed that nothing but water is expelled; and ſome chemiſts, who have given the reſults, have alſo determined the weight of the alkali which enters into the neutral mixture, by evaporating to dryneſs an equal quantity of the alkaline ſolution which had been employed in the ſaturation, and weighing the dry ſolution, on the ſuppoſition that nothing is expelled but water. It is certain, however, that in the evaporation both of alkalies and neutral ſalts, a conſiderable portion of the ſaline matter is elevated towards the end, when the liquor becomes concentrated and acquires a degree of heat conſiderably above that of boiling water. The following method appears beſt for determining the relative quantities of acid and alkali, or other ſubſtance exiſting in neutral ſalts.

"To a given number of grains, ſuppoſe 100 of the ſtandard vitriolic acid, or to a proportionable quantity of any other acid, add as much of the alkali or other ſoluble ſubſtance as is requiſite for the ſaturation, and note the quantity required, which ſuppoſe to be 150 grains. We have thus a ſolution of the neutral ſalt, which is the object of the experiment; the quantities of acid and baſis contained in which are known, and the general proportion of the quantity of the acid to its baſis in the neutral ſalt determined, *viz.* as 100 to 150. The next thing to be diſcovered is the weight of the dry neutral ſalt contained in this ſolution, in order to know the proportion of the dry neutral ſalt to its acid and baſis. For this purpoſe, let a given quantity of the ſame neutral ſalt, either in the ſtate of cryſtals or dried to any given degree, be diſſolved in water. Let this ſolution be brought to the ſame denſity as the former, by adding water to the heavier of the two: then, by knowing the weight of each ſolution, and the quantity of dry neutral ſalt which was actually diſſolved in one of them, the quantity contained in the other may be deduced; and thence the quantities of ſtandard acid, or of other acid proportioned to it, and of the alkali employed, or other ſoluble ſubſtance contained in a given quantity of the neutral ſalt, are determined; alſo the quantity of water contained in the neutral ſalt, that is greater or leſs than what is contained in the quantity of acid employed, will be known, over and above any water that may have been contained in the alkali or other baſis of the neutral ſalt; the quantity of which water, if any, cannot be determined.

"By this method may be aſcertained the proportion of the acid, of the baſis, and of the neutral ſalt, to each other; not indeed the quantity of acid and of alkali deprived of all water, but the quantity of acid, equal in intenſity of acidity to a known portion of the ſtandard acid; and alſo the quantity of ſuch alkali or other ſoluble ſubſtance as was employed; the relative ſtrength of which is known from its ratio to the ſtandard acid."

6th 510 Objection to Kirwan's calculation of the quantity of phlogiſton in ſulphur.

The tranſlator of Wiegleb's Syſtem of Chemiſtry totally diſagrees with Mr Kirwan's calculation of the quantity of phlogiſton contained in ſulphur; but as his objection ſeems to ariſe rather from an inclination to the antiphlogiſtic doctrine that a real diſcuſſion of the ſubject, this can have but little weight. It is poſſible indeed that Mr Kirwan may have over-rated the quantity of phlogiſton this ſubſtance contains, which is indeed larger than that allowed by other chemiſts. "Brandt (ſays the tranſlator), who has been moſt generally followed, reckons it only at $\frac{1}{16}$; and it has always appeared to me, that the weight of phlogiſton in ſulphur is almoſt infinitely ſmall." His objection proceeds on a maxim which he thinks he has demonſtrated, *viz.* that ſulphur is compoſed, not of the vitriolic acid and phlogiſton, but of the *baſe* of vitriolic acid and phlogiſton. No experiments hitherto made, however, have been able to ſhow this baſe diſtinct from the acid; nor have we any reaſon to ſuppoſe that the increaſe of weight in the vitriolic acid above the ſulphur from

from which it is produced, ariſes from any thing beſides the acceſſion of mere water, which the air parts with during the combuſtion. Hence, if the ſulphur is burnt in a very moiſt air, the quantity of acid obtained will be four or five times the weight of the ſulphur.

SECT. IV. *Earths.*

THESE are divided into five claſſes: 1. Abſorbent, alkaline, or calcareous earths: 2. Argillaceous earths or clay: 3. The flinty: 4. The fuſible earths: and, 5. The talks.

511 Quicklime.

1. The firſt claſs comprehends all thoſe that are capable of being converted into lime. They are found of various degrees of hardneſs; but none of them are capable of totally reſiſting the edge of a knife, or ſtriking fire with ſteel. They are found to conſiſt of a very friable earth, joined with a large quantity of air and ſome water. They effervеſce with an acid when poured on them; by which they are diſtinguiſhed from all other kinds of earth, except the argillaceous. When calcined by a ſtrong fire, they part with the water and air which they contained, and then acquire a great degree of cauſticity, loſe their power of effervеſcing with acids, and become what is called *quicklime*. They are ſoluble in acids, but not equally ſo in all. The vitriolic and tartareous acids form compounds with them very difficultly ſoluble; the *ſelenites*, formed by the vitriolic acid and calcareous earth, requiring, according to Mr Beaumé, an ounce of water to diſſolve a ſingle grain of it. The ſolubility of the tartareous ſelenite hath not yet been determined.—With the other mineral acids, the calcareous earths become eaſily ſoluble; and by proper management form concretes which appear luminous in the dark, and are called *phoſphori*.

512 Argillaceous.

2. The argillaceous earths differ from the calcareous, in not being convertible into quicklime. When mixed into a paſte with water, and expoſed to the fire, they ſhrink remarkably, crack in many places, and become exceſſively hard. By being gently dried in the open air before they are turned, they do not crack, and thus may be formed into veſſels of any ſhape. Of this kind of earth are formed all the brown ſort of earthen ware. The pureſt kind of argillaceous earth naturally found, is that whereof tobacco-pipes are made.

All the argillaceous earths are ſoluble in acids. With the vitriolic they diſſolve into a gelatinous tough liquor very difficultly cryſtallizable; but which, on the addition of ſome fixed or volatile alkali, may be ſhot into cryſtals of the ſalt called *alum*. With the other acids they form aſtringent ſalts of a ſimilar nature.

The attraction between the argillaceous earths and acids is very weak, yielding not only to alkaline ſalts both fixed and volatile, but even to ſome metals, particularly iron; but theſe earths have as yet been but little the ſubject of chemical examination in this way. They have a remarkable property of abſorbing the colouring matter of cochineal, Braſil-wood, *&c.* as have alſo the calces of ſome metals.

Both the calcareous and argillaceous, and indeed all earths when pure, reſiſt the utmoſt violence of fire; but when mixed together will readily melt, eſpecially if in contact with the burning fuel. Dr Lewis having made covers to ſome crucibles of clay and chalk mixed together, found that they melted into a yellow glaſs, before the mixtures in the crucibles were fuſed in the leaſt. But though they melted thus readily when in contact with the fuel, it was with great difficulty he could bring them to a tranſparent glaſs when put into a crucible.

The other ſpecies of earths, *viz.* the flinty, fuſible, and talky, being no other way the ſubjects of chemiſtry than as they are ſubſervient to the making of glaſs, all that can be ſaid of them will moſt properly come under that article. For their different ſpecies, ſee MINERALOGY.

513 Anomalous earths.

Beſides the abovementioned ſpecies of earths, there are others which may be called *anomalous*, as having ſome reſemblance of the calcareous and argillaceous, and yet being eſſentially different from them. Theſe are the white earth called *magneſia alba*, the earth of burnt vegetables, and that produced from burning animal ſubſtances.

514 Magneſia.

Magneſia alba was at firſt prepared from the thick liquor remaining after the cryſtallization of nitre; and is now found to be contained in the liquor called *bittern*, which is left after the ſeparation of common ſalt from ſea-water. In the former caſe it was united with the nitrous, in the latter with the vitriolic, acid. It is alſo found naturally in the ſoft kind of ſtone called *ſteatites* or "ſoap-ſtone;" and in the concrete uſed for taking ſpots out of cloaths, called *French chalk*. It differs from the calcareous earths, in not acquiring any cauſticity when deprived of its air, of which it contains ſo large a quantity as to loſe two-thirds of its weight when calcined. From the argillaceous it differs in not burning hard when mixed with water, nor forming a tough ductile paſte. It is eaſily ſoluble in all the acids, even the vitriolic; with which it forms the bitter purging ſalt commonly called *Epſom ſalt*, from its being firſt diſcovered in the waters of Epſom. With all the other acids it likewiſe forms purgative compounds, which are either very difficultly or not at all cryſtallizable.—Like other pure earths, it cannot be melted by itſelf; but, on proper additions, runs into a beautiful green glaſs.

515 Vegetable and animal earths.

The earth of burnt vegetables is thought by Dr Lewis to be the ſame with magneſia alba; but on trying the common wood aſhes, they were found to be very different. This kind of earth is fuſible, by reaſon of the alkaline ſalts contained in it. Animal earth is both very difficult of ſolution in acids, and impoſſible to be melted in the ſtrongeſt fire. It diſſolves, however, in acid liquors, though ſlowly; but the nature of the compounds formed by ſuch an union are as yet unknown. The ſofter parts of animals, ſuch as blood, fleſh, *&c.* are ſaid to yield a more ſoluble earth than the others. Animal earth has lately been ſuppoſed to be compounded of calcareous earth and phoſphoric acid; but this opinion is ſhown to be erroneous under the article BONES. The phoſphoric acid produced from theſe, is with reaſon ſuppoſed to be only the vitriolic acid changed.

SECT. V. *Inflammable Subſtances.*

516 Phenomena on burning.

THESE comprehend all vegetable, animal, and ſome mineral ſubſtances. They are diſtinguiſhed from all others,

others, by emitting a groſs thick ſmoke and flame, when a certain degree of heat is applied. To this, however, ſpirit of wine and all preparations from it are exceptions. They burn without the leaſt ſmoke; and if a glaſs bell is held over the burning ſpirit, no ſoot is formed, only a quantity of water is found condenſed on its ſides. Even the groſſer oils, if ſlowly burnt with a very ſmall flame, will yield no ſoot; and an exceeding great quantity of water, fully equal in weight and bulk to the oil employed, may be obtained from them. We can ſcarcely, however, credit, that ſo great a quantity of water comes from the oil; as this would be a real tranſmutation; and we know that, beſides water, the oils contain alſo ſome quantity of fixed air, as well as earth. It is probable, therefore, that, as it is impoſſible to ſuſtain flame without a decompoſition of that part of the air which ruſhes in to ſupport it, part of the water in this caſe comes from the air, which always contains moiſture in abundance.

Inflammable matters, on being burnt, generally leave behind a ſmall quantity of earthy matter called *aſhes;* but to this, ſpirit of wine, camphor, the more volatile oils, and the mineral oil called *naptha*, are exceptions.

517 On diſtillation.

Vegetable ſubſtances, when diſtilled in cloſe veſſels, give out a quantity of air, ſome acid, and an empyreumatic oil, leaving behind a black ſpongy maſs called *charcoal*. To this too there are a few exceptions, *viz.* ſpirit of wine, and the preparations from it, camphor, and perhaps ſome of the more volatile oils, or naphtha. Animal ſubſtances yield only a very fetid empyreumatic oil, and volatile alkali.

518 Treated with different acids.

In general, all inflammable matters are acted upon with ſome violence by the vitriolic and nitrous acids, excepting only camphor and naphtha. With the vitriolic acid, when in a liquid ſtate, they render it volatile and ſulphureous; if in a dry ſtate, they form actual ſulphur. With the nitrous, they firſt impart a high colour and great degree of volatility to the acid, then a violent flame enſues, if the matter is attempted to be dried. With ſpirit of wine the effects are conſiderably different; and very volatile compounds are formed, which are called *ether*, on account of their exceeding great diſpoſition to riſe in vapour. Similar compounds are likewiſe produced, but with more difficulty, from the marine acid and concentrated vinegar. The ſal ſedativus of borax mixes with ſpirit of wine, and cauſes it burn with a green flame; but does not ſeem to produce any other change upon it. How the acid of phoſphorus and of ants act upon ſpirit of wine, is not exactly known; but that of tartar by digeſtion with it, is converted into the acetous acid. With any other inflammable matter, the phoſphorine acid reproduces phoſphorus.

519 Singular productions.

There are two ſingularities obſerved among the inflammable ſubſtances. One is that bituminous matter called *amber*, which yields a volatile ſalt of an acid nature on diſtillation: When combined with alkalies, this acid is found to yield compounds ſimilar to thoſe made with the acetous acid and alkali. The other is, that gum called *benzoin*, which is uſed as a perfume, and yields by ſublimation a kind of volatile ſalt in fine ſhining cryſtals like ſmall needles, and of a moſt grateful odour. Theſe diſſolve very readily in ſpirit of wine; but not at all in water, unleſs it is made very hot: ſo that they ſeem to contain more oily than ſaline matter. Neither the nature of theſe flowers, however, nor that of the ſalt of amber, is fully known.

Sect. VI. *Metalline Subſtances.*

These are diſtinguiſhed from all other bodies by their great ſpecific gravity, exceeding that of the moſt denſe and compact ſtones. The heavieſt of the latter do not exceed the ſpecific gravity of water in a greater proportion than that of 4 to 1; but tin, the lighteſt of all the metals, exceeds the ſpecific gravity of water in the proportion of 7 to 1. They are alſo the moſt opaque of all known bodies, and reflect the rays of light moſt powerfully.

520 Metals ſoluble in acids.

Metallic bodies poſſeſs the quality of diſſolving in and uniting with acid ſalts, in common with earths and alkalies; but, in general, their union is leſs perfect, and they are more eaſily ſeparable. They efferveſce with acids, as well as calcareous earths and alkalies; but their efferveſcence is attended with very different appearances. In the efferveſcence of acids with alkalies, or with calcareous earths, there is a diſcharge of the fluid called *fixed air*, which is ſo far from being inflammable, that it will immediately extinguiſh a candle or other ſmall flame immerſed in it. The mixture alſo is notably diminiſhed in weight. When a metallic ſubſtance is diſſolved in an acid, the weight of the mixture is never very much diminiſhed, and ſometimes it is increaſed. Thus, an ounce of quickſilver being ſlowly dropped into as much aquafortis as was ſufficient to diſſolve it, and the ſolution managed ſo as to take up almoſt a whole day, the whole was found to have gained ſeven grains. There is alſo a remarkable difference between the nature of the vapour diſcharged from metals and that from alkalies; the former, in moſt caſes, taking fire and exploding with violence; the latter, as already obſerved, extinguiſhing flame.

521 Their compoſition.

The metallic ſubſtances, at leaſt ſuch as we are able to decompound, are all compoſed of a certain kind of earth, and the inflammable principle called *phlogiſton*. The earthy part by itſelf, in whatever way it is procured goes by the name of *calx*. The other principle has already been proved to be the ſame with charcoal.

522 Calcination and revivification

When theſe two principles are ſeparated from one another, the metal is then ſaid to be *calcined*. The calx being mixed with any inflammable ſubſtance, ſuch as powdered charcoal, and urged with a ſtrong fire melts into metal again; and it is then ſaid to be *reduced*, or revivificated: and this takes place whether the metal has been reduced to a calx by diſſolution in an acid or by being expoſed to a violent fire. If, however, the calcination by fire has been very violent and long continued, the calx will not then ſo readily unite with the phlogiſton of the charcoal, and the reduction will be performed with more difficulty. Whether, by this means, *viz.* a long continued and violent calcination, metallic earths might entirely loſe their property of combining with phlogiſton, and be changed into thoſe of another kind, deſerves well to be inquired into.

523 Calcination and increaſe of weight by acids.

When a metallic ſubſtance is diſſolved in any kind of acid, and an alkali or calcareous earth not deprived of its fixed air is added, the alkali will immediately be attracted by the acid, at the ſame time that the fixed ed air contained in the alkali is diſengaged, and the calx of the metal, having now no acid to keep it diſſolved, immediately joins with the fixed air of the alkali, and falls to the bottom. Something ſimilar to this happens when metals are calcined by fire. In this caſe there is a continual decompoſition of the air which enters the fire; and the fixed air contained in it, being, by this decompoſition, ſet looſe, combines with the calx; whence, in both caſes, there is a conſiderable increaſe of weight. If the air is excluded from a metal, it cannot be calcined even by the moſt violent fire.

524
Reaſon of the increaſe of weights in metalline calces.

When a metal is precipitated by a mild alkali, or by an uncalcined calcareous earth, the reaſon of the increaſe of weight is very evident; namely, the adheſion of the fixed air to the metalline calx: but, though it is not ſo much increaſed when precipitated by cauſtic alkali, or by quicklime, there is nevertheleſs a very evident increaſe, which is not ſo eaſily accounted for. M. Lavoiſier has mentioned ſome experiments made on mercury and iron diſſolved in aquafortis, which deſerve to be taken notice of, as in a great meaſure accounting for the phenomenon already mentioned of the ſolution of metalline ſubſtances gaining an addition of weight; and likewiſe ſhow the proportion of increaſe of weight with the mild, or calcined calcareous earth.

525
M. Lavoiſier's experiments.

“ Exactly 12 ounces of quickſilver (ſays he) were put into a matraſs, and 12 ounces of ſpirit of nitre poured on it. Immediately a ſpontaneous efferveſcence enſued, attended with heat. The red vapours of the nitrous acid aroſe from the mixture, and the liquor aſſumed a greeniſh colour. I did not wait till the ſolution was entirely accompliſhed before I weighed it; it had loſt one drachm 18 grains. Three hours after, the mercury was nearly all diſſolved: but having again weighed the ſolution, I was much aſtoniſhed to perceive that it had increaſed inſtead of being diminiſhed in weight; and that the loſs, which was one drachm 18 grains at firſt, was now only 54 grains. The next day the ſolution of the mercury was entirely finiſhed, and the loſs of weight reduced to 18 grains; ſo that in 12 hours the ſolution, though confined in a narrow necked matraſs, had acquired an augmentation in weight of one drachm. I added ſome diſtilled water to my ſolution, to prevent it from cryſtallizing; the total weight of it was then found to be 48 ounces 1 drachm and 18 grains.

“ I weighed ſeparately, in two veſſels, 8 ounces 15 grains of the above ſolution, each of which portions, according to the preceding experiment, ought to contain 2 ounces of nitrous acid and 2 ounces of quickſilver. On the other ſide I prepared 6 drachms 36 grains of chalk, and 4 drachms 36 grains of lime; theſe proportions having been found by former experiments juſt neceſſary to ſaturate two ounces of nitrous acid. I put the chalk in the one veſſel, and the lime in the other.

“ An efferveſcence attended the precipitation by chalk, but without heat; the mercury precipitated in a light yellow powder, at the ſame time the chalk was diſſolved in the nitrous acid. The precipitation by the lime was effected without efferveſcence, but with heat; the mercury was precipitated in a browniſh powder. When the precipitates were well ſubſided, I decanted off the liquors from them, and carefully edulcorated them. After which, I cauſed them to be dried in a heat nearly equal to that in which mercury boils.

“ The precipitate by the chalk weighed 2 ounces 2 drachms 45 grains; that by the lime weighed 2 ounces 1 drachm 45 grains.

“ Sixteen ounces of the nitrous acid, the ſame as employed in the former experiments, were placed in a matraſs, and ſome iron filings gradually added. The efferveſcence was briſk, attended with great heat, red vapours, and a very rapid diſcharge of elaſtic fluid: the quantity of iron neceſſary to attain the point of ſaturation was 2 ounces 4 drachms; after which, the loſs of weight was found to be 4 drachms 19 grains. As the ſolution was turbid, I added as much diſtilled water as made the whole weight of the ſolution to be exactly 6 pounds.

“ I took two portions, each weighing 12 ounces of the above ſolution, and containing 2 ounces of nitrous acid, and 2 drachms 36 grains of iron filings. I placed them in two ſeparate veſſels. To one were added 6 drachms 36 grains of chalk; and to the other 4 drachms 36 grains of ſlacked lime, being the quantities neceſſary to ſaturate the acid.

“ The precipitation was effected by the chalk with efferveſcence and tumefaction, that by the lime without either efferveſcence or heat. Each precipitate was a yellow brown ruſt of iron. They were waſhed in ſeveral parcels of diſtilled water, and then dried in an heat ſomewhat ſuperior to that uſed in the laſt experiment.

“ The precipitate by the chalk, when dried, was a greyiſh ruſt of iron, inclining even to white by veins. It weighed 6 drachms 35 grains. That by the lime was rather yellower, and weighed 4 drachms 69 grains.

526
Conſequences from his experiments;

“ The reſult of theſe experiments (ſays M. Lavoiſier) are, 1. That iron and mercury diſſolved in the nitrous acid acquire a remarkable increaſe of weight, whether they be precipitated by chalk or by lime. 2. That this increaſe is greater in reſpect to iron than mercury. 3. That one reaſon for thinking that the elaſtic fluid contributes to this augmentation is, that it is conſtantly greater when an earth is employed ſaturated with elaſtic fluid, ſuch as chalk, than when an earth is uſed which has been deprived of it, as lime. 4. That it is probable that the increaſe of weight which is experienced in the precipitation of lime, although not ſo great as that by chalk, proceeds in part from a portion of the elaſtic fluid which remains united to the lime, and which could not be ſeparated by the calcination.”

527
Not well founded.

But though we are naturally enough inclined to think that the increaſe of weight in the precipitates formed by lime proceeded from ſome quantity of elaſtic fluid or fixed air which remained combined with the lime, it is by far too great to be accounted for in this way, even according to the experiments mentioned by M. Lavoiſier himſelf, and which, from the manner in which they are told, appear to have been performed with the greateſt accuracy. He found, that 1 ounce 5 drachms and 36 grains of ſlaked lime contained 3 drachms and 3 quarters of a grain of water,

and

and only 16 grains and an half of elaſtic fluid were ſeparable from it. In the experiments above related, where only 4 drachms and 36 grains were employed, the quantity of elaſtic fluid could not exceed 6 or 8 grains. Yet the calx was increaſed in mercury by no leſs than 105 grains, and in iron by 203 grains; a quantity quite unaccountable from the elaſtic fluid or fixed air which we can ſuppoſe to be contained in the lime made uſe of. It is much more probable, that the increaſed weight of metallic precipitates, formed by lime, ariſes from an adheſion of part of the acid.

530 What metals are calcinable, & with what degrees of heat.

Metals are found to be compounded of a kind of earth mixed with the inflammable principle or phlogiſton; and by a diſſipation of the latter, all metallic bodies, gold, ſilver, and platina excepted, are capable of being reduced to a calx, but very different degrees of heat are required for calcining them. Lead and tin begin to calcine as ſoon as they are melted, long before they are made red-hot. The ſame happens to the ſemimetals biſmuth and zinc; the latter indeed being combuſtible, cannot bear a greater heat in open veſſels than that which is barely ſufficient to melt it. Iron and copper require a red heat to calcine them; though the former may be made partly to calcine by being frequently wetted in a degree of heat conſiderably below that which is ſufficient to make it red.

541 Ruſting of metals

Moſt metals undergo a kind of ſpontaneous calcination in the open air, which is called their *ruſting*; and which has given occaſion to various conjectures. But M. Lavoiſier has ſhown, that this ariſes from the fixable part of the atmoſphere attaching itſelf to their earthy part, and diſcharging the phlogiſton. According to him, no metallic body can ruſt but where there is an abſorption of air; and conſequently metals can be but imperfectly ruſted when kept under a receiver.

542 Fuſibility of metallic compounds.

543 Great fuſibility of compounds of tin and biſmuth.

544 One fuſible by the heat of boiling water.

If two metals are mixed together, the compound generally turns out more fuſible than either of them was before the mixture. There are indeed great differences in the degrees of heat requiſite to melt them. Thus, lead and tin melt below that degree of heat which is required to make quickſilver or linſeed-oil boil. Silver requires a full red heat, gold a low white heat, copper a full white, and iron an extreme white heat, to make it melt. The ſemimetal called biſmuth melts at about 460° of Fahrenheit's thermometer, and tin at about 422°. When mixed in equal quantities, the compound melted at 283°. When the tin was double the biſmuth, it required 334° to melt it; with eight times more tin than biſmuth, it did not melt under 392°. If to this compound lead is added, which by itſelf melts in about 540°, the fuſibility is ſurpriſingly increaſed. Mr Homberg propoſed for an anatomical injection a compound of lead, tin, and biſmuth, in equal parts; which he tells us keeps in fuſion with a heat ſo moderate that it will not ſinge paper. Sir Iſaac Newton contrived a mixture of the abovementioned metallic ſubſtances, in ſuch proportions that it melted and kept fluid in a heat ſtill ſmaller, not much exceeding that of boiling water. A compound of two parts of lead, three parts of tin, and five of biſmuth, did but juſt ſtiffen at that very heat, and ſo would have melted with very little more; and when the lead, tin, and biſmuth, were to one another in the proportions of 1, 4, and 5, the compound melted in 246°. We have ſeen, however, a piece of metal compounded of theſe three, the proportions unknown, which melted, and even underwent a ſlight degree of calcination, in boiling water, and barely ſtiffened in a degree of heat ſo gentle that the hand could almoſt bear it.

545 Solubility of metals increaſed by calcination.

A ſlight degree of calcination ſeems to give the acids a greater power over metallic ſubſtances; a greater makes them leſs ſoluble; and if long and violently calcined, they are not acted upon by acids at all. Of all the acids, the marine has the greateſt attraction for metallic calces, and volatilizes almoſt every one of them.

346 Effects of ſulphur on metals.

Sulphur readily unites with moſt metals, deſtroys their malleability, and even entirely diſſolves them. On gold and platina, however, it has no effect, till united with a fixed alkaline ſalt, when it forms the compound called *hepar ſulphuris*; which is a very powerful ſolvent, and will make even gold and platina themſelves ſoluble in water, ſo as to paſs the filter. This preparation is thought to be the means by which Moſes diſſolved and gave the Iſraelites to drink the golden calf which they had idolatrouſly ſet up.

When a metal is diſſolved in an acid, it may be precipitated, not only by means of calcareous earth and alkalies, but alſo by ſome other metals; for acids do not attract all metals with equal ſtrength; and it is remarkable, that when a metal is precipitated by another, the precipitate is not found in a calcined ſtate, but in a metallic one. The reaſon of this is, that the precipitating metal attracts the phlogiſton which is expelled from that which is diſſolving, and immediately unites with it, ſo as to appear in its proper form. The various degrees of attraction which acids have for the different metals is not as yet fully determined. The beſt authenticated are mentioned in the Table of Affinities or elective attractions (Sect. IX.)

547 Diviſion into metals and ſemimetals.

548 Properties of arſenic.

Metalline ſubſtances are divided into metals and ſemimetals. The metals which are diſtinguiſhed from the ſemimetallic ſubſtances by their malleability or ſtretching under the hammer, are in number ſeven; gold, ſilver, copper, iron, lead, tin, and platina. To theſe is added quickſilver; which Mr Brown's experiments have ſhown to be a real malleable metal, as well as others, but requiring ſo little heat to keep it in fuſion, that it is always found in a liquid ſtate. The ſemimetals are biſmuth or tin-glaſs, zinc, regulus of antimony, and cobalt, nickel, and arſenic. This laſt ſubſtance is now diſcovered to be compounded of an acid of a peculiar kind and phlogiſton; and as the quantity of the latter is great or ſmall, the arſenic aſſumes either a metallic or ſaline form. It likewiſe unites with ſulphur, with which it forms a compound of a red or yellow colour, according as more or leſs ſulphur is uſed. This compound is eaſily fuſible; though the arſenic, by itſelf, is ſo volatile as to go all off in vapour rather than melt. In common with the ſalts, it poſſeſſes the properties of diſſolving in water, and uniting itſelf to alkalies. Water will diſſolve about $\frac{1}{15}$ of its weight of pure arſenic; but if arſenic is boiled in a ſtrong alkaline lixivium, a much greater proportion will be diſſolved. Indeed ſtrong alkaline lixivia will diſſolve

Scot Philad.

ſolve a part of almoſt every metalline ſubſtance, except gold, ſilver, and platina; but, excepting copper, which may be formed into cryſtals by means of the volatile alkali, none of them will aſſume a cryſtalline form when united with alkalies. Arſenic, on the contrary, unites very readily with fixed alkalies, and ſhoots with them into a neutral ſalt. If it is mixed with nitre, it unites itſelf to the alkaline baſis of that ſalt, and expels the acid in very volatile fumes, which are difficultly condenſed into a blue liquor. The reaſon of this is the great attraction between the nitrous acid and phlogiſton, which are always diſpoſed to unite when a proper degree of heat is applied. Was the phlogiſton contained in large quantity in the arſenic, and the heat ſufficiently great, a violent deflagration would enſue; but as the acid of arſenic attracts the alkaline part of the nitre, at the ſame time that the nitrous acid attracts the phlogiſton, a double decompoſition enſues, in a leſs degree of heat than would otherwiſe be neceſſary; and the nitrous acid ariſes in a very volatile ſtate, as it always is when combined with phlogiſton, which is the occaſion of the blueneſs in aquafortis ſo produced. The arſenic is alſo decompoſed by being deprived of its proper quantity of phlogiſton; in conſequence of which its acid attaches itſelf to the fixed alkali of the nitre, and forms a neutral arſenical ſalt. For the extraction of metallic ſubſtances from their ores, and the various methods of refining them, ſee METALLURGY.

SECT. VII. *Waters.*

549 Water, how far an object of chemiſtry.

THE pure element of water, like that of fire, is ſo much an *agent* in moſt chemical operations, as to be itſelf very little the *object* of practical chemiſtry. Some late experiments, however, have ſhown that this fluid really conſiſts, in part at leaſt, of phlogiſton, and an inviſible ſubſtance which forms the baſis of pure air: and conſequently water is generated in the deflagration of dephlogiſticated air; but as the baſis of the former cannot be perceived by itſelf, we can as yet ſay nothing about it. Waters, therefore, can only be the objects of chemiſtry, in conſequence of the impurities they contain: and as theſe impurities are moſt commonly of the ſaline kind, it is impoſſible that any general theory can be given of waters, diſtinct from that of the ſalts contained in them; which all depend on the general properties belonging to ſalts, and which we have already mentioned. Any thing that can be ſaid with regard to waters, then, muſt be poſtponed to the particular conſideration of the properties of each of the ſaline bodies with which water is capable of being adulterated. We ſhall therefore refer entirely to the article WATER in the order of the alphabet, for what can be ſaid on this ſubject.

SECT. VIII. *Animal and Vegetable Subſtances.*

550 Chemical properties.

THE general chemical properties of theſe have been already taken notice of under the name of *inflammable ſubſtances*. They agree in giving out a very thick fetid oil, when diſtilled by a ſtrong fire; but in other reſpects they differ very conſiderably. Moſt kinds of vegetables give out an acid along with the oil; but all animal ſubſtances (ants, and perhaps ſome other inſects, excepted) yield only a volatile alkali. Some kinds of vegetables, indeed, as muſtard, afford a volatile alkali on diſtillation, ſimilar to that from animal ſubſtances; but inſtances of this kind are very rare, as well as of animals affording an acid. Both animal and vegetable ſubſtances are ſuſceptible of a kind of fermentation, called *putrefaction*, by which a volatile alkali is produced in great plenty: there is, however, this remarkable difference between them, that many vegetable ſubſtances undergo two kinds of fermentation before they arrive at the putrefactive ſtage. The firſt is called the *vinous*, when the ardent ſpirits are produced, which we have already mentioned when ſpeaking of inflammable ſubſtances. This is ſucceeded by the *acetous*, wherein the vegetable acid called *vinegar* is produced in plenty: and laſtly, the putrefactive ſtage ſucceeds when a volatile alkali is only produced; not the ſmalleſt veſtige either of ardent ſpirits or of vinegar remaining. On the other hand, animal ſubſtances ſeem ſuſceptible only of the putrefactive fermentation; no inſtance having ever occurred where there was the leaſt drop, either of ardent ſpirit or of vinegar, produced from a putrified animal ſubſtance. (See FERMENTATION and PUTREFACTION.)

SECT. IX. *Of the Chemical Characters, and Tables of Elective Attraction.*

551 Invention of marks or characters.

THE numerous *marks* or *characters* by which the ancient chemiſts uſed to denote many different ſubſtances were invented rather from a ſuperſtitious and fantaſtical principle than from any real neceſſity; or, perhaps, like the enigmatical language uſed by the alchemiſts, they have thereby ſought to conceal their myſteries from the vulgar. In contriving theſe marks, they affected a great deal of ingenuity; intending them as ſymbols of the qualities poſſeſſed by each of the different ſubſtances. A circle being ſuppoſed the moſt perfect figure, was therefore uſed to repreſent the moſt perfect metal in nature, that is, *gold*. Silver being likewiſe a perfect and indeſtructible metal, is placed next to gold; but, on account of its inferiority, is expreſſed only by a creſcent, as if but half gold. A circle was likewiſe uſed to denote ſalt of any kind, as being ſomething elaborate and perfect. A croſs was uſed to denote acrimony of any kind, and conſequently employed for the acrimonious ſalts of vitriol, alkali, &c. Hence all the inferior metals have the croſs ſome how or other combined with the marks deſigned to repreſent them. Thus, the mark for quickſilver denotes, that it hath the ſplendor of ſilver, the weight of gold, but its perfection is hindered by an acrimony repreſented by the croſs at bottom, &c. Fire is repreſented by an equilateral triangle, having one of its angles uppermoſt. This may be conſidered as a rude repreſentation of flame, which is always pointed at top. Water, again, is repreſented by a triangle, with an angle downwards, ſhowing the way in which that element exerts its ſtrength, &c. All theſe marks, however, as they were of no real uſe at firſt, ſo they are now becoming every day more and more neglected. Such of them, however, as may moſt readily occur in chemical books are repreſented and explained on Plate CXXXII.

552 New chemical language.

The French chemiſts have of late attempted to introduce a kind of new chemical language; and by adopting it themſelves, may perhaps make it at laſt univerſal, as it is now impoſſible to underſtand their writings ~~without~~ knowing it. See the Table at the end of this article.

553
Of tables of affinities.

Tables of affinities, or *elective attractions*, are but of late invention. They are conſequences of an improved ſtate of chemiſtry, when the different ſubſtances were found to act upon one another in moſt caſes according to a fixed and ſettled rule. The moſt approved table of this kind for a long time was that compoſed by Mr Geoffroy. It was, however, found to be very incomplete, not only as to its extent, but likewiſe as heat and ſome other circumſtances were found to vary the attractions conſiderably, and ſometimes even to reverſe them. Other tables have been conſtructed by Mr Gellert, &c. but none hath yet appeared ſo complete but that many additions may be made to it. The following is that at preſent exhibited by Dr Black in his courſe of chemiſtry.

1. VITRIOLIC ACID.

Phlogiſton
Terra ponderoſa
Fixed alkali
Calcareous earth
Zinc
Iron
Tin
Copper
Quickſilver
Silver
Volatile alkali
Magneſia
Earth of alum.

2. NITROUS ACID.

Phlogiſton
Fixed alkali
Calcareous earth
Zinc
Iron
Lead
Tin
Copper
Quickſilver
Silver
Volatile alkali.

3. MARINE ACID.

Fixed alkali
Calcareous earth
Zinc
Iron
Lead
Tin
Copper
Regulus of antimony
Quickſilver
Silver
Spirit of wine
Volatile oils
Gold.

4. SULPHUR.

Fixed alkali
Calcareous earth
Iron
Nickel
Copper
Lead
Tin
Silver
Regulus of antimony
Quickſilver
Arſenic.

5. HEPAR SULPHURIS is partially decompounded by

Quickſilver
Solution of fixed alkali
Lime-water
Volatile alkali.

6. FIXED AIR.

Calcareous earth
Fixed alkali
Magneſia
Volatile alkali.

7. ALKALINE SALTS.

Vitriolic acid
Nitrous acid
Marine acid
Acetous acid
Volatile vitriolic acid
Sedative ſalt
Fixed air
Sulphur
Expreſſed oils.

8. CALCAREOUS EARTH.

Vitriolic acid
Nitrous acid
Marine acid
Acid of tartar
Acetous acid
Sulphureous acid and ſedative ſalt
Sulphur.

9. METALLIC SUBTSANCES, Lead and Regulus of Antimony excepted.

Marine acid.
Vitriolic acid
Nirtous acid
Sulphur and acetous acid.

10. LEAD.

Vitriolic acid
Marine acid
Nitrous acid
Acetous acid
Expreſſed oils.

11. REGULUS of ANTIMONY.

Vitriolic acid
Nitrous acid
Marine acid
Acetous acid.

12. ARSENIC.

Zinc
Iron
Copper
Tin
Lead
Silver
Gold.

13. REGULUS of ANTIMONY with Metals.

Iron
Copper
Tin
Lead
Silver
Gold.

14. QUICKSILVER.

Gold
Lead and tin
Copper
Zinc, biſmuth, and regulus of antimony.

15. SILVER.

Lead
Copper
Iron.

16. WATER.

Fixed alkali
Spirit of wine
Milk, alkaline ſalts, and ſome neutrals.

17. SPIRIT of WINE.

Water
Oils and reſins.

In conſequence of heat, ſedative ſalt and the other ſolid acids decompound vitriolated tartar, nitre, and ſea-ſalt.

Double Elective Attractions; which, in ſome caſes, may be conſidered as exceptions to the foregoing table.

I. Thoſe which happen in mixtures of watery ſubſtances.

1.	Acids	Volatile alkali
	Calc. earths, or metallic ſubſtances	Fixed air.
2	Vitriolic or marine acids	Mercury, ſilver, or lead,
	Alkalies or earths	Nitrous or acetous acids.
3	Lead	Vitriol acid
	Nitrous marine, or acetous acids	Alkalies, earths, or M. S.
4.	Silver	Marine acid
	Vitriolic, nitrous, or acetous acids	Alkaline ſalts, earths, or M. S.
5.	Volatile alkali	Fixed air
	Acids	Fixed alkali.
6.	Nitrous, marine, or acetous acids	Volatile alkali, magneſia, or earth of alum
	Calcareous earths	Vitriolic acid.

II. Thoſe which happen in diſtillations or ſublimations, and require heat.

1.	Vol. alkali	Fixed air
	Acids	Calcareous earths.
2.	Vol. alkali	Nitrous, marine, or acetous acids
	Vitriol. acid	Fixed alkali.
3.	Vol. alkali	Acetous acid
	Nitrous, marine, or vitriolic acids	Fixed alkali, or abſorbent earths.

4.	Reg. of antimon.	Marine acid
	Sulphur	Quickſilver.

III. Thoſe which happen in mixtures by fuſion.

1.	Tin	Iron
	Silver	Lead.
2.	Copper	Sulphur
	Gold	Lead.
3.	M. S.	Sulphur
	Gold	Reg. of ant.

The firſt of theſe tables requires very little explanation. The names printed in ſmall capitals, are thoſe of the ſubſtances which have the affinity with or attract thoſe below them. Thus, vitriolic acid attracts moſt powerfully the phlogiſton, or inflammable principle: next, fixed alkali; then, calcareous earth; and ſo on, in the order in which they are marked. — The tables of double elective attractions cannot be made quite ſo diſtinct; though an explanation of one example will make this likewiſe eaſy to be underſtood. Thus in Table I. the firſt caſe is, "If a combination of acids with calcareous earths or metallic ſubſtances is mixed with a combination of volatile alkali and fixed air, the acids will unite themſelves to the volatile alkali, and the fixed air to the calcareous earth or metallic ſubſtance.

Sect. X. *Of the different Operations in Practical Chemiſtry, and the proper Inſtruments for performing each.*

554 Operations in chemiſtry.

The moſt remarkable operations in chemiſtry, and by which the greateſt changes are made upon thoſe bodies which are the objects of that ſcience, may be comprehended under the following names. 1. Solution. 2. Filtration. 3. Precipitation, or coagulation. 4. Evaporation. 5. Cryſtallization. 6. Diſtillation. 7. Sublimation. 8. Deflagration. 9. Calcination. 10. Fuſion. 11 Maceration, or digeſtion. To which we may add, 12. Trituration, or levigation.

555 Chemiſts how divided.

Before we proceed to a particular account of each of theſe operations, it is neceſſary to take notice, that there are two different things propoſed by thoſe who enter on the practice of chemiſtry. Some have nothing farther in view than the enlargement of their knowledge, or making improvements in arts which are to be practiſed by others for their own advantage. Others deſign to follow chemiſtry as a trade, by which they hope to enrich themſelves, or to get a comfortable livelihood. But the apparatus and utenſils neceſſary for performing the very ſame operations are exceedingly different when experiments only are to be made, from what they muſt be when theſe operations are performed with a view to profit; and ſo great is this difference, than thoſe who purſue chemiſtry with a view to advantage, will always find themſelves very conſiderable loſers if they follow the plan of an apparatus or a laboratory deſigned only for making experiments. Along with the apparatus, therefore, which is commonly deſcribed in chemical books, and proper only for experiments, we ſhall alſo give that which is neceſſary for preparing great quantities of any chemical article in the way of trade.

556 Glaſs veſſels, when to be uſed.

In general, thoſe who practice chemiſtry merely with an experimental view, ought, as much as poſſible, to make uſe of glaſs veſſels, as not being liable to be corroded by the moſt powerful ſolvents; and, by their tranſparency, giving an opportunity of obſerving what paſſes within them during the operation. But by thoſe who practiſe chemiſtry with a different view, theſe veſſels ought, with equal care, to be avoided, on account of their expence and brittleneſs. This laſt quality, indeed, is poſſeſſed by glaſs in ſo eminent a degree, that glaſs veſſels will ſometimes fly to pieces, and that with conſiderable violence, when ſtanding by themſelves, and nothing touching them. The principle objects which a chemiſt ought to have in view, in performing his operations, ought to be to ſave time and fuel, eſpecially the former; and for this purpoſe, he would find himſelf a conſiderable gainer, though he ſhould be at much greater expence in his apparatus than he would otherewiſe have occaſion for.

557 Dr Black's obſervations on chemical veſſels.

On the ſubject of chemical veſſels Dr Black obſerves, that "with regard to the material of which theſe are compoſed, we are very much at a loſs; and indeed there are no ſuch materials in nature as are capable of anſwering the purpoſes of chemiſts in abſolute perfection.—The qualities are, 1. Tranſparency to allow us to ſee the changes going on; 2. The power of reſiſting the action of acids and corroſive ſubſtances; 3. That they bear ſudden alterations of heat and cold without breaking; 4. That they be ſtrong, in order to confine elaſtic vapours; and, 5. That they bear very great heat without melting. As theſe qualities, however, are not to be met with united in any one ſubſtance, the chemiſts are obliged to have recourſe to different ſubſtances which poſſeſs ſome of them differently. Theſe are, *glaſs*, *metal*, and *earthen ware*.

558 Good and bad qualities of glaſs as a material for chemical veſſels.

Glaſs is poſſeſſed of the two firſt properties, but has the inconvenience of being apt to crack and fly in pieces, on any ſudden tranſition from heat to cold, or from cold to heat. The beſt method of remedying this defect, is to have the glaſs made very thin, and of a round figure, that it may be all heated as equally as poſſible; as it is the unequal application of the heat which cauſes it break. Another requiſite in the choice of chemical glaſſes, is that they be well annealed.

559 Extreme fragility of glaſs not well annealed.

If this is not done, the glaſs will either immediately fly to pieces, or be liable to break on the ſmalleſt accident. That ſuch glaſſes ſhould be liable to be broken on every ſlight occaſion, is a phenomenon that has hitherto received no explanation. If you touch them with a diamond, with a piece of flint, glaſs, *&c.* or expoſe them to the heat of the ſun, they break immediately. Dr Black has had great veſſels of glaſs, which broke immediately on his throwing a little ſand into them to clean them. This manifeſtly depends upon the ſame principles as the qualities of what are called *glaſs tears*.

560 Good and bad qualities of metals as materials for chemical veſſels.

Glaſs when well annealed is univerſally to be preferred, where great and ſudden changes of heat, or much ſtrength, are not required. Flint-glaſs is the beſt; but the coarſer kinds, as bottle-glaſs, are very apt to break.

The metals have the third and fourth qualities in perfection, but are deficient in all the reſt. The moſt troubleſome property is, that they are liable to be corroded by acids and other bodies, as is the caſe with iron and copper; though this is in ſome meaſure remedied by tinning; which, though it wants ſome of the qualities from its melting too ſoon, yet reſiſts the action of many acrid ſubſtances without being ſo readily injured by them; but it is not entirely free from this imperfection, and is liable to be ſomewhat corroded and ruſted. In nice operations, therefore, recourſe is had to ſilver and even to gold veſſels.

561 Of earthen ware.

Earthen ware poſſeſſes only the fifth quality in perfection, *viz.* that of bearing a violent heat without fuſion. The baſis of theſe veſſels is clay, which, when good, is very convenient for the formation of veſſels, and it has been uſed from the earlieſt ages of chemiſtry for this purpoſe. The requiſite qualities are, 1. A conſiderable degree of toughneſs when mixed with water. 2. A great degree of hardneſs when burnt in the fire with a violent degree of heat. The beſt kind of clay thus contracts a degree of hardneſs ſcarce inferior to flint, as is the caſe with that of which tobacco-pipes are made; but moſt other kinds, ſuch as that of which bricks are conſtructed, are apt to melt with a ſtrong heat into a ſpongy matter. Clay, however, can ſeldom be uſed alone; for when burnt to extreme hardneſs, the veſſels are very liable to crack. This is remedied by mixing ſand reduced to a particular degree of fineneſs, with the clay of which the veſſels are made. For this purpoſe both the fineſt and the coarſeſt particles of the ſand muſt be thrown away.

562 Black lead a valuable material for ſome purpoſes.

Another ſubſtance known by the name of black lead, uſed in the making of pencils, reſiſts the fire exceedingly. This, however, does not contain an ore of lead, but ſulphur, and ſome mineral ſubſtances; when mixed with clay, however, it makes it reſiſt the fire ſurpriſingly. But there are ſome particular caſes in which neither ſand nor black lead can be uſed as a material; for the ſand is eaſily corroded by acrid matters, and the black lead would produce other inconveniences. Clay is therefore to be taken in its unburnt ſtate, reducing it to a powder like ſand; then burning this powder with a violent heat, ſo as to convert it into ſand. Mixing it then with raw clay, it forms a compoſition which anſwers very well for making chemical veſſels, and may be employed in thoſe particular caſes where ſand would not anſwer. Pott of Berlin has written upon the different kinds of earthen ware proper to be employed in the conſtruction of chemical veſſels. There is a French tranſlation of it in four or five volumes.

563 Porcelain veſſels when to be uſed.

In caſes where the utmoſt compactneſs of texture is required, procelain veſſels are to be choſen; which is compoſed of the fineſt clay, mixed with a ſtony matter, that has the quality of melting in a violent heat, and gives more compactneſs to the clay than it is naturally capable of receiving; but theſe are rather too coſtly for moſt operations. Reaumur has taught a way of converting glaſs into porcelain.

We ſhall now proceed to a particular deſcription of each of the operations abovementioned.

564 Solution.

I. SOLUTION. By this is underſtood the diſſolving a ſolid ſubſtance in a fluid, ſo as that the ſolid ſhall totally diſappear, and become part of a tranſparent liquor. This operation applies particularly to ſalts, earths, and metals: as well as to ſeveral unctuous and inflammable ſubſtances. For performing this operation in a ſmall way, common vials are in many caſes ſufficient. Where the ſolution is attended with efferveſence and a diſcharge of vapours, the long-necked glaſſes called *matraſſes*, or *bolt-heads*, (fig. 5.), are neceſſary. Florence flaſks are indeed exceedingly well adapted for this operation, as being of the proper ſhape, and capable of bearing heat ſo well, that they may be filled with any fluid, and ſet on a common fire like a metalline veſſel. Solution is much promoted by agitating the veſſel, and by heat. In ſome caſes, indeed, it will not take place till the mixture becomes very hot; and in ſuch caſes it will be proper to make the fluid boiling hot by itſelf, and then ſlowly to add the ſubſtance to be diſſolved.

Plate CXXXIV.

When large quantities of ſaline matter are to be diſſolved, metalline veſſels muſt be uſed: but before any are made uſe of for this purpoſe, it will be neceſſary to make an experiment whether the ſalt receives any impregnation from the metal of which the veſſel intended to be made uſe of is formed; and if this is found to be the caſe, it muſt not be uſed. The metals moſt liable to be corroded by ſaline bodies are iron and copper; and indeed, unleſs it be for the ſingle purpoſe of diſſolving fixed alkaline ſalts, iron veſſels ſeem totally unfit for ſaline ſolutions of any kind. Copper veſſels are alſo very liable to be corroded, and to communicate very miſchevous qualities to the liquors which corrode them; for which reaſon, they ought never to be made uſe of for the purpoſes of ſolution. The metal leaſt liable to be corroded, next to gold and ſilver, is lead; and therefore a chemiſt ought rather to provide himſelf with leaden veſſels than thoſe of any other metal. But though lead is not apt to be corroded by many kinds of ſalts, there are ſome which are found to act upon it, and to form therewith a very dangerous poiſon. The vegetable acid of vinegar is particularly apt to receive a dangerous impregnation from this metal; and therefore no ſolution of any ſalt containing this acid ought to be made in leaden veſſels. It appears to be very little affected by the vitriolic or marine acids; and therefore any ſaline ſubſtance containing either of theſe acids may be ſafely enough diſſolved in veſſels made of lead.

In order to ſave time in making ſolutions, the veſſels ought to be as large as poſſible; though even in this there muſt be a certain limit: for two ſmall veſſels filled with water will ſooner acquire the neceſſary degree of heat than one large one; and in proportion as the veſſel is made more capacious, the ſides and bottom muſt be thicker, which conſiderably increaſes the expence. Fifteen or twenty Engliſh gallons is the utmoſt capacity of which they ever will be required; and is rather above what will on moſt occaſions be neceſſary. They ought to be of a conical figure, round at the bottom; and to have a cover of thick plate-iron all around that part which is expoſed to the action of the fire, that the lead may not bend on the application of heat, which it would otherwiſe be very apt to do. When the ſolution is to be made, the leaden veſſel is firſt to be filled up with water ſo far as to have room for the quantity of ſalt intended to be diſſolved: a fire is then to be applied ſo as to make it boil: and then the ſalt is to be added ſlowly, ſo as ſcarcely to hinder the boiling; for if a great quantity was thrown in at once, ſo as to cool the liquor very much, great part of the ſalt would concrete on the bottom, in ſuch

a manner as not only to be very difficultly ſoluble, but even endanger the melting of the veſſel. It is of ſome conſequence alſo to avoid the hot ſteam which proceeds from the boiling water, and which iſſues with great force from a narrow-mouthed veſſel, ſuch as we have been deſcribing. That the operator may be out of the reach of this, and likewiſe diſſolve the ſalt in a regular and gradual manner, without any danger of its concreting on the bottom, it will be proper to have a leaden, or even a wooden, veſſel, with a long handle; which is to be filled with the ſubſtance to be diſſolved, then immerſed in the boiling liquor, and ſhaken about in it, till the ſalt is made into a kind of thick pap, which will be in no danger of concreting. It will alſo be proper not to ſaturate the water perfectly with ſalt; for it will in that caſe be impoſſible to hinder part of it from ſettling on the bottom, where it ſoon acquires ſuch a degree of heat as to melt the lead. Before any ſaline ſubſtance is put into water for ſolution, it ought to be pounded and ſifted through a hair ſieve.

Where large quantities of metal are to be diſſolved in acids, eſpecially the nitrous acid, glaſs veſſels are in a manner indiſpenſable; although the common ſtoneware bottles, eſpecially thoſe made in Holland, will anſwer the purpoſe very well, as not being liable to corroſion, and not ſo apt to break as the glaſs veſſels are. They may be got of ſuch a ſize as to hold three or four gallons: but no veſſel in which metalline ſolutions are made ought ever to be above half full.

In ſolutions of oily and inflammable ſubſtances, caſt iron veſſels are perhaps the moſt proper of any; though copper ones are generally preferred. The copper is exceſſively ſoluble in oil, eſpecially if it is left to cool in ſuch a veſſel; but iron is not ſoluble in any inflammable matter except ſulphur. Copper has, however, this advantage over iron, that it is ſooner cooled, as the veſſels made of copper are thinner than they can be made of caſt iron: ſo that if too great heat is applied to a copper veſſel, it may be eaſily remedied by taking it off the fire; but in a caſt iron veſſel the heat continues ſo long as may ſometimes produce dangerous conſequences, even after the fire is removed.

565
Dr Black's directions for ſolution.

Dr Black obſerves, that for the purpoſe of ſolution, if no particular nor uncommon conſequence follow the application of the two bodies to each other, and if none of them be very volatile, any glaſs or porcelain veſſel that can reſiſt the action of the ſubſtances will anſwer the purpoſe; but it often happens that they break out into violent ebullition, which produces ſteam; and here a common veſſel is not ſo proper, as we would wiſh to have the vapour confined or condenſed. We therefore chooſe a cloſe veſſel that will bear the heat ſuddenly produced by the mixture, or the heat that may be neceſſary to promote the action of ſuch bodies upon one another. Of this kind is the *phiala chemica*, or matraſs, in which the vapours will have time to circulate and to be condenſed again, without being allowed to eſcape. Where the matter is in ſmall quantity, ſmaller veſſels ſomewhat of the ſame form are uſed, as Florentine flaſks, which bear ſudden changes of heat and cold remarkably well, on account of their thinneſs. In order to promote the action of bodies, it is ſometimes neceſſary to make the fluids boil; and for this purpoſe we muſt have a matraſs with a large neck, or apply another veſſel to it that will receive theſe ſteams, and give them ſtill more room for their condenſation, and direct them to fall back again, when condenſed, into the matraſs. This is called *circulation*. Macquer deſcribes another veſſel called the *pelican*, which has been made uſe of for this purpoſe; but it is hardly ever employed, on account of its being ſo troubleſome to procure and manage it; and the advantages ariſing from it may be obtained by a more ſimple apparatus.

566
Pelican. Fig. 6.

567
Papin's digeſter. Plate CXXXIII.

To this head we muſt refer Papin's digeſter, which is repreſented Fig. 4. It is generally made of copper, very thick and ſtrong, open at the top, with a lid fitted to it, which applies very exactly. There are uſually two projections on the ſide, deſigned to make the lid go in a particular manner, but they are unneceſſary. There are other two, to which are fitted the two ſides of a croſs bar B B; in which croſs bar there is a ſtrong ſcrew D, by which the lid can be preſſed down very ſtrongly. Its uſe is to force water to bear a ſtronger heat than it can do under the ordinary preſſure of the atmoſphere. It is ſometimes furniſhed with an apparatus for letting out the ſteam, leſt it ſhould be in danger of burſting the veſſel. A pipe is paſſed through the lid which is fitted with a valve, on which paſſes a lever at a very ſmall diſtance from its centre of motion; and this can be made to preſs on the valve with different weights, according to the diſtance of theſe weights from the centre. In one conſtructed by Dr Black, there was another pipe below, into which a thermometer could be introduced, in order to meaſure the degree of heat to which the ſteam was raiſed. This machine was pretty much employed ſome time ago, and its effects were much admired; but we find that moſt things which can be diſſolved in this way, can likewiſe be diſſolved in the ordinary way by boiling water, provided it is continued for a longer time, as animal bones, from which the gelatinous parts are indeed extracted very quickly by this veſſel; but the ſame change is produced by boiling them in water for a long time in the ordinary degree of heat.

568
Filtration.

II. Filtration. This operation is generally the attendant of ſolution: very few ſubſtances, of the ſaline kind eſpecially, are capable of being diſſolved without leaving ſome impurities, from which they muſt be freed; and the doing of this, ſo as to render the ſolution perfectly tranſparent, is what is underſtood by the word *filtration*.

For purpoſes merely experimental, a glaſs funnel and piece of paper are generally ſufficient. The paper is formed into a conical cap, which being placed in the funnel with its point downwards, the funnel is then placed in the mouth of a vial; and the ſolution or other liquor to be filtered is poured into the paper cap, through which the liquor paſſes tranſparent, leaving its impurities on the paper. For the purpoſe of filtration, paper has come into ſuch general uſe, that a particular kind of it is prepared under the name of *filtering paper*. This is of a reddiſh colour; but Dr Lewis prefers the whitiſh grey paper which comes from Holland about the pill boxes, as not giving any colour to the ſolutions which paſs through it.

This operation though apparently ſo ſimple and eaſy, is nevertheleſs attended with very troubleſome circumſtances, on account of the great time it takes up. Even where very ſmall quantities of liquor are to be filtered, merely for experiment's ſake, the impurities frequently ſettle on the paper ſo ſoon, and obſtruct its pores to ſuch a degree, that the operator is often quite wearied out: often, too, the paper breaks; and thus the whole is ſpoiled, and the operation muſt be begun over again.

To avoid theſe inconveniences, another method of filtration has been propoſed; namely, to uſe a number of cotton threads, the ends of which are to be immerſed in the liquor, and the other ends are to hang over the ſide of the veſſel which contains it, and to hang lower than the ſurface of the liquor. By this means they will act as ſo many capillary ſyphons, (ſee Syphon); the liquor will ariſe in them quite pure, and be diſcharged from their lower extremities into a veſſel placed to receive it. That the liquor may flow freely into the cotton, it will be proper to wet the threads before they are uſed.

In point of efficacy, no doubt, this method excels every other; and where the operator has abundance of time and patience, may be proper for experiments; but, in the way of trade, ſuch a contrivance is evidently uſeleſs. For filtering large quantities of liquor, therefore, recourſe has been had to large funnels; earthen cullenders, or baſons full of holes in the bottom, lined with filtering paper; and to conical bags of flannel or canvas

The inconveniences attending funnels, when uſed only in the way of experiment, are much greater when they are employed for filtering large quantities of liquor; and therefore they are generally laid aſide. The earthen cullenders, too, do not anſwer any good purpoſe; nor indeed does filtration through paper in general ſucceed well. The conical flannel or canvas bags are greatly preferable: but they have this inconvenience, that the preſſure of the liquor is directed chiefly againſt one particular point, or a ſmall part of the bottom, and therefore the impurities are forcibly driven into that place; and thus the operation becomes inſufferably tedious.

The beſt method of obviating the inconveniences of filtration ſeems to be the following. Let a wooden frame of about three feet ſquare be made, having four holes, one in each corner, about three quarters of an inch in diameter. This frame is to be ſupported by four feet, the ends of which muſt project an inch or two through the holes. Thus the whole may be occaſionally ſet up and taken down ſo as to go into very little compaſs; for if the feet are properly placed, each with a little projection outwards, there will be no danger of its falling. A ſquare piece of canvas muſt alſo be procured, ſomewhat leſs than the wooden frame. On each corner of it there muſt be a very ſtrong loop, which ſlips on one of the projecting ends of the feet, ſo that the canvas may hang a little ſlack in the middle of the frame. The liquor to be filtered is now poured into the canvas, and a veſſel placed underneath to receive it. At firſt it will paſs through very foul; but being returned two or three times will become perfectly tranſparent, and will continue to run with great velocity, if the filter is kept conſtantly full. A filter of the ſize juſt now mentioned will contain ten gallons of liquid; which is a very great advantage, as the heat of ſuch a quantity of liquor is not ſoon diſſipated, and every ſolution filters much faſter when hot than when allowed to cool.

The advantages of a filter of this kind above others ariſe from the preſſure of the liquor being more equally diffuſed over a large ſpace, by which the impurities are not forced ſo ſtrongly into the cloth as to ſtop it up entirely. Yet even here, where large quantities of liquor require filtration, the cloth is apt to be ſtopped up ſo as to make the operation not a little tedious and diſagreeable. It will be proper therefore to have ſeveral cloths, that one may be applied as ſoon as another is taken off.

To promote the operation of filtration, it is very proper to let the liquors to be filtrated ſettle for ſome time; that ſo their groſſer feculencies may fall to the bottom, and thus there will be the fewer to retard the laſt part of the operation. Sometimes, however, theſe feculencies refuſe to ſettle till after a very long time; and where this happens to be the caſe, a little powdered quicklime thrown into the boiling liquor remarkably promotes the ſeparation. This, however, can only be uſed in certain caſes.

569
Schemes for filtering large quantities of water.

In ſome caſes, the diſcovery of a ready way of filtering a large quantity of liquor would be a matter of great conſequence; as where a town is ſupplied with river water, which is generally far from being clear, and often imparts a diſagreeable colour to clothes waſhed with it. Some years ago, a ſcheme was propoſed by a chemiſt for filtering muddy water in any quantity. His method was, to have a large caſk covered over in the bottom with ſtraw to the depth of ſome inches, and then filled up with ſand. This caſk was entirely open at one end, and had a hole in the other, which, by means of a leaden pipe, communicated with a large reſervoir of the water to be filtered, and which ſtood conſiderably higher than the caſk. The water which deſcended through the pipe into the caſk, having a tendency to riſe up to the ſame level with that in the reſervoir, would preſs violently againſt the ſand, and, as he thought, run over the mouth of the caſk perfectly filtrated, and free from its impurities. By this contrivance, indeed, a very violent preſſure was occaſioned, if the height of the reſervoir was conſiderable: but the conſequence was, not a filtration, but a greater degree of impurity in the water; for the ſand was forced out of the caſk along with it, and, however confined, the water always aroſe as muddy as it went in.

Where water is to be filtered in large quantity, as for the purpoſes of a family, a particular kind of ſoft ſpongy ſtones called *filtering ſtones*, are employed. Theſe, however, though the water percolates through them very fine, and in ſufficient quantity at firſt, are liable to be obſtructed in the ſame manner as paper, and are then rendered uſeleſs. A better method ſeems to be, to have a wooden veſſel, lined with lead, three or four feet wide at top, but tapering ſo as to end in a ſmall orifice at the bottom. The under part of the veſſel is to be filled with very rough ſand, or gravel, well freed from earth by waſhing. Over this, pretty fine ſand may be laid to the depth of 12 or 14 inches, but which muſt likewiſe be well freed from earthy particles. The veſſel may then be filled up to the top with water, pouring it gently at firſt, leſt the ſand ſhould be too much diſplaced. It will ſoon filter thro' the ſand, and run out at the lower orifice exceedingly tranſparent, and likewiſe in very conſiderable quantity. When the upper part of the ſand begins to be ſtopped up, ſo as not to allow a free paſſage to the water, it may occaſionally be taken off, and the earthy matter waſhed from it, when it will be equally ſerviceable as before.

570 Precipitation.

III. PRECIPITATION or COAGULATION. This operation is the very reverſe of ſolution, and is the bringing a body ſuddenly from a fluid to a ſolid ſtate. It differs from cryſtallization, in that it generally requires leſs time; and in cryſtallization the ſubſtance aſſumes regular figures, whereas precipitates are always in the form of powders.

Precipitation is generally preceded by ſolution and filtration: it is uſed for ſeparating earths and metals from the acids which had kept them ſuſpended. When a precipitation is made of the more valuable metals, glaſs veſſels are to be uſed. When earths, or the imperfect metallic ſubſtances, are to be precipitated in large quantity, wooden ones anſwer every purpoſe. If a metal is to be precipitated by an alkali, this ſalt muſt firſt be diſſolved in water, then filtered, and gradually added to the metallic ſolution. If particular circumſtances do not forbid, the ſalt for precipitation ſhould be choſen in its cauſtic ſtate, or deprived of its fixed air, becauſe then a very troubleſome efferveſcence is avoided. To promote the operation alſo, the mixture, if contained in a glaſs, is to be ſhaken; or if in any other veſſels, to be well ſtirred after every addition of alkali. If an earth is employed to precipitate a metal, the mixture muſt be in a manner conſtantly ſtirred or ſhaken, in order to promote the precipitation; and if one metal is to be precipitated by another, that which is uſed as a precipitant muſt be beaten into thin plates, that ſo they may be frequently cleaned from the precipitating metal, which would otherwiſe very ſoon totally impede the operation.

Sometimes a precipitation enſues on the addition of water or ſpirit of wine: but in moſt caſes care muſt be taken not to add too much of the ſubſtance which is uſed to precipitate the other; becauſe, in ſuch a caſe, the precipitate may be diſſolved after it has been thrown down. Thus, though volatile alkali will ſeparate copper from aquafortis, it will as effectually diſſolve the precipitate, if too much of it is uſed, as the acid itſelf. It is proper, therefore, to proceed cautiouſly, and examine a ſmall quantity of the liquor from time to time. If an addition of the precipitant throws down any more, it will be proper to add ſome more to the whole ſolution.

571 Edulcoration.

It is ſeldom or never that precipitation can be performed ſo perfectly, but that one or other of the ingredients will prevail; and though they ſhould not, a new compound, conſiſting of the acid united with the alkali, or other ſubſtance uſed for precipitation, is contained in the liquor through which the precipitate falls. It is proper, therefore, to waſh all precipitates; otherwiſe they can never be obtained perfectly pure, or free from a mixture of ſaline ſubſtances. This is beſt done by pouring the whole into a filter, and letting the fluid part run off, as long as it will drop, without ſhaking the cloth. Some water is then to be cautiouſly poured all over the ſurface of the precipitate, ſo as to diſturb it as little as poſſible. This water will puſh before it the ſaline liquor which is mixed with the powder, and render it much purer than before. A ſecond or third quantity of water may be uſed, in order to waſh off all the ſaline matter. This is called *edulcorating* the precipitate.

572 Evaporation.

IV. EVAPORATION. This operation conſiſts in diſſipating the moiſt fluid or volatile parts of any ſubſtance by means of heat. It moſt generally ſucceeds ſolution and filtration, being a preparatory for the operation of cryſtallization.

For the evaporation of ſaline ſolutions, which have been already filtered, and which it is of conſequence to preſerve from even the leaſt impurities, diſtilling veſſels are unqueſtionably the moſt proper; both as, by their means, the ſolution will be kept perfectly free from duſt, and as the quantity of liquor evaporated can be known with certainty by meaſuring that which comes over. This alſo is probably the moſt expeditious method of evaporating, and which requires the leaſt fuel. (See the detached articles EVAPORATION and DISTILLATION). With regard to veſſels for evaporation, the ſame thing muſt be applicable which was mentioned above under *Solution*. No ſaline liquor muſt be evaporated in a veſſel which would be corroded by it; and hence iron veſſels are abſolutely improper for evaporations of any kind of ſaline liquor whatever.—Lead is in this caſe the metal moſt generally uſeful. It muſt only be uſed, however, where the evaporation is not carried to dryneſs; for, on account of the great fuſibility of this metal, nothing could be exſiccated in it without great danger of its melting. Where a ſaline liquor therefore is to be perfectly exſiccated, the evaporation, if performed in lead veſſels, muſt be carried on ſo far only as to form a ſaline pellicle on the ſurface of the liquor. It is then to be drawn off; for which purpoſe, all evaporating veſſels ſhould have a cock near the bottom. The liquor muſt now be put into a number of ſtone-ware baſons, ſet on warm ſand, where the exſiccation may be finiſhed.

573 Cryſtallization.

V. CRYSTALLIZATION. This, though commonly accounted one of the proceſſes in chemiſtry, is in reality only a *natural* one, and which the chemiſt can only prepare for, leaving the operation entirely in the hands of nature.—By cryſtallization is meant the ſeparation of a ſalt from the water in which it has been diſſolved, in tranſparent maſſes regularly figured, and differently formed, according to the different nature of the ſalts.

This proceſs depends upon the conſtitution of the atmoſphere more than any other; and therefore is difficult to be performed, nor does it always ſucceed equally well; neither have there yet been laid down any rules whereby beautiful and regular cryſtals can with certainty be formed at all times.

As the different ſalts aſſume very different figures when cryſtallized, they are not ſubject to the ſame general rules in cryſtallization. Nitre, Glauber's ſalt, vitriol of iron, and many others, cryſtallize beſt on having their ſolutions ſet in a cold place after proper evaporation. Sal polychreſt, and common ſalt, require the ſolution to be kept as hot as the hand can bear it during the time of cryſtallizing. Soluble tartar too, and other deliqueſcent ſalts, require to be kept warm while this operation is going on: and there are many ſaline ſubſtances, ſuch as the combinations of calcareous earths and magneſia with acids, which can ſcarcely be cryſtallized at all.

Mr Beaumé has diſcovered, that when two or more ſalts are diſſolved in the ſame quantity of water, when one cryſtallizes, the cryſtals of that ſalt will not contain the leaſt quantity of any of the others: neither, although the liquor was acid or alkaline, will the cryſtals for that reaſon be either acid or alkaline, but will remain perfectly neutral; and the acid or alkaline liquor which adheres to the outſide of the cryſtals may be abſorbed by merely ſpreading them on filtering paper.—Hence we are furniſhed with a better method of ſhooting ſalts into large and well formed cryſtals than merely by diſſolving them in water; namely, by adding to the ſolutions, when ſet to cryſtallize, a certain quantity of acid or alkaline liquor, according to the nature of the ſalts themſelves. Theſe additions, however, are not equally proper for all ſalts; and it is not yet determined what kinds of ſalts ought to be cryſtallized in alkaline, and what in acid liquors.—Soluble tartar and Seignette's ſalt cryſtallize beſt when the liquor is alkaline. Sal ſedativus, ſal Glauberi, and ſal polychreſt, require an acid if cryſtallized in the cold; but ſal polychreſt forms into very fine and large cryſtals when the ſolution is alkaline, and kept as hot as the hand can eaſily bear.

The beſt general direction that can be given with regard to the regular cryſtallization of ſalts is, that they ought to be ſet to cryſtallize in as large a quantity at once as poſſible; and this, as far as we have obſerved, without any limit; for by this means, the cryſtals are formed much larger and better figured than they poſſibly can be by any other method hitherto known.—As to the form of the veſſels in which ſalts are to be cryſtallized, little can be ſaid with certainty. They are generally flat, and wider at top than at the bottom. The only proper material, in the large way, is lead.

574 Diſtillation.

VI. DISTILLATION. This is a kind of evaporation; only in ſuch a manner, that the part of the liquor evaporated is not diſſipated in the air, but preſerved by making the ſteam paſs through a ſpiral pipe, which goes through a large veſſel full of cold water, or into cold glaſs receivers.

This is one of the moſt common chemical operations; and as there are a variety of ſubjects which require to be diſtilled, there is conſequently a conſiderable variety both in the form of the diſtilling veſſels to be uſed on different occaſions, and likewiſe in the materials of which they are made, as well as the management of the fire during the time of the operation.

Plate CXXXIV.

The moſt ſimple and eaſily performed diſtillation is that by the common copper ſtill, (fig. 3). It conſiſts of two parts; one called the *body*, and the other the *head*. The body is a cylindrical veſſel of copper, which is ſometimes tinned over in the inſide; but where diſtillation is performed without any regard to the reſiduum, the tinning is uſeleſs. The upper part of the body terminates in a kind of arch, in the middle of which is a circular aperture, about one half, or ſomething leſs, in diameter, of the breadth of the whole body.—Into this aperture, a round head, made likewiſe of copper, is fitted, ſo as to be removeable at pleaſure. In the top, or ſometimes in the ſide of the head, is inſerted a pewter pipe, which communicates with a ſpiral one of the ſame metal, that paſſes through a large wooden veſſel, called the *refrigeratory*, filled with cold water; each of its ends projecting a little above and below. The ſtill is to be filled two-thirds full of the ſubſtance to be diſtilled, the head put on, and the junctures well cloſed with mixture of linſeed meal and water, or common flour or chalk and water will anſwer the ſame purpoſe. This mixture is called the *luting*, or *lute*. A fire being kindled under the ſtill, the vapours will ariſe; and, being condenſed by the cold water, through which the ſpiral pipe called the *worm* paſſes, will run in a ſtream more or leſs ſtrong as the fire is more or leſs haſtily urged, and is catched in a receiver ſet underneath.

This kind of diſtilling veſſels is proper for procuring the eſſential oils of vegetables, vinous ſpirits from fermented liquor, and for the rectification of theſe after they are once diſtilled. Even the acetous acid may be very conveniently diſtilled in a copper veſſel, provided the worm and all the deſcending parts of the pipe which communicates with it be of pewter, otherwiſe a miſchievous impregnation of copper would be communicated to the diſtilled vinegar. The reaſon of this is, that copper is not diſſolved by vinegar, or in very ſmall quantity, when that acid is boiled in it; but if the metal is expoſed to the action of the acid, when cold, or to its vapours, a conſiderable diſſolulution takes place. For this reaſon, too, the ſtill muſt be waſhed out after the operation while it continues hot, and muſt be very carefully freed from the leaſt remains of acid, otherwiſe it will be much corroded.

Copper-ſtills ought to be of as large a ſize as poſſible: but Dr Lewis very juſtly obſerves, that, in common ones, the width of the worm is by no means proportionable to the capacity of the ſtill: hence the vapour which iſſues from a large ſurface being violently forced through a ſmall tube, meets with ſo much reſiſtance as ſometimes to blow off the ſtill-head. This inconvenience is ridiculouſly endeavoured to be prevented by ſtrongly tying or otherwiſe forcing down the head; by which means, if the worm ſhould happen to be choaked up, a terrible exploſion would enſue: for no ligatures, or any other obſtacle whatever, have yet been found ſtrong enough to reſiſt the elaſtic force of ſteam, and the greater obſtacle it has to overcome, the greater would the exploſion be.—Dangers of this kind might be totally avoided by having the worm of a proper degree of wideneſs.

575 Mineral acids how diſtilled.

Sometimes, however, matters are to be diſtilled, ſuch as mineral acid ſpirits, which would corrode any kind of metalline veſſels; and for theſe only earths, or the cloſeſt kind of ſtone-ware, can be uſed. Theſe are more eaſily condenſed than the ſteams of aqueous or vinous liquors, and therefore do not require to be paſſed through a pipe of ſuch a length as is uſed for condenſing the ſteams from the common ſtill. In theſe caſes, where a violent heat is not neceſſary, and the

576 Retort.

diſtillation is to be performed in glaſs veſſels, the retort is uſed (fig. 4.) When a fluid is to be put into this veſſel, the retort muſt be laid upon its back on ſand, or any other ſoft matter that will ſupport it without breaking. A funnel muſt alſo be procured with a long ſtem, and a little crooked at the extremity, that the liquor may paſs at once into the belly of the retort, without touching any part of its neck; otherwiſe the quantity which adhered to the neck would paſs into the receiver when the retort was placed in a proper ſituation for diſtilling, and foul the produce. When the veſſel is properly filled, which ought never to be above two-thirds, it is to be ſet in a ſand-bath: that is, in an iron pot, of a proper thickneſs,

neſs, and covered over in the bottom, to the deph of one or two inches, with dry ſand. When the retort is put in, ſo as to ſtand on its bottom, the pot is to be filled up with ſand, as far as the neck of the retort. A glaſs receiver is then to be applied, which ought to be as large as poſſible, and likewiſe pretty ſtrong; for which reaſon it will be proper not to let the capacity of it be above what is neceſſary to hold ten gallons. In the hinder part of it ſhould be drilled a ſmall hole, which may be occaſionally ſhut by a ſmall wooden peg. The mouth of the receiver ought to be ſo wide as to let the noſe of the retort enter to the middle of it, or very near to it; for if the vapours are diſcharged very near the luting, they will act upon it much more ſtrongly than when at a diſtance. It is likewiſe proper to have the neck of the retort as wide as may be; for this has a very great effect in the condenſation, by preſenting a larger ſurface to the condenſing vapour.

577 Luting for acid ſpitits.

The luting for acid ſpirits ought to be very different from that uſed in other diſtillations; for theſe will penetrate the common lutes ſo as to make them liquid and fall down into the receiver. Some have uſed retorts the necks of which were ground to the receivers with emery; but theſe are very difficult to be procured, and are expenſive, and conſequently have never come into a general uſe. Various kinds of lutes have been propoſed, but the preference ſeems due to a mixture of clay and ſand. We are not to underſtand, however, that every kind of clay is fit for this purpoſe: it muſt only be ſuch as is not at all, or very little, affected by acids; and this quality is only poſſeſſed by that kind of which tobacco-pipes is made. Trial ought to be made of this before the diſtillation is begun, by pouring a little nitrous acid on the clay intended to be made uſe of. If a violent efferveſcence is raiſed, we may be ſure that the clay is unfit for the purpoſe. Finely powdered alabaſter would anſwer extremely well, had it the ductility of clay. As this kind of lute remains ſoft for a conſiderable time, it ought to be farther ſecured by a bit of rag ſpread with ſome ſtrong cement, ſuch as quicklime mixed with the white of an egg, *&c.* Matters, however, ought to be managed in ſuch a manner, that the luting may give way, rather than the veſſel burſt; which would not only occaſion a certain loſs of the materials, but might endanger the perſons who are ſtanding by.

578 *Balneum arenæ.*

The iron pots commonly uſed for diſtillations by the ſand-bath, or *balneum arenæ*, are commonly made very thick; and are to be ſold at large founderies, under the name of *ſand-pots*. The ſhape of theſe, however, is by no means eligible: for, as they are of a figure nearly cylindrical, if the retort is of ſuch a ſize as almoſt to fill their cavity, it cannot be put into them when full, and often pretty heavy, without great danger of touching the ſides of the pot; and in this caſe, touching and *breaking* are ſynonymous expreſſions. It is much better, therefore, to have them in the figure of a punch-bowl; and the common caſt-iron kettles, which may be had much cheaper than the ſand-pots uſually ſold, anſwer extremely well. If the diſtilling veſſel is placed in a pot filled with water, the diſtillation is ſaid to be performed in a water-bath, or *balneum mariæ*.

When the matter to be condenſed is very volatile, a number of open receivers with two necks, called *adopters* (fig. 7.) may be uſed, with a cloſe receiver at the end. Each of theſe adopters muſt be luted with as much care as when only a ſingle receiver is made uſe of. Veſſels of a ſimilar kind were formerly much uſed by chemiſts for particular ſublimations, under the name of *aludels*.

579 Adopters of aludels.

Formerly, inſtead of retorts, a veſſel called a *cucurbit*, (fig. 5, and 6.) with a head like the common ſtill, called an *alembic*, were uſed; but the more ſimple figure of the retort gives it greatly the preference. It is but ſeldom that veſſels of this kind are uſeful, which will be taken notice of when deſcribing the particular operations; and if at any time an alembic head ſhould be neceſſary, its uſe may be ſuperſeded by a crooked glaſs tube, which will anſwer the purpoſe equally well.

Sometimes a very violent fire is required in diſtillations by the retrot. Here, where it is poſſible, glaſs or earthen veſſels ſhould be avoided, and iron pots ſubſtituted in their ſtead. The hardeſt and beſt caſt iron, however, will at laſt melt by a vehement heat; and therefore there is a neceſſity for uſing earthen ware, or coated glaſs. This laſt is better than moſt kinds of earthen ware, as being leſs porous; for when the veſſel is urged by a very intenſe heat, the glaſs melts, and forms a kind of ſemivitreous compound with the inſide of the coating, ſo that its figure is ſtill preſerved, and the accidental cracks in the luting are filled up.

580 Coating of glaſſes.

For coating of veſſels, mixtures of colcothar of vitriol, ſand, iron filings, blood, chopped hair, *&c.* have been recommended. We cannot help thinking, however, that the ſimple mixture of tobacco-pipe clay and ſand is preferable to any other; eſpecially if, as Dr Black directs, that part next the glaſs is mixed with charcoal duſt.

The proportions recommended by the Doctor for luting the joints of veſſels, are four parts of ſand and one of clay; but for lining the inſides of furnaces, and we ſhould think, likewiſe for coating glaſs veſſels, he directs 6 or 7 of ſand to 1 of clay, that the contraction of the clay in drying may thereby be the more effectually prevented. Beſides this, he directs a mixture of three parts of charcoal-duſt with one of clay to be put next the furnace itſelf, as being more apt to confine the heat; but poſſibly the firſt compoſition might be ſufficient for glaſſes.

The coating of large glaſſes muſt be a very troubleſome and tedious operation; and therefore coated glaſs is never uſed but in experiments. When large diſtillations are to be performed in the way of trade, recourſe muſt be had either to iron pots, or to earthen ware. Of the moſt proper kinds of earthen ware for reſiſting violents heat, we ſhall take notice under the article *Fuſion*.

In all diſtillations by the retort, a conſiderable quantity of air, or other incondenſible vapour, is extricated; and to this it is abſolutely neceſſary to give vent, or the veſſel would be burſt, or the receiver thrown off. For this purpoſe, Dr Lewis recommends an open pipe to be inſerted at the luting, of ſuch an height as will not allow any of the vapour to eſcape; but this we cannot approve of, as by that means a conſtant communication is formed between the external atmoſphere and the matters contained in the retort and receiver, which is at all times to be avoided as much as poſſible, and in ſome caſes, as the diſtillation of phoſphorus, would be very dangerous. The having a ſmall

ſmall hole drilled in the receiver, which is to be now and then opened, muſt anſwer the purpoſe much better, although it takes more attendance; but if the operator is obliged to leave the veſſels for ſome time, it will be convenient either to leave the little hole open, or to contrive it ſo that the wooden peg may be puſhed out with leſs force than is ſufficient to break the lute.

581 Sublimation. VII. Sublimation. This, properly ſpeaking, is only the diſtillation of a dry ſubſtance; and therefore, when volatile matters, ſuch as ſalt of hartſhorn, are to be ſublimed, the operation is performed in a glaſs retort ſet in a ſand-bath; and the ſalt paſſes over into the receiver. The cucurbit and alembic were formerly much in uſe for this purpoſe; and a blind head, without any ſpout, was applied. A much ſimpler apparatus, however, is now made uſe of. A globe made of very thin glaſs, or an oblong veſſel of the ſame kind, anſwers the more common purpoſes of ſublimation. For experiments, Florence flaſks are excellent: as being both very cheap, and having the neceſſary ſhape and thinneſs requiſite for bearing the heat without cracking. The matter to be ſublimed muſt not, on almoſt any occaſion, take up more than a third part of the ſubliming veſſel. It is to be ſet in a ſand-bath, that the heat may be more equally applied than it could otherwiſe be. The heat muſt be no greater, or very little, than is neceſſary for ſublimation, or it will be in danger of flying out at the mouth of the ſubliming veſſel, or of choaking it up ſo as to burſt. The upper part of the veſſel, too, muſt by no means be kept cool, but ſlightly covered with ſand, that the matter may ſettle in a kind of half melted ſtate, and thus form a compact hard cake, which is the appearance ſublimates are expected to have. Hence this operation requires a good deal of caution, and is not very eaſily performed.

582 Deflagration. VIII. Deflagration. This operation is always performed by means of nitre, except in making the flowers of zinc. It requires open veſſels of earth or iron; the latter are very apt to be corroded, and the former to imbibe part of the matter. To perform this proceſs with ſafety, and without loſs, the nitre ought to be mixed with whatever matter is to be deflagrated with it, and thrown, by little and little into the veſſel previouſly made red-hot. If much is put in at once, a great deal will be thrown out by the violent commotion; and to perform this operation in cloſe veſſels is in a manner impoſſible, from the prodigious quantity of elaſtic vapour generated by the nitre. Care muſt alſo be taken to remove the whole mixture to ſome diſtance from the fire, and not to bring back any ſpark from the quantity deflagrating, with the ſpoon which puts it in; otherwiſe the whole would irremediably be conſumed at once.

583 Calcination. IX. Calcination. This is the ſubjecting any matter to a heat ſo violent as to diſſipate ſome part of it, without melting what remains. It is often practiſed on metallic ſubſtances, particularly lead, for obtaining the calx of that metal called *minium*, or red lead.

This operation, as indeed all other chemical ones, is beſt performed in large quantities, where a particular furnace is conſtructed on purpoſe, and a fire kept on day and night without interruption. The flame is made to play over the ſurface of the metal, and it is continually ſtirred ſo as to expoſe different parcels of it to the action of the heat.

584 Fuſion. X. Fusion. This is when a ſolid body is expoſed to ſuch a degree of heat as makes it paſs from a ſolid to a fluid ſtate; and as different ſubſtances are poſſeſſed of very different degrees of fuſibility, the degrees of melting heat are very various.

Beſides the true fuſion, there are ſome kinds of ſalts which retain ſo large a proportion of water in their cryſtals, as to become entirely fluid upon being expoſed to a very ſmall degree of heat. This is commonly called the *watery fuſion*; but is really a *ſolution* of the ſalt in that quantity of water retained by it in its cryſtalline form: for ſuch ſalts afterwards become ſolid by the evaporation of the water they contained: and then require a ſtrong red heat to melt them thoroughly, or perhaps are abſolutely infuſible.

Of all known ſubſtances, unctuous and inflammable ones become fluid with the leaſt heat: then come the more fuſible metals, lead, tin, and antimony; then ſome of the more fuſible ſalts; and then the harder metals, ſilver, gold, copper, and iron; then the mixtures for making glaſs; and laſt of all, the metal called *platina*, which has hitherto been incapable of fuſion, except by the violent action of the ſun-beams in the focus of a large burning glaſs. This ſubſtance ſeems to be the moſt refractory of all others, even the hardeſt flints melting into glaſs long before it. (See Platina.)

Fuſion of ſmall quantities of matter is uſually performed in pots called *crucibles*; which, as they are required to ſtand a very violent heat, muſt be made of the moſt refractory materials poſſible.

585 Crucibles, proper materials for. The making of crucibles belongs properly to the potter: but as a *chemiſt* ought to be the judge of their compoſition, we ſhall here give ſome account of the different attempts to make theſe veſſels of the neceſſary ſtrength.

All earthen veſſels are compoſed, at leaſt partly, of that kind which is called the *argillaceous earth* or *clay*, becauſe theſe only have the neceſſary ductility, and can be formed into veſſels of the proper form. Pure clay is, by itſelf, abſolutely unfuſible; but is exceedingly apt to crack when expoſed to ſudden changes of heat and cold. It is alſo very apt to melt when mixed with other ſubſtances, ſuch as calcareous earths, &c. When mixed in a certain proportion with other materials, they are changed with violent heat into a kind of half-melted ſubſtance, ſuch as our ſtone-bottles. They cannot be melted completely, however, by almoſt any fire; they are alſo very compact, and will contain the moſt fuſible ſubſtances, even glaſs of lead itſelf; but as they are very apt to crack from ſudden changes of heat and cold, they are not ſo much uſed; yet, on particular occaſions, they are the only ones which can be made uſe of.

The more denſe any kind of veſſels are, the more apt they are, in general, to break by a ſudden application of heat or cold: hence crucibles are not, in general, made of the greateſt denſity poſſible: which is not at all times required. Thoſe made at Heſſe, in Germany, have had the beſt reputation for a long time. Mr Pott, member of the Academy of Sciences at Berlin, hath determined the compoſition of theſe crucibles to be, one part of good refractory clay, mixed with two parts of ſand, of a middling fineneſs, from which the fineſt part has been ſifted. By ſifting the finer particles from the ſand, too great compactneſs is avoided: but

but at the ſame time this mixture renders them apt to be corroded by vitrifying matters kept a long time in fuſion; for theſe do not fail to act upon the ſand contained in the compoſition of the crucible, and, forming a vitreous maſs, at laſt run through it.

This inconvenience is prevented, by mixing, inſtead of ſand, a good baked clay in groſs powder. Of a compoſition of this kind are made the glaſs-houſe pots, which ſometimes ſuſtain the violent heat employed in making glaſs for ſeveral months. They are, however, gradually conſumed by the glaſs, and become conſtantly more and more thin.

586 Platina, a deſirable material.

As the containing veſſel, however, muſt always be expoſed to a more violent heat than what is contained in it, crucibles ought to be formed of ſuch materials as are not vitrifiable by the heat of any furnace whatever. But from the attempts made to melt platina, it appears, that of all known ſubſtances it would be the moſt deſirable for a melting veſſel. Heſſian crucibles, glaſs-houſe pots, Sturbridge clay, in ſhort every ſubſtance which could be thought of to reſiſt the moſt violent heat, were melted in ſuch a manner as even to ſtop up the pipes of large bellows, while platina was not altered in the leaſt; and Meſſrs Macquer and Beaume have ſhown, that though platina cannot be melted ſo as to caſt veſſels of it, it may nevertheleſs be cupelled with lead ſo as to become malleable, and thus veſſels might otherwiſe be made from that ſubſtance. The extreme ſcarcity of this mineral, however, leaves as yet little room to hope for any thing from it, though Mr Achard has found a method of forming crucibles from this refractory ſubſtance. It conſiſts in moulding the precipitate made with ſal ammoniac into the form of a crucible, and then applying a ſudden and very violent heat, which fuſes this calx.

587 Achard's method of making crucibles of platina.

Mr Pott has made ſo many experiments upon clays mixed with different ſubſtances, that he has in a manner exhauſted the ſubject. The baſis of all his compoſitions was clay. This he mixed in different proportions with metallic calces, calcined bones, calcareous earths, talcs, amianthus, aſbeſtus, pumice-ſtones, tripoli, and many others; but he did not obtain a perfect compoſition from any of them. The beſt crucibles, according to Scheffer, cannot eaſily contain metals diſſolved by ſulphur, in the operation of parting by means of ſulphur. They may be made much more durable and ſolid, by ſteeping them a few days in linſeed-oil, and ſtrewing powdered borax upon them before they are dried.

588 Mr Pott's directions.

The reſult of Mr Pott's experiments are: 1. Crucibles made of fat clays are more apt to crack when expoſed to ſudden heat, than thoſe which are made of lean or meagre clays. *Meagre clays* are thoſe which contain a conſiderable quantity of ſand along with the pure argillaceous earth: and *fat clays* are thoſe which contain but little. 2. Some crucibles become porous by long expoſure to the fire, and imbibe part of the contained metals. This may be prevented, by glazing the internal and external ſurfaces; which is done by moiſtening theſe with oil of tartar, or by ſtrewing upon them, when wetted with water, powdered glaſs of borax. Theſe glazings are not capable of containing glaſs of lead. 3. Crucibles made of burnt clay groſsly powdered, together with unburnt clay, were much leſs liable to crack by heat than crucibles made of the ſame materials where the burnt clay was finely powdered, or than crucibles made entirely of unburnt clay. 4. If the quantity of unburnt clay be too great, the crucible will be apt to crack in the fire. Crucibles made of 10 ounces of unburnt clay, 10 ounces of groſsly powdered burnt clay, and three drachms of calcined vitriol, are capable of retaining melted metals, but are pervaded by glaſs of lead. The following compoſition is better than the preceding: Seven ounces of unburnt clay, 14 ounces of groſsly powdered burnt clay, and one drachm of calx of vitriol. Theſe crucibles may be rendered more capable of containing glaſs of lead, by lining their internal ſurfaces, before they are baked, with unburnt clay diluted with water. They may be further ſtrengthened by making them thicker than is uſually done; or by covering their external ſurfaces with ſome unburnt clay, which is called *arming* them. 5. The compoſition of crucibles moſt capable of containing the glaſs of lead, was 18 parts of groſsly powdered burnt clay, as much unburnt clay, and one part of fuſible ſpar. Theſe crucibles muſt not, however, be expoſed too ſuddenly to a violent heat. 6. Crucibles capable of containing glaſs of lead very well, were made of 24 parts of unburnt clay, four parts of burnt clay, and one part of chalk. Theſe require to be armed. 7. Plume alum powdered, and mixed with whites of eggs and water, being applied to the internal ſurface of a Heſſian crucible, enabled it to retain for a long time glaſs of lead in fuſion. 8. One part of clay, and two parts of Spaniſh chalk, made very good crucibles. The ſubſtance called *Spaniſh chalk* is not a calcareous earth, but appears to be a kind of ſteatites. 9. Two parts of Spaniſh chalk, and one part of powdered tobacco-pipes, made good lining for common crucibles. 10. Eight parts of Spaniſh chalk, as much burnt clay, and one part of litharge, made ſolid crucibles. 11. Crucibles made of black lead are fitter than Heſſian crucibles for melting metals; but they are ſo porous, that fuſed ſalts paſs entirely thro' them. They are more tenacious than Heſſian crucibles, are not ſo apt to burſt in pieces, and are more durable. 12. Crucibles placed with their bottoms upwards, are leſs apt to be cracked during the baking, than when placed differently. 13. The paſte of which crucibles are made, ought not to be too moiſt; elſe, when dried and baked, they will not be ſufficiently compact: hence they ought not to be ſo moiſt as to be capable of being turned on a potter's lathe; but they muſt be formed in braſs or wooden moulds.

589 Materials moſt capable of reſiſting glaſs of lead.

590 Dr Lewis's obſervations.

On this ſubject Dr Lewis hath alſo made ſeveral obſervations; the principal of which are, 1. Pure clay ſoftened to a due conſiſtence for being worked, not only coheres together, but ſticks to the hands. In drying, it contracts 1 inch or more in 12; and hence it is very apt to crack, unleſs it is dried exceeding ſlowly. In burning, it is ſubject to the ſame inconvenience, unleſs very ſlowly and gradually heated. When thoroughly burnt, if it has eſcaped thoſe imperfections, it proves ſolid and compact; and ſo hard as to ſtrike fire with ſteel. Veſſels made of it are not penetrated by any kind of liquid; and reſiſt ſalts and glaſſes brought into the thinneſt fuſion, excepting thoſe which by degrees corrode and diſſolve the earth itſelf, as glaſs of lead; and even this penetrating glaſs is reſiſted by it better than by almoſt any other earth; but, in counterbalance to theſe good qualities, they cannot be heated or cooled, but with ſuch precautions as can rarely be complied with in the way of buſineſs, without cracking, or flying in pieces.

2. Clay that has been once expoſed to any conſiderable degrees of heat, and then powdered, has no longer any tenacity. Freſh clay, divided by a due proportion of this powder, proves leſs tenacious than by itſelf; not ſticking to the hands, though cohering ſufficiently together. It ſhrinks leſs in drying, is leſs apt to crack, and leſs ſuſceptible of injury from alterations of heat and cold; but at the ſame time is leſs ſolid and compact. Conſiderable differences are obſerved in theſe reſpects; not only according to the quantity of dividing matter, but according as it is in finer or coarſer powder.

3. Veſſels made with a moderate proportion of fine powder, as half the weight of the clay, are compact and ſolid, but ſtill very apt to crack, from ſudden heat or cold: thoſe with a larger proportion, as twice or thrice the quantity of the clay, are free from that imperfection, but ſo friable as to crumble between the fingers. Nor does there appear to be any medium between a diſpoſition to crack and to crumble; all the compounds made of clay and fine powders having the one or the other, or both imperfections. Coarſer powders of the ſize of middling ſand, form, with an equal weight of clay, compounds ſufficiently ſolid, and much leſs apt to crack than the mixtures with fine powders. Two parts of coarſe powder, and one of clay, prove moderately ſolid, and but little diſpoſed to crack: a mixture of three parts and one, tho' heated and cooled ſuddenly, does not crack at all, but ſuffers very fluid ſubſtances to tranſude through it; ſolidity, and reſiſtance to quick viciſſitudes of heat and cold, ſeeming here alſo to be incompatible.

4. Pure clay, mixed with pure clay that has been burnt, is no other than one ſimple earth; and is neither to be melted nor ſoftened, nor made in any degree tranſparent with the moſt intenſe fires.

5. Mixtures of clay with gypſeous earths burn whiter than clay alone; in certain proportions, as two parts of clay to three of gypſum, they become, in a moderate fire, ſemi-tranſparent, and in a ſtrong one they melt.

6. Calcareous earths in ſmall proportion bake tolerably compact and white; and added to other compoſitions, ſeem to improve their compactneſs. If the quantity of the calcareous earth nearly equals that of the clay, the mixture melts into a yellow glaſs; if it conſiderably exceeds, the product acquires the qualities of quicklime.

7. Veſſels made from clay and ſand, in whatever proportion, do not melt in the ſtrongeſt fire; but they ſometimes bend or ſoften, ſo as to yield to the tongs. Glaſſes in thin fuſion penetrate them by diſſolving the ſand. If gypſeous or calcareous earths e urged in ſuch crucibles with a vehement heat, the veſſels and their contents run all into one maſs. In moderate fires, theſe veſſels prove tolerably compact, and retain moſt kinds of ſalts in fuſion: but they are liable to crack, eſpecially when large; and do not long ſuſtain melted metals, being burſt by their weight. Such are the Heſſian crucibles.

8. Mixtures of clay and black-lead, which ſeems a ſpecies of talc, are not liable to crack from alternations of heat and cold; but are extremely porous. Hence black-lead crucibles anſwer excellently for the melting of metals, and ſtand repeated fuſions; whilſt ſalts flowing thin, tranſude through them almoſt as water through a ſieve: ſulphureous bodies, as antimony, corrode them.

9. Pure clay, ſoftened with water, and incruſtated on earthen veſſels, that have been burnt, does, not adhere to them, or ſcales off again upon expoſure to the fire; applied to unburnt veſſels, it adheres and incorporates. Divided clay unites with them in both ſtates. Vitreous matters, melted in veſſels of pure clay, adhere ſo firmly as not to be ſeparated; from veſſels of divided clay they may be knocked off by a hammer.

10. The ſaline fluxes which promote the fuſion of clay, beſides the common ones of all earths, alkali and borax, are chiefly arſenic fixed by nitre, and the fuſible ſalt of urine; both which have little effect on the other earths though mixed in a lager proportion. Nitre, which readily brings the cryſtalline earths into fuſion, and ſal mirabile and ſandiver, powerful fluxes for the calcareous earths, do not perfectly vitrify with clay. Burnt clay does not differ in theſe reſpects from ſuch as has not been burnt; nor in that ſingular property of vitrifying with gypſeous or calcareous earths, without any ſaline or metallic addition; the utmoſt vehemence of fire ſeeming to deſtroy only its ductility, or that power by which it coheres when its parts are moiſtened with water.

591 More perfect veſſels to be hoped for from porcelain.

But though it ſeems impoſſible to make perfect veſſels from mixtures of clay in its two different ſtates, of burnt and unburnt, more is to be hoped from the mixtures which are employed in making porcelain. Manufactories of this kind of ware have been attempted in different countries, (ſee PORCELAIN); and in ſome places the qualities requiſite for chemical veſſels have been given to it in a very ſurpriſing degree. The count de Lauraguais, a French nobleman, and member of the academy of ſciences, has diſtinguiſhed himſelf in a very eminent manner by attempts of this kind. The tranſlator of the chemical dictionary aſſures us, that he had it from a gentleman of undoubted veracity, that this nobleman having heated a piece of his porcelain red hot, threw it into cold water, without breaking or cracking it.

592 Mr Reaumur's porcelain.

The moſt uſeful attempt, however, for the purpoſes of chemiſtry, ſeems to be the diſcovery by Mr Reaumur of converting common green glaſs into porcelain. This was publiſhed as long ago as the year 1739; yet we have ſcarce heard of any chemiſt, no not Dr Lewis himſelf, who has made trial of chemical veſſels formed of this ſort of porcelain, although the very uſe to which Mr Reaumur thought the preparation could be applicable was that of bringing chemical veſſels to a degree of perfection which could not otherwiſe be done. The following is the reſult of Mr Reaumur's experiments.

Green glaſs, ſurrounded with white earthy matters, as white ſand, gypſum, or plaſter of Paris, *&c.* and expoſed to a conſiderable heat not ſtrong enough to alter its figure, as that of a potter's furnace, acquires different ſhades of blue, and by degrees begins to grow white. On breaking the glaſs, the white coat appears to be compoſed of fine, white, gloſſy, ſatin-like fibres, running tranſverſely, and parallel to one another; the glaſs in the middle being ſcarcely altered. On continuing the cementation, the change proceeds further and further, till at length the white fibrous parts

parts from both ſides meet in the middle, and no appearance of glaſs remains. By this means, entire veſſels of glaſs may be changed into procelain.

The ſubſtance into which glaſs is thus converted, is opaque, compact, internally of great whiteneſs, equal to that of the fineſt china-ware; but, externally, of a much duller hue. It is conſiderably harder than glaſs, much leſs fuſible in the fire, and ſuſtains alterations of heat and cold without injury. Veſſels of it, cold, bear boiling liquors; and may be placed on the fire at once, without danger of their cracking. "I have put a veſſel of this porcelain (ſays the author) into a forge, ſurrounded it with coals, and kept vehemently blowing for near a quarter of an hour; I have melted glaſs in this veſſel, without its having ſuffered any injury in its figure." If means could be found of giving the outſide a whiteneſs, equal to the internal part, glaſs veſſels might thus be converted into a valuable kind of porcelain ſuperior to all that have hitherto been made. Chemiſtry, ſays he, may receive from this diſcovery, in its preſent ſtate, ſuch veſſels as have been long wanted; veſſels which, with the compactneſs and impenetrability of glaſs, are alſo free from its inconveniences.

The common green glaſs bottles yield a procelain of tolerable beauty; window-glaſſes, and drinking-glaſſes, a much inferior one; while the finer kinds of cryſtalline glaſſes afforded none at all. With regard to the cementing materials, he found white ſand and gypſum, or rather a mixture of both, to anſwer beſt. Coloured earths generally make the external ſurface of a deeper or lighter brown colour; ſoot and charcoal, of a deep black, the internal part being always white.

593 Dr Lewis's experiments.

The account of this kind of porcelain given by Mr Reaumur, induced Dr Lewis, who had alſo obſerved the ſame changes on the bottom of glaſs-retorts expoſed to violent heat in a ſand-bath, to make further experiments on this matter; an account of which he has publiſhed in his *Philoſophical Commerce of Arts*. The reſults of his experiments were, 1. Green glaſs, cemented with white ſand, received no change in a heat below ignition. 2. In a low red heat, the change proceeded exceeding ſlowly; and in a ſtrong red heat, approaching to white, the thickeſt pieces of glaſs bottles were thoroughly converted in the ſpace of three hours. 3. By continued heat, the glaſs ſuffered the following progreſſive changes: firſt, its ſurface became blue, its tranſparency was diminiſhed, and a yellowiſh hue was obſervable when it was held between the eye and the light. Afterwards it was changed a little way on both ſides into a white ſubſtance, externally ſtill bluiſh; and, as this change advanced ſtill further and further within the glaſs, the colour of the vitreous part in the middle approached nearer to yellow: the white coat was of a fine fibrous texture, and the fibres were diſpoſed nearly parallel to one another, and tranſverſe to the thickneſs of the piece: by degrees the glaſs became white and fibrous throughout, the external bluiſhneſs at the ſame time going off, and being ſucceeded by a dull whitiſh or dun colour. By a ſtill longer continuance in the fire, the fibres were changed gradually from the external to the internal part, and converted into grains; and the texture was then not unlike that of common porcelain. The grains, at firſt fine and ſomewhat gloſſy, became by degrees, larger and duller; and at laſt the ſubſtance of the glaſs became porous and friable, like a maſs of white ſand ſlightly cohering. 4. Concerning the qualities of this kind of porcelain, Dr Lewis obſerves, that, while it remained in the fibrous ſtate, it was harder than common glaſs, and more able to reſiſt the changes of heat and cold than glaſs, or even porcelain; but, in a moderate white heat, was fuſible into a ſubſtance not fibrous, but vitreous and ſmooth, like white enamel; that when its texture had become coarſely granulated, it was now much ſofter and unfuſible: and laſtly, that when ſome coarſely granulated unfuſible pieces, which, with the continuance of a moderate heat, would have become porous and friable, were ſuddenly expoſed to an intenſe fire, they were rendered remarkably more compact than before; the ſolidity of ſome of them being ſuperior to that of any other ware.

594 This ſubject ſtill imperfect.

It ſeems ſurpriſing that this able chemiſt, who on other occaſions had the improvements of the arts ſo much at heart, did not put ſome veſſels of this kind of porcelain to other ſevere trials, beſides attempting to fuſe it by itſelf with a violent fire: for though pieces of it were abſolutely unfuſible, we are not ſure but they might have been corroded by alkaline ſalts, acids, calcareous earths, or glaſs of lead; nay, it ſhould ſeem very probable that they would have been ſo: in which caſe they would not be much ſuperior to the veſſels made from earthy materials. When a firſt-rate chemiſt publiſhes any thing in an imperfect ſtate, inferior ones are diſcouraged from attempting to finiſh what he has begun; and thus, notwithſtanding that theſe experiments have been ſo long publiſhed, nobody has yet attempted to inveſtigate the properties of this kind of porcelain, by getting chemical veſſels made of it, and trying how they anſwer for crucibles, or retorts.

All that has been ſaid concerning the proper materials for crucibles, muſt likewiſe be applicable to the materials for retorts, which are required to ſtand a very violent heat. Mr Reaumur's porcelain bids faireſt for anſwering the purpoſe of retorts as well as crucibles. The great diſadvantage of the common, earthen ones, is, that they ſuffer a quantity of volatile and penetrating vapours to paſs through them. This is very obſervable in the diſtillation of phoſphorus; and though this ſubſtance has not hitherto been uſed for any purpoſe in medicine, and very little in the arts, its acid only being ſometimes uſed as a flux, if veſſels could be made capable of confining all the ſteams and at the ſame time bearing the heat neceſſary for its diſtillation, phoſphorus, perhaps, might be obtained in ſuch quantity, as to ſhow that it is a preparation not altogether uſeleſs.

595 [596] Stone-ware veſſels corroded.

With regard to ſtone-ware veſſels, and all thoſe into which the compoſition of ſand or flint enters, we ſhall only further obſerve, that they will be corroded by fixed alkaline ſalts, eſpecially of the cauſtic kind, in a very moderate heat. Dr Black, having evaporated ſome cauſtic ley in a ſtone-ware baſon, and then melted the dry ſalt in the ſame veſſel, found it ſo corroded, as afterwards to be full of ſmall holes; and he found nothing to reſiſt the action of this ſalt ſo well as ſilver.

597 Wedgewood's ware.

On the ſubject of chemical veſſels, we have now, however, to add the improved earthen ware of Mr Wedgewood; in which the properties of compactneſs, infuſibility and the power of reſiſting ſudden changes of heat and cold, are ſaid to be united, ſo that it promiſes to be a very valuable addition to the chemical apparatus.

598 Maceration.

11. Maceration, or Digestion. This is the mixing two bodies, generally a ſolid and a fluid, together, and then expoſing them to a moderate degree of heat for a conſiderable length of time, that ſo they may have the better opportunity of acting upon one another. Digeſtion is uſually performed in the glaſſes already mentioned, called *matraſſes* or *bolt-heads;* and is done in a ſand-heat. When any of the ſubſtances are very volatile, as ſpirit of wine; or when the matter requires to be heated ſo conſiderably that a quantity of vapour will be raiſed, the necks of the bolt-heads ought to be pretty long; or a tin pipe may be inſerted, of ſufficient length to prevent the eſcape of any part of the ſteam.

599 Levigation.

12. Levigation. This is the reducing any body to a very fine powder, which ſhall feel quite ſoft between the fingers or when put into the mouth. It is performed by grinding the ſubſtance upon a flat marble ſtone, with ſome water, or by rubbing it in a marble mortar. In the large way, levigation is performed by mills drawn by horſes, or driven by water; ſome of them are ſo ſmall as to be turned by the hand. They conſiſt of two ſmooth ſtones, generally of black marble, or ſome other ſtone equally hard, having ſeveral grooves in each, but made to run in contrary directions to one another when the mill is ſet in motion. The matter being mixed with water, is put in by a funnel, which is fixed into a hole in the upper ſtone, and turns along with it. The under milſtone has round it a wooden ledge, whereby the levigating matter is confined for ſome time, and at length diſcharged, by an opening made for that purpoſe, when it has accumulated in a certain quantity.

In this operation, when the matters to be levigated are very hard, they wear off a part of the mortar, or ſtones on which they are levigated; ſo that a ſubſtance perfectly hard, and which could not be worn by any attrition, is as great a deſideratum for the purpoſes of levigation, as one which could not be melted is for thoſe of fuſion. Dr Lewis propoſes the porcelain of Mr Reaumur as an improvement for levigating planes, mortars, *&c.* becauſe, while in its fibrous ſtate, it is conſiderably harder than glaſs, and conſequently much leſs liable to abraſion by the harder powders.

In many caſes levigation is very much accelerated by what is called *elutriation*. This is the method by which many of the painters colours are prepared of the requiſite fineneſs; and is performed by mixing any ſubſtance not totally reduced to the neceſſary degree of fineneſs, with a ſufficient quantity of water, and ſtirring them well together. The finer parts of the powder remain ſome time ſuſpended in the water, while the groſſer particles fall to the bottom. The ſeparation is then eaſily made, by pouring off the water impregnated with theſe fine parts, and committing the reſt to the levigating mill, when it may again be waſhed; and this may be repeated till all the powder is reduced to the utmoſt fineneſs. Subſtances ſoluble in water cannot be levigated in this manner.

Of Chemical Furnaces.

The two general diviſions we have already mentioned of thoſe who practice chemiſtry, namely, thoſe who have no other view than mere experiment, and thoſe who wiſh to profit by it, render very different kinds of furnaces neceſſary. For the firſt, thoſe furnaces are neceſſary which are capable of acting upon a ſmall quantity of matter, yet ſufficient for all the changes which fire can produce from ſimple digeſtion to the moſt perfect vitrification. For the others, thoſe are to be choſen which can produce the ſame changes upon very large quantities of matter, that as much may be done at once as poſſible.

600 Portable furnace.

To avoid the trouble and expence of a number of furnaces, a portable one hath long been a deſideratum among thoſe chemiſts who are fond of making experiments. One of the beſt of thoſe, if not the very beſt, that hath yet appeared, is that deſcribed in Shaw's edition of Boerhaave's chemiſtry, and repreſented fig. 1. Plate CXXXIV.

This furnace is made of earth; and, as the workmanſhip of a furnace requires none of the neatneſs or elegance which is required in making potters veſſels, any perſon may eaſily make a furnace of this kind for himſelf, who has time and patience for ſo doing. With regard to the moſt proper materials, all that we have ſaid concerning crucibles and retorts muſt be applicable to the materials for conſtructing a furnace; only here we need not care ſo much for the poroſity, or diſpoſition to crumble, as when crucibles or other diſtilling veſſels are to be made.

Plate iron is commonly directed for the outſide of portable furnaces; but we cannot help thinking this is a very needleſs expence, ſeeing the coating which it neceſſarily requires on the inſide may be ſuppoſed to harden to ſuch a degree as ſoon to ſupport itſelf, without any aſſiſtance from the plate-iron. This will be the leſs neceſſary, if we conſider, that, for the thickneſs of the walls of any furnace where a conſiderable heat is wanted, two or three inches are by no means ſufficient. When the inſide of a furnace is heated, the walls, if very thin, are ſoon penetrated by the heat, and great part of it by this means diſſipated in the air. If they are of a ſufficient thickneſs, the heat cannot penetrate ſo eaſily; and thus the inner part of the furnace preſerves the heat of the fuel, and communicates it to the contained veſſel. In the conſtruction of a portable furnace, therefore, it will be convenient to have all parts of it ſix inches thick at leaſt. This will alſo give it a ſufficient degree of ſtrength; and, as it is formed of ſeveral different peices, no inconvenience can follow from the weight of each of them taken ſeparately.

In Boerhaave's chemiſtry, this furnace is repreſented as narrower at the bottom than at the top; but we cannot ſuppoſe any good reaſon for ſuch a form, ſeeing a cylindrical one muſt anſwer every purpoſe much better, as allowing a larger quantity of air to paſs through the fuel, and likewiſe not being ſo apt to be overturned as it neceſſarily muſt be where the upper part is conſiderably heavier than the lower. We have, therefore, given a repreſentation of it as of a cylindrical form.

The furnace conſiſts of five or more parts. C, repreſents the dome, or top of the furnace, with a ſhort earthen funnel E for tranſmitting the ſmoke. B, B, B, are moveable cylinders of earth, each provided with a door D, D, D. In Boerhaave's chemiſtry theſe doors are repreſented as having iron hinges and latchets; but they may be formed to more advantage of ſquare pieces of earth, having two holes in the middle, by which they may be occaſionally taken out, by introducing an iron fork. In like manner, the domes and cylinders,

cylinders, in Boerhaave's chemiſtry, are repreſented with iron handles; but they may be almoſt as eaſily taken off by the cheaper contrivance of having four holes in each, two directly oppoſite to one another, into which two ſhort forks may be introduced when the parts are to be ſeparated.

In the lowermoſt cylinder is to be placed an iron-grate, a little below the door, for ſupporting the fire. In the under part is a ſmall hole, big enough for introducing the pipe of a pair of good perpetual bellows when the fire is to be violently excited. Dr Lewis prefers the organ-bellows to any other kind.

When the bellows is uſed, the whole muſt ſtand upon a cloſe cylinder A, that the air may be confined, and made to paſs through the fuel. By having more bellows, the fire may be excited to a moſt intenſe degree. In this caſe, the pipe of every one of them muſt enter the cylinder B.

Each of the cylinders ſhould have, in its upper part a round hole, oppoſite to its door, for carrying off the ſmoke, by means of a pipe inſerted into it, when the furnace is uſed for diſtillations by the ſand-bath. Each cylinder ought likewiſe to have a ſemicircular cut in the oppoſite ſides, both above and below, that when the under cut of the upper cylinder is brought directly above the upper cut of the lower one, a perfect circle may be formed. Theſe are for giving a paſſage to the necks of retorts, when diſtillation by the retort is to be performed. The holes may be occaſionally filled with ſtopples made of the ſame materials with the body of the furnace.

The moſt convenient ſituation for a furnace of this kind would be under a chimney, the vent of which might be eaſily ſtopped up by a broad plate of iron, in which a hole ought to be cut for the reception of the earthen tube of the dome. By this means the uſe of a long tube, which at any rate muſt be very troubleſome, might be eaſily avoided, and a very ſtrong blaſt of air would paſs through the fuel. If it is found convenient to place the furnace at ſome diſtance from the chimney, a plate-iron pipe muſt be procured to fit the earthen pipe of the dome, and carry the ſmoke into the chimney. This pipe will alſo be of uſe, when the furnace is uſed for diſtillations by the ſand-bath; it muſt then be inſerted into the hole oppoſite to the door of any of the cylinders, and will convey away the ſmoke, while the mouth of the cylinder is totally covered with a ſand-pot.

601
Dr Lewis's portable furnaces.

For portable furnaces, Dr Lewis greatly recommends the large black crucibles, marked n° 60, on account of their reſiſting a violent heat, and being very eaſily cut by a knife or ſaw, ſo that doors, &c. may be formed in them at pleaſure. The bottom of one of theſe large ones being cut out, a grate is to be put into the narrow part of it. For grates, the doctor recommends caſt iron-rings, having each three knobs around them. Theſe knobs go into correſponding cavities of the outer rings, and the knobs of the outermoſt reſt on the crucible, which is to be indented a little to receive them, that ſo the grate may reſt the more firmly, and the furnace not be endangered from the ſwelling of the iron by heat. When this is to be made uſe of as a melting-furnace, and a violent heat to be excited, another crucible muſt be inverted on that which contains the fuel, which ſerves inſtead of the dome of the laſt mentioned furnace: and as whatever is ſaid of it muſt likewiſe be applicable to the two crucibles when placed above one another, we need give no farther deſcription of the doctor's portable furnace.

602
Objection to their uſe in ſome caſes.

No doubt, the great experience of Dr Lewis, in chemical matters muſt give very conſiderable weight to any thing he advances; and the warmth with which he recommends the furnaces muſt convince us, that he has found them abundantly anſwer the purpoſes of experiments. We cannot help thinking, however, that where a very great and laſting heat is to be given, the thickneſs, and even the *form*, of theſe crucibles, is ſome objection to their uſe. It is certain that ſuch a permanent, or, as the workmen call it, a *ſolid* heat, can never be given where the walls of a furnace are thin, as when they are of ſufficient thickneſs. They are alſo very apt to burſt with great heat; and, for this reaſon, Dr Lewis deſires his furnace to be ſtrengthened with copper hoops. This diſpoſition to burſt proceeds from the inner parts which are more intenſely heated than the outer, expanding more than theſe do, and conſequently burſting them. Hence the doctor deſires his furnace to be ſtrengthened alſo by putting it within another crucible of a larger ſize, and the intermediate ſpace to be filled up with a mixture of ſifted aſhes and water. For moſt chemical proceſſes, where only a ſmall degree of heat is requiſite, theſe furnaces anſwer beyond any thing that has hitherto been attempted. The whole is to be ſupported by an iron ring with three feet

2d 602
Dr Black's furnace deſcribed. Plate CXXXIII fig. 5, 8, 9.

Dr Black has contrived a furnace in which all theſe inconveniences are avoided. Two thick iron plates, above and below, are joined by a thinner plate, forming the body of the furnace, which is of an oval form. The upper part is perforated with two holes; the one A, pretty large, which is the mouth of the furnace, and which is of a circular form: the other behind it, B, of an oval form, and deſigned for faſtening the end of the vent which is ſcrewed down upon it. The undermoſt thick plate has only the large circular opening G near to the middle, but not altogether ſo, being nearer to one ſide of the ellipſe than the other, where the round hole in the top is placed; ſo that a line paſſing this circular hole has a little obliquity forwards. The aſh-pit C E is likewiſe made of a nelliptical form, and a very ſmall matter widened; ſo that the bottom of the furnace is received within the ellipſe. A little below, there is a border D that receives the bottom of the furnace; and except the holes of the damping-plate E, the parts are all cloſed by means of ſoft lute, upon which the body of the furnace is preſſed down; by which means the joining of the two parts, and of all the different pieces, are made quite tight; for the body, fire place, aſh-pit, vent, and grate, are all ſeparable from one another. As the furnace comes from the workman, the grate is made to apply to the outſide of the lower part. It conſiſts of a ring laid on its edge, and then bars likewiſe laid on their edges; and from the outer ring proceed four pieces of iron, by means of which it may be ſcrewed down; ſo it is kept out of the cavity of the furnace, and preſerved from the extremity of the heat. Thus it laſts much longer, and indeed hardly liable to any decay; for by being expoſed to the cool air, it is kept ſo cool, that it is never hurt by the heat of the fuel. The ſides, which are made of plate iron muſt be luted within, to confine the heat, and preſerve them from its action.

603 How adapted to the various operations of chemiſtry.

To adapt this to the various operations of chemiſtry, we may obſerve, that for a melting furnace it is very convenient; we need only provide a cover for the opening above, which is made the door; and which being immediately over the grate, is convenient for introducing the ſubſtances to be acted upon, and for allowing us to look into the veſſel and take it out. This cover may be a piece of tile, or two bricks rendered flat and ſquare. Dr Black commonly uſes a kind of lid with a rim containing a quantity of lute; and to augment the heat, we may increaſe the height of the vent. It can be employed in moſt operations in the way of eſſaying; and the ſituation of the door allows us to ſee the ſubſtances very readily. It does not admit the introduction of the muffle; but can be employed in all thoſe operations where the muffle is made uſe of; and in Cornwall in England ſuch a furnace is made uſe of for eſſaying of metals. To preſerve the ſubſtance from the contact of the fuel, they cut off about a third part of the length of a brick, and then put it on one end on the middle of the grate. They chooſe their fuel of large pieces, that the air may have free paſſage through it, and open a little of the door, which occaſions a ſtream of air to flow in; and this ſtrikes upon the ſubſtance and produces the effect deſired; ſo that it may be uſed in the calcination of lead to convert it into litharge. It alſo anſwers very well in operations for producing vapour. If we deſire to employ it in diſtillations which require an intenſe heat, the earthen retort is to be ſuſpended by means of an iron ring having three branches ſtanding up from it, and which hangs down about half a foot from the hole; ſo that the bottom of the retort reſts upon the ring, and is immediately hung over the fuel: and the opening between the mouth of the furnace and retort is filled up with broken crucibles and potſherds, which are covered over with aſhes that tranſmit the heat very ſlowly; ſo it anſwers for diſtillations performed with the naked fire. Dr Black has ſometimes cauſed them be provided with a hole in the ſide, from which the neck of the retort may be made to come out; and in this way has diſtilled the phoſphorus of urine, which requires a very ſtrong heat. For diſtillations with retorts performed with the ſand-bath, there is an iron pot fitted for the opening of the furnace, which is ſet on and employed as a ſand-pot. The vent of the furnace then becomes the door; and it anſwers very well for that purpoſe; and is more eaſily kept tight than if it were in the ſide, and may be kept cloſe with a lid of charcoal and clay. In like manner it anſwers well for the common ſtill, which may be adapted to it; part of it being made to enter the open part of the furnace, and hang over the fire, as in Plate CXXXIII. fig. 8. and 9. that the bottom part of that ſtill may be made to enter; and the vent becomes the door, by which freſh fuel may be added. Indeed it is ſeldom neceſſary to add freſh fuel during any operation. In the ordinary diſtillations it is never neceſſary; and even in diſtilling mercury, phoſphorus, &c. it generally contains enough to finiſh the operation; ſo effectually is the heat preſerved from loſs or diſſipation, and ſo very ſlow is the conſumption of the fuel.

604 Luting proper for his furnace.

For luting this and other furnaces, the doctor finds nothing perferable to a ſimple mixture of ſand and clay. The proportions for ſtanding the violence of fire are four parts of ſand to one of clay; but when deſigned for the lining of furnaces, he uſes ſix or ſeven of ſand to one of clay, the more effectually to prevent the contraction of the latter; for it is known from experiments, that clay, when expoſed to a ſtrong heat, contracts the more in proportion to its purity. The ſand ſettles into leſs bulk when wet, and does not contract by heat, which it alſo reſiſts as well as the clay itſelf.

605 Method of applying the lute.

Beſides this outſide lining next the fire, Dr Black uſes another to be laid on next the iron of the furnace; and this conſiſts of clay mixed with a large portion of of charcoal duſt. It is more fit for containing the heat, and is put next to the iron, to the thickneſs of an inch and a half. That it may be pretty dry when firſt put in, he takes three parts by weight of the charcoal duſt, and one of the common clay, which muſt be mixed together when in dry powder, otherwiſe it is very difficult to mix them perfectly. As much water is added as will form the matter into balls; and theſe are beat very firm and compact by means of a hammer upon the inſide of the furnace. The other lute is then ſpread over it to the thickneſs of about half an inch, and this is alſo beat ſolid by hammering; after which it is allowed to dry ſlowly, that all cracks and fiſſures may be avoided: and after the body of the furnace is thus lined, the vent is ſcrewed on and lined in the ſame manner. It muſt then be allowed to dry for a long time; after which a fire may be kindled, and the furnace gradually heated for a day or two. The fire is then to be raiſed to the greateſt intenſity; and thus the luting acquires a hardneſs equal to that of free-ſtone, and is afterwards as laſting as any part of the furnace.

2d 605 Melting furnace.

When furnaces are uſed in the large way, they are always built of brick, and each particular operation has a furnace allotted for itſelf. The melting-furnace, where very large quantities of matter are not to be melted at once, requires only to be built of brick in ſuch a form as we have already deſcribed; only, as it would perhaps be troubleſome to procure a dome of the proper figure, the forepart of it may be left entirely open for the admiſſion of melting veſſels. The opening may be cloſed up with bricks and earth during the operation. There is no neceſſity for having the inſide of a circular form; a ſquare one will anſwer the purpoſe equally well. According to the author of the Chemical Dictionary, when the internal diameter D C of ſuch a furnace is 12 or 15 inches, the diameter of the tube G I 8 or 9 inches, and its height 18 or 20 feet, and when the ſurface is well ſupplied with fuel, and extreme heat is produced; in leſs than an hour the furnace will be white and dazzling like the ſun; its heat will be equal to the ſtrongeſt glaſs-houſe furnace; and in leſs than two hours will be melted whatever is fuſible in furnaces. The hotteſt part is at H F, 4 or 6 inches above the grate. A plate-iron tube may be advantageouſly ſupplied by a ſhort chimney of bricks, built under a pretty high vent, ſo as the whole may eaſily be ſtopped, except that paſſage which tranſmits the ſmoke of the furnace. By this means a very ſtrong current of air will be made to paſs through the fuel.

Plate CXXXIV. fig. 2.

606 Mr Pott's melting furnace deſcribed.

On this ſubject Dr Black informs us, that Mr Pott of Berlin employs one almoſt ſimilar to the above, for

for making experiments on earthen ware; by which he ſhowed that many ſubſtances formerly rekoned infuſible, might nevertheleſs be melted by fire raiſed to a very intenſe degree; and that ſeveral of theſe bodies, when mixed together, form compounds which may be melted without any difficulty. From this a tube ariſes to ſome height, and there is an additional tube which may be put on to the height of above 10 feet.

607 Reaſons for making the fire-place of a roundiſh form.

The fire-place is narrow below, but widens towards the middle, and contracts again at top, for the ſake of the veſſels which are put into it, and which are wider at top than at bottom. Thus the veſſel is equally heated, and there is room above for containing a quantity of fuel, which deſcends as faſt as it is conſumed. Different reaſons have been aſſigned for this form: thus Dr Boerhaave imagines that the melting furnace ſhould be made of a parabolic form, and Macquer, that it ſhould be in the form of an ellipſe; and that the crucible ſhould be placed in one of the foci, where they imagined the heat would be concentrated; but it is very plain, that the materials are ſuch as are not capable of reflecting the rays of heat in a regular manner; and even though they could do ſo, it would be to no purpoſe, becauſe the heat and light do not come from any ſingle point, but from a great number, ſtriking the furnace in all poſſible directions, and which muſt conſequently be reflected in directions as numerous. The furnace is made of iron lined with clay; and as it is difficult to beat out the iron into this roundiſh form, it may as well be made cylindrical; and it is eaſy to give the inſide what form we pleaſe by means of a luting of clay; neither need the dome have the roundiſh form, but may be ſimply made conical. The vent ſhould be made about two-thirds of the diameter of the furnace, or ſuch as will give an area of about one-half the grate. A ſmall portable furnace of this kind is very convenient for ordinary crucibles; the largeſt of which are only about four or five inches high; the wideſt part of the furnace may be beat out about 10 inches diameter; and when made of thin plate iron, and lined within, are very convenient, and may be heated at very little expence of fuel. But for heating much larger veſſels, it is proper to conſtruct them of brick, when they have pretty much the ſame form; only it is neceſſary to make them ſquare, and round on the inſide with a luting of ſand and clay. The top is generally made flat, and covered over with two or three bricks; the vent goes a little backwards, and then is raiſed to a proper height. Where the veſſel to be heated is very large, it is common to leave the front open for putting in the veſſel; and then to build it up with bricks, clay, and ſand; which can be eaſily pulled down again when the operation is over.

608 When bellows are neceſſary.

There are ſome caſes in which it is neceſſary to have a rapidity of inflammation even beyond what this furnace can give; and in theſe we have recourſe to bellows of various conſtructions, by which the air can be compreſſed and made to enter the fuel with great velocity. Theſe again are ſometimes wrought by water; but there is another machine which produces a greater effect, viz. the *water-blaſt* deſcribed by Lewis in his *Commercium Philoſoph. Technicum.*

609 In what caſes the eolipile may be made uſe of.

The eolipile too may be employed for driving air into fuel. The effect of this has been conſidered as a proof that air acts by its elaſticity in animating fuel, as an elaſtic fluid vapour from the eolipile produces, the ſame effect. But when we contrive to ſend ſteam inſtead of air, the ſame effect is not produced; and the true manner in which this inſtrument increaſes the inflammation is by driving air through the fuel: the ſteam from the veſſel ſpreading and mixing with the air, and driving it before it, makes it ſtrike upon the fuel.

Chemiſts have generally believed that a wide and high aſh-hole greatly increaſes the power of a melting furnace; but this advantage is found to be merely imaginary, as well as that of introducing the air through a long tube to the aſh-hole; unleſs where the furnace is placed in a cloſe room, ſo that it is neceſſary to furniſh a greater blaſt of air than can otherwiſe have acceſs.

For the form of the furnaces neceſſary in eſſaying and ſmelting of ores or making glaſs, ſee ESSAYING GLASS, and SMELTING.

610 Stills, ſand-pots &c. how to ſet.

When large ſtills, ſand-pots, &c. are to be fixed with a view to daily uſe, it is a matter of no ſmall conſequence to have them put up in a proper manner. The requiſites here are, 1. That the whole force of the fire ſhould be ſpent on the diſtilling veſſel or ſand-pot, except what is neceſſarily imbibed by the walls of the furnace. 2. That the veſſel ſhould be ſet in ſuch a manner as that they may receive heat even from the furnace walls; for a ſtill which contains any liquid can never be made ſo hot as a piece of dry brick. 3. It is abſolutely neceſſary that the force of the fire be not allowed to collect itſelf upon one particular part of the veſſel; otherwiſe that part will ſoon be deſtroyed. 3. The draught of air into furnaces of this kind ought to be moderate; only ſo much as will prevent ſmoke. If a ſtrong blaſt of air enters, not only a great part of the heat will be waſted by going up the chimney, but the outſide of the veſſel will be calcined every time the fire is kindled, and thus muſt be ſoon rendered unfit for uſe.

There are few of the common workmen that are capable of building furnaces properly; and it is very neceſſary for a chemiſt to know when they are properly done, and to make the workmen act according to his directions. As the ſtill, or whatever veſſel is to be fixed, muſt have a ſupport from the furnace on which it is built, it is evident the *whole* of its ſurface cannot be expoſed to the fire. For this reaſon many of theſe veſſels have had only their bottom expoſed to the fire, no more ſpace being left for the action of the heat, than the mere circular area of the ſtill bottom; and the fire paſſing directly through a hole in the back part of the building, which communicated with a chimney, and conſequently had a ſtrong draught, ſcarce ſpent any of its force on the ſtill, but went furiouſly up the chimney. By this means an extraordinary waſte of fuel was occaſioned; and that part of the ſtill-bottom which was next the chimney receiving the whole force of the flame, was ſoon deſtroyed. Attempts were made to remedy this inconvenience, by putting the fire ſomething forward, that it might be at greater diſtance from the chimney, and conſequently might not ſpend its force in the air. This too was found to avail very little. A contrivance was then fallen upon to make the vent paſs round the body of the ſtill in a ſpiral form. This was a conſiderable improvement; but had the inconvenience of making the fire ſpend itſelf uſeleſsly on the walls of the furnace, and beſides waſted that part of the ſtill which touched

the

the under part of the vent. A much better method is to build the back part of the furnace entirely cloſe, and make the fire come out through a long narrow opening before; after which it paſſes out through a flue in the back and upper part of the furnace into the chimney.

The only convenience of this form is, that the vent muſt either be very wide, or it is apt to choak up with ſoot, which laſt is a very troubleſome circumſtance. If the vent is made very wide, a prodigious draught of air ruſhes through the fuel, and increaſes the heat to ſuch a degree as to calcine the metal of which the ſtill is made; and, on the other hand, nothing can be more diſagreeable than to have the vent of a furnace ſtopped up with ſoot. Theſe inconveniences, however, are totally avoided by making two ſmall vents, one on each ſide of the diſtilling veſſel, which may communicate with a chimney by means of two tubes either of plate-iron or formed with clay or bricks, which may be occaſionally taken off if they happen to be choaked up. The veſſel is to be ſuſpended by three trunnions, ſo that the whole ſurface may be expoſed to the fire, excepting a ring the thickneſs of a brick all round; ſo that a very ſtrong heat will be communicated although the furnace draws but little. The two ſmall vents on each ſide will draw the flame equally; and by this means the moſt equable heat can be preſerved, and may be puſhed ſo far as to make the whole bottom and ſides of the veſſel intenſely red. Such a conſtruction as this is more eſpecially uſeful for ſand-pots, and thoſe which are uſed for diſtilling alkaline ſpirits from bones.

In the uſe of the furnaces hitherto deſcribed, the attendance of the operator is neceſſary, both for inſpecting the proceſſes, and for ſupplying and animating the fuel. There are ſome operations, of a ſlower kind, that require a gentle heat to be continued for a length of time; which demand little attendance in regard to the operations themſelves, and in which, of conſequence, it is extremely convenient to have the attendance in regard to the fire as much as poſſible diſpenſed with. This end has been anſwered by the furnace called *athanor*; but the uſe of it has been found attended with ſome inconveniences, and it is now gerally laid aſide.

611 Lamp furnace.

Sundry attempts have been made for keeping up a continued heat, with as little trouble as in the athanor, by the flame of a lamp; but the common lamp-furnaces have not anſwered ſo well as could be wiſhed. The lamps require frequent ſnuffing, and ſmoke much; and the ſoot accumulated on the bottom of the veſſel placed over them, is apt, at times, to fall down and put out the flame. The largeneſs of the wick, the irregular ſupply of oil from the reſervoir by jets, and the oil being ſuffered to ſink conſiderably in the lamp, ſo that the upper part of the wick burns to a coal, appeared to be the principal cauſes of theſe inconveniences; which accordingly were found to be in great meaſure remedied by the following conſtruction.

Plate CXXXIV. fig. 8.

The lamp conſiſts of a braſs pipe 10 or 12 inches long, and about a quarter of an inch wide, inſerted at one end into the reſervoir of the oil, and turned up at the other to an elbow, like the bole of a tobacco-pipe, the aperture of which is extended to the width of near two inches. On this aperture is fitted a round plate, having 5, 6, or 7 ſmall holes, at equal diſtances, round its outer part, into which are inſerted as many pipes about an inch long: into theſe pipes are drawn threads of cotten, all together not exceeding what in the common lamps form one wick: by this diviſion of the wick, the flame expoſes a larger ſurface to the action of the air, the fuliginous matter is conſumed and carried off, and the lamp burns clear and vivid.

The reſervoir is a cylindric veſſel, eight or ten inches wide, compoſed of three parts, with a cover on the top. The middle partition communicates, by the lateral pipe, with the wicks; and has an upright open pipe ſoldered into its bottom, whoſe top reaches as high as the level of the wick; ſo that, when this part is charged with oil, till the oil riſes up to the wicks in the other end of the lamp, any further addition of oil will run down through the upright pipe into the lower diviſion of the reſervoir. The upper diviſion is deſigned for ſupplying oil to the middle one; and, for that purpoſe, is furniſhed with a cock in the bottom, which is turned more or leſs, by a key on the outſide, that the oil may drop faſt enough to ſupply the conſumption, or rather faſter, for the overplus is of no inconvenience, being carried off by the upright pipe; ſo that the oil is always, by this means, kept exactly at the ſame height in the lamp. For common uſes, the middle diviſion alone may be made to ſuffice; for, on account of its width, the ſinking of the oil will not be conſiderable in ſeveral hours burning. In either caſe, however, it is expedient to renew the wicks every two or three days; oftener or ſeldomer according as the oil is more or leſs foul; for its impure matter, gradually left in the wicks, occaſions the flame to become more and more dull. For the more convenient renewing of them, there ſhould be two of the perforated plates; that when one is removed, another, with wicks fitted to it, may be ready to ſupply its place.

One of the black-lead pots, recommended by Dr Lewis for his portable furnace, makes a proper furnace for the lamp. If one is to be fitted up on purpoſe for this uſe, it requires no other aperture than one in the bottom for admitting air, and one in the ſide for the introduction of the elbow of the lamp. The reſervoir ſtands on any convenient ſupport without the furnace. The ſtopper of the ſide aperture conſiſts of two pieces, that it may be conveniently put in after the lamp is introduced; and has a round hole at its bottom fitting the pipe of the lamp. By theſe means, the furnace being ſet upon a trevet or open foot, the air enters only underneath, and ſpreads equally all around, without coming in ſtreams, whence the flame burns ſteady. It is not adviſeable to attempt raiſing the heat higher than about the 450th degree of Fahrenheit's thermometer; a heat ſomewhat more than ſufficient for keeping tin in perfect fuſion. Some have propoſed giving a much greater degree of heat in lamp-furnaces, by uſing a number of large wicks; but when the furnace is ſo heated the oil emits copious fumes, and its whole quantity takes fire. The balneum or other veſſel including the ſubject-matters, is ſupported over the flame by an iron ring, as already deſcribed in the ſand-bath and ſtill: a bath is here particularly neceſſary, as the ſubject would otherwiſe be very unequally heated, only a ſmall part of the veſſel being expoſed to the flame. Since the new invention of Argand's lamps, which perfectly conſume the oil, attempts have been made to

conſtruct

conſtruct lamp-furnaces on their principles; though, on the whole, it is to be doubted whether they are preferable to the above conſtruction or not.

Explanations of the Plates.

Plate CXXXIII. fig. 1. ſhows the figure of the ſtill recommended by Dr Black; the bottom formed in ſuch a manner as to go into his furnace. A, the body; B, the head; C C, the tube conveying the ſteam into the worm; D F, the figure of the worm; E, the worm-tub.

Fig. 2. A head taller than the common, proper for rectifying ardent ſpirits.

PART II. PRACTICE.

SECT. I. *Salts.*

§ 1. *Of the* VITRIOLIC *Acid, and its Combinations.*

612 Never found pure. THE vitriolic acid is never found pure, but always united with ſome proportion, either of phlogiſton or metallic and earthy ſubſtances. Indeed there is ſcarce any kind of earth which does not contain ſome portion of this acid, and from which it may always ſome way or other be ſeparable. When pure, the vitriolic acid appears in the form of a tranſparent colourleſs liquor. By diſtilling in a glaſs retort, the aqueous part ariſes, and the liquor which is left becomes gradually more and more acid. 613 Rectification. This operation is generally called the *rectification*, or *dephlegmation*, of the acid. After the diſtillation has gone on for ſome time, the water adheres more ſtrongly to what remains in the retort, and cannot be forced over without elevating part of the acid along with it. The remaining acid, being alſo exceedingly concentrated, begins to loſe its fluidity, and puts on the appearance of a clear oil. This is the ſtate in which it is uſually ſold, and then goes by the name of *oil of vitriol*. If the diſtillation is ſtill farther continued, with a heat below 600° of Fahrenheit's thermometer, the acid gradually loſes more and more of its fluidity, till at laſt it congeals in the cold, and becomes like ice. In this ſtate it is called the *icy oil of vitriol*. Such exceedingly great concentration, however, is only practiſed on this acid for curioſity. If the heat be ſuddenly raiſed to 600°, the whole of the acid riſes, and generally cracks the receiver. Clear oil of vitriol is immediately turned black by an admixture of the ſmalleſt portion of inflammable matter.

614 Attracts moiſture from the air. The icy oil of vitriol, and even that commonly ſold, attracts the moiſture of the air with very great force. Newmann relates, that having expoſed an ounce of this acid to the air, from September 1736 to September 1737, at the end of the twelvemonth it weighed ſeven ounces and two drachms; and thus had attracted from the air above ſix times its own weight of moiſture. This quantity, however, ſeems extraordinary; and it is probable, that in ſo long a time ſome water had been accidentally mixed with it; for Dr Gould, profeſſor at Oxford, who ſeems to have tried this matter fully, relates, that three drachms of oil of vitriol acquired, in 57 days, an increaſe only of ſix drachms and an half. The acid was expoſed in a glaſs of three inches diameter; the increaſe of weight the firſt day was upwards of one drachm; in the following days leſs and leſs, till, on the fifty-ſixth, it ſcarce amounted to half a grain. The liquor, when ſaturated with humidity, retained or loſt part of its acquired weight according as the atmoſphere was in a moiſt or dry ſtate; and this difference was ſo ſenſible as to afford an accurate hygrometer. Hoffman having expoſed an ounce and two ſcruples in an open glaſs-diſh, it gained ſeven drachms and a ſcruple in 14 days.

615 Productive both of cold and heat. This acid, when mixed with a large quantity of water, makes the temperature ſomething colder than before; but if the acid bears any conſiderable proportion to the water, a great heat is produced, ſo as to make the veſſel inſupportable to the hand; and therefore

fore ſuch mixtures ought very cautiouſly, or rather not at all, to be made in glaſs veſſels, but in the common ſtone-bottles, or leaden veſſels, which are not apt to be corroded by this acid. The greateſt heat is produced by equal parts of acid and water.

616 Quantity of alkali ſaturated by it.

Though the vitriolic acid unites itſelf very ſtrongly with alkalies, both fixed and volatile, it does not ſaturate near ſo much of the latter as of the former. A pound of oil of vitriol will ſaturate two of the common fixed alkali, but ſcarce one of volatile alkali. The ſpecific gravity of good oil of vitriol is to water as 17 to 8.

617 Effects on the human body.

If the concentrated acid is applied ſlightly and ſuperficially to the ſkin of a living animal, it raiſes a violent burning heat and pain; but a larger quantity preſſed on, ſo as to prevent the ingreſs of aerial moiſture, occaſions little pain or eroſion. If diluted with a little water, it proves corroſive in either caſe. Largely diluted with water, this acid is employed medicinally for checking putrefaction, abating heat, and quenching thirſt; in debilities of the ſtomach, and heartburn. To perſons of weak and unſound lungs, to women who give ſuck, to hydropic or emaciated perſons, it is injurious. Some recommend it as a collyrium for ſore eyes; but as it coagulates the animal juices, corroding and indurating the ſolids, it ſeems very unfit for being applied to that tender organ.

618 Difficulty of procuring it by itſelf.

The vitriolic acid is ſo much uſed in different arts and manufactures, that the making of it has become a trade by itſelf; and the procuring it in plenty, and at a cheap rate, would be a very advantageous piece of knowledge to any perſon who could put it in practice. This, however, is very far from being eaſily done; for though it exiſts in almoſt every mineral ſubſtance, the attraction betwixt this acid and the baſes with which it unites, is found to be ſo ſtrong, that we can only decompoſe ſuch combinations by preſenting another ſubſtance to the acid, to which it has a greater attraction than that one wherewith it is joined. Thus the firſt combination is indeed diſſolved, but we have another from which it is eqally difficult to extricate the acid by itſelf. Thus, if we want to diſengage the vitriolic acid from any metallic ſubſtance, ſuppoſe iron, this may be eaſily done by throwing a calcareous earth into a ſolution of green vitriol. We have now a compound of vitriolic acid with the calcareous earth, which is known by the name of *gypſum* or *ſelenites*. If we want to decompoſe this we muſt apply a volatile or or a fixed alkali; and the reſult of this will conſtantly be a new combination, which we are as unable to decompoſe, and indeed more ſo, than the firſt. There are two general methods which have been in uſe for procuring the vitriolic acid in ſuch quantity as to ſupply the demands of trade. The one is from pyrites, and the other from ſulphur.

I. From *Pyrites*, with the making of Copperas, and obtaining the pure Oil of Vitriol from it.

619 Pyrites, where found.

Pyrites are found in large quantity in the coal-mines of England, where moſt of the copperas is made. They are very hard and heavy ſubſtances, having a kind of braſſy appearance, as if they contained that metal; and hence they are called *braſſes* by the workmen. A very large quantity of theſe is collected, and ſpread out upon a bed of ſtiff clay to the depth of three feet. After being ſome time expoſed to the air, the uppermoſt ones loſe their metallic appearance, ſplit, and fall to powder. The heaps are then turned, the under part uppermoſt, ſo as to expoſe freſh pyrites to the air. When they are all reduced to powder, which generally requires three years, the liquor, which is formed by the rain-water running from ſuch a large maſs, becomes very acid, and has likewiſe a ſtyptic vitriolic taſte. It is now conveyed into large ciſterns lined with clay, whence it is pumped into a very large flat veſſel made of lead. This veſſel, which contains about 15 or 20 tons of liquor, is ſupported by caſt-iron plates about an inch thick, between which and the lead a bed of clay is interpoſed. The whole reſts upon narrow arches of brick, under which the fire is placed. Along with the liquor, about half a ton or more of old iron is put into the evaporating veſſel. The liquor, which is very far from being ſaturated with acid, acts upon the iron, and, by repeated filling up as it evaporates, diſſolves the whole quantity. By the time this quantity is diſſolved, a pellicle is formed on the ſurface. The fire is then put out; and as ſuch a prodigious quantity of liquor does not admit of filtration, it is left to ſettle for a whole day, and then is let off by a cock placed a little above the bottom of the evaporating veſſel, ſo as to allow the impurities to remain behind. It is conveyed by wooden ſpouts to a large leaden ciſtern, five or ſix feet deep, ſunk in the ground, and which is capable of containing the whole quantity of liquor. Here the copperas cryſtallizes on the ſides, and on ſticks put into the liquor. The cryſtallization uſually takes up three weeks. The liquor is then pumped back into the evaporating veſſel; more iron, and freſh liquor from the pyrites, are added; and a new ſolution takes place.

Copperas is uſed, in dyeing, for procuring a black colour; and is an ingredient in making common ink. It is alſo uſed in medicine as a corroborant, under the name of *ſalt of ſteel;* but before it is uſed with this intention, it is rediſſolved in water, and cryſtallized, with the addition of a little pure oil of vitriol. Whether it is at all mended by this ſuppoſed purification, either in appearance or quality, is very doubtful.

This proceſs furniſhes us firſt with a very impure vitriolic acid, which could not be applied to any uſeful purpoſe; afterwards with an imperfect neutral ſalt, called *green vitriol,* which is applicable to ſeveral purpoſes where the pure acid itſelf could not be uſed; but ſtill the acid by itſelf is not to be had without a very troubleſome operation.

620 Diſtillation of vitriolic acid from copperas.

Though this acid adheres very ſtrongly to iron, it is capable of being expelled from it by fire; yet not without a very violent and long-continued one. If we attempt to diſtil green vitriol in a retort, it ſwells and boils in ſuch a manner by the great quantity of water contained in its cryſtals, that the retort will almoſt certainly crack; and though it ſhould not, the ſalt would be changed into an hard ſtony maſs, which the fire could never ſufficiently penetrate ſo as to extricate the acid. It muſt therefore be calcined previous to the diſtillation. This is beſt done in flat iron-pans, ſet over a moderate fire. The ſalt undergoes the watery

Fig. 9

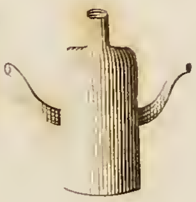

Fig. 3

Fig. 5

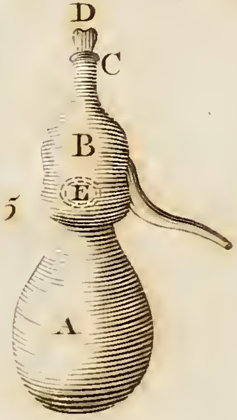

Fig. 7

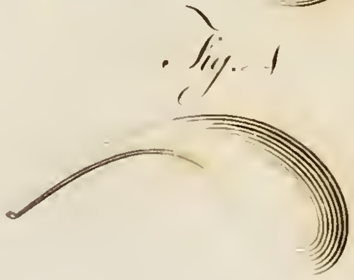
Fig. 4



Scot Philada sc

tery fuſion, (See Fusion); after which it becomes opaque and white. By a continuance of the fire, it becomes brown, yellow, and at laſt red. For the purpoſes of diſtillation, it may be taken out as ſoon as it has recovered its ſolidity.

The dry vitriol, being now reduced to powder, is to be put into an earthen retort, or rather long neck (a kind of retort where the neck iſſues laterally, that the vapours may have little way to aſcend), which it may nearly fill. This retort muſt be placed in a furnace capable of giving a very ſtrong heat, ſuch as the melting furnace we have already deſcribed. A large receiver is to be fitted on; and a ſmall fire made in the furnace to heat the veſſels gradually. White fumes will ſoon come over into the receiver, which will make the upper part warm. The fire is to be kept of an equal degree of ſtrength, till the fumes begin to diſappear, and the receiver grows cool. It is then to be increaſed by degrees; and the acid will become gradually more and more difficult to be raiſed, till at laſt it requires an extreme red, or even white, heat. When nothing more will come over, the fire muſt be ſuffered to go out, the receiver be unluted, and its contents poured into a bottle fixed with a glaſs ſtopper. A ſulphureous and ſuffocating fume will come from the liquor, which muſt be carefully avoided.

621 Preſervatives of wood.

In the retort, a fine red powder will remain, which is uſed in painting, and is called *colcothar of vitriol*. It is uſeful on account of its durability; and, when mixed with tar, has been employed as a preſervative of wood from rotting; but Dr Lewis prefers finely powdered pit-coal. As a preſervative for maſts of ſhips, he recommends a mixture of tar and lampblack; concerning which he relates the following anecdote.

"I have been favoured by a gentleman on board of a veſſel in the Eaſt-Indies, with an account of a violent thunder-ſtorm, by which the main-maſt was greatly damaged, and whoſe effects on the different parts of the maſt were pretty remarkable. All the parts which were greaſed or covered with turpentine were burſt in pieces: thoſe above, between, and below the greaſed parts, as alſo the yard-arms, the round-top or ſcaffolding, coated with tar and lamp-black, remained unhurt."

622 Rectification.

Oil of vitriol, when diſtilled in this manner, is always of a black colour, and muſt therefore be rectified by diſtillation in a glaſs retort. When the acid has attained a proper degree of ſtrength, the blackneſs either flies off, or ſeparates and falls to the bottom, and the liquor becomes clear. The diſtillation is then to be diſcontinued, and the clear acid which is left in the retort kept for uſe.

This was the firſt method by which the vitriolic acid was obtained; and from its being diſtilled from vitriol has ever ſince retained the name of *oil of vitriol*. Green vitriol is the only ſubſtance from which it is practicable to draw this acid by diſtillation; when combined with calcareous earths, or even copper (though to this laſt it has a weaker attraction than to iron), it reſiſts the fire moſt obſtinately. When diſtillation from vitriol was practiſed, large furnaces were erected for that purpoſe, capable of containing an hundred long necks at once: but as it has been diſcovered to be more eaſily procurable from ſulphur, this method has been laid aſide, and it is now needleſs to deſcribe theſe furnaces.

II. To procure the Vitriolic Acid from *Sulphur*.

623 Quantity of acid in ſulphur.

This ſubſtance contains the vitriolic acid in ſuch plenty, that every pound of ſulphur, according to Mr Kirwan's calculation, contains more than one-half of pure acid; which being in a ſtate perfectly dry, is conſequently of a ſtrength far beyond that of the moſt highly rectified oil of vitriol. Common oil of vitriol requires to be diſtilled to one-fourth of its quantity before it will coagulate when cold; and even in this ſtate it undoubtedly contains ſome water.

624 Quantity produced from it.

No method, however, has as yet been fallen upon to condenſe all the ſteams of burning ſulphur, at leaſt in the large way, nor is any other profitable way of decompoſing ſulphur known than that by burning; and in this way the moſt ſucceſsful operators have never obtained more than 14 ounces of oil from a pound of ſulphur.

625 Methods of obviating the difficulties in this proceſs.

The difficulties here are, that ſulphur cannot be burnt but in an open veſſel; and the ſtream of air, which is admitted to make it burn, alſo carries off the acid which is emitted in the form of ſmoke. To avoid this, a method was contrived of burning ſulphur in large glaſs globes, capable of containing an hogſhead or more. The fume of the burning ſulphur was then allowed to circulate till it condenſed into an acid liquor. A greater difficulty, however, occurs here; for though the ſulphur burns very well, its ſteams will never condenſe. It has been ſaid, that the condenſation is promoted by keeping ſome warm water continually ſmoking in the bottom of the globe; and even Dr Lewis has aſſerted this: but the ſteam of warm water immediately extinguiſhes ſulphur, as we have often experienced; neither does the fume of burning ſulphur ſeem at all inclinable to join with water, even when forced into contact with it. As it ariſes from the ſulphur, it contains a quantity of phlogiſton, which in a great meaſure keeps it from uniting with water; and the deſideratum is not ſomething to make the ſulphur burn freely, but to deprive the fumes of the phlogiſton they contain, and render them miſcible with water. For this purpoſe nitre has been advantageouſly uſed. This conſumes a very large quantity of the phlogiſton contained in ſulphur, and renders the acid eaſily condenſible: but it is plain that few of the fumes, comparatively ſpeaking, are thus deprived of the inflammable principle; for the veſſel in which the ſulphur and nitre are burnt, remains filled with a volatile and moſt ſuffocating fume, which extinguiſhes flame, and iſſues in ſuch quantity as to render it highly dangerous to ſtay near the place. It has been thought that nitre contributes to the burning of the ſulphur in cloſe veſſels; but this too is a miſtake. More ſulphur may be burnt in an oil of vitriol globe without nitre than with it, as we have often experienced; for the acid of the ſulphur unites with the alkaline baſis of the nitre, and forms therewith an uninflammable compound, which ſoon extinguiſhes the flame, and even prevents a part of the ſulphur from being burnt either at that time or any other.

626 Effervеſcence between the nitrous and ſulphureous fumes.

In the condenſation of the fumes of ſulphur by means of nitre, a remarkable effervеſcence happens, which naturally leads us to think that the condenſation is produced by ſome ſtruggle between the vitriolic and nitrous acids.—Dr Lewis is of opinion, that the acid thus obtained is perfectly free from an admixture of the nitrous acid: but in this he is certainly miſtaken; for, on rectifying the acid produced by ſulphur and nitre, the firſt fumes that come over are red, after which they change their colour to white. How the nitrous acid ſhould exiſt in the liquor, indeed, does not appear; for this acid is totally deſtructible by deflagration with charcoal: but it does not follow, that becauſe the nitrous acid is deſtroyed when deflagrated with charcoal, it muſt likewiſe be ſo if deflagrated with ſulphur. Indeed it certainly is not; for the clyſſus of nitre made with ſulphur is very different from that made with charcoal.

The proportions of nitre to the ſulphur, uſed in the large oil of vitriol works, are not known, every thing being kept as ſecret as poſſible by the proprietors. Dr Lewis reckons about ſix pounds of nitre to an hundred weight of ſulphur; but from ſuch experiments as we have made, this appears by far too little. An ounce and an half, or two ounces, may be advantageouſly uſed to a pound of ſulphur. In greater proportions, nitre ſeems prejudicial.

627 Lead veſſels, an improvement.

A very great improvement in the apparatus for making oil of vitriol, lies in the uſing lead veſſels inſtead of glaſs globes. The globes are ſo apt to be broken by accident, or by the action of the acid upon them, that common prudence would ſuggeſt the uſe of lead to thoſe who intend to prepare any quantity of vitriolic acid, as it is known to have ſo little effect upon the metal. The leaden veſſels, according to the beſt accounts we have been able to procure, are cubes of about three feet, having on one ſide a door about ſix inches wide. The mixture of ſulphur and nitre is placed in the hollow of the cube, in an earthen ſaucer, ſet on a ſtand made of the ſame materials. The quantity which can be conſumed at once in ſuch a veſſel is about two ounces. To prevent the remains from ſticking to the ſaucer, it is laid on a ſquare bit of brown paper. The ſulphur being kindled, the door is to be cloſe ſhut, and the whole let alone for two hours. In that time the fumes will be condenſed. The door is then to be opened; and the operator muſt immediately retire, to eſcape the ſuffocating fumes which iſſue from the veſſel. It will be an hour before he can ſafely return, and introduce another quantity of materials, which are to be treated preciſely in the ſame manner.

Where oil of vitriol is made in large quantities, the ſlowneſs of the operation requires a great number of globes, and conſtant attendance day and night. Hence the making of this acid is very expenſive: The apparatus for a large work uſually coſts L.1500. ſterling.

Vitriolic Acid COMBINED,

628 Vitriolated tartar.

I. *With Fixed Alkali.* Dilute a pound of oil of vitriol with ten times its quantity of water; diſſolve alſo two pounds of fixed alkaline ſalt in ten pounds of water, and filter the ſolution. Drop the alkali into the acid as long as any efferveſcence ariſes; managing matters ſo that the acid may prevail. The liquor will now be a ſolution of the neutral ſalt, called *vitriolated tartar*, which may be procured in a dry form, either by exſiccation or cryſtallization. In caſe the latter method is made uſe of, ſome more alkali muſt be added when it is ſet to evaporate, for this ſalt cryſtallizes beſt in an alkaline liquor.

629 [630] Different methods of preparing vitriolated tartar.

Other methods, beſides that above deſcribed, have been recommended for preparing vitriolated tartar; particularly that of uſing green vitriol inſtead of the pure vitriolic acid. In this caſe the vitriol is decompoſed by the fixed alkali: but as the alkali itſelf diſſolves the calx of iron after it is precipitated, it is next to impoſſible to procure a pure ſalt by ſuch a proceſs; neither is there occaſion to be ſolicitous about the preparation of this ſalt by itſelf, as the materials for it are left in greater quantity than will ever be demanded, after the diſtillation of ſpirit of nitre.

631 Uſes.

Vitriolated tartar is employed in medicine as a purgative; but is not at all ſuperior to other ſalts which are more eaſily prepared in a cryſtalline form. It is very difficultly ſoluble in water, from which proceeds the difficulty of cryſtallizing it: for if the acid and alkali are not very much diluted, the ſalt will be precipitated in powder, during the time of ſaturation.—It is very difficult of fuſion, requiring a ſtrong red heat; but, notwithſtanding its fixedneſs in a violent fire, it ariſes with the ſteam of boiling water in ſuch a manner as to be almoſt totally diſſipated along with it by ſtrong boiling.—This ſalt has been uſed in making glaſs; but with little ſucceſs, as the glaſs wherein it is an ingredient always proves very brittle and apt to crack of itſelf.

632 Glauber's ſalt.

If, inſtead of the vegetable fixed alkali, the vitriolic acid is ſaturated with the foſſile one called the *ſalt of Soda*, a kind of neutral ſalt will be produced, having very different properties from the vitriolated tartar. This compound is called *Glauber's ſalt*. It diſſolves eaſily in water, ſhoots into long and beautiful cryſtals, which contain a large quantity of water, in conſequence of which they undergo the aqueous fuſion when expoſed to heat. They are alſo more eaſily fuſible than vitriolated tartar.—This kind of ſalt was formerly much recommended as a purgative, and from its manifold virtues was intitled by its inventor *ſal mirabile*. It is, however, found to poſſeſs no virtue different from that of other purgative ſalts: and its uſe is, in many places, entirely ſuperſeded by a ſalt prepared from the *bittern*, or liquor which remains after the cryſtallization of ſea-ſalt, which ſhall be afterwards deſcribed.

633 Glauber's ſecret ſalt ammoniac.

II. *With volatile alkali.* Take any quantity of volatile alkaline ſpirit; that prepared with quicklime is perferable to the other, on account of its raiſing no efferveſcence. Drop into this liquor, contained in a bottle, diluted oil of vitriol, ſhaking the bottle after every addition. The ſaturation is known to be complete by the volatile ſmell of the alkali being entirely deſtroyed. When this happens, ſome more of the ſpirit muſt be added, that the alkali may predominate a little, becauſe the exceſs will fly off during the evaporation. The liquor, on being filtered and evaporated, will ſhoot into fine fibrous plates like feathers. This ſalt, when newly prepared, has a ſulphureous ſmell, and a penetrating pungent taſte. It readily diſſolves in water, and increaſes the coldneſs of the liquor; on ſtanding for a little time, it begins to ſeparate from the water, and vege-

vegetate, or ariſe in efflorefcences up the ſides of the glaſs. It eaſily melts in the fire; penetrates the common crucibles; and if ſublimed in glaſs veſſels, which requires a very conſiderable heat, it always becomes acid, however exactly the ſaturation was performed.

This ſalt has been dignified with the names of *Glauber's ſecret ſal ammoniac*, or *philoſophic ſal ammoniac*, from the high opinion which ſome chemiſts have entertained of its activity upon metals: but from Mr Pott's experiments, it appears, that its effects have been greatly exaggerated. It diſſolves or corrodes in ſome degree all thoſe metals which oil of vitriol diſſolves, but has no effect upon thoſe on which that acid does not act by itſelf.

634
Properties of the ſalts.

Gold is not touched in the leaſt, either by the ſalt in fuſion, or by a ſolution of it: the ſalt added to a ſolution of gold in aqua-regia occaſions no precipitation or change of colour. On melting the ſalts with inflammable matters, it forms a ſulphureous compound, which diſſolves gold in fuſion, in the ſame manner as compoſitions of ſulphur and fixed alkaline ſalt. Melted with ſilver, it corrodes it into a white clax, which partially diſſolves in water: it likewiſe precipitates ſilver from its ſolution in aquafortis. It acts more powerfully on copper; elevates a part of the metal in ſublimation, ſo as to acquire a bluiſh colour on the ſurface; and renders the greateſt part of the reſiduum ſoluble in water. This ſolution appears colourleſs, ſo that it could not be ſuppoſed to hold any copper; but readily diſcovers that it abounds with that metal, by the blue colour it acquires on an addition of volatile alkali, and the green calx which fixed alkalies precipitate. In evaporation it becomes green without addition. Iron is corroded by this ſalt in fuſion, and diſſolved by boiling in a ſolution of it. Zinc diſſolves more freely and more plentifully. Lead unites with it, but does not become ſoluble in water. Tin is corroded, and a part of the calx is ſoluble in boiling water. Of regulus of antimony alſo a ſmall portion is made ſoluble. Alkalies precipitate from the ſolution a bluiſh powder. Calcined biſmuth-ore treated with its equal weight of the ſalt, partly diſſolved in water into a pale red liquor, which became green from heat, in the ſame manner as tinctures made from that ore by aqua-regia. The undiſſolved part yielded ſtill, with frit, a blue glaſs. On treating mangaueſe in the ſame manner, aluminous cryſtals were obtained: the undiſſolved part of the manganeſe gave ſtill a violet colour to glaſs.

635
Gypſum.

III. *With Calcareous Earth*. This combination may be made by ſaturating diluted oil of vitriol with chalk in fine powder. The mixture ought to be made in a glaſs; the chalk muſt be mixed with a pretty large quantity of water, and the acid dropped into it. The glaſs muſt be well ſhaken after every addition, and the mixture ought rather to be over ſaturated with acid; becauſe the ſuperfluous quantity may afterwards be waſhed off; the *ſelenite*, as it is called, or *gypſum*, having very little ſolubility in water.

This combination of vitriolic acid with chalk or calcareous earth, is found naturally in ſuch plenty, that it is ſeldom or never made, unleſs for experiment's ſake, or by accident. Mr Pott indeed ſays, that he found ſome ſlight differences between the natural and artificial gypſum, but that the former had all the eſſential properties of the latter.

The natural gypſums are found in hard, ſemitranſparent maſſes, commonly called *alabaſter*, or *plaſter of Paris*. (See ALABASTER, GYPSUM, and PLASTER.) By expoſure to a moderate heat, they become opaque, and very friable. If they are now reduced to fine powder, and mixed with water, they may be caſt into moulds of any ſhape: they very ſoon harden without ſhrinking; and are the materials whereof the common white images are made. This property belongs likewiſe to the artificial gypſum, if moderately calcined.

636
Beaume's obſervations.

Mr Beaumé has obſerved, that gypſum may be diſſolved in ſome meaſure by acids; but is afterwards ſeparable by cryſtallization in the ſame ſtate in which it was before ſolution, without retaining any part of the acids. This compound, if long expoſed to a pretty ſtrong heat, loſes great part of its acid, and is converted into quicklime. In glaſs veſſels it gives over no acid with the moſt violent fire. It may be fuſed by ſuddenly applying a very intenſe heat. With clay it ſoon melts, as we have obſerved when ſpeaking of the materials for making crucibles. A like fuſion takes place when pure calcareous earth is mixed with clay; but gypſum bubbles and ſwells much more in fuſion with clay than calcareous earth.

From natural gypſum we ſee that vitriolated tartar may be made, in a manner ſimilar to its preparation from green vitriol. If fixed alkaline ſalt is boiled with any quantity of gypſum, the earth of the latter will be precipitated, and the acid united with the alkali. If a mild volatile alkali is poured on gypſum contained in a glaſs, and the mixture frequently ſhaken, the gypſum will in like manner be decompoſed, and a *philoſophic* ſal ammoniac will be formed. With the cauſtic volatile alkali, or that made with quicklime, no decompoſition enſues.

637
Alum of the ancients different from ours.

IV. *With Argillaceous Earth*. The produce of this combination is the aſtringent ſalt called *alum*, much uſed in dyeing and other arts. It has its name from the Latin word *alumen* called στυπτηρια by the Greeks; though by theſe words the ancients expreſſed a ſtalactitic ſubſtance containing very little alum, and that entirely enveloped in a vitriolic matter. The alum uſed at preſent was firſt diſcovered in the oriental parts of the world; though we know not when, or on what occaſion. One of the moſt ancient alum-works of which we have any account was that of *Roccho*, now Edeſſa, a city of Syria: and from this city was derived the appellation of *Roch-alum*; an expreſſion ſo little underſtood by the generality, that it has been ſuppoſed to ſignify *rock-alum*. From this, and ſome works in the neighbourhood of Conſtantinople, as well as at Phocaea Nova, now Foya Nova, near Smyrna, the Italians were ſupplied till the middle of the 15th century, when they began to ſet up works of a ſimilar kind in their own country. The firſt Italian alum-work was eſtabliſhed about 1459 by Bartholomew Perdix, or Pernix, a Genoeſe merchant, who had diſcovered the proper matrix, or ore of alum, in the iſland of Iſchia. Soon after the ſame material was diſcovered at Tolfa by John de Caſtro, who had viſited the alum manufactories at Conſtantinople. Ha-

Whence the name of rock alum is derived.

639
Alum-works ſet up in Italy.

ving obſerved the ilex aquilifolium to grow in the neighbourhood of the Turkiſh manufactories, and finding the ſame near Tolfa, he concluded that the materials for alum were to be found there alſo; and was quickly confirmed in his ſuſpicions by the taſte of the ſtones in the neighbourhood. Theſe alum-works proſpered exceedingly, and their ſucceſs was augmented by an edict of Pope Pius II. prohibiting the uſe of foreign alum.

640 In Spain, England, and Sweden.

In the 16th century an alum manufactory was erected at Alamaron, in the neighbourhood of Carthagena, where it ſtill continues. Several others were erected in Germany; and in the reign of Queen Elizabeth one was erected in England by Thomas Chaloner. The preparation of this ſalt was not known in Sweden till the 17th century.

641 Its component parts firſt diſcovered by Meſſ. Boulduc and Geoffroy.

The component principles of this ſalt were long unknown; but at laſt Meſſrs Boulduc and Geoffroy diſcovered, that it conſiſted of argillaceous earth ſuperſaturated with vitriolic acid. This is confirmed by the experiments of other chemiſts. It is found to redden the tincture and paper of turnſole; and on taking away the ſuperabundant acid, it loſes its ſolubility and all the other properties of alum. Mr Morveau, indeed, will not admit of a ſuperabundance of acid in alum, which he thinks would neceſſarily be ſeparated by edulcoration and cryſtallization; and he is of opinion with Mr Kirwan, that the turning vegetable juices red is not any unequivocal ſign of the preſence of an acid. In the preſent caſe, however, we certainly know that there is a ſuperabundance of acid, and that a certain portion of the vitriolic acid adheres to the clay leſs tenaciouſly than the remainder. If we put a piece of iron into a ſolution of alum, it will attract this portion of acid; and the vitriolated clay when deprived of the ſuperfluous quantity, will fall down to the bottom in an inſoluble powder.

642 Miſtake of Morveau detected by Mr Kirwan.

643 Alum deprived of its ſuperfluous acid inſoluble in water.

Alum in its ordinary ſtate contains a conſiderable quantity of water, and cryſtallizes by proper management into octohedral and perfectly tranſparent and colourleſs cryſtals. When expoſed to a moderate fire, it melts, bubbles, and ſwells up; being gradually changed into a light, ſpongy, white maſs, called *burnt alum*. This, with the addition of ſome vitriolic acid, may be cryſtallized as before. The principles it contains, therefore, are water, vitriolic acid, and argillaceous earth. The proportions may be aſcertained in the following manner. 1. The water and ſuperfluous vitriolic acid may be diſſipated by evaporation, or rather diſtillation; and the loſe of weight ſuſtained by the ſalt, as well as the quantity of liquid which comes over into the receiver, ſhows the quantity of aqueous phlegm and unſaturated acid. 2. By combining this with as much cauſtic fixed alkali as is ſufficient to ſaturate the acid which comes over, we know its proportion to the water; and by rediſtilling this new compound, we have the water by itſelf. 3. The earth may be obtained by precipitation with an alkali in its cauſtic ſtate, either fixed or volatile: but this part of the proceſs is attended with conſiderable difficulty; for the alkalies firſt abſorb the ſuperfluous acid, after which the earth combined to ſaturation with the acid falls to the bottom, and the digeſtion with the alkaline ſalt muſt be continued for a very conſiderable time before the acid is totally ſeparated. By analyſing alum in this manner, Mr Bergman determined the principles of alum to be 38 parts of vitriolic acid, 18 of clay, and 44 of water, to 100 of the cryſtallized ſalt.

644 Bergman's method of finding the ingredients and their proportions.

645 Difficulty in obtaining the pure earth of alum.

646 Proportions of ingredients according to Mr Bergman.

It has been a queſtion among chemiſts, whether the earth of alum is to be conſidered as a pure clay or not. The ſalt was extracted from common clay by Meſſrs Hellot and Geoffroy. The experiment was repeated with ſucceſs by Mr Pott; but he ſeemed to conſider it rather as the production of a new ſubſtance during the operation, than a combination of any principle already exiſting with the vitriolic acid. Margraaf, however, from ſome very accurate experiments, demonſtrated, that all kinds of clay conſiſt of two principles mechanically mixed: one of which conſtantly is the pure earth of alum. This opinion is eſpouſed by Bergman; who concludes, that ſince an equal quantity of it may be extracted from clay by all the acids, it can only be mixed with theſe clays; for if it was generated by the menſtrua during the operation, it muſt be procured in different quantities, if not of different qualities alſo, according to the difference of the ſolvents made uſe of. Notwithſtanding this, the matter ſeems to be rendered ſomewhat obſcure by an experiment of Dr Lewis. "Powdered tobacco-pipe clay (ſays he) being boiled in a conſiderable quantity of oil of vitriol, and the boiling continued to dryneſs, the matter when cold diſcovers very little taſte, or only a ſlight acidulous one. Expoſed to the air for a few days, the greateſt part of it was changed into lanuginous effloreſcences taſting exactly like alum. The remainder, treated with freſh oil of vitriol, in the ſame manner exhibits the ſame phenomena till nearly the whole of the clay is converted into an aſtringent ſalt." Hence he concludes, that the clay is in ſome degree changed before the aluminous ſalt is produced. Without this ſuppoſition, indeed, it is difficult to ſee why the ſalt ſhould not be produced immediately by the combination of the two principles. An hundred parts of cryſtallized alum requires, according to Mr Bergman, in a mean heat 1412 parts of diſtilled water, but in a boiling heat only 75 of the ſame parts for its ſolution. The ſpecific gravity of alum, when computed from the increaſe of bulk in its ſolution, is 2.071 when the air-bubbles are abſtracted; but if they are ſuffered to remain, it is no more than 1.757. Theſe bubbles conſiſt of aerial acid, but cannot be removed by the air-pump, though they fly off on the application of heat.

647 Whether the earth of alum be a pure clay or not.

648 Component parts of all kinds of clay inveſtigated by Margraaf.

649 Lewis's experiment, tending to ſhow that clay undergoes ſome change in being converted into earth of alum.

650 Solubility of alum in warm and in cold water.

651 Bergman's account of the Swediſh ores of alum.

The ores from which alum is prepared for ſale, according to Mr Bergman, are of two kinds: one containing the alum already formed, the other its principles united by roaſting. What he calls the aluminous ſchiſt, is nothing but an argillaceous ſchiſt impregnated with a dried petroleum, from whence the oil is eaſily extracted by diſtillation; but by applying proper menſtrua it diſcovers ſeveral other ingredients, particularly an argillaceous martial ſubſtance, frequently amounting to $\frac{3}{4}$ of the whole; a ſiliceous matter amounting to $\frac{1}{6}$; and commonly alſo a ſmall proportion of calcareous earth and magneſia; the reſt being all pyritous. By roaſting this ore the bituminous part is deſtroyed and the pyrites decompoſed; on which part of the vitriolic acid adheres to the iron of the pyrites, and the reſt to the pure clay of the ſchiſt, forming green vitriol with the former, and alum with the latter. If any calcareous earth or magneſia are preſent, gypſum and Epſom ſalt will be produced at the ſame time. No ſalt is obtained by

652 Component parts of the aluminous ſchiſt.

653 How changed by roaſting.

654 The preſence of pyrites only neceſſary for the production of alum.

by lixiviating this ſchiſt before calcination, though Mr Bergman thinks nothing more is neceſſary for the production of the ſalt but the preſence of a pyrites. This, he tells us, is generally diſperſed through the maſs in form of very minute particles, though it ſometimes appears in ſmall nuclei. The goodneſs of the ore, therefore, depends on the proper proportion of the pyrites to the clay, and its equal diſtribution through the whole. The moſt denſe and ponderous is moſt eſteemed, while that which contains ſo much pyrites as to be viſible is rejected as having too much iron. The ore which produces leſs than four pounds of alum from 100 of the ore does not pay the expence of manufacturing in Sweden. Sometimes this kind of ore produces ſalts without the application of fire; but this muſt be attributed to a kind of ſpontaneous calcination.

655 Ores containing alum ready formed, only to be met with in volcanic countries.

That ſpecies of ore which contains the principles already united into alum, according to Mr Bergman, is to be met with only in volcanic countries; and of this kind are the principal Italian ores of alum, particularly that employed at Tolfa near Cincelles, for boiling the Roman alum. Mr Monnet, however, is of opinion, that even this ore does not contain alum perfectly formed, but a combination of nearly equal parts of clay and ſulphur, which by expoſure to air during calcination, is converted into alum. He found a little martial earth alſo contained in it, to which he aſcribes the reddiſh colour of that alum. The aluminous ore at Solfatara in Italy conſiſts of old lava whitened by the phlogiſticated vitriolic acid. The clay thus becomes a component part of the aluminous ſalt, and the maſs effloreſces in the ſame manner, and for the ſame reaſon, as the maſs left after boiling tobacco-pipe clay in oil of vitriol mentioned by Dr Lewis. Mr Bergman, who examined this ore, found, that 100 pounds of it contained eight of pure alum, beſides four of pure clay; and that the remainder was ſiliceous. This proportion, however, muſt be very variable, according to the quantity of rain which falls upon the ore.

656 Aluminous ore at Solfatara in Italy.

657 Analyzed by Mr Bergman.

658 Aluminous ores in Haſſia, Bohemia, and Scania.

A variety of aluminous ores are to be met with in different parts of the world. In Haſſia and Bohemia this ſalt is obtained from wood impregnated with bitumen. At Helſingborg in Scania, a turf is found conſiſting of the roots of vegetables mixed with nuts, ſtraw, and leaves, often covered with a thin pyritous cuticle, which, when elixated, yields alum: Even the ſulphureous pyrites is generally mixed with an argillaceous matter, which may be ſeparated by menſtrua. In ſome places, ſulphur, vitriol, and alum are extracted from the ſame material. The ſulphur riſes by diſtillation; the reſiduum is expoſed to the air till it effloreſces, after which a green vitriol is obtained by lixiviation, and alum from the ſame liquor, after no more vitriol will cryſtallize. The *alum ſlate*, from which ſalt is made near York in England, contains a conſiderable quantity of ſulphur; and therefore produces alum on the principles already mentioned.

659 Alum, ſulphur, and vitriol extracted from the ſame ore.

660 Alum ſlate found at York in England.

661 Bergman's directions for the preparation of alum.

Mr Bergman has given very particular directions for the preparation of this ſalt from its ores, and minutely deſcribes the ſeveral operations which they muſt undergo. Theſe are.

662 Uſe of roaſting the ore.

1. ROASTING. This is abſolutely neceſſary in order to deſtroy the pyrites; for on this the formation of the alum entirely depends; as the ſulphur of the pyrites will not part with its phlogiſton without a burning heat in the open air. By long expoſure to the air, indeed, the ſame effect will follow; but unleſs the ore be of a particular kind, and looſe in texture, ſo that the air can freely pervade it, the proceſs we ſpeak of cannot take place. The hard ores, therefore, cannot be treated in this manner; and the earthy ores are not only unfit for ſpontaneous calcination, but for roaſting alſo, as they will not allow the air to pervade them and extinguiſh the fire. Such as are capable of ſpontaneous calcination, ſhould be ſupplied with ſome quantity of water, and laid on a hard clay bottom, as directed for making green vitriol. The roaſting is performed in Sweden in the following manner. Small pieces of the ore are ſtrewed upon a layer of burning ſticks to the thickneſs of half a foot. When the ſticks are conſumed, theſe are covered, nearly to the ſame thickneſs, with pieces burned before and four times lixiviated: Thus ſtrata are alternately laid of ſuch a thickneſs, and at ſuch intervals of time, that the fire may continue, and the whole maſs grow hot and ſmoke, but not break out into flame. The upper ſtrata may ſometimes be increaſed to a double thickneſs on account of the long continuance of the fire. When eight ſtrata are laid, another row is placed contiguous to the former; when this is finiſhed, a third; and ſo on until the heap be of a proper ſize, which rarely requires more than three rows. When the ore is once roaſted, it ſtill contains ſo much phlogiſton that water acts but little upon it; but after the operation is two or three times repeated, the ore yields its principles more freely: the roaſting may even be repeated to advantage till the whole be reduced to powder. The bitumen keeps up the fire; for which reaſon alternate layers of the crude ore are uſed; and in rainy weather theſe layers of unburnt ore ſhould be thicker. An heap, 20 feet broad at the baſe, two feet at the top, and conſiſting of 26 rows, is finiſhed in three weeks, but requires two or three months to be well burned, and three weeks to cool. The greater pyritous nuclei explode like bombs. In this proceſs the ſulphur of the pyrites is ſlowly conſumed, and the phlogiſticated acid penetrating the maſs, is fixed; after which the remaining phlogiſton is gradually diſſipated. The chief art conſiſts in moderating the heat in ſuch a manner as to avoid with ſafety the two extremes; for too ſmall a fire would not be capable of forming the ſalt, while a heat too ſtrong would deſtroy it by melting the ore. The ſcoria are inſoluble in water, and therefore thrown away as uſeleſs. They are produced by violent winds, or by a ſtrong heat too much cloſed up; for it is neceſſary to make holes in the red ſtrata, that the fire may reach the back ſtratum which is to be laid on. Another method of burning was invented by the celebrated Rinman, and is practiſed at a place called *Garphyttan* in Sweden. There the ore itſelf is ſet on fire; and after burning is boiled, and yields alum in the ſame manner as the former. The heaps are formed in the following manner: Firſt the ſchiſt, burning from the furnace, is laid to the depth of four feet; if the fire be ſlow, then wood is added; after that a thin ſtratum of elixated ſchiſt; the third conſiſts of ſchiſt not burned; and the fourth of elixated ſchiſt a foot and a half thick; after that the burning ſchiſt, and ſo on. This method, however, is attended with ſome inconveniences. The vitriolic acid is partly diſſipated by the fire, and thus

663 Expoſure to the air has ſometimes the ſame effect.

664 Earthy ores unfit for both operations.

665 Method of roaſting the ore in Sweden.

666 How often the operation is to be repeated.

667 Danger of raiſing the heat too much.

668 Rinman's method of burning the ore at Garphyttan.

the quantity of alum is diminiſhed: ſo much ſchiſt alſo is requiſite in this method that it cannot all be elixated; and thus the heap muſt be perpetually increaſing. The hard ores containing bitumen, ſuch as thoſe of Tolfa, are burned upon wood for ſome hours like limeſtone, until they become pervious to water, and effloreſce. The fire is extinguiſhed as ſoon as the flame becomes white, and the ſmell of ſulphureous acid begins to be perceived. When the ore cools, thoſe particles which were neareſt to the fire are placed outermoſt, and thoſe which had been outermoſt within, the fire being again lighted. The ore is ſufficiently burned when it can be broken with the hands. It is then heaped up near certain trenches, and watered five times a-day, particularly when the ſun ſhines clear; the operation being deſtroyed by a continued rain and cloudy ſky. In ſome places the ore is firſt burned and afterwards elixated; neither is there any way of knowing the proper methods of managing it but by experiment.

699 Method of burning the hard ores at Tolfa in Italy.

670 Method of elixating the burned ore at Garphyttan with cold water.

2. Elixation. This is performed in ſome places with hot, and at others with cold, water. At Garphyttan in Sweden, where the latter method is choſen, the receptacles, in the year 1772, were of hewn ſtone, having their joints united by ſome cement capable of reſiſting the liquor. Every ſet conſiſted of four ſquare receptacles diſpoſed round a fifth, which was deeper than the reſt. The firſt receptacle is filled with roaſted ſchiſt, and the ore lies in water for 24 hours; the water is then drawn off by a pipe into the fifth; from thence into the ſecond, containing ſchiſt not yet waſhed; from that in like manner, after 24 hours, through the fifth into the third, and ſo into the fourth The lixivium is then conveyed to the fifth, and allowed to ſtand in it; and laſtly is drawn off into a veſſel appropriated for its reception.—In other places the water paſſes over the ſchiſt that has been waſhed three times for ſix hours; then that which has been twice waſhed, next what has been once waſhed, and laſtly, the ore which has been newly roaſted. Thoſe who ſuperintend the alum manufactories are of opinion that the alum is deſtroyed by paſſing the water firſt over the newly burnt ore, and then over that which has been previouſly elixated.

671 Other methods.

672 Singular circumſtance by which the alum may be deſtroyed.

673 Of the proper ſtrength of the lixivium before boiling.

The lixivium, before boiling, ought to be as richly impregnated with alum as poſſible, in order to ſave fuel, though this is frequently neglected. In ſome places the taſte is uſed as the only criterion; but in others the weight of water which fills a ſmall glaſs bottle is divided into 64 equal parts, each of which is called in Sweden a *panning*; and the quantity by which the ſame bottle, full of lixivium, exceeds it when filled with water, is ſuppoſed to indicate the quantity of ſalt diſſolved.—This method may undoubtedly be reckoned ſufficiently accurate for work conducted on a large ſcale: and though Mr Bergman gives formulae by which the matter may be determined to a ſcrupulous exactneſs, it does not appear that ſuch accuracy is either neceſſary or indeed practicable in works conducted in a great way.

Thoſe who manage the alum manufactories aſſert, that the cold lixivium ought to be made no richer than when the weight of the bottle filled with lixivium exceeds it when filled with water by $4\frac{1}{5}$ pannings, which ſhows the water to be loaded with $\frac{1}{3.7}$ of its weight of alum. If the overplus amounts to ſix pannings, which indicates its containing $\frac{1}{5.4}$ of ſalt, cryſtals are then depoſited.—Congelation is of no uſe to concentrate the aluminous lixivium; for water ſaturated with alum freezes almoſt as readily as pure water.

674 Conſtruction of the evaporating veſſel.

3. Boiling the ley for chrystallization. The ley being firſt brought from the pits through canals made for the purpoſe, is put into a leaden boiler, at the back of which is a reſervoir, out of which the loſs ſuſtained by evaporation is conſtantly ſupplied, ſo that the ſurface of that in the boiler continues always nearly at the ſame height. Various ſigns are uſed by different manufacturers to know when the ley is properly evaporated: ſome determining the matter by the floating of a new laid egg; others by dropping a ſmall quantity on a plate, and obſerving whether it cryſtallizes on cooling; and laſtly, others weigh the lixivium in the bottle abovementioned. The boiling is ſuppoſed to be finiſhed if the increaſe of weight be equal to 10 pannings; that is, if the water be loaded with $\frac{1}{1.69}$ of its own weight. It might, however, take up above $\frac{1}{3}$ of its weight, or nearly 27 pannings; but as it has to be depurated by ſtanding quiet before the cryſtals are formed, the liquor muſt not be fully ſaturated with ſalt.

675 Proper ſtrength of the evaporated liquor.

676 Of the firſt cryſtallization.

The lixivium, when ſufficiently concentrated by evaporation, flows through proper channels into coolers, where it is allowed to reſt for about an hour to free it from the groſſer ſediment; after which it is put into wooden or ſtone receptacles to cryſtallize. In eight or ten days the remaining liquor, commonly called *mother ley*, or *magiſtral water*, is let off into another veſſel. A great number of cryſtals, generally ſmall and impure, adhere to the bottom and ſides of the veſſel, which are afterwards collected and waſhed in cold water.

677 Depuration of the cryſtals.

When a ſufficient quantity of the ſmall cryſtals are collected, thy muſt then be put into the boiler for depuration. They are now diſſolved in as ſmall a quantity of water as poſſible; after which the lixivium is poured into a great tub containing as much as the boiler itſelf. In 61 or 81 days the hoops of the tub are looſed, and the aluminous maſs bound with an iron ring; and in 28 days more the reſiduum of the ſolution is let out through a hole, and collected in a trench; after which the ſaline maſs, which at Garphyttan in Sweden amounts to 26 tons, is dried and ſold as depurated alum. The boiler emptied for the firſt cryſtallization is next filled two-thirds full with the magiſtral lixivium; and as ſoon as the liquor arrives at the boiling point, the other third is filled with crude lixivium, with which the evaporation is alſo conſtantly ſupplied. A certain quantity of the aluminous impurities left by waſhing the ſalts of the firſt cryſtallization in water is then added, and the above deſcribed proceſs repeated. Only the firſt boiling in the ſpring is performed with the crude lixivium alone, the reſt are all done as juſt now related.—Mr Bergman remarks, that the time required for cryſtallization may undoubtedly be ſhortened. The reſervoirs uſed in Sweden for this purpoſe (he ſays), are deep and narrow at the top; on which account they are not only long

678 Bergman's remarks on the proper form of the coolers.

long in cooling, but the evaporation, which is abſolutely neceſſary for the cryſtallization, goes on very ſlowly, excepting in extremely warm weather, at the ſame time that the doors and windows are diſpoſed in ſuch a manner as to direct a current of air along the ſurface. In Italy he tells us that conical reſervoirs are uſed with the wide part uppermoſt.

679
Alum cannot be formed by merely evaporating and cooling the ley, on account of the exceſs of acid.

It is remarkable, that pure alum cannot be obtained in very conſiderable quantity by merely evaporating and cooling the ley. The reaſon of this is, that the lixivium ſometimes acquires ſuch a conſiſtence, that it both cryſtallizes with difficulty, and produces impure cryſtals. The cauſe was unknown till the time of Mr Bergman, who has ſhown that it proceeds from an exceſs of vitriolic acid. Hence alſo we may ſee the reaſon why alkaline ſalts, volatile alkali in its pure ſtate, or even putrefied urine, when added to this thick ſolution, produce good cryſtals of alum when they cannot be obtained otherwiſe.

680
This exceſs cannot be removed by mineral alkali, though it may be by vegetable and volatile alkalies, and beſt of all by pure clay.

It is remarkable that this impediment to cryſtallization is not removed by mineral alkali, though it is ſo by the vegetable and volatile alkalies, which is a phenomenon hitherto unexplained. According to our author, however, an addition of pure clay, to abſorb the ſuperabundant acid, is preferable to any other; and indeed it is reaſonable to think ſo, as the union of vitriolic acid and pure clay forms the ſalt deſired, which is not the caſe with any of the alkalies. To aſcertain this, he made the following experiments.

681
Experiment ſhowing that an exceſs of vitriolic acid impedes the cryſtallization of alum.

1. He diſſolved 215 grains of pure alum in diſtilled water, in a ſmall cucurbit, and evaporated it over the fire till the ſurface of the liquor ſtood at two marks, which indicated, in a former evaporation, that it was fit for cryſtallization. 2. Having poured out this into a proper glaſs veſſel, he diſſolved other 215 grains, and added to the ſolution 24¼ grains of concentrated vitriolic acid. 3. This ſolution being likewiſe poured out, the experiment was repeated a third time, with the addition of 53 grains of vitriolic acid; and the glaſſes being at laſt ſet in a proper place for cryſtallization, the firſt yielded 155¾, the ſecond 130, and the third 100¼ grains of alum.

682
Experiment to determine the uſefulneſs of adding clay to the ley.

This ſhows that an exceſs of vitriolic acid impedes the cryſtallization of the alum; but to determine how far this could be remedied by the addition of clay, farther experiments were neceſſary. Having therefore employed a magiſtral reſiduum, in which the exceſs of acid was nearly in the proportion already related, he added two drachms of clay in fine powder to a kanne, or Swediſh cantharus, of the liquor: he boiled the mixture for ten minutes; and on ſeparating the clay that remained, he found that 25½ grains were diſſolved, which indicates an increaſe of 141 grains of alum. On gently boiling the liquor for half an hour, 75 grains of the clay were diſſolved, which indicated an increaſe of 416 grains of alum.

683
Advantages of uſing clay rather than alkalies.

The addition of clay muſt therefore be much preferable to that of alkaline ſalts, not only as the former produces a conſiderable increaſe of alum, but alſo as there is no danger of adding too much; for we have already ſhown, that when the liquor is entirely deprived of its ſuperabundant acid, the neutrallized clay is inſoluble in water. The earth itſelf, however, diſſolves ſo ſlowly, that there is not the leaſt danger of the acid being overſaturated by ſimply boiling them together.

684
Alum generally contaminated by dephlogiſticated vitriol.

Alum, as commonly made, though depurated by a ſecond cryſtallization, yet is almoſt always found contaminated by dephlogiſticated vitriol; whence it grows yellow, and depoſits an ochre in ſolution when old. This is equally uſeful in ſome arts with the pureſt kind, and is even ſo in dyeing where dark colours are required; but where the more lively colours are wanted, every thing vitriolic muſt be avoided. This is done by the addition of pure clay, which precipitates the iron, and produces an alum entirely void of any noxious or heterogeneous matter.

685
This defect remedied by the addition of pure clay.

Nor is this contrary to the laws of chemical attraction; for though iron is diſſolved by a ſolution of alum, and the earthy baſe of alum precipitated, and though in a ſolution of vitriol and alum the white earth falls firſt on an addition of alkali, and then the ochre; this happens only in conſequence of employing phlogiſticated or metallic iron, or ſuch as is but very little dephlogiſticated; for if the inflammable principle be any further diminiſhed, the attraction is thereby ſo much weakened, that the clay has a greater attraction for the vitriolic acid than the iron. The truth of this may be proved in many different ways. Thus, let a portion of alum be diſſolved in a ſolution of highly dephlogiſticated vitriol, and an alkali then added, the ochre of the vitriol will be firſt depoſited and then the clay: and provided there be a ſufficient quantity of the latter, the iron will all be precipitated; and hence we ſee that an aluminous ſolution mixed only with one of dephlogiſticaeated vitriol may readily be freed from it

686
Perfect vitriol cannot be deſtroyed by clay.

But a ſolution of alum containing perfect vitriol cannot be freed from it effectually either by clay or alkali; for the former effects no decompoſition, and the latter, although it can deſtroy the vitriol, will undoubtedly decompoſe the alum in the firſt place. As long, therefore, as the ſolution is rich in alum, in may be employed in the common manner; but when the vitriolic ſalt begins to predominate, it muſt either be cryſtallized in its proper form, or be deſtroyed in ſuch a manner as to produce alum, which may be accompliſhed in the following manner.

687
How the phlogiſton may be abſtracted from the vitriol.

Let the lixivium be reduced to a tenacious maſs with clay, and formed into cakes, which muſt be expoſed in an houſe to the open air. Thus the phlogiſton, which is powerfully attracted by the dephlogiſticated part of the atmoſphere, by degrees ſeparates from the iron, while the clay is taken up by its ſuperior attraction for the acid. The calcination is accelerated by fire; but it muſt be cautiouſly employed, leſt the acid ſhould be expelled.

688
Epſom ſalt may be produced from the mother liquor.

In the alum manufactories in Sweden, a conſiderable quantity of vitriolated magneſia, or Epſom ſalt, is mixed with the alum. Mr Bergman directs this to be ſeparated by means of an uncalcined calcareous earth, which entirely deſtroys both the alum and vitriol; falling down to the bottom with the acid in form of a ſelenitic matter. This muſt be added to the boiling liquor gradually, leſt the effervеſcence ſhould cauſe the maſs to ſwell and run over the top of the veſſel. A juſt proportion deſtroys both the aluminous and vitriolic ſalt, on being properly agitated and heated; neither is there any danger of the Epſom ſalt being decompoſed in this proceſs, the uncalcined earth being unable to ſeparate the magneſia from the acid. Were this method followed in the Swediſh manufactories, he is of opinion, that as much Epſom ſalt might be produced from them as would ſupply the conſumpt of that kingdom.

689 Superfluous acid might be advantageouſly diſtilled.

With regard to the quantity of ſuperfluous acid found in the magiſtral lixivium, Mr Bergman informs us, that it amounted to five ounces in one kanne; ſo that in a ſingle boiler there is nearly 250 lb. But vitriol, when well dephlogiſticated, retains its acid ſo looſely that it may eaſily be ſeparated by fire. He has no doubt, therefore, that if the ſurface of ſuch a lixivium were firſt increaſed in order to let the phlogiſton evaporate, the liquor might afterwards be advantageouſly committed to diſtillation for the ſake of its acid.

From what has been above delivered the neceſſity will be ſufficiently apparent of not continuing the coction even with pure clay to perfect ſaturation of the liquor: and this is further confirmed by M. Beaumé, who relates, that having boiled four ounces of earth of alum with two ounces of the ſalt, in a ſufficient quantity of water, the acid became ſaturated to ſuch a degree with earth, that the liquor loſt its aluminous taſte entirely, and aſſumed that of hard ſpring water. After filtration and evaporation, only a few micaceous cryſtals, very difficult of ſolution, were formed by letting the liquor ſtand for ſome months.—Dr Sieffert informs us, that by boiling half an ounce of alum with half a drachm of ſlaked lime, cubical cryſtals of alum may be obtained.

690 Epſom ſalt.

V. *With Magneſia.* The earthy ſubſtance called *magneſia alba* is never found by itſelf, and conſequently this combination cannot originally take place by art. The vitriolic acid, however, is found combined with magneſia in great plenty in the bitter liquor which remains after the cryſtallization of common ſalt; from whence the magneſia is procured by precipitating with a fixed alkali. If this liquor, which, when the common ſalt is extracted, appears like clean oil of vitriol, is ſet by for ſome time in a leaden veſſel, a large quantity of ſalt ſhoots, very much reſembling Glauber's ſal mirabile. This ſalt is in many places ſold inſtead of the true Glauber's ſalt; and is preferred to it, becauſe the true ſal mirabile calcines in dry air, which the ſpurious kind does not. If after the firſt cryſtallization of the bittern, the remainder is gently evaporated farther, a freſh quantity of Glauber's ſalt will ſhoot; and if the liquor is then haſtily evaporated, a ſalt will ſtill be cryſtallized; but inſtead of large regular cryſtals, it will concrete into very ſmall ones, having ſomething of the appearance of ſnow when taken out of the liquid. Theſe ſalts are eſſentially the ſame, and are all uſed in medicine as purgatives. The ſalt ſhot into ſmall cryſtals is termed *Epſom ſalt,* from its being firſt produced from the purging waters at Epſom in England. The bittern affording this kind of ſalt in ſuch great plenty, theſe waters were ſoon neglected, as they yielded it but very ſparingly, and the quantity prepared from them was inſufficient for the demand. Neumann ſays, that having inſpiſſated 100 quarts of Epſom water, he ſcarce obtained half an ounce of ſaline matter.—According to Mr Scheele's experiments, if a ſolution of Epſom and common ſalt be mixed together, a double decompoſition enſues, and the mixture contains Glauber's ſalt and a combination of magneſia with marine acid. From this lixivium the Glauber's ſalt may be cryſtallized in winter, but not in ſummer; a great degree of cold being neceſſary for this purpoſe. From twelve pounds of Epſom ſalt and ſix of common ſalt, Mr Scheele obtained, in a temperature three degrees below the freezing point, ſix pounds of Glauber ſalt; but in a degree of cold conſiderably greater, the produce was ſeven pounds and three quarters.

691 With ſilver.

VI. *With Silver.* Oil of vitriol boiled on half its weight of ſilver-filings, corrodes them into a ſaline maſs. This ſubſtance is not uſed in medicine nor in the arts. The only remarkable property of it is, that it has a very ſtrong attraction for mercury; coagulating and hardening as much quickſilver as the acid weighed at firſt. If the hard concrete be diluted with freſh acid, it melts eaſily in the fire, and does not part with the mercury in the greateſt heat that glaſs veſſels can ſuſtain. The vitriolic acid, by itſelf, ſtrongly retains mercury, but not near ſo much as when combined with ſilver.

Silver thus corroded by the vitriolic acid, or precipitated by it from the nitrous, may in great part be diſſolved, by cautiouſly applying a very little water at a time; and more effectually by boiling in freſh oil of vitriol.

692 Copper.

VII. *With Copper.* With this metal the vitriolic acid cannot be combined, unleſs in its concentrated ſtate, and ſtrongly heated. If pure oil of vitriol is boiled on copper filings, or ſmall pieces of the metal, it diſſolves it into a liquor of a deep blue colour, which eaſily cryſtallizes. The cryſtals are of a beautiful blue colour, and are ſold under the name of *blue vitriol,* or *Roman vitriol.*

693 Blue vitriol, how made.

Where ſulphur is found in great plenty, however, Roman vitriol is made by ſtratifying thin plates of copper with ſulphur; and upon ſlowly burning the ſulphur, its acid corrodes the copper. The metal is then to be boiled in water, that the ſaline part may be diſſolved. The operation is to be repeated till all the copper is conſumed; and all the ſaline liquors are to be evaporated together to the cryſtallizing point. By this method, however, a great part of the acid is loſt; and in Britain, where the ſulphur muſt be imported, we ſhould think the pure acid preferable for thoſe who prepare blue vitriol.

694 Phenomena on diſtillation.

This ſalt, on being expoſed to the fire, firſt turns white, then of a yellowiſh red colour. On urging it with a ſtrong fire, the acid ſlowly exhales, and a dark red calx of copper remains. The whole of the vitriolic acid cannot be expelled from copper by heat: as much of it ſtill remains as to render a part of the metal ſoluble in water. After this ſoluble part has been extracted, a little acid is ſtill retained amounting to about $\frac{1}{4}$ of the calx.

695 Uſes.

Vitriol of copper is employed in medicine as a cauſtic, in which reſpect it is very uſeful; but when uſed internally, is dangerous, as indeed all the preparations of copper are found to be. It has, nevertheleſs, according

cording to Neumann, been recommended in all kinds of intermittents, and the lepra. The ſmalleſt portion, he ſays, occaſions a ſickneſs and nauſea; a ſomewhat larger, reaching and violent vomitings, accompanied often with convulſions. If the quantity taken has been conſiderable, and is not ſoon diſcharged by vomiting, the ſtomach and inteſtines are corroded, intenſe pains, inflammations, and death, ſucceed.

696 Iron.

VIII. *With Iron.* The vitriolic acid does not act upon this metal till conſiderably diluted. Common oil of vitriol requires to be mixed with ten or twelve times its quantity of water before it will act briſkly on the metal. In this ſtate it efferveſces violently with iron filings, or ſmall bits of the metal, and a great quantity of inflammable vapour is diſcharged (ſee Air). The liquor aſſumes a fine green colour; and by evaporation and ſlow coolings, very beautiful rhomboidal cryſtals are formed. Theſe are named *ſalt of ſteel*, and are uſed in medicine; but for the ſalt made of the pure acid and iron, the common copperas, made with the impure acid extracted from pyrites, is commonly ſubſtituted. This is generally eſteemed a venial fraud, and no doubt is ſo in medicinal reſpects; but when it is conſidered, that, by this ſubſtitution, common copperas is impoſed on the ignorant, at the price of 2 *s per* pound, the affair appears in a different light.

697 Salt of Steel

698 Precipitation of iron from the vitriolic acid.

Pure vitriol of iron is originally of a much more beautiful appearance than common copperas, and retains its colour much better; the reaſon of which is, that the ſalt thus prepared has more phlogiſton than the copperas. If either of the kinds, however, are expoſed to the air for a ſufficient length of time, part of the acid is diſſipated, and the vitriol becomes yellowiſh or browniſh. If the ſalt is now diſſolved in water, a brown precipitate falls, which is part of the iron in a calcined ſtate. If the liquor is ſeparated from this precipitate by filtration, a ſimilar one forms in a ſhort time, and by long ſtanding a conſiderable quantity ſubſides. According to Dr Lewis, the precipitation is greatly expedited by a boiling heat; by which more of the metal ſeparates in a few minutes than by ſtanding without heat for a twelvemonth. This change takes place in no other metallic ſolutions.

699 Yellow for houſe painting.

The calx of iron, precipitated by quicklime from green vitriol, appears, when dry of a yellow colour; and it is recommended in the Swediſh tranſactions, inſtead of yellow ochre, as a colour for houſe-painting.

700 Preſervative for wood.

Solutions of green vitriol are alſo recommended for preſerving wood, particularly the wheels of carriages, from decay. When all the pieces are fit for being joined together, they are directed to be boiled in a ſolution of vitriol for three or four hours; and then kept in a warm place for ſome days to dry. By this preparation, it is ſaid, wood becomes ſo hard, that moiſture cannot penetrate it; and that iron nails are not ſo apt to ruſt in this vitriolated wood as might be expected, but laſt as long as the wood itſelf.

701. Tin.

IX. *With Tin.* This metal cannot be diſſolved in the vitriolic acid, but in the ſame manner as ſilver; namely, by boiling concentrated oil of vitriol to dryneſs upon filings of the metal. The ſaline maſs may then be diſſolved in water, and the ſolution will cryſtallize. The ſalt, however, formed by this union, is not applied to any uſeful purpoſe. A ſalt of tin, indeed, formed by the union of vitriolic acid with this metal, has been recommended for ſome medical purpoſes, and proceſſes are given for it in the diſpenſatories; but they have never come much into practice.

702 Lead.

X. *With Lead.* While lead is in its metallic ſtate, the vitriolic acid acts very little upon it, either in a diluted or concentrated ſtate; but if the metal is diſſolved in any other acid, and oil of vitriol added, a precipitation immediately enſues, which is occaſioned by the combination of vitriolic acid with the lead. This precipitate will be more or leſs white as the metal is more or leſs deprived of its phlogiſton by calcination before ſolution. If a little ſtrong ſpirit of nitre is poured upon *litharge*, which is lead calcined to the greateſt degree poſſible without vitrification, the acid unites itſelf to the metal with conſiderable efferveſcence and heat. Some water being now poured on, and the phial containing the mixture ſhaken, a turbid ſolution of the litharge is made. If a little oil of vitriol is then added, it throws down a beautifully white precipitate; and the acid of nitre, being left at liberty to act upon the remaining part of the litharge, begins anew to diſſolve it with efferveſcence. When it is again ſaturated, more oil of vitriol is to be dropped in, and a white precipitate is again thrown down. If any of the litharge is ſtill undiſſolved, the nitrous acid, being ſet at liberty a ſecond time, attacks it as at firſt; and by continuing to add oil of vitriol, the whole of the litharge may be converted into a moſt beautiful and durable white. Unfortunately this colour cannot be uſed in oil, though in water it ſeems ſuperior to any. If the proceſs is well managed, an ounce of ſpirit of nitre may be made to convert ſeveral pounds of litharge into a white of this kind.

703 A beautiful white colour.

704 Quickſilver.

XI. *With Quickſilver.* The diſſolution of quickſilver in vitriolic acid cannot be performed but by a concentrated oil and ſtrong boiling heat. The metal is firſt corroded into a white calx, which may afterwards be eaſily diſſolved by an addition of freſh acid. Every time it is diſſolved, the mercury becomes more and more fixed and more difficult to dry. If the exſiccation and diſſolution has been repeated ſeveral times, the matter becomes at laſt ſo fixed as to bear a degree of red heat. This combination is the baſis of a medicine formerly of ſome repute, under the name of *turbith mineral*. The proceſs for making turbith mineral is given by the author of the Chemical Dictionary as follows.

705 Turbith mineral.

“Some mercury is poured into a glaſs retort, and upon it an equal quantity of concentrated oil of vitriol, or more, according to the ſtrength of the acid. Theſe matters are to be diſtilled together, in the heat of a ſand-bath, till nothing remains in the retort but a dry ſaline maſs, which is a combination of the vitriolic acid and mercury. The acid which paſſes into the receiver is very ſuffocating and ſulphureous; which qualities it receives from the phlogiſton of the mercury. The white ſaline maſs which is left at the bottom of the retort is to be put into a large veſſel; and upon it are to be poured large quantities of hot water at ſeveral different times. The water weakens the acid, and takes it from the mercury; which is then precipitated towards the bottom of the veſſel, in form of a very ſhining yellow powder. The water with which it is waſhed contains the acid that was united with the mercury, and likewiſe a little mercury rendered ſoluble by means of the very large quantity of acid

Moſt chemiſts have believed, that a portion of vitriolic acid remains united with the turbith mineral, only too little to render it ſoluble in water. But Mr Beaumé, having examined this matter, affirms, that turbith mineral contains no acid, when it has been ſufficiently waſhed; and that, by frequently boiling this preparation in a large quantity of diſtilled water, not a veſtige of acid will adhere to it."

706 Dr Lewis's directions. Dr Lewis, who is of opinion that the whole of this mercurial calx is ſoluble in a very large quantity of water, deſires the water with which it is waſhed to be impregnated with ſome alkaline ſalt; which makes the yield of turbith greater than when pure water is uſed. The author of the Chemical Dictionary alſo obſerves, that the precipitate remains white till well freed from the acid; and the more perfectly it is waſhed, the deeper yellow colour it acquires.

707 Zinc. XII. *With Zinc.* This ſemimetal is not acted upon by the vitriolic acid in its concentrated ſtate; but, when diluted, is diſſolved by it with effervеſcence, and with the extrication of an inflammable vapour in the ſame manner as iron. Neumann obſerves, that, during the diſſolution, a grey and blackiſh ſpongy matter fell to the bottom; but, on ſtanding for ſome days, was taken up, and diſſolved in the liquor, nothing being left but a little yellowiſh duſt ſcarcely worth mentioning. Six parts of oil of vitriol, diluted with an equal quantity of water, diſſolves one part of zinc.

708 White vitriol. The product of this combination is *white vitriol;* which is uſed in medicine as an ophthalmic, and in painting for making oil-colours dry quickly: what is uſed for this purpoſe, however, is not made in Britain, but comes from Germany. It is made at Goſlar by the following proceſs. An ore containing lead and ſilver, having been previouſly roaſted for the obtaining of ſuphur (ſee METALLURGY), is lixiviated with water, and afterwards evaporated in leaden boilers, as for the preparation of green vitriol: but here a regular cryſtallization is prevented; for when the ſalt has aſſumed any kind of cryſtalline form, theſe cryſtals are made to undergo the watery fuſion in copper caldrons. It is then kept conſtantly ſtirring till a conſiderable part of the moiſture is evaporated, and the matter has acquired the conſiſtence of fine ſugar. White vitriol generally contains ſome ferruginous matter, from which it may be entirely freed by ſome freſh zinc; for this ſemimetal precipitates from the vitriolic acid all other metallic ſubſtances; but notwithſtanding this ſtrong attraction, the vitriolic acid is more eaſily expelled by diſtillation from white than green or blue vitriol. Towards the end of the diſtillation of white vitriol, the acid ariſes exceedingly concentrated, though ſulphureous: ſo that, if mixed with common oil of vitriol, it will heat it almoſt as much as oil of vitriol heats water.

709 Regulus of antimony. XIII. *With Regulus of Antimony.* To combine vitriolic acid with regulus of antimony, the ſame method muſt be uſed as directed for uniting it with quickſilver, for making turbith mineral, *viz.* to employ a very concentrated acid, and to diſtil in cloſe veſſels. The ſame phenomena alſo occur in this caſe as in making turbith mineral; a very ſuffocating ſulphureous acid ariſes; and as Mr Geoffroy obſerves, a true ſulphur ſublimes into the neck of the retort; a white, ſaline, tumefied, maſs remains in the veſſel; and when the veſſels are unluted, a white fume iſſues, as in the ſmoking ſpirit of libavius. See *Combinations of marine acid with tin,* infra.

710 Regulus of cobalt. XIV. *With Regulus of Cobalt.* From a combination of the vitriolic acid with cobalt, a red ſalt may be obtained. To procure it, one part of cobalt, reduced to a very fine powder, may be mixed with two or three of concentrated acid, diluting the liquor after it has been digeſted for 24 hours, and then filtering and evaporating it.

711 Arſenic. XV. *With arſenic.* Neumann relates, that powdered white arſenic being diſtilled in a retort with oil of vitriol, a tranſparent ſublimate like glaſs aroſe, which in a few days loſt its tranſparency, and became opaque like the arſenic itſelf. The arſenic remaining in the retort ſuſtained an open fire without any ſenſible alteration. The author of the Chemical Dictionary ſays, that if a concentrated vitriolic acid is diſtilled from arſenic, the acid which comes over ſmells exactly like marine acid. When the ſolution is diſtilled till no more acid ariſes, the retort is then almoſt red-hot, and no arſenic is ſublimed; but remains fuſed at the bottom of the retort; and, when cold, is found to be an heavy, compact maſs, brittle and tranſparent as cryſtal-glaſs. This kind of arſenical glaſs, expoſed to the air, ſoon loſes its tranſparency from the moiſture it attracts, which diſſolves and partly deliquiates it. This deliquium is extremely acid—By digeſting one part of arſenic with two of concentrated oil of vitriol, diluting the ſolution with water, and then filtering and evaporating, we obtain a yellowiſh ſalt which ſhoots into pyramidal, tranſparent, and ſhining cryſtals. None of the three laſt mentioned combinations have been found applicable to any uſeful purpoſe.

712 Oil. XVI. *With Oil.* The product of this combination is a thick black ſubſtance, very much reſembling balſam of ſulphur in colour and conſiſtence; to which it is ſometimes ſubſtituted. If this ſubſtance is diſtilled with a gentle heat, great part of the acid becomes volatile, and evaporates in white fumes, having a pungent ſmell reſembling that of burning ſulphur. 713 Volatile ſulphureous acid. This goes by the name of *volatile* or *ſulphureous vitriolic acid*; and a ſalt was formerly prepared from it by ſaturation with fixed alkali, which was thought to poſſeſs great virtues. From its inventor it was called the *ſulphureous ſalt of Stahl.* The moſt ſingular property of this volatile acid is, that though the vitriolic in its fixed ſtate is capable of expelling any other acid from its baſis, the volatile one is expelled by every acid, even that of vinegar. It is very difficultly condenſible, as we have already taken notice; and, when mixed with water, ſeems ſcarcely at all acid, but rather to have a bitteriſh taſte.

Several methods have been propoſed for procuring this acid from burning ſulphur, which yields it in its greateſt degree of volatility, as well as concentration; but the produce is ſo exceedingly ſmall, that none of them are worth mentioning. 714 How procured by Dr Prieſtley. Dr Prieſtley has given very good directions for obtaining the volatile vitriolic acid in the form of air. His method was, to pour, on ſome

ſome oil of vitriol contained in a phial, a very ſmall quantity of oil olive; as much as was ſufficient to cover it. He then applied the proper apparatus for the reception of air in quickſilver (ſee Air); and, holding a candle to the phial, the volatile vitriolic acid ruſhed out in great quantity. Had he received this air in water, inſtead of quickſilver, the conſequence would have been, that ſome part of it, at leaſt, would have been abſorbed by the water, and a ſulphureous acid liquor produced. This ſeems indeed almoſt the only method of procuring the ſulphureous vitriolic acid of any tolerable ſtrength; but it is never required in the form of a liquor, except for experimental purpoſes. The only uſeful-property hitherto diſcovered about this kind of acid is, that it is remarkably deſtructive of colours of all kinds; and hence the fumes of ſulphur are employed to whiten wool, &c.

715 Charcoal. XVII. *With Phlogiſton of charcoal.* If charcoal is mixed with concentrated vitriolic acid, and the mixture diſtilled, the ſame kind of acid is at firſt obtained, which comes over when oil is uſed; and towards the end, when the matter begins to grow dry, a true ſulphur ſublimes. The beſt way, however, of producing ſulphur from the vitriolic acid is by combining it, when in a perfectly dry ſtate, with the phlogiſton. By this means ſulphur may very readily be made at any time. The proceſs is generally directed to be performed in the following manner.

716 Sulphur prepared from vitriolated tartar. Reduce to fine powder any quantity of vitriolated tartar. Mingle it carefully with a 16th part of its weight of charcoal-duſt. Put the whole into a covered crucible ſet in a melting furnace. Give a heat ſufficient to melt the ſalt; and when thoroughly melted, pour it out on a flat ſtone. The vitriolated tartar and charcoal will now be converted into a ſulphureous maſs, ſimilar to a combination of alkaline ſalts with ſulphur. See *Alkaline Salts*, below.

717 Spirit of wine. XVIII. *With Spirit of wine.* The reſult of this combination is one of the moſt extraordinary phenomena in chemiſtry; being that fluid, which, for its extreme degree of volatility, was firſt diſtinguiſhed by the name of *ether*: and now, ſince a liquor of the like kind is diſcovered to be preparable from ſpirit of wine by means of other acids, this ſpecies is diſtinguiſhed by the name of *vitriolic ether*. The method of preparing this ſubtle liquor recommended by M. Beaumé, ſeems to be the beſt of any hitherto diſcovered.

718 Ether. Mix together equal parts by weight, of highly rectified ſpirit of wine and concentrated oil of vitriol, or ſomewhat more than two meaſures of ſpirit of wine with one of the acid. The mixture is to be made in a flint glaſs retort, the bottom and ſides of which are very thin, that it may not break from the heat which is ſuddenly generated by the union of theſe two ſubſtances. The ſpirit of wine is firſt put into the retort, and then the acid is poured in by a glaſs-funnel, ſo that the ſtream may be directed againſt the ſide of the glaſs; in which caſe it will not exert much of its force on the ſpirit, but will lie quietly below at the bottom. The retort is now to be very gently ſhaken, that the acid may mingle with it by little and little. When the mixture is completed, very little more heat will be neceſſary to make the liquor boil.

This mixture is to be diſtilled with as briſk and quick a heat as poſſible; for which reaſon, immediately after the acid and ſpirit are mixed, the retort ſhould be put into a ſand furnace heated as much as the mixture is. The diſtillation ſhould be continued only till about one-third of the liquor is come over; if it is continued farther, part of the vitriolic acid riſes in a ſulphureous ſtate. In the retort a thick, black, acid matter remains, which is ſimilar to a combination of oil of vitriol with any inflammable matter, and from which a little ſulphur may be obtained. Along with the ſulphureous acid, a greeniſh oil, called *oleum vitrioli dulcis*, ariſes, which has a ſmell compounded of that of the ether and ſulphureous acid: and Mr Beaumé has ſhown that it is compounded of theſe two; for if it is rectified with an alkali, to attract the acid, it is changed into ether. If, after the diſtillation of the ether, ſome water be poured into the retort, the liquor by diſtillation may be brought back to the ſtate of a pure vitriolic acid.

As the ſteams of the ethereal liquor are exceedingly volatile, and at the ſame time a quick fire is neceſſary to the ſucceſs of the operation, the receiver muſt be carefully kept cool with very cold water or with ſnow. Care muſt alſo be taken to prevent any of the ſulphureous acid ſteams from coming over; but as it is impoſſible to prevent this totally, the liquor requires rectification. This is the more neceſſary, as a part of the ſpirit of wine always riſes unchanged. From this acid the liquor is eaſily ſet free, by adding a ſmall quantity of alkaline ſalt, and re-diſtilling with a very gentle heat; but as ſpirit of wine is likewiſe very volatile, the diſtillation muſt be performed in a very tall glaſs. Dr Black recommends a matraſs, or bolt-head, with a tin-pipe adapted to the head, ſo as to convey the ſteams at a right angle, to be condenſed in the receiver. When this fluid is to be prepared in great quantities, the ether, by proper management, may be made to equal half the weight of the ſpirit of wine employed. Mr Dollfuſs has made many important experiments on this ſubject; of which the following is an abſtract: 1. Two pounds of vitriolic acid were mixed with as much of ſpirit of wine, and the mixture diſtilled with a very gentle fire. The firſt ten ounces that came over conſiſted of a liquor ſtrongly impregnated with ether, and of an agreeable odour. This was put by itſelf and marked A. It was followed by a ſtronger ethereal liquor, of which a ſmall quantity only would mix with water. Of this there were 12 ounces, which were alſo put by themſelves, and marked B. By continuing the proceſs two ounces more were obtained, which ſmelled of ſulphur, and were marked C. The diſtillation was now continued with a view to concentrate the vitriolic acid, when three drachms of a thicker kind of ether were found ſwimming on a weak ſulphureous acid. This thick liquid was not in the leaſt volatile, and in conſiſtence reſembled an expreſſed oil. 2. Twenty-four ounces of ſpirit of wine were now added to the reſiduum of the former diſtillation, and the proceſs recommenced. The firſt ſeven ounces that came over were poured to the dulcified ſpirit marked A. Next paſſed over ten ounces of a tolerably pure ether, which was mixed with the contents of B; beſides two ounces that had a ſulphureous ſmell, which were mixed with C. By a repeated dephlegmation of what remained in the retort were obtained five ounces of a weak ſulphureous acid; and the remainder being again mixed with 20 ounces of ſpirit of wine, yielded firſt ſix ounces of the liquor marked A; then four ounces of pure ether put into that marked B; and after that another ounce marked C. By continuing the diſtillation four ounces of weak ſulphureous acid were obtained, on which floated a little oil of wine. 3. The remainder, which was very thick, and covered with a ſlight pellicle, was mixed with 20 ounces of ſpirit of wine, and yielded five ounces of dulcified ſpirit marked A; eight ounces of pure ether marked B; and at laſt one ounce of the ſame, which had rather a ſulphureous ſmell. This was followed by a few drops of acid; but the remainder frothed up with ſuch violence, that an end was put to the operation, in order to prevent its paſſing over into the receiver.

By theſe four diſtillations there were obtained from ſix pounds of ſpirit of wine and two of oil of vitriol, 28 ounces of dulcified ſpirit of vitriol and 38 of ether; which laſt, when rectified by diſtillation over manganeſe, yielded 28 ounces of the beſt ether. At the end of this diſtillation were produced 13 ounces of weak acetous acid; and the liquor of the laſt running marked C, afforded, by rectification, four ounces of good ether. The ſulphureous acid liquor yielded four ounces of weak acetous acid, and three drachms of naphtha reſembling a diſtilled oil in conſiſtence.

By theſe proceſſes the vitriolic acid was rendered quite thick and black; its weight being reduced to 24 ounces. The blackneſs was found to be owing to a powder which floated in the liquid, and could neither be ſeparated by ſubſiding to the bottom nor riſing to the top. The liquor was therefore diluted with eight ounces of water, and filtered through powdered glaſs; by which means the black ſubſtance was collected, partly in powder, and partly in grains of different ſizes. It felt very ſoft between the fingers, and left a ſtain upon paper like Indian ink; but though waſhed with 24 ounces of water, ſtill taſted acid. Half an ounce of it diſtilled in a retort yielded a drachm and an half of weak acetous mixed with a little ſulphureous acid; the reſiduum was a black coal, which by calcination in an open fire for a quarter of an hour, yielded 25 grains of white aſhes, conſiſting of ſelenite, calcareous earth, and magneſia. A drachm of it digeſted with nitrous acid, which was afterwards diſtilled from it, and then diluted with diſtilled water and filtered, yielded a few cryſtals, which appeared to be genuine ſalt of tartar, an inſoluble ſelenite being left behind. On rectifying the vitriolic acid freed from the black matter and diluted with eight ounces of water, nine ounces of ſulphureous acid were firſt obtained, after which followed an ounce of acid rather high-coloured, and then the vitriolic acid quite colourleſs. It now weighed only $19\frac{3}{4}$ ounces, and its ſpecific gravity was but 1.723, while that of the acid originally employed had been 1.989.

On repeating the proceſs with ſix pounds of ſpirit of wine to two of oil of vitriol, the firſt 12 ounces that came over were ſpirit of wine almoſt totally unchanged; then two ounces ſmelling a little of ether; and afterwards two pounds, of which about one-third were ether. When about five pounds had been drawn off, the diſtilling liquor began to ſmell ſulphureous; and after nine ounces more had been drawn off, the frothing up of the matter in the retort obliged him to put an end to the operation. The acid was then filtered through pounded glaſs as before, and afterwards committed to diſtillation. The three firſt ounces were a weak ſulphureous acid; then followed an ounce more concentrated, and of a red colour; then another of a yellowiſh caſt; after which the reſt of the acid came over quite colourleſs. The whole weighed 27 ounces, and the ſpecific gravity of it compared with diſtilled water was as 1.667 to 1.000.

719 Properties of ether.

Ether is the lighteſt of all known fluids, except air; and is ſo volatile, that *in vacuo* its boiling point is 20° below 0° of Fahrenheit's thermometer. If a ſmall quantity is poured out on the ground, it inſtantly evaporates, diffuſing its fragrance all through the room, and ſcarce perceptibly moiſtening the place on which it fell. It difficultly mixes with water, as being of an oily nature: ten parts of water, however, will take up one part of ether. Its great volatility renders it ſerviceable in nervous diſeaſes, and removing pains, when rubbed on with the hand, and kept from evaporating immediately. By ſpontaneous evaporation, it produces a great degree of cold. (See EVAPORATION and CONGELATION). The moſt extraordinary property, however, is, that if gold is diſſolved in aqua-regia) ſee *Metallic Subſtances*, below), and ether added to the ſolution, the gold will leave the acid and permanently unite with the ether. The exceeding great volatility of ether renders it very eaſily inflammable even on the approach of flame; and therefore it ought never to be diſtilled, or even poured from one veſſel to another, by candle-light. If a leſs quantity of the vitriolic acid is added to the ſpirit of wine than what is ſufficient to produce ether, the product is called *ſpiritus vitrioli dulcis*. The following experiment made by Wallerius, induced him and others to think, that the vitriolic acid was convertible into the nitrous.

720 Experiment in favour of the transmutation of vitriolic into nitrous acid.

"Some ſalt of tartar (ſays he) being mixed with the dulcified ſpirit of vitriol, or perhaps with the ether (for the author expreſſes himſelf a little ambiguouſly), the full bottle ſtopt with a cork, tied over with bladder, and laid on its ſide; on ſtanding for four months, the greateſt part of the ſpirit was found to have eſcaped, and the ſalt was ſhot into hexangular priſmatic cryſtals reſembling nitre. It taſted ſtrongly of the ſpirit, but had no other particular taſte. Laid on a burning coal, it crackled, exploded with a bright flaſh, and flew into the air. He afterwards found, that by adding to the ſpirit a drop or two of any acid, the ſalt cryſtallizes the ſooner; that in this caſe it has a ſouriſh taſte, but in other reſpects is the ſame with that made without acid. This ſalt-petre (ſays the author) promiſes, from the violence of its exploſion, to make the ſtrongeſt gun-powder in the world, but a very dear one. Though the experiment ſhould not be applicable to any uſe in this way, it will probably contribute to illuſtrate the generation of nitre: as it palpably ſhows nitre, that is, the acid or characteriſtic part of nitre, produced from the vitriolic acid and phlogiſton.

721 Not concluſive.

We cannot here help again regretting that chemiſts of ſuperior abilities ſhould ſometimes leave very important diſcoveries only half finiſhed, ſo that chemiſts of an inferior rank know not what to make of them. Had

Wallerius,

Wallerius, who ſeems more than once to have been in poſſeſſion of this ſalt, only poured on it a few drops of oil of vitriol, the peculiar colour and ſmell of its fumes muſt have been a much more convincing proof of the reality of the tranſmutation than that of mere deflagration; becauſe the latter can be otherwiſe accounted for.

722
Violent exploſions from the application of heat.

It is certain, that many ſuſtances, water itſelf not excepted, will explode with great violence if ſuddenly heated beyond what they are able to bear. If ſpirit of wine is confined in a cloſe veſſel, it will alſo by means of heat burſt it as effectually as water; and as the vapours of this ſubſtance are inflammable, the exploſion will be attended with a flaſh if any flame is near. In like manner ether, on the approach of a candle, takes fire, and goes off in a flaſh like lightning; but this happens, not from any thing nitrous, but from its great volatility and inflammability. If therefore the vapours of the ethereal liquors are confined, and heat is applied ſuddenly to the containing veſſel, their great volatility will cauſe them make an inſtantaneous effort againſt the ſides of it, which increaſing with a ſwiftneſs far beyond that of aqueous or ſpirituous vapours, will make a much quicker as well as a much ſtronger exploſion than either of them; and if a flaming ſubſtance is near, the exploſion will be attended with a bright flaſh like that of the ether itſelf.

In the experiment now before us, the ſalt taſted ſtrongly of the ſpirit, or ether, from which it was made. The ſpirit was therefore confined in the cryſtals of ſalt; and this volatile liquor, which, even under the preſſure of the atmoſphere, boils with the heat of 100° of Fahrenheit, was, in a confined ſtate, ſubjected to the heat of a burning coal; that is, to more than ten times the degree of heat neceſſary to convert it into vapour. The conſequence of this could be no other, than that the particles of ſalt, or perhaps the air itſelf, not being capable of giving way ſoon enough to the forcible expanſion of the ether, a violent exploſion would happpen, and the ſalt be thrown about; which accordingly came to paſs, and might very reaſonably be expected, without any thing nitrous contained in the ſalt.

2d 722
Cavallo's method of purifying ether.

Mr Cavallo deſcribes an eaſy and expeditious method of purifying ether, though a very expenſive one; as out of a pound of the common kind ſcarce three or four ounces will remain of that which is purified. The method of purifying it, he ſays, was communicated to him by Mr Winch chemiſt in London, and is to be performed in the following manner. "Fill about a quarter of a ſtrong bottle with common ether, and pour upon it twice as much water; then ſtop the bottle and give it a ſhake, ſo as to mix the ether for ſome time with the water. This done, keep the bottle for ſome time without motion, and the mouth of it downwards, till the ether be ſeparated from the water, and ſwims above it; which it will do in three or four minutes. Then opening the bottle with the mouth ſtill inverted, let the greateſt part of the water run out very gently; after this, turn the bottle with the mouth upwards; pour more water upon the ether, ſhaking and ſeparating the water as before. Repeat this operation three or four times; after which the ether will be exceedingly pure, and capable of diſſolving elaſtic gum, though it could not do ſo before."

As great part of the ether undoubtedly remains mixed with the water after this proceſs, our author remarks, that it might be worth while to put the water into a retort and diſtil the ether from it, which will come ſufficiently pure for common uſe. He obſerves alſo, that "it is commonly believed that water combines with the pureſt part of the ether when the two fluids are kept together; though the contrary ſeems to be eſtabliſhed by this proceſs. According to Mr Waſtrumb, we may obtain from the reſiduum of vitriolic ether a reſin containing vitriolic acid, vinegar, Glauber's ſalt, ſelenite, calcareous earth, ſilex, iron, and phoſphoric acid.

§ 2. *Of the* NITROUS *Acid and its Combinations.*

THIS acid is far from being ſo plentiful as the vitriolic. It has been thought to exiſt in the air; and the experiments of Mr Cavendiſh have ſhown, that it may be artificially compoſed, by taking the electric ſpark in a mixture of dephlogiſticated and phlogiſticated air. See AEROLOGY, n° 77.

724
Of the preparation of nitre.

With regard to the preparation of nitre, Dr Black obſerves, that it is made in great plenty in the more ſouthern parts of Europe; likewiſe in the ſouthern parts of Perſia, in China, the Eaſt Indies, and in North America. We have had no accounts of the manner in which it is prepared in the Eaſt Indies, no perſon on the ſpot having taken particular notice of the manufacture. The general account is, that it is obtained from the ſoil of certain diſtricts which are called *ſaltpetre grounds*; where the ſoil is very cold, barren, and unhealthy. The ſalt is there ready formed by nature. It is only neceſſary to gather large quantities of the earth, and to put it into a cavity through which a great quantity of water is poured, which diſſolves the nitre; and the lixivium runs into an adjacent pit, out of which it is lifted in order to be evaporated and obtained in the form of cryſtals. This account, however, has been thought unſatisfactory; becauſe there is hardly any part of Europe in which it is found in this manner. It is diſcovered indeed in ſome very large diſtricts in Poland, particularly in Podolia, where the country is flat and fertile, and had been once very populous, but is now in a great meaſure deſerted. It is there obtained from tumuli or hillocks, which are the remains of former habitations; but theſe are the only places in which it is found in any conſiderable quantity. In Spain, it is ſaid that the inhabitants extract it from the ſoil after a crop of corn. It has been found in America in lime-ſtone grounds, in the floors of pigeon-houſes, tobacco-houſes, or the ruins of old ſtables, where a number of putrefying vegetables were once collected. In general, however, it is extracted from artificial compounds or accidental mixtures, where animal and vegetable ſubſtances have been fully putrefied by being expoſed to the air with any ſpongy or looſe earth, eſpecially of the calcareous kind, and open to the north or north-eaſt wind, and more or leſs covered from the heat or rains. This laſt particular is abſolutely neceſſary to its formation in any quantity; for the heat, by evaporating the moiſture too much, prevents it from being produced, and the rains waſh it away after it is already made. Cramer, an author of the greateſt credit, informs us in his Docimaſtics, that he made a little hut expoſed to the freſh air of the country,

725
Diſcovered in ſome places in Podolia in Poland;

726
In Spain and America.

727
Requiſites for its formation.

728
Cramer's artificial compoſt for making nitre.

country, with windows to admit the winds. In this he put a mixture of garden mold, the rubbiſh of lime, and putrid animal and vegetable ſubſtances. This he frequently moiſtened with urine; and in a month or two found his compoſition very rich in nitre, yielding at leaſt one-eight part of its weight.

729 How prepared in Hanover.

It is manufactured in Europe by making artificial compounds with leſs trouble. In Hanover it is got by collecting the rakings of the ſtreets; which are built up into mud-walls that are allowed to remain a certain time, when the ſurface is found covered with a white ſaline efflореſcence. A perſon is employed to ſcrape this off; and putting it into a veſſel, it is waſhed with water to diſſolve the nitre, and the remaining earthy matter is again plaſtered on the mud-walls, and freſh matter brought from the ſtreets to renew them occaſionally: and by this ſimple method a conſiderable quantity is obtained.

730 In other parts of Germany.

In Germany the peaſants are directed by law to build mud-walls of this kind with the dung and urine of animals, and ſome ſtraw. After they have ſtood for ſome time, and the vegetable and animal ſubſtances are rotten, they afford a conſiderable quantity of nitre.

731 In France.

In France it is obtained from accidental collections of this kind; as where looſe earth has been long expoſed to the contact of animal ſubſtances, as the ruins of old ſtables, pigeon-houſes, &c. Sometimes from the mould upon the ground where dunghills have been lying. A particular ſet of people go about in ſearch of theſe materials; and when, by making a ſmall eſſay, they find that they will turn to account, they put the materials into a large tub with a perforated bottom, and another which is water-proof put below it. Some ſtraw is interpoſed betwixt the two; and on pouring water upon the materials, it ſoaks through them, undergoes a kind of filtration in paſſing through the ſtraw, and is then drawn off by a cock placed in the the under-tub, and boiled to a proper conſiſtence for cryſtallization. The cryſtals are at firſt brown and very impure, but by repeated diſſolution and cryſtallization become pure and white.

732 Dr Black's concluſions concerning the nature of ſalt-petre.

From theſe particulars relating to the hiſtory of ſalt-petre, Dr Black concludes, that it is not properly a foſſil, being produced at the ſurface of the ground. Margraaf diſcovered a ſmall quantity of it in the analyſis of ſome of the waters about Berlin, and others have found it in the wells about ſome great cities: but no true nitre has ever been found in ſprings; ſo that this nitrous ſalt may be ſuppoſed to have derived its origin from the quantity of putrid matters with which all cities abound. All rich and fertile ſoils are found to contain it; and in the hot countries, where the products of nature are numerous, and putrefaction carried on very faſt, they are often very rich in nitre. This may happen in ſome places from the conflux of waters; which remaining for ſome time on the ſurface, and afterwards exhaling, left the ſaline particles behind.

733 Suppoſed to be the laſt effect of putrefaction.

On the whole, Dr Black concludes, that neither nitre nor its acid does exiſt in the air, becauſe it might eaſily be detected there; though many have embraced this opinion from its being uſually found at the ſurface of the ground. He is of opinion, that it is the effect of the laſt ſtage of putrefaction of animal and vegetable ſubſtances; and it is never to be found except where theſe or their effluvia are preſent, and never till the putrefaction is complete. It has been a matter of diſpute, whether it exiſted in thoſe matters before the proceſs of putrefaction, or was produced by it. But it is pretty certain, ſays the Doctor, that it originated in them; for the ſun-flower, tobacco, and other plants, are found to contain it before putrefaction: and ſome have even aſſerted, that plants placed in the earth, deprived of all its ſaline ſubſtances, will yield it. The compoſitions recommended by Cramer are the fitteſt for producing a complete degree of putrefaction, provided they contain a moderate degree of humidity, and that the quantity expoſed to the air be defended from too great a heat by the ſun, which would dry up its moiſture; and likewiſe from too great a degree of cold, which likewiſe checks fermentation. The importance of the calcareous earth in ſuch a compoſition would likewiſe favour the concluſions juſt now drawn; for the moſt remarkable effect of this earth is to promote and perfect the putrefaction of theſe ſubſtances. It would ſeem, therefore, that the true ſecret of the production of nitre is to mix properly together animal and vegetable ſubſtances with earth, particularly of the calcareous kind; expoſing them to the air with a moderate degree of humidity, ſufficient to promote their putrefaction in the moſt effectual manner; and when the putrefaction is carried to the utmoſt height, we may then expect that nitre will be produced.

734 Diſtinguiſhing characteriſtic of the nitrous acid.

The diſtinguiſhing characteriſtic of the nitrous acid is its great diſpoſition to unite with the phlogiſton; and, when ſo united, firſt to become exceedingly volatile, and at laſt to be diſſipated in a very white bright flame: this is called its *detonation* or *deflagration*. In the ſtrongeſt ſtate in which this acid is procurable in a liquid form, it is of a reddiſh yellow colour, and continually exhales in denſe, red, and very noxious fumes; and in this ſtate is called *ſmoking*, or, from its inventor, *Glauber's*, ſpirit of nitre.

I. To extract the Nitrous Acid by means of the *Vitriolic*.

735 Spirit of nitre.

Into a glaſs retort put two pounds of good ſalt-petre, and pour upon it 18 ounces of concentrated oil of vitriol; ſet the retort in a ſand-heat, and lute on a large receiver with the compoſition already recommended, for reſiſting acid fumes; the mixture will grow very warm, and the retort and receiver will be filled with red vapours. A ſmall fire is then to be kindled, and cautiouſly raiſed till no more drops will fall from the noſe of the retort. What comes over will be a very ſtrong and ſmoking ſpirit of nitre.

736 Rectification.

In this proceſs, the nitrous acid is generally mixed with part of the vitriolic which comes over along with it, and from which it muſt be freed if deſigned for nice purpoſes. This is moſt effectually done by diſſolving in it a ſmall quantity of nitre, and rediſtilling the mixture. The vitriolic acid which came over in the firſt diſtillation is kept back by the nitre in the ſecond, combining with its alkaline baſis, and expelling a proportionable quantity of the nitrous acid.

737 Different methods of diſtilling.

We have here directed the pure vitriolic acid to be uſed, in order to expel the nitrous one; but for this purpoſe any combination of the vitriolic acid with a metallic or earthy baſis may be uſed, though not with equal advantage. If calcined vitriol is made uſe of,

as

as much phlogiſton is communicated by the calx of iron contained in that ſalt as makes the nitrous acid exceedingly volatile, ſo that great part of it is loſt. If calcined alum, or ſelenite, is made uſe of, the vitriolic acid in theſe ſubſtances immediately leaves the earth with which it was combined, in order to unite with the alkaline baſis of the nitre, and expels its acid: but the moment the nitrous acid is expelled from the alkali, it combines with the earth which the vitriolic acid had left; from which it cannot be driven without a violent fire; and part of it remains obſtinately fixed, ſo as not to be expelled by any degree of heat. Hence the produce of ſpirit, when nitre is diſtilled with ſuch ſubſtances, always turns out conſiderably leſs than when the pure vitriolic acid is uſed. Alum is preferable to ſelenite, for the purpoſes of diſtilling ſpirit of nitre; becauſe the acid does not adhere ſo ſtrongly to argillaceous as to calcareous earth.

According to Weigleb, the nitrous acid may be expelled not only by clay, gypſum, and other ſubſtances containing the vitriolic acid, but even by various kinds of vitrifiable earth. Clean pebbles, quartz in the form of ſand, pieces of broken china and ſtone ware, powdered glaſs, *&c* mixed with nitre in the proportion of ſix to one, always expel the acid, though imperfectly. In France the acid is always extracted by means of clay.

The reaſon of theſe decompoſitions is, that the alkaline baſis of the nitre attracts the ſiliceous earth, whoſe fixedneſs in a vehement fire gives it an advantage over the volatile nitrous acid, in the ſame manner that the weak acid of phoſphorus or arſenic will alſo expel it by reaſon of their fixedneſs in the fire.

Even ſpirit of ſalt, according to Margraaff's experiments, may be uſed for diſtilling the ſpirit of nitre. That celebrated chemiſt informs us, that on diſtilling nitre with eight or nine times its quantity of ſtrong marine acid, a ſpirit comes over which conſiſts chiefly of the nitrous acid, but has alſo ſome portion of that of ſea-ſalt. The reaſon of this is ſhown in Mr Kirwant's experiments on chemical attractions*. In the preſent caſe, however, the decompoſition may be facilitated by the ſtrong attraction of the nitrous acid for phlogiſton; for it is well known, that on mixing the nitrous and marine acids together, the latter is always dephlogiſticated. It ſeems therefore that in this caſe a double decompoſition takes place, the nitrous acid uniting itſelf to the phlogiſton of the marine, and the latter attaching itſelf to the alkali of the nitre.

738 Uſes. Spirit of nitre is very uſeful in the arts of dyeing and refining, where it is known by the name of *aquafortis*; and therefore an eaſy and cheap method of procuring it is a valuable piece of knowledge. Many difficulties, however, occur in this proceſs, as well as that for the vitriolic acid. Oil of vitriol, indeed, always expels the nitrous acid with certainty; and on diſtilling the mixture, a ſpirit of nitre ariſes; but if a glaſs retort is uſed for the purpoſe of diſtilling this acid, the quantity of reſiduum left in diſtillation is ſo great, and ſo inſoluble in water, being no other than vitriolated tartar, that the retort muſt always be broken in order to get it out; and the produce of ſpirit will ſcarce afford the breaking a retort. If earthen retorts are made uſe of, they muſt certainly be of that kind called ſtone-ware, and the price of them will be very little if at all inferior to that of glaſs. Iron pots are ſaid to be made uſe of in the diſtillation of common aquafortis in large quantities; but they have the great inconvenience of making a quantity of the acid ſo volatile, that it not only will not condenſe, but ſpreads its ſuffocating vapours all round in ſuch a manner as to prove very dangerous to thoſe who are near it. If an iron veſſel, therefore, is thought of for the purpoſe of diſtilling aquafortis, it will be proper at leaſt to attempt luting over the inſide with a mixture of gypſeous earth and ſand, to prevent as much as poſſible the acid from attracting the metal.

Dephlogiſticated ſpirit of nitre is obtained by diſtilling the ſmoking kind with a gentle heat, until what remains is as colourleſs as water. It is diſtinguiſhed by emitting white and not red fumes like the other kind, when ſet in a warm place. It muſt be kept conſtantly in the dark, otherwiſe it will again become phlogiſticated, and emit red vapours by the action of the light; the ſame thing will alſo take place if it be heated with too violent a fire.

II. To procure the Nitrous Acid by means of *Arſenic*.

739 Blue aquafortis. Pulveriſe equal quantities of dried nitre and white cryſtalline arſenic; mix them well together, and diſtil in a glaſs-retort with a fire very cautiouſly applied; for the arſenic acts on the nitre with ſuch a violence, and the fumes are here ſo volatile, that unleſs great care is taken, a moſt dangerous exploſion will almoſt certainly happen. As, in this caſe, the nitrous fumes ariſe in a perfectly dry ſtate, ſome water muſt be put into the receiver, with which they may unite and condenſe. The aquafortis ſo produced will have a blue colour, owing to the inflammable principle ſeparated from the arſenic, by which its extreme volatility is likewiſe occaſioned. If this blue aquafortis is expoſed to the air, its colour ſoon flies off. If inſtead of the white arſenic we employ the pure arſenic acid, the diſtilled liquor will have no blue colour.

Nitrous Acid COMBINED,

740 Salt-petre. I. *With Vegetable fixed Alkali.* This ſalt, combined with the nitrous acid to the point of ſaturation, regenerates nitre. It is obſervable, however, according to Neumann, that there is always ſome diſſimilarity between the original and regenerated nitre, unleſs quicklime is added. The regenerated ſalt, he ſays, always corrodes tin, which the original nitre does not; owing probably to a quantity of phlogiſticated acid remaining in it. Boiling with quicklime deprives it of this quality, and makes it exactly the ſame with original nitre.

741 Cubic-nitre. II. *With Foſſile alkali.* The neutral ſalt ariſing from a combination of the nitrous acid and foſſile alkali is ſomewhat different from common nitre; being more difficult to cryſtallize, inclining to deliquate in the air, and ſhooting into cryſtals of a cubical form, whence it gets the name of *cubic nitre*. Its qualities are found ſomewhat inferior to the common nitre; and therfore it is never made, unleſs by accident, or for experiments.

742 Fuſibility. Nitre is one of the moſt fuſible ſalts. It is liquefied in a heat much leſs than what is neceſſary to make it red; and thus remain in tranquil fuſion, without ſwelling. If nitre thus melted be left to cool and fix, whe-

---

* See n° 292.

whether it has been made red-hot or not in the fuſion, it coagulates into a white, ſemi-tranſparent, ſolid maſs, called *mineral cryſtal*, having all the properties of nitre itſelf. By this fuſion, Mr Beaumé obſerves that nitre loſes very little, if any, of the water contained in its cryſtals, ſince the weight of mineral cryſtal is nearly the ſame with that of the nitre employed.

When nitre is kept in fuſion with a moderate heat, and at the ſame time does not touch any inflammable matter, nor even flame, it remains in that ſtate without ſuffering any very ſenſible alteration; but if it is long kept in fuſion with a ſtrong fire, part of the acid is deſtroyed by the phlogiſton which penetrates the crucible; and hence the nitre becomes more and more alkaline.

743 Uſes.

Nitre is of very extenſive uſe in different arts; being the principal ingredient in gun-powder; and ſerving as an excellent flux to other matters; whence its uſe in glaſs making. (See GLASS.) It is alſo poſſeſſed of a conſiderable antiſeptic power; whence its uſe in preſerving meat, to which it communicates a red colour. In medicine, nitre is uſed as a diuretic, ſedative, and cooler; but very often ſits uneaſy on the ſtomach. The reſemblance of the cryſtals of nitre to thoſe of Glauber's ſalt has ſometimes been the occaſion of dangerous miſtakes. Dr Alexander mentions a ſwelling over the whole body of a woman, occaſioned by her taking a ſolution of nitre inſtead of Glauber's ſalt. Two miſtakes of the ſame kind we have alſo known. In one an ounce, and in the other upwards of two ounces, of nitre were ſwallowed. The ſymptoms occaſioned were univerſal coldneſs and ſhivering, extreme debility and ſickneſs at ſtomach, cold ſweats and faintings. Neither of the caſes proved mortal. The cure was effected by cordials and corroborants.

744 Sal prunella.

A proceſs has obtained a place in the diſpenſatories for a ſuppoſed purification of nitre by means of flower of brimſtone. A pound of ſalt-petre is to be melted in a crucible, or ſmall iron veſſel; and an ounce of flowers of ſulphur thrown upon it, by ſmall quantities at a time: a violent deflagration enſues on each addition; and after the whole is put in, the ſalt is poured out in moulds, and then called *ſal prunella*. It has been diſputed whether the nitre was at all depurated by this proceſs; Dr Lewis thinks it is not. From our own experience, however, we can affirm, that by this means a ſediment falls to the bottom, which carries with it any impurities that may have been in the nitre, and leaves the fluid ſalt clear and tranſparent as water. This precipitate is probably no other than a vitriolated tartar formed by the union of the ſulphureous acid and alkali of the nitre, which being leſs fuſible than the nitre, ſubſides in a ſolid form and clarifies it.

745 Nitrous ammoniac.

III. *With Volatile Alkali.* The nitrous acid ſeems peculiarly adapted to an union with volatile alkali; ſaturating as much, or rather more of it than the ſtrongeſt vitriolic acid is capable of doing. The product is a very beautiful ſalt, called *volatile nitre*, or *nitrous ſal ammoniac*. It very readily diſſolves, not only in water, but in ſpirit of wine, which diſtinguiſhes it from the vitriolic and common kind of ſal ammoniac. It alſo requires leſs heat for its ſublimation: indeed care muſt be taken not to apply too great a heat for this purpoſe, as the nitrous ſal ammoniac has the property of deflagrating by itſelf without any addition of inflammable matter; and this it does more or leſs readily, as the volatile alkali with which it was made was more or leſs impure and oily.

746 Dr Ward's white drop.

The medical virtues of this kind of nitre have not been inquired into. It ſeems to have made the principal ingredient in the famous Dr Ward's white drop, which was celebrated as an antiſcorbutic; with what juſtice thoſe who have tried it muſt determine.

747 Calcareous nitre.

IV. *With Calcareous Earths.* Theſe the nitrous acid diſſolves into a tranſparent colourleſs liquor; but for this purpoſe it muſt be very much diluted, or the ſolution will have a gelatinous conſiſtence. This compound is not applicable to any uſeful purpoſe. It has a very acrid taſte; and, if inſpiſſated, attracts moiſture from the air. If it is totally dried, it then reſembles an earthy matter, which deflagrates very weakly. By diſtillation in a retort, almoſt all the acid may be expelled, and what little remains flies off in an open fire.

748 Nitrous acid decompoſed.

Mr Pott, who has particularly examined the combination of nitrous acid with quicklime, ſays that the acid ſuffered remarkable alterations by diſtillation from quicklime, and repeated cohobations upon it. By theſe experiments he obtained a ſalt more ſenſibly ſuſceptible of cryſtallization and detonation, than what can be obtained by a ſingle combination. From his experiments it would ſeem, that nitrous acid, by this treatment with quicklime, was capable of being entirely decompoſed.

749 Phoſphorus.

If a ſolution of chalk in the nitrous acid be evaporated to dryneſs, and then gently calcined, it acquires the property of ſhining in the dark, after having been expoſed to the ſun's rays, or even to the light of a candle. This ſubſtance, from its inventor, is called *Baldwin's phoſphorus*; or, from its being neceſſary to keep it in a glaſs hermetically ſealed, *phoſphorus hermeticus*. (See EARTHS).

V. *With Argillaceous Earths and Magneſia.* All that is known concerning the combinations of nitrous acid with theſe earths is, that the firſt produce aſtringent, and the ſecond purgative compounds, ſimilar to alum and Epſom ſalt, and which are not ſuſceptible of cryſtallization.

750 Gold.

VI. *With Gold.*—Till very lately it has been the opinion of chemiſts, that the nitrous acid by itſelf was incapable of acting upon this metal.—Dr Brandt, however, produced before the Swediſh academy of ſciences, a ſolution of gold in the nitrous acid, obtained in parting, by that acid, a mixture of gold and ſilver. —The mixed metal was boiled with aquafortis in a glaſs body fitted with a head and receiver, the liquor poured off, and the coction repeated with freſh parcels of ſtronger and ſtronger nitrous ſpirit, till all the ſilver was judged to be extracted. The laſt parcel was boiled down till the matter at the bottom looked like a dry ſalt; on boiling this in freſh aquafortis in cloſe veſſels, as before, a part of the gold was diſſolved, and the liquor tinged yellow. But though gold is by this means truly ſoluble in the nitrous acid, the union is extremely ſlight; the gold being not only precipitated on the addition of ſilver, but likewiſe ſpontaneouſly on expoſure to the air.—Dr Lewis very juſtly obſerves, that this ſolution may have been often made unknown to the chemiſt who did ſo; and probably occaſioned the miſtakes which ſome have fallen into, who thought that they were in poſſeſſion of aquafortis capable of tranſmuting ſilver into gold. Notwithſtanding theſe authorities, Mr Kirwan is of opinion that the nitrous acid is in no caſe able to diſſolve gold; the metal being only intimately mixed or diffuſed through it.

751 Silver.

II. *With Silver.*—Pure ſpirit of nitre will diſſolve its own weight of ſilver; and ſhoots with it into fine white cryſtals of a triangular form, conſiſting of very thin plates joined cloſely one upon another. Theſe cryſtals are ſomewhat deliqueſcent; of an extremely bitter, pungent, and nauſeous taſte; and, if taken internally, are highly corroſive and poiſonous. They melt in a ſmall heat, and form, on cooling, a dark-coloured maſs ſtill more corroſive, called *lunar cauſtic*, or *lapis infernalis*. They readily diſſolve in water; and, by the aſſiſtance of warmth, in ſpirit of wine. In the *Acta Naturæ Curioſorum*, tom. vi. there is a remarkable hiſtory of ſilver being volatilized by its combination with the nitrous acid. Four ounces of ſilver being diſſolved in aquafortis, and the ſolution ſet to diſtil in an earthen retort, a white tranſparent butter roſe into the neck, and nothing remaining behind; by degrees the butter liquefied, and paſſed down into the phlegm in the receiver. The whole being now poured back into the retort, the ſilver aroſe again along with the acid. The volatilization being attributed to the liquor having ſtood in a laboratory where charcoal was bringing in, the experiment was repeated with a freſh ſolution of ſilver, and a little powdered charcoal, with the ſame event.

752 Lunar cauſtic.

753 Colours produced by ſolution of ſilver.

Solution of ſilver in the nitrous acid ſtains hair, bones, and other ſolid parts of animals, and different kinds of wood, of all the intermediate ſhades from a light brown to a deep and laſting black. The liquors commonly ſold for ſtaining hair brown or black, are no other than ſolutions of ſilver in aquafortis, ſo far diluted in water as not ſenſibly to corrode the hair.

It gives a permanent ſtain likewiſe to ſundry ſtones; not only to thoſe of the ſofter kind, as marble, but to ſome of conſiderable hardneſs, as agates and jaſpers. The ſolution for this purpoſe ſhould be fully ſaturated with the metal; and the ſtone, after the liquor has been applied, expoſed for ſome time to the ſun. M. du Fay obſerves (in a paper on this ſubject in the French memoirs for 1728), that if the ſolution be repeatedly applied, it will penetrate into the whitiſh agate, or chalcedony, about one-twelfth of an inch: that the tincture does not prove uniform, on account of the veins in the ſtone: that the colours, thus communicated by art, are readily diſtinguiſhed from the natural, by diſappearing on laying the ſtone for a night in aquafortis: that, on expoſing it to the ſun afterwards for ſome days, the colour returns: that the ſolution gave ſomewhat different tinctures to different ſtones; to oriental agate, a deeper black than to the common chalcedony; to an agate ſpotted with yellow, a purple; to the jade ſtone, a pale browniſh; to the common emerald, an opaque black; to common granite, a violet unequally deep; to ſerpentine ſtone, an olive; to marble, a reddiſh, which changed to purple, and fixed in a brown; that on ſlates, talcs, and amianthus, it had no effect.

754 Arbor Dianæ.

If a ſolution of ſilver be diluted with pure water, a conſiderable quantity of pure mercury added, and the whole ſet by in a cold place; there will form by degrees a precipitation and cryſtallization reſembling a little tree, with its root, trunk and branches, called *arbor Dianæ*, or the *philoſophic ſilver tree*. Another kind of artificial vegetation may be produced by ſpreading a few drops of ſolution of ſilver upon a glaſs plate, and placing in the middle a ſmall bit of any of the metals that precipitate ſilver, particularly iron. The ſilver quickly concretes into curious ramifications all over the plate.

755 Solution of ſilver decompoſed.

Like other metallic ſolutions, this combination of the nitrous acid with ſilver is decompoſed by fixed and volatile alkalies, calcareous earths, and ſeveral metals, (ſee the *Table of Affinities*); but with ſeveral peculiar circumſtances attending the precipitation. With metals, the ſilver is readily and copiouſly thrown down at firſt, but ſlowly and difficultly towards the end. The menſtruum generally retains ſome portion of the ſilver, as the ſilver almoſt always does of the metal which precipitated it. For recovering the ſilver from aquafortis after parting, the refiners employ copper. The ſolution, diluted with water, is put into a copper veſſel, or into a glaſs one with thin plates of copper, and ſet into a gentle warmth. The ſilver begins immediately to ſeparate from the liquor in form of fine grey ſcales, or powder; a part of the copper being diſſolved in its place, ſo as to tinge the fluid more or leſs of a bluiſh green colour. The plates are now and then ſhaken, that ſuch part of the ſilver as is depoſited upon them may fall off, and ſettle to the bottom. The digeſtion is continued till a freſh bright plate, kept for ſome time in the warm liquor, is no longer obſerved to contract any powdery matter on the ſurface; when the liquor is poured off, and the precipitate waſhed with freſh parcels of boiling water. It is obſervable, that though the acid in this proceſs ſaturates itſelf with the copper, in proportion as it lets go the ſilver, yet the quantity of copper which it takes up is not near ſo great as that of ſilver which it depoſits. One drachm of copper will precipitate three of ſilver, and ſaturate all the acid that held the three drachms diſſolved.

756 Characters curiouſly marked on the inſide of a glaſs by means of the ſun's light.

Calcareous earths, as chalk or quicklime, throw down a part of the ſilver, but leave a very conſiderable part ſuſpended in the liquor. If the earth be moiſtened with the ſolution into the conſiſtence of a paſte, and expoſed to the ſun, it changes its white colour to a dark purpliſh black; diſtinct characters may be exhibited on the matter, by intercepting a part of the ſun's light by threads, ſlit paper, *&c.* placed on the outſide of the glaſs. Culinary fire does not affect its colour: after the maſs has been exſiccated by this, it changes as before, on expoſure to the ſun.

Mild volatile alkaline ſpirits, added to a ſolution of ſilver, precipitate but little, and cauſtic volatile alkalies none. Pure fixed alkalies, and alkalies rendered cauſtic by quicklime, throw down the whole. Fixed alkalies impregnated with inflammable matter by calcination with animal coals, occaſion at firſt a conſiderable precipitation; but if added to a larger quantity, take up a great part of the metal again. Mr Margraaf relates, that edulcorated calces of ſilver totally diſſolve, both in a lixivium of theſe alkalies and in volatile ſpirits; and that the marine acid precipitates the ſilver from the volatile, but not from the fixed, alkaline ſolution. Kunckel reports that the calx precipitated by volatile ſpirits made with quicklime, fulminates or explodes in the fire; and that by inſpiſſating a ſolution of pure ſilver, melting the dry reſiduum, pouring it on ſpirit of urine ſuperſaturated with ſalt, and ſetting the mixture in a gentle warmth, a blood-red maſs is produced, ſo tough as to admit of being wound about the fingers.

757 Copper.

758 Verditer.

III. *With Copper*. The nitrous acid very readily diſſolves this metal into a green-coloured and very cauſtic liquor. The ſolution, if properly evaporated, will cryſtallize; but the cryſtals are deliqueſcent, and therefore difficult to be preſerved. The only uſe of this combination is for the preparation of the pigment called *verditer*. Of this there are two kinds, the blue and green. The blue is by far the brighteſt colour, and conſequently the moſt valuable. It has been ſaid that this is obtained by precipitating a ſolution of copper by any calcareous earth; and therefore is ſold by the refiners who have large quantities of ſolution of copper accidentally made. The ſolution is ſaid to be precipitated by chalk, or whiting; and that the precipitate is the beautiful blue colour called *verditer*. By this method, however, only the green kind can be obtained. The blue we have found to be of a quite different nature, and formed by precipitation with a gentle heat from a ſolution of copper in volatile alkali. See the article COLOUR-MAKING.

759 Iron.

IV. *With Iron*. On this metal the concentrated nitrous acid acts very violently, and plentifully corrodes, but does not diſſolve it; the calx falling almoſt as faſt as diſſolved; and when it is once let fall, freſh acid will not take it up again. If the acid was diluted at firſt, it takes up a conſiderable porportion, provided the metal be leiſurely added. If the ſolution is performed with extreme ſlowneſs, the colour will be green; but if otherwiſe, of a dark red. It does not cryſtallize; and, if inſpiſſated to dryneſs, deliquates in the air.

760 Tin.

V. *With Tin*. Concentrated nitrous acid acts upon tin with great force, but only corrodes the metal into a white indiſſoluble maſs. In order to obtain a perfect ſolution of tin in the nitrous acid, the metal muſt be put in by very little at a time, and a diluted aquafortis made uſe of. This ſolution has been conſiderably uſed in dyeing, and is remarkable for heightening red colours of all kinds; but the ſolution made with *aqua-regis* is preferable.

161 Lead.

VI. *With Lead*. Proof aquafortis, lowered with an equal quantity of water, diſſolves about half its weight of lead. On diluting the ſolution with a large quantity of water it turns milky, and depoſites great part of the metal. The ſolution ſhoots, upon exhaling part of the menſtruum, into ſmall pyramidal cryſtals with ſquare baſes, of an auſtere ſweet taſte.

762 Quickſilver ſuppoſed to be extracted from lead.

In the memoirs of the French academy for 1733, there is a particular account of an experiment, in which mercury is ſaid to have been extracted from lead by diſſolving in it the nitrous acid. During the diſſolution, there fell a precipitate which is plainly proved to be mercury, and was looked upon to be one of the conſtituent parts of the lead ſeparated by this ſimple proceſs: it ſeems probable, however, that the mercury in this caſe had been contained in the aquafortis; for pure lead diſſolved in pure aquafortis gives no ſuch precipitate.

The cryſtals of lead in the nitrous acid, when thrown into the fire, do not deflagrate as other combinations of this acid with metallic or ſaline baſes; but crackle violently, and fly round, with great danger to the by-ſtanders. If they are rubbed into very fine powder, they may then be melted without any danger. By repeated diſſolutions in freſh aquafortis, they at laſt form a thick fluid like oil, which cannot be dried without great difficulty. This compoſition is not adapted to any particular uſe, and is a violent poiſon.

763 Quickſilver.

764 Red precipitate.

VII. *With Quickſilver*. Aquafortis of ſuch a degree of ſtrength as to take up half its weight of ſilver, diſſolves with eaſe above equal its weight of mercury into a limpid liquor, intenſely corroſive and poiſonous, which ſpontaneouſly ſhoots into white cryſtals. Theſe cryſtals, or the ſolution exſiccated, and moderately calcined, aſſume a ſparkling red colour; and are uſed in medicine as an eſcharotic, under the name of *red precipitate*. The precipitate has ſometimes been given internally, it is ſaid, in very large quantities; even a whole drachm at one doſe. But this would ſeem incredible; and the peſent practice does not countenance the taking of red precipitate inwardly. This ſolution ſeems to have been what gave the efficacy to Ward's white drop.

When red precipitate is prepared in quantity, it is proper to diſtil the mercurial ſolution; becauſe moſt of the aquafortis may then be ſaved. It is exceedingly pure, if by purity we mean its being free of any admixture of vitriolic or marine acid; but is conſiderably tainted with the inflammable principle of the mercury extricated during the diſſolution. In conſequence of this, it is very volatile and ſmoking; which has generally, though improperly, been taken as a ſign of ſtrength in the nitrous acid.

765 Biſmuth.

VIII. *With Biſmuth*. This ſemimetal is very readily acted upon by the nitrous acid. Proof aquafortis diſſolves about half its weight of biſmuth. If the metal was haſtily added, the ſolution proves of a greeniſh colour; if otherwiſe, it is colourleſs and tranſparent. Unleſs the acid was diluted with about an equal quantity of water, a part of the biſmuth cryſtallizes almoſt as faſt as it diſſolves. The metal is totally precipitated both by fixed and volatile alkalies. The laſt, added in greater quantities than are ſufficient for precipitation, take it up again. The liquor generally appears greeniſh; by alternate additions of the alkaline ſpirit and ſolution, it becomes bluiſh or purple. Fixed alkalies calcined with inflammable matter likewiſe diſſolve the biſmuth after they have precipitated it.

766 Magiſtery of biſmuth.

The only uſe of this compound is for the precipitate, which is uſed as a coſmetic, under the name of *magiſtery of biſmuth*. The common way of preparing this is by diluting the ſolution very largely with water, upon which it turns milky, and a fine white precipitate falls, which is to be well edulcorated with water, and is then employed as a coſmetic both in waſhes and pomatums.

Concerning the preparation of this coſmetic, Neumann obſerves, that there are ſundry variations.—"Some (ſays he) takes aqua-regia for the menſtruum; and for the precipitant a ſolution of ſea-ſalt, alkalies, ſpirit of wine, &c. Some mix with the ſolution of biſmuth a ſolution of benzoin in ſpirit of wine, and thus obtain a magiſtery compounded of biſmuth and benzoin. Others add a ſolution of chalk to the metalline ſolution, and precipitate both together by alkalies. I have made trial with a good number of different precipitants; and found, that with common fixed alkali and cauſtic alkali, with watery and vinous alkaline ſpirits, the magiſtery was white, and in conſiderable quantity; the liquor, after the precipitation with volatile ſpirits, appearing blue. That oil of vitriol threw down a white precipitate very copiouſly: but that with ſpirit of ſalt, or ſpirit of vitriol, the precipitate was in very ſmall quantity, in colour like the foregoing; diſtilled vinegar making no precipitation at all. Common rectified ſpirit of wine, and tartarized ſpirit, common water, and lime-water, gave white precipitates. Solutions of nitre, vitriolated tartar, ſal mirabile, alum, borax, common ſalt, ſal ammoniac, the combination of marine acid with calcareous earth, and terra foliata tartari, all precipitated the biſmuth white. With a ſolution of gold in aqua-regia the magiſtery proved grey; with a ſolution of the ſame metal in aqua-regia made with ſpirit of ſalt, the precipitate was likewiſe grey, and in ſmall quantity; with ſolution of copper in aquafortis, white, and in very ſmall quantity, the liquor continuing blue; with ſolution of vitriol of copper, white; with ſolution of mercury ſublimate, white and plentiful; with ſolution of iron in aquafortis, yellowiſh; with ſolution of lead in aquafortis, and of ſugar of lead, white; with ſolution of zinc in aquafortis there was little precipitate; and with ſolutions of ſilver, tin, regulus of antimony, and of mercury, in the ſame acid, none at all."

767 Zinc.

IX. *With Zinc.* Upon this ſemimetal the nitrous acid acts with greater violence than any other, and will forſake any other metallic ſubſtance for it. The whole is very ſoon diſſolved into a tranſparent colourleſs liquor. The calces of flowers of zinc are likewiſe ſoluble in the nitrous acid; but neither the ſolution of the flowers, nor of the metal itſelf, have been yet found applicable to any uſeful purpoſe. Neumann remarks, that on extracting with nitrous acid the ſoluble parts of calamine, which is an ore of zinc, the ſolution, inſpiſſated to dryneſs, left a reddiſh brown maſs, which on digeſtion with ſpirit of wine exploded and burſt the veſſel.

768 Regulus of antimony.

X. *With Regulus of Antimony.* The nitrous acid rather corrodes than diſſolves this ſemimetal. The corroded powder forms a medicine formerly uſed under the name of *bezoar mineral*, but now diſregarded.

769 Regulus of cobalt.

770 Regulus of cobalt, how diſcovered in ores.

XI. *With Regulus of Cobalt.* This ſemimetal diſſolves readily in the nitrous acid, both in its metallic form and when reduced to a calx. The ſolution is of a red colour. Hence the nitrous acid furniſhes means of diſcovering this ſemimetal in ores after ſtrong calcination; very few other calces being ſoluble in the nitrous acid, and thoſe that are not influencing the colour.

XII. *With Nickel.* This ſemimetal is eaſily diſſolved by the nitrous acid into a deep green liquor; but neither this ſolution, nor indeed the ſemimetal of which it is made, has hitherto been found of any uſe.

XIII. *With Arſenic.* This ſubſtance is readily diſſolved by the nitrous acid; which abſtracts the phlogiſton, and leaves the pure arſenical acid behind. See below *Acid of Arſenic*.

771 Oils.

772 Unguentum citrinum.

XIV. *With Expreſſed Oils.* Theſe, as well as all other fatty or unctuous ſubſtances, are conſiderably thickened and hardened by their union with the nitrous acid. There is only one preparation where this combination is applied to any uſe. It is the *unguentum citrinum* of the ſhops. This is made by adding to ſome quantity of melted hog's-lard a ſolution of quickſilver in the nitrous acid. The acid, though in a diluted ſtate, and combined with mercury, nevertheleſs acts with ſuch force on the lard, as to render the ointment almoſt of the conſiſtence of tallow.

773 Spirit of wine.

774 Spiritus nitri dulcis.

XV. *With Vinous Spirits.* If highly rectified ſpirit of wine and ſtrong ſpirit of nitre are ſuddenly mixed together, the acid inſtantly becomes volatile, and is diſſipated with great heat and efferveſcence in highly noxious red fumes. If the acid is cautiouſly poured into the ſpirit, in the proportion of five, ſix, or even ten parts of ſpirit to one of acid, and the mixture diſtilled in a glaſs retort ſet in a water-bath, an exceedingly fragrant and volatile ſpirit comes over, uſed in medicine as a diuretic and cooler, under the name of *ſpiritus nitri dulcis*. This liquor is not acid; nor has what remains in the retort any more the characteriſtics of nitrous acid, which ſeems to be entirely decompoſed in this proceſs. (See the following article.)

775 Nitrous ether.

With the nitrous acid and ſpirit of wine, may alſo be made an exceedingly volatile liquor, called *nitrous ether*, to diſtinguiſh it from the vitriolic abovementioned. The proportions of nitrous acid and ſpirit of wine to each other for nitrous ether, are two of the acid by weight to three of the ſpirit. Dr Black's proceſs for making it is as follows. Take four ounces of ſtrong phlogiſticated nitrous acid; and having cooled it by putting it into a mixture of ſalt and ſnow, or into water cooled very near the freezing point, by putting pieces of ice into it, he puts it into a phial, and pours upon it an equal quantity of water, likewiſe cooled very low, in ſuch a manner that the water may float as much as poſſible on the ſurface of the ſpirit. Six ounces of ſtrong ſpirit of wine are then put in, ſo as to float in like manner on the ſurface of the water; the phial is placed in a veſſel containing cold water: and ſo great is the power of cold in reſtraining the action of bodies, that if the mixture was too cold, no ether would be produced; but at the temperature juſt mentioned, the ether begins to be formed in a few hours, with ſome little efferveſcence, and an expulſion of a ſmall quantity of nitrous air. We muſt provide for the eſcape of this elaſtic fluid, by having an hole in the cork, or the veſſel would be broken. The whole of the ether will be formed in a few days, and may be ſeparated from the reſt of the liquor by means of a funnel, ſhaped as in Pl. CXXXIV. fig. 9.

776 Woulfe's proceſs for procuring it in large quantities.

To procure the nitrous ether in large quantities, Mr Woulfe recommends the following proceſs. Put into a retort four pounds of nitre, then mix together four pounds of vitriolic acid, and three pounds five ounces of ſpirit of wine. Theſe are poured on the nitre by adding only two ounces at a time: the vitriolic acid acting on the nitre, produces a ſufficient degree of heat; and the acid of the nitre uniting with

Nitrous acid and its combinations.

the ſpirit, forms a nitrous ether, which flies off from the mixture, and is condenſed in a number of veſſels placed in cold water.—To obtain good nitrous ether readily, and at one diſtillation, Mr Dollfuſs adviſes to diſtil four parts of nitre of mangangeſe, four of vitriolic acid, and eight parts of ſpirit of wine.

777 Inquiry into the nature of ether.

Macquer ſuppoſes that ether is the moſt oily part or quinteſſence of ſpirit of wine. But it cannot be proved that ether contains any oil. And, beſides, if this were the caſe, thoſe acids which have the ſtrongeſt attraction for water would produce the greateſt quantity of ether; which is found not to be the caſe: and it is moſt probable that ether is produced by a combination of ſome part of the acid with a portion, particularly the inflammable part, of the ſpirit of wine; and it has been ſhown by chemical experiments, that every kind of ether contains a part of the acid employed. Dr Black himſelf has formed ether without any ſpirit at all, by expoſing nitrous acid highly phlogiſticated for ſome months to the light of the ſun. This was owing to the attraction of the principle of inflammability; which it is well known that light has the power of affording to bodies that attract it with force.

Nitrous Acid DECOMPOSED,

778 Oils fired by ſpirit of nitre.

I. *By Eſſential Oils.* If equal quantities of ſtrong nitrous acid and oil of cloves are poured into the ſame veſſel, the mixture inſtantly takes fire; both acid and oil burning with great fury till only a light ſpongy coal remains. Dr Lewis obſerves, that this experiment does not always ſucceed, and that there are but few oils which can be fired with certainty, without attending to a particular circumſtance firſt diſcovered by M. Rouelle, and communicated in the French Memoirs for the year 1747. "On letting fall into the oil equal its quantity of acid, the mixture effervеſces, ſwells, and a light fungous coal ariſes: a little more of the acid poured upon this coal ſets it inſtantly on fire. By this method almoſt all the diſtilled oils may be fired by ſpirit of nitre of moderate ſtrength. Expreſſed oils alſo may be ſet on fire by a mixture of the nitrous acid and oil of vitriol; the uſe of which laſt ſeems to be to abſorb the aqueous humidity of the ſpirit of nitre.

779 Nitre alkalized.

II. *By Charcoal.* By this ſubſtance the nitrous acid cannot be conveniently decompoſed, unleſs it is combined with an alkaline or metallic baſe. For the purpoſe of decompoſing the acid, common ſaltpetre is moſt convenient. The proportions recommended by Dr Lewis for alkaliſating nitre, are four ounces of the ſalt to five drachms of powdered charcoal. If theſe are carefully mixed, and injected by little and little into a tubulated retort made red hot, and fitted with a large receiver and a number of adopters, a violent deflagration will enſue on every addition, attended with a great quantity of air, and ſome vapours which will circulate for ſome time, and then condenſe in the veſſels. This liquor is called *clyſſus of nitre.* If ſulphur is uſed inſtead of nitre, the clyſſus is of a different kind, conſiſting of a mixture of the nitrous and vitriolic acids. The reſiduum, when charcoal is uſed, is a very ſtrong and pure alkali; with ſulphur it is vitriolated tartar. To prevent the loſs occaſioned by the violent deflagration, when this operation is performed in open veſſels, Dr Black recommends to have the materials ſomewhat moiſt.

780 Clyſſus of nitre.

III. *By Vinous Spirits.* In the proceſs already mentioned for making *ſpiritus nitri dulcis,* a total decompoſition of the acid ſeems to take place: for neither the dulcified ſpirit itſelf, nor the acid matter left in the retort, ſhow any ſigns of deflagration with inflammable matters, which is the peculiar characteriſtic of nitrous acid.

Marine acid and its combinations.

781 Reſiduum of ſpiritus nitri dulcis analized by Mr Pott.

Mr Pott has given an analyſis of the oleaginous reſiduum of the diſtillation. Diſtilled by a ſtronger fire, it gave over a yellow, acid, ſlightly empyreumatic ſpirit; which being ſaturated with fixed alkali, the liquor evaporated, and the dry neutral ſalt laid on burning coals, did not deflagrate. After this ſpirit aroſe a red empyreumatic oil; and in the bottom of the retort was left a ſhining black maſs like ſoot; which, burnt in a crucible, left a white fixed earth, convertible by a vehement fire into glaſs. Another parcel of the above reſiduum was evaporated to the conſiſtence of pitch. In this ſtate it gave a yellow tincture to ſpirit of wine, flamed vividly and quietly on burning coals, and at laſt ſwelled up like bitumen. Another portion was ſaturated with alkaline ley, with which it immediately effervеſced, and then evaporated as the former. It gave, as before, a yellow colour to rectified ſpirit of wine, and a much deeper yellow to dulcified ſpirit of nitre; and in the fire diſcovered no footſtep of detonation. M. Macquer ſuppoſes this acid to have been not the nitrous, but the acetous, which enters into the compoſition of the ſpirit of wine; and his conjecture is now confirmed by late experiments.

§ 3. *Of the* MARINE *Acid and its Combinations.*

782 Marine acid.

THIS acid is never, at leaſt very rarely, found but in a ſtate of ſaturation with the mineral alkali; in which caſe it forms the common ſalt uſed in food. Almoſt the only exception to this is human urine, and perhaps that of ſome other animals; for there the marine acid is found ſaturated, not with the mineral, but the common vegetable, fixed alkali. From being found in ſuch plenty in the waters of the ocean, it has the name of *marine acid.*

783 Marine acid thought to be the ſame with the vitriolic.

It is commonly thought that this acid is no other than the vitriolic, ſomehow or other diſguiſed by the inflammable principle; to which ſome have added another, called by them a *mercurial earth.*

The reaſons given for this ſuppoſition, however, are but very ſlight, conſiſting chiefly in the reſemblance between the volatile vitriolic acid and the marine, both in the white colour of their vapours, and likewiſe the great volatility of both. As to the exiſtence of that principle called a mercurial earth, it hath never been proved; and, till that time, can never be allowed to be an ingredient in the compoſition of any ſubſtance whatever. As we do not remember to have read of any experiments where the marine acid was directly produced from that of vitriol, we ſhall content ourſelves with relating one very remarkable fact which happened to fall under our own obſervation.

784 A tranſmutation.

As vitriolated tartar, or Glauber's ſalt, when fuſed with charcoal duſt, is converted into an hepar ſulphuris, attempts have been made on this principle to ſeparate the pure alkali from the reſiduum of Glauber's ſpirit of nitre and ſpirit of ſalt. In an attempt of this kind, which, by the bye, proved unſucceſsful, as all others of the ſame kind muſt do, 30 or 40 pounds

pounds of the maſs for Glauber's ſalt were fuſed in a ſtrong iron pot, with a ſufficient quantity of common coal powdered and ſifted. As the quantity of powdered coal was pretty large, the maſs was thereby hindered from flowing into thin fuſion; and, that the whole might be perfectly alkaliſated, it was frequently ſtirred up with an iron ladle, and kept very intenſely heated for ſome hours. The maſs was now taken out by means of an iron ladle, and laid on a flat ſtone; and, as it was but half fluid, every ladleful concreted into a black irregular ſaline maſs, which had the appearance of a cinder; but which, however, conſiſted of an hepar ſulphuris mixed with ſome coal-duſt. As there was a conſiderable quantity of this matter, and the ladlefuls were thrown at random above one another, it ſo happened, that between two or three of the pieces, a kind of chimney was formed, ſo that there being a ſmall draught of air through the interſtices, and the maſſes containing a quantity of coal-duſt, the internal parts were in a ſtate of ignition, while the external were quite cold. From theſe ignited places a white fume aroſe; which being collected on the colder maſſes, aſſumed the form of white flowers. Theſe were found to be genuine ſal ammoniac, compoſed of a volatile alkali and marine acid; both of which we have the greateſt reaſon to think were produced at that very time, and that a double tranſmutation took place; namely, of the vitriolic acid into the marine, and of the fixed alkali into the volatile. Our reaſons for being of this opinion are, 1. That the matter had been ſubjected to ſuch an extreme and long continued heat, that, had any ſal ammoniac been pre exiſtent in the mixture, it muſt have certainly been diſſipated, as this ſalt always ſublimes with a degree of heat below ignition. 2. Though the matter was taken out of the pot of a very intenſe red heat, ſo that the ſaline part was evidently melted, yet no ammoniacal fume iſſued from it at that time, nor till the maſſes had been for ſome time expoſed to the air, and were become cool, excepting only thoſe interſtices where the air kept up a burning heat, by a ſmall draught being formed from the ſituation of the ſaline maſſes. 3. In thoſe ignited places, when cool, the fixed ſalt was entirely decompoſed, neither alkaline ſalt, Glauber's ſalt, fixed alkali, nor ſulphur remaining; but the whole was conſumed to a kind of ferruginous aſhes. We are therefore of opinion, that the marine acid and volatile alkali are, in ſome caſes, mere creatures of the fire, and moſt commonly produced at the ſame time, from the ſlow combuſtion of mineral ſubſtances. Hence, where heaps of hot cinders are thrown out, ſmall quantities of the true ſal ammoniac are always formed, when the ignited ones happen to fall in ſuch a manner as to occaſion a ſmall draught of air through them.

785
Dr Prieſtley's obſervations on marine acid.

The marine acid, or ſpirit of ſalt, is weaker than either the vitriolic or nitrous; though Dr Prieſtley hath obſerved, that, when concentrated to the utmoſt degree, in which ſtate it was perfectly inviſible and elaſtic as air, it was then able to ſeparate the nitrous acid from an alkali. In ſome other caſes, too, it appears not only ſtronger than the nitrous, but even than the vitriolic; of which we ſhall take notice in courſe. —Mr Berthollet ſays, that he has been able alſo to procure the marine acid in a ſolid ſtate, by diſtilling it in Mr Woulfe's apparatus, kept perfectly cool with ice.

The yellow colour of the marine acid is ſometimes owing to iron, which may be precipitated from it by means of an alkali. In certain caſes, however, it is obſerved to have a much darker and nearly a brown colour, without containing the ſmalleſt particle of this metal.—Mr Dollfuſs is of opinion, that the yellow colour of the marine acid is owing to a portion of dephlogiſticated air which it generally contains. A pretty ſtrong proof that it emits this kind of air indeed is, that a candle will burn longer in a bottle containing ſome marine acid, than it will in an equal quantity of common air.

I. To procure the Marine Acid by means of the *Vitriolic*.

786
Spirit of ſea-ſalt.

Put any quantity of ſea-ſalt into a tubulated glaſs-retort, to which a large receiver is firmly luted, having a quantity of water in it, more or leſs as you want your ſpirit of ſalt to be more or leſs ſtrong. Having placed your retort in a ſand-bath, take of concentrated oil of vitriol half as much as you put ſalt into the retort. Through the aperture in the upper part of the retort, pour a ſmall quantity of the vitriolic acid; a violent efferveſcence will immediately ariſe, and white vapours will aſcend, and come over into the receiver. Theſe vapours are the marine acid in its moſt concentrated ſtate; and, as they are very greedy of moiſture, they will unite with the water in a very ſhort time, unleſs too much oil of vitriol is put in at once; in which caſe, part of them will be diſſipated through the ſmall hole in the receiver. When you perceive the firſt fumes condenſed, add a little more oil of vitriol, taking care to ſtop the aperture of the retort as ſoon as you drop in the vitriolic acid, that the marine acid may not eſcape. Continue this by intervals, till your acid is all put in; and then make a very gentle fire, that the retort may be no warmer than the hand can bear. This degree of heat muſt be continued a long time, otherwiſe very much of the acid will be loſt. To perform this operation perfectly, no more acid ſhould be forced over, than what the water in the receiver can take up; and by this means the operator's patience will be rewarded with a vaſtly larger produce of acid than can be procured by haſty diſtillation. When the vapours become a little more fixed, a greater heat is neceſſary, but nothing equal to what the nitrous acid requires. For diſtilling ſpirit of ſalt, Mr Wiegleb recommends four pounds of oil of vitriol to ſix of common ſalt.—It may alſo be obtained from the bittern remaining after the cryſtallization of common ſalt, by adding one pound of oil of vitriol to five of bittern. It may even be obtained from this liquid by ſimple diſtillation without any additional acid; but a violent fire will then be neceſſary, and it is almoſt impoſſible to prevent the liquor from ſwelling and running over the neck of the retort in the beginning of the proceſs.

787
Why diſtillation of ſea-ſalt with copperas does not ſucceed.

The marine acid cannot be procured by means of combinations of the vitriolic acid with metallic and earthy baſes, as the nitrous is; for though, by means of calcined vitriol, for inſtance, the marine acid is effectually expelled from its alkaline baſis, yet it immediately combines with the calx of iron left by the vitriolic acid, and not only adheres obſtinately, but even ſublimes the metal; ſo that what little ſpirit can be ob-

obtained, is never pure. This inconvenience is not ſo great when uncalcined copperas is made uſe of: for the marine acid has a very ſtrong attraction to water; which partly diſſolves its union with the metalline calx. If gypſum is uſed, inſtead of calcined vitriol, not a drop of ſpirit will be obtained. Alum and ſal catharticus amarus anſwer better.

II. To procure the Marine Acid by means of the *Nitrous*.

788 Aqua-regis.

Take equal quantities of ſea-ſalt and Glauber's ſpirit of nitre; put the ſalt into a retort, and pour on it the nitrous acid; let them ſtand for 10 or 12 hours; then diſtil with a gentle heat; an acid liquor will come over, which is a compound of the nitrous and marine acids, called *aqua-regis*. When the diſtillation is finiſhed, and the veſſels cooled, pour back the diſtilled liquor on the maſs which is left on the retort, and diſtil again: the ſecond produce will be more of the nature of ſpirit of ſea-ſalt than the former. Continue to do this, pouring the diſtilled liquor either on the maſs left in the retort, or upon freſh ſea-ſalt, till you obſerve that no nitrous acid ariſes. No experiments have been made on this ſpirit of ſalt, by which we can judge whether it is different from that procured by the vitriolic acid or not.

III. To procure the Marine Acid, by diſtilling Salt *per ſe*.

789 Spirit of ſalt *per ſe*.

Put into a retort any quantity of common ſalt which has not been dried, and diſtil in a ſand-heat till nothing more will come over. In the receiver you will have a liquor conſiderably more acid than vinegar, in weight about the fourth part of the ſalt employed. On the dry ſalt left in the retort, pour ſome water, ſomewhat leſs in quantity than the liquor which came over. Let it ſtand till the ſalt has thoroughly imbibed the moiſture, and then diſtil again. You will again have an acid, but weaker than the former. Repeat this ſix or ſeven times; after which you will obtain no more marine acid in this way. It has been thought that ſea-ſalt was capable of total decompoſition by means of moiſture alone; but that is found to be a miſtake. The reaſon of any acid being procurable in this way, is the impurity of the common ſalt, which is always mixed with a quantity of ſal catharticus amarus, and of marine acid combined with magneſia, from which laſt it is ſeparable by moiſture. If a pure ſalt be formed by combining marine acid with ſalt of ſoda, no ſpirit will be obtained.

IV. To dephlogiſticate the Marine Acid.

790 Marine acid dephlogiſticated by that of nitre or by manganeſe.

The marine acid, when mixed either with that of nitre or with manganeſe, loſes that peculiar ſmell by which it is uſually diſtinguiſhed, and acquires one much more volatile and ſuffocating. When mixed with the former, the compound is called *aqua-regia*; when ſubjected to the action of manganeſe, the product is called *dephlogiſticated ſpirit of ſalt*. The method of procuring this acid recommended by Mr Scheele is as follows:

791 Scheele's method of dephlogiſticating it by manganeſe.

Mix common muriatic acid in any quantity with levigated manganeſe in a glaſs retort; to which lute on with blotting paper a receiver capable of containing about 12 ounces of water. Put about two drachms of liquid into it; and in about a quarter of an hour, or ſomewhat more, a quantity of elaſtic fluid, which is the true dephlogiſticated ſpirit of ſalt, will paſs over, and communicate a yellow colour to the air in the receiver; after which the latter is to be ſeparated from the retort. If the paper has been cloſely applied, a quantity of the air will now ruſh out with ſome violence; a cork muſt therefore inſtantly be put into it, and another receiver applied, having in like manner two drachms of water in it, which will alſo be filled in a ſhort time; and thus may ſeveral phials full of this aerial acid be procured in a ſhort time. Care ſhould be taken, that the retort be placed in ſuch a manner as that any drops of liquid which chance to ariſe may fall down again into it. The water put into the receivers ſeems to condenſe the vapours of the marine acid; and it is moſt proper to uſe ſmall receivers, on account of the great quantity of vapour which is loſt at every operation.

792 Properties of dephlogiſticated ſpirit of ſalt.

The effects of this dephlogiſticated marine acid, which can ſcarcely be condenſed into a liquid, are, 1. The lute is corroded in diſtillation, and the corks become yellow, as from aquafortis. 2. Paper coloured with lacmus becomes nearly white, as well as all vegetable red, blue, and yellow flowers; and the ſame change is likewiſe produced upon the green colour of vegetables; nor can any of theſe colours be recovered either by alkalies or acids. 3. Expreſſed oils and animal fats, expoſed to the vapour, become as tenacious as turpentine. 4. Cinnabar grew white on the ſurface; and when it was waſhed, a pure ſolution of corroſive ſublimate was obtained; but ſulphur was not changed. 5. Green vitriol became red and deliqueſcent; but white and blue vitriol remained unchanged. 6. Iron filings were diſſolved; and on evaporating the ſolution to dryneſs, common muriatic acid was obtained by diſtillation with marine acid. 7. In like manner all the metals, even gold itſelf, were diſſolved; and by precipitation with volatile alkali, the ſolution of gold yielded aurum fulminans. 8. The cauſtic volatile alkali produced a white cloud, and emitted a number of air-bubbles, which on burſting diſcharged an elaſtic vapour. 9. Fixed alkali was changed into common ſalt, which decrepitated in the fire. 10. Arſenic became deliqueſcent, inſects died, and fire was inſtantaneouſly extinguiſhed in the vapour.

793 Miſtake of Stahl accounted for.

Theſe phenomena proceed from the ſtrong attraction of dephlogiſticated marine acid for the phlogiſton it has loſt; and which is one of the eſſential parts of it, without which it can ſcarce at all be condenſed into a liquor. "Perhaps (ſays Mr Scheele) Stahl obtained ſuch a dephlogiſticated muriatic acid by means of iron; and from the yellow colour of the cork was led to ſuppoſe that the muriatic acid had been changed into the nitrous. If you make a mixture of manganeſe, muriatic acid, or diluted vitriolic acid, and alcohol; and after ſome days digeſtion diſtil it by a gentle fire, no efferveſcence enſues: but the ſpirit of wine goes over; and, what is very remarkable, has a ſtrong ſmell of nitrous ether.

2d 793 New ſalt reſembling nitre by Mr Berthollet.

A new ſalt has been produced by Mr Berthollet from the union of dephlogiſticated ſpirit of ſalt with vegetable alkali. This appears to be of the nitrous kind, as having a cool taſte and detonating ſtrongly in the fire. The compound was in very ſmall quantity, and ſeemed to require more pure air for its compoſition than an equal bulk of acid. The greateſt part of the ſalt produced was the common ſalt of Sylvius, or digeſtive ſalt, formed by a combination of the phlogiſticated marine acid with alkali. Six parts of the dephlogiſticated acid are required to give their air to one of the ſalt. When the fixed alkali is employed, ſome of the dephlogiſticated acid eſcapes with the pure air; and in general, when not expoſed to a bright heat, the ſalt we ſpeak of is formed. Some of the dephlogiſticated acid remains in its proper form after the ſalt is made, and may be ſeparated by the volatile alkali. It is to be obſerved, that if the cauſtic alkali be employed, and the ſolution much concentrated, even though not under the influence of a bright light (for it is the light which produces the extrication of the dephlogiſticated air*), a great effervеſcence will enſue, and a quantity of dephlogiſticated air eſcape; whence of conſequence, little ſalt can be obtained.

This ſalt is ſoluble in greater quantity in hot than in cold water; and not only detonates like nitre, but with much greater violence. The reaſon is, that, like nitre, it not only contains dephlogiſticated air, but has it in greater quantity; an hundred grains of ſalt giving 75 of air. Attempts have been made to procure gunpowder by means of this ſalt, but as yet they have been attended with little ſucceſs.

The other properties of this ſalt as yet diſcovered are, that it ſhoots into rhomboidal cryſtals; it does not precipitate mercury, ſilver, or lead, from their ſolutions in nitrous acid; and it gives out its air again in ſuch a pure ſtate as ſcarcely to be paralleled in any other ſubſtance.

With the mineral alkali the dephlogiſticated acid forms a deliqueſcent ſalt, ſoluble in ſpirit of wine; and which, even in a fluid ſtate, detonates with burning charcoal. With lime, when ſo far quenched that the air in its interſtices is ſeparated, the dephlogiſticated acid unites but weakly. It may be recovered from the lime, however, provided the light be obſcure, with very little loſs, and almoſt unchanged.

Marine Acid COMBINED,

794 Sal digeſtivus ſylvii.

I. *With Vegetable Fixed Alkali.* This combination is accidentally formed after the diſtillation of volatile ſalts, by means of ſalt of tartar (ſee *Alkaline Salts*). It was formerly known by the name of *ſal digeſtivus Sylvii;* and a proceſs for making it was inſerted in the diſpenſatories, under the name of *ſpiritus ſalis marini coagulatus;* but as it has been found to poſſeſs no virtues ſuperior, or even equal, to common ſalt, it is fallen into diſuſe.

The cryſtals of this kind of ſalt are not cubical, like thoſe of common ſalt, but parallelopipeds, and if thrown into the fire crack and leap about with violence. They are ſoluble in greater quantity by hot water than cold; and therefore are cryſtallized by evaporating the ſolution to a pellicle, and then letting it cool.—It is very remarkable, that though by a direct combination of vitriolic acid with vegetable fixed alkali, the ſalt called *vitriolated tartar* is formed; yet if this alkali is once ſaturated with ſpirit of ſalt, ſo as to form a *ſal digeſtivus*, upon the decompoſition of this ſalt by means of oil of vitriol, the reſiduum of the diſtillation will not be a vitriolated tartar, but a ſalt eaſily ſoluble in water, and which bears a ſtrong reſemblance to Glauber's ſalt. Whether, by means of ſpirit of ſea-ſalt, the vegetable alkali could be converted into the mineral, or ſalt of ſoda, is a queſtion well worthy of being ſolved.

II. *With Minenal Alkali.* This combination is the common alimentary ſalt, and is never made but for experiment's ſake; as the marine acid cannot be had but from ſea-ſalt. For the extraction of this ſalt from ſea-water, ſee the article SALT.

795 Sal ammoniac.

III. *With Volatile Alkali.* The produce of this combination is the common ſal ammoniac, which is uſed in different arts, and which has the property of making tin unite very readily with iron and copper, ſo is much uſed by copperſmiths and in the manufactory of tinned iron.

Sal ammoniac is uſually ſold in large ſemi-tranſparent cakes, which are again capable of being ſublimed into maſſes of the like kind. If they are diſſolved in water, the ſalt very eaſily ſhoots into ſmall cryſtals like feathers. Expoſed to a moiſt air, it deliquates. It is one of the ſalts which produces the moſt cold by its ſolution; ſo as to ſink the thermometer 18 or 20 degrees, or more, according to the temperature of the atmoſphere. According to Mr Gellert, a ſolution of ſal ammoniac has the property of diſſolving reſins. According to Neumann, the volatility of ſal ammoniac is ſo much diminiſhed by repeated ſublimations, that at laſt it remains half fluid in the bottom of the ſubliming veſſel. In its natural ſtate, it ſublimes with a degree of heat neceſſary to melt lead. Pott ſays, that a ſmall quantity of ſal ammoniac may be produced by diſtilling ſea-ſalt with charcoal, or with alum, or by diſtilling marine acid with Armenian bole. The ſame author affirms, that the inflammability of ſulphur is deſtroyed by ſubliming it with twice its quantity of ſal ammoniac.

796 How made.

The method of making this ſalt was long unknown; and it was imported from Egypt, where it was ſaid to be prepared by ſublimation from ſoot alone, or from a mixture of ſea-ſalt, urine, and ſoot. That it ſhould be produced from ſoot alone is very improbable; and the other method, from the known principles of chemiſtry, is abſolutely impoſſible. The compoſition of this ſalt, however, being once known, there remained no other deſideratum than a method of procuring thoſe competent parts of ſal ammoniac ſufficiently cheap, ſo as to afford ſal ammoniac made in Britain at a price equally low with what was imported. The volatile alkali is to be procured in plenty from animal ſubſtances or from ſoot; and the low price of the vitriolic acid made from ſulphur affords an eaſy method of decompoſing ſea-ſalt, and obtaining its acid at a low rate. A ſal ammoniac work has, accordingly, been eſtabliſhed for ſeveral years paſt in Edinburgh; the principal material made choice of for procuring the volatile alkali is ſoot; and though no perſons are admitted to ſee the work, the large quantities of oil of vitriol brought into it, and the quantities of genuine *ſal mirabile* which are there made, evidently ſhow that the proceſs for making ſal ammoniac alſo produces Glauber's ſalt, by the decompoſition of common ſalt by means of vitriolic acid. The method of conducting the proceſs is unknown; but it is plain that there can be no other difficulty than what ariſes from the volatility of the vapours of the alkali and of the marine acid. In the common way of diſtilling thoſe ſubſtances, a great part of both is loſt; and if it is attempted to make ſal ammoniac by combining theſe two when diſtilled by the common apparatus, the pro-

---

* See *Aërology*, nº 36, *et ſeq.*

duce will not pay the coſt; a little ingenuity, however, will eaſily ſuggeſt different forms and materials for diſtilling-veſſels, by which the marine acid and volatile alkali may be united without loſing a particle of either.

If a ſolution of vitriolic or Glauber's ſecret ſal ammoniac is mixed with ſea-ſalt, the vitriolic acid ſeizes the alkaline baſis of the ſea-ſalt, and expels the marine acid; which immediately unites with the volatile alkali left by the vitriolic acid, and forms a true ſal ammoniac. If this ſolution is now evaporated to dryneſs, and the ſaline maſs ſublimed, the ſal ammoniac riſes, and leaves a combination of vitriolic acid and mineral alkali at the bottom. This fixed maſs being diſſolved, filtered, and evaporated, affords Glauber's ſalts. This has ſometimes been thought a preferable method of making ſal ammoniac, as the trouble of diſtilling the marine acid was thereby prevented; but it is found vaſtly inconvenient on another account, namely, that when ſal ammoniac is mixed with any fixed ſalt, it is always more difficult of ſublimation, and a part of it even remains entirely fixed, or is deſtroyed. The maſs of Glauber's ſalt alſo, by reaſon of the inflammable and oily matter contained in impure volatile alkalies, is partly changed into a ſulphureous maſs, ſo that the ſolution refuſes to cryſtallize; at leaſt the operation is attended with intolerable trouble.

797 Fixed ſal ammoniac.

IV. *With Earths.* The combinations of this acid with earths of any kind have never been found applicable to any purpoſe, and therefore they are ſeldom made or inquired into. The combination with calcareous earth is indeed pretty frequently made accidentally, in the diſtillation of volatile alkali from ſal ammoniac by means of chalk or quicklime. When melted in a crucible and cooled, it appears luminous when ſtruck, and has been called *phoſphorus ſcintillans*. See Earths.

798 Phoſphorus.

799 Solution of gold in ſpirit of ſalt.

V. *With Gold.* The marine acid has no action on gold in its metallic ſtate, in whatever manner the acid be applied; but if the metal is previouſly attenuated, or reduced to a calx, either by precipitation from aqua-regis or by calcination in mixture with calcinable metals, this acid will then perfectly diſſolve, and keep it permanently ſuſpended. Gold, precipitated from aqua-regis by fixed alkalies, and edulcorated by repeated ablutions, may be diſſolved even in a very weak ſpirit of ſalt by moderate digeſtion. This ſolution appears of the ſame yellow colour as that made in aqua-regis; gives the purple ſtain to the ſkin, feathers, bones, and other ſolid parts of animals; the ſame violet ſtain to marble; and ſtrikes the ſame red colour with tin. Even when common aqua-regia is made uſe of for the menſtruum, it ſeems to be chiefly by the marine acid in that compound liquor that the gold is held in ſolution. In diſtillation the nitrous acid ariſes, and the marine acid remains combined with the gold in a blood-red maſs, ſoluble, like moſt of the combinations of metallic bodies with this acid, in ſpirit of wine. If, towards the end of the diſtillation, the fire is haſtily raiſed, part of the gold diſtils in a high ſaffron-coloured liquor; and part ſublimes into the neck of the retort in cluſters of long ſlender cryſtals of a deep red colour, fuſible in a ſmall heat, deliquating in the air, and eaſily ſoluble in water. By repetitions of this proceſs the whole of the gold may be elevated, except a ſmall quantity of white powder whoſe nature is not known.—This red ſublimate of gold is ſaid to be eaſily fuſible with the heat of one's hand, and to be ſhown by the Papiſts for the blood of St Januarius; the ſublimate contained in a phial, being warmed by the hands of the prieſts who hold it, conſtitutes the miracle of that ſaint's blood melting on his birth-day.

800 Blood of St Januarius.

801 Silver.

VI. *With Silver.* Strong ſpirit of ſalt corrodes leaf-ſilver into a white powder, but has no effect on filings or larger maſſes of the metal. If applied in the form of vapour to maſſes of ſilver, and ſtrongly heated at the ſame time, it readily corrodes them. Thus, if filings, grains, or plates, of ſilver are mixed with about twice their weight of mercury ſublimate, and expoſed to a moderate fire, in a retort, or other diſtilling veſſel, a part of the marine acid in the ſublimate will be ſeparated and unite with the ſilver, leaving the mercury to ariſe in the form of mercurius dulcis. Marine acid is commonly ſuppoſed to be incapable of diſſolving ſilver into a liquid ſtate; but Henckel relates, that if red ſilver ore, which conſiſts of ſilver intimately mixed with red arſenic, be digeſted in ſpirit of ſalt, the ſilver will be extracted and kept permanently diſſolved.

802 Luna cornea.

The combination of marine acid with ſilver is called *luna cornea*. The moſt ready way of preparing it is by diſſolving ſilver in the nitrous acid, and then adding ſpirit of ſalt, or a ſolution of ſea-ſalt, when a precipitation inſtantly enſues; the marine acid expels the nitrous, and uniting with the ſilver, falls to the bottom in form of a white powder. The ſame precipitation would take place, if a ſolution of ſilver was made in the vitriolic acid.

803 Its properties.

Luna cornea weighs one-fourth more than the ſilver employed; yet, when perfectly waſhed, it is quite inſipid to the taſte. It does not diſſolve in water, ſpirit of wine, aqua-fortis, or aqua-regis; but is in ſome ſmall degree acted upon by the vitriolic acid. It melts in the fire as ſoon as it grows red-hot; and, on cooling, forms a ponderous browniſh maſs, which being caſt into thin plates, becomes ſemitranſparent, and ſomewhat flexible, like horn; whence its name *luna cornea*. A ſtronger fire does not expel the acid from the metal, the whole concrete either ſubliming entire, or paſſing through the crucible. It totally diſſolves in volatile alkaline ſpirits without any ſeparation of the metal. Expoſed to the fire in a cloſe copper veſſel, it penetrates the copper, and tinges it throughout of a ſilver colour. Kunckel obſerves, that when carefully prepared, melted in a glaſs veſſel, and ſuffered to cool ſlowly, to prevent its cracking, it proves clear and tranſparent; and may be turned into a lathe and formed into elegant figures. He ſuppoſes this to be the preparation which gave riſe to the notion of malleable glaſs.

804 Copper.

VII. *With Copper.* In the marine acid, copper diſſolves but ſlowly. The ſolution, if made without heat, appears at firſt brown; but, on ſtanding for ſome time, depoſits a white ſediment, and becomes green. On adding freſh copper, it becomes brown again, and now recovers its greenneſs more ſlowly than before. The white ſediment, on being barely melted, proves pure and perfect copper of the ſame colour as at firſt. Copper calcined by fire communicates a reddiſh colour to this acid.

805 Iron.

VIII. *With Iron.* The marine acid acts upon iron leſs

leſs vehemently than the nitrous, and does not diſſolve ſo much; nevertheleſs, it attacks the metal briſkly, ſo as to raiſe conſiderable heat and efferveſcence, and diſſolve it into a yellow liquor. During the ſolution, an inflammable vapour ariſes as in the ſolution of this metal by vitriolic acid. This ſolution of iron does not cryſtallize. If it is evaporated, it leaves a greeniſh ſaline maſs, which is ſoluble in ſpirit of wine, and runs in the air into a aſtringent yellow liquor.

806 **Iron volatilized.**

On diſtillation, ſome of the acid ſeparates, and towards the end of the operation the ſpirit becomes yellow. This is followed by a yellowiſh or deep reddiſh ſublimate, which gliſtens like the ſcales of fiſhes; leaving behind a ſubſtance which conſiſts of thin, gloſſy plates, like talc.

807 **Tinctura martis.**

The ſolution of iron in ſpirit of ſalt, with the addition of ſome ſpirit of wine, is uſed in medicine as a corroborant, under the name of *tinctura martis*. The ſublimate of iron is alſo uſed for the ſame purpoſe, and called *ens veneris*, or *flores martiales*. It is commonly directed to be prepared by ſubliming iron filings and ſal ammoniac together. In the proceſs, the ſal ammoniac is partly decompoſed, and a cauſtic alkaline liquor diſtils.

808 **Flores martiales.**

Then the undecompoſed ſal ammoniac, and the martial ſublimate abovementioned, ariſe together. The ſublimate has a deeper or lighter yellow colour, according as it contains more or leſs iron. The name *ens veneris* is improper. It was given by Mr Boyle, who diſcovered this medicine. He imagined it to be a preparation of copper, having made uſe of a colcothar of vitriol containing both iron and copper.

2d 808 **Beſtuchef's tincture.**

A medicine of this kind was lately ſold with great reputation on the Continent, under the name of *Beſtuchef's nervous tincture*. It was introduced by M. Beſtuchef Field Marſhal in the Ruſſian ſervice: but not long after it came into vogue in Pruſſia and other northern kingdoms of Europe: it made its appearance alſo in France, under the name of *General de la Motte's golden drops*. This happened through the infidelity of Beſtuchef's operator, who, for a ſum of money, violated the oath of ſecrecy he had taken to Beſtuchef, and diſcovered the ſecret to de la Motte. To the latter it proved a very valuable acquiſition; for he not only procured a patent for it from the king of France in 1730, with the excluſive privilege of ſelling it, but had a handſome penſion ſettled upon him; ſelling his medicine beſides a half a Louis d'or per phial.

3d 808 **Miſtakes concerning it.**

The attention of the public was particularly drawn to theſe drops, by their remarkable property of loſing their yellow colour in the ſun, and regaining it in the ſhade, which induced many to believe that they contained gold; and in which opinion they were encouraged by de la Motte. Even chemiſts of no little reputation were deceived by this appearance; and M. Beaumé, imagining he had diſcovered the ſecret, publiſhed a preparation to the world as the true arcanum of la Motte's drops. It conſiſted of a calx of gold precipitated from aqua-regia by means of fixed alkali, and rediſſolved in nitrous acid, to which was added a large quantity of ſpirit of wine. Others, however, who could find nothing but iron by an analyſis of the drops, refuſed their aſſent; and at length, in 1780, M. Beaumé's miſtake was made evident by the publication of the proceſs at the deſire of the empreſs of Ruſſia, who gave 3000 rubles for the receipt.

4th 808 **True method of preparing it.**

The original *recipe* is perplexed, tedious, and expenſive; but when deprived of its ſuperfluous parts, is nearly as follows. Six pounds of common pyrites and twelve of corroſive ſublimate are to be triturated together, and then ſublimed ſix or eight times till all the mercury is expelled. The reſiduum is to be boiled three times with thrice its quantity of water, and as often filtered, and laſtly, diſtilled to dryneſs. By increaſing the fire, a martial ſalt is at laſt ſublimed into the neck of the retort; to three drachms of which are to be added 12 ounces of highly rectified ſpirit of wine, and the whole expoſed to the rays of the ſun. This is the yellow tincture; but there was alſo a white one, which, however, ſeems to be but of little value. It is made by pouring on the reſiduum of the laſt ſublimation twelve pounds of highly rectified ſpirit of wine, and drawing it off by a gentle diſtillation after a few days digeſtion.

5th 808 **Suppoſed to abſorb phlogiſton from the ſun's rays.**

—Mr Klaproth imagines, from the following experiment, that Beſtuchef's tincture abſorbs phlogiſton from the rays of the ſun. He poured a few drops of a ſolution of tartar into two ounces of diſtilled water, and divided this into two parts. Into one glaſs having poured a few drops of the tincture that had not been expoſed to the ſun, the iron was precipitated in the uſual form of a yellow ochre; but on treating in the ſame manner a portion of the tincture that had been expoſed to the ſolar rays, the precipitate fell of a bluiſh green colour.

809 **Solution of tin.**

IX. *With Tin.* Though the concentrated marine acid has a greater attraction for tin than any other acid, it does not readily diſſolve this metal while the acid is in its liquid ſtate; but may be made to diſſolve it perfectly by the addition of a ſmall quantity of ſpirit of nitre. Neumann obſerves, that an ounce of ſpirit of ſalt, with only a ſcruple of ſpirit of nitre, diſſolved tin perfectly: but on inverting the proportions, and taking a ſcruple of marine acid to an ounce of the nitrous, four ſcruples, or four and an half, of tin, were diſſolved into a thick pap; ſome more of the marine acid being gradually added, the whole was diſſolved into a clear liquor. In making theſe ſolutions, a ſmall quantity of black matter uſually ſubſides.

The ſolution of tin is ſometimes colourleſs; ſometimes of a bluiſh, or yellow colour, according to different circumſtances of the proceſs. It is of the greateſt conſequence in dyeing, by not only heightening the colours, but making them more durable (See DYEING). It ſhoots into ſmall cryſtals; and, if inſpiſſated, deliquates in the air.

810 **Smoking liquor of Libavius.**

Marine acid in its concentrated ſtate volatilizes tin, and forms with it a thick liquor, which, from its inventor, is called *ſmoking liquor of Libavius*. To prepare this ſmoking liquor, an amalgam muſt be made of four parts of tin and five of mercury. This amalgam is to be mixed with an equal weight of corroſive mercury. by triturating the whole together in a glaſs mortar. The mixture is then to be put into a glaſs retort, and the diſtillation performed with a fire gradually increaſed. A very ſmoking liquor paſſes into the receiver; and towards the end of the diſtillation, a thick, and even concrete matter. When the operation is finiſhed, the liquor is to be poured quickly into a cryſtal glaſs-bottle, with a glaſs ſtopper. When this bottle is opened, a white, copious, thick, the poignant fume iſſues, which remains long in the air without diſappearing.

The acid in this liquor is far from being ſaturated, and

and is capable of ſtill diſſolving much tin in the ordinary way. From this imperfect ſaturation, together with its concentration, proceeds partly its property of ſmoking ſo conſiderably: nevertheleſs, ſome other cauſe probably concurs to give it this property; for though it ſmokes infinitely more than the moſt concentrated ſpirit of ſalt, its vapours are, notwithſtanding, much leſs elaſtic. It has all the other properties of concentrated marine acid when imperfectly ſaturated with tin. If it is diluted with much water, moſt of the metal ſeparates in light white flocks. In dyeing, it produces the ſame effects as ſolution of tin made in the common way. If the diſtillation is continued after the ſmoking liquor of Libavius has come over, the mercury of the corroſive ſublimate will then ariſe in its proper form.

811 Lead.

X. *With Lead.* Marine acid, whether in its concentrated or diluted ſtate, has little effect upon lead, unleſs aſſiſted by heat. If ſpirit of ſalt is poured on filings of lead, and the heat is increaſed ſo as to make the liquor boil and diſtil, a part of the acid will be retained by the metal, which will be corroded into a ſaline maſs; and this, by a repetition of the proceſs, may be diſſolved into a limpid liquor. If lead is diſſolved in aquafortis, and ſpirit of ſea-ſalt, or ſea-ſalt itſelf, added, a precipitation of the metal enſues; but if ſome aqua-regia is added, the precipitate is rediſſolved.

812 Plumbum corneum.

The combination of lead with marine acid, has, when melted, ſome degree of tranſparency and flexibility like horn; whence, and from its reſemblance to luna cornea, it is called *plumbum corneum*. This ſubſtance is uſed in preparing phoſphorus, according to Mr Margraaf's method.

813 Quickſilver.

XI. *With Quickſilver.* Marine acid in its limpid ſtate, whether concentrated or diluted, has no effect upon quickſilver, even when aſſiſted by a boiling heat; but if mercury is diſſolved in the vitriolic or nitrous acids, and ſea-ſalt, or its ſpirit, is added to the ſolution, it immediately precipitates the quickſilver in the ſame manner as it does ſilver or lead.
814 Corroſive ſublimate.
If concentrated marine acid, in the form of vapour, and ſtrongly heated, meets with mercury in the ſame ſtate, a very intimate union takes place; and the produce is a moſt violent corroſive and poiſonous ſalt, called *corroſive ſublimate mercury*. This ſalt is ſoluble, though ſparingly, in water; but is far from being perfectly ſaturated with mercury; for it will readily unite with almoſt its own weight of freſh quickſilver, and ſublime with it into a ſolid white maſs (which, when levigated, aſſumes a yellowiſh colour) called *mercurius dulcis*, *aquila alba*, or *calomel*.

815 Different methods of making.

There have been many different ways of preparing corroſive mercury, recommended by different chemiſts. Neumann mentions no fewer than ten. 1. From mercury, common ſalt, nitre, and vitriol. 2. From mercury, common ſalt, and vitriol. 3. Mercury, common ſalt, and ſpirit of nitre. 4. Solution of mercury in aquafortis, and ſalt. 5. Solution of mercury in aquafortis, and ſpirit of ſalt, or the white precipitate. 6. Mercury, common ſalt, nitre, and oil of vitriol. 7. Edulcorated turbith mineral, and common ſalt. 8. Red precipitate, common ſalt, and oil of vitriol. 9. Edulcorated turbith mineral, and ſpirit of ſalt. 10. Mercury, ſal ammoniac, and oil of vitriol.

From a view of theſe different methods, it is evident, that the intention of them all is to combine the marine acid with quickſilver; and as this combination can be effected without making uſe of the nitrous acid, the greateſt chemiſts have imagined that this acid, which is by far the moſt expenſive of the three, might be thrown out of the proceſs altogether, and the ſublimate be more conveniently made by directly combining marine acid and mercury in a proceſs ſimilar to the diſtillation of ſpirit of ſalt. This method was formerly recommended by Kunckel; then publiſhed in the memoirs of the Academy of Sciences for 1730; and has been adopted and recommended by Dr Lewis.

The proceſs conſiſts in diſſolving mercury in the vitriolic acid, as directed for making turbith mineral. The white maſs remaining on the exſiccation of this ſolution is to be triturated with an equal weight of dried ſalt, and the mixture is then to be ſublimed in a ſand-heat; gradually increaſing the fire till nothing more ariſes.

816 Differences of quality.

Neumann obſerves, that there is a conſiderable difference in the quality of ſublimates made by the different methods he mentions; particularly in thoſe made with or without nitre. This we have alſo found to be the caſe; and that ſublimate made without the nitrous acid is never ſo corroſive, or ſoluble in water, as that which is made with it: nor will it afterwards take up ſo large a quantity of crude mercury as it otherwiſe would, when it is to be formed into calomel. The above proceſs, therefore, tho' very convenient and eaſy, is to be rejected; and ſome other in which the nitrous acid is uſed, ſubſtituted in its ſtead. The reaſon of theſe differences is, that the ſpirit of ſalt muſt by ſome means or other be dephlogiſticated before it can unite in ſufficient quantity with the metal, into the compound deſired, which is accompliſhed by the addition of nitrous acid.

From Tachenius, Neumann gives us the following proceſs, which he ſays was the method of making ſublimate at London, Venice, and Amſterdam. Two hundred and eighty pounds of quickſilver, 400 pounds of calcined vitriol, 200 pounds of nitre, the ſame quantity of common ſalt, and 50 pounds of the caput mortuum remaining after a former ſublimation, or (in want of it) of the caput mortuum of aquafortis, making, in all, 1130 pounds, are well ground, and mixed together; then ſet to ſublime in proper glaſſes placed in warm aſhes, the fire is increaſed by degrees, and continued for five days and nights. In the making ſuch large quantities, he ſays, ſome precautions are neceſſary, and which thoſe conſtantly employed herein are beſt acquainted with. The principal are, the due mixture of the ingredients, which in ſome places is performed in the ſame manner as that of the ingredients for gun-powder: that a head and receiver be adapted to the ſubliming glaſs, to ſave ſome ſpirit of nitre which will come over. (Here a bent tube of glaſs will anſwer the purpoſe, as already mentioned). The fire muſt not be raiſed too haſtily. When the ſublimate begins to form, the aſhes muſt be removed a little from the ſides of the glaſs, or the glaſs cautiouſly raiſed up a little from the aſhes. (This laſt, we think, is highly imprudent.) Laſtly, the laboratory muſt have a good chimney, capable of carrying off the noxious fumes. The above-mentioned quantities commonly yield 360 pounds of ſublimate; the 280 pounds of quickſilver gaining 80 from the 200 pounds of ſea-ſalt. The makers of ſublimate

limate in France, he ſays, employ, in one operation, only 20 pounds of mercury. This they diſſolve in aquafortis, evaporate the ſolution to dryneſs, mix the dry matter with 20 pounds of decrepitated ſea-ſalt and 60 of calcined vitriol, and then proceed to ſublimation.

817 Obſervations on the different methods.

The above proceſſes, particularly the laſt, are unexceptionable as to the production of a ſublimate perfectly corroſive; but the operation, it is evident, muſt be attended with conſiderable difficulty, by reaſon of the large quantity of matter put into the glaſs at once. We muſt remember, that always on mixing a volatile ſalt with a quantity of fixed matter, the ſublimation of it becomes more difficult than it would have been had no ſuch matter been mixed with it. It is of conſiderable conſequence, therefore, in all ſublimations, to make the quantity of matter put into the glaſs as little as poſſible. It would ſeem more proper, inſtead of the calcined vitriol uſed in the proceſſes laſt mentioned, to diſſolve the mercury in the vitriolic acid, as directed in turbith mineral, and ſublime the dry maſs mixed with nitre and ſea-ſalt.

818 Suppoſed adulteration with arſenic.

It has been ſaid, that corroſive ſublimate mercury was frequently adulterated with arſenic; and means have even been pointed out for detecting this ſuppoſed adulteration. Theſe means are, to diſſolve a little of the ſuſpected ſalt in water, and add an alkaline lixivium to precipitate the mercury. If the precipitate was of a black colour, it was ſaid to be a certain ſign of arſenic. This, however, ſhows nothing at all, but that either the alkali contains ſome inflammable matter, which, joining with the precipitate, makes it appear black; or that the ſublimate is not perfectly corroſive; for if a volatile alkali is poured on levigated *mercurius dulcis*, the place it touches is inſtantly turned black.

819 Mercurius dulcis.

Mercurius dulcis, or calomel, is prepared by mixing equal parts, or at leaſt three of quickſilver with four of ſublimate; after being thoroughly ground together in a glaſs or ſtone mortar, they are to be poured through a long funnel into a bolt-head, and then ſublimed. The medicine has been thought to be improved by repeated ſublimations, but this is found to be a miſtake. Mr Beaumé has found that mercurius dulcis cannot be united with corroſive ſublimate in the way of ſublimation; the former, by reaſon of its ſuperior volatility, always riſes to the top of the veſſel.

820 Zinc volatilized.

XII. *With Zinc.* This ſemimetal diſſolves readily in the marine acid into a tranſparent colourleſs liquor. It is volatilized, as well as moſt other metallic ſubſtances by this combination, as appears from the following proceſs delivered by Neumann.

“ Equal parts of filings of zinc and powdered ſal ammoniac being mixed together, and urged with a gradual fire in a retort; at firſt aroſe, in a very gentle heat, an exceſſively penetrating volatile ſpirit, ſo ſtrong as to ſtrike a man down who ſhould inadvertently receive its vapour freely into the noſe. This came over in ſubtile vapours, and was followed by a ſpirit of ſalt in denſe white fumes. In an open fire, white flowers ſucceeded; and at length a reddiſh and a black butter. In the bottom of the retort was found a portion of the zinc in its metallic form, with a little ponderous and fixed butyraceous matter which liquefied in the air. The lump was far more brittle than zinc ordinarily is; of a reddiſh colour on the outſide, and blackiſh within. The bottom of the retort was variegated with yellow and red colours, and looked extremely beautiful. The remaining zinc was mixed afreſh with equal its weight of ſal ammoniac, and the proceſs repeated. A volatile alkaline ſpirit and marine acid were obtained as at firſt; and in the retort was found only a little black matter. When the zinc was taken at firſt in twice the quantity of the ſal ammoniac, the part that preſerved its metallic form proved leſs brittle than in the foregoing experiment, and the retort appeared variegated in the ſame manner. On endeavouring to rectify the buttter, the retort parted in two by the time that one half had diſtilled.” The nature of this combination is unknown.

821 Butter of antimony.

XIII. *With Regulus of Antimony.* This ſemimetal cannot be united with the marine acid unleſs the latter is in its moſt concentrated ſtate. The produce is an exceſſively cauſtic thick liquid, called *butter of antimony*. The proceſs for obtainining this butter is ſimilar to that for diſtilling the ſmoking ſpirit of Libavius. Either crude antimony, or its regulus, may be uſed: for the ſpirit of ſalt will attack the reguline part of this mineral without touching the ſulphureous. Three parts of corroſive ſublimate are to be mixed with one of crude antimony; the mixture to be digeſted in a retort ſet in a ſand-heat; the marine acid in the ſublimate will unite with the reguline part of the antimony. Upon increaſing the fire, the regulus ariſes, diſſolved in the concentrated acid, not into a liquid form, but that of a thick unctuous ſubſtance like butter, from whence it takes its name. This ſubſtance liquefies by heat, and requires the cautious application of a live coal to melt it down from the neck of the retort. By rectification, or expoſure to the air, it becomes fluid like oil but ſtill retains the name of butter. If water is added to butter of antimony, either when in a butyraceous form, or when become fluid by rectification, the antimony is precipitated in a white powder called *powder of algaroth*, and improperly *mercurius vitæ*. This powder is a violent and very unſafe emetic. The butter itſelf was formerly uſed as a cauſtic; but it was totally neglected in the preſent practice, until lately that it has been recommended as the moſt proper material for preparing emetic tartar. (See below.) Mr Dollfuſs recommends the following method as the beſt for making butter of antimony; *viz.* two ounces and a quarter of the grey calx of antimony, eight ounces of common ſalt, and ſix of acid of vitriol. By diſtilling this mixture, ten ounces of the antimonial cauſtic were obtained; and in order to determine the quantity of metal contained in it, he mixed two ounces of the cauſtic with four ounces of water; but thus ſuch a ſtrong coagulum was formed, that he was not able to pour off any of the water even after ſtanding 24 hours. The precipitate, when carefully dried, weighed 50 grains. The reſult was much the ſame when glaſs of antimony was uſed, only that the precipitate was much more conſiderable, half an ounce of the cauſtic then yielding 60 grains, though at another time only 50 grains were obtained. In the reſiduum of the former experiment he found 30 grains of an earthy ſubſtance, chiefly a combination of calcareous earth with muriatic acid.

When the mercurius vitæ precipitates, the union between the marine acid and regulus is totally diſſolved; ſo that the powder, by frequent waſhings, becomes perfectly free from every particle of acid, which unites with the water made uſe of, and is then called very improperly, *philoſophic ſpirit of vitriol.*

822 Sympathetic ink. XIV. *With Regulus of Cobalt.* Pure ſpirit of ſalt diſſolves this ſemimetal into a reddiſh yellow liquor, which immediately becomes green from a very gentle warmth. On ſaturating the ſolution with urinous ſpirits, the precipitate appears at firſt white, but afterwards becomes blue, and at length yellow. If the nitrous acid is added to ſolutions of regulus of cobalt, they aſſume a deep emerald green when moderately heated, and on cooling become red as at firſt. Duly evaporated, they yield roſe-coloured cryſtals, which change their colour by heat in the ſame manner. This ſolution makes a curious ſympathetic ink, the invention of which is commonly aſcribed to M. Hellot, though he himſelf acknowledges that he received the firſt hint of it from a German chemiſt in 1736. Any thing wrote with this ſolution is inviſible when dry and cold; but aſſumes a fine green colour when warm, and will again diſappear on being cooled; but if the heat has been too violent, the writing ſtill appears. M. Hellot obſerves, that if nitre or borax be added to the nitrous ſolution, the characters wrote with it become roſe-coloured when heated; and if ſea-ſalt is afterwards paſſed over them, they become blue; that with alkali ſufficient to ſaturate the acid, they change purple and red with heat.—A blue ſympathetic ink may be made from cobalt in the following manner. Take of an earthy ore of cobalt, as free from iron as poſſible, one ounce. Bruiſe it, but not to too fine a powder. Then put it into a cylindrical glaſs, with 16 ounces of diſtilled vinegar, and ſet the mixture in hot ſand for the ſpace of ſix days, ſtirring it frequently; or elſe boil it directly till there remain but four ounces. Filter and evaporate it to one half. If your ſolution be of a roſe colour, you may be certain that your cobalt is of the right ſort. A red brown colour is a ſign of the ſolution containing iron; in which caſe the proceſs fails. To two ounces of the ſolution thus reduced, add two drachms of common ſalt.—Set the whole in a warm place to diſſolve, and the ink is made.

823 Oil of arſenic. XV. *With Regulus of Arſenic.* This ſubſtance is ſoluble in all acids; but the nature of the compounds formed by ſuch an union is little known. If half a pound of regulus is diſtilled with one pound of corroſive ſublimate, a thin ſmoking liquor and a butyraceous ſubſtance will be obtained, as in making the ſmoking liquor of Libavius. By repeated rectifications, this butter may be almoſt all converted into ſpirit. If equal parts of the arſenic and ſublimate are uſed, a ponderous black oil comes over along with the ſpirit, which cannot be mixed with it. By rectification in a clean retort they will become clear, but ſtill will not incorporate. If they are now returned upon the red maſs remaining in the firſt retort, and again diſtilled, a much more ponderous oil than the former will be obtained.

824 Marine ether. XVI. *With Inflammable Subſtances.* The acid of ſea-ſalt is very little diſpoſed to contract any union with the phlogiſton, while in a liquid ſtate; and much leſs ſo, even in its moſt concentrated ſtate, than either the vitriolic or nitrous. Mr Beaumé, however, has found, that a ſmall quantity of ether, ſimilar to that prepared with the vitriolic and nitrous acids, may be obtained by cauſing the fumes of the marine acid unite with thoſe of ſpirit of wine. Others, and particularly ſome German Chemiſts, attempted to make this liquor, by employing a marine acid previouſly combined with metallic ſubſtances, ſuch as butter of antimony. The ſmoking liquor of Libavius ſucceeds beſt. If equal parts of this liquor and highly rectified ſpirit of wine are diſtilled together, a conſiderable quantity of true ether is produced; but which, like the vitriolic and nitrous ether, muſt be rectified in order to its greater purity. The tin contained in the ſmoking liquor is ſeparated and precipitated in white powder. In this proceſs, the acid is probably more diſpoſed to unite with the ſpirit of wine, by having already begun to combine with the inflammable principle of the metal.—For marine ether, Mr Dollfuſs recommends to put into a retort four ounces of digeſtive ſalt previouſly well dried and powdered, and two ounces of manganeſe; pouring upon this a mixture of five ounces of ſpirit of wine and two of oil of vitriol; the firſt five ounces and a half of the diſtilled liquor being poured back on the reſiduum, and the whole afterwards drawn off by a gentle heat. The ſpirit of ſalt thus obtained had a very penetrating agreeable odour, ſomewhat like that of nitrous ether; and at firſt ſwam upon the top of water; but at length mixed with it on being agitated for a long time. Towards the end of the diſtillation a little oil was obtained, which did not mix with the water; and by the addition of four ounces more of ſpirit of wine, more of the dulcified acid was obtained. With regard to this kind of ether, however, Mr Weſtrumb denies that it can be made by any method hitherto known; and inſiſts, that all the liquids as yet produced under the name of marine ether are in reality dulcified ſpirit of ſalt, and not true ether, which will ſwim on the top of water.

825 Attraction for phlogiſton. Dr Prieſtley has obſerved, that the pure marine acid, when reduced to an inviſible aerial ſtate, has a ſtrong affinity with phlogiſton; ſo that it decompoſes many ſubſtances that contain it, and forms with them an air permanently inflammable. By giving it more time, it will extract phlogiſton from dry wood, cruſts of bread not burnt, dry fleſh; and, what is ſtill more extraordinary, from flints. From what has been above related, it appears that the dephlogiſticated ſpirit of ſalt has a very ſtrong attraction for phlogiſton.

Eſſential oil of mint abſorbed the marine acid air pretty faſt, and preſently became of a deep brown colour. When taken out of this air, it was of the conſiſtence of treacle, and ſunk in water, ſmelling differently from what it did before; but ſtill the ſmell of the mint was predominant. Oil of turpentine was alſo much thickened; and became of a deep brown colour, by being ſaturated with acid air. Ether abſorbed the air very faſt; and became firſt of a turbid white, and then of a yellow and brown colour. In one night a conſiderable quantity of ſtrongly inflammable air was produced.

Having once ſaturated a quantity of ether with acid air,

air, he admitted bubbles of common air to it, through the quickſilver by which it was confined, and obſerved that white fumes were made in it, at the entrance of every bubble, for a conſiderable time. Having at another time, ſaturated a ſmall quantity of ether with this kind of air, and the phial which contained it happenning to be overturned, the whole room was inſtantly filled with a white cloud, which had very much the ſmell of ether, but peculiarly offenſive. Opening the door and window of the room, this light cloud filled a long paſſage and another room. The ether, in the mean time, was ſeemingly all vaniſhed: but, ſometime after, the ſurface of the quickſilver in which the experiment had been made was covered with a very acid liquor, ariſing probably from the moiſture in the atmoſphere, attracted from the acid vapour with which the ether had been impregnated. This ſeems to ſhow, that however much diſpoſed the marine acid may be to unite with phlogiſtic matters when in its aerial ſtate, the attraction it has for them is but very ſlight, and ſtill inferior to what it has for water.

Camphor was preſently reduced into a fluid ſtate by imbibing this acid air; but there ſeemed to be ſomething of a whitiſh ſediment in it. After continuing two days in this ſituation, water was admitted to it, upon which the camphor immediately reſumed its former ſolid ſtate; and to appearance was the ſame ſubſtance that it had been before.

Strong concentrated oil of vitriol, being put to marine acid air, was not at all affected by it in a day and a night. In order to try whether it would not have more power in a condenſed ſtate, it was compreſſed with an additional atmoſphere; but, on taking off this, the air expanded again, and was not in the leaſt diminiſhed. A quantity of ſtrong ſpirit of nitre was alſo put to it without any ſenſible effect. From theſe laſt experiments it appears, that the marine acid is not able to diſloge the other acids from their union with water.

2d 825
New acid diſcovered by Mr Homberg.

Beſides the acids already mentioned, Mr Homberg deſcribes an artificial one generated by mixing two ounces and a half of luna cornea, with an ounce and a half of tin calcined alone and without addition, by means of fire. The mixture is to be expoſed to a naked fire in a coated retort, of which two-thirds ought to be left empty; when a browniſh matter, an ounce and a half in weight, will adhere to the neck of the retort. This matter is tin combined with the marine acid, and the reſiduum is ſilver deprived of the ſame acid, which may therefore now be melted together without any loſs. The ſublimate, well powdered and dried, is to be equally divided into two phials, and ſublimed; by repeating which operation two or three times, a volatile ſalt, of an acid nature, very white and tranſparent, is obtained. The reſiduum of theſe ſublimations is always calx of tin.

§ 4. *Of the* FLUOR *Acid.*

826
Firſt diſcovered by Mr Margraaf.

THIS acid was diſcovered ſome time ago by Mr Margraaf, and more fully inveſtigated by Mr Scheele. The experiments by which it was originally produced, and its properties aſcertained, are as follows:

827
How prepared.

I. Two ounces of concentrated vitriolic acid were poured upon an equal quantity of fluor, which had been previouſly pounded in a glaſs mortar, and then put into a retort, to which a receiver was adapted, and the juncture cloſed with grey blotting-paper. On the application of heat, the maſs began to efferveſce and ſwell, inviſible vapours penetrated every where through the joining of the veſſels, and towards the end of the proceſs white vapours aroſe, which covered all the internal parts of the receiver with a white powder.—The maſs remaining in the retort was as hard as a ſtone, and could not be taken out without breaking the veſſel. The lute was quite corroded and friable.

828
Forms a white earthy cruſt with water

II. The proceſs was repeated exactly in the ſame manner, excepting only that a quantity of diſtilled water was put into the receiver. A white ſpot ſoon began to form on the ſurface of the water, juſt in the centre, and immediately under the mouth of the retort. This ſpot continually increaſed, till at laſt it covered the whole ſurface of the water, forming a pretty thick cruſt, which prevented the communication of the water with new vapours that came over. On gently agitating the receiver, the cruſt broke, and fell to the bottom; ſoon after which a new cruſt like the former was produced. At laſt the receiver, and ſoon after the retort alſo, became white in the inſide. The veſſels, when cooled, were found much corroded internally. In the receiver was an acid liquor mixed with much white matter, ſeparable by filtration.

829
Which has the properties of ſiliceous earth.

III. This white matter when edulcorated and dried, ſhowed itſelf to be ſiliceous earth by the following properties. 1. It was rare, friable, and white. 2. It was not ſenſibly ſoluble in acids. 3. It did not make a tough paſte with water, but was looſe and incoherent after being dried. 4. It diſſolved by boiling in lixivium tartari, and the ſolution in cooling aſſumed a gelatinous conſiſtence. 5. In its pure ſtate it ſuffered no change in the ſtrongeſt heat; but when mixed with alkali, it boiled, frothed up, and formed a glaſs in a melting heat. 6. It diſſolved in borax without ſwelling.

830
Scheele's experiment to determine the origin of this earth.

IV. To determine whether this earth was formed during the proceſs, he poured vitriolic acid upon powdered fluor contained in a cylinder of braſs which was cloſed exactly with a cover, after having ſuſpended over the mixture an iron nail and a bit of charcoal. On opening the veſſel two hours afterwards, he found the nail and charcoal unchanged; but on moiſtening them, he found both covered with a white powder in a ſhort time. This powder had all the properties of ſiliceous earth; and as in the experiment he had made no uſe of glaſs veſſels, he concluded that it did not proceed from the glaſs veſſels as might have been ſuſpected from their being ſo much corroded, but was generated in ſome other way.

831
Artificial fluor yields a ſimilar reſult.

V. Having recompoſed fluor by ſaturating the acid with calcareous earth, he treated the compound in the ſame manner as the natural fluor, with a ſimilar reſult; and repeating the experiment five times over, he conſtantly found the ſiliceous earth and acid diminiſh conſiderably, ſo that at laſt ſcarce any mark of acidity was left. Thence he concluded, that all the fluor acid united itſelf by degrees with the vapours of the water, and thus formed the ſiliceous earth. "It may be objected (ſays Mr Scheele), that the fluor acid is perhaps already united by nature with a fine ſiliceous powder,

der, which it volatilizes, and carries over in diſtillation, but leaves it as ſoon as it finds water to unite with, juſt as muriatic acid parts with the regulus of antimony, when butter of antimony is dropped into water. But if this was the caſe, the fluor acid would leave the whole quantity of ſiliceous earth thus combined with it in the firſt diſtillation, and therefore ſhow no mark of its preſence in the following proceſſes. When I put ſpirit of wine into the receiver inſtead of water no ſiliceous earth was produced; but the alcohol became ſour. When I put an unctuous oil into the receiver, all the fluor acid penetrated through the crevices of the lute, and neither united with the oil, nor produced a ſiliceous earth. This happened alſo when acid of vitriol was put into the receiver. If therefore the ſiliceous earth was not a product of each diſtillation, but, being previouſly contained in the acid, was only depoſited from it in conſequence of the union of the acid with a third ſubſtance, I think the ſiliceous earth ought equally to appear when alcohol was put into the receiver, with which it unites, as well as with water; but as this does not happen, I conclude that not all the ſiliceous earth, which is depoſited upon the ſurface of water during the diſtillation of the fluor acid, was previouſly diſſoved in this acid."

832 Mr Scheele's concluſion that the earth proceeds from an union of the acid with water.

833 Conteſted by Meſſrs Boullanger Monnet, &c.

834 Their opinions ſhown to be erroneous by Mr Scheele.

835 Fluor acid proved to be different from that of ſea-ſalt.

This opinion of Mr Scheele did not meet with general approbation. M. Boullanger endeavoured to ſhow, that the fluor acid is no other than the muriatic intimately combined with ſome earthy ſubſtance; and Mr Monnet maintained that it is the ſame with that of vitriol volatilized by ſome extraordinary connection with the fluor; which opinion was alſo maintained by Doctor Prieſtley. Mr Scheele conteſted theſe opinions, but found much greater difficulty in ſupporting his own opinions than in overthrowing thoſe of his adverſaries. Boullanger inſiſted that fluor acid precipitates the ſolutions of ſilver and quickſilver, producing luna cornea with the former, and mercurius dulcis with the latter. Mr Scheele owns that fluor acid precipitates both theſe metals, but the precipitate obtained is in very ſmall quantity, and the little that is produced ariſes only from a ſmall quantity of ſea-ſalt with which the fluor, as well as all other calcareous ſubſtances, is generally mixed. The greateſt part of the acid, therefore, will not precipitate the ſolutions of theſe metals, which it ought to do upon Mr Boulanger's hypotheſis. Mr Scheele then proceeds to ſhow a method of ſeparating this ſmall quantity of marine acid from that of fluor. A ſolution of ſilver made with nitrous acid is to be precipitated with alkali of tartar, and as much acid of fluor poured upon the edulcorated powder as is ſufficient to give an exceſs of acid; after which the ſolution is to be filtered. This ſolution of ſilver in fluor acid is then to be dropped into that acid we deſire to purify, till no more precipitation enſues; after which the acid is filtered through grey paper, and diſtilled to dryneſs in a glaſs retort. The aqueous part comes over firſt, but is ſoon followed by fluor acid, which covers the inſide of both the veſſels, together with the ſurface of the water in the receiver, with a thick ſiliceous cruſt. The acid thus rectified, does not precipitate ſolution of ſilver in the leaſt, or otherwiſe ſhow the ſmalleſt ſign of muriatic acid.

836 And from that of vitriol.

That the fluor acid is different from that of vitriol Mr Scheele proved by the following experiment. Upon one ounce of pure levigated fluor with alkohol, he poured three ounces of concentrated oil of vitriol, and diſtilled the mixture in a ſand-bath, having previouſly put 12 ounces of diſtilled water into the receiver. He then took other three ounces of the ſame acid diluted with 24 ounces of water, to which he afterwards added lixivium tartari previouſly weighed, till he attained the exact point of ſaturation. After the diſtillation he weighed the remaining lixivium; having kept up ſuch a degree of heat for eight hours as was not ſufficient to raiſe the vitriolic acid. On breaking the retort, and reducing the maſs to powder he boiled it in a glaſs veſſel with 24 ounces of water for ſome minutes; after which he added juſt as much lixivium tartari as he had found before to be requiſite for the ſaturation of three ounces of the vitriolic acid, and continued the boiling for a few minutes longer. On examining the ſolution, it was found to contain a vitriolated tartar perfectly neutralized, neither acid nor alkali prevailing in any degree; which ſhowed that no vitriolic had paſſed into the receiver. The ſaline matter being then extracted with hot water, the remaining earth was found to weigh 9½ drachms. Two drachms of this diſſolved in muriatic acid, excepting only a ſmall quantity of matter which ſeemed to be fluor undecompoſed, and which on being dried weighed only nine grains. Into one part of this ſolution he poured ſome acid of ſugar, and into another vitriolic acid. The former produced ſaccharated lime, and the latter gypſum. A third part was evaporated to dryneſs, and left a deliqueſcent ſalt; and the remaining part of the earth burned in a crucible, produced a real quick lime.

837 Quicklime the baſis of fluor.

Thus it appeared that the real baſis of fluor is quicklime, and likewiſe that the fluor acid is different from that of vitriol, as appears farther from the following conſiderations: 1. Pure fluor acid does not precipitate terra ponderoſa, nor ſolution of lead in nitrous acid. 2. The ſame acid, when ſaturated with alkali of tartar, evaporated to dryneſs, and afterwards melted with powdered charcoal, does not produce any hepar ſulphuris.

838 Miſtake of Mr Monnet on this ſubject.

Mr Monnet, in order to ſupport his hypotheſis, denies that fluor contains any calcareous earth. In proof of which he adduces the following experiment: Equal quantities of alkali and fluor were melted together, with little or no change on the mineral; for, after having taken away by lixiviation the alkali employed, he diſſolved the fluor remaining on the filter in nitrous acid, adding vitriolic acid to the ſolution; and becauſe he obtained no precipitate, concluded at once, that fluor contains no calcareous earth. Mr Scheele on the contrary affirms, that all ſolutions of fluor yield a precipitate of gypſum whenever vitriolic acid is added to them. He explains Mr Monnet's failure, by ſuppoſing that he had diluted his ſolution with too great a quantity of water.

839 Wiegleb's experiments on the origin of the ſiliceous earth.

Mr Wiegleb, diſſatisfied with the hypotheſis of Scheele, as well as others, concerning the fluor acid, began a new ſet of experiments on the mineral. Having firſt accurately repeated thoſe made by Mr Scheele, he proceeded to inquire into the origin of the ſiliceous earth, in the following manner: Having firſt weighed the retort deſtined for the experiment in an an accurate manner, and found that its weight was two ounces and five drachms, he put into it two ounces of calcined fluor in powder, adding, by means of a glaſs tube, 2½ ounces of oil of vitriol. The retort was then placed on the furnace; and a receiver, which when empty weighed two ounces, two drachms, and 30 grains, and now contained two ounces of diſtilled water, was luted to it. The diſtillation was conducted with all poſſible care, and at laſt puſhed till the retort grew red hot; but it was found impoſſible to prevent a few vapours from penetrating through the lute. Next day the retort, ſeparated from the receiver, was found to weigh, together with its contents, five ounces, five drachms, and 30 grains; and conſequently had loſt in weight one ounce, three drachms, and 30 grains. The receiver, which, with the water, had originally weighed four ounces, two drachms, and 30 grains, now weighed five ounces and three drachms, and had therefore gained one ounce and 30 grains. This gain, compared with the loſs of the retort, ſhows that the retort loſt more by three drachms than the receiver gained; ſo that theſe muſt have undoubtedly paſſed through the luting in form of vapour.

To determine the point in queſtion, the empty veſſels, with what had been put into them, were accurately weighed; when the weights and loſs upon the whole were found to be as follows.

	oz.	dr.	gr.
The empty retort - -	2	5	0
Calcined fluor - - -	2	0	0
Oil of vitriol - -	2	4	0
Total weight before diſtillation	7	1	0
After it -	5	5	30
Loſs of retort - -	1	3	30
The empty receiver weighed -	2	2	30
The water put into it - -	2	0	0
Total weight before diſtillation	4	2	30
Total weight after diſtillation -	5	3	0
Gain of receiver -	1	0	30

Deducting this grain of weight in the receiver from the loſs of weight in the retort, we find, that three drachms were wanting on the whole, which muſt undoubtedly, as already obſerved, have been diſſipated in vapour. The retort being now broken, and the dry earth both in its neck and arch ſeparated as accurately as poſſible, it was found to weigh three drachms; the reſiduum in the retort weighed three ounces, two drachms, and 40 grains. Now, as the maſs in the retort had originally weighed four ounces and four drachms, it appeared, by deducting the reſiduum, to have ſuffered, on the whole, a loſs of one ounce, one drachm, and 20 grains. To determine the loſs more accurately, the following calculations were made:

	oz.	dr.	gr.
The white earth ſeparated from the neck and arch of the retort -	0	3	0
Gain of the receiver - -	1	0	30
Loſt in vapour - - - -	0	3	0
Total	1	6	3

Here Mr Wiegleb was ſurpriſed to find, that the matter which came from the retort amounted to more by five drachms ten grains than the maſs in the retort had loſt of its original weight; to illuſtrate which it was neceſſary to weigh the retort and receiver by themſelves. The pieces of the retort now weighed only one ounce ſeven drachms and 50 grains; whereas, before the proceſs, the weight of the retort was two ounces five drachms. It appeared, therefore, that it had loſt five drachms ten grains, the very quantity which had been gained by the receiver. This laſt had loſt nothing of its original weight.

The fluid in the receiver was next diluted with four ounces of diſtilled water, and the whole poured out on a filter, in order to ſeparate the earthy matter with which it was mixed, and freſh water poured upon it to take out all the acid: after which the earth was dried, and found to weigh 57 grains. The clear liquor was then diluted with more diſtilled water, and afterwards precipitated with ſpirit of ſal ammoniac prepared with fixed alkali. A briſk effervescence took place before any precipitate began to fall, but ceaſed ſoon after the precipitation took place. The whole mixture become gelatinous; and the precipitate, when dry, weighed two drachms. The whole quantity of earth, therefore, obtained in this proceſs amounted to five drachms 47 grains, which is forty-ſeven grains more than the retort had loſt in weight. This exceſs is, by our author, attributed to part of the acid ſtill adhering to it, and to the acceſſion of ſome moiſture from the air; to determine which he heated each of the parcels of earth red hot ſeparately, and thus reduced them to four drachms 52 grains, which is leſs by 18 grains than the loſs of the retort, and which, he is of opinion, muſt have eſcaped in the three drachms of vapour.

840
The earthy cruſt proceeds from the ſolution of the glaſs diſtilling veſſels.

From this experiment Mr Wiegleb concludes, that the earth produced in the diſtillation of fluor proceeds neither from the ſpar nor from a combination of the acid with water, but from the ſolution of the glaſs by the ſparry acid. To his opinion alſo Dr Crell accedes. "In diſtilling fluor (ſays he) with oil of vitriol, I have found the retort as well as the receiver very much corroded. I poured the acid obtained by the proceſs into a phial furniſhed with a glaſs ſtopper, and obſerved after ſome time conſiderable depoſition. I then poured the liquor into another phial like the former; and that it might neither on the one hand attack the glaſs, nor on the other compoſe ſiliceous earth with the particles of water, according to Mr Scheele's hypotheſis, I added highly rectified ſpirit of wine. I ſaw, however, after ſome time, another conſiderable depoſition. This ſeemed alſo to proceed from the glaſs that had been before diſſolved, which the acid let fall in conſequence of the gradual combination with the ſpirit of wine; otherwiſe we muſt ſuppoſe, what to me appears incredible, that the acid decompoſes the ſpirit, attracts the water, and forms the earth."

841
Mr Mayer's examination of the fluor acid.

This ſingular acid has been ſtill further examined by Mr Meyer. He informs us, that, among Mr Scheele's experiments, he was particularly ſtruck by one in which no earthy cruſt was obtained, after putting ſpirit of wine into the receiver. Mr Meyer repeated this experiment, hoping, that when but little ſpirit was put into the receiver, he might be able to procure a new kind of ether. An ounce of finely powdered fluor, which had been previouſly heated red hot, was put into a glaſs retort, to which was fitted a receiver containing three ounces of highly rectified French brandy. The diſtillation was continued for three hours with a gentle heat: when the acid, having made its way through the bottom, put and end to the proceſs. No cruſt could be perceived on the ſurface of the ſpirit: but in the place where it had been in contact with the receiver there was a thin ring of tranſparent jelly. The ſame mixture of oil of vitriol and fluor was therefore again put into a retort of very ſtrong glaſs, and the ſame ſpirit put into the receiver. The diſtillation was conducted two hours with a gentle and afterwards with a ſtronger, heat. When it was half over, the ſpirit began to change into a thin jelly; and at the end of the proceſs ſome firmer pieces were found at the bottom. Theſe were waſhed with ſpirit of wine; and in order to obtain the ſpirit together with the acid in a pure ſtate, it was put into a large retort, and again ſubjected to diſtillation. As the retort grew warm, the opal-coloured ſpirit became clear and ſwelled, what remained becoming again gelatinous; a good deal of earth remained behind, but did not adhere firmly to the retort, which was ſmooth in the inſide, though full of ſhallow excoriations. It was alſo evident, that the glaſs was actually corroded, and that the earthy matter is not a mere cruſt adhering to the inſide. The jelly being thoroughly edulcorated, as well as the earth that remained in the retort after the rectification, and that which was diſſolved in the water precipitated by ſpirit of ſal ammoniac, the whole quantity amounted to two drachms. That which had ſeparated ſpontaneouſly was ſemitranſparent. "As this earth (ſays he) ſhowed the properties of ſiliceous earth, and the glaſs, which was ſo much corroded, conſiſts in great meaſure of it, the greateſt part of it might come from the glaſs, and the reſt of it perhaps be a conſtituent part of the fluor itſelf.

842
How to procure the acid free from ſiliceous earth.

In order to aſcertain this it was neceſſary to obtain the fluor acid quite free from ſiliceous earth. I therefore expoſed the ley, which I had procured by the precipitation of the earth with ſal ammoniac, to a gentle evaporation in a ſlightly covered glaſs veſſel. The product was one drachm 56 grains of an ammoniacal ſalt; the glaſs did not appear to have been attacked. Half a drachm of this ſalt was ſublimed in a ſmall retort, which, towards the end of the operation, was laid on the bare fire. No cruſt appeared on the ſurface of the water in the receiver. At the bottom of the retort lay a little flocculent earth of a light grey colour, above which the internal ſurface was covered with a white pellicle that reflected various colours; and in the neck there was a ſublimate. The thin pellicle eaſily ſeparated in many places from the glaſs, which was ſmooth beneath, though not without ſome ſmall furrows. I poured water both upon the ammoniacal ſalt and cruſt; in conſequence of which it acquired a very ſour taſte, and coloured the tincture of turnſole red. The white cruſt that was left behind undiſſolved weighed five grains, and melted into a green glaſs without addition. This was nothing but the glaſs that had been corroded by the fluor acid; but as this acid can be ſet looſe only by ſtrong heat, it had done no more than corrode the glaſs, without paſſing over along with it in the form of vapour, and then depoſing it again on the water. For, upon pouring two drachms of oil of vitriol upon half a drachm of this ammoniacal ſalt a little moiſtened, and placed in a glaſs retort, a great foam aroſe, and the thick vapours that aſcended covered the water in the receiver with a white cruſt. A ſcruple of the ſalt on ſolution, left behind a grain of earth, which, as I conjecture, it had taken up during the evaporation in the glaſs veſſel."

To prevent this, our author diſtilled half an ounce of fluor with an ounce of oil of vitriol for five hours. The cruſts were ſeparated from th water; they weighed, after being well waſhed and dried, eleven grains; they were white and very flocculent; thirty-two grains of ſiliceous earth were precipitated from the filtered water: the ley was then evaporated in a leaden veſſel and yielded 80 grains of ſalt.

843
Experiments made with an iron diſtilling veſſel.

As glaſs veſſels were no longer to be truſted, a piece of a gun-barrel furniſhed with a cover, and terminated by a bent tube, intended to ſerve inſtead of the neck of a retort, was afterwards uſed; and with this apparatus the following experiments were made:

1. Half a drachm of the newly prepared ſal-ammoniac was diſtilled for two hours with two drachms of oil of vitriol, into a glaſs receiver containing an ounce of water. No veſtige of a cruſt could be perceived on the water, but ſome earth was perceived in the receiver, where the vapours having aſcended through the tube, came into contact with the wet glaſs; and here the ſurface was become ſenſibly rough. On the addition of volatile alkali, a few flocculi of ſiliceous earth, a mounting only to one-fourth of a grain, were thrown down out of the water.

2. A drachm of vitriol was added to a drachm and an half of the ſalt; but a leaden receiver was now uſed, containing an ounce of water as before. The water acquired an unpleaſant ſmell, but ſhowed no ſigns of a cruſt. On the addition of ſpirit of ſal ammoniac, a little grey earth weighing half a grain fell to the bottom.

844
No cruſt formed by mixing ſand, with a ſalt containing fluor acid.

3. A ſcruple of this ſalt, mixed with an equal quantity of white ſand in fine powder, and diſtilled with a drachm and an half of oil of vitriol, into an ounce of water in the leaden receiver, ſhowed no ſign of a cruſt. The water had a putrid ſmell, and left on the filter two grains and an half of grey earth, which ran under the blow-pipe into a grain of lead. Volatile alkali precipitated five grains of grey earth, which melted on the addition of a little ſalt of tartar into a black globule, though the blow-pipe alone made no change in it.

845
But a great one by uſing powdered glaſs.

4. To 13 grains of the ſame ammoniacal ſalt a drachm of oil of vitriol and two ſcruples of green glaſs, broken into ſmall pieces, were added. The iron tube had ſcarce become warm, when a great cruſt of ſiliceous earth was perceived on the ſurface of the water, and the ſame appearance on the moiſt ſides of the veſſel. It did not, however, ſeem to increaſe during the remainder of the diſtillation. A grain and a quarter of earthy matter remained on the filter, conſiſting partly of white films, which ran under the blow-pipe into a greeniſh glaſs.

5. To aſcertain this matter ſtill more clearly, a different ſpecies of mineral fluor was uſed, which being diſtilled with a double quantity of oil of vitriol, and with a drachm of water in the receiver, yielded a thin pellicle of the appearance of lead, but no ſiliceous cruſt. Volatile alkali threw down 2¼ grains of grey earth.

earth.—A drachm mixed with the ſame quantity of pulverized ſand afforded a pellicle of lead interſperſed with a few particles of white cruſt, which ran into glaſs under the blow-pipe. Volatile alkali precipitated eight grains.—A drachm, mixed with an equal quantity of green glaſs reduced to powder, ſwelled a good deal, and yielded a thick ſiliceous cruſt.

6. To a drachm of green fluor that had been heated and powdered were added two drachms of oil of vitriol, ſtill employing the iron tube. A piece of wet charcoal was alſo ſuſpended in the inſide, a cover fixed on the tube, and the latter was heated for about 15 minutes in a ſand-bath. Obſerving now that the charcoal was dry, and had no earth upon it, a ſcruple of ſand in fine powder was added, the charcoal was wetted and replaced, but nothing appeared. Some bits of green glaſs were then thrown into the mixture which inſtantly foamed up and ran over. The charcoal was not replaced in the tube, nor was it any longer neceſſary, as it gained a covering of white powder by being held a very few moments over the orifice.

846 An experiment of Mr Scheele's explained.

Mr Scheele, in one of his experiments, obſerves, that he obſerved the white powder on a piece of charcoal that had been moiſtened and ſuſpended over fluor to which vitriolic acid was added. As this experiment was made in metallic veſſels, Mr Meyer conjectures, that the mortar uſed for reducing the fluor to powder was of ſoft glaſs, and that the phenomenon was occaſioned by the abraſion of ſome particles of glaſs.

847 Of the quantity of ſiliceous earth carried along with fluor acid.

7. To determine whether the acid can carry up much more of the ſiliceous earth than is ſufficient to ſaturate it, an ounce and an half of pure oil of vitriol was added in a retort of glaſs, and three ounces of water put into the receiver. The retort was corroded through in an hour's time, and the cruſt on the water weighed ten grains The liquid being then filtered and divided into two eqnal parts, one was precipitated with cauſtic volatile, and the other with mild fixed vegetable alkali. The former yielded 25 grains of ſiliceous earth, and the latter 68 grains of a precipitate, which flowed under the blow-pipe, ran into the pores of charcoal, and gave ont ſtrong vapours of fluor acid. The reaſon of this difference ſhall be explained when we come to treat of ſiliceous earth.

848 Violent action of fluor acid upon glaſs.

8. To a mixture of half an ounce of fluor and the ſame quantity of glaſs, in powder, 12 drachms of oil of vitriol were put in a ſmall retort, half filled with the mixture. The ingredients acted upon each other ſo violently that they roſe up into the neck of the retort; and the operation being intermitted on account of the noxious vapour they emitted, the retort was found next day covered with faſciculated cryſtals like hoarfroſt.—The experiment being repeated in a more capacious retort, and the mixture thoroughly blended by agitation, it became a thick maſs, and ſwelled like dough in fermentation: the bottom of the retort grew very hot, and the ſiliceous cruſt appeared on three ounces of water in the receiver. The diſtillation being continued for three hours, 16 grains of ſiliceous earth were found on the ſurface, and the precipitate by volatile alkali weighed 56 grains; the retort was much leſs corroded than uſual.

9. Thirty grains of this precipitate, diſtilled in a glaſs retort with a drachm and an half of oil of vitriol, produced no ſiliceous earth on the water in the receiver, or that with which the earth was edulcorated. The ley of fluorated volatile alkali was mixed with a ſolution of chalk in nitrous acid till no more precipitation took place. The mixture was paſſed through nitrous acid, and the precipitate edulcorated. It weighed, when dry, two drachms and 36 grains.

10. Two drachms of oil of vitriol being added to a drachm of this precipitate contained in a glaſs retort, the precipitate was attacked in the cold, but no cruſt appeared; the heat, however, was ſcarce applied, when the whole ſurface of the water was covered, and the ſame phenomena exhibited which are produced by the natural fluor.

849 Farther proofs that the earthy cruſts proceeds from the glaſs veſſels.

11. Mr Scheele having obſerved that a mixture of fluor as tranſparent as mountain cryſtal, and oil of vitriol in a metallic cylinder, produced no appearance of ſiliceous earth, on a wet ſponge ſuſpended on the inſide, at Mr Meyer's requeſt he made a new experiment by adding oil of vitriol to portions of fluor of this tranſparent kind placed in two tin cylinders; ſome ſiliceous earth was put into one, and a wet ſponge ſuſpended in both. The next morning the ſponge that was ſuſpended over the cylinder which held the ſiliceous earth, was covered with the white powder, but no appearance of it was ſeen on the other. The experiment was repeated by Mr Meyer with the ſame reſult, but the white cruſt did not appear till after a night's ſtanding.

12. A drachm of fluor, mixed with two of oil of vitriol, afforded, after a diſtillation of two hours, a thin film of lead on the ſurface of the water in the receiver, but no ſiliceous earth. The ſame mixture was afterwards diſtilled with the uſe only of a glaſs receiver inſtead of a lead one. In the beginning of the diſtillation a ſmall ſpot appeared under the neck of the retort, and the neck itſelf was covered with white powder, but it ſoon diſappeared; and though the empty part of the receiver was corroded, yet no more than half a grain of earth was procured.

850 Mr Wenzel's experiments in a leaden retort.

Theſe experiments ſo clearly point out the origin of the ſiliceous cruſt on the ſurface of the fluor acid, that its exiſtence as a diſtinct acid is now univerſally allowed, even by thoſe who formerly contended for its being only the vitriolic or ſome other acid diſguiſed.—Experiments of a ſimilar kind were made by Mr Wenzel, who performed his diſtillation in a leaden retort, furniſhed with a glaſs receiver. The water was covered with a variegated cruſt, and yielded a gelatinous precipitate with fixed alkali. On examining the receiver, he found its internal ſurface corroded, ſo that it appeared as if it had been rubbed with coarſe ſand. By ſubſtituting a leaden receiver, however, inſtead of a glaſs one, he obtained the acid entirely free from ſiliceous matter, and containing only a ſmall quantity of iron and aluminous earth.

2d 850 Fluor acid procurable by nitrous, muriatic, and phoſphoric acid.

The fluor acid may alſo be procured by the nitrous, muriatic, and phoſphoric acids.—Mr Scheele diſtilled one part of the mineral with two of concentrated nitrous acid. One part went over into the receiver along with the fluor acid, and a thick cruſt was formed on the water of the receiver. The maſs remaining in the retort was calcareous earth ſaturated with nitrous acid.

Fluor acid and its combinations.

With an equal quantity of marine acid, that of fluor paſſed over into the receiver with a large quantity of the muriatic; the internal ſurface of the receiver, as well as of the water contained in it, being covered with a white cruſt. The reſiduum was fixed ſal ammoniac.

Phoſphoric acid digeſted with powdered fluor, diſſolved a good deal of it; and on diſtilling this ſolution, the fluor acid went over together with the watery particles of the mixture; the remaining maſs in the retort had the properties of the aſhes of bones.

3d 850 Appearance and properties of fluor acid.

The fluor acid procured in any of theſe ways is not diſtinguiſhable by the ſmell from that of ſea-ſalt: in ſome caſes it acts as muriatic acid, in others like that of tartar; but in moſt caſes it ſhows properties peculiar to itſelf.

4th 850 Combined with fixed alkali.

With fixed alkali the fluor acid forms a gelatinous and almoſt inſipid matter, which refuſes to cryſtallize. By evaporation a ſaline maſs was obtained, which was in weight only the ſixth part of the fixed alkali diſſolved; did not change the colour of ſyrup of violets, but precipitated lime water, and likewiſe the ſolutions of gypſum and Epſom ſalt. With mineral alkali the ſame phenomena were produced as with the vegetable.

851 With volatile alkali.

Volatile alkali with fluor acid formed likewiſe a jelly, which when ſeparated from the liquor appeared to be ſiliceous earth. The clear liquid taſted like vitriolic ammoniac, and ſhot into very ſmall cryſtals, which by ſublimation yielded firſt a volatile alkali, and then a kind of acid ſal ammoniac. By diſtillation with chalk and water, all the volatile alkali quickly came over. Lime water inſtantly threw down a regenerated fluor, which was the caſe alſo with ſolutions of lime in the nitrous and muriatic acids.—Solution of ſilver let fall a powder, which, before the blow-pipe, reſumed its metallic form, the acid being diſſipated, and forming a white ſpot on the charcoal round the reduced ſilver. Solution of quickſilver in nitrous acid was precipitated, and the powder was entirely volatile in the fire; but a ſolution of corroſive ſublimate remained unchanged. Lead was totally precipitated from nitrous acid; and a ſolution of Epſom ſalt was rendered turbid. Oil of vitriol produced a fluor acid by diſtillation, which formed at the ſame time a thick cruſt on the water of the receiver. The regenerated fluor procured either by means of lime water or ſolutions of the earth in acids, was decompoſed by fixed, but not by volatile alkali.

852 With earths.

With lime, magneſia, and earth of alum, this acid became gelatinous. Part of the two laſt were diſſolved.

853 With metal.

Gold was not touched by the fluor acid either alone or mixed with that of nitre. Silver, in its metallic ſtate, underwent no change. Its calx, precipitated by an alkali, was partly diſſolved; but the remainder formed an inſoluble maſs at the bottom Vitriolic acid expelled the fluor acid in its uſual form. Quickſilver was not diſſolved, but its calx precipitated from the nitrous ſolution was partially ſo. The remaining inſoluble part of the calx united with the acid, and formed a white powder, from which the fluor acid was expelled by the vitriolic. The ſame powder formed, by means of the blow-pipe, a yellowiſh glaſs; which, however, evaporated by degrees, leaving a ſmall globule of fixed glaſs behind. Lead was not diſſolved, but the acid formed a ſweet ſolution with its calx; from whence the latter could be precipitated by the acids of vitriol, and ſea-ſalt, as alſo by ſal ammoniac. On digeſting a quantity of acid with calx of lead, which had been previouſly digeſted in the ſame, a ſpontaneous precipitation took place. The precipitate melted eaſily before the blow-pipe, and ran into metal; but part of the glaſs remained fixed in the fire. Copper was partially diſſolved, as appeared by the blue colour aſſumed by the liquid on the addition of volatile alkali. The calx of copper was eaſily ſoluble; and the liquor, though gelatinous, yielded blue cryſtals, partly of a cubic and partly of an oblong form, from which the acid could not be ſeparated but by heat. Iron was violently attacked, and gave out inflammable vapours during the ſolution. The liquor refuſed to cryſtallize; but, by evaporation, congealed into an hard maſs after the moiſture was diſſipated; and from this maſs the fluor acid might be expelled as uſual by oil of vitriol. The ſame effect was alſo produced by heat alone; the acid riſing in vapours, and leaving a red ochre behind. Calx of iron was alſo diſſolved, and the ſolution taſted like alum; but it could not be reduced to cryſtals. Tin, biſmuth, and regulus of cobalt, were not attacked in their metallic ſtate; but the calces of all of them were ſoluble. Regulus of antimony and powdered antimony were not ſenſibly acted upon. Zinc produced the ſame effects as iron, excepting that the ſolution ſeemed more inclined to cryſtallize.

Fluor acid and its combinations.

854 Glaſs corroded by this acid, as well as the ſalt formed by its combination with volatile alkali.

The moſt remarkable property of this acid, however, is its readily diſſolving glaſs and carrying it off in the form of vapour. This ſingular property belongs not only to the pure acid, but alſo to the ammoniacal ſalt formed by combining it with the volatile alkali. Mr Wiegleb informs us, that on evaporating to dryneſs, in a cup of Miſnia porcelain, a ſolution of this kind of ammoniac, which by its ſmell ſhowed an exceſs of volatile alkali, the glazing of the inſide was entirely corroded, and the bottom left as rough as a file. During the evaporation the cup was covered with white paper, which when dry appeared full of ſmall cryſtals of an acid taſte, eaſily diſtinguiſhable by the naked eye. Theſe, as well as the ammoniacal ſalt, powerfully attracted the moiſture of the air.

855 It is very difficult to be kept.

This property of the fluor acid renders it extremely difficult to be kept. Mr Meyer informs us, that having kept ſome upwards of a year in a glaſs phial, it corroded the glaſs in many points ſurrounded with concentric circles, depoſiting a powder which adhered to the bottom. He is of opinion that golden veſſels would be moſt proper for keeping this acid, as alſo for making experiments on the fluor itſelf. A phial covered in the inſide with wax and oil has been recommended for the ſame purpoſe.

856 Golden veſſels moſt proper for this purpoſe.

857 Dr Prieſtley's experiments on converting this acid into a kind of air.

This acid, as well as thoſe of vitriol, nitre, and ſea-ſalt, has been exhibited by Dr Prieſtley in an aerial form. Having put ſome pounded ſpar into a phial, and poured oil of vitriol upon it, adopting at the ſame time the uſual apparatus for obtaining air, he obſerved that a permanent cloud was formed by the vapour iſſuing out from the mouth of the tube, which he attributed to the attachment of the acid to the aqueous moiſture of the atmoſphere. The moment that water came

came in contact with this air, its ſurface became opaque and white by a ſtony film, which retarded the aſcent of the water, till the air inſinuating itſelf through the pores and cracks of the cruſt, the water neceſſarily roſe as the air diminiſhed; and breaking the cruſt, preſented a new ſurface to the air, which was immediately covered with another cruſt. Thus one ſtony incruſtation was formed after another till every particle of the air was united to the water; and the different films being collected and dried, formed a white powdery ſubſtance, generally a little acid to the taſte; but when waſhed in much pure water, perfectly inſipid. The property of corroding glaſs he found to belong to the fluor acid air only when hot. From ſome other experiments he concluded, that the fluor acid air was the ſame with what he had formerly obtained from vitriolic acid: but the experiments made ſince that time by various chemiſts, have now convinced him that it is an acid of a nature entirely different from all others.

2d 857 Method of engraving on glaſs.

By means of the fluor acid, a new art has been diſcovered, viz. that of engraving upon glaſs. For this purpoſe a looking-glaſs plate is to be covered with melted wax or maſtic; and when the coating becomes hard, it is to be engraved upon by a very ſharp-pointed needle or other inſtrument of that kind. A mixture of oil of vitriol and fluor acid are then to be put upon the plate, and the whole covered with an inverted China veſſel, to prevent the evaporation of the fluor acid. In two days the glaſs plate may be cleared of its coating, when all the traces of the needle will be found upon it.

§ 5. *Of the* SAL SEDATIVUS, *or Acid of Borax.*

858 Found in a mineral in Germany, &c.

THIS is a ſaline ſubſtance of a very ſingular nature, and till lately found no where but in borax itſelf. Its origin in different parts of the world is related under the article BORAX: but ſince that article was printed, we have accounts of its being diſcovered in a mineral of a peculiar kind found at Lunenburg near Hartz. This is frequently tranſparent, but ſometimes alſo a little opaque, and ſtrikes fire ſlightly with ſteel. It has hitherto been found only in ſmall cryſtals inveloped in a gypſeous matter. Theſe generally affect the cubical form, though they are ſometimes irregular, and from the truncatures frequently appear to be of different kinds. One of them had fourteen faces, ſix ſmall ſquare planes, and eight hexahedral; though all theſe are modifications of cubes. Mr Weſtrumb analized it with ſome difficulty; but at laſt found that 100 parts of the mineral contained 60 of ſedative ſalt, ten of magneſia, and ten of calcareous earth; of clay and flint five parts, ſometimes ten of iron, though frequently but five. The ſame acid has alſo been diſcovered in Peru, and a little in Hungary from an analyſis of petroleum. This bitumen ariſes from a rock between Pecklenicza and Moſcowina. It ſeems at firſt to be white, but ſoon grows black by expoſure to the air. It was analyſed by profeſſor Winterl, who found it to contain a tranſparent oil in a butyraceous form, and a true ſedative ſalt, united with the oil by means of an exceſs of phlogiſton. The ſedative ſalt was firſt diſcovered by Bechr, and afterwards more accurately deſcribed by Homberg; but its nature was at firſt very much miſunderſtood, being named the *narcotic ſalt of vitriol*, on account of the vitriolic acid uſed in ſeparating it from the borax. From this it is ſeparable either by ſublimation or cryſtallization. The method by ſublimation is that recommended by Homberg.

2d 858 How prepared from borax.

His proceſs conſiſts in mixing green vitriol with borax, diſſolving them in water, filtering the ſolution, and evaporating till a pellicle appears: the liquor is then to be put into a ſmall glaſs alembic, and the ſublimation promoted till only a dry matter remains in the cucurbit. During this operation, the liquor paſſes into the receiver; but the internal ſurface of the capital is covered with a ſaline matter forming very ſmall, thin, laminated cryſtals, very ſhining, and very light. This is the ſedative ſalt. The capital is then to be unluted, and the adhering ſalt ſwept off with a feather; the part of the liquor which paſſed laſt into the receiver, is to be poured on the dry matter in the cucurbit; and a new ſublimation is to be promoted as before, by diſtilling till the matter in the cucurbit is dry. Theſe operations are to be frequently repeated in the ſame manner, till no more ſedative ſalt can be obtained.

To obtain the ſedative ſalt by cryſtallization, borax is to be diſſolved in hot water; and to this ſolution any one of the three mineral acids is to be gradually added, by a little at a time, till the liquor be ſaturated, and even have an exceſs of acid, according to Mr Beaumé's proceſs. The liquor is then to be left in a cold place; and a great number of ſmall, ſhining, laminated cryſtals will be formed; theſe muſt be waſhed with a little very cold water, and drained upon brown paper. The ſedative ſalt obtained by this proceſs is ſomewhat denſer than that obtained by ſublimation; the latter being ſo light that 72 grains are ſufficient to fill a large phial.

859 Fixed in the fire.

Sedative ſalt, though thus capable of being once ſublimed, is not, however, volatile; for it ariſes only by means of the water of its cryſtallization; and when it has once loſt its water by drying, it cannot be raiſed into vapours by the moſt violent fire, but remains fixed, and melts into a vitreous matter like borax itſelf. This glaſs is ſoluble in water; and then becomes ſedative ſalt again. A great quantity of water is required to diſſolve the ſedative ſalt, and much more of cold than of boiling water; whence it is cryſtallizable by cold, as it alſo is by evaporation; a ſingular property, which ſcarce belongs to any other known ſalt.

860 Its properties.

This ſubſtance has not an *acid*, but a ſomewhat bitteriſh, taſte, accompanied with a ſlight impreſſion of coolneſs. It nevertheleſs unites with alkaline ſalts as acids do, and forms with them neutral ſalts. It is ſoluble in ſpirit of wine, to which it communicates the property of burning with a green flame. It makes no change on the blue colour of vegetables, as other acids do. It expels the other acids from their baſes, when diſtilled with a ſtrong heat; though theſe are all capable of expelling it in the cold, the acid of vinegar not excepted.

861 Mr Bourdelin's experiments.

The compoſition of ſedative ſalt is very much unknown, as no means ſufficient for its decompoſition have hitherto been found out. Mr Bourdelin, who made many experiments on this ſalt, found that it was unalterable by treatment with inflammable matters, with ſulphur, with mineral acids diſengaged, or united with metallic ſubſtances, and with ſpirit of wine. He could only perceive ſome marks of an inflammable matter, and a little marine acid. The former diſcovered itſelf by its communicating a ſulphureous ſmell to the vitriolic acid employed; and the latter by a white precipitate formed in a ſolution of mercury in the nitrous acid, by the liquor which came over on diſtilling the ſalt with powdered charcoal.

862 Mr Cadet's experiments. Mr Cadet, in the Memoirs of the Royal Academy of Sciences for 1766, has given an account of ſome experiments made by him on borax and its acid: from which he infers (1). That the acid contained in borax itſelf is the marine, and not ſedative, ſalt. (2.) That it is the marine, he proves by having made a corroſive ſublimate with this acid and *mercurius precipitatus per ſe*. That ſedative ſalt does not enter the compoſition of borax itſelf, he proves, by the impoſſibility of recompoſing borax from uniting the ſedative ſalt with foſſile alkali. The ſalt ſo produced, he owns, is very like borax, but unfit for the purpoſes of ſoldering metals as borax is. He therefore thinks, that, in the decompoſition of borax, the principles of the ſalt are ſomewhat changed, by the addition of that acid which extricates the ſedative ſalt; and that this ſalt is compoſed of the marine acid originally exiſting in the borax, of the vitriolic acid employed in the operation, and of a vitreſcible earth. (If this is true, then ſedative ſalt either cannot be procured by any other acid than the vitriolic, or it muſt have different properties according to the acid which procures it.) The vitreſcible earth, he ſays, is that which ſeparates from borax during its ſolution in water, and which abounds more in the unrefined than refined borax, and which he thinks conſiſts of a calx of copper, having obtained a regulus of copper from it. As he has never been able, however, to compoſe borax by the union of theſe ingredients, his experiments are by no means deciſive. Mr Beaumé has aſſerted that it is always produced by rancid oils; but Dr Black thinks his proofs by no means ſatisfactory.

Sedative Salt COMBINED,

I. *With Vegetable Alkali.* This ſalt forms a compound very much reſembling borax itſelf in quality; but in what reſpects it differs from, or how far it is applicable to, the purpoſes of borax, hath not yet been determined.

863 Borax. II. *With Mineral Alkali.* This ſalt has generally been thought to recompoſe borax: and though Mr Cadet has denied this, yet as his experiments are hitherto imperfect and unſupported, we ſhall here give the hiſtory of that ſalt, as far as it is yet known.

This ſalt is prepared in the Eaſt Indies. It is ſaid, that from certain hills in theſe countries there runs a green ſaline liquor, which is received in pits lined with clay, and ſuffered to evaporate with the ſun's heat; that a bluiſh mud which the liquor brings along with it is frequently ſtirred up, and a bituminous mather, which floats upon the ſurface, taken off; that when the whole is reduced to a thick conſiſtence, ſome melted fat is mixed, the matter covered with vegetable ſubſtances and a thin coat of clay; and that when the ſalt has cryſtallized, it is ſeparated from the earth by a ſieve. In the ſame countries is found native the mineral alkali in conſiderable quantity; ſometimes tolerably pure, at other times blended with heterogeneous matters of various kinds. This alkali appears to exiſt in borax, as a Glauber's ſalt may be formed from a combination of borax with vitriolic acid. For a further account See BORAX.

864 Refined. Borax, when imported from the Eaſt Indies, conſiſts of ſmall, yellow, and glutinous cryſtals. It is refined, ſome ſay, by diſſolving it in lime-water; others, in alkaline lixivia, or in a lixivium of cauſtic alkali; and by others, in alum-water. Refined borax conſiſts of large eight-ſided cryſtals, each of which is compoſed of ſmall, ſoft, and bitteriſh ſcales. It has been ſaid that cryſtals of this ſize can by no means be obtained by diſſolving unrefined borax in common water; that the cryſtals obtained in this way are extremely ſmall, and differ conſiderably from the refined borax of the ſhops; inſomuch that Cramer calls the large cryſtals, not a purified, but an adulterated borax. When diſſolved in lime-water, the borax ſhoots into larger cryſtals; and largeſt of all, when the veſſel is covered, and a gentle warmth continued during the cryſtallization. All this, however, is denied by Dr Black; who ſays, that in order to accompliſh the purification, we have only to diſſolve the impure borax in hot water; to ſeparate the impurities by filtration, after which the ſalt ſhoots into the cryſtals we commonly ſee. During the diſſolution, borax appears glutinous, and adheres in part to the bottom of the veſſel. From this glutinous quality, peculiar to borax among the ſalts, it is uſed by dyers for giving a gloſs to ſilks.

865 Its properties. All acids diſſolve borax ſlowly, and without efferveſcence. It precipitates from them moſt, but not all, metallic ſubſtances; along with which a conſiderable part of the borax is generally depoſited. It does not abſorb the marine acid of luna cornea, or of mercury ſublimate. It melts upon the ſurface of the former without uniting, and ſuffers the latter to riſe unchanged: the borax in both caſes becomes coloured; in the firſt, milky with red ſtreaks; in the latter, amethyſt or purple. Mixed with ſal ammoniac, it extricates the volatile alkali, and retains the acid; but mixed with a combination of the marine acid with calcareous earths, it unites with the earth, and extricates the acid. It extricates the acid of nitre without ſeeming to unite with the alkaline baſis of that ſalt; nor does it mingle in fuſion with the common fixed alkaline ſalts, the borax flowing diſtinct upon their ſurface. A mixture of borax with twice its weight of tartar, diſſolves in one ſixth of the quantity of water that would be neceſſary to diſſolve them ſeparately: the liquor yields, on inſpiſſation, a viſcous, tenacious maſs like glue; which refuſes to cryſtallize, and which deliquates in the air. Borax affords likewiſe a glutinous compound with the other acids, except the vitriolic; whence this laſt is generally preferred for making the ſedative ſalt. It proves moſt glutinous with the vegetable, and leaſt with the marine. With oils, both expreſſed and diſtilled, it forms a milky, ſemi-ſaponaceous compound. It partially diſſolves in ſpirit of wine. In conjunction with any acid, it tinges the flame of burning matters green; the precipitate thrown down by it from metallic ſolutions has this effect. It does not deflagrate with nitre. Fuſed with inflammable matters, it yields nothing ſulphureous, as thoſe ſalts do which

which contain vitriolic acid. By repeatedly moiſtening it when conſiderably heated, it may be entirely ſublimed.

Borax retains a good quantity of water in its cryſtals; by which it melts and ſwells up in a heat inſufficient to vitrify it. It is then ſpongy and light, like calcined alum; but, on increaſing the fire, it flows like water.

§ 6. *Of the* Acetous *Acid and its Combinations.*

867 How procured.

This acid is plentifully obtained from all vinous liquors, by a fermentation of a particular kind, (ſee Fermentation, and Vinegar.) It appears firſt in the form of an acid liquor, more or leſs deeply coloured, as the vinegar is more or leſs pure. By diſtillation in a common copper-ſtill, with a pewter head and worm, this acid may be ſeparated from many of its oily and impure parts. Diſtilled vinegar is a purer but not a ſtronger acid than the vinegar itſelf; for the acid is originally leſs volatile than water, though, by certain operations, it becomes more ſo. After vinegar has been diſtilled to about $\frac{1}{10}$ of its original bulk, it is ſtill very acid, but thick and black. This matter continues to yield, by diſtillation, a ſtrong acid ſpirit, but tainted with an empyreumatic oil. If the diſtillation is continued, a thick black oil continues to come over; and at laſt ſome volatile alkali, as in the diſtillation of animal ſubſtances. The caput mortuum left in the diſtilling veſſel, being calcined in an open fire, and afterwards lixiviated, yields ſome fixed alkaline ſalt.

Acetous Acid combined,

868 Sal diureticus.

I. *With Vegetable Alkali.* The produce of this combination is the *terra foliata tartari*, or ſal diureticus of the ſhops; but to prepare this ſalt of a fine white flaky appearance, which is neceſſary for ſalt, is a matter of ſome difficulty. The beſt method of performing this operation is, after having ſaturated the alkali with the vinegar, which requires about 15 parts of common diſtilled vinegar to one of alkali, to evaporate the liquor to dryneſs; then melt the ſaline maſs which remains with a gentle heat; after which it is to be diſſolved in water, then filtered, and again evaporated to dryneſs. If it is now diſſolved in ſpirit of wine, and the liquid abſtracted by diſtillation, the remaining maſs being melted a ſecond time, will, on cooling, have the flaky appearance deſired.

A good deal of caution is neceſſary in the firſt melting; for the acetous acid is eaſily diſſipable, even when combined with fixed alkali, by fire. It is proper, therefore, that, when the ſalt is melted, a little ſhould be occaſionally taken out, and put into water; and when it readily parts with its blackneſs to the water, muſt then be removed from the fire. The ſalt, when made, has a very ſtrong attraction for water, inſomuch that it is not eaſily preſerved, even when put into glaſs bottles. To keep it from deliquating, Dr Black, therefore, recommends the corks to be covered with ſome bituminous matter; otherwiſe they would tranſmit moiſture enough to make the ſalt deliquate.

869 Acetous acid with foſſile alkali.

II. *With Foſſile Alkali.* This alkali, combined with the acetous acid, forms a ſalt whoſe properties are not well known. Dr Lewis affirms, that it is nearly ſimilar to the terra foliata tartari. The author of the Chemical Dictionary, again, maintains it to be quite different: particularly that it cryſtallizes well, and is not deliqueſcent in the air; whereas the former cannot be cryſtallized; and even when obtained in a dry form, unleſs great care is taken to exclude the air, will preſently deliquate.

870 Vegetable ammoniac.

III. *With Volatile Alkali.* This combination produces a ſalt ſo exceedingly deliqueſcent, that it cannot be procured in a dry form without the greateſt difficulty. In a liquid ſtate, it is well known in medicine, as a ſudorific, by the name of *ſpiritus mindereri*. It may, however, be procured in a dry form, by mixing equal parts of vitriolic ſal ammoniac and terra foliata tartari, and ſubliming the mixture with a very gentle heat. When the ſalt is once procured, the utmoſt care is requiſite to preſerve it from the air.

871 Anomalous ſalts.

IV. *With Earths.* Combinations of this kind are but little known. With the calcareous and argillaceous earths compounds of an aſtringent nature are formed. According to the author of the Chemical Dictionary, the ſalt reſulting from a combination of vinegar with calcareous earth eaſily cryſtallizes, and does not deliquate. With magneſia the acetous acid does not cryſtallize; but, when inſpiſſated, forms a tough maſs, of which two drachms, or two and a half, are a briſk purgative.

872 Diſtilled verdegris.

V. *With Copper.* Upon this metal the acid of vinegar does not act briſkly, until it is partly at leaſt calcined. If the copper is previouſly diſſolved in a mineral acid, and then precipitated, the calx will be readily diſſolved by the acetous acid. The ſolution is of a green colour, and beautiful green cryſtals may be obtained from it. The ſolution, however, is much more eaſily effected, by employing verdegris, which is copper already united with a kind of acetous or tartareous acid, and very readily diſſolves in vinegar. The cryſtals obtained by this proceſs are uſed in painting, under the name of *diſtilled verdegris*.

The moſt ready, and in all probability the cheapeſt, method of preparing the cryſtals of verdegris is that propoſed by Mr Wenzel, by mixing together the ſolutions of ſugar of lead and blue vitriol, when an exchange of baſes takes place; the lead being inſtantly precipitated by the vitriolic acid, and the acetous acid uniting with the copper. From 15 ounces and two drachms of ſugar of lead with twelve ounces of blue vitriol, five ounces of the cryſtals were obtained. The precipitate of lead, though waſhed ſeveral times with water, never loſt its green colour. It may either be uſed, he ſays, in this ſtate, as a green pigment, or it may be made perfectly white by digeſtion in dilute nitrous acid.

873 Iron liquor for printing cloth.

VI. *With Iron.* Vinegar acts very readily upon iron, and diſſolves it into a very brown and almoſt black liquor, which does not eaſily cryſtallize, but, if inſpiſſated, runs per deliquium. This liquor is employed in the printing of linens, calicoes, &c. being found to ſtrike a finer black with madder, and to injure the cloth leſs, than ſolutions of iron in the other acids.

874 Lead.

VII. *With Lead.* The acetous acid diſſolves lead in its metallic ſtate very ſparingly; but if the metal is calcined, it acts upon it very ſtrongly. Even after lead is melted into glaſs, the acetous acid will receive a ſtrong impregnation from it; and hence it is dangerous to to put vinegar into ſuch earthen veſſels as are glazed with lead. In the metallic ſtate, only a drachm of lead can be diſſolved in eight ounces of diſtilled vinegar.

875 Ceruſs.

If lead is expoſed to the vapours of warm vinegar, it is corroded into a kind of calx, which is uſed in great quantities in painting, and is known by the name of *ceruſs* or *white lead*. The preparation of this pigment has become a diſtinct trade, and is practiſed in ſome places in Britain where lead is procurable at the loweſt price. The proceſs for making ceruſs is thus given by the author of the Chemical Dictionary.

“ To make ceruſs, leaden plates rolled ſpirally, ſo that the ſpace of an inch ſhall be left between each circumvolution, muſt be placed vertically in earthen pots of a proper ſize, containing ſome good vinegar. Theſe leaden rolls ought to be ſo ſupported in the pots that they do not touch the vinegar, but that the acid vapour may circulate freely betwixt the circumvolutions. The pots are to be covered, and placed in a bed of dung, or in a ſand-bath, by which a gentle heat may be applied. The acid of vinegar being thus reduced into vapour, eaſily attaches itſelf to the ſurface of theſe plates, penetrates them, and is impregnated with the metal, which it reduces to a beautiful white powder, called *ceruſs*. When a ſufficient quantity of it is collected on the plates, the rolls are taken out of the pots, and unfolded ; the ceruſs is then taken off, and they are again rolled up, that the operation may be repeated.

“ In this operation, the acid being overcharged with lead, this metal is not properly in a ſaline ſtate ; hence ceruſs is not in cryſtals, nor is ſoluble in water : but a ſaline property would render it unfit for painting, in which it is chiefly employed.”

876 Obſervations on the proceſs for ceruſs.

Though this proceſs may in general be juſt, yet there are certainly ſome particulars neceſſary to make ceruſs of a proper colour, which this author has omitted ; for though we have carefully treated thin plates of lead in the manner he directs, yet the calx always turned out of a dirty grey colour. It is probable, therefore, that after the lead has been corroded by the ſteam of vinegar, it may be waſhed with water ſlightly impregnated with the vitriolic and nitrous acids.

This preparation is the only white hitherto found fit for painting in oil : but the diſcovery of another would be very deſirable, not only from the faults of ceruſs as a paint, but alſo from its injuring the health of perſons employed in its manufacture, by affecting them with a ſevere colic ; which lead, and all its preparations, frequently occaſion.

877 Sugar of lead.

If diſtilled vinegar is poured on white lead, it will diſſolve it in much greater quantity than either the lead in its metallic form, or any of its calces. This ſolution filtered and evaporated, ſhoots into ſmall cryſtals of an auſtere ſweetiſh taſte called *ſugar of lead*. Theſe are uſed in dyeing, and externally in medicines. They have been even given internally for ſpitting of blood. This they will very certainly cure ; but at the ſame time they as certainly kill the patient by bringing on other diſeaſes. If theſe cryſtals are repeatedly diſſolved in freſh acids, and the ſolutions evaporated, an oily kind of ſubſtance will at laſt be obtained, which can ſcarcely be dried.

878 Inflammable ſpirit from ſugar of lead.

From all the metallic combinations of the acetous acid, it may be recovered in an exceedingly concentrated form, by ſimple diſtillation, ſugar of lead only excepted. If this ſubſtance is diſtilled in a retort with a ſtrong heat, it hath been ſaid that an inflammable ſpirit, and not an acid comes over ; but this is denied by Dr Black.

879 Tin.

VIII. *With Tin.* The combination of acetous acid with tin is ſo little known, that many have doubted whether diſtilled vinegar is capable of diſſolving tin or not.

880 Dr Lewis's experiments concerning the ſolubility of tin.

Dr Lewis obſerves, “ That plates of pure tin put into common vinegar begun in a few hours to be corroded, without the application of heat. By degrees a portion of the metal was taken up by the acid, but did not ſeem to be perfectly diſſolved, the liquor appearing quite opaque and turbid, and depoſiting great part of the corroded tin to the bottom, in a whitiſh powder. A part of the tin, if not truly diſſolved, is exquiſitely divided in the liquor; for, after ſtanding many days and after paſſing through a filter, ſo much remained ſuſpended as to give a whitiſhneſs and opacity to the fluid. Acid juices of fruits, ſubſtituted to the vinegar, exhibited the ſame phenomena. Theſe experiments are not fully concluſive for the real ſolubility of tin in theſe acids, with regard to the purpoſes for which chemiſts have wanted ſuch a ſolution : but they prove what is more important; that tin, or tinned veſſels, however pure the tin be, will give a metallic impregnation to light vegetable acids ſuffered to ſtand in them for a few hours.”

With regard to other metallic ſubſtances, neither the degree of attraction which the acetous acid has for them, nor the nature of the compounds formed by the union of it with ſuch ſubſtances, are known; only, that as much of the reguline part of antimony is diſſolved in this acid as to give it a violent emetic quality. See *Regulus of Aatimony*.

Concentration of the *Acetous Acid*.

881 Concentrated vinegar.

Common vinegar, as any other weak acid, may be advantageouſly concentrated by froſt ; as alſo may its ſpirit or the diſtilled vinegar of the ſhops : but as the cold, in this country, is ſeldom or never ſo intenſe as to freeze vinegar, this method of concentration cannot be made uſe of here. If diſtilled vinegar be ſet in a water-bath, the moſt aqueous part will ariſe, and leave the more concentrated acid behind. This method, however, is tedious, and no great degree of concentration can be produced, even when the operation is carried to its utmoſt length. A much more concentrated acid may be obtained by diſtilling in a retort the cryſtals of copper, mentioned (n° 872) under the name of *diſtilled verdegris*. A very ſtrong acid may thus be obtained, which has a very pungent ſmell, almoſt as ſuffocating as volatile ſulphureous acid. The Count de Lauraguais diſcovered that this ſpirit, if heated in a wide-mouthed pan, would take fire on the contact of flaming ſubſtances, and burn entirely away, like ſpirit of wine, without any reſiduum.

882 Salt of vinegar.

The ſame nobleman alſo obſerved, that this ſpirit, when well concentrated, eaſily cryſtallizes without addition.

Acetous acid and its combinations.

This may ſeem to be the moſt proper method of obtaining the acetous acid in its greateſt degree of ſtrength and purity : but as the proceſs requires a very ſtrong heat to be uſed towards the end of the operation, it is probable that part of the acetous acid may be by that means entirely decompoſed. It would ſeem preferable, therefore, to decompoſe pure terra foliata tartari by means of the vitriolic acid, in the ſame manner as nitre or ſea-ſalt are decompoſed for obtaining their acids. In this caſe, indeed, the acetous acid might be a little mixed with the vitriolic ; but that could eaſily be ſeparated by a ſecond diſtillation. A ſtill better method of preparing the acid ſeems to be by diſtilling ſugar of lead with oil of vitriol. The proportion uſed by M. Lorenzen of Copenhagen, is three ounces of vitriolic acid to eight of the ſugar of lead. Mr Dollfuſs recommends two parts of ſugar of lead to one of vitriolic acid.

883 Dr Prieſtley's experiments.

Dr Prieſtley, who gives us ſeveral experiments on the vegetable acid when reduced to the form of air, mentions his being eaſily able to expel it from ſome exceedingly ſtrong concentrated vinegar, by means of heat alone. This ſeems ſomewhat contrary to the count de Lauraguais's obſervation of the diſpoſition of the *ſpirit of verdegris*, as it is commonly called, to cryſtallize : but a ſtill greater difference is, that the vegetable acid air extinguiſhed a candle, when according to the Count's obſervation, it ought to have been inflammable. The moſt curious property obſerved by Dr Prieſtley is, that the vegetable acid air being imbibed by oil olive, the oil was rendered leſs viſcid, and clearer, *almoſt like an eſſential oil.* This is an uſeful hint ; and, if purſued, might lead to important diſcoveries.

Acetous acid combined with *Inflammable Matter.*

884 Vegetable ether.

The only method yet known, of combining acetous acid with the principle of inflammability, is by mixing together equal parts of the ſtrongly concentrated acid called *ſpirit of verdegris*, and ſpirit of wine. The reſult is, a new kind of *ether*, ſimilar to the vitriolic, nitrous, and marine. This ether, however, retains ſome of the acidity and peculiar ſmell of the vinegar. By rectification with fixed alkali, it may be freed from this acidity, and then ſmells more like true ether, but ſtill retaining ſomething of the ſmell, not of the acid, but the inflammable part of the vinegar.

In this proceſs a greater quantity of ether is obtained than by employing the vitriolic acid: which ſhows that the vegetable acid is eſſentially fitter to produce ether than the vitriolic. For making the acetous ether readily, Mr Dollfuſs recommends eight ounces of ſugar of lead dried by a very gentle heat, until it loſes the water of cryſtallization, when it will weigh five ounces and ſix drachms. It is then to be put into a glaſs retort and a mixture of five ounces of vitriolic acid, with eight of ſpirit of wine, poured upon it, and the whole diſtilled with a very gentle fire. The firſt ounce that paſſes over will be dulcified acetous acid, the next almoſt all ether, and the third ether in its pureſt ſtate.

An ether may alſo be obtained from vinegar of wood. To make it, the moſt concentrated acid of this kind is to be made uſe of. For this purpoſe an empyreumatic acid muſt firſt be diſtilled from beech-wood, and then rectified by a ſecond diſtillation. Three pounds of this require for their ſaturation five ounces of purified alkali, which by evaporation and fuſion affords three ounces and a quarter of terra foliata tartari. From this, one ounce ſix drachms of concentrated acid are obtained ; and this, on being mixed with an equal quantity of alcohol, yields two ounces one drachm and a half of genuine ether.

Acid of tartar and its combinations.

§ 7. *Of the Acid of* TARTAR.

885 Tartar.

TARTAR is a ſubſtance thrown off from wine, after it is put into caſks to depurate. The more tartar that is ſeparated, the more ſmooth and palatable the wine is. This ſubſtance forms a thick hard cruſt on the ſides of the caſks : and, as part of the fine dregs of the wine adhere to it, the tartar of the white wines is of a greyiſh white colour, called *white tartar* ; and that of red wine has a red colour, and is called *red tartar*.

886 Cream of tartar.

When ſeparated from the caſks on which it is formed, tartar is mixed with much heterogeneous matter ; from which, for the purpoſes of medicine and chemiſtry, it requires to be purified. This purification is performed at Montpelier ; and conſiſts firſt in boiling the tartar in water, filtrating the ſolution, and allowing the ſalt to cryſtallize, which it very ſoon does ; as tartar requires nearly twenty times its weight of water to diſſolve it.

The cryſtals of tartar obtained by this operation are far from being perfectly pure ; and therefore they are again boiled in water, with an addition of clay, which abſorbs the colouring matter ; and thus, on a ſecond cryſtallization, a very pure and white ſalt is obtained. Theſe cryſtals are called *cream*, or *cryſtals of tartar* ; and are commonly ſold under theſe names.

Dr Black obſerves, that in the purification of tartar, it is neceſſary to add ſome earthy ſubſtances, in order to abſorb or carry down the colour. Macquer thinks that theſe ſubſtances unite in part with the tartar, and render it more ſoluble, but they have little diſpoſition to unite with acids ; they are the purer kinds of clay, and promote the complete depoſition of its impurities ; ſo that in the management of wines it is neceſſary to add certain powdery ſubſtances which have ſome weight, and fall to the bottom readily ; and which, in falling, carry down a number of particles that would otherwiſe float in the liquor for a long time, being ſo light that they could hardly be made to ſubſide ; but the particles of clay adhering to them increaſe their gravity ; and probably it anſwers the ſame purpoſe in the refinement of tartar.

To obtain the pure Acid of *Tartar*.

887 Scheele's analyſis of cream of tartar.

For a long time the cream or cryſtals of tartar were conſidered as the pureſt acid which could be obtained from this ſubſtance ; but, in the year 1770, an analyſis of tartar was publiſhed in the Swediſh tranſactions, by Mr Scheele. His method of decompoſing the ſalt was, to diſſolve it in a ſufficient quantity of boiling water, then to add chalk in fine powder till the effervеſcence ceaſed. A copious precipitation enſued ; and the remaining liquor being evaporated;

Acid of tartar and its combinations.

porated, afforded a ſoluble tartar. This proved that cream of tartar is not, as was commonly ſuppoſed, an acid of a peculiar kind, joined with a great deal of earthy impurities; but really a compound ſalt, containing an alkali joined with an acid; and that the alkali produced from burnt tartar is not generated in the fire, but pre-exiſtent in the ſalt.

The whole ſediment contained in this experiment, is the calcareous earth combined with the acid of tartar, which may juſtly be called *ſelenites tartareus*. If ſome diluted vitriolic acid is poured upon this ſelenites tartareus, the vitriolic acid expels the acid of tartar, forming a true ſelenite with the earth, while the liquor contains the pure acid of tartar. By inſpiſſation this acid may be made ſtronger, and even formed into ſmall white cryſtals, which do not deliquate in the air. A particular ſpecies of tartar extracted from ſorrel hath been ſold for taking ſpots out of clothes, under the name of *eſſential ſalt of lemons*, and which is now diſcovered to be the ſame with the acid of ſugar.

888 Eſſential ſals of lemon.

This experiment was ſoon after confirmed by Dr Black; who farther obſerved, that if quicklime was uſed inſtead of chalk, the whole acid would be abſorbed by the lime, and the remaining liquor, inſtead of being a ſolution of ſoluble tartar, would be a cauſtic lixivium. The moſt ready method, however, of procuring the pure acid of tartar ſeems to be that recommended by Mr Schiller in the Chemical Annals for 1787. One pound of cream of tartar is to be boiled in five or ſix pounds of water, and a quartar of a pound of oil of vitriol added by little and little, by which means a perfect ſolution will be obtained. By continuing the boiling, all the vitriolated tartar is precipitated. When the liquor is evaporated to one half, it muſt be filtered; and if, on the renewal of the boiling, any thing farther is precipitated, the filtration is to be repeated. The clear liquor is then to be reduced to the conſiſtence of a ſyrup, and ſet in a temperate, or rather a warm place, when very fine cryſtals will be formed, and as much acid obtained as is equal in weight to half the cream of tartar employed. If too ſmall a quantity of vitriolic acid has been employed, the undecompoſed cream of tartar falls along with the vitriolated tartar.

Acid of Tartar COMBINED,

889 Soluble tartar.

I. *With Vegtable Alkali.* If the pure acid of tartar be combined with this alkali to the point of ſaturation, a neutral ſalt is produced, which deliquates in the air, and is not eaſily cryſtallized, unleſs the liquor be kept warm, and likewiſe be ſomewhat alkaline. This ſalt, called *ſoluble tartar*, is uſed in medicine as a purgative; but as its deliqueſence does not admit of its being kept in a cryſtalline form, it is always ſold in powder. Hence thoſe who prepare ſoluble tartar, take no further trouble than merely to rub one part of fixed alkaline ſalt with three of cream of tartar, which renders the compound ſufficiently neutral, and anſwers all the purpoſes of medicine. Dr Black informs us, that in medical preſcriptions, where ſoluble tartar is ordered as a purgative along with a decoction of tamarinds, the acid of the latter will decompoſe the ſoluble tartar, and thus the preſcription may perhaps be rendered ineffectual. The ſaline mixture uſed in fevers is nothing but a tartarus ſolubilis in ſolution.

According to Mr Scheele, cream of tartar may be recompoſed from the pure acid and alkali in the following manner: "Upon fixed vegetable alkali pour a ſolution of the acid of tartar. Continue this till the effervescence is over; the fluid will then be tranſparent; but if more of the acid is added, it will become turbid and white, and ſmall cryſtals like white ſand will be formed in it. Theſe cryſtals are a perfect cream of tartar.

890 Regenerated cream of tartar.

Upon theſe principles, another method of decompoſing cream of tartar might be tried; namely, adding to it as much oil of vitriol as would ſaturate the alkali, then diſſolving and cryſtallizing the ſalt: but, by this method, there would be danger of the acid being adulterated with vitriolic tartar.

891 Siegnette's or Rochelle ſalt.

II. *With Foſſile Alkali.* The ſalt produced from an union of cream of tartar with foſſile alkali, has been long known under the names of *Siegnette's ſalt*, *ſal Rupellenſis*, or *Rochelle ſalt*; but as the cream of tartar is now diſcovered to be not a pure acid, but adulterated with a portion of ſoluble tartar, poſſibly ſome differences might be obſerved if the pure acid was uſed.

This ſalt was firſt invented and brought into vogue by one Seignette, an apothecary at Rochelle, who kept the compoſition a ſecret as long as he could. Meſſrs Boylduc and Geoffroy afterwards diſcovered and publiſhed its compoſition.

To prepare this ſalt, cryſtals of mineral alkali are to be diſſolved in hot water, and powdered cream of tartar thrown in as long as any effervеſcence ariſes. For the better cryſtallization of the ſalt, the alkali ought to prevail. The liquor muſt then be filtered and evaporated, and very fine large cryſtals may be obtained by cold, each of which is the half of a polygonous priſm cut in the direction of its axis. This ſection, which forms a face much larger than the reſt, is, like them, a regular rectangle, diſtinguiſhable from the others, not only by its breadth, but alſo by two diſtinct diagonal lines which interſect each other in the middle. The following method of preparing Siegnette's ſalt, recommended by Mr Scheele, ſeems preferable to any other on account of its eaſe and cheapneſs. Thirty ſix ounces of cryſtals of tartar are to be ſaturated with potaſh, and eleven ounces of common ſalt diſſolved in the ley. When it is grown cold, and the vitriolated tartar has ſubſided to the bottom, it is filtered and evaporated till a pellicle appears; the two firſt cryſtallizations yield a fine Seignette's ſalt; the third contains ſome digeſtive ſalt; and the fourth is entirely compoſed of it. The reaſon of this formation of Seignette's ſalt is, that the vegetable alkali has a greater attraction for acids than the mineral, and therefore decompoſes the ſea-ſalt, whoſe baſis is then at liberty to combine with the acid of tartar; while the ſtronger marine acid takes the vegetable alkali.—A ſalt of the ſame kind will be produced by adding Glauber's ſalt inſtead of common ſea-ſalt.

892 Cream of tartar.

III. *With Volatile Alkali.* With regard to this combination, all we know as yet is, that if the alkali is over-ſaturated with acid, a cream of tartar, almoſt as difficult of ſolution as that of fixed alkali, will be obtained. When the ſaturation has been pretty exact, a beautiful ſalt, compoſed of four ſided pyramids, and which does not deliquate in the air, is produced. It is inſtantly decompounded, and emits a pungent volatile ſmell on being mixed with fixed alkali.

Acid of tartar and its combinations.

IV. *With Earths.* All that is as yet known concerning theſe combinations, is, that with the calcareous earth a compound not eaſily ſoluble in water is formed. The other properties of this ſubſtance, and the nature of combinations of tartareous acid with other earths, are entirely unknown.

893 Selenites tartareous.

V. *With Copper.* In its metallic ſtate, cream of tartar acts but weakly on the metal, but diſſolves verdegris much more prfectly than diſtilled vinegar can. The ſolution of cream of tartar, being evaporated, does not cryſtallize, but runs into a gummy kind of matter; which, however, does not attract the moiſture of the air. It readily diſſolves in water, and makes a beautiful bluiſh green on paper, which has the property of always ſhining, as if covered with varniſh. The effects of the pure acid on this metal have not yet been tried.

894 A fine green colour.

895 Chalybeated tartar.

VI. *With Iron.* The effects of a combination of iron with the pure acid have not hitherto been tried. Cream of tartar diſſolves this metal into a green liquor, which being evaporated runs *per deliquium.* It has been attempted to ſubſtitute a ſolution of this kind to the liquor uſed in printing calicoes formed of iron and ſour beer; but this gave a very dull browniſh colour with madder. Poſſibly, if the pure acid was uſed, the colour might be improved. In medicine, a combination of cream of tartar with iron is uſed, and probably may be an uſeful chalybeate.

VII. *With Regulus of Antimony.* See Sect. III.

§ 8. *Of the Acid of* SUGAR.

896 Saccharine acid.

THAT ſugar contains an acid, which on diſtillation by a ſtrong fire ariſes in a liquid form, in common with that of moſt other vegetable ſubſtances, has been generally known; but how to obtain this acid in a concrete form, and to appearance as pure and cryſtallizable as the acid of tartar, we were entirely ignorant, till the appearance of a treatiſe intitled, *Diſſertatio Chemica, de acido Sacchari, auctore* Johanne Afzelio Arvidſſon, 4to, *Upſaliæ.*

Of the method of procuring, and the properties of, this new acid, we have the following account in the Edinburgh Medical Commentaries, vol. iv.

" 1. To an ounce of the fineſt white ſugar in powder, in a tubulated retort, add three ounces of ſtrong ſpirit of nitre.

" 2. The ſolution being finiſhed, and the phlogiſton of the ſpirit of nitre moſtly exhaled, let a receiver be properly fitted to the retort and luted, and the liquor then made to boil gently.

" 3. When the ſolution has obtained a browniſh colour, add three ounces more of ſpirit of nitre, and let the ebullition be continued till the fumes of the acid are almoſt gone.

897 Chryſtals of ſaccharine acid.

" 4. The liquor being at length emptied in a *larger* veſſel, and expoſed to a proper degree of cold, quadrangular priſmatic cryſtals are obſerved to form; which being collected, and dried on ſoft paper, are found to weigh about 109 grains.

" 5. The remaining liquor being again boiled in the ſame retort, with two ounces of freſh ſpirit of nitre, till the red vapours begin to diſappear, and being then in the ſame manner expoſed to cryſtallize, about 43 grains of ſaline ſpiculæ are obtained.

Acid of ſugar and its combinations.

" 6. To the liquid that ſtill remains, about two ounces more of ſpirit of nitre being added, and afterwards the whole being, *both by boiling and evaporation,* reduced to a dry maſs, a brown, ſaline, gelatinous kind of ſubſtance is produced, which, when thoroughly dry, is found to weigh about half a drachm.

" In the ſame manner, a ſimilar acid, we are told, may be obtained from different ſaccharine ſubſtances, as *gum-arabic, honey, &c.*; but from none in ſuch quantities, or ſo pure, as from fine ſugar."

898 Preſumption of its expelling the vitriolic acid.

This ſalt poſſeſſes ſome very ſingular properties, of which what appears to us the moſt remarkable, and which we cannot help reading with ſome degree of doubt, is, that it produces an effervеſcence on being added to ſuch *alkaline, earthy, or metallic ſubſtances, as contain the vitriolic acid.* From this we ſhould be apt to think, that this acid was capable of diſlodging even the vitriolic acid from its baſis.

Acid of ſugar, being diſtilled in a retort, gives over about $\frac{3}{10}$ of its weight of water. By an intenſe heat it melts, and is partly ſublimed; leaving in the retort a dark grey maſs, of about the fifth part of the weight of the cryſtals made uſe of. The ſublimed ſalt eaſily recovers the cryſtalline form, and ſeems to have undergone no further change by ſublimation than being rendered more pure. During the diſtillation a great quantity of elaſtic vapour ruſhes out (about 100 cubic inches from half an ounce of the cryſtals), which, from the diſtilled liquor's precipitating lime-water, we may judge to be fixed air. In a ſecond ſublimation, white fumes are ſent over, which, when cold, appear to be an acid, glaſſy-coloured liquor, but cannot be again cryſtallized. " Such parts of the ſalts as adhere to the ſides and necks of the veſſels do not appear to be in the leaſt changed in the proceſs." On a third ſublimation, theſe parts produced ſuch claſtic vapours as burſt the receiver.

899 Great acid power.

This ſingular ſalt has a conſiderable acid power; twenty grains of it giving a very conſiderable degree of acidity to a large tankard of water. It diſſolves in an equal weight of diſtilled water, but concretes on the liquor's growing cool. It is alſo ſoluble in ſpirit of wine; 100 parts of boiling ſpirit of wine diſſolving 56 of the ſaccharine cryſtals, but no more than 40 when cold. The ſolution in ſpirit of wine ſoon becomes turbid; and depoſites a mucous ſediment, in quantity about $\frac{1}{40}$ of the acid made uſe of. When cold, irregular ſcaly cryſtals are formed, which when dry are perfectly white.

900 Incredible quantity of volatile alkali ſaturated by it.

With vegetable alkali, the acid of ſugar can ſcarcely be formed into cryſtals, unleſs either the alkali or acid predominate. With mineral alkali, a ſalt very difficult of ſolution is formed. The quantity of volatile alkali ſaturated by this acid is incredible. " Six parts of a pure volatile alkali may be ſaturated with one of the acid of ſugar. The produce is a quadrangular priſmatic ſalt. With lime this acid unites ſo ſtrongly, as to be ſeparable by no other means than a ſtrong heat. What kind of a ſalt reſults from this combination we are not told; but the author is of opinion, that this ſhows the uſe of lime in the purification of ſugar, in order to abſorb the ſuperfluous acid. Being ſaturated with ſome of the *terra ponderoſa,* the acid of ſugar immediately depoſits a quantity of pellucid angular cryſtals, ſcarcely ſoluble in water. With magneſia

Acid of ſugar and its combinations.

ſia the ſalt appears in form of a white powder, ſoluble neither in water nor ſpirit of wine, unleſs the acid prevails. It has a ſtronger affinity with magneſia than any of the alkaline ſalts. With earth of alum, no cryſtals are obtained; but a yellow pellucid maſs, of a ſweetiſh and ſomewhat aſtringent taſte; which, in a moiſt air, liquefies, and increaſes two-thirds in weight.

901 Its effects on metals.

This acid acts upon all metals, gold, ſilver, platina, and quickſilver, not excepted, if they have been previouſly diſſolved in an acid, and then precipitated. Iron in its metallic ſtate is diſſolved in very large quantity by the ſaccharine acid; 45 parts of iron being ſoluble in 55 of acid. By evaporation, the liquor ſhoots into yellow priſmatic cryſtals, which are eaſily ſoluble in water. With cobalt, a quantity of yellow-coloured cryſtals are obtained, which being diſſolved in water, and ſea-ſalt added to the ſolution, form a ſympathetic ink. The elective attractions of this ſingular acid are, firſt, lime, than the *terra ponderoſa*, magneſia, vegetable alkali mineral alkali, and laſtly clays.

902 Saccharine ether.

With ſpirit of wine an ether was obtained which cannot eaſily be ſet on fire unleſs previouſly heated, and burns with a blue inſtead of a white flame.

903 Whether this acid is produced from the nitrous.

Towards the concluſion of his diſſertation the author obſerves, that ſome may imagine that the acid of nitre made uſe of in theſe experiments, may have a conſiderable ſhare in the production of what he has termed *acid of ſugar*. But though he acknowledges that this acid cannot in any way be obtained but by the aſſiſtance of ſpirit of nitre, he is thoroughly convinced that it does not, in any degree, enter into its compoſition.

What occurs to us on this ſubject is, that if the acid really pre-exiſts in the ſugar, it muſt give ſome tokens of its exiſtence by mixing the ſugar with other ſubſtances beſides ſpirit of nitre. The author himſelf thinks that lime acts upon the acid part of the ſugar: from whence we are apt to conclude, that by mixing lime, in a certain proportion, with ſugar, a compound ſhould be obtained ſomewhat ſimilar to what was formed by a direct combination of lime with the pure acid. In this caſe, we might conclude that the nitrous acid produces this ſalt, by combining with the inflammable part of the ſugar, becoming thereby volatile, and flying entirely off, ſo as to leave the acid of the ſugar pure. In the diſtillation of dulcified ſpirit of nitre, however, we have an inſtance of the nitrous acid itſelf being very much altered. This muſt therefore ſuggeſt a doubt that the acid ſalt obtained in the preſent caſe is only the nitrous acid deprived of its phlogiſton, and united with ſome earthy particles.

In a treatiſe lately publiſhed by Mr Rigby, however, we are informed that ſugar itſelf may be recompoſed by uniting the acid of ſugar with phlogiſton; which aſſertion, if well founded, undoubtedly decides the diſpute in favour of the ſaccharine acid being originally contained in the ſugar.

2d 903 The ſame with the acid of ſorrel.

Late experiments have determined it to be the ſame with that of ſorrel; for which, as well as many other valuable acquiſitions, the ſcience of chemiſtry is indebted to Mr Scheele. Having diſſolved as much acid of ſugar in cold water as the liquor could take up, he added to this ſolution ſome lixivium of tartar drop by drop, waiting a little after each drop, and found the mixture, during the effervescence, full of ſmall cryſtals, which were genuine ſalt of wood-ſorrel.

Acid of phoſphorus and its combinations.

3d 903 Fulminating quickſilver.

M. Klaproth having precipitated a nitrous ſolution of quickſilver with ſalt of wood-ſorrel, perfectly neutralized by vegetable alkali, obtained a white precipitate; which, when edulcorated and dried, and gently heated in a tea-ſpoon, fulminated with a noiſe not inferior to that of fulminating gold. Acid of ſugar perfectly neutralized with vegetable alkali, afforded the ſame precipitate, and fulminated in the ſame manner.

§ 9. *Of the Acid of* PHOSPHORUS.

904 Phoſphoric acid.

THIS acid was firſt diſcovered by Homberg in urine; afterwards by Margraaf in muſtard and cruciferous plants: M. Bochante diſcovered it in wheat; and laſtly, M. Haſſenfratz has traced it in the mineral kingdom with great attention.—He has found that phoſphorated iron is contained in all the Pruſſian blues, when not purified; but that this acid is produced by the coals employed in the proceſs, and is no conſtituent part of the tinging matter. According to him it occurs almoſt univerſally in the minerals of iron which are found in the ſlimy ſtrata of the earth, as well as thoſe which are undoubtedly modern, whether primary or ſecondary; unleſs the iron be ſo far of a metallic nature as to be attracted by the magnet, or very near that ſtate. It is afforded by the ochry ſtrata, and thoſe which contain hæmatites as well as the ſlimy kind. Into theſe it is ſuppoſed to have come by the decompoſition of vegetables; and to inveſtigate this matter he examined the hibiſcus paluſtris, ſolidago, virga aurea, antirrhinum, lunaria, ſolanum nigrum, vulgatum, ſtachys paluſtris, artemiſia Zeylandica, ruta graveolens, lycopus Europeus, carex acuta; vinca major, nepeta Pannonica, and noa Abyſſina. All theſe plants afforded the acid of wood-ſorrel and the phoſphoric acid. The quantity of the former varied from two ounces to two drachms 18 grains of acid ſalt containing ſome calcareous earth, to two drachms 24 grains in a pound of each plant; the quantity of calcareous phoſphoric ſalt being from one ounce ſix drachms 48 grains to one drachm 12 grains.—M. Haſſenfratz alſo obſerves, that the phoſphoric acid is procurable from all ſorts of iron; though in ſome it ſeems to proceed from that contained in the earth, and in others from the coals employed in the reduction.

The phoſphoric acid is alſo found by Dr Marquart to be contained in the gaſtric juice of animals. One pound four ounces of the gaſtric juice of oxen gave 10 grains of a lymphatic matter, exactly like the blood in its qualities; 16 grains and ſix-ſevenths of phoſphoric acid, which with a blow-pipe was changed into a very pure and deliqueſcent glaſs of phoſphorus; five grains of phoſphorated lime, two grains of reſin, 14 grains of ſal ammoniac, 29 grains of common ſalt, a very ſmall quantity of an extract whoſe nature was difficult to aſcertain; one pound three ounces ſix drachms and 67$\frac{1}{7}$ grains of water; ſo that the ſolid contents were only 166th part of the bulk.

In ſheep, the quantity of gaſtric juice was about eight ounces in quantity, of a deeper and brighter green

green than that of oxen or calves; but affording the ſame ingredients, though in a different proportion; though no other acid than that of phoſphorus could be diſcovered. It was alſo more diſpoſed to putrefaction. Calves furniſhed from four to ſix ounces of gaſtric juice, which contained very little lymph, but afforded ſome quantity of dry jelly, though the whole was not equal to the proper proportion of lymph. The phoſphorated lime was in the uſual quantity, but the diſengaged phoſphoric acid in a very ſmall proportion. The lacteal acid was found in great quantity; to which, along with that of phoſphorus, our author ſuppoſes the property of curdling the milk in the animal's ſtomach to be owing.

The phoſphoric acid has alſo been found in very large quantity in the calcareous ſtones of Andaluſia; and Mr Klaproth has found the ſame combined with calcareous earth in a kind of beryl, cryſtallized in hexahedral priſms, called by M. Verner *apatit*.—Formerly the beſt method of obtaining it was from urine, where it is contained in very conſiderable quantity in combination with the volatile alkali, and forming a ſalt called the *microcoſmic*, or *eſſential ſalt of urine*.

905
Microcoſmic ſalt, how procured.

To procure this, a large quantity of urine is to be evaporated to the conſiſtence of a thin ſyrup; which, being ſet in a cold place, will yield, in three or four weeks, foul brown-coloured cryſtals, which are the microcoſmic ſalt, mixed with the marine, and other ſalts of urine. Theſe cryſtals are to be diſſolved in hot water; the ſolution filtered whilſt it continues hot, and ſet to cryſtallize again; and the ſolution, filtration, and cryſtallization, repeated till the ſalt becomes pure and white. In all the cryſtallizations the microcoſmic ſalt ſhoots firſt, and is eaſily diſtinguiſhed and ſeparated from the others. If the urine which remains after the firſt cryſtallization be further evaporated, and again ſet in the cold, it will yield more cryſtals; but browner and more impure than the former; and therefore requiring to be purified by themſelves. From 20 gallons of urine may be obtained four ounces of pure ſalt; a conſiderable part being ſtill left in the reſiduum.

In theſe operations the heat ought to be gentle, and the veſſels either of glaſs or compact ſtone-ware. Urine being evaporated in a copper veſſel, afforded only a green ſolution of that metal.

906
Mr Margraaf's experiments.

Concerning the nature of the microcoſmic ſalt obtained by the above proceſs, Mr Margraaf gives the following account in the Berlin memoirs for 1746.

"Sixteen ounces of the ſalt, diſtilled in a glaſs retort, in a heat gradually raiſed, gave over eight ounces of a volatile urinous ſpirit, reſembling that made from ſal ammoniac by quicklime. The reſiduum was a porous brittle maſs, weighing eight ounces. This, urged with a ſtronger fire in a crucible, bubbled and frothed much, and at length ſunk down into the appearance of glaſs, without ſeeming to ſuffer any further diminution of its weight in the moſt vehement heat.

The vitreous matter diſſolved in twice or thrice its quantity of water, into a clear, tranſparent, acid liquor, ſomewhat thick, not ill reſembling in conſiſtence concentrated oil of vitriol. This liquor totally corroded zinc into a white powder, which, being diluted with water, appeared in great part to diſſolve, fixed alkalies occaſioning a plentiful precipitation. It acted powerfully upon iron, with ſome effervеſcence; and changed the metal into a kind of muddy ſubſtance inclining to bluiſh, in part ſoluble in water like the preceding. It diſſolved likewiſe a portion of regulus of antimony, and extracted a red tincture from cobalt. On lead and tin it had very little action. Copper it corroded but ſlightly. On biſmuth, ſilver, and gold, it had no effect at all, either by ſtrong digeſtion, or a boiling heat. Nor did the adding of a conſiderable portion of nitrous acid enable it to act upon gold.

"The vitreous ſalt in its dry form, melted with metallic bodies with a ſtrong fire, acts upon them more powerfully. In each of the following experiments, two drachms of the ſalt were taken to two ſcruples of the metal reduced to ſmall parts. (1.) Gold communicated a purple colour to the vitreous ſalt; on weighing the metal, however, its diminution was not conſiderable. (2.) Silver loſt four grains, or $\frac{1}{10}$; and rendered the ſalt yellowiſh, and moderately opaque. (3.) Copper loſt only two grains, or $\frac{1}{20}$, though the ſalt was tinged of a deep green colour. It ſeemed as if a portion of the ſalt had been retained by the metal, which, after the fuſion, was found to be whiter and more brittle than before. (4.) During the fuſion with iron, flaſhes like lightning were continually thrown out; a phoſphorus being generated from the combination of the acid with the inflammable principle of the iron. Great part of the mixture riſes up in froth; which, when cold, appears a vitreous ſcoria, covered on the ſurface with a kind of metallic ſkin, which, on being rubbed, changes its green colour to a yellowiſh. The reſt of the iron remains at the bottom of the crucible, half melted, half vitrified, and ſpongy. (5.) Tin loſt 18 grains, or nearly one-half its weight, and rendered the ſalt whitiſh; the remaining metal being at the ſame time remarkably changed. It was all over leafy and brilliant, very brittle, internally like zinc. Laid on burning coals, it firſt began to melt, then burnt like zinc, or phoſphorus. (6.) Lead loſt 16 grains, and gave the ſame whitiſh colour to the ſcoriæ that tin does. The remaining lead was in like manner inflammable, but burnt leſs vehemently than the tin; from which it differed alſo in retaining its malleability. (7.) Mercury precipitated from aquafortis, and well edulcorated, being treated with the ſalt in a glaſs retort, with a fire raiſed to the utmoſt, only 12 grains of mercury ſublimed; 28 remaining united with the acid, in a whitiſh, ſemi-opaque maſs. A ſolution of this mixed in diſtilled water, depoſited a quantity of a yellowiſh powder; which, by diſtillation in a glaſs retort, was in great part revived into a running mercury. A part alſo remained diſſolved in the clear liquor; for a drop let fall on poliſhed copper inſtantly whitened it. (8.) Regulus of antimony melted with the vitreous ſalt, loſt eight or nine grains, (about $\frac{1}{5}$); the regulus aſſumed a fine, brilliant, ſtriated appearance; the ſcoriæ were ſomewhat opaque. (9.) Biſmuth loſt eight grains; the ſcoriæ were like the preceding, but the biſmuth itſelf ſuffered little change. (10.) Zinc, mixed with the ſalt, and diſtilled in a glaſs retort, yielded a true phoſphorus, which aroſe in a very moderate heat. The reſiduum was of a grey colour, a little melted at the

the bottom, in weight not exceeding two drachms; ſo that two ſcruples had ſublimed. This reſiduum, urged further in a ſmall Heſſian crucible to perfect fuſion, emitted an infinity of phoſphorine flaſhes, with a kind of detonation. The matter, grown cold, looked like the ſcoriæ of melted glaſs. (11.) White arſenic, mixed with this ſalt, ſeparated in the fire, greateſt part of it ſubliming, and only as much remaining behind as increaſed the weight of the ſalt eight or nine grains. This compound appeared at firſt tranſparent; but, on being expoſed to the air, became moiſt, and of an opaque whiteneſs, much reſembling cryſtalline arſenic. (12.) Cinnabar totally ſublimed; ſuffering no change itſelf, and occaſioning none in the ſalt. Sulphur did the ſame. (13.) One part of the ſalt, mixed with ten of mangane ſe, and melted in a cloſe veſſel, gave a ſemitranſparent maſs, ſome parts of which were bluiſh. The crucible was lined with a fine purple glazing, and the edges of the maſs itſelf appeared of the ſame colour.

"The vitreous ſalt diſſolved alſo, in fuſion, metallic calces and earths. Chalk, with one-third its weight of the ſalt, formed a ſemitranſparent vitreous maſs: calcined marble, with the ſame proportion, flowed ſo thin as to run all through the crucible; gypſum, likewiſe, ran moſtly through the crucible; what remained was ſemitranſparent. Lapis ſpecularis ran entirely through the veſſel. Spaniſh chalk gave a ſemitranſparent maſs, which ſparkled on breaking; and fine white clay, a ſimilar one. Saxon topaz and flint were changed into beautiful opal-coloured maſſes; the earth of alum into a ſemitranſparent maſs, and quicklime into an opaque white one. The maſs with flints imbibed moiſture from the air; the others not.

"Oil of vitriol, poured upon one-fourth its weight of this ſalt in a retort, raiſed an efferveſcence, acquired a browniſh colour, and afterwards became turbid and white. On raiſing the fire, the oil of vitriol diſtilled, and the matter in the bottom of the retort melted. In the neck was found a little ſublimate, which grew moiſt in the air; as did likewiſe the remaining ſalt, which was opaque and whitiſh. Concentrated ſpirit of nitre, diſtilled with this ſalt in the above proportion, came over unchanged; no ſublimate appeared; the reſiduum looked like glaſs of borax. The diſtilled ſpirit did not act in the leaſt upon gold, even by coction. Strong ſpirit of ſea-ſalt being diſtilled in the ſame manner, no ſenſible change was made either in the ſpirit or the ſalt.

"Equal parts of the vitrified microcoſmic ſalt and ſalt of tartar being urged with the ſtrongeſt fire that a glaſs retort could bear, nothing ſenſible came over, nor did the mixture appear in thin fuſion. Diſſolved in water, filtered, and duly evaporated, it afforded, very difficultly, oblong cryſtals, ſomewhat alkaline; the quantity of alkali having been more than enough to ſaturate the acid. A whitiſh matter remained on the filter, amounting to ſeven or eight grains, from two drachms of the mixture; this, after being waſhed and dried, melted before a blow-pipe, as did likewiſe the cryſtals.

907 Expels the acids of vitriolated tartar, nitre, and ſea-ſalt.

"This ſalt ſeems to extricate, in part, the acids of vitriolated tartar, nitre, and ſea-ſalt. (1.) On diſtilling a mixture of it with an equal quantity of vitriolated tartar, there came over ſome ponderous acid drops, which, ſaturated with fixed alkali, formed a neutral ſalt greatly reſembling the vitriolated tartar. The reſiduum readily diſſolved in water, and difficultly cryſtallized. (2.) Nitre, treated with the ſame proportion of the ſalt, began to emit red vapours. The reſiduum was of a peach-bloſſom colour, appeared to have melted leſs perfectly than the preceding, and diſſolved more difficultly in water. The ſolution depoſited a little earthy matter; and, on being ſlowly evaporated, ſhot into cryſtals, which did not deflagrate in the fire. (3.) Sea-ſalt, diſtilled in the ſame manner, manifeſtly parted with its acid; the reſiduum was whitiſh, readily diſſolved in water, and afforded ſome cubical cryſtals. (4.) Sal ammoniac ſuffered no change. (5.) Borax, with an equal quantity of vitreous ſalt, run all through the crucibles.

"Solutions of this ſalt precipitated the earthy part of lime-water, of ſolution of alum, of flint diſſolved in fixed alkali, and the combination of marine acid with chalk or quicklime. The precipitate from this laſt liquor is tenacious like glue, and does not diſſolve even in boiling water; expoſed to a ſtrong fire, it froths prodigiouſly, and at laſt melts into a thick ſcoria.

"Solutions of this ſalt precipitate alſo ſundry metallic ſolutions; as butter of antimony, ſolutions of ſilver, copper, lead, iron, mercury, and biſmuth, in the nitrous acid; and of tin in aqua-regis. The precipitate of iron from ſpirit of ſalt is a tenacious maſs; that of ſilver from aquafortis, ſometimes a white powder, ſometimes tenacious. Copper from aquafortis is ſometimes thrown down in form of a white powder, and ſometimes in that of a green oil, according to the proportions and diluteneſs of the liquor. Silver is not precipitated at all by this acid from its ſolution in vinegar, nor gold from aqua-regis.

"An ounce of the vitreous ſalt, well mixed with half an ounce of ſoot, and committed to diſtillation, yielded a drachm of fine phoſphorus. The black reſiduum, being elixated with boiling water, and the liquor paſſed through a filter, there remained upon the filter eight ſcruples of a black matter; and, on evaporating and cryſtallizing the liquor, about ſeven drachms were obtained of oblong cryſtals, which did not deliquate in a moiſt air, but became powdery in a warm one. Theſe cryſtals, treated afreſh with inflammable matter, yielded no phoſphorus. Before a blow-pipe they melted into a tranſparent globular maſs, which on cooling, became turbid and opaque. Diſſolved in water, they precipitated ſolutions of ſilver, mercury, copper, and of chalk; though they did not act upon the latter ſo powerfully, nor produce with it a gluey maſs, as before they had been deprived of their phoſphorine acid."

Mr Wiegleb informs us, that the phoſphoric acid exhibits leſs affinity with calcareous earth, in the moiſt way, than the vitriolic; though it cannot be ſeparated from the ultimate reſiduum of the calcareous earth by that acid. It expels, however, all the liquid acids from their baſis in the dry way. It precipitates iron from a ſolution in vitriolic acid, of a perfectly white colour. For the uſes of this acid as a flux, ſee the article *Blow-pipe*.

§ 10. *Of the Acid of* ANTS.

2d 907 How procured.

The acid may be obtained from theſe inſects either by

Acid of phoſphorus and its combinations.

by diſtillation, or ſimple infuſion in water. From twenty-four ounces of ants, Neumann obtained eleven ounces and a half of acid as ſtrong as good vinegar, by diſtillation in balneo mariæ. Of this acid, Mr Margraaf gives the following account in the Berlin Memoirs for 1749.

908 Its properties.

“ The acid of ants efferveſces with alkaline ſalts, both fixed and volatile. With volatile alkalies it forms a neutral liquor, which, like that compoſed of the ſame alkalies and vinegar, yields no concrete ſalt on diſtillation. With fixed alkalies it concretes, upon proper exhalation, into oblong cryſtals, which deliquate in the air. The cryſtals, or the ſaturated neutral liquor uncryſtallized, on being diſtilled with a fire increaſed till the retort began to melt, yielded, a liquor ſcarce ſenſibly acid, and afterwards a ſmall quantity of an urinous and partly ammoniacal liquor. The remaining black matter, diſſolved in diſtilled water, filtered and evaporated, ſhot into large cryſtals which did not deliquate in the air, though they were in taſte ſtrongly alkaline, efferveſced with acids, and had all the other properties by which fixed alkalies are diſtinguiſhed.

“ This acid diſſolves, with great efferveſcence, coral, chalk and quicklime; and concretes with them all into cryſtals which do not deliquate in the air.

“ It does not precipitate ſilver, lead, or mercury, from the nitrous acid; nor quicklime from the marine. Hence it appears to have no analogy to the marine or vitriolic acids; the firſt of which conſtantly precipitates the metallic ſolutions, and the other the earthy.

“ It does not act upon filings of ſilver; but (like vegetable acids), it totally diſſolves, by the aſſiſtance of heat, the calx of ſilver precipitated from aquafortis by ſalt of tartar.

“ It does not diſſolve calces of mercury, (as vegetable acids do); but revives them into running quickſilver.

“ It acts very weakly upon filings of copper; but perfectly diſſolves copper that has been calcined. The ſolution yields beautiful compact green cryſtals.

“ It diſſolves iron-filings with violence; the ſolution duly evaporated, ſhoots into cryſtals more readily than that made in diſtilled vinegar. It ſcarcely acts at all upon filings of tin.

“ It does not, according to Mr Margraaf, corrode filings of lead; but diſſolves, by the aſſiſtance of heat the red calx of lead. The ſolution cryſtallizes into a ſaccharum ſaturni. In Mr Ray's philoſophical letters, it is ſaid, that *lead* put into the acid ſpirit, or fair water, together with the animals themſelves, makes a good *ſaccharum ſaturni;* and that this ſaccharum, on being diſtilled will afford the ſame acid ſpirit again, which the ſaccharum ſaturni made with vinegar will not do, but returns an inflammable oil with water, but nothing that is acid; and ſaccharum ſaturni made with ſpirit of verdegris doth the ſame in this reſpect with the ſpirit of piſmires.

“ It diſſolves zinc with vehemence, and ſhoots, upon due evaporation, into inelegant cryſtals, not at all like thoſe produced with diſtilled vinegar. On biſmuth, or regulus of antimony, it has little effect, either when calcined or in their metalline ſtate.

§ II. *Of the Acid of* Amber.

Acid of amber and its combinations.

The nature of this acid is as yet but little known, and Mr Pott is the only chemiſt who ſeems to have examined it with accuracy. We ſhall therefore give an abſtract of the principal obſervations and experiments he has made on this ſalt.

909 Mr Pott's experiments.

“ Salt of amber requires a large quantity of water for its ſolution. In the firſt cryſtallization (being much impregnated with the oil which riſes from the amber along with it), it ſhoots into ſpongy flakes, in colour reſembling brown ſugar-candy; the cryſtals which ſucceed prove darker and darker coloured. On repeating the depuration, the cryſtals appear at top of a clear yellow or whitiſh colour, in form of long needles or feathers; at bottom, darker, and more irregular, as are likewiſe the cryſtals which ſhoot afterwards. The cryſtals neither liquefy nor become powdry in the air: rubbed, they emit a pungent ſmell like that of radiſhes, eſpecially if warmed a little; their taſte is acid, not in the leaſt corroſive, but with a kind of oily pungency.

“ This ſalt, kept in the heat of boiling water, loſes nothing of its weight, and ſuffers no alteration. In a great heat it melts like oil; after which a little oily acid ariſes, then oily ſtriæ appear in the lower part of the retort, and the ſalt ſublimes into the neck, partly in the form of a dark yellow butter, and partly in that of feathers, a black coaly matter remaining at bottom; ſo that, by this proceſs, a part of the ſalt is deſtroyed.

“ Oil of turpentine has no action on this ſalt. Highly rectified ſpirit of wine gains from it a yellow colour in the cold; and, on the application of heat, diſſolves a conſiderable quantity, but depoſites great part of it on cooling. The ſalt thus depoſited is ſomewhat whiter than before, but ſtill continues ſenſibly yellow. The dulcified ſpirit of ſal ammoniac diſſolves it readily, without efferveſcence, into a yellow liquour; if the ſalt was foul, the ſolution proves of a red colour; on burning of the vinous ſpirit, a neutral liquor remains.

“ A ſolution of ſalt of amber in water, ſaturated with a pure alkaline lixivium, yielded, on inſpiſſation, a ſaline matter, which would not cryſtallize, and which when exſiccated by heat, deliquated in the air, leaving a conſiderable proportion of an earthy, unctuous matter. Being again gently inſpiſſated, it left a browniſh ſalt very ſoluble, weighing one half more than the ſalt of amber employed. This ſalt efferveſced with the vitriolic and nitrous acids: the vapour, which exhaled, was not acid, but oily and ſulphureous. On repeating the experiment, and fully ſaturating the alkali with the ſalt of amber, the neutral ſalt made no efferveſcence with theſe acids. This ſalt did not perfectly melt before a blow-pipe; continued in the fire for ſome time, it efferveſced with aquafortis. In diſtillation it yielded a bitter, oily, alkaleſcent ſpirit, much reſembling the ſpirit of tartar; and towards the end, an empyreumatic oil. The reſiduum elixated, yielded the alkaline ſalt again of a brown colour.

“ Salt of amber efferveſces ſtrongly with volatile alkalies; and, on ſaturation, forms with them an oily am-

ammoniacal liquor, which, in diſtillation, totally ariſes in a fluid form, except that a ſmall portion of a penetrating, oily, ſaline matter, concretes towards the end.

910 Extricates the acids of ſal ammoniac and nitre.

" On diſtilling ſalt of amber with an equal quantity of common ſal ammoniac, a marine acid ſpirit came over, of a ſtrong ſmell, and a brown colour: afterwards, a little white ſal ammoniac ſublimed; at length aroſe ſuddenly a large quantity of a fuliginous or bituminous matter, leaving behind a ſmall portion of a like ſhining black ſubſtance. The coaly matter was conſiderably more in quantity than the ſalt of amber employed. On treating it with nitre, red vapours aroſe, and the mixture detonated with violence. A mixture of it with borax, frothed and ſwelled up much more than borax by itſelf; and, on raiſing the fire, yielded only ſome oily drops; the acid being deſtroyed by this ſalt, as by fixed alkalies and quicklime.

911 Purified by the marine acid.

" Spirit of ſea-ſalt, poured upon one-fourth its weight of ſalt of amber, made ſcarce any ſolution in the cold: on the application of heat, nearly the whole coagulated into the conſiſtence of a jelly. In diſtillation, the ſpirit of ſalt aroſe firſt; then almoſt the whole of the ſalt of amber, partly like firm butter, partly like long ſtriated plumous alum, very pure, and of a fine white colour, its oily matter being changed into a coal at the bottom. The ſalt, thus purified, makes no precipitation in the ſolution of ſilver, and conſequently retains nothing of the marine acid; nor does it precipitate ſolution of quicklime made in ſpirit of ſalt, and conſequently contains nothing vitriolic. If any of the mineral acids was contained in this ſalt, it could not here eſcape diſcovery; the oil, which in the rough ſalt is ſuppoſed to conceal the acid, being in this proceſs ſeparated.

912 Effects of ſpirit of nitre on it.

" Aquafortis being poured upon one-fourth its weight of ſalt of amber, extracted a yellowiſh colour from it in the cold, but diſſolved little: on the application of heat, the whole diſſolves into a clear liquor, without any coagulation: if the ſalt is very oily, the ſolution proves red. In diſtillation, the greateſt part ariſes in a liquid form, with only a very ſmall quantity of concrete ſalt. The ſpirit does not act upon gold, but diſſolves ſilver, and quickſilver, as at firſt; a proof that it has received no marine acid from the ſalt of amber.

913 Of oil of vitriol.

" Oil of vitriol being added to twice its weight of ſalt of amber diluted with a little water, a moderate fire elevated an acidulous, liquor, which appeared to proceed from the ſalt of amber; for its making no change in ſolution of fixed ſal ammoniac, ſhowed it not to be vitriolic. On continuing the diſtillation by a ſtronger fire, greateſt part of the ſalt ariſes undeſtroyed, and the oil of vitriol along with it; a black, light, porous earth remaining.

914 Of quickſilver.

" Equal parts of quicklime and ſalt of amber gave over in diſtillation only an acidulous phlegm; the reſiduum, elixated with water, yielded a ſolution of the lime in the acid of amber, reſembling a ſolution of the ſame earth in vegetable acids, precipitable by alkaline ſalts, and by the vitriolic acid. Lime, added to a watery ſolution of ſalt of amber, diſſolves with ſome efferveſcence; after which, the whole coagulates into the conſiſtence of a jelly: this, diluted with water, proves ſimilar to the foregoing ſolution.

915 Effects of ſalt of amber on the metals.

" Solution of ſalt of amber makes no precipitation in ſolution of ſilver or quickſilver. It diſſolves zinc, as all acids do: fixed alkalies precipitate the zinc: the volatile do not; and when a ſufficient quantity of the volatile has been added, the fixed make no precipitation. It acts exceedingly ſlowly and difficultly upon copper; but corrodes calcined copper in a ſhorter time. It ſoon corrodes iron, by coction, into a crocus, and diſſolves a part into a liquid form: the ſolution has little colour; but alkaine ſalts readily diſcover that it holds iron, by rendering it turbid and whitiſh, and throwing down a conſiderable quantity of a greeniſh calx."

§ 12. *Of the acid of* Arsenic.

916 How firſt diſcovered.

Mr Scheele firſt perceived, from ſome experiments on manganeſe, that arſenic contained phlogiſton: from whence he was led to an analyſis of this ſubſtance, which produced an acid of a very ſingular kind; by uniting of which with phlogiſton in certain proportions, either white arſenic or its regulus may be compoſed at pleaſure.

917 Two ways of decompounding arſenic.

White arſenic may be decompounded in two ways. 1. Put two ounces of it reduced to a fine powder in a glaſs mortar into a retort of the ſame materials; pour upon it ſeven ounces of pure muriatic acid, whoſe ſpecific gravity is to that of water as 10 to 8; and lute on a receiver. The arſenic is quickly diſſolved in a boiling heat, which muſt be brought on as quickly as poſſible.

918 By means of nitrous acid.

After the ſolution is accompliſhed, while the liquor is ſtill warm, three ounces and a half of nitrous acid, of the ſame ſpecific gravity with the muriatic above-mentioned, is to be added, and the liquid which had already gone over into the receiver poured back. The receiver is then to be put on again, but not luted; the mixture ſoon begins to efferveſce, and red vapours go over into the receiver. The diſtillation is to be continued till theſe vapours ceaſe; when an ounce of finely powdered arſenic is again to be added, the receiver applied as before, and a gentle ebullition continued till the ſecond quantity of arſenic be diſſolved. An ounce and an half of nitrous acid is then to be added, and the mixture diſtilled to dryneſs, increaſing the fire towards the end, ſo as to make the retort red hot. The acid which comes over into the receiver may ſerve again ſeveral times. The white maſs which remains in the retort is the dry acid of arſenic. It may be reduced to a liquid form by pouring upon it, in coarſe powder, twice its weight of diſtilled water, and boiling for a few minutes, pouring back the liquor which comes over, and afterwards filtering the ſolution through blotting paper, which has been previouſly waſhed in hot water.

In this proceſs the nitrous acid attacks the phlogiſton of the arſenic, is volatilized in conſequence of its union with it, and leaves the more fixed but leſs powerful acid of arſenic behind. The nitrous acid would alone be ſufficient for this purpoſe, could it accurately come into contact with the particles of arſenic; but this cannot be done withtout ſolution, and the nitrous acid is capable of diſſolving arſenic only in pro-

Acid of arſenic and its combinations.

proportion to the water it contains. Too great a quantity would therefore be required were this acid to be uſed by itſelf; but by the uſe of muriatic acid for the ſolution, a ſmaller quantity of ſpirit of nitre is admitted to intimate contact with all the arſenical particles, and has an opportunity of depriving them of their phlogiſton. Aqua-regia might be poured upon the arſenic at once; but the greateſt efferveſcence it excites would throw the mineral up to the top in ſuch a manner that the menſtruum could not act upon it. By the operation of dephlogiſtication, arſenic loſes a fifth part, which is ſuppoſed to be pure phlogiſton.

919
By dephlogiſticated ſpirit of ſalt.

The other method of decompoſing arſenic is, by means of the dephlogiſticated ſpirit of ſalt. For this purpoſe, take one part of powdered mangancſe, and mix it with three of the muriatic acid above-mentioned. Put it into a retort, of which it may fill one-fourth; a receiver containing one-fourth of powdered arſenic, with one-eighth of diſtilled water, is to be luted on, and the retort put into a ſand-bath. The dephlogiſticated muriatic acid, going over into the receiver, is inſtantly abſorbed by the arſenic; which ſome hours afterwards will be diſſolved, and two different liquid ſtrata, which cannot be mixed together, will be perceived in the receiver. This ſolution is now to be put into a clean glaſs retort, and diſtilled to dryneſs; increaſing the fire at laſt to ſuch a degree as to make the whole red hot: and in this proceſs alſo two different liquids paſs over into the receiver which do not unite together.

Here the mangancſe attracts the phlogiſton of the muriatic acid; and as this dephlogiſticated acid has a very ſtrong attraction for phlogiſton, it deprives the arſenic of its phlogiſton, and thus recompoſes the ordinary phlogiſticated muriatic acid. This portion of recompoſed acid diſſolves part of the arſenic, forming with it what is called *butter of arſenic*. The other part of the arſenic which has been decompoſed, diſſolves in the water, and forms a liquid ſpecifically lighter than the butter, and therefore ſwims above it. On rectifying the two liquids, the undecompoſed portion of the arſenic ariſes along with the muriatic acid, and goes over into the receiver in form of an heavy oil, while the acid of arſenic remains behind in the retort. The acid obtained in this way is preciſely the ſame with the former, and one would hardly believe that it is an acid, becauſe it has no acid taſte; but after ſome days it grows moiſt in the air, and at laſt deliquates, aſſuming the appearance of oil of vitriol. As the deliqueſcence, however, is very ſlow, it is proper to diſſolve it in a certain quantity of water, when a ſmall quantity of white powder remains undiſſolved, after preparing it by the firſt proceſs, which is ſiliceous earth derived from the retort. This ought to be carefully ſeparated from the acid by filtration; and in order to prevent the glue of the blotting-paper from mixing with the acid, it was directed to waſh the filter with hot water previous to the operation.

920
Acid of arſenic equally poiſonous with the white arſenic itſelf.

The firſt experiment M. Scheele tried on this acid after he had obtained it, was to diſcover if it was as noxious to animals as when combined with phlogiſton. Having mixed a little with honey, the flies that eat of it died in an hour; and eight grains reduced a cat to the point of death in two hours. Some milk, however, being then given to the animal, it vomited violently, and ran away.

921
Eaſily reſumes its phlogiſton.

2. An ounce of dry acid of arſenic, heated in a ſmall phial to near the point of ignition, melts into a clear liquid, which congeals when cold; but if the heat be increaſed till the veſſel begins to melt, the acid begins to boil, reſumes its phlogiſton, and arſenic ſublimes in greater quantity as the heat is longer continued. After ſubjecting the acid to this violent heat in a retort for an hour, the veſſel melted, and the acid had riſen up as high as the neck.

3. In a crucible the arſenic attracts phlogiſton in greater quantity, and is entirely diſſipated in arſenical vapours; a little clear and difficultly fuſible glaſs, conſiſting of clay and the acid of arſenic, remaining in the crucible.

922
Takes fire and ſublimes charcoal.

3. With powder of charcoal the arſenical acid undergoes no change; but if the mixture be put into a retort, the moiſture all driven off, a receiver then luted on, and the heat increaſed till the bottom of the retort becomes red hot, the whole maſs takes fire with violence; all the acid is reduced, and ſublimed into the neck of the retort; a ſhining regulus is obtained, mixed with a little arſenic and charcoal duſt. A few drops of water are found in the receiver, but they do not contain a particle of acid.

923
Appearance with oil of turpentine, &c.

4. The arſenical acid, after ſome days digeſtion with oil of turpentine, unctuous oil, and ſugar, becomes black and thick. If ſome muriatic acid be diſtilled from this, a little nitrous acid added, and the diſtillation repeated, ſome acid of arſenic is left behind. Spirit of wine undergoes no change either by digeſtion or diſtillation with arſenical acid.

924
With ſulphur.

5. Six parts of acid digeſted with one of ſulphur ſuffer no change; but when the mixture is evaporated to dryneſs, and then ſubjected to diſtillation in a glaſs retort, the two unite with great violence at that degree of heat in which ſulphur melts; and the whole maſs riſes almoſt in the ſame inſtant, in form of a red ſublimate; a little ſulphureous acid in the mean time going over into the receiver.

925
Combined with vegetable fixed alkali.

6. Acid of arſenic, ſaturated with vegetable fixed alkali, forms a deliqueſcent ſalt which does not cryſtallize, but turns ſyrup of a violet green, though it produces no change on the tincture of lacmus. On the addition of a little more acid, however, when it reddens lacmus, but makes no alteration on the ſyrup of violets, the liquor will afford fine cryſtals like Mr Macquer's neutral ſalt of arſenic. On keeping this ſalt for an hour in fuſion in a crucible covered with another luted upon it, the inſide of the veſſel was found covered with a white glazing, and a ſalt remained, which was ſtill the ſame arſenicated ſalt with exceſs of acid.

926
This ſalt decompoſed by charcoal.

7. On diſtilling this ſalt in a retort with an eighth part of charcoal-duſt, it began to boil very violently as ſoon as the retort became red-hot, and a very fine regulus of arſenic ſublimed. The black reſiduum contained the alkali entirely ſeparated from the arſenical acid.

927
Combined with mineral alkali.

8. With mineral alkali the acid of arſenic forms cryſtals when perfectly neutralized, but not if added to exceſs. In that caſe, the maſs becomes deliqueſcent like the former when neutral.

928
With volatile alkali.

9. With volatile alkali a ſalt much reſembling the

Acid of arſenic and its combinations.

two former is produced. It does not change lacmus, but turns the ſyrup of violets green. A gentle heat drives off part of its volatile alkali, and leaves the remainder ſuperſaturated with acid; in which caſe it ſhoots into long radiated and deliqueſcent cryſtals. Theſe, urged by a ſtronger heat, part with the whole of their alkali, which is partly decompoſed; ſome arſenic is formed by the union of the phlogiſton of the alkali with part of the arſenical acid; the remainder of which aſſumes a milky colour, and lies in the bottom of the retort.

929 Expels the acid of vitriolated tartar by dry diſtillation.

10. Acid of arſenic diſtilled with vitriolated tartar expels the vitriolic acid in a violent heat, which comes over in a concentrated but ſulphureous ſtate, leaving the arſenical ſalt formed of the acid and alkali united. With Glauber's ſalt the vitriolic acid alſo riſes, and with leſs heat than when vitriolated tartar is made uſe of.

930 Acid of nitre;

11. One part of nitre diſtilled with three of acid of arſenic, yielded a ſpirit of nitre, together with the neutral arſenical ſalt already mentioned.

931 Of common ſalt.

12. One part of common ſalt with three of arſenical acid, yielded ſome ſmoking part of ſalt. The reſiduum diſſolved in water gave cryſtals of common ſalt, and a thick magnum, which would not cryſtallize till the ſuperfluous arſenical acid was taken away by adding powdered chalk, when it yielded cryſtals ſimilar to thoſe produced by the acid and pure alkali.

932 Phenomena with ſal ammoniac.

13. With ſal ammoniac the product was firſt fuming muriatic acid, then volatile alkali in a liquid ſtate, after that arſenic, and laſtly part of the arſenical acid remained in the retort.

633 Decompoſes ſpathum ponderoſum and gypſum.

14. Spathum ponderoſum, and gypſum, both parted with their acids, which were become ſulphureous. The former did not yield its acid till the retort began to melt.

634 Cannot expel the fluor acid.

15. One part of fluor mineral was mixed with four of acid of arſenic, and diſtilled into a receiver having a little water in it. When the retort grew red-hot, firſt a yellow and then a red ſubſtance ſublimed. Some ſulphureous acid, but none of the acid of fluor, went over. A grey-coloured reſiduum was left in the retort; which being divided into two parts, one was mixed with charcoal-powder and diſtilled with a ſtrong fire, without the production of either arſenic or regulus; the other was mixed with four parts of acid of arſenic, and ſubjected to a ſecond diſtillation. When the maſs grew dry, a little yellow ſal ammoniac was ſublimed, and the water was covered with a cruſt of ſiliceous earth, as in the uſual diſtillations of that mineral.

635 Precipitates lime water

16. Arſenical acid precipitates lime-water, by uniting with the calcareous earth diſſolved in it. By the addition of more acid, the precipitate is diſſolved, and the liquor yields ſmall cryſtals, which let fall a ſelenite on the addition of vitriolic acid.

636 Phenomena with chalk.

17. On the addition of powdered chalk to arſenical acid diluted with water, the earth is at firſt diſſolved, but by adding more chalk the whole is coagulated into ſmall cryſtals.

937 With magneſia.

18. Magneſia diſſolves in the arſenical acid, and the ſolution coagulates when it comes to the point of ſaturation. On diſſolving the coagulum in a larger quantity of water, it becomes gelatinous by evaporation; and if the jelly be lixiviated with water, filtered, and evaporated, a viſcid maſs remains, which refuſes to cryſtallize.

Acid of arſenic and its combinations.

938 With earth of alum.

19. Earth of alum precipitated by alkali of tartar, is eaſily ſoluble in arſenical acid, and coagulates as ſoon as it arrives at the point of ſaturation. Evaporated to dryneſs, mixed with ſome charcoal powder, and then ſubjected to ſtrong diſtillation, a little yellow ſublimate ariſes into the neck of the retort, as likewiſe ſome ſhining regulus, while a volatile ſulphureous acid paſſes over into the receiver. The reſiduum diſſolves with difficulty in the vitriolic acid, though ſome cryſtals of alum will form in the ſpace of two months.

939 With white clay.

20. Four parts of arſenical acid mixed with one of powdered white clay, did not diſſolve any part by digeſtion for a fortnight. By diſtillation in a retort till the veſſel began to melt, it was converted into a thick flux, and a little arſenic ſublimed. By mixing the reſiduum with a little powdered charcoal, a ſhining regulus was ſublimed.

940 With terra ponderoſa.

21. Terra ponderoſa diſſolves readily in the acid of arſenic, but precipitates again as ſoon as it has attained the point of ſaturation. The ſolution is precipitated by acid of vitriol, and forms regenerated ponderous ſpar.

941 With gold.

22. Gold is not acted upon by acid of arſenic, either by digeſtion or otherwiſe; nor is its ſolution precipitated, though the retorts uſed in the operation were ſtained with red and yellow ſpots, which could not be taken off; nor is its action increaſed by mixture with muriatic or with nitrous acid.

942 Platina.

23. Pure platina is not acted upon. Its ſolution is not precipitated by the pure arſenical acid, but readily by the arſenical ſalts. The precipitate is yellow, and diſſolves in a large quantity of water, but contains no mark of arſenical acid. Addition of muriatic or of nitrous acid makes no change in its effects.

943 Silver.

24. Pure ſilver is not acted upon by the arſenical acid in digeſtion. On augmenting the fire till the acid melted, and keeping up this degree of heat for half an hour, the metal diſſolved, and on breaking the retort, a colourleſs glaſſy maſs, nearly tranſparent, was found in it; the retort being covered with a flame-coloured glazing, which could not be ſeparated from it. By a great degree of heat the ſilver was reduced without addition. Solution of ſilver is precipitated by pure acid of arſenic, but more effectually by the neutral arſenical ſalts: the precipitate is of a brown colour, and by digeſtion in muriatic acid is changed into lunea cornea; it is alſo ſoluble in ſpirit of ſal ammoniac prepared with quicklime. The action of the arſenical acid upon ſilver is conſiderably increaſed by mixing it with ſpirit of ſea-ſalt; the former attacking the phlogiſton of the metal, while the latter attacks its earthy baſis.

944 Quickſilver.

25. Quickſilver is not acted upon by digeſtion with arſenical acid. On putting the mixture into a retort, diſtilling to dryneſs, and then increaſing the fire, the maſs becomes yellow, quickſilver riſes into the neck of the retort, with a little arſenic, and ſome yellow ſublimate; but though the fire was augmented till the retort began to melt, the maſs could not be fuſed. Three drachms and an half of quickſilver were obtained out of ſix employed in the experiment; the arſenical acid, therefore, contained two and an half. The maſs was ſomewhat yellow: it diſſolved very readily in muriatic acid, but ſcarcely at all in the nitrous or vitriolic; on evaporation to dryneſs and diſtillation, ſome corroſive ſublimate

ſublimate roſe into the neck of the retort; the reſiduum, melted in a very ſtrong fire, proved to be acid arſenic. Another portion of the maſs, diſtilled with two parts of common ſalt, yielded corroſive ſublimate.

945
With corroſive ſublimate.

26. Acid of arſenic diſtilled with corroſive ſublimate undergoes no change; but by ſublimation with mercurius dulcis, a corroſive ſublimate is obtained. Some have aſſerted, that by ſubliming arſenic with corroſive ſublimate, a butter of arſenic is obtained; but Mr Scheele informs us that this is a miſtake; and that by diſtilling this mixture, he conſtantly obtained corroſive ſublimate at firſt, and arſenic afterwards. With regulus of arſenic, however, a ſmoking butter of arſenic, mercurius dulcis, and ſome quickſilver, are obtained. The ſame thing happens with a mixture of orpiment and corroſive ſublimate.

946
Butter of arſenic is not obtained by this proceſs.

947
With copper.

27. Arſenical acid diſſolves copper by a digeſting heat. The ſolution is of a green colour: a quantity of light blue powder is depoſited, and attaches itſelf to the copper. This powder conſiſts of the acid of arſenic and calcined copper. On mixing two parts of dry acid of arſenic, in fine powder, with one of filings of copper, and diſtilling the mixture, ſome arſenic roſe into the neck, and the maſs melted and turned blue. On boiling it with water, the ſolution was ſimilar to one made directly from acid of arſenic and copper. A little copper remained in the bottom of the retort, which was tinged with brown, red, and yellow ſpots, inſoluble in any menſtruum. The ſolutions of this metal are not precipitated by arſenical acid, but the acetous ſolution is. Neutral arſenical ſalts throw down a blue precipitate, which by expoſure to a ſtrong fire, turns brown and covers the inſide of the containing veſſel with a yellow enamel. On mixing the ſcoria in a fine powder with a little lampblack, ſome fine regulus of arſenic ſublimed, and the copper in the reſiduum was reduced.

948
With iron.

28. With iron the acid of arſenic forms a gelatinous ſolution, which by expoſure to the air grows ſo thick that in two hours time it will not flow out at the mouth of a phial. With alkali of tartar a whitiſh green powder is thrown down; which being edulcorated and diſtilled in a glaſs retort, yields ſome arſenic, and leaves a red ochre behind. On diſtilling four parts of arſenical acid with one of iron filings, the maſs effervefced ſtrongly towards the end; and when it became dry, took fire in the retort upon increaſing the heat, when both arſenic and regulus of arſenic were ſublimed. The reſiduum was black, friable, and contained but little acid of arſenic; the retort was covered with yellowiſh brown ſpots. Solutions of iron in mineral acids are not precipitated by acid of arſenic, but the acetous ſolution lets fall a dark brown powder. All the ſolutions are precipitated by the arſenical neutral ſalts, the precipitates by a ſtrong fire, converted into black ſcoriæ; which mixed with powdered charcoal, and calcined, yield copious vapours of arſenic, and are afterwards attracted by the magnet.

949
With lead.

29. Lead digeſted with arſenical acid turns black at firſt, but in a few days is ſurrounded with a light greyiſh powder, containing ſome arſenic which may be ſeparated by ſublimation. On diſtilling one part of ſhavings of lead with two of dry acid of arſenic, the lead was diſſolved, the maſs flowed clear, and a little arſenic roſe into the neck of the retort. A milky glaſs was found in the bottom, which by boiling in diſtilled water, let fall a quantity of white powder, the ſuperfluous acid being diſſolved in the water; the edulcorated powder yielded regulus of arſenic by diſtillation with charcoal. Solutions of lead in nitrous and muriatic acids are precipitated by arſenical acid.

950
With tin.

30. Tin digeſted with acid of arſenic becomes firſt black, then is covered with a white powder, and afterwards becomes gelatinous. One part of tin filings diſtilled with two of acid of arſenic, took fire as ſoon as the retort became red-hot, and immediately after both arſenic and a little regulus were ſublimed. The tin was diſſolved into a limpid liquor, which became milky when cold.—By waſhing in water, a quantity of white powder was ſeparated, inſoluble in any acid, and containing very little of that of arſenic.

251
With zinc.

31. Arſenical acid diſſolves zinc with effervefcence. The metal grows black, and the tranſparency of the acid is deſtroyed by a quantity of black powder. This powder edulcorated, dried, and put on an iron plate heated nearly red-hot, emits a blue flame and white arſenical ſmoke in the dark, leaving behind a white powder; thus manifeſting itſelf to be moſtly regulus of arſenic. One part of filings of zinc diſtilled with two of acid of arſenic, took fire in the retort with a very bright flame, and burſt the veſſel with an exploſion. Some regulus of arſenic and flowers of zinc were found in the neck.

952
With biſmuth.

32. Biſmuth digeſted with acid of arſenic is covered with a white powder; water precipitates the ſolution, and the precipitate conſiſts of calcined biſmuth and acid of arſenic. On diſtilling one part of the biſmuth with three of arſenical acid, the maſs melted, the metal was calcined, but remained undiſſolved in the bottom of the veſſel; a little arſenic roſe into the neck; and after the retort became cool, water was poured on the reſiduum, which diſſolved the acid, but the calx of biſmuth remained unchanged. Solution of this ſemimetal in the acid of nitre was precipitated by arſenical acid. This precipitate, as well as the calx, are very difficult of fuſion, but on adding a little powdered charcoal, the mixture inſtantly melts, the arſenic goes off in vapours, and the biſmuth is reduced.

953
Regulus of antimony.

33. With regulus of antimony a quantity of white powder is produced by digeſtion, and the clear ſolution is likewiſe precipitated by dropping it into pure water. This powder is ſoluble only by muriatic acid, and may be precipitated again by the addition of water. One part of regulus of antimony diſtilled with three parts of arſenical acid, took fire as ſoon as the maſs melted, and regulus of arſenic with a red matter were ſublimed; a little volatile ſulphureous acid came over into the receiver. On boiling the reſiduum in water, the acid was diſſolved, a white ſhining powder remained behind, which on being mixed with charcoal powder and diſtilled, an ebullition took place, ſome regulus of arſenic roſe into the neck of the retort, and the antimony was reduced. Butter of antimony was not precipitated by the pure acid, but very readily by the arſenical ſalts. Acetous and tartareous ſolutions of glaſs of antimony are preciptated by arſenical acid

Acid of arſenic and its combinations.

954 With cobalt.

34. Cobalt is partially diſſolved, and the ſolution aſſumes a roſe-colour; on putting the whole maſs into a retort, diſtilling off the liquid, and then augmenting the fire, the maſs melted, and a little arſenic was ſublimed. The reſiduum when cold had a ſemi-tranſparent violet colour. On pouring water upon it, and putting it on hot ſand, the acid was diſſolved, the violet colour diſappeared, and the ſolution aſſumed a dark-red colour. The bottom of the retort had a blue tinge, which could not be taken off. Solutions of cobalt in mineral acids are readily precipitated by the arſenical neutral ſalts. The precipitate is of a roſe-colour, but melts with difficulty into a dark blue ſcoria.

955 With nickel.

35. Nickel, with acid of arſenic, aſſumes a dark green colour, and lets fall a green powder containing arſenic in ſubſtance, which may be ſeparated from it by a gentle heat. One part of nickel diſtilled with two of dry arſenical acid, melted with ſome appearance of inflammation, yielding ſome arſenic at the ſame time. The maſs was yellow, with a number of grey elevated ſtreaks upon it, which appeared like vegetation, and were formed during the diſtillation. On boiling the yellow maſs in water, the acid was diſſolved, leaving a yellow powder behind; which, when treated with charcoal-powder, yielded regulus of arſenic, but was not reduced itſelf. The ſolutions of nickel in acids are not preciptated by arſenical acid, not even that in vinegar, but the neutral arſenical ſalts throw down a whitiſh green powder.

956 With manganeſe.

36. Manganeſe in its natural ſtate is diſſolved only in ſmall part; but when phlogiſticated it diſſolves readily and totally; though, whenever the acid arrives at the point of ſaturation, the ſolution coagulates into ſmall cryſtals.

957 With regulus of arſenic.

37. Regulus of arſenic digeſted with its own acid ſoon becomes covered with a white powder, which is arſenic in ſubſtance. On diſtilling one part of the regulus with two of the acid, the former ſublimed and the latter melted. If ſmall pieces of regulus of arſenic be gradually added to the acid of arſenic in fuſion, an inflammation takes place, and arſenic is ſublimed.

2d 957 Strange phenomenon of arſenic with terra foliata tartari.

On diſtilling a mixture of equal parts of terra foliata tartari and arſenic, a limpid liquor like water firſt came over, ſmelling ſtrongly of garlic; on changing the receiver, a liquor of a browniſh red colour was collected, which filled the receiver with a thick cloud, emitting an intolerable ſmell of arſenic. On pouring this upon a filter, hardly a few drops had paſſed when a very thick ſtinking ſmoke ſuddenly aroſe as high as the cieling of the room; an ebullition enſued towards the edge of the filtering-paper, and a fine roſe-coloured flame broke out, that laſted for ſome moments.

§ 13. *Of the Acid of* MOLYBDÆNA.

958 How to reduce molybdæna to powder.

Acid of molybdæna and its combinations.

959 Effects of the acid of arſenic upon it.

960 Violent action of concentrated nitrous acid upon this ſubſtance.

We owe this, as well as the ſucceeding acids to the induſtry of the late Mr Scheele. The ſubſtance from which he extracted it is named by Cronſtedt *molybdæna membranacea nitens*.—As this ſubſtance is of a flaky nature, and incapable of pulverization by itſelf, our author mixed ſome pieces of vitriolated tartar along with it in a glaſs mortar; by the attrition of which it was at laſt reduced to a fine powder, and which was afterwards freed from the vitriolated tartar by waſhing with hot water. He then treated this powder with all the known acids, but found none of them to have any effect upon it excepting thoſe of arſenic and nitre. No ſenſible effect was perceived from the acid of arſenic until the water was evaporated; after which, by increaſing the fire, a little yellow orpiment was ſublimed in the neck of the retort, and ſome ſulphureous acid paſſed over into the receiver. On pouring two parts of concentrated nitrous acid upon one part of powdered molybdæna, the mixture was ſcarce warm in the retort, when it paſſed altogether into the recipient with great heat, and in the form of dark red vapours. Had the quantity been larger, he had no doubt that it would have taken fire; for which reaſon the experiment was repeated with diluted nitrous acid. Six ounces of diluted nitrous acid being poured on an ounce and a half of powdered molybdæna, no effect was perceptible till the liquor began to boil; after which a great number of red elaſtic vapours began to appear, and the mixture ſwelled conſiderably. The diſtillation being continued to dryneſs, the reſiduum appeared of a grey colour; the ſame quantity of nitrous acid was poured on, and the proceſs repeated, when the reſiduum was whiter; and on ſtill repeating the operation a fourth and fifth time, the remaining powder became at laſt as white as chalk. This reſiduum, after being edulcorated with hot water, was quite taſteleſs and inſipid when dry. The limpid liquor which ran from it being evaporated to half an ounce, firſt aſſumed a fine blue colour, and then grew thick. On being examined, it was found to contain ſome iron, and was otherwiſe chiefly acid of vitriol. The colour diſappeared on diluting the acid with water.

961 Acid of molybdæna obtained by fire alone.

The white powder juſt mentioned is the true acid of molybdæna, and may be obtained by the help of fire alone. A ſmall piece of molybdæna expoſed on a ſilver plate to the blow-pipe, makes a beautiful appearance, when the white vapours attach themſelves to the plate in the form of ſmall ſhining ſcales, in the direction of the flame. This white ſublimate becomes blue whenever it is in contact with the blue flame; but changes to white whenever the point of the flame is directed againſt it. An ounce of powdered molybdæna was mixed with four ounces of purified nitre, and detonated in a crucible heated thoroughly red hot. The maſs thus obtained was of a reddiſh colour. On diſſolving it in water, the ſolution was clear and colourleſs. A ſmall quantity of red powder fell to the bottom of the veſſel; which, when dry, weighed 11 grains, and ſhowed itſelf to be an iron ochre. By evaporation vitriolated tartar and nitre were obtained; but a good deal of lixivium remained, which refuſed to cryſtallize, though no mark of ſuperfluous alkali remained. It was then mixed with ſome water, to which diluted acid of vitriol was added, until no more precipitate fell. The white powder which precipitated weighed three drachms; but if too much acid be added, the precipitate will be rediſſolved, and the water itſelf retains a part of it in ſolution. A precipitate is likewiſe obtained by means of nitrous or muriatic acid.

962 Its chemical properties.

The precipitate thus obtained, like thoſe which reſult from the two former proceſſes, is the true acid of molybdæna, and has the following chemical properties.

1. The ſolution reddens lacmus, coagulates a ſolution of ſoap, and precipitates hepar ſulphuris. 2. If this ſolution be boiled with the filings of any of the imperfect metals, it aſſumes a bluiſh colour. 3. By the addition of a little alkali of tartar, the earth becomes ſoluble in greater quantity in water; and after evaporation ſhoots into ſmall confuſed cryſtals. 4. Under the blow-pipe this earth is ſoon abſorbed by charcoal; but when placed on a ſilver plate it melts, and evaporates with the ſame phenomena as molybdæna itſelf. 5. By the addition of alkali, the earth is deprived of its property of being volatilized in the fire. 6. The ſolution, whilſt hot, ſhows its acid power more evidently than when cold, and tinges lacmus of a deeper colour. It effervesces with chalk, with magneſia, and with earth of alum; with all of which it forms ſalts very difficult of ſolution in water. 7. It precipitates, from the nitrous acid, ſilver, quickſilver, and lead, as alſo lead diſſolved in marine acid. Theſe precipitates are reduced on burning charcoal, and the melted metal runs into the pores. Corroſive ſublimate is not precipitated; neither are the ſolutions of the other metals. 8. Terra ponderoſa is alſo precipitated from the nitrous and marine acids; and the precipitate is ſoluble in a large quantity of cold water. None of the ſolutions of the other earths are precipitated. 9. Fixed air is alſo expelled by this acid from the fixed and volatile alkalies, and forms with them neutral ſalts which precipitate all other metallic ſolutions. Gold, corroſive ſublimate, zinc, and manganeſe, are precipitated in form of a white powder; iron and tin, from their ſolution in marine acid, of a brown colour; cobalt of a roſe colour; copper of a blue; the ſolutions of alum and quicklime, white; and if the ammoniacal ſalt formed by the earth of molybdæna and volatile alkali be diſtilled, the earth parts with its alkali in a gentle heat, and remains in the retort in form of a grey powder. 10. Concentrated vitriolic acid diſſolves a great quantity of this earth by means of heat. The ſolution acquires a fine blue colour; which, however, diſappears on being heated, or by diluting the acid with water. In a ſtronger heat the acid flies off, leaving the earth unaltered behind. This ſolution becomes thick on cooling. 11. The nitrous acid has no effect upon the earth of molybdæna. 12. Boiled with the muriatic acid it diſſolves in conſiderable quantity; and, on diſtilling the mixture to dryneſs, a dark-blue reſiduum remains. On increaſing the heat, white flowers ariſe, with a little blue ſublimate, and a ſmoking muriatic acid is found in the receiver. The reſiduum is of a grey colour. Theſe flowers are only the earth of molybdæna volatilized by means of the muriatic acid, and therefore manifeſts the ſame properties. 13. If one part of this earth be diſtilled with two parts of vitriolated tartar, a little vitriolic acid paſſes over, at leaſt when the heat is very ſtrong; and the remaining earth is more ſoluble in water than before. 14. With two parts of nitre it expels, by means of diſtillation, a ſtrong nitrous acid; the reſiduum diſſolved in water is a neutral ſalt which precipitates all metallic ſolutions, and is ſimilar to that formed by a direct union of the acid and fixed alkali. 15. Diſtilled with two parts of pure common ſalt, the acid is expelled in a ſmoking ſtate, and white, yellow, and violet-coloured flowers ariſe, which become moiſt in the air, and when ſprinkled on metals give them a blue colour. Theſe flowers, as has been already remarked, are only the acid of molybdæna volatilized by that of ſea-ſalt.

963 Is capable of uniting with phlogiſton.

The blue colour acquired by this earth on the contact of flame, alſo in the moiſt way in ſome caſes, ſhows that it is capable of contracting an union with the phlogiſton. To reduce this to certainty, Mr Scheele diſſolved ſome of the earth of molybdæna in boiling water, with the addition of a little alkali. Into this ſolution he poured ſome drops of muriatic acid, and divided it into ſeveral parts, into each of which he put filings of ſeveral metals. The ſolutions ſoon acquired a bluiſh colour, which grew deeper and deeper; and in an hour's time, during which the bottle was now and then ſhaken, the liquor aſſumed a fine dark blue. That this colour depends on phlogiſton, he infers from the following circumſtances: 1. If, inſtead of the metals themſelves, you take their calces, no blue colour is produced. 2. If there be dropped into the blue ſolution a few drops of acid of nitre, and the ſolution be then put into a warm place, the colour diſappears. It is therefore no matter of ſurpriſe, that both ſilver and quickſilver ſhould be attacked, ſince a double elective attraction takes place; the muriatic acid uniting with the metallic calx, and the earth of molybdæna with the phlogiſton of the metals. Gold, however, is not attacked in this way. 3. Too great a quantity of muriatic acid produces not a blue but a yellowiſh colour, which at laſt turns brown if the mixture be digeſted; but on adding this ſolution to a ſolution of the earth of molybdæna, a blue colour as uſual is produced. 4. Lixivium ſanguinis, in which the acid prevails, throws down the earth of a brown colour, and the infuſion of galls of a dark brown.

964 Shows no ſign of containing any metal.

The acid of molybdæna, treated with various fluxes, and with charcoal, ſhows no ſigns of containing any metallic matter. Moiſtened with oil-olive, and committed to diſtillation in a ſtrong fire, it did not ſublime, but remained in the retort in the form of a black powder; which, on being calcined in a crucible, ſublimed in white flowers as uſual. On inverting another crucible into the former, and luting the juncture, the earth remained unchanged and of a black colour, without any ſign of fuſion. This black powder did not diſſolve in boiling water, nor even with alkali, which on other occaſions ſo readily diſſolves it; but when mixed with a triple quantity of ſalt of tartar, a great effervescence enſued; the produce was a neutral ſalt reſembling that formed by the direct union of the acid and alkali.

965 Properties of the acid obtained by nitre.

The earth of molybdæna, procured by nitre, requires much leſs water for its ſolution; it does not expel the acid from vitriolated tartar; is more eaſily fuſed, and does not ſublime in an open crucible. When fuſed with charcoal-powder, it affords a ſolution with water, containing a neutral ſalt, which precipitates all others. The reaſon of theſe differences is, that it contains a portion of alkali, though it be ever ſo frequently purified by ſolution and cryſtallization. That this is the caſe we know from the following experiments: 1. If to a ſolution of the nitrous earth of molybdæna we add ſome nitrous acid, the latter attacks the alkali, and the greateſt part of the diſſolved earth is precipitated. This, however, does not happen, except by long boiling. 2. The neutral ſalt obtained by fuſion proves the ſame. This neutral ſalt is produced in the following manner. The earth which contains

tains only a ſmall quantity of alkali operates as an acid, as appears from its changing the colour of lacmus to red; but the alkali prevents as much earth from entering into it as is neceſſary to its ſaturation with phlogiſton; for the acid of molybdæna has a greater attraction for alkali than for phlogiſton. The charcoal which remains after lixiviating the compound of acid of molybdæna and charcoal, yields vapours in an open crucible, and gives a ſublimate containing the phlogiſticated earth of manganeſe. This alkali fixes the earth in the open air; and hence we ſee alſo the reaſon why this earth does not expel the acid from vitriolated tartar; for its attraction for the alkali muſt diminiſh in proportion as it comes nearer the point of ſaturation; and as the pure earth contains no alkali, it attracts a little from the vitriolated tartar; and conſequently there can appear but a ſlight veſtige of vitriolic acid. This ſmall quantity of acid likewiſe occaſions its more eaſy ſolubility in water.

966 Molybdæna recompoſed by uniting its acid with ſulphur.

The pure acid of molybdæna recompoſes that ſubſtance by being combined with ſulphur. Mr Scheele having mixed ſome very fine powder of this earth with three parts of ſulphur, and committed the mixture to diſtillation in a glaſs retort, the receiver was filled with the ſuperfluous ſulphureous vapours, which had alſo the fetid ſmell of volatile ſpirit of ſulphur. In the retort a black powder remained, which on every chemical trial was found to be a true molybdæna; ſo that there is now no doubt of this ſubſtance being compoſed of a particular kind of acid united to ſulphur.

§ 14. *Of the Acid of* Lapis Ponderosus, Tungsten, *or* Wolfram.

967 This ſubſtance conſidered as a metallic earth by Mr Bergman.

This ſubſtance has been analyſed both by Mr Scheele and Mr Bergman, though the former has the merit of diſcovering the acid contained in it; which the latter conſiders, as well as the earth of molybdæna, not as truly acid, but as metallic earths. Mr Scheele's experiments for analyſing this ſubſtance were as follow:

968 Scheele's method of analyſing it.

1. On one part of finely powdered tungſten were poured two parts of concentrated acid of vitriol. By diſtillation the acid paſſed over unchanged; the reſiduum, which was of a bluiſh colour, after being boiled for a ſhort time, and the liquor filtered off, depoſited ſome vitriolated lime or gypſum by ſtanding. 2. Twelve ſcruples of common nitrous acid, or pure aquafortis, being poured on two of finely powdered tungſten, no efferveſcence enſued; but on expoſing the mixture to a ſtrong digeſting heat, it aſſumed a citron yellow colour. The acid was then poured off into another phial, and the yellow powder edulcorated with water. 3. On this yellow powder eight ſcruples of cauſtic volatile alkali were poured, and the phial expoſed to heat; on which the yellow colour inſtantly vaniſhed, and the powder became white. This ſolution was in like manner put into a ſeparate phial, and the powder edulcorated; and as the matter was ſenſibly diminiſhed by theſe operations, they were alternately repeated, till at length the whole was diſſolved, excepting three grains, which ſeemed to be ſiliceous earth. The ſame effects enſued on treating this ſubſtance with muriatic acid, only the ſolution was of a deeper yellow colour. 4. The ſolutions made in the foregoing manner with nitrous acid being all mixed together, ſome drops of phlogiſticated alkali were added; by which about three grains of Pruſſian blue were precipitated. 5. The mixture was then ſaturated with cauſtic volatile alkali; but as no precipitate appeared, a ſolution of fixed alkali was added, which threw down two ſcruples and five grains of white earth of a mild calcareous kind. On adding ſome nitrous acid to the extracts made by volatile alkali, a white powder was precipitated, which, on edulcoration, proved to be the true acid of tungſten.

969 Effects of heat upon it.

On treating tungſten with a ſtrong heat in the dry way, the following appearances took place: 1. One part of tungſten mixed with four of alkali of tartar was melted in an iron crucible, and then poured out on an iron plate. Twelve times its weight of boiling water being then poured upon it, a white powder ſubſided to the bottom, which diſſolved in a great meaſure in nitrous acid. 2. The undiſſolved part of the powder was tried; and being again mixed with four parts of alkali, was melted as before: and the maſs being alſo diſſolved in water, and nitrous acid poured on the reſiduum, only a very ſmall portion of grey powder was left undiſſolved. 3. The ley being ſaturated with nitrous acid, grew thick by the precipitation of a white powder; which was afterwards waſhed with cold water and dried, and then proved to be the ſame acid of tungſten with that already deſcribed. The ſolution in nitrous acid precipitated with fixed alkali gave a white precipitate, which was found to be calcareous earth.

970 Its chemical properties.

The properties of the acid of tungſten are, 1. Under the blow-pipe it became firſt of a reddiſh yellow colour, then brown, and at laſt black. It neither ſmoked nor gave any ſigns of fuſion. 2. With borax it produced a blue, and with microcoſmic ſalt, a ſea-green glaſs. 3. Boiled with a ſmall portion of the nitrous or marine acids, the powder becomes yellow, and with the acid of vitriol bluiſh. 4. On ſaturating a ſolution of the acid with fixed alkali, a neutral ſalt in very ſmall cryſtals is obtained. 5. With volatile alkali this acid forms an ammoniacal ſalt, ſhaped like the points of ſmall pins. On diſtillation the alkali ſeparates in a cauſtic ſtate, the acid remaining behind in the retort in form of a dry yellow powder. On mixture with a ſolution of lime in ſpirit of nitre, a double elective attraction takes place, the acid of tungſten uniting itſelf with the lime, and that of nitre with the volatile alkali. 6. With magneſia the acid of tungſten forms a ſalt very difficult of ſolution. 7. It produces no change on ſolutions of alum or lime, but decompoſes a ſolution of terra ponderoſa in acetous acid, and the compound is totally inſoluble in water. 8. It precipitates of a white colour ſolutions of iron, zinc, and copper, in the vitriolic acid; ſilver, quickſilver, and lead, in that of nitre; and lead in the acid of ſea-ſalt. Tin combined with the ſame acid is thrown down of a blue colour; but corroſive ſublimate and ſolutions of gold undergo no change. 9. On calcining the acid of tungſten in a crucible, it loſes its ſolubility in water. 10. It turns black by calcination with inflammable matters and with ſulphur, but in other reſpects continues unaltered. 11. Solution of hepar ſulphuris is precipitated of a green colour by this acid, and the phlogiſticated alkali white; the latter precipitate being ſoluble in water. On the addition of a few drops of muriatic acid to a ſolution of the

Acid of lapis ponderoſus and its combinations.

971 Differences betwixt the acid of tungſten and molybdæna.

acid of tungſten in water, and ſpreading the liquor on poliſhed iron, zinc, or even tin, it acquires a beautiful blue colour; and the ſame thing happens when theſe metals are put into the acid. 12. It differs from the acid of molybdæna in not being volatile in the fire; in having little attraction for phlogiſton or ſulphur; in turning lime yellow, and forming an inſoluble compound with it as well as with ponderous earth. It has alſo a ſtronger attraction for lime than the acid of molybdæna; for if a combination of lime and acid of molybdæna be digeſted in a ſolution of the ammoniacal ſalt formed by uniting the acid of tungſten with volatile alkali, the latter expels the former, and produces regenerated tungſten. 13. By uniting the acid of tungſten to a calcareous earth, a regenerated tungſten is conſtantly procured.

972 Bergman's opinion concerning the acids of tungſten and molybdæna.

Mr Bergman obſerves, that the acid earth of tungſten is nearly allied to that of molybdæna; and both are in a ſtate much reſembling that of white arſenic. "It is well known (ſays he) that arſenic, in its ſemimetallic ſtate, is nothing but a peculiar acid ſaturated with phlogiſton; and that the white calx is an intermediate ſtate between acid and metal, containing juſt phlogiſton enough to coagulate the acid, but remaining ſtill ſoluble in water, and ſhowing ſigns of acidity. If a concluſion from analogy be admiſſible, all the other metals ſhould conſiſt in a combination of the ſame nature of the different radical acids, which with a certain quantity of phlogiſton are coagulated to a dry earthy ſubſtance; and on full ſaturation are reduced to the ſtate of complete metals."

973 Why he ſuppoſed the acids to be metallic earths.

The reaſons which induced Mr Bergman to ſuppoſe that the acids in queſtion are metallic earths, are as follow: 1. They both ſhow a ſtriking reſemblance to white arſenic in form, in producing effects like acids, and in their difficult ſolubility in water. 2. Their ſpecific gravity; that of arſenic being 3750, the earth of molybdæna 3460, and the acid of tungſten 3000. 3. Their precipitation with phlogiſticated alkali; a property hitherto deemed peculiar to metallic calces. Arſenic alſo, properly diſſolved in muriatic acid, gives, with the phlogiſticated alkali, a precipitate ſoluble in water, in the ſame manner as the acid of tungſten. 4. From their property of tinging vitreous matters; which, as well as that of precipitating with the phlogiſticated alkali, is reckoned to be a peculiar property of metals. The acid of tungſten produces by itſelf ſome efferveſcence with mineral alkali. With microcoſmic ſalt it produces a globule at firſt of a light blue; more of the acid makes it a dark blue; but ſtill it remains free from redneſs by refraction. A further addition makes it brown. Borax requires a ſlight tinge of blue, and with more of the acid becomes of a yellowiſh brown colour; but remains tranſparent, provided no further addition be made. This ultimate brown colour cannot be driven off either by nitre or the point of the flame urged by a blow-pipe. Acid of molybdæna is no leſs powerful; for with microcoſmic ſalt it produces a beautiful green colour: borax well ſaturated with it appears grey when viewed by the reflected rays, but of a dark violet by the refracted.

§ 15. *Of the Acid of* MILK.

Acid of milk and its combinations.

974 Milk moſt ſtrongly acid after ſtanding a fortnight.

975 Component principles of ſour whey.

It is univerſally known, that in the ſummer-time milk grows ſour and thick in a few days, and that this ſourneſs continues for ſome time to increaſe. It is ſtrongeſt after a fortnight has elapſed; after which, if the whey be filtered and evaporated to one-half the quantity, a few curds will ſtill ſettle to the bottom. By ſaturating the whey with volatile alkali, a ſmall quantity of animal earth precipitates; and the ſame thing takes place on the addition of lime-water. On the addition of a ſmall quantity of acid of tartar, the latter ſoon becomes partially ſaturated with vegetable alkali, and is converted into tartar. Thus the acid of milk beſides its proper acid part, contains animal earth and vegetable alkali in a looſe ſtate, and which is attracted by the acid of tartar; beſides all theſe it has alſo a ſmall quantity of the ſame alkali ſaturated with muriatic acid. It is no eaſy matter to ſeparate theſe ſubſtances from one another; becauſe the acid is not ſufficiently volatile to riſe in diſtillation by a gentle heat, nor are its principles ſufficiently fixed to bear the action of a ſtrong fire. With the one therefore it remains almoſt entirely in the retort, and with the other it is deſtroyed. Mr Scheele therefore uſed the following proceſs.

976 Scheele's method of procuring the pure acid of milk.

He evaporated ſour whey till only one-eighth part remained; when the cheeſy part being totally ſeparated, he ſtrained the acid; and in order to obtain the animal earth, ſaturated the liquor with lime, diluting the ſolution with a triple quantity of water. In order to ſeparate the lime, he employed the acid of ſugar, which has a ſtronger attraction than any other for lime. This earth therefore being ſeparated, the matter was evaporated to the conſiſtence of honey, and highly rectified ſpirit of wine poured upon it to diſſolve the acid part; which being accompliſhed, the other ſaline ſubſtances were left by themſelves: and, laſtly, the acid ſolution being diluted with pure water, and the ſpirit ſeparated by diſtillation, the pure acid remained in the retort.

977 Properties of this acid.

The properties of the acid of milk are, 1. Evaporated to the conſiſtence of a ſyrup, it yields no cryſtals; and when evaporated to dryneſs, it deliqueſces. 2. By diſtillation it yields firſt water, then a weak acid like ſpirit of tartar; afterwards ſome empyreumatic oil, with more of the ſame acid, fixed air, and inflammable air; in the retort was left a fixed coal. 3. By ſaturation with fixed vegetable alkali it yields a deliqueſcent ſalt, ſoluble in ſpirit of wine. 4. A ſalt of a ſimilar kind is obtained by combining it with mineral alkali. 5. With volatile alkali a deliqueſcent ſalt is produced, which by diſtillation yields a great deal of its alkali before the acid is deſtroyed by heat. 6. It forms deliqueſcent ſalts with terra ponderoſa, lime, and clay; but with magneſia it forms ſmall cryſtals, which, however, are again deliqueſcent. 7. It has no effect either by digeſtion or boiling on biſmuth, cobalt, regulus of antimony, tin, quickſilver, or gold. However, after digeſtion with tin, it precipitated gold from its ſolution in aqua-regia, in the form of a black powder. 8. It diſſolves iron and zinc, producing inflammable air during the ſolution. The liquor produced by the diſſolution of iron was brown, and yielded no cryſtals; but the ſolution of zinc cryſtallizes. 9. Copper diſſolved in this acid communicates to the liquor firſt a blue, then a green, and then a dark blue colour, without cryſtallizing. 10. Lead was diſſolved after

ſome

Acid of milk and its combinations.

ſome days digeſtion; the ſolution had a ſweet aſtringent taſte, and would not cryſtallize. A ſmall quantity of white matter fell to the bottom, which on examination was found to be vitriol of lead.

978 It ſeems to be of the acetous kind.

“ From theſe experiments (ſays Mr Scheele) it appears, that the acid of milk is of a peculiar kind; and though it expels the vinegar from the acetated vegetable alkali, yet it ſeems deſtined, if I may ſo ſpeak, to be vinegar; but from the want of ſuch ſubſtances as, during fermentation, produce ſome ſpirituous matter, it ſeems not to be volatilized, though a portion of it indeed arrives at this point, and really becomes vinegar: for without a previous ſpiritous fermentation, or without brandy, there never ariſes any vinegar.

979 Milk capable of complete fermentation.

But that the milk enters into a complete fermentation though there be no ſign of brandy preſent, appears from the following experiment: If a bottle full of freſh milk be inverted into a veſſel containing ſo much of the ſame liquor that the mouth of the bottle reaches below the ſurface of the latter, and if you expoſe this bottle to a degree of heat a little greater than our ſummer, you will find, in the ſpace of 24 hours, that the milk is not only coagulated, but in part expelled out of the bottle; and that in a couple of days afterwards, the aerial acid extricated from the milk will have expelled the greater part of it. It was ſaid above, that the acid of milk cannot be converted into vinegar, from the want of ſuch ſubſtances as during fermentation produce brandy;

2d 979 Converted into vinegar.

which appears to be evident from this: If to a kanne of milk you add five ſpoonfuls of good brandy, and expoſe the veſſel, well corked, in ſuch a manner, however, that you now and then give vent to the air developed during fermentation, you will find in a month, ſooner or latter, that the whey will be changed into good vinegar, which, ſtrained through a cloth, may be kept in bottles.”

980 Acid of ſugar of milk how procured.

The acid of ſugar of milk is conſiderably different from that juſt now deſcribed. To procure it, Mr Scheele poured 12 ounces of diluted nitrous acid on four ounces of finely powdered ſugar of milk contained in a glaſs retort, to which a receiver was adapted. The retort was placed in a ſand-bath, and as ſoon as the mixture acquired a certain degree of heat, it began to efferveſce violently; for which reaſon, the retort and receiver were taken away from the fire. The mixture, however, continued to grow hotter and hotter, with a great emiſſion of dark red vapours continually increaſing, for half an hour. A conſiderable quantity of nitrous air and aerial acid were extricated during that time. Care muſt be taken, therefore, to have the retort and receiver both of a ſufficient ſize, and not to make the luting too tight. When the efferveſcence had ſubſided, the retort was again placed in the ſand-bath, and the nitrous acid thus diſtilled off till the maſs acquired a yellowiſh colour; on which the retort was immediately taken away from the fire. In two days time the ſolution ſeemed to have undergone no remarkable change, nor was there any appearance of cryſtals. Eight ounces more of the ſame nitrous acid were therefore added, and the whole expoſed to the ſame degree of heat as before. When the maſs grew warm, another efferveſcence, though weaker than the former, enſued; the yellow colour diſappeared, and the nitrous acid was again abſtracted, till the ſolution, which had been rendered opaque by the appearance of a white powder in it, aſſumed a yellowiſh colour, on which the retort was again removed from the ſand. After it was grown cool, the maſs in the retort was found to be inſpiſſated; it was rediſſolved in eight ounces of water, and filtered. Seven and a half drachms of white powder remained on the filter; the ſolution which paſſed through the filter was very acid. It was evaporated to the conſiſtence of a ſyrup, four ounces more nitrous acid poured upon it, and the evaporation repeated in a ſand-heat. After the whole was cool, ſome ſmall long acid cryſtals were found, together with a ſmall quantity of white powder which was ſeparated from it, and ſome more nitrous acid poured on the remaining maſs, and on evaporation, more ſuch cryſtals made their appearance. The ſame proceſs was repeated ſeveral times; by which means the whole maſs was at laſt changed into ſuch cryſtals, and weighed about five drachms, ſhowing in every reſpect the ſame phenomena produced by acid of ſugar. The white powder, weighing ſeven and a half drachms, was the true acid of ſugar of milk; and its properties are,

981 Properties of this acid.

1. It burns in a red hot-crucible like oil, without leaving behind it any mark or aſhes. 2. It diſſolves in boiling water in the proportion of one of ſalt to 60 of the liquid. 3. One fourth part of the diſſolved powder ſeparates from the liquid on cooling, in form of very ſmall cryſtals. 4. Half an ounce of the ſalt was diſſolved in a glaſs veſſel in 30 ounces of boiling water, and the ſolution filtered when cold. It had a ſouriſh taſte, reddened the tincture of lacmus, and efferveſced with chalk. 5. Two drachms of the ſalt expoſed to an open fire in a glaſs retort, melted, grew black, and frothed very much; a brown ſalt was found ſublimed into the neck of the retort, which ſmelled like a mixture of ſalt of benzoin and ſalt of amber, eleven grains of coal remaining in the retort. The receiver contained a brown liquid without any mark of oil, ſmelling like the ſublimed ſalt. It contained alſo ſome of the ſalt diſſolved, which was ſeparated from it by a gentle evaporation. The ſublimed ſalt weighed 35 grains, had a ſour taſte, and was eaſily ſoluble in ſpirit of wine, but with more difficulty in water, and burned in the fire with a flame. 6. Concentrated vitriolic acid, diſtilled with this ſalt, became very black, frothed much, and decompoſed the ſalt entirely. 7. Acid of ſugar of milk, gradually added to a hot ſolution of alkali, occaſioned an efferveſcence and coagulation in conſequence of the formation of a vaſt number of cryſtals, which require eight times their weight of water to diſſolve them, and ſeparate again in a great meaſure from the liquid on cooling. The ſame phenomena took place with the mineral alkali, only the ſalt was ſomewhat more ſoluble, requiring only five times its weight of water for ſolution. If to a ſolution of it a ſolution of alkali of tartar be added, a number of ſmall cryſtals will ſoon be formed at the bottom of the veſſel, on account of the greater attraction of this acid with the vegetable alkali. 8. With volatile alkali it forms a kind of ſal ammoniac, which, after being gently dried, has a ſouriſh taſte. By diſtillation, the volatile alkali is firſt ſeparated, the lime-water precipitates, and the reſiduum yields the ſame products by diſtillation as the pure acid. 9. With all the earths, acid of ſugar of milk forms inſoluble ſalts.

Lithiſiac acid and its combinations.

ſalts. If a ſolution of ponderous earth in muriatic or nitrous acid be dropped into a ſolution of acid of ſugar of milk, the former is inſtantly decompoſed, and the earth falls to the bottom in combination with the acid of ſaccharum lactis. The ſame phenomena take place with ſolutions of lime in the nitrous and marine acids; but ſolution of gypſum is not decompoſed. The ſame alſo takes place with ſolutions of magneſia in vegetable or mineral acids, and with earth of alum; all of which are decompoſed by the neutral ſalts abovementioned. 10. The ſolution of this acid, by reaſon of the ſmall quantity diſſolvable in water, has no ſenſible effects on metals in their perfect ſtate; but when they are reduced to calces, it then acts upon them, and forms ſalts, very little or not at all ſoluble in water. Silver, mercury, and lead are precipitated in form of a white powder; blue, green, and white vitriol, as well as manganeſe combined with acid of vitriol, are not precipitated; but all metallic ſolutions are precipitated by the neutral ſalts.

§ 16. *Of the* LITHISIAC *Acid, or Acid of the human Calculus.*

982 Calculi all of the ſame nature.

THE calculi examined by Mr Scheele, with a view to diſcover their conſtituent parts, were, as he informs us, all of the ſame nature, whether flat and poliſhed, or rough and angular. A ſmall quantity of calculus in powder was put into a retort, and ſome diluted vitriolic acid, poured upon it. The powder was not affected by a digeſting heat; however, it was diſſolved when the humidity was abſtracted by diſtillation. After the diſſipation of the acid, a black coal was left in the retort, and the vitriolic acid which had paſſed into the receiver was become ſulphureous. The marine acid, whether diluted or concentrated, had no effect upon the calculus, not even when boiled with it. The nitrous acid diluted, or aquafortis, had ſome effect on the calculus, even when cold. On the application of heat, an efferveſcence enſued with red vapours, and the calculus was diſſolved. Repeating the experiment in a retort with lime-water, the latter was precipitated. The ſolution of calculus is acid, though the menſtruum be boiled with a ſuperabundant quantity of powder, ſo that there may remain a portion of it undiſſolved.

983 Properties of the acid of calculus.

It produces deep red ſpots on the ſkin in half an hour after it is applied; and if the ſaturated ſolution be a little more evaporated, it aſſumes of itſelf a blood-red colour, which however, diſappears on dropping in a ſingle drop of nitrous acid. Terra ponderoſa is not precipitated by it from the muriatic acid; nor are metallic ſolutions ſenſibly changed. With alkalies it becomes ſomewhat more yellow when the alkali is ſuperabundant. The mixture, in a ſtrong digeſting heat aſſumes a roſe colour, and ſtains the ſkin in the ſame manner, without any ſenſation of burning. The mixture likewiſe precipitates metals of different colours; vitriol of iron, black; of copper, green; ſolution of ſilver, grey; corroſive ſublimate, zinc, and lead, of a white colour. Lime water precipitates a white powder ſoluble in muriatic and nitrous acids without efferveſcence; and though there be an exceſs of precipitated powder, the ſolution will be acid. This white powder, therefore, is the acid of the calculus itſelf, the exiſtence of which is alſo confirmed by Mr Bergman's experiments. The further analyſis of this is related under the article CALCULUS, below.

Flowers of benzoin, &c.

§ 17. *Of the* FLOWERS *of* BENZOIN, ACID *of* LEMONS, *with other anamolous vegetable acids, and the reſemblance which the vegetable acids in general bear to one another.*

984 Flowers of benzoin obtained by ſublimation.

IT has long been known, that the reſinous ſubſtance, improperly called gum benzoin, yields by ſublimation with a gentle heat a quantity of fine ſaline matter of a moſt agreeable odour, and ſlightly acid taſte, called *flowers* of *benzoin*.

985 By lixiviation.

Another method of obtaining this ſubſtance is by lixiviating the gum with water, and cryſtallizing the ſalt.

986 Quantities obtained by both methods.

Mr Scheele, determined to try what quantity of the flowers could be obtained from the reſin, found that, by ſublimation, he was able to obtain from one pound of benzoin between nine and twelve drachms of flowers. By lixivation the quantity obtained was conſiderably leſs than the former, owing to the ſaline particles being ſo much covered by the reſin, that the water could not have ſufficient acceſs to diſſolve them all.

987 Attempts to procure all the flowers the reſin is capable of yielding.

It was next attempted to procure all the flowers which the benzoin was capable of yielding.

988 Boiling with chalk inſufficient;

This was firſt done by boiling pounded chalk and benzoin in water, and then filtering the decoction; but no cryſtals appeared. On pouring ſome drops of vitriolic acid into the liquor, the ſalt of benzoin ſoon afterwards precipitated (for this ſalt, which is an acid, was united to the chalk); but the quantity of ſalt was no greater than that obtained by lixiviation.

989 And with alkaline ley.

Alkaline ley was next tried, and the ſolution ſaturated with an acid. Thus the ſalt of benzoin was obtained by precipitation; but here this inconvenience was met with, that the powder of benzoin ran together during the boiling, and floated on the ſurface like a tenacious reſin.

990 Boiling with lime the beſt method.

One only method, therefore, remained to be tried, and that was to boil the benzoin with quick-lime; and as the particles of lime, by interſperſing themſelves betwixt thoſe of the benzoin would prevent their running together, and lime has likewiſe the property of acting upon the reſinous particles, this ſeems to be the beſt method of procuring the flowers of benzoin in the greateſt quantity, and alſo of the beſt quality; and thus we may obtain from 12 to 14 drachms of flowers from a pound of benzoin.

991 Mr Scheele's receipt for preparing the flowers of benzoin by this method.

Mr Scheele's receipt for preparing them after this new method, is as follows: " Pour 12 ounces of water upon four of unſlaked lime, and after the ebullition is over, add eight pounds (of 12 ounces each) of water; put then a pound of finely powdered reſin of benzoin into a tinned pan, pour upon it firſt about ſix ounces of the lime-water abovementioned; mix them well together, and thus add all the reſt of the lime-water in ſucceſſion. The reaſon of adding the lime-water thus by portions, is, that if it be poured in all at once, it will not mix with the benzoin, which will likewiſe coagulate and run together into a maſs. This mixture muſt be boiled over a gentle fire for half an hour, agitating it conſtantly; then taking it from the fire, let it ſtand quiet for ſome time to ſettle, after which the clear liquor is to be poured off into a glaſs veſſel. Pour then eight pounds of water more upon the lime in the veſſel, and uſe this lime-water as before, repeating this proceſs twice more, making four times in all; and laſtly, putting all the reſiduum together on a filter, pour hot water upon them. During this proceſs, the calcareous earth of the lime-water combines with the acid of benzoin, and ſeparates it from the reſinous particles of this ſubſtance; but a ſmall quantity of reſin is diſſolved by the lime-water, and gives it a yellow colour.

"All theſe liquors being mixed together and boiled down to two pounds, are then to be ſtrained into another glaſs veſſel. They are inſpiſſated ſo far, becauſe the ſuperfluous water would hold a great quantity of the ſalt in ſolution; and a little of the reſin being ſoluble in a large quantity of lime-water, but not in a ſmall, falls to the bottom on the liquor being inſpiſſated. When the liqour has become cold, after being ſtrained the laſt time, add muriatic acid till the flowers be totally precipitated, which happens by reaſon of the ſtronger attraction of the marine acid for the calcareous earth. The precipitated coagulum is then to be put upon a filter; and, after being well dried, to be edulcorated ſufficiently, by repeatedly pouring cold water upon it, when it muſt be dried with a gentle heat. As the water made uſe of for this purpoſe, however, is capable of diſſolving a little of the ſalt of benzoin, it ought to be evaporated, and afterwards ſet to cryſtallize. In order to give this ſalt a ſhining appearance, let it be diſſolved in a ſufficient quantity, ſix, ounces, for inſtance, of water by gentle boiling; then ſtrain it immediately, while yet warm, through a cloth, into a glaſs veſſel which has been heated before; and thus a number of fine cryſtals will ſhoot as ſoon as the ſolution is grown cold. The water is then to be ſtrained from the cryſtals, and the reſt of the ſalt ſuſpended in the water may be obtained by repeated evaporation and cryſtallization. In this method, however, a great quantity of the flowers are loſt by reaſon of their volatility; it will therefore be more convenient to keep them in the form of their original precipitate, which is always in fine powder. Cloth anſwers beſt for the filtration of the hot ſolution: when blotting paper is uſed, the ſalt ſometimes cryſtallizes in the filter, and obſtructs it. The filteration itſelf might be omitted, were it not that about two grains of reſin of benzoin remain united to the liquor, from whence it cannot be ſeparated but by the operation juſt mentioned."——The properties of this ſalt as an acid are but little known. It has a moſt agreeable flavour; which, however, ceaſes as ſoon as it unites with calcareous earth, but is recovered again on being ſeparated by any other acid.

992 Flavour of the flowers may be taken away and produced at pleaſure.

993 Anomalous vegetable acids how divided.

994 Of the eſſential acids.

With regard to the other vegetable acids, they may be divided into the eſſential, the fermented, and empyreumatic. The eſſential acids are pure, as exemplified in thoſe of lemons, ſorrel, and ſorrel-dock; or but little altered by the admixture of other matters, as thoſe of cherries, barberries, tamarinds, &c. In ſweet fruits they are generally ſo much covered when ripe as ſcarce to be diſtinguiſhed: however, theſe latent acids become more evident, partly in fermentation, and partly by dry diſtillation. By the former method, all flowers, excepting a few which bear cruciform flowers, are made to yield vinegar; and by dry diſtillation only a very few yield a volatile alkali.

995 Empyreumatic acids.

The acid which paſſes over in dry diſtillation is ſcarce perceptible while the ſubject retains its natural form; but when once produced, has the ſame eſſential qualities with the other; whence it was naturally ſuppoſed that all vegetable acids are at bottom the ſame. Chemiſts, however, have been divided in their opinions on this ſubject; ſome ſuppoſing that the acid of ſugar or of tartar is the baſis, and others that vinegar is the baſis of them all. In proof of this latter hypotheſis, it has been urged, that the acid of lemons may be cryſtallized; of which we have the following account in Scheele's Eſſays. "The juice will not ſhoot into cryſtals by mere evaporation, even when thickened to the conſiſtence of a ſyrup. This our author ſuppoſed to proceed from the great quantity of mucilaginous matter with which the juice abounds; for which reaſon he mixed the inſpiſſated juice with ſtrong ſpirit of wine which coagulated the whole: but even thus he could obtain no cryſtals by evaporation. He therefore employed the method uſed for procuring the pure acid of tartar, and which is formerly deſcribed. The lemon juice, while boiling, was ſaturated with pulveriſed chalk, and the compound immediately fell to the bottom in a form nearly reſembling tartariſed lime. To ſeparate the acid, a quantity of oil of vitriol, equal in weight to the chalk employed, but diluted with ten times it weight of water was neceſſary. This mixture muſt be boiled in a glaſs veſſel for a few minutes; and when grown cold, the acid is to be ſeparated from the gypſum by filtration. In order to cryſtallize it, we muſt evaporate the whole to the conſiſtence of a thin ſyrup; but great care is to be taken, leſt any of the calcareous earth remain in the evaporated liquour: to determine which, a little of it is to tried with freſh oil of vitriol, which will throw drown the remainder: and in this caſe ſome more muſt be added to the whole quantity; for the leaſt particle of lime remaining prevents the cryſtallization, while the ſuperfluous quantity of oil of vitriol, if too much happens to be added, remains in the liquor. The cryſtals ſhoot equally well in a hot as in a cold temperature, which is very unuſual."

996 Whether the acid of ſugar or of tartar is the baſis of vegetable of acids.

997 Dr Crell's method of cryſtallizing the acid of lemons.

998 The cryſtallization prevented by the ſmalleſt particle of lime.

999 Salt of lemons cannot be converted into acid of ſugar.

It is very remarkable that this cryſtallized ſalt of lemons cannot be converted into acid of ſugar by means of that of nitre, though the extract of the juice itſelf may. Sour cherries afford acid of ſugar, and another ſalt ſuppoſed to be tartar; and a kind of ſugar may be obtained not only from roots of various kinds, but from fine raiſins, and, as Dr Crell thinks, from expreſſed muſt; but whether the ſaccharine acid can be procured from this kind of ſugar in equal quantity as from the common, or even whether it yields the ſame products with common ſugar by dry diſtillation, is ſtill a matter of doubt.

1000 Product of acid of tartar by dry diſtillation.

Pure acid of tartar yields on diſtillation *per ſe* an empyreumatic acid, and a coal conſiſting of oily particles and calcareous earth. Dr Crell therefore aſks, May not the acetous acid be mere acid of tartar, which did not meet with alkaline ſalt and earth enough with which it might combine and become more fixed; but, on the contrary, attracted more ſubtile oily particles, and thus become more volatile? In diſtilling terra foliata tartari in the dry way, the acid of vinegar which enters its compoſition is almoſt entirely deſtroyed, only $\frac{1}{480}$th of pure acid being obtained, the reſiduum in the retort, as well as the reſt of that which comes over into the receiver, being entirely alkakine; and the

1001 Acetous acid almoſt entirely deſtoyed by fire.

ſame thing happens to the acid of tartar, the empyreumatic acid abovementioned being extremely weak. Mr Beaumé likewiſe informs us, that if any calcareous earth, egg-ſhells, for inſtance, be diſſolved in vinegar, and the cryſtallized ſalt be diſtilled, we obtain $\frac{23}{64}$ of a red and very fiery inflammable fluid, ſmelling like empyreumatic acetous ether, which reddens tincture of turnſole. Muſt, diſtilled before fermentation, yields only an empyreumatic acid reſembling ſpirit of tartar. The conjecture therefore ſeems reaſonable, that vinegar and tartar have for their baſis the ſame ſpecies of acid, which in the caſe of vinegar is combined with a greater proportion of oil, and in tartar with more earth.

1002 Requiſites for bringing vinegar nearer the ſtate of tartar.

To bring vinegar therefore nearer the ſtate of tartar, we muſt deprive it of its fine volatilizing phlogiſton, combine it with more fixed matter, and reſtore its groſſer oil. All this, however, is extremely difficult to be effected.

1003 Mr Weſtrumb's unſucceſsful attempt.

Mr Weſtrumb, who attempted it, added nitrous acid in various proportions, but could only produce a phlogiſtication of the latter, and dephlogiſtication of the vinegar; but as he could not think of any method of ſeparating the two acids from one another, he was unable to inveſtigate the properties of vinegar thus dephlogiſticated.

1304 Dr Crell's opinion of the poſſibility of tranſmutation.

Dr Crell is of opinion, that this might have been done by vegetable alkali, lime, and terra ponderoſa. The nitrous acid, with vegetable alkali, would have ſhot into the ordinary hexangular cryſtals of nitre: the acetous acid would have formed a compound not eaſily cryſtallized, provided it had remained unchanged; and, though it had approached the nature of ſaccharine acid, would ſtill have formed a compound difficultly cryſtallizable. The effects of theſe acids, indeed, on lime, are directly oppoſite to what they are on terra ponderoſa. With the former, nitrous acid forms a liquor which can ſcarce be cryſtallized; with the latter it produces ſalts difficult to be diſſolved: while the acetous acid, with terra ponderoſa, forms deliqueſcent ſalts; with lime, ſuch as effloreſce in the air. But if the vinegar, by means of the operation already mentioned, had been made to approach towards the nature of acid of ſugar, tranſparent cryſtals would immediately have fallen by reaſon of the ſtrong attraction of this acid for lime.

1005 Method recommended by him for attempting the experiment.

Dr Crell therefore recommends the following method. Let nitrous acid be ſeveral times diſtilled off from vinegar; and when the former, upon being newly added, produces no more red vapours, ſaturate the liquor with lime or terra ponderoſa, ſeparating the ley, which will not ſhoot, from the cryſtals. The nature of the ſalt which does not contain nitrous acid, may be determined from the figure of its cryſtals, or from the effects of other ſalts in conſequence of a double elective attraction. We might likewiſe add freſh nitrous acid to the ſeparated ſalt, or to the whole mixture, without any ſeparation of the nitrous ſalt, till the earthy ſalt, which does not contain any nitrous acid, be ſaturated. The vinegar, if unaltered by the operation, would riſe on diſtilling the liquor; and if converted into ſaccharine acid, would not be diſlodged from lime by ſpirit of nitre. In like manner, diſtilled vinegar ſhould be ſaturated with chalk, the compound reduced to cryſtals, and then expoſed to as ſtrong a fire as it can bear without expelling the acid, in order to diſſipate ſome phlogiſtic particles. Let it then be diſſolved, filtered, and cryſtallized again; after which it may be treated with nitrous acid as above directed. "Perhaps (ſays Dr Crell), the acetous acid may by this combination acquire more fixity; ſo that the nitrous acid ſhall be able to produce a greater change. Should it paſs over again in the form of acetous acid unchanged, let it be combined once more with calcareous earth; and let the foregoing experiment be repeated, in order to try whether ſome ſenſible change will not enſue. Should this method fail, try the oppoſite; that is, endeavour to add more groſs phlogiſtic matter to the vinegar. Try to combine ſtrong vinegar, and that which has been diſtilled, with unctuous oils. Thus we might perhaps bring it nearer to tartar; and again, by means of nitrous acid, convert it into acid of ſugar.

1006 His attempts to prove that all the vegetable acids may be reduced to one.

In another diſſertation on this ſubject, Dr Crell undertakes to ſhow, that all the vegetable acids may be converted into one, and that this is contained in the pureſt ſpirit of wine. The following are adduced as proofs.

1007 From the reſiduum of dulcified ſpirit of nitre.

1. If the reſiduum of dulcified ſpirit of nitre be boiled with a large quantity of nitrous acid, care being taken at the ſame time to condenſe the vapours by a proper apparatus; and if the liquid which has paſſed over be ſaturated with vegetable alkali, nitre and terra foliata tartari will be obtained; and on ſeparating the latter by means of ſpirit of wine, the vinegar may be had in the ordinary way of decompoſing the ſalt.

2. On boiling the reſiduum over again with nitrous acid, the ſame products are obtained; and the more frequently this proceſs is repeated, the leſs acid of ſugar is procured, until at length no veſtige of it is to be met with.

1008 From the decompoſition of acid of ſugar.

3. Pure acid of ſugar, boiled with 12 or 14 times its quantity of nitrous acid, is entirely decompoſed, and the receiver is found to contain phlogiſticated nitrous acid, vinegar, fixed air, and phlogiſticated air, while a little calcareous earth remains in the retort.

1009 From the production of acid of tartar from the reſiduum of dulcified ſpirit of nitre.

4. Acid of ſugar is likewiſe decompoſed by boiling with ſix times its quantity of vitriolic acid. In the receiver we find vinegar phlogiſticated with vitriolic acid, aërial acid; while pure vitriolic acid remains in the retort.

5. By ſaturating the reſiduum of dulcified ſpirit of nitre with chalk, there is formed an inſoluble ſalt, which by treatment with vitriolic acid yields a real acid of tartar, conſtituting a cream of tartar with vegetable alkali.

1010 From the production of empyreumatic acid of tartar from the liquor in which tartarous ſelenite is boiled.

6. On evaporating the liquor from which the tartareous ſelenite was obtained, a dark-coloured matter remains, yielding on diſtillation an empyreumatic acid of tartar, and a ſpongy coal. Hence it would ſeem, that ſpirit of wine conſiſts of acid of tartar, of water, and phlogiſton; ſo that it is a native dulcified acid: and nitrous acid, on being mixed with it in moderate quantity, diſlodges the acid of tartar. On the addition of more nitrous acid, the acid of tartar is reſolved into acid of ſugar and phlogiſton; and by a ſtill greater addition, the ſaccharine acid is changed into vinegar.

1011 From the ſolution of mangaueſe by nitrous acid and acid of ſugar.

7. On boiling one part of the acid of ſugar with one and an half of mangancſe and a ſufficient quantity of nitrous

nitrous acid, the mangane$e will be almoſt entirely diſſolved, and phlogiſticated nitrous acid along with vinegar will paſs over into the receiver.

8. On boiling together acid of tartar, mangane$e, and nitrous acid, we obtain a ſolution of the mangane$e, with phlogiſticated nitrous acid and vinegar as before.

1012 From the ſolution of the ſame with vitriolic acid and that of tartar.

9. If acid of tartar be boiled along with vitriolic acid and mangane$e, the latter will be diſſolved, and vinegar with vitriolic acid will paſs over into the receiver.

1013 From the digeſtion of acid of tartar with ſpirit of wine.

10. On digeſting acid of tartar and ſpirit of wine for ſeveral months, the whole is converted into vinegar, the air in the veſſel being partly converted into cretaceous acid, and partly into phlogiſticated air.

1014 From the ſolution of mangane$e with vitriolic acid and ſpirit of wine.

11. On boiling ſpirit of wine with vitriolic acid and mangane$e, it will be converted into vinegar and phlogiſticated air.

1015 From the diſtillation of ſpirit of wine with cauſtic alkali.

12. By diſtilling ſpirit of wine upwards of 20 times from cauſtic alkali, it was changed into vinegar, and a conſiderable quantity of water was obtained.

Hence it appears, ſays Dr Crell, that the acids of tartar, ſugar, and vinegar, are modifications of the ſame acid, as it contains more or leſs phlogiſton. The acid of tartar has the greateſt quantity, the acid of ſugar ſomewhat leſs, and vinegr the leaſt of all. In theſe experiments, however, care muſt be taken that neither the nitrous acid nor fixed alkali employed contain any marine acid, otherwiſe the reſults will be uncertain.

§ 18. *Of the Acid of Fat.*

2d 1015 How procured.

This may be obtained from ſuet by means of many repeated diſtillations. A ſmall quantity is ſeparated at each diſtillation; but by diſtilling the empyreumatic oil into which the ſuet is thus converted over and over, a freſh quantity is always obtained. The acid of fat in ſome reſpects has a reſemblance to that of ſea-ſalt; but in others is much more like the vegetable kind, as being deſtructible in a ſtrong fire, forming compounds which do not deliqueſce with calcareous earth, and uniting intimately with oily ſubſtances.

3d 1015 Its effects on alkalies, &c.

With alkalies it forms ſalts entirely different from thoſe yielded by the other acids; with the volatile alkali, particularly, it produces a concrete volatile ſalt. When ſaturated with calcareous earth, it yields brown cryſtals; and a ſalt of the ſame kind was obtained by Dr Crell from a mixture of quicklime and ſuet diſtilled to dryneſs, and boiling up the reſiduum with water. The cryſtals were hexagonal, and terminated by a plane ſurface; their taſte was acrid and ſaltiſh; they did not deliqueſce in the air, and were eaſily and copiouſly diſſolved in water. With magneſia and earth of alum a gummy maſs is obtained, which refuſes to cryſtallize.

4th 1015 On metals.

With regard to the metals, Dr Crell informs us, that the acid of fat copiouſly diſſolves mangane$e into a clear and limpid liquor. It diſſolves the precipitate of cobalt, but not the regulus. White arſenic is acted upon but ſparingly, and nickel not at all, though it forms a green ſolution with the precipitate from nitrous acid. Regulus of antimony, by the aſſiſtance of heat is diſſolved into a clear liquor, which became milky in the cold: it cryſtallized on evaporation, and did not deliquate in the air. Zinc readily diſſolved, and imparted a peculiar metallic taſte, falling to the bottom in the form of a white powder on the addition of an alkali. Biſmuth in the metallic ſtate was not diſſolved; but the precipitate was. It acted upon mercury after being twice diſtilled from it, and poured afreſh upon the metal. The mercury could not be entirely precipitated by common ſalt. It acted more vigorouſly upon a precipitate from corroſive ſublimate; from the ſolution of which a white ſublimate was obtained after the liquor had been drawn off by diſtillation. A gold-coloured ſolution was obtained from platina by diſtilling the acid from it to dryneſs, and then pouring it back again; the precipitate of this metal from aqua-regia by ſpirit of wine was diſſolved in great abundance. Iron was very eaſily diſſolved in it, and exhibited a liquor of an aſtringent taſte, which ſhot into needle-like cryſtals that did not deliqueſce in the air. Lead was corroded and rendered the acid turbid. Minium was converted into a white powder, and then diſſolved with greater eaſe. The ſolution has a ſweet taſte, and cannot be precipitated by ſea-ſalt. Tin was corroded into a yellow calx, and diſſolved but in very ſmall quantity. Copper was diſſolved, even in the cold, into a green liquor; but the ſolution was greatly promoted by heat. On evaporation it ſhowed ſome diſpoſition to cryſtallize, but again attracted moiſture from the air. Silver-leaf was attacked only in a very ſmall degree; however, ſome was precipitated by means of copper, and the marine acid rendered the liquor turbid. The calx precipitated from aquafortis was diſſolved more copiouſly. Silver was precipitated of a white colour from aquafortis by the pure acid itſelf, as well as by its ammoniacal ſalt. Half an ounce of the acid diſtilled four times almoſt to dryneſs from ſome gold-leaves, and at length poured back upon them, the precipitate of a dilute ſolution of tin obtained by it, gained only a faint colour, rather inclining to red; but a mixture of two parts of acid with one of aquafortis, diſſolved gold very readily.

§ 19. *Of Fixed Alkaline Salts.*

1016 How procured.

Of theſe there are two kinds; the vegetable and mineral. The former is never found by itſelf, and but rarely in combination with any acid; but is always prepared from the aſhes of burnt vegetables. It is got in the greateſt quantity from crude tartar; from which, if burned with proper care and attention, we may obtain one pound of alkali out of $2\frac{1}{4}$ of the tartar. The latter is found native in ſome parts of the earth. It is likewiſe found in very large quantities combined with the marine acid, in the waters of the ocean, and in the bowels of the earth; thus forming the common alimentary ſalt. It is alſo produced from the aſhes of certain ſea-plants, and of the plant called *kali;* from whence both the mineral and vegetable alkalies have taken their name.

1017 Vegetable alkali cryſtallized.

The vegetable alkali difficultly aſſumes a cryſtalline form; nevertheleſs, it may be partially united with ſome acids in ſuch a manner as to cryſtallize, and loſe its property of deliquating in the air, without at the ſame time ceaſing to be an alkali. Of this we have an example in the acid of ants abovementioned. Something

thing of the ſame kind we have obſerved in treating vegetable fixed alkali with ſpirit of wine. A gallon of pretty ſtrong ſpirit of wine being drawn over from a pound of ſalt of tartar, a black unctuous liquor was left, which ſhot into cryſtals very much reſembling vitriolated tartar, and which did not deliquate in the air, but were nevertheleſs ſtrongly alkaline. Dr Black, however, informs us, that the vegetable alkali may be ſhot into fine cryſtals; but which cannot be preſerved, on account of their great attraction for moiſture, unleſs cloſely ſhut up from the air. They have not ſuch a quantity of water as to undergo the aqueous fuſion.

1018 Change on the vegetable alkali.

The mineral alkali in its natural ſtate always aſſumes a cryſtalline form, ſomewhat reſembling that of ſal mirabile. It does not deliquate in the air, nor does it ſeem to have ſo ſtrong an attraction for water, even when in its moſt cauſtic ſtate, as the vegetable alkali: hence mineral alkali is preferable to it in making ſoap, which is always of a firmer conſiſtence with mineral than with vegetable alkali. If vegetable alkali is combined with ſpirit of ſalt, ſome change ſeems to be thereby induced upon it; as the ſalt produced by expelling the marine acid by means of the vitriolic, and then cryſtallizing the maſs, cryſtallizes differently from vitriolated tartar. Whether the vegetable alkali might by this means be entirely converted into the mineral, deſerves a further inquiry.

1019 Difference between vegetable and mineral alkalies.

Both mineral and vegetable alkalies, when applied to the tongue, have a very ſharp, pungent, and urinous taſte; but the vegetable conſiderably more ſo than the mineral. They both unite with acids, and form different neutral ſalts with them: but the vegetable alkali ſeems to have rather a greater attraction for acids than the other; although this difference is not ſo great as that a neutral ſalt, formed by the union of mineral alkali with any acid, can be perfectly decompoſed by an addition of the vegetable alkali, unleſs in conſiderable exceſs.

1020 Compoſed of a cauſtic ſalt and fixed air.

Both vegetable and mineral alkali appear to be compoſed of an exceedingly cauſtic ſalt united with a certain quantity of fixed air. This may be increaſed ſo far, as to make the vegetable alkali aſſume a cryſtalline form, and loſe great part of its alkaline properties: but as the adheſion of great part of this air is very ſlight, it eaſily ſeparates by a gentle heat. Some part, however, is obſtinately retained; and the alkali cannot be deprived of it by the moſt violent calcination *per ſe*. The only method of depriving it entirely of its fixed air is, by mixing an alkaline ſolution with quicklime.

Fixed Alkalies COMBINED,

1021 Hepar ſulphuris.

I. *With Sulphur.* The produce of this is the red fetid compound called *hepar ſulphuris*, or liver of ſulphur. It may be made by melting ſulphur with a gentle heat, and ſtirring into it, while melted, four times its weight of dry alkaline ſalt. The whole readily melts and forms a red maſs of a very fetid ſmell, and which deliquates in the air. If ſulphur is boiled in a ſolution of fixed alkaline ſalt, a like combination will take place.

1022 Decompoſed.

In this proceſs, when the hepar is made either in the dry or the moiſt way, the fixed air of the alkali is diſcharged, according to Dr Prieſtley's obſervation. Neither does a fixed alkali, when combined with fixed air, ſeem capable of uniting with ſulphur; nor will the union be accompliſhed without heat, unleſs the alkali is already in a cauſtic ſtate. Hence a cold ſolution of hepar ſulphuris may be decompounded, partly at leaſt, by fixed air. On adding an acid, however, the decompoſition takes place much more rapidly; and the ſulphur is precipitated to the bottom, in form of a white powder.

1023 Inflammable vapour in the compoſition of it.

During the precipitation of the ſulphur from an alkali, by means of acids, a thick white ſmoke ariſes, of a moſt fetid ſmell and ſuffocating nature. It burns quietly, without exploſion, on a candle's being held in it. Calces of ſilver, lead, iron, or biſmuth, are rendered black by it. Hence, if any thing is wrote with a ſolution of lead, and a ſolution of hepar ſulphuris is paſſed over it when dry, the writing, formerly inviſible, will immediately appear of a blackiſh brown colour. Silver, in its metallic ſtate, is prodigiouſly blackened either by the contact of this vapour, or by being immerſed in a ſolution of the hepar ſulphuris itſelf. Litharge is inſtantly reſtored to its metallic ſtate, on being immerſed even in a cold ſolution of hepar ſulphuris.

1024 Phlogiſton of ſulphur diſpoſed to quit the acid.

By being united with an alkali, the acid of ſulphur ſeems very much diſpoſed to quit the phlogiſton. If a ſolution of hepar ſulphuris is expoſed to the air for ſome time, it is ſpontaneouſly decompoſed; the phlogiſton of the ſulphur flying off, and the acid remaining united with the alkali into a vitriolated tartar. This decompoſition takes place ſo remarkably, when liver of ſulphur is diſſolved in water, that, by a ſingle evaporation to dryneſs, it will be almoſt totally changed into vitriolated tartar. If this ſubſtance, in a dry ſtate, be expoſed to a moderate degree of heat, and the maſs kept conſtantly ſtirring, a like decompoſition will follow; the phlogiſton of the ſulphur will fly off, and the acid unite with the alkali.

1025 Metals and charcoal diſſolved by it.

Liver of ſulphur is a great ſolvent of metallic matters; all of which, except zinc, it attacks, particularly in fuſion. It ſeems to diſſolve gold more effectually than other metals. This compound alſo diſſolves vegetable coals, even by the humid way; and theſe ſolutions, if ſuffered to ſtand in the open air, always precipitate a black powder, no other than the coal they had diſſolved, in proportion to the quantity of hepar ſulphuris decompoſed. When vegetable coal is thus diſſolved by liver of ſulphur in fuſion, it is of a much deeper red than in its natural ſtate. The ſolution in water is of a green colour.

1026 Soap.

II. *With Expreſſed Oils.* The reſult of this combination is *ſoap*; for the preparation of which in large quantities in the way of trade, ſee SOAP. The ſoap which is uſed in medicine is prepared without heat, in the following manner, according to the author of the Chemical Dictionary.

"One part of quicklime, and two parts of good Spaniſh ſoda (the ſalt prepared from the aſhes of the herb kali), are boiled together during a ſhort time in an iron caldron. This lixivium is to be filtered, and evaporated by heat, till a phial, capable of containing an ounce of water, ſhall contain an ounce and 216 grains of this lixivium. One part of this lixivium is to be mixed with two parts of oil of olives, or of ſweet almonds, in a glaſs or ſtone-ware veſſel. The mixture ſoon becomes thick and white; and muſt be ſtirred from time to time with an iron ſpatula. The combi-

Fixed alkaline ſalts and their combinations.

nation is gradually completed, and in ſeven or eight days a very white and firm ſoap is obtained."

In attempting combinations of this kind, it is abſolutely neceſſary that the alkali be deprived of its fixed air as much as poſſible; otherwiſe the ſoap will be quite unctuous and ſoft: for fixed alkalies have a greater attraction for fixed air than for oil, and hence ſoap is decompounded by blowing fixed air into a ſolution of it in water. It may be made either with tallow, wax, ſpermaceti, butter of cocoa, the coarſer reſinous ſubſtances, or animal oils.

1027 Starkey's ſoap. III. *With Eſſential Oils.* The volatility of theſe oils in a great meaſure hinders them from being acted upon by alkalies: nevertheleſs, combinations of this kind have been attempted; and the compounds ſo produced have been called *Starkey's ſoap*, from one Starkey a chemiſt, who endeavoured to volatilize ſalt of tartar by combining it with oil of turpentine. His method was to put dry ſalt of tartar into a matraſs, and pour upon it eſſential oil of turpentine to the height of two or three fingers breadth. In five or ſix months, a part of the alkali and oil were combined into a white ſaponaceous compound. This muſt be ſeparated from the mixture, and more of it will afterwards be formed by the ſame method.

Chemiſts, imagining this ſoap to be poſſeſſed of conſiderable medical virtues, have endeavoured by various methods to ſhorten this tedious proceſs. Of theſe one of the moſt expeditious is that recommended by Mr Beaumé; which conſiſts in triturating, for a long time, alkaline ſalt upon a porphyry, and adding oil of turpentine during the trituration. According to him, the thick reſinous part of the oil only can combine with the ſalt; and, during the time this combination is effected, the more ſubtile and attenuated parts will fly off. Hence he finds that the opeartion is conſiderably abridged by the addition of a little turpentine or common ſoap. The moſt expeditious of all, however, is that mentioned by Dr Lewis; which conſiſts in heating the alkali red hot, and then throwing it into oil of turpentine, ſtirring them well together; on which they immediately unite into a ſaponaceous maſs.

This kind of ſoap is ſubject to great alterations from keeping; particularly the loſs of its colour, and a kind of decompoſition occaſioned by the extraction of an acid from the oil of turpentine, which unites with the alkali, and cryſtallizes not only all over the ſurface, but in the very ſubſtance of the ſoap. The nature of this ſalt is unknown, but certainly deſerves conſideration.

1028 Phlogiſticated alkalies. IV. *With Phlogiſton.* This combination is effected by calcining them with the charcoal either of vegetable or animal matters. The conſequence is, that they are greatly altered in their properties; ſometimes ſo much as to be enabled to precipitate calcareous earths from their ſolutions in acids. Metallic ſolutions precipitated by them in this ſtate, aſſume different colours.

Differences obſerved between Fixed Alkalies obtained from different *Vegetables*.

Theſe differences we muſt conceive to ariſe from ſome proportion of the oily and phlogiſtic matter of the vegetable remaining in the aſhes from whence the ſalts are extracted; for when reduced to their utmoſt purity, by repeated calcinations in a ſtrong fire, and deliquations in the air, all of them, the marine alkali excepted, appear to be the very ſame.

1029 Mr Gmelin's experiments. On this ſubject Mr Gmelin has given a great number of experiments in the fifth volume of the *Commentaria Petropolitana*; and found very conſiderable differences, not only between the alkaline ſalts, but likewiſe the pure vegetable earths obtained from different vegetables by burning. The ſalts of the ſeveral plants examined were prepared with great care, and all of them exactly in the ſame manner; each vegetable being burnt in a ſeparate crucible, with the ſame degree of fire, till no remains of coaly matter could any longer be perceived; and the aſhes elixated in glaſs veſſels with cold diſtilled water. The ſalts, thus obtained, were found to produce different colours on mixture with certain liquors, and to effervеſce in very different degrees with acids: certain metallic ſolutions were by ſome precipitated, by others only rendered thicker, by others both precipitated and rendered thick; whilſt ſome occaſioned neither the one nor the other of theſe changes, but left the fluid clear and tranſparent. Thus, with the vitriolic acid, the ſalts of ſouthernwood and ſage ſtruck a pale brown colour; thoſe of pine-tops and rue, a yellow; that of fern, a reddiſh yellow; and that of ſanicle, a dark leek-green: that of dill yielded a leek-green precipitate, with elegant green flakes floating in the liquor. This laſt ſalt alſo gave a greeniſh precipitate with the marine acid, and a red one with the nitrous. Solution of corroſive ſublimate was changed yellow by ſalt of ſouthernwood; of a browniſh colour, by that of colt's-foot; of a deep red, by that of wormwood; and of a pitch-colour, by that of dill. That of fern threw down an opal-colour; of ſage, a ſulphur-yellow; of elder flowers, a citron yellow; of ſanicle, a ſaffron colour; and of milfoil, a deep-red precipitate. From ſolution of ſilver, ſalt of *carduus benedictus* threw down a white; of camomile, a grey; of hyſſop, a browniſh; of dill, a blackiſh brown; of ſcabious, a yellowiſh; and that of pine-tree tops, a ſulphur yellow precipitate. Solution of vitriol of copper was changed by ſalt of ſouthernwood to a bright ſea-green; by that of dill, to an unſightly green; of agrimony, to a greeniſh blue; and by that of milfoil, to a bright ſky-blue: the ſalt of penny-royal made the liquor thick as well as blue, and that of feverfew made it thick and green: the ſalt of hyſſop threw down a green precipitate, that of ſcurvy-graſs a blue one, and that of fumitory a greeniſh blue:—whilſt the ſalt of fern made ſcarcely any change either in the colour or conſiſtency of the liquor.

§ 19. *Of Volatile Alkali.*

1030 Whence obtained. This is a kind of ſalt obtained from all animal, ſome vegetable, ſubſtances, from ſoot by diſtillation with a ſtrong heat, and from all vegetable ſubſtances by putrefaction. Though a volatile alkali is procurable from all putrid animal ſubſtances by diſtillation, yet the putrefactive proceſs does not ſeem to prepare volatile alkali in all of theſe. Putrid urine, indeed, contains a great quantity of alkali ready formed, whence its uſe in ſcouring, *&c.* but the caſe is not ſo with putrid blood or fleſh. Theſe afford no alkali till after the phlegm has ariſen; and this they would

Volatile alkali and its combinations.

would do, though they had not been putrefied. According to Mr Wiegleb, volatile alkali is found in limeſtone, lapis ſuillus, chalk, marble, coals, turf, loam, clay, and many other kinds of earth. Its exiſtence in theſe ſubſtances may be diſcovered merely by diſtilling them with a briſk fire, but ſtill better by the addition of ſome quantity of fixed alkali or quicklime before the diſtillation.—It has even been found in all mineral ſalts and their acids, as vitriol, nitre, common ſalt, and the acid liquors drawn from theſe ſubſtances, alſo in gypſum and ſulphur: from all which it may be ſeparated by means of quicklime.—In the vegetable kingdom it is produced by dry diſtillation from muſtard-ſeed, elder flowers and leaves; the leaves of the wild cherry-tree, white water-lilies, tobacco, and ſage; as well as from many other plants. According to our author, the plaineſt proof of its exiſting almoſt univerſally in the vegetable kingdom, is, that the ſoot of our chimneys affords a volatile alkali by diſtillation, either with or without quicklime.

Volatile alkali, when pure, appears of a ſnowy whiteneſs; has a very pungent ſmell, without any diſagreeable empyreuma; is very eaſily evaporable, without leaving any reſiduum; effervesces with acids much more ſtrongly than fixed alkali; and forms with them neutral compounds called *ammoniacal ſalts*, which we have already deſcribed, and which are different according to the nature of the acid made uſe of; for all volatile alkalies, when perfectly purified, appear to be the very ſame, without the ſmalleſt difference.

Like fixed alkalies, theſe ſalts contain a great quantity of fixed air, on which their ſolidity depends; and which may be ſo increaſed as perfectly to neutralize, and deprive them of their peculiar taſte and ſmell. When neutralized by fixed air, they have a very agreeable pungent taſte, ſomewhat reſembling that of weak fermenting liquors. When totally deprived of fixed air, by means of lime, they cannot be reduced to a ſolid form; but are diſſipated in an inviſible and exceedingly pungent vapour, called by Dr Prieſtley *alkaline air*. When volatile alkaline ſalt is diſſolved in water, the ſolution is called *volatile alkaline ſpirit.*

Diſtillation and Purification of *Volatile Alkalies*.

1031
Diſtilling veſſel, and method of performing the operation.

The materials moſt commonly uſed for preparing volatile alkalies are the ſolid parts of animals, as bones, horns, *&c.* Theſe are to be put into an iron pot of the ſhape recommended for ſolution; to this muſt be fitted a flat head, having a hole in the middle about two inches diameter. From this a tube of plate-iron muſt iſſue, which is to be bent in ſuch a manner that the extremity of it may enter an oily jar, through an hole made in its upper part, and dip about half an inch under ſome water placed in the lower part. The mouth of the jar is to be fitted with a cover, luted on very exactly; and having a ſmall hole, which may be occaſionally ſtopped with a wooden peg. The junctures are to be all luted as cloſe as poſſible, with a mixture of clay, ſand, and ſome oil; and thoſe which are not expoſed to a burning heat, may be further ſecured by quicklime and the white of an egg, or by means of glue. A fire being now kindled, the air contained in the diſtilling veſſel is firſt expelled, which is known by the bubbling of the water; and to this vent muſt be given by pulling out the wooden peg. A conſiderable quantity of phlegm will then come over, along with ſome volatile alkali, a great quantity of fixable air, and ſome oil. The alkali will unite with the water, and likewiſe ſome part of the fixed air, the oil ſwimming above. A great many incoercible vapours, however, will come over, to which vent muſt be given from time to time, by pulling out the peg. The diſtillation is to be continued till all is come over; which may be known by the ceſſation, or very ſlow bubbling of the water. The iron pipe muſt then be ſeparated from the cover of the diſtilling veſſel, leſt the liquid in the jar ſhould return into it, on the air being condenſed by its cooling. In the jar will be a volatile ſpirit, more or leſs ſtrong according as there was leſs or more water put in, with an exceedingly fetid black oil floating upon it.

1032
Rectification.

The rectification of the volatile alkali is moſt commodiouſly performed at once by combining it with an acid; and, as ſpirit of ſalt has the leaſt affinity with inflammable matter, it is to be choſen for this purpoſe, in preference to the vitriolic or nitrous. As the ſpirit is exceſſively oily, though already much weakened by the admixture of the water in the jar, if a very large quantity was not originally put in, an equal quantity of water may ſtill be added, on drawing off the ſpirit. That as little may be loſt as poſſible, the ſpirit ſhould be received in a ſtone bottle; and the marine acid, likewiſe in a diſtilled ſtate, added by little and little, till the effervefcence ceaſes. The liquor, which is now an impure ſolution of ſal ammoniac, is to be left for ſome time, that the oil may ſeparate itſelf; it is then to be filtered, evaporated, and cryſtallized in a leaden veſſel. If the cryſtals are not ſufficiently pure at the firſt, they will eaſily become ſo on a ſecond diſſolution.

1033
Volatile ſal ammoniac.

From ſal ammoniac thus obtained pure, the volatile alkali may be extricated by diſtillation with chalk, alkaline ſalts, or quicklime. Alkaline ſalts act more briſkly than chalk, and give a much ſtronger volatile alkali. The ſtrength of this, however, we know may be altered at pleaſure, by adding to, or depriving it of, its natural quantity of fixed air. Hence, perhaps, the beſt method would be, to prepare volatile alkalies altogether in a fluid ſtate, by means of quicklime; and then add fixed air to them, by means of an apparatus ſimilar to that directed by Dr Prieſtley for impregnating water with fixed air. To prevent lime from adhering to the diſtilling veſſels in which it is put, the tranſlator of Wiegleb's chemiſtry recommends the putting in three or four ounces of common ſalt along with the other ingredients.

Volatile alkalies COMPINED,

1034
Cuprum ammoniacale.

I. *With Metals.* There are only three metals, *viz.* copper, iron, and lead, upon which, while in their metallic form, volatile alkalies are capable of acting. Copper-filings are diſſolved by volatile alkali, eſpecially in its cauſtic ſtate, into a liquor of a moſt admirable blue colour. It is remarkable, that this colour depends entirely upon the air having acceſs to the ſolution: for if the bottle containing it is cloſe ſtopt, the liquor becomes colourleſs; but, however, reſumes its blue colour on being expoſed to the air. On evapoporation, a blue ſaline maſs is obtained, which, mixed with fats, or other inflammable matters, tinges their flame green, leaving a red calx of copper, ſoluble again in volatile ſpirits as at firſt. This ſaline ſubſtance

ſtance has beed received into the laſt edition of the Edinburgh Diſpenſatory, under the name of *cuprum ammoniacale*, as an antiepileptic.

1035 Copper, fulminating.

The blue mixture of ſolution of copper in aquafortis with volatile ſpirits, yields ſapphire-coloured cryſtals, which diſſolve in ſpirit of wine, and impart their colour to it. If, inſtead of cryſtallization, the liquor be totally evaporated, the remaining dry matter explodes, in a moderate heat, like aurum fulminans. This is given as a fact by Dr Lewis; but hath not ſucceeded upon trial by Dr Black. Various phenomena, ſays Mr Wiegleb, occur in the diſſolution of copper by the volatile alkali.—On ſaturating dilute ſpirit of ſal ammoniac with copper-filings, cryſtals are formed of a dark-blue colour, but which, by expoſure to the air, fall to pieces and become green. Vinous ſpirit of ſal ammoniac impregnated with copper, loſes in an inſtant its blue colour, on the affuſion of an equal quantity of ſaturated ſolution of fixed alkaline ſalt. The copper is then taken up by the fixed alkaline ſolution, which of conſequence acquires a blue colour, while the ſpirit of wine, deprived of the metal, floats clear on the top. When filings of copper are put into a bottle, and that bottle quite filled with cauſtic volatile alkali, and is immediately ſtopped up, no ſolution takes place: but when the bottle is left open, only for a ſhort time, or an empty ſpace is left in it, a colourleſs ſolution is obtained, which in the air obtains a blue colour; but which may be deprived of this colour as often as we pleaſe, by ſhutting it up exactly from the air, and letting it ſtand, in this ſituation, on freſh filings of copper.—From theſe phenomena Mr Wiegleb concludes, that copper does not diſſolve in volatile alkali until it has loſt part of its phlogiſton, to which the air, by the attraction it exerts upon it, contributes its ſhare. If this has taken place only in a ſmall proportion, and the farther acceſs of air be prevented, the remainder will be diſſolved without any colour; which, however, appears in the inſtant that, by a freſh acceſſion of air, the phlogiſton ſtill remaining finds means to eſcape. The diſſolved copper is always precipitated when the ſolution meets with phlogiſticated copper. The colourleſs ſolution is precipitated by zinc and vitriolic acid, but not by iron. It taſtes rather ſweet, and does not ſmell very ſtrong of volatile alkali; while, on the contrary, the blue ſolution has a pungent ſmell, and is precipitated by diſtilled water.

On the other two metals the action of volatile alkali is by no means ſo evident; it diſſolves iron very ſlowly into a liquor, the nature of which is not known; and lead is corroded by it into a mucilaginous ſubſtance.

1036 Sal volatile oleoſum.

II. *With Inflammable Subſtances.* With expreſſed oils, the cauſtic volatile alkali unites into a ſoft unctuous maſs, of a very white colour, imperfectly ſoluble in water, and which is ſoon decompoſed ſpontaneouſly. Compoſitions of this kind are frequently uſed for removing pains, and ſometimes with ſucceſs. With eſſential oils, volatile alkalies may be united, either in their dry or liquid form, by means of diſtillation. The produce is called *ſal volatile oleoſum*; it is much more frequently uſed in a liquid than in a dry form. The general method of preparation is by diſtilling volatile alkali along with eſſential oils and ſpirit of wine, or the aromatic ſubſtance from whence the eſſential oils are drawn. Theſe compoſitions are variable at pleaſure; but certain forms are laid down in the diſpenſatories, with which it is expected that all the chemiſts ſhould comply in the preparation of theſe medicines.

1037 Spiritus volatilis ſuccinatus.

III. *Eau de Luce.* This is the name given to an exceedingly volatile ſpirit, which ſome years ago was pretty much in vogue; and indeed ſeems very well calculated to anſwer all the purpoſes for which volatile alkalies can be uſed. It was of a thick white colour, and ſmelled ſomewhat of oil of amber. A receipt appeared in Lewis's Diſpenſatory for the preparation of this fluid, under the name of *ſpiritus volatilis ſuccinatus*. The method there directed, however, did not ſucceed; becauſe, though the alkaline ſpirit is capable of keeping a ſmall quantity of oil of amber ſuſpended, the colour is greatly more dilute than that of genuine eau de luce. In the Chemical Dictionary we have the following receipt: “Take four ounces of rectified ſpirit of wine, and in it diſſolve 10 or 12 grains of white ſoap; filter this ſolution; then diſſolve in it a drachm of rectified oil of amber, and filter again. Mix as much of this ſolution with the ſtrongeſt volatile ſpirit of ſal ammoniac, as will be ſufficient, when thoroughly ſhaken to give it a beautiful milky appearance. If upon its ſurface be formed a cream, ſome more of the oily ſpirit muſt be added.”

This receipt likewiſe ſeems inſufficient. For the oil of amber does not diſſolve in ſpirit of wine: neither is it probable that the ſmall quantity of ſoap made uſe of could be of any ſervice; for the ſoap would diſſolve perfectly in the alkaline ſpirit, without ſuffering any decompoſition. The only method which we have found to anſwer is the following. Take an ounce, or any quantity at pleaſure, of balſamum Canadenſe; place it in a ſmall china baſon, in a pan of boiling water, and keep it there till a drop of it taken out appears of a reſinous conſiſtence when cold. Extract a tincture from this reſin with good ſpirit of wine; and having impregnated your volatile ſpirit with oil of amber, lavender or any other eſſential oil, drop in as much of the ſpiritous tincture as will give it the deſired colour. If the volatile ſpirit is very ſtrong, the eau de luce will be thick and white, like the cream of new milk; nor is it ſubject to turn brown with keeping

1038 Volatile alkali combined with ſulphur.

IV. *With Volatile Tincture of Sulphur.* This is a combination of the cauſtic volatile alkali, or ſpirit of ſal ammoniac, with ſulphur. It is uſually directed to be made by grinding lime with the ſulphur and afterwards with the ſal ammoniac, and diſtilling the whole in a retort, but the produce is by this method very ſmall, and even the ſucceſs uncertain. A preferable method ſeems to be, to impregnate the ſtrongeſt cauſtic volatile ſpirit with the vapour which ariſes in the decompoſitions of hepar ſulphuris by means of an acid, in the ſame manner as directed for impregnating water with fixed air.

1039 Sympathetic ink.

This preparation has a moſt nauſeous fetid ſmell, which ſpreads to a conſiderable diſtance; and the effluvia will blacken ſilver or copper, if barely placed in the neighbourhood of the unſtopped bottle. This property renders it capable of forming a curious kind of ſympathetic ink; for if paper is wrote upon with a ſolution of ſaccharum ſaturni, the writing, which diſappears when dry, will appear legible and of a

browniſh

Phenomena from mixtures of acid, &c. ſalts.

browniſh black, by barely holding it near the mouth of the bottle containing volatile tincture of ſulphur. The vapours of this tincture are ſo exceedingly penetrating, that it is ſaid they will even penetrate through a wall, ſo as to make a writing with ſaccharum ſaturni appear legible on the other ſide; but this is much to be doubted. It is even ſaid that it cannot penetrate through the ſubſtance of paper, but only inſinuates itſelf betwixt the leaves; and hence if the edges of the leaves are glued together no black colour will appear.

§ 20. *Of the* PHENOMENA *reſulting from different mixtures of the Acid, Neutral, and Alkaline* SALTS, *already treated of.*

1040 Of mixing the acid ſpirits with one another.

1. IF concentrated oil of vitriol is mixed with ſtrong ſpirit of nitre, or ſpirit of ſalt, the weaker acid will become exceedingly volatile, and emit very elaſtic fumes; ſo that if a mixture of this kind is put into a cloſe ſtopt bottle, it will almoſt certainly burſt it. The ſame effect follows upon mixing ſpirit of ſalt and ſpirit of nitre together. In this caſe, both acids become ſurpriſingly volatile; and much of the liquor will be diſſipated in fumes, if the mixture is ſuffered to ſtand for any conſiderable time. Such mixtures ought therefore to be made only at the time they are to be uſed.

1041 Diſſolving vitriolic ſalts in nitrous or marine acids.

2. If vitriolated tartar is diſſolved in an equal quantity of ſtrong ſpirit of nitre, by heating them together in a matraſs, the ſtronger vitriolic acid will be diſplaced by the weaker nitrous one, and the liquor, on cooling, will ſhoot into cryſtals of nitre. The ſame thing happens alſo upon diſſolving vitriolated tartar, or Glauber's ſalt, in ſpirit of ſalt. This obſervation we owe to Monſ. Beaumé, and the reaſon of it has been already explained. See n° 285.

1042 Decompoſition of vitriolic ſalts by ſolutions of earth, &c. in nitrous or marine acids.

3. If vitriolated tartar, or Glauber's ſalt, is diſſolved in water, and this ſolution mixed with another conſiſting of calcareous earth, ſilver, mercury, lead, or tin, diſſolved in the nitrous or marine acids, the vitriolic acid will leave the fixed alkali with which it was combined, and, uniting with the calcareous earth or metal, fall with it to the bottom of the veſſel. This decompoſition takes place only when the vitriolic acid meets with ſuch bodies as it cannot eaſily diſſolve into a liquid, ſuch as thoſe we have juſt now mentioned; for though vitriolated tartar is mixed with a ſolution of iron, copper, &c. in the nitrous or marine acids, no decompoſition takes place. The caſe is not altered, whatever acid is made uſe of; for the marine acid will effectually ſeparate ſilver, mercury, or lead, from the vitriolic or nitrous acids.

1043 By lime-water.

4. According to Dr Lewis, if a ſolution of vitriolated tartar is dropt into lime-water, the acid will unite with the lime, and precipitate with it in an indiſſoluble ſelenite, the alkali remaining in the water in a pure and cauſtic ſtate.

1044 Of green vitriol by ſaccharum ſaturni.

5. If green vitriol is mixed with any ſolution containing ſubſtances which cannot be diſſolved into a liquid by the vitriolic acid, the vitriol will be immediately decompoſed, and the liquor will become a ſolution of iron only. Thus, if green vitriol is mixed with a ſolution of ſaccharum ſaturni, the vitriolic acid immediately quits the iron for the lead, and falls to the bottom with the latter, leaving the vegetable acid of the ſaccharum ſaturni to combine with the iron.

Phenomena from mixtures of acids, &c. ſalts.

1045 Of ſolution of tin by ſaccharum ſaturni.

6. If ſolution of tin in aqua-regia is mixed with ſolution of ſaccharum ſaturni, the marine acid quits the tin for the lead contained in the ſaccharum; at the ſame time, the acetous acid, which was combined with the lead, is unable to diſſolve the tin which was before kept ſuſpend by the marine acid. Hence, both the ſaccharum ſaturni, and ſolution of tin, are very effectually decompoſed, and the mixture becomes entirely uſeleſs. Dyers and callico-printers ought to attend to this, who are very apt to mix theſe two ſolutions together; and no doubt many of the faults of colours dyed or printed in particular places, ariſe from injudicious mixtures of a ſimilar kind. See DYEING.

1046 Of calcareous ſolutions by mild volatile alkali.

7. If mild volatile alkali, that is, ſuch as remains in a concrete form, by being united with a large quantity of fixed air, is poured into a ſolution of chalk in the nitrous or marine acids, the earth will be precipitated, and a true ſal ammoniac formed. If the whole is evaporated to dryneſs, and a conſiderable heat applied, the acid will again part with the alkali, and combine with the chalk. Thus, in the purification of volatile alkalies by means of ſpirit of ſalt, the ſame quantity of acid may be made to ſerve a number of times. This will not hold in volatile ſpirits prepared with quicklime.

1047 Sal alembroth.

8. If equal parts of ſal ammoniac and corroſive ſublimate mercury are mixed together and ſublimed, they unite in ſuch a manner as never to be ſeparable from one another without decompoſition. The compound is called *ſal alembroth*; which is ſaid to be a very powerful ſolvent of metallic ſubſtances, gold itſelf not excepted. Its powers in this, or any other reſpect, are at preſent but little known. By repeated ſublimations, it is ſaid this ſalt becomes entirely fluid, and refuſes to ariſe in the ſtrongeſt heat.

1048 Solution of ſalts promoted by vitriolic acid.

9. If vitriolic acid is poured upon any ſalt difficult of ſolution in water, it becomes then very eaſily ſoluble. By this means, vitriolated tartar, or cream of tartar, may be diſſolved in a very ſmall quantity of water.

SECT. II. *Earths.*

THE general diviſions and characters of theſe ſubſtances we have already given; and moſt of their combinations with ſaline ſubſtances have been mentioned, excepting only thoſe of the terra ponderoſa; a ſubſtance whoſe properties have been but lately inquired into, and are not yet ſufficiently inveſtigated. In this ſection, therefore we have to take notice only of their various combinations with one another, with inflammable, or metallic ſubſtances, &c. As they do not, however, act upon one another till ſubjected to a vitrifying heat, the changes then induced upon them come more properly to be treated of under the article GLASS. Upon metallic and inflammable ſubſtances (ſulphur alone excepted), they have very little effect; and therefore what relates to theſe combinations ſhall be taken notice of in the following ſections. We ſhall here confine ourſelves to ſome remarkable alterations in the nature of particular earths by combination with certain ſubſtances, and to the phoſphoric quality of others.

§ 1. *The Terra Ponderosa.*

1049 Uſually found united with the vitriolic acid.

This earth is of the true calcareous kind, and capable of being converted into a very acrid lime; but in other reſpects is very different. It is moſt commonly met with in the veins of rocks, united with the vitriolic acid in a maſs ſomewhat reſembling gypſum, but much heavier and more opaque; and from the great weight of this ſubſtance the earth itſelf has its name, though when freed from the acid it is by no means remarkable for this property. Its properties were firſt taken notice of by the foreign chemiſts; but they have been more accurately inveſtigated by Dr Withering, who has publiſhed his obſervations in the 74th volume of the Philoſophical Tranſactions. His experiments were not made on the gypſeous ſubſtance abovementioned; but on a combination of the earth with fixed air, which is much more uncommon, and like the other poſſeſſes a very conſiderable degree of ſpecific gravity. Both theſe combinations have the general name of *ſpathum ponderoſum*, or *ponderous ſpar;* the former being alſo called *baroſelenite*, &c.

1050 Dr Withering's experiment.

1051 Combination of terra ponderoſa with aërial acid deſcribed.

The ſpar uſed by Dr Withering was got out of a lead mine at Alſton moor in Cumberland. Its appearance was not unlike that of a lump of alum; but on cloſer inſpection it appeared to be compoſed of ſlender ſpiculæ in cloſe contact, more or leſs diverging, and ſo ſoft that it might be cut by a knife; its ſpecific gravity from 4.300 to 4.338. It efferveſced with acids, and melted, though not very readily, under the blow-pipe.

1052 Effects of fire upon it.

In a common fire it loſt its tranſparency; and on being urged with a ſtronger heat in a melting furnace, it adhered to the crucible, and ſhowed ſigns of fuſion; but did not appear to have loſt any of its fixed air, either by diminution in weight, becoming cauſtic, or loſing its power of efferveſcing with acids.

1053 Treated with marine acid.

Five hundred grains of this ſpar, by ſolution in muriatic acid, loſt 104 grains in weight, and left an inſoluble reſiduum of three grains. In another experiment, 100 grains of ſpar loſt 21; and there remained only 0.6 of a grain of inſoluble matter.

On diſſolving another hundred grains in dilute muriatic acid, 25 ounce-meaſures of air were obtained, which by proper trials appeared to be pure aërial acid; and, on precipitating the ſolution with mineral alki, 100 grains of earth were again obtained; but on diſſolving the precipitate in freſh muriatic acid, only 20 ounce-meaſures of air were produced.

1054 Precipitated by mild and cauſtic fixed alkalies.

Mild vegetable alkali precipitated a ſaturated ſolution of this ſpar in marine acid, with the eſcape of a quantity of fixed air; and the ſame effect took place on the addition of foſſil alkali; but with cauſtic alkalies there was no appearance of efferveſcence, though a precipitate likewiſe fell.

Fifty parts of ſpar, diſſolved in marine acid, loſt $10\frac{1}{2}$; and with cauſtic vegetable alkali, a precipitate weighing $45\frac{1}{2}$ was obtained. Phlogiſticated alkali precipitated the whole of the earth, as appeared by the addition of mild fixed alkali afterwards, which occaſioned no farther precipitation.

1055 Convertible into lime capable of decompoſing vitriolic ſalts.

Part of the precipitate thrown down by the mild alkali was expoſed to a ſtrong heat in a crucible, and then put into water. The liquid was inſtantly converted into a very acrid lime-water, which had the following remarkable properties: The ſmalleſt portion of vitriolic acid, added to this water, occaſioned an immediate and copious precipitation, which appeared even after the liquid was diluted with 200 times its bulk of pure water. 2. A ſingle drop let fall into a ſolution of Glauber's ſalt, vitriolated tartar, alum, vitriolic ammoniac, Epſom ſalt, or ſelenite, occaſioned an immediate and copious precipitate in all of them: the reaſon of which was the ſuperior attraction of the ponderous earth for the acid of theſe ſalts, which forming with it an indiſſoluble concrete, inſtantly fell to the bottom.

1056 Inſoluble precipitate thrown down by cauſtic alkali.

The precipitate thrown down by the cauſtic vegetable alkali was put into water, but exhibited no ſuch appearances as the other: even the mixture was boiled; nor had it any acrimonious taſte. On adding the three mineral acids to ſeparate portions of the precipitate itſelf, neither efferveſcence, nor any ſign of ſolution, appeared. After ſtanding an hour, water was added, and the acids were ſuffered to remain another hour on the powder; but on decanting them afterwards, and adding foſſile alkali to the point of ſaturation, no precipitate appeared.

The precipitate thrown down by the phlogiſticated alkali, mixed with nitre and borax, and melted with a blow-pipe on charcoal, formed a black glaſs; on flint-glaſs, a white one; and on a tobacco-pipe, a yellowiſh white one. Another portion, melted with ſoap and borax in a crucible, formed a black glaſs.

The ſmall quantity of inſoluble reſiduum formerly mentioned, appeared to be the combination of ponderous earth with vitriolic acid, called *heavy* gypſum, marmor metallicum, baroſelenite, *&c.*

1057 Analyſis and properties of aërated ponderous ſpar.

From theſe experiments the Doctor concludes, that 100 parts of this ſpar contain 78.6 of pure ponderous earth, $\frac{6}{10}$ of a grain of marmor metallicum, and 20.8 grains of fixed air. 2. The quantity of mild alkali neceſſary to ſaturate any given portion of acid, contains a greater quantity of fixed air than can be abſorbed by that quantity of terra ponderoſa which the acid is able to diſſolve. 3. The terra ponderoſa, when precipitated by means of a mild alkali, readily burns to lime; and this lime-water proves a very nice teſt of the preſence of vitriolic acid. 4. In its native ſtate the terra ponderoſa will not burn to lime; when urged with a ſtrong fire, it melts and unites with the crucible, without becoming cauſtic; nor can it be made to part with its fixed air by any addition of phlogiſton. He conjectures, therefore, that as cauſtic lime cannot unite to fixed air without moiſture, and as this ſpar ſeems to contain no water in its compoſition, it is the want of water which prevents the fixed air aſſuming its elaſtic aerial ſtate. "This ſuppoſition (ſays he) becomes ſtill more probable, if we obſerve, that when the ſolution of the ſpar in an acid is precipitated by a mild alkali, ſome water enters into the compoſition of the precipitate; for it has the ſame weight as before it was diſſolved, and yet produces only 20 ounce-meaſures of fixed air, while the native ſpar contains 25 of the ſame meaſures: ſo that there is an addition of weight equal to five ounce-meaſures of air, or three one-half grains, to be accounted for; and this can only ariſe from the water. 5. The precipitate formed by the cauſtic alkali, taking ſome of the latter down with it, forms a ſubſtance neither ſoluble in acids nor water. This inſoluble compound is alſo formed by adding the lime-water already

Terra ponderoſa and its combinations.

1058 Terra ponderoſa a teſt of the preſence of vitriolic acid.

1059 White matter contained in vitriolic acid found to be gypſum.

ready mentioned, to a ſolution of cauſtic vegetable, or foſſile fixed alkali, but not with volatile alkali. 6. Fixed vegetable as well as mineral alkali, and even volatile alkalies, whether mild or cauſtic, are capable of ſeparating terra ponderoſa from any other acid excepting the vitriolic; but from it neither mild nor cauſtic alkalies are capable of ſeparating this earth, excepting the vegetable fixed alkali, which will partly do it by an intenſe heat in the dry way. 7. This earth affords an excellent method of purifying the nitrous and marine acids from any portion of the vitriolic; for the attraction between terra ponderoſa and this acid is ſo ſtrong, that the leaſt portion of the latter will be inſtantly detected by the lime-water above mentioned. The vitriolic acid, Dr Withering obſerves, is commonly adulterated with a white powder, which diſcovers itſelf by turning the liquor milky when the acid is diluted with water; and this powder he finds to be gypſum, from the following properties:

1. By repeated boiling in water, ſix grains and a half were reduced to two. 2. By gentle evaporation this ſolution afforded five grains of cryſtals as hard and taſteleſs as ſelenite. 3. A precipitate was formed by mild foſſile alka on adding it to a ſolution of theſe cryſtals in water. 4. On expoſing this powder to a pretty ſtrong heat, and then putting it into water, the latter became acrid, and acquired the taſte of lime-water. 5. The inſoluble part ſuffered no change by boiling in nitrous acid: one half of it mixed with borax, and expoſed to the blow-pipe upon charcoal, melted into glaſs; the other half, mixed with borax, and expoſed to the blow-pipe upon charcoal, did the ſame; whence it appears, ſays our author, that the greateſt part of this ſubſtance was calx vitriolate or ſelenite; the remainder a vitrifiable earth. He had before found, that the heavy gypſum, or marmor metallicum, would diſſolve in concentrated vitriolic acid, but always ſeparated upon the addition of water; and from his experiments it now appears that ſelenite does the ſame.

1060 Experiments on the marmor metallicum.

1061 Deſcription of a kind found near Edinburgh.

Dr Withering next proceeds to give a ſet of experiments on the heavy gypſum, marmor metallicum of Cronſtadt, or the Baroſelenite of others, already mentioned. The ſpecimens he obtained were from Kilpatrick hills near Glaſgow, and a ſort with ſmaller cryſtals found among the iron ore about Ketley in Shropſhire, and in the lead-mines at Alſton-Moor. He deſcribes it as white, nearly tranſparent, but without the property of double refraction; compoſed of laminæ of rhomboidal cryſtals, and decrepitating in the fire; the ſpecific gravity from 4.402 to 4.440. The ſpecimens we have ſeen differ conſiderably from this deſcription, being compoſed, to appearance, of thin laminæ; which all together form a very opaque white maſs, which has not the leaſt tranſparency unleſs ſplit exceſſively thin. They are found about three miles to the ſouthweſt of Edinburgh, near Pentland hills, and likewiſe betwixt Edinburgh and Leith. In the former place they lie in ſmall veins of a rock conſiſting of a kind of iron ſtone, and ſo cloſely adhering to it, that it would ſeem either that the ſtone is converted into the ſpathum ponderoſum, or the latter into the ſtone. It is therefore often intermixed with the rock ſo intimately, that it is impoſſible to ſeparate them perfectly from each other.

Terra ponderoſa and its combinations.

1062 Effects of heat upon it.

1063 May be diſſolved in very concentrated vitriolic acid.

Dr Withering having expoſed 100 grains of the marmor metallicum to a red heat for an hour, in a black crucible, found that it had loſt five grains of its weight; but as a ſulphureous ſmell was perceptible, he ſuſpected that a decompoſition had taken place, and therefore expoſed another portion to a ſimilar heat in a tobacco-pipe, which had no ſmell of ſulphur, nor was it diminiſhed in weight. It melted with borax into a white opaque glaſs, but was barely fuſible by itſelf under the blow pipe. It did not ſeem to diſſolve in water, nor in any of the acids, except the vitriolic, when by long boiling it had become very concentrated and almoſt red hot. It then appeared perfectly diſſolved; but ſeparated again unchanged on the addition of water. On expoſing the vitriolic ſolution to the atmoſphere for ſome days, beautiful radiated cryſtals were formed in it.

1064 Precipitated from it unchanged by vegetable fixed alkali.

1065 May be decompoſed in the dry way by ſalt of tartar.

On adding a ſolution of mild vegetable alkali to this vitriolic ſolution, a precipitate appeared; but it conſiſted of marmor metallicum unchanged. An ounce of it in fine powder was then fuſed with two of ſalt of tartar until it ran thin, when ſix drachms of a reſiduum inſoluble in water were left. On the addition of nitrous acid, only 52 grains were left, which appeared to be marmor metallicum unchanged. On ſaturating the alkaline ſolution with diſtilled vinegar, and waſhing the precipitate, the liquor was found to contain terra foliata tartar, formed by the union of the acetous acid with part of the alkali; and of vitriolated tartar, formed by that of the alkali with the native acid of the marmor metallicum.

1066 Nitrous ſolution ſhoots into fine cryſtals.

The ſalt formed by the nitrous acid ſhot readily into beautiful permanent cryſtals of a rough bitteriſh taſte. Some of the ſalt deflagrated with nitre and charcoal, left by waſhing the terra ponderoſa very white, capable of being burnt into lime, and again forming an inſoluble compound with vitriolic acid. An hundred grains of aerated terra ponderoſa, diſſolved in marine acid, and precipitated by the vitriolic, were augmented 17 grains in weight. Hence it appears,

1067 Analyſis and properties of the marmor metallicum.

1. That the marmor metallicum is compoſed of vitriolic acid and terra ponderoſa. 2. That this compound has very little ſolubility in water. 3. That it can only be diſſolved in highly concentrated oil of vitriol, from which it ſeparates unchanged on the addition of water. 4. That it cannot be decompoſed in the moiſt way, by mild fixed alkali, though it may be ſo in the dry. 5. That it may be decompoſed by the union of inflammable matter to its acid, by which ſulphur is formed, though the acid cannot be diſſipated by mere heat. 6. An hundred parts of this ſubſtance contain 32.8 of pure vitriolic acid, and 57.2 of terra ponderoſa. The marmor metallicum, our author remarks, may poſſibly be uſeful in ſome caſes where a powerful flux is wanted; for having mixed ſome of it with the black flux, and given the mixture a ſtrong heat in a crucible, it ran entirely through the pores of the veſſel.

1068 Cauk, a ſubſtance of this kind, found in Derbyſhire in England.

Dr Withering deſcribes two other kinds of this ſubſtance, known by the name of *cauk*, and found in the mines of Derbyſhire, and other places. Theſe differ from the other only in containing a ſmall proportion of iron. On the whole, he concludes, that "the terra ponderoſa ſeems to lay claim to a middle place betwixt the earths and metallic calces. Like the for-

Tranſmutation of flints into an earth ſoluble in acids.

mer it cannot be reduced to a metallic form, though like the latter it may be precipitated by phlogiſticated alkali. In many of its properties it much reſembles the clax of lead, and in others the common calcareous earth. Its moſt remarkable properties are its decompoſing the vitriolic neutral ſalts, and forming, with the nitrous and marine acids, cryſtals which do not deliqueſce.

§ 2. *Tranſmutation of* Flints *into an* Earth *ſoluble in Acids.*

1069 Solution of flint.

This is effected by mixing powdered flints with alkaline ſalt, and melting the mixture by a ſtrong fire. The melted maſs deliquates in the air, like alkaline ſalts; and if the flint is then precipitated, it becomes ſoluble in acids, which it entirely reſiſted before.

In this proceſs the alkali, by its union with the flint, is deprived of its fixed air, and becomes cauſtic. To this cauſticity its ſolvent power is owing; and therefore the flint may be precipitated from the alkali, not only by acids, but by any ſubſtance capable of furniſhing fixed air; ſuch as magneſia alba or volatile alkali. The precipitate in both caſes proves the ſame; but the nature of it hath not hitherto been determined. Some have conjectured that the vitriolic acid exiſted in the flint; in which caſe, the alkali made uſe of in this proceſs ought to be partly converted into vitriolated tartar.

1070 Solubility of this earth denied by Mr Bergman.

The above proceſs is delivered on the authority of former chemiſts; but Mr Bergman, who has publiſhed a diſſertation on this ſubject, aſſerts that it cannot be diſſolved except by the fluor acid. The vitriolic, nitrous, or marine acids, have no effect upon it, even when newly precipitated from the liquor of flints waſhed and ſtill wet, and though a thouſand parts of acid be added to one of the earth, and boiled upon it for an hour: but when three parts of alkaline ſalt are melted in a crucible with one of quartz, the ſalt diſſolves at the ſame time about ſeven hundreth parts of its own weight of the clay which compoſes the crucible; and the ſolubility of this has given occaſion to the miſtake abovementioned. If the fuſion be performed in an iron veſſel, no ſoluble part will be obtained, excepting the very ſmall portion of clay which the quartz contains; and when this is once exhauſted by an acid, no more can be procured by any number of fuſions with alkali.

1071 Reaſon of the miſtake of former chemiſts.

1072 Cryſtals of flint artificially formed by Mr Bergman.

The fluor acid, he obſerves, is never obtained entirely free from ſiliceous earth, and conſequently its power as a menſtruum muſt be weakened in proportion to the quantity it contains. In order to obſerve its ſolvent power, however, our author, in the year 1772, put ſome quartz, very finely powdered, into a bottle containing $\frac{1}{8}$ of a kanne of fluor acid. The bottle was then ſlightly corked, and ſet by in the corner of a room. Two years afterwards it was examined; and on pouring out the liquor there were found concreted at the bottom of the veſſel, beſides innumerable ſmall priſmatic ſpiculae, 13 cryſtals of the ſize of ſmall peas, but moſtly of an irregular form. Some of theſe reſembled cubes, whoſe angles were all truncated, ſuch as are often found in the cavities of flints. Theſe were perfect ſiliceous cryſtals, and very hard, but not comparable with quartz, though they agreed with it in eſſential properties. "Poſſibly (ſays he) the length of a century may be neceſſary for them to acquire, by exſiccation, a ſufficient degree of hardneſs. The bottom itſelf, as far as the liquor had reached, was found covered with a very thin ſiliceous pellicle, which was ſcarcely viſible, but ſeparated on breaking the bottle. It was extremely pellucid, flexible, and ſhowed priſmatic colours. Theſe phenomena ſhow that much ſiliceous matter is diſſolved and ſuſpended." (in the fluor acid). "Whether any of the quartz was taken up in this experiment is uncertain; but it appears probable that little or none was diſſolved; ſince, by the help of heat during the diſtillation, the acid had previouſly taken up ſo much ſiliceous earth, that upon ſlow evaporation it was unable to retain it. Hence appears the origin of the cryſtals and the pellicle; and hence appears the cauſe which impedes the action of fluor acid upon flint; namely, that the acid obtained in the ordinary way is already ſaturated with it.

1073 Why the fluor acid will not diſſolve flint directly.

1074 Siliceous earth moſt completely precipitated by volatile alkali.

The volatile alkali precipitates ſiliceous earth moſt completely from fluor acid: and thus we find, that one part of it is contained in 600 of the acid, diluted to ſuch a degree, that its ſpecific gravity is only 1.064. This precipitate has all the properties of pure flint; but that precipitated either by vegetable or mineral fixed alkali does not afford a pure ſiliceous earth, but a peculiar kind of triple ſalt, formed of the earth, fluor acid, and fixed alkali, which diſſolves, though with difficulty, in warm water, eſpecially the earth procured by vegetable alkali, but is eaſily decompoſed by lime-water and lets fall the mineral fluor regenerated.

1075 A triple ſalt formed by precipitation with fixed alkali.

1076 Siliceous earth diſſolved by boiling in ſolution of alkali.

Fixed alkaline ſalts attack this earth by boiling, but not unleſs it be reduced to very fine powder, and newly precipitated from the liquor. Oil of tartar per deliquium takes up about one-ſixth of its weight, and the liquor becomes gelatinous on cooling, though at firſt diluted with 16 times its weight of water. This ſolution is effected only by the cauſtic part; for when fully ſaturated with fixed air, it cannot enter into any union with it. Volatile alkali, even though cauſtic, has no effect.

1077 Has a remarkable attraction for it in the dry way.

The attraction betwixt ſiliceous earth and fixed alkali is much more remarkable in the dry way; for thus it melts with one half its weight of alkali into an hard, firm, and tranſparent glaſs, the aerial acid and water going off in a violent efferveſcence. In proportion as the alkali is increaſed, the glaſs becomes more ſoft and lax, until at laſt it diſſolves totally in water, as has been already mentioned. The ſiliceous matter thus precipitated is of a very rare and ſpongy texture, and ſo much ſwelled by water, and its bulk when wet is at leaſt twelve times greater than when dry; nor does it contract more though ſuffered to remain a long time in the water. Hence it is eaſy to reduce the liquor of flints to a jelly, by diluting it with four or eight times its weight of water, and adding a ſufficient quantity of precipitate; but if an overproportion of water be uſed, for inſtance, 24 times the weight, the liquor will then remain limpid though we add as much acid as is ſufficient for ſaturating the alkali. The reaſon of this Mr Bergman ſuppoſes to be, that the ſiliceous particles are removed to ſuch a diſtance from one another, that they cannot overcome the

1078 Is very rare and ſpongy when precipitated.

1079 Why it cannot ſometimes be precipitated by an acid without heat.

the friction they muſt neceſſarily meet with in their paſſage downwards through the fluid; but if the liquor be boiled, which at once diminiſhes its quantity and tenacity, the ſiliceous matter is inſtantly ſeparated.

1080 **Liquor of flints decompoſed by too great a quantity of water, and by fluor acid**

Liquor of flints is alſo decompoſed by too great a quantity of water; for by this the efficacy of the menſtruum is weakened, and it is alſo partly ſaturated by the aerial acid contained in the water. A precipitate alſo falls when the fluor acid is made uſe of; the reaſon of which is the ſame as the precipitation by other acids: in this caſe, however, the alkali makes part of the precipitate, as has been already obſerved; and therefore the matter which falls is fuſible before the blowpipe, and ſoluble in a ſufficient quantity of water.

§ 3. *Of* PHOSPHORIC *Earths.*

1081 **Bolognian ſtone.**

THESE are ſo called from their property of ſhining in the dark. The moſt celebrated and anciently known of this kind is that called the *Bolognian ſtone*, from Bologna, a city in Italy, near which it is found. The diſcovery, according to Lemery, was accidentally made by a ſhoe-maker called *Vincenzo Caſciarolo*, who uſed to make chemical experiments. This man, having been induced to think, from the great weight and luſtre of theſe ſtones, that they contained ſilver, gathered ſome, and calcined them; when carrying them into a dark place, probably by accident, he obſerved them ſhining like hot coals.

Mr Margraaf deſcribes the Bolognian ſtone to be an heavy, ſoft, friable, and cryſtallized ſubſtance, incapable of effervescence with acids before calcination in contact with burning fuel. Theſe properties ſeem to indicate this ſtone to be of a ſelenitic or gypſeous nature.

1082 **How rendered luminous.**

When theſe ſtones are to be rendered phoſphoric, ſuch of them ought to be choſen as are the cleaneſt, beſt cryſtallized, moſt friable and heavy; which exfoliate when broken, and which contain no heterogeneous parts. They are to be made red hot in a crucible; and reduced to a very fine powder in a glaſs-mortar, or upon a porphyry. Being thus reduced to powder, they are to be formed into a paſte with mucilage of gum tragacanth, and divided into thin cakes. Theſe are to be dried with a heat, which at laſt is to be made pretty conſiderable. An ordinary reverberating furnace is to be filled to three quarters of its height with charcoal, and the fire is to be kindled. Upon this charcoal the flat ſurfaces of the cakes are to reſt, and more charcoal to be placed above them, ſo as to fill the furnace. The furnace is then to be covered with its dome, the tube of which is to remain open; all the coal is to be conſumed, and the furnace is to be left to cool; the cakes are then to be cleanſed from the aſhes by blowing with bellows upon them. When they have been expoſed during ſome minutes to light, and afterwards carried to a dark place, they will ſeem to ſhine like hot coals; particularly if the perſon obſerving them has been ſome time in the dark, or have ſhut his eyes, that the pupils may be ſufficiently expanded. After this calcination through the coals, if the ſtones be expoſed to a ſtronger calcination, during a full half hour, under a muffle, their phoſphoric quality will be rendered ſtronger.

1083 **Analyſis of the phoſphorus.**

From attending to the qualities of this ſtone, and the requiſites for making this phoſphorus, we are naturally led to think, that the Bolognian phoſphorus is no other than a compoſition of ſulphur and quicklime. The ſtone itſelf, in its natural ſtate, evidently contains the vitriolic acid, from its not effervescing with acids of any kind. This acid cannot be expelled from earthy ſubſtances by almoſt any degree of fire, unleſs inflammable matter is admitted to it. In this caſe, part of the acid becomes ſulphureous, and flies off; while part is converted into ſulphur, and combines with the earth. In the abovementioned proceſs, the inflammable matter is furniſhed by the coals in contact with which the cakes are calcined, and by the mucilage of gum tragacanth with which the cakes are made up. A true ſulphur muſt therefore be formed by the union of this inflammable matter with the vitriolic acid contained in the ſtone; and part of this ſulphur muſt remain united to the earth left in a calcareous ſtate, by the diſſipation, or converſion into ſulphur, of its acid.

1084 **All calcareous ſtones phoſphoric, according to Mr du Fay.**

In the year 1730, a memoir was publiſhed by Mr du Fay; wherein he aſſerts, that all calcareous ſtones, whether they contain vitriolic acid or not, are capable of becoming luminous by calcination: with this difference only, that the pure calcareous ſtones require a ſtronger, or more frequently repeated, calcination to convert them into phoſphorus; whereas thoſe which contain an acid, as ſelenites, gypſum, ſpars, *&c.* become phoſphoric by a ſlighter calcination. On the contrary, Mr Margraaf aſſerts, that no other ſtones can be rendered phoſphoric but thoſe which are ſaturated with an acid; that purely calcareous ſtones, ſuch as marble, chalk, limeſtone, ſtalactites, *&c.* cannot be rendered luminous, till ſaturated with an acid previouſly to their calcination.

We have already taken notice, that the compounds formed by uniting calcareous earths with the nitrous and marine acids become a kind of phoſphori; the former of which emits light in the dark, after having been expoſed to the ſun through the day; and the latter becomes luminous by being ſtruck. **1085 Signior Beccaria's obſervation.** Signior Beccaria found, that this phoſphoric quality was capable of being given to almoſt all ſubſtances in nature, metals perhaps excepted. He found that it was widely diffuſed among animals, and that even his own hand and arm poſſeſſed it in a very conſiderable degree. **1086 Mr Wilſon's experiments.** In the year 1775, a treatiſe on this kind of phoſphori was publiſhed by B. Wilſon, F. R. S. and member of the Royal Academy at Upſal. In this treatiſe he ſhows, that oyſter-ſhells, by calcination, acquire the phoſphoric quality in a very great degree, either when combined with the nitrous acid or without it.

The firſt experiment made by our author was the pouring ſome aquafortis, previouſly impregnated with copper, on a quantity of calcined oyſter-ſhells, ſo as to form them into a kind of paſte; he put this paſte into a crucible, which was kept in a pretty hot fire for about 40 minutes. Having taken out the maſs, and waited till it was cool, he preſented it to the external light. On bringing it back ſuddenly into the dark, he was ſurpriſed with the appearance of a variety of colours like thoſe of the rainbow, but much more vivid. In conſequence of this appearance of the priſmatic colours, he repeated the experiment in various ways, combining the calcined oyſter-ſhells with different metals and metallic ſolutions, with the different acids, alkaline and neutral ſalts, as well as with ſulphur, charcoal, and other inflammable ſubſtances; and by all of theſe he produced phoſphori, which emitted variouſly coloured light.

1087 Surpriſing phoſphoric quality of oyſter-ſhells.

What is more remarkable, he found that oyſter-ſhells poſſeſſed the phoſphoric quality in a ſurpriſing degree; and for this purpoſe nothing more was requiſite than putting them into a good ſea-coal fire, and keeping them there for ſome time. On ſcaling off the internal yellowiſh ſurface of each ſhell, they become excellent phoſphori, and exhibit the moſt vivid and beautiful colours. As we know that neither the vitriolic nor any other acid is contained in oyſter-ſhells, we cannot as yet ſay any thing ſatisfactory concerning the nature of this phoſphorus.

§ 4. *Of the* Vegetable *Earth.*

1088 DrLewis's opinion.

This is produced from vegetables by burning, and, when perfectly pure, by lixiviating the aſhes with water, to extract the ſalt; and then repeatedly calcining them, to burn out all the inflammable matter; and is perhaps the ſame from whatever ſubſtance it is obtained: in this ſtate, according to Dr Lewis, it is of the ſame nature with magneſia. In the ſtate, however, in which this earth is procurable by ſimply burning the plant, and lixiviating the aſhes, it is conſiderably different, according to the different plants from which it is obtained.

1089 Mr Gmelin's experiments.

The aſhes of mugwort, ſmall centaury, chervil, and dill, are of a browniſh grey; goat's beard and lungwort afford white aſhes; thoſe of ſanicle are whitiſh; thoſe of Roman wormwood of a greeniſh grey; thoſe of rue, agrimony, ſaxifrage, brown; thoſe of tanſey, of a duſky green; thoſe of dodder, of a fine green; eyebright, ſouthern-wood, common wormwood, and ſcabious, afford them grey; ſcurvy-graſs, of a whitiſh grey; hyſſop, yarrow, and ſowbane, of a duſky grey; melilot, and oak-leaves, as alſo plantain, colts-foot, pine-tops, and fumitory, of a duſky brown; penny-royal, of a pale brown, with ſome ſpots of white; elder-flowers, ſage, and mother of thyme, afford yellow aſhes; thoſe of ſtrawberry-leaves are of a pale brimſtone colour; thoſe of cat-mint, of a duſky red; of prunella, brick-coloured; of honey-ſuckle, blue; of fern, blackiſh; and thoſe of St John's wort, feverfew, origanum, and pimpernel, all of a deep black. The only uſe to which this kind of earth has yet been put, is that of glaſs-making and manure.

Sect. III. *Of Metallic Subſtances.*

§ 1. *Gold.*

This metal is reckoned of all others the moſt perfect and indeſtructible. When in its greateſt purity, it has very little elaſticity, is not ſonorous, its colour is yellow, it is exceedingly ſoft and flexible, and is more ductile than any other metal whatever. (See Gold *Leaf*, and Wire-Drawing.) Of all bodies it is the moſt ponderous, except platina; its gravity being to that of water, according to Dr Lewis, as 19,280, or 19,290, to one. For its fuſion it requires a low degree of white heat, ſomewhat greater than that in which ſilver melts. Whilſt fluid, it appears of a bluiſh green colour; when cold, its ſurface looks ſmooth, bright, and conſiderably concave: it ſeems to expand more in the act of fuſion, and to ſhrink more in its return to ſolidity, than any of the other metals; whence the greater concavity of its ſurface. Before fuſion it expands the leaſt of all metals, except iron. By ſudden cooling it becomes, as well as other metals, brittle; which effect has been erroneouſly attributed to the contact of fuel during fuſion.

1090 Unites readily with all the metals.

Gold amalgamates very readily with mercury, and mingles in fuſion with all the metals. It is remarkably diſpoſed to unite with iron; of which it diſſolves many times its own weight, in a heat not much greater than that in which gold itſelf melts; the mixture is of a ſilver colour, very brittle and hard. All the metals, except copper, debaſe the colour of gold; and, if their quantity is nearly equal to that of the gold, almoſt entirely conceal it.

1091 Said to loſe its malleability remarkably with tin.

The malleability of gold is impaired by all the metals, but leſs by copper and ſilver than any others. Tin has had a remarkably bad character in this reſpect; and it has been a received opinion among metallurgiſts, that the ſmalleſt quantity of this metal entirely deſtroys the ductility of gold; and Dr Lewis tells us, that "the moſt minute portion of tin or lead, and even the vapours which riſe from them in the fire, though not ſufficient to add to the gold any weight ſenſible on the tendereſt balance, make it ſo brittle, that it flies to pieces under the hammer."

1092 Mr Alchorne's experiments in oppoſition.

On ſo reſpectable an authority, this continued to be believed as an undoubted fact, until, in the year 1784, a paper appeared in the Philoſophical Tranſactions by Mr Alchorne of the mint: in which it was clearly diſproved by the following experiments:

1. Sixty Troy grains of pure tin were put into 12 ounces of pure gold in fuſion; after which the mixture was caſt into a mould of ſand, producing a flat bar an inch wide, and an eight of an inch thick. The bar appeared ſound and good, ſuffered flatting under the hammer, drawing ſeveral times between a pair of ſteel-rollers, and cutting into circular pieces of near an inch diameter, which bore ſtamping in the money-preſs by the uſual ſtroke, without ſhowing the leaſt brittleneſs, or rather with much the ſame ductility as pure gold.
2. With 90 grains of tin the bar was ſcarce diſtinguiſhable from the former.
3. With 120 grains it was rather paler and harder; and on drawing between the rollers the edges were a little diſpoſed to crack.
4. With 140 grains, the paleneſs, hardneſs, and diſpoſition to crack, were evidently increaſed; nevertheleſs it bore every other operation, even ſtamping under the preſs, without any apparent injury.
5. With an ounce of tin the bar was lead-coloured and brittle, ſplitting into ſeveral pieces on the firſt paſſing between the rollers.

1093 Gold not rendered brittle by the fumes of tin.

6. A ſmall crucible filled with ſtandard gold $\frac{11}{12}$ fine, was placed in a larger one, having in it an ounce of melted tin. The whole was covered with a large crucible inverted, in order to direct the fumes of the tin downward upon the gold. The metals were kept in fuſion

fuſion for half an hour, during which time a full quarter of the tin was calcined; yet the gold remained altogether unchanged.

7. The mixture of gold and tin produced in exp. 1. was melted a ſecond time in a ſtronger fire than at firſt, and kept in fuſion for half an hour; during which time ſix grains of weight were loſt, but the gold remained equally perfect as before.

1094 Nor by the addition of copper.

8. and 9. The mixtures of exp. 2. and 4. viz. 90 and 140 grains to 12 ounces of gold, were re-melted ſeparately, and an ounce of copper added to each. On being caſt as uſual, they bore all the operations of manufacturing as before, though ſenſibly harder. The laſt cracked at the edges as it had done without the copper, but bore cutting rather better than in its former ſtate.

10. and 11. A quarter of an ounce of the laſt mixture, being tin 140 grains, and copper an ounce, and gold 12 ounces, with as much of the bar from experiment 3. conſiſting of 140 grains of tin to 12 ounces of gold, were each melted by a jeweller in a common ſea-coal fire, into ſmall buttons, without any loſs of weight. Theſe buttons were afterwards forged into ſmall bars, nealing them often with the flame of a lamp, and afterwards drawn each about twenty times through the apertures of a ſteel plate, into fine wire, with as much eaſe as coarſe gold commonly paſſes the like operation.

12. Sixty grains of tin were added to 12 ounces of ſtandard gold $\frac{11}{12}$ fine; and the compound paſſed every one of the operations already deſcribed, without ſhowing the leaſt alteration from the tin.

1095 Malleability of gold deſtroyed by regulus of arſenic.

Several other trials were made with different mixtures of copper, tin, and ſilver, with gold, even as low as two ounces and a half of copper, with half an ounce of tin, to twelve ounces of gold; all of which bore hammering and flatting by rollers to the thinneſs of ſtiff paper, and afterwards working into watch-caſes, cane-heads, &c. with great eaſe. They grew more hard and harſh indeed in proportion to the quantity of alloy; but not one of them had the appearance of what workmen call brittle gold. Mr Alchorne therefore is of opinion, that when brittleneſs has been occaſioned by the addition of tin to gold, the former has been adulterated with arſenic; as he has found, that by adding 12 grains of regulus of arſenic to as many ounces of fine gold, the compound has been rendered altogether unmalleable,

1096 Surpriſing tenacity of its parts.

When gold is ſtruck during a certain time by a hammer, or when violently compreſſed, as by the wire-drawers, it becomes more hard, elaſtic, and leſs ductile; ſo that it is apt to be cracked and torn. Its ductility is, however, reſtored by the ſame means uſed with other metals, namely, heating it red hot, and letting it cool ſlowly. This is called *annealing* metals; and gold ſeems to be more affected by this operation than any other metal. The tenacity of the parts of gold is alſo very ſurpriſing; for a wire of $\frac{1}{10}$ of an inch in diameter will ſupport a weight of 500 pounds.

1097 Not liable to ruſt.

Gold is unalterable by air or water. It never contracts ruſt like other metals. The action of the fierceſt furnace-fires occaſions no alteration in it. Kunckel kept gold in a glaſs-houſe furnace for a month, and Boyle kept ſome expoſed to a great heat for a ſtill longer time, without the loſs of a ſingle grain. It is ſaid, however, to be diſſipable in the focus of a large burning mirror.

1098 Mr Boyle's experiments for the deſtructibility of gold.

Mr Boyle relates a very curious and extraordinary experiment, which he thought was ſufficient to prove the total deſtructibility of gold. About an eighth part of a grain of powder, communicated by a ſtranger, was projected upon two drachms of fine gold in fuſion, and the matter kept melted for a quarter of an hour. During the fuſion, it looked like ordinary gold; except only once, that his aſſiſtant obſerved it to look exactly of the colour of opal. When cold, it was of a dirty colour, and, as it were, overcaſt with a thin coat, almoſt like half-vitrified litharge: the bottom of the crucible was overlaid with a vitrified ſubſtance, partly yellow, and partly reddiſh brown; with a few ſmall globules, more like impure ſilver than gold. The metal was brittle, internally like braſs or bell-metal; on the touchſtone more like ſilver than gold: its ſpecific gravity was to that of water only as $15\frac{6}{5}$ to 1. There was no abſolute loſs of weight. By cupellation, 60 grains of this maſs yielded 53 grains of pure gold, with ſeven grains of a ponderous, fixed, dark-coloured ſubſtance.

1099 Solution in aqua-regia.

We have already mentioned, that in certain circumſtances gold is ſoluble in the nitrous and marine acids ſeparately. It is, however, always ſoluble by the two united, but diſſolves ſlowly even then. The moſt commodious method of obtaining this ſolution is, by putting the gold, either in leaves, or granulated, or cut into ſmall thin pieces, into a proper quantity of aquafortis; then adding, by degrees, ſome powdered ſal ammoniac, till the whole of the gold is diſſolved. By this means a much ſmaller quantity of the menſtruum proves ſufficient, than if the ſal ammoniac was previouſly diſſolved in the aquafortis; the conflict, which each addition of the ſalt raiſes with the acid, greatly promoting the diſſolution. Aquafortis of moderate ſtrength will, in this way, take up about one-third of its weight of gold; whereas an aqua-regis, ready prepared from the ſame aquafortis, will not take up above one-fifth its weight. Common ſalt anſwers better for the preparation of the aqua-regis than ſal ammoniac.

1100 Properties of the ſolution.

This ſolution, like all other metallic ones, is corroſive. It gives a violet colour to the fingers, or to any animal matters. If the ſolution is evaporated and cooled, yellow tranſparent cryſtals will be formed: but, if the evaporation is carried too far, the acids with which the gold is combined may be driven from it by heat alone; and the gold will be left in the ſtate of a yellow powder, called *calx of gold*.

1101 Gold precipitated from it.

Gold may be precipitated from its ſolution by thoſe ſubſtances which commonly precipitate metals, ſuch as alkaline ſalts and calcareous earths. It may alſo be precipitated in a fine purple powder, by tin or its ſolution.

When fixed alkalies are made uſe of, the precipitate weighs about one-fourth more than the gold employed. With volatile alkalies alſo, if they are added in no greater proportion than is ſufficient to ſaturate the acid, the quantity of precipitate proves nearly the ſame: but if volatile ſpirit is added in an over-proportion, it rediſſolves part of the gold which it had before precipitated, and the liquor becomes again conſiderably yellow. The whole of the precipitate, however,

ever, could not be rediſſolved, either by the mild or cauſtic alkali; nor did either of theſe ſpirits ſenſibly diſſolve or extract any tinge from precipitates of gold which had been thoroughly edulcorated with boiling water.

1102 Separated from other metals by vitriol of iron.

All the metallic bodies which diſſolve in aqua-regia, precipitate gold from it. Mercury and copper throw down the gold in its bright metalline form; the others, in that of a calx or powder, which has no metallic aſpect. Vitriol of iron, though it precipitates gold, yet has no effect upon any other metal; hence it affords an eaſy method of ſeparating gold from all other metals. The precipitation with tin ſucceeds certainly only when the metal in ſubſtance is uſed, and the ſolution of gold largely diluted with water. It is obſervable, that though the gold is precipitated from the diluted ſolution by tin, yet, if the whole is ſuffered to ſtand till the water has in a great meaſure exhaled, the gold is taken up afreſh, and only a white calx of tin remains.

1103 Aurum fulminans.

1104 Known in the 15th century.

1105 Baſil Valentine's directions for its preparation.

Gold precipitated from its ſolution in aqua-regia explodes by heat with much greater violence than any other ſubſtance in nature. This property was known in the 15th century; but whether the ancient alchemiſts knew any thing of it or not, is a matter of uncertainty. Baſil Valentine firſt gave any diſtinct account of it. He directs the gold to be diſſolved in aqua-regia made with ſal ammoniac, and then precipitated by vegetable fixed alkali, to be twelve times waſhed with water, and laſtly dried in the open air, where the ſun's rays cannot reach it. He forbids it to be dried over a fire, as it explodes with a gentle heat, and flies off with inconceivable violence.

1106 Uſe of volatile alkali but lately known.

Succeeding chemiſts have performed this operation with ſome little differences; but the neceſſity of employing volatile alkali was but little regarded till the beginning of the preſent century.

1107 Increaſe of the weight of gold by being changed into aurum fulminans.

1108 Prodigious force with which it explodes.

1109 Does not explode in cloſe veſſels.

1110 Heat requiſite for the exploſion.

1111 Explodes readily by friction.

1112 Inſtances of its miſchievous effects.

The calx of gold is always ſomewhat increaſed in weight by being converted into aurum fulminans; but authors are not agreed about the quantity of augmentation. Becher makes it heavier by one-fifth part; Lemery by one-fourth; and Juncker by one-fourth. All agree, however, that it explodes with a violence almoſt inconceivable. Crollius relates, that 20 grains of this powder explodes with more force than half a pound of gun powder, and exerts its force downwards, though M. Teykmeyer frequently ſhowed in his lectures that it would throw a florin upwards above ſix ells. A great number of experiments were made before the Royal Society at London, in order to determine the comparative forces of theſe two powders. Equal parts of gunpowder and aurum fulminans were included in iron globes placed among burning coals; thoſe which contained the former burſt with great violence, but the globes containing the aurum fulminans remained perfectly ſilent. But though no exploſion takes place in cloſe veſſels, the utmoſt caution is neceſſary in managing this ſubſtance in the open air; eſpecially when it is ſubjected to friction, or to a ſlight degree of heat; for ſuch is the nature of the calx we ſpeak of, that it is not neceſſary, in order to cauſe it explode, to touch it with an ignited ſubſtance, or to make it red-hot. The heat requiſite for this purpoſe is, according to Dr Lewis, intermediate between that of boiling water and the heat which makes metals of an obſcure red. With friction, however, it ſeems ſtill more dangerous; for in this caſe it explodes with what we ſhould think ſcarce ſufficient to communicate any degree of heat whatever. Orſchal relates, that this powder ground in a jaſper mortar, exploded with ſuch violence as to burſt the veſſel in a thouſand pieces; Dr Lewis gives an inſtance of a ſimilar kind in England; and Dr Birch tells us of doors and widows torn to pieces by the violence of this exploſive matter. Mr Macquer relates the following accident to which he was witneſs. "A young man, who worked in a laboratory, had put a drachm of fulminating gold into a bottle, and had neglected to wipe the inner ſurface of the neck of the bottle, to which ſome of the powder adhered. When he endeavoured to cloſe the bottle, by turning round the glaſs ſtopper, the friction occaſioned an exploſion of part of the powder. By this the young man was thrown ſome ſteps backward, his face and hands wounded by the fragments of the bottle, and his eyes put out; yet, notwithſtanding this violent exploſion, the whole drachm of fulminating gold certainly did not take fire as much of it was afterwards found ſcattered about the laboratory."

1113 Force of the exploſion is not directed entirely downwards.

It has already been mentioned, that ſome imagine the force of this exploſion to be directed downwards; but Dr Lewis is of opinion that it is equally directed every way. Certain it is, that the quantity of from 10 to 12 grains of aurum fulminans, exploded on a metalline plate, lacerates it; a ſmaller quantity forms a cavity, and a ſtill ſmaller only ſcratches the ſurface; effects which are never produced by gunpowder in ever ſo large a quantity. A weight laid upon the powder is thrown upwards in the moment of exploſion. If it be of ſilver or copper, this weight is marked with a yellowiſh ſpot, as the ſupports will alſo be, if made of either of theſe metals. A large grain, ſays Mr Bergman, brought near to the ſide of the flame of a candle, blows it out with great noiſe; and a few ounces exploding together by incautious drying, has been known to ſhatter the doors and windows of the apartment: hence it is evident, that aurum fulminans exerts its force in all directions; yet it cannot be denied, that it ſtrikes bodies with which it is in contact more violently than thoſe which are at a ſmall diſtance, though in its vicinity: thus, if a ſmall portion of it explodes in a paper box, it lacerates only the bottom, unleſs the top be preſſed down cloſe, in which caſe it perforates both the top and bottom. When carefully and gradually exploded in a glaſs phial or a paper box, it leaves a purple ſoot, in which are found many particles of ſhining gold; and if the quantity exploded be large, ſeveral grains remain totally unchanged, as it is only the lowermoſt ſtratum that is inflamed.

1114 Exploſion of moiſt aurum fulminans.

Aurum fulminans, when moiſt, does not explode at all: but as it dries, the grains go off in ſucceſſion like the decrepitation of common ſalt.—In glaſs veſſels cloſed, or with their mouths immerſed in water, it explodes, but with a very weak report. An elaſtic vapour, in the quantity of ſeven inches, from half a drachm of the powder, broke forth in the moment of exploſion, which, by our author's account, ſeems to be phlogiſticated air. In metallic veſſels ſufficiently ſtrong, the gold is ſilently reduced when they are perfectly

fectly ſound; but if they have any very ſmall chinks in them, the vapour makes its way through them with a hiſſing noiſe.

1115 Cauſe of this exploſion attributed to a ſaline principle.

1116 This opinion ſhown to be erroneous by Mr Bergman.

The cauſe of this extraordinary exploſive force of gold has been attributed chiefly to a ſaline principle, *viz.* The combination of nitrous acid with volatile alkali; and this opinion has been ſupported by an aſſertion, that the fulminating property is deſtroyed by treating the calx with vitriolic acid or with fixed alkali; the former expelling the nitrous acid, and the latter diſengaging the volatile alkali. Mr Bergman allows that fixed alkali deſtroys the fulminating property; but affirms, that it acts only by ſeparating the particles when the two are triturated together; and this might be done by many other ſubſtances as well as fixed alkali: But when the alkali, inſtead of being triturated in the dry way with the calx, was boiled in water along with it, the exploſion not only took place, but was much more violent than uſual. It muſt be obſerved, however, that heat alone deſtroys the fulminating property of this calx; and therefore, if the alkaline ſolution be made too ſtrong, the additional heat which it then becomes capable of ſuſtaining, is ſufficient to deprive the calx of its fulminating property. The caſe is the ſame with the vitriolic acid; for this has no effect upon the calx, either by digeſtion in its concentrated ſtate, or by boiling in its diluted ſtate. If it be boiled in its concentrated ſtate indeed with the fulminating calx, the heat conceived by the acid is ſufficient to deſtroy the fulminating property of the former; and in like manner, unleſs the calx be in ſome meaſure deſtroyed, or reduced to its metallic ſtate, it can never be deprived of its fulminating property.

1117 Aurum fulminans can be made without nitrous or marine acids.

It was further proved, that the fulminating property did not depend on the preſence either of nitrous or marine acids, for it can be made without them. A calx of gold, not fulminating, diſſolved in vitriolic acid, and precipitated by cauſtic volatile alkali, had acquired this property. A ſolution of the ſame calx in nitrous acid, let fall a precipitate by the addition of pure water; and this precipitate edulcorated, and digeſted with volatile alkali, fulminated as if it had been originally precipitated with that alkali. The experiment was repeated on the other non-fulminating precipitates with the ſame ſucceſs. Leſt any ſuſpicion, however, ſhould remain, that a ſmall quantity of aqua-regia might ſtill be left, which, by combining with the volatile alkali, would make a proportionable quantity of nitrum flammans, the precipitate was digeſted 24 hours in vitriolic acid, then waſhed in pure water, and immerſed in aqueous and ſpirituous ſolutions of alkali, both mild and cauſtic; but the event was the ſame. Laſtly, an inert calx of gold may always be made to fulminate by digeſting it with volatile alkali; nor can this property be communicated to it by any means without the uſe of this alkali.

1118 Fixed air not the cauſe of the exploſion.

It has been ſuppoſed by ſome very eminent chemiſts, among whom we may number Dr Black, that fixed air is the cauſe of the fulmination of gold: but it is evident that this cannot be the caſe: becauſe, 1. Gold fulminates as well when precipitated by the cauſtic volatile alkali, as by that which contains fixed air, 2. This metal does not combine, during precipitation, with fixed air. 3. Gold, when precipitated by mild fixed alkali, does not fulminate, unleſs the menſtruum contain volatile alkali.

1119 Menſtruum ſine ſtrepitu.

The fulminating calx of gold may be prepared either with the compound aqua-regia of pure nitrous and marine acids; of pure nitrous acid and ſal ammoniac; or of a compound of alum, nitre, and ſea-ſalt. When this kind of liquor is made uſe of, the acid of the alum expels the other two, and thus forms an aqua-regia. This was formerly called *menſtruum ſine ſtrepitu.* By whatever method the gold is diſſolved, it always affords a yellow calx with alkalies, but the volatile alkali moſt readily throws down the metal. Dephlogiſticated ſpirit of ſalt very readily diſſolves gold, and produces a fulminating precipitate as well as aqua-regia.

1120 Mr Bergman's theory of the cauſe of the exploſion.

We ſhall conclude this account of aurum fulminans with an abſtract of Mr Bergman's theory of the exploſion.—He obſerves, that volatile alkali contains phlogiſton; an undoubted proof of which is given by Dr Prieſtley, by coverting alkaline into phlogiſticated air. This phlogiſton, ſays he, may be ſeparated by means of a ſuperior attraction; ſo that the volatile alkali is decompoſed, and the reſiduum diſſipated in form of an elaſtic fluid, altogether ſimilar to that which is extricated during the fulmination: the ſource then from whence the elaſtic fluid is derived muſt be obvious; and it only remains to examine the medium by which the volatile alkali is dephlogiſticated.

'In thoſe metals which are called *perfect*, ſo great is the firmneſs of texture, and ſo cloſe the connection of the earthy principle with the phlogiſton, that by means of fire alone theſe principles cannot be diſunited: but when diſſolved by acid menſtrua, they muſt neceſſarily loſe a portion of their phlogiſton; and therefore, when afterwards precipitated by alkalies which cannot ſupply the loſs, they fall down in a calcined ſtate, though they attract phlogiſton ſo ſtrongly, that they can be reduced to a metallic ſtate, merely by an intenſe heat penetrating the veſſels. It may therefore be laid down as a fundamental poſition, that gold is calcined by ſolution.

1121 Volatile alkali the cauſe of the exploſion.

" Let us now conſider the conſequence of expoſing the powder conſiſting of calx of gold and volatile alkali intimately united, to an heat gradually increaſed. The calx which is united with the volatile alkali, by the aſſiſtance of a gentle heat, ſeizes its phlogiſton; and when this is taken away, the reſiduum of the ſalt is inſtantaneouſly expanded into the form of an elaſtic fluid, which is performed with ſo much violence, that the air muſt yield a very acute ſound."

1122 Volatile alkali exhibits a flaſh when thrown into a hot crucible.

1123 Great quantity of elaſtic fluid produced by aurum fulminans.

Our author proceeds to explain this phenomenon upon the principles aſſumed by him and Mr Scheele, of heat being a compoſition of light, and the phlogiſton or principle of inflammability; but as this hypotheſis is by no means ſatisfactory, we ſhall omit his reaſoning founded upon it: That the volatile alkali, however, is really capable of producing a flaſh is eaſily proved, becauſe it exhibits one when thrown into a hot crucible. A ſingle cubic inch of gun-powder generates about 244 of elaſtic fluid; but the ſame quantity of aurum fulminans yields at leaſt four times as much; and hence we may eaſily underſtand the difference in their exploſive force.

" That careful calcinations ſhould deſtroy the ful-

1124 Why ſlight calcination deſtroys the fulminating property.

minating property, is not to be wondered at, as the volatile alkali is the indiſpenſible material cauſe; but, the peculiar alacrity which it acquires before the exploſive force is totally extinguiſhed, depends upon the nature of the materials, and of the operation. Thus the heat, when inferior to that neceſſary for fulmination, acts upon both the principles of the aurum fulminans, it prepares the metallic calx for a more violent attraction for phlogiſton; it alſo acts upon the phlogiſton of the volatile alkali, and leſſens its connection; which two circumſtances muſt tend to the union producing the exploſion. But this effect has a maximum; and at this period the ſlighteſt friction ſupplies the defect of neceſſary heat, and produces the fulmination. The calcined gold alſo ſeems to collect and fix the matter of heat, though ſtill inſufficient by means of its phlogiſton, in a certain degree; ſo that by means of friction, though but very ſlight, it becomes capable of exerting its force; but when the heating is often repeated without procuring its effect, the volatile alkali is by degrees diſſipated, and at length ſo much diminiſhed that the calx becomes inert.

1125 Why it will not explode in cloſe veſſels.

“ But if aurum fulminans is capable of producing ſuch a prodigious quantity of elaſtic fluid, how does it happen that it remains mute and inert when reduced in cloſe veſſels? Of this the reaſon may be, that every elaſtic fluid, in the act of breaking forth, requires a ſpace to expand in; and if this be wanting, it remains fixed. Taking this for granted, a calx of gold cannot be reduced in cloſe veſſels either by heat or by the phlogiſton of volatile alkali; for in either caſe it muſt evolve its elaſtic fluid, which by ſuppoſition it cannot do. Nothing remains to ſolve this difficulty but the ignition of the ſurrounding metal; by means of which the calx, in virtue of its ſuperior attraction, ſeizes the phlogiſton of the metal, which that ſubſtance here, as well as in other inſtances, is capable of loſing without the eruption or abſorption of any fluid whatever.”

1126 Mr Bergman's opinions of the ſublimation of other calces.

Several chemiſts have aſſerted, that the calces of copper or ſilver may be made to fulminate like that of gold. But Mr Bergman informs us, that theſe experiments never ſucceeded with him; “ ſo (ſays he) they have either been ſilent upon ſome circumſtances neceſſary in the operation, or perhaps have been deceived by the detonation of nitrum flammans, or ſome other accidental occurrence. It is not ſufficient for the volatile alkali to adhere to the precipitate; for platina thrown down by this alkali retains a portion of it very obſtinately, but yet does not fulminate on the expoſure of fire —Beſides the preſence of volatile alkali, it ſeems to be neceſſary that the metallic calx ſhould be reducible by a gentle heat, in order to decompoſe it; but every exploſion is not to be derived from the ſame cauſes; nay, in this reſpect, aurum fulminans, gun-powder, and pulvis fulminans, differ very much, though they agree in ſeveral particulars.” Of late, however, it has been found that the calx of ſilver may be made to fulminate in a manner ſtill more extraordinary than that of gold. See the next article.

1127 Solution of gold by hepar ſulphuris.

If gold is melted with an hepar ſulphuris, compoſed of equal parts of ſulphur and fixed alkaline ſalt, the metal readily unites with it into an uniform maſs, capable of diſſolution in water without any ſeparation of its parts. The ſolution, beſides a nauſeous taſte from the ſulphur, has a peculiar penetrating bitterneſs, not diſcoverable in any other metalline ſolution made by the ſame means.

Though the compoſitions of ſulphur and alkali ſeem to unite more intimately with gold than any other metal, their affinity with it is but ſlight; copper, or iron, added to the matter in fuſion, diſunite, and precipitate the gold. The metal thus recovered, and purified by the common proceſſes, proves remarkably paler-coloured than at firſt. In an experiment related by Dr Brandt, in the Swediſh Memoirs, the purified gold turned out nearly as pale as ſilver, without any diminution of weight.

1128 Medicinal virtues of gold.

Gold has been thought to be poſſeſſed of many extraordinary virtues as a medicine; which, however, are long ago determined to be only imaginary. It is not indeed very eaſy to prepare this metal in ſuch a manner that it can be ſafely taken into the human body. The ſolution in aqua-regia is poiſonous; but if any eſſential oil is poured on this ſolution, the gold will be ſeparated from the acid, and united to the eſſential oil; with which, however, it contracts no laſting union, but in a few hours ſeparates in bright yellow film to the ſides of the glaſs. Vitriolic ether diſſolves the gold more readily and perfectly than the common eſſential oils; and keeps it permanently ſuſpended, the acid liquor underneath appearing colourleſs. The yellow ethereal ſolution poured off, and kept for ſome time in a glaſs ſtopt with a cork, ſo that the ſpirit may ſlowly exhale, yields long, tranſparent, priſmatic cryſtals, in ſhape like thoſe of nitre, and yellow like topaz. What the nature of theſe cryſtals is, either as to medicinal effects, or other purpoſes, is as yet unknown.

1129 Etheral ſolution.

Rectified ſpirit of wine mingles uniformly with the ſolution of gold made in acids: if the mixture is ſuffered to ſtand for ſome days in a glaſs ſlightly covered, the gold is by degrees revived, and ariſes in bright pellicles to the ſurface. Groſſer inflammable matters, wine, vinegar, ſolutions of tartar, throw down the gold, in its metallic form, to the bottom. Gold is the only metal which is thus ſeparable from its ſolution in acids by theſe ſubſtances; and hence gold may be purified by theſe means from all admixtures, and ſmall proportions of it in liquors readily diſcovered.

1130 Colour of gold reſtored.

When the colour of gold is by any means rendered pale, it may be recovered again by melting it with copper, and afterwards ſeparating the copper; or by a mixture of verdigris and ſal ammoniac with vitriol or nitre. The colour is alſo improved by fuſion with nitre, injecting ſal ammoniac upon it in the fuſion, quenching it in urine, or boiling it in a ſolution of alum. When borax is uſed as a flux, it is cuſtomary to add a little nitre or ſal ammoniac, to prevent its being made pale by the borax. Juncker reports, that by melting gold with four times its weight of copper, ſeparating the copper by aquafortis unpurified, then melting the gold with the ſame quantity of freſh copper, and repeating this proceſs eight or nine times, the gold becomes at length of a deep red colour, which ſuſtains the action of lead, antimony, and aquafortis.

§. 2. *Silver.*

1131 Ductility of ſilver. THIS, next to gold, is the moſt perfect, fixed, and ductile of all the metals. Its ſpecific gravity is to that of water nearly as 11 to 1. A ſingle grain has been drawn into a wire three yards long, and flatted into a plate an inch broad. In common fire it ſuffers no diminution of its weight; and, kept in the vehement heat of a glaſs-houſe for a month, it loſes no more than one ſixty-fourth. In the focus of a large burning-glaſs, it ſmokes for a long while, then contracts a greyiſh aſh on the ſurface, and at length is totally diſſipated.

Silver is ſomewhat harder and more ſonorous than gold, and is fuſible with a leſs degree of heat. The tenacity of its parts alſo is nearly one half leſs than that of gold; a ſilver wire of $\frac{1}{10}$ of an inch diameter being unable to bear more than 270 pounds.

Mercury unites very readily with ſilver-leaf, or with the calx of ſilver precipitated by copper; but does not touch the calces precipitated by alkaline ſalts. 1132 Effects of ſulphur on it. The vapours of ſulphureous ſolutions ſtain ſilver yellow or black. Sulphur, melted with ſilver, debaſes its colour to a leaden hue, renders it more eaſily fuſible than before, and makes it flow ſo thin as to be apt in a little time to penetrate the crucible: in a heat juſt below fuſion, a part of the ſilver ſhoots up, all over the ſurface, into capillary efflorefcence. Aquafortis does not act upon ſilver in this compound; but fixed alkaline ſalts will abſorb the ſulphur, and from a hepar ſulphuris, which, however, is capable of again diſſolving the metal. If the ſulphurated ſilver is mixed with mercury ſublimate, and expoſed to the fire, the mercury of the ſublimate will unite with the ſulphur, and carry it up in the form of cinnabar, whilſt the marine acid of the ſublimate unites with the ſilver into a luna cornea, which remains at the bottom of the glaſs. Fire alone is ſufficient, if continued for ſome time, to expel the ſulphur from ſilver.

1133 Purification. From the baſer metals, ſilver is purified by cupellation with lead. (See REFINING.) It always retains, however, after that operation, ſome ſmall portion of copper, ſufficient to give a blue colour to volatile ſpirits, which has been erroneouſly thought to proceed from the ſilver itſelf. It is purified from this admixture by melting it twice or thrice with nitre and borax. The ſcoria, on the firſt fuſion, is commonly blue; on the ſecond, green; and on the third, white, which is a mark of the purification being completed.

1134 Luna cornea reduced. The moſt effectual means, however, of purifying ſilver, is by reviving it from luna cornea; becauſe ſpirit of ſalt will not precipitate copper as it does ſilver. The ſilver may be recovered from luna cornea, by fuſion with alkaline and inflammable fluxes; but, in theſe operations, ſome loſs is always occaſioned by the diſſipation of part of the volatile calx, before the alkali or metal can abſorb its acid. 1135 Mr Margraaf's method. Mr Margraaf has diſcovered a method of recovering the ſilver with little or no loſs; mercury aſſiſted by volatile ſalts, imbibing it by trituration without heat. One part of luna cornea, and two of volatile ſalt, are to be ground together in a glaſs-mortar, with ſo much water as will reduce them to the conſiſtence of a thin paſte, for a quarter of an hour, or more; five parts of pure quickſilver are then to be added, with a little more water, and the triture to be continued for ſome hours. A fine amalgam will thus be obtained; which is to be waſhed with freſh parcels of water, as long as any white powder ſeparates. Nearly the whole of the ſilver is contained in the amalgam, and may be obtained perfectly pure by diſtilling off the mercury. The white powder holds a ſmall proportion ſeparable by gentle ſublimation; the matter which ſublimes is nearly ſimilar to mercurius dulcis.

The colour of ſilver is debaſed by all the metals, and its malleability greatly injured by all but gold and copper. The Engliſh ſtandard ſilver contains one part of copper to twelve and one-third of pure ſilver. 1136 Attraction for lead. This metal diſcovers in ſome circumſtances a great attraction for lead; though it does not retain any of that metal in cupellation. If a mixture of ſilver and copper be melted with lead in certain proportions, and the compound afterwards expoſed to a moderate fire, the lead and ſilver will melt out together, bringing very little of the copper with them; by this means ſilver is often ſeparated from copper in large works. The effect does not wholly depend upon the different fuſibility of the metals; for if tin, which is ſtill more fuſible than lead, be treated in the ſame manner with a mixture of ſilver and copper, the three ingredients are found to attract one another ſo ſtrongly as to come all into fuſion together. Again, if ſilver be melted with iron, and lead added to the mixture, the ſilver will forſake the iron to unite with the lead, and the iron will float by itſelf on the ſurface.

1137 Whitened externally. Silver is purified and whitened externally by boiling in a ſolution of tartar and common ſalt. This is no other than an extraction of the cupreous particles from the ſurface of the ſilver, by the acid of the tartar acuated by the common ſalt.

1138 Fulminating ſilver. M. Berthollet has lately diſcovered a method of imparting to the calx of ſilver a fulminating property, and that much more terrible than fulminating gold itſelf. 1139 How prepared. His receipt for making it is, "Take cupelled ſilver, and diſſolve it in the nitrous acid; precipitate the ſilver from the ſolution by lime-water, decant the clear liquor, and expoſe the precipitate three days to the open air. Mix this dried precipitate with the cauſtic volatile alkali, it will turn black; and when dried in the air, after decanting the clear liquor, is the fulminating powder required."

The properties of this powder are ſaid to be ſo extraordinary, that it is impoſſible to imagine how any part of it can ever be ſeparated from the reſt after it is once prepared. 1140 Fulminates by the touch of any ſubſtance whether cold or hot. To make this fulminate, it ſeems no ſenſible degree of heat is neceſſary, the contact of a cold body anſwering that purpoſe as well as any other. After it is once made, therefore, it muſt not be touched, but remain in the veſſel in which it is dried; and ſo violent is the exploſion, that it is dangerous to attempt it in larger quantities than a grain at a time. 1141 Dangerous when more than a grain is fulminated at a time. For the ſame reaſon it undoubtedly follows, that no more than a grain ought to be made at a time, or at leaſt in one veſſel, becauſe no part of it could ever afterwards be ſeparated from the reſt. We are told, that, "the wind having turned over a paper containing ſome atoms of this powder," (we ought to have been

been informed how the atoms came there, conſidering what we have juſt now related,) "the portion touched by the hand fulminated, and of courſe that which fell upon the ground. A drop of water which fell upon this powder cauſed it to fulminate. A ſingle grain of fulminating ſilver, which was in a glaſs cup, reduced the glaſs to powder, and pierced ſeveral doubles of paper.

1142 Fulminating cryſtals.

"If the volatile alkali, which has been employed with the above powder, be put into a thin glaſs matraſs and boiled, then, on ſtanding in the cold, ſmall cryſtals will be found ſublimed on the interior ſides of the veſſel, and covering the liquor. On touching one of theſe cryſtals the matraſs will be burſt with conſiderable exploſion.

1143 Cautions to be uſed in preparing it.

"The dangerous properties of this powder ſuggeſt the neceſſity of not preparing it but when the face is covered with a maſk with glaſs eyes; and to avoid the rupture of the glaſs cups, it is prudent to dry the fulminating ſilver in ſmall metalline veſſels." To this we may add, that as the powder does not fulminate when wet, it may in that ſtate be put up in very ſmall quantities on paper, to be fulminated afterwards as occaſion offers. This will perhaps account for the appearance of the few atoms abovementioned on the paper which the wind overturned.

1144 Abſurd theory of the antiphlogiſtons.

With regard to the cauſe of this extraordinary fulmination we can ſay nothing ſatisfactory; the following curious reaſon is aſſigned by the antiphlogiſtons; which at once ſhows the futility of their theory, and ſets in a very ridiculous light the hard words with which they would obſcure the ſcience of chemiſtry. "The oxygenous principle * (ſay they) unites with the hydrogenous principle † of the volatile alkali, and form water in a vaporous ſtate. This water (in a vaporous ſtate) being inſtantaneouſly *thrown into a ſtate of vapour*, poſſeſſing elaſticity and expanſive force, is the principal cauſe of this phenomenon, in which the *azotic* ‡ air which is diſengaged from the volatile alkali, with its whole expanſile power, has a great ſhare."

* Dephlogiſticated air.
† Inflammable air.
‡ Phlogiſticated air.

1145 Remarks on this and other theories.

1146 The phenomenon probably owing to electricity.

On this, as well as other theories, in which elaſtic fluids are alleged to be the cauſe of exploſions, it is obvious to remark, that ſhould we allow this to be the caſe, we are utterly at a loſs to find a ſource of heat ſufficient to rarefy the vapour to ſuch a degree as is neceſſary for producing the effect aſcribed to it. In the preſent caſe, we can ſcarce ſuppoſe a grain weight of metalline calx, already dry, to contain as much either of fire or water as is neceſſary to produce the effect; nor can we explain why the touch of any cold body, and which may be ſuppoſed to contain leſs fire than the calx itſelf, ſhould produce ſuch an effect. As to the oxygenous and hydrogenous principles, they were there before the touch, and ought to have produced their effects, not to mention that the water produced by them could not have amounted to the thouſandth part of a grain. It is much more probable, therefore, that the whole is to be conſidered as an effect of electricity, though we cannot tell how the fluid comes here to be excited in ſuch a violent manner.

§ 3. *Copper.*

1147 Always ſofter than iron.

This is one of thoſe metals which, from their deſtructibility by fire, and contracting ruſt in the air, are called *imperfect*. Of theſe, however, it is the moſt perfect and indeſtructible. It is of a reddiſh colour when pure; eaſily tarniſhes in a moiſt air, and contracts a green ruſt. It is the moſt ſonorous of all the metals, and the hardeſt and moſt elaſtic of all but iron. In ſome of its ſtates, copper is as difficultly extended under the hammer as iron, but always proves ſofter to the file; and is never found hard enough to ſtrike a ſpark with flint or other ſtones; whence its uſe for chiſſels, hammers, hoops, *&c.* in the gunpowder works. When broke by often bending backwards and forwards, it appears internally of a dull red colour without any brightneſs, and of a fine granulated texture reſembling ſome kinds of earthen ware. It is conſiderably ductile, though leſs ſo than either gold or ſilver; and may be drawn into wire as fine as hair, or beaten into leaves almoſt as thin as thoſe of ſilver. The tenacity of its parts is very conſiderable; for a copper wire of $\frac{1}{10}$ of an inch diameter will ſupport a weight of $299\frac{1}{4}$ pounds without breaking. The ſpecific gravity of this metal, according to Dr Lewis, is to that of water as 8.830 to 1.

1148 How granulated.

Copper continues malleable when heated red; in which reſpect it agrees with iron; but is not, like iron, capable of being welded, or having two pieces joined into one. It requires for its fuſion a ſtronger heat than either gold or ſilver, though leſs than that requiſite to melt iron. When in fuſion, it is remarkably impatient of moiſture; the contact of a little water occaſioning the melted copper to be thrown about with violence, to the great danger of the by-ſtanders. It is, nevertheleſs, ſaid to be granulated in the braſs-works at Briſtol, without exploſion or danger, by letting it fall in little drops, into a large ciſtern of cold water covered with a braſs-plate. In the middle of the plate is an aperture, in which is ſecured with Sturbridge clay a ſmall veſſel, whoſe capacity is not above a ſpoonful, perforated with a number of minute holes, through which the melted copper paſſes. A ſtream of cold water paſſes through the ciſtern. If ſuffered to grow hot, the copper falls liquid to the bottom, and runs into plates.

1149 Calcined.

Copper, in fuſion, appears of a bluiſh green colour, nearly like that of melted gold. Kept in fuſion for a long time, it becomes gradually more and more brittle; but does not ſcorify conſiderably, nor loſe much of its weight. It is much leſs deſtructible than any of the imperfect metals, being very difficultly ſubdued even by lead or biſmuth. If kept in a heat below fuſion, it contracts on the ſurface thin powdery ſcales; which, being rubbed off, are ſucceeded by others, till the whole quantity of the metal is thus changed into a ſcoria or calx, of a dark reddiſh colour. This calx does not melt in the ſtrongeſt furnace fires; but, in the focus of a large burning mirror, runs eaſily into a deep red, and almoſt opaque, glaſs. A flaming fire, and ſtrong draught of air over the ſurface of the metal, greatly promote its calcination. The flame being tinged of a green, bluiſh, or rainbow colour, is a mark that the copper burns.

1150 Solubility.

This metal is very readily ſoluble by almoſt all ſaline ſubſtances; even common water, ſuffered to ſtand long in copper-veſſels, extracts ſo much as to gain a coppery taſte. It is obſervable, that water is much more impregnated with this taſte, on being ſuffered to ſtand in the cold, than if boiled for a longer time in the veſſel. The ſame thing happens in regard to the mild vegetable acids. The confectioners prepare the moſt acid ſyrups, even thoſe of lemons and oranges, by by boiling in clean copper-veſſels, without the preparations receiving any ill taſte from the metal; whereas, either the juices themſelves, or the ſyrups made from them, if kept cold in copper veſſels, ſoon become impregnated with a diſagreeable taſte, and with the pernicious qualities of the copper.

1151 Altered by combination with vegetable acids.

By combination with vegetable acids, copper becomes in ſome reſpects remarkably altered. Verdigris, which is a combination of copper with a kind of acetous or tartareous acid, is partially ſoluble in diſtilled vinegar; the reſiduum, on being melted with borax and linſeed oil, yields a brittle metallic ſubſtance, of a whitiſh colour, not unlike bell-metal. The copper alſo, when revived from the diſtilled verdigris, was found by Dr Lewis to be different from the metal before diſſolution; but neither of theſe changes have yet been ſufficiently examined.

1152 Amalgamation with mercury.

Copper, in its metallic ſtate, is very difficultly amalgamated with mercury; but unites with it more eaſily if divided by certain admixtures. If mercury and verdigris be triturated together with common ſalt, vinegar, and water, the copper in the verdigris will be imbibed by the mercury, and form with it, as Boyle obſerves, a curious amalgam, at firſt ſo ſoft as to receive any impreſſion, and which, on ſtanding, becomes hard like brittle metals. Braſs leaf likewiſe gives out its copper to mercury, the other ingredient of the braſs ſeparating in the form of powder.

1153 Dr Lewis's method.

Eaſier methods of amalgamating copper are publiſhed by Dr Lewis in his notes on Wilſon's Chemiſtry, p. 432. His receipts are,—"Diſſolve ſome fine copper in aquafortis: when the menſtruum will take up no more of the metal, pour it into an iron mortar, and add ſix times the weight of the copper, of mercury, and a little common ſalt: grind the whole well together with an iron peſtle; and, in a little time, the copper will be imbibed by the mercury, and an amalgam formed, which may be rendered bright by waſhing it well with repeated affuſions of water.

"*Another method.* Take the muddy ſubſtance which is procured in the poliſhing of copper plates with a pumice ſtone, and grind it well with a ſuitable portion of mercury, a little common ſalt, and ſome vinegar, in an iron mortar, (a marble one will do, if you make uſe of an iron peſtle), till you perceive the mercury has taken up the copper." The copper recovered from theſe amalgams retains its original colour, without any tendency to yellow. Even when braſs is made uſe of for making the amalgam, the recovered metal is perfect red copper; the ingredient from which the braſs received its yellowneſs being, as above obſerved, ſeparated in the amalgamation.

1154 Braſs, how prepared.

Copper is the baſis of ſeveral metals for mechanic uſes; as braſs, prince's metal, bell-metal, bath-metal, white copper, &c. Braſs is prepared from copper and calamine, with the addition of powdered charcoal, cemented together, and at laſt brought into fuſion. The calamine is to be previouſly prepared by cleanſing it from adhering earth, ſtone, or other matters; by roaſting, or calcining it; and by grinding it into a fine powder. The length of time, and degree of heat, requiſite for the calcination of the calamine, are different according to the qualities of that mineral. The calamine, thus calcined, cleanſed, and ground, is to be mixed with about a third or fourth part of charcoal duſt, or powdered pit-coal, as is done in ſome parts of England. The malleability of the baſis is diminiſhed by the uſe of pit-coal, which is therefore only employed for the preparation of the coarſer kinds. To this compoſition of calamine and coal, ſome manufacturers add common ſalt, by which the proceſs of making braſs is ſaid to be haſtened. In Goſlar, where the cadmia adhering to the inſides of the furnaces is uſed inſtead of the native calamine, a ſmall quantity of alum is added, by which they pretend the colour of the braſs is heightened. With this compoſition, and with thin plates or grains of copper, the crucibles are to be nearly filled. The proportion of the calamine to the copper varies according to the richneſs of the former, but is generally as three to two. The copper muſt be diſperſed through the compoſition of calamine and coal; and the whole muſt be covered with more coal, till the crucibles are full. The crucibles, thus filled, are to be placed in a furnace ſunk in the ground, the form of which is that of the fruſtum of a hollow cone. At the bottom of the furnace, or greater baſis of the fruſtum, is a circular grate, or iron-plate. This plate is covered with a coat of clay and horſe-dung, to defend it from the action of the fire; and pierced with holes, through which the air maintaining the fire paſſes. The crucibles ſtand upon the circular plate, forming a circular row, with one in the middle. The fuel is placed betwixt the crucibles, and is thrown into the furnace at the upper part of it, or the leſſer baſis of the fruſtum. To this upper part or mouth of the furnace is fitted a cover made of bricks or clay, kept together with bars of iron, and pierced with holes. This cover ſerves as a regiſter. When the heat is to be increaſed, the cover muſt be partly or entirely taken off, and a free draught is permitted to the external air, which paſſes along a vault under-ground to the aſh-hole, through the holes in the circular grate or plate, betwixt the crucibles, and through the upper mouth, along with the ſmoke and flame, into an area where the workmen ſtand, which is covered with a large dome or chimney, through which the ſmoke and air aſcend. When the heat is to be diminiſhed, the mouth of the furnace is cloſed with the lid; through the holes of which the air, ſmoke, and flame paſs. The crucibles are to be kept red-hot during eight or ten hours; and in ſome places much longer, even ſeveral days, according to the nature of the calamine. During this time, the zinc riſes in vapour from the calamine, unites with the copper, and renders that metal conſiderably more fuſible than it is by itſelf. To render the metal very fluid, that it may flow into one uniform maſs at the bottom, the fire is to be increaſed a little before the crucibles are taken out, for pouring off the fluid metal into moulds. From 60 pounds of good calamine, and 40 of copper, 60 pounds of braſs may be obtained, notwithſtanding a conſiderable quantity of the zinc is diſſipated in the operation. The quantity of braſs obtained has been conſiderably augmented ſince the introduction of the method now commonly practiſed, of granulating the copper; by which means a larger ſurface of this metal is expoſed to the vapour of zinc, and conſequently leſs of that vapour eſcapes. To make the finer and more malleable kinds of braſs, beſides the choice of pure calamine and pure copper, ſome

ſome manufacturers cement the braſs a ſecond time with calamine and charcoal; and ſometimes add to it old braſs, by which the new is ſaid to be meliorated.

Braſs is brittle when hot; but ſo ductile when cold, that it may be drawn into very fine wire, and beat into very thin leaves. Its beautiful colour, malleability, and its fuſibility, by which it may be eaſily caſt into moulds, together with its being leſs liable to ruſt than copper, render it fit for the fabrication of many utenſils.

Although zinc be fixed to a certain degree in braſs, by the adheſion which it contracts with the copper; yet when braſs is melted, and expoſed to a violent fire, during a certain time, the zinc diſſipates in vapours, and even flames away, if the heat be ſtrong enough; and if the fire is long enough continued, all the zinc will be evaporated and deſtroyed, ſo that what remains is copper.

2d 1154 Princes metal. Prince's metal is made by melting zinc in ſubſtance with copper; and all the yellow compound metals prepared in imitation of gold are no other than mixtures of copper with different proportions of that ſemimetal, taken either in its pure ſtate, or in its natural ore calamine, with an addition ſometimes of iron-filings, *&c.* Zinc itſelf unites moſt eaſily with the copper; but calamine makes the moſt ductile compound, and gives the moſt yellow colour. Dr Lewis obſerves, that a little of the calamine renders the copper pale; that when it has imbibed about $\frac{1}{17}$ its own weight, the colour inclines to yellow; that the yellowneſs increaſes more and more, till the proportion comes to almoſt one half; that on further augmenting the calamine, the compound becomes paler and paler, and at laſt white. The crucibles, in which the fuſion is performed in large works, are commonly tinged by the matter of a deep blue colour.

1155 Bell-metal. Bell-metal is a mixture of copper and tin; and tho' both theſe metals ſingly are malleable, the compound proves extremely brittle. Copper is diſſolved by melted tin eaſily and intimately, far more ſo than by lead. A ſmall portion of tin renders this metal dull-coloured, hard, and brittle. Bell-metal is compoſed of about ten parts of copper to one of tin, with the addition commonly of a little braſs or zinc. A ſmall proportion of copper, on the other hand, improves the colour and conſiſtency of tin, without much injuring its ductility. Pewter is ſometimes made from one part of copper and twenty or more of tin.

1156 Dr Lewis's obſervations on the ſpecific gravity of the metal. It has long been obſerved, that though tin is ſpecifically much lighter than copper, yet the gravity of the compound, bell-metal, is greater than that of the copper itſelf. The ſame augmentation of gravity alſo takes place where the lighter metal is in the greateſt proportion; a mixture even of one part of tin with two of copper, turning out ſpecifically heavier than pure copper. Moſt metallic mixtures anſwer to the mean gravity of the ingredients, or ſuch as would reſult from a bare appoſition of parts. Of thoſe tried by Dr Lewis, ſome exceeded the mean, but the greater number fell ſhort of it; tin and copper were the only ones that formed a compound heavier than the heavieſt of the metals ſeparately.

1157 White copper. White copper is prepared by mixing together equal parts of arſenic and nitre, injecting the mixture into a red-hot crucible, which is to be kept in a moderate fire till they ſubſide, and flow like wax. One part of this mixture is injected upon four parts of melted copper, and the metal, as ſoon as they appear thoroughly united together, immediately poured out. The copper, thus whitened, is commonly melted with a conſiderable proportion of ſilver, by which its colour is both improved and rendered more permanent. The white copper of China and Japan appears to be no other than a mixture of copper and arſenic. Geoffroy relates, that, on repeated fuſions, it exhaled arſenical fumes, and became red copper, loſing with its whiteneſs, one ſeventh of its weight.

§ 4. *Iron.*

Iron is a metal of a greyiſh colour; ſoon tarniſhing in the air into a duſky blackiſh hue; and in a ſhort time contracting a yellowiſh, or reddiſh ruſt. It is the hardeſt of all metals: the moſt elaſtic; and, excepting platina, the moſt difficult to be fuſed. 1158 Tenacity of its parts. Next to gold, iron has the greateſt tenacity of parts; an iron wire, the diameter of which is the tenth part of an inch, being capable of ſuſtaining 450 pounds. Next to tin, it is the lighteſt of all the metals, loſing between a ſeventh and eighth part of its weight when immerſed in water. When very pure, it may be drawn into wire as fine as horſe-hair; but is much leſs capable of being beaten into thin leaves than the other metals, excepting only lead,

Iron grows red-hot much ſooner than any other metal; and this, not only from the application of actual fire, but likewiſe from ſtrong hammering, friction, or other mechanic violence. It nevertheleſs melts the moſt difficultly of all metals except manganeſe and platina; requiring, in its moſt fuſible ſtate, an intenſe, bright, white heat. When perfectly malleable, it is not fuſible at all by the heat of furnaces, without the addition or the immediate contact of burning fuel; and, when melted, loſes its malleability: all the common operations which communicate one of theſe qualities deprive it at the ſame time of the other; as if fuſibility and malleability were in this metal incompatible. When expoſed to the focus of a large burning mirror, however, it quickly fuſed, boiled, and emitted an ardent fume, the lower part of which was a true flame. At length it was changed into a blackiſh vitrified ſcoria.

1159 Iron a combuſtible ſubſtance. From the great waſte occaſioned by expoſing iron to a red but eſpecially to a white heat, this metal appears to be a combuſtible ſubſtance. This combuſtion is maintained, like that of all other combuſtible ſubſtances, by contact of air. Dr Hook, having heated a bar of iron to that degree called *white heat*, he placed it upon an anvil, and blowed air upon it by means of bellows, by which it burnt brighter and hotter. Expoſed to a white heat, it contracts a ſemivitreous coat, which burſts at times, and flies off in ſparkles. No other metallic body exhibits any ſuch appearance. On continuing the fire, it changes by degrees into a dark red calx, which does not melt in the moſt vehement heat procurable by furnaces, and, if brought into fuſion by additions, yields an opaque black glaſs. When ſtrongly heated, it appears covered on the ſurface with a ſoft vitreous matter like varniſh. In this ſtate, pieces of it cohere; and, on being

1160 The only metal capable of being welded.

being hammered together, weld or unite, without diſcovering a juncture. As iron is the only metal which exhibits this appearance in the fire, ſo it is the only one capable of being welded. Thoſe operations which prevent the ſuperficial ſcorification, deprive it likewiſe of this valuable property: which may be reſtored again, by ſuffering the iron to reſume its vitreous aſpect; and, in ſome meaſure, by the interpoſition of foreign vitreſcible matters; whilſt none of the other metals will unite in the ſmalleſt degree, even with its own ſcoria.

1161 Contracts in fuſion.

Iron expands the leaſt of all metals by heat. In the act of fuſion, inſtead of continuing to expand, like the other metals, it ſhrinks; and thus becomes ſo much more denſe, as to throw up ſuch part as is unmelted to the ſurface; whilſt pieces of gold, ſilver, copper, lead, or tin, put into the reſpective metals in fuſion, ſink freely to the bottom. In its return to a conſiſtent ſtate, inſtead of ſhrinking like the other metals, it expands; ſenſibly riſing in the veſſel, and aſſuming a convex ſurface, while the others become concave. This property, firſt obſerved by Raumur, excellently fits it for receiving impreſſions from moulds. By the increaſe of bulk which the metal receives in congelation, it is forced into the minuteſt cavities, ſo as to take the impreſſion far more exactly than the other metals which ſhrink.

1162 Diſſolved by all metals except lead and mercury.

Iron is diſſolved by all the metals made fluid, except lead; though none of them act ſo powerfully upon it as gold: but, as Cramer obſerves, if the iron contains any portion of ſulphur, it can ſcarcely be made to unite at all with gold.

Among the ſemimetallic bodies, it is averſe to an union with mercury; no method of amalgamating theſe two having yet been diſcovered; though quickſilver, in certain circumſtances, ſeems in ſome ſmall degree to act upon it. A plate of tough iron, kept immerſed in mercury for ſome days, becomes brittle; and mercury will often adhere to and coat the ends of iron peſtles uſed in triturating certain amalgams with ſaline liquors. Mr Jones has alſo diſcovered, that by plunging iron, while heated to an intenſe white heat, into mercury, the latter will adhere to the ſurface of the iron, and completely ſilver it over.

Next to mercury, zinc is the moſt difficultly combined with iron; not from any natural indiſpoſition to unite, but from the zinc being difficultly made to ſuſtain the heat requiſite. The mixture is hard, ſomewhat malleable, of a white colour approaching to that of ſilver. Regulus of antimony, as ſoon as it melts, begins to act on iron, and diſſolves a conſiderable quantity. If the regulus be ſtirred with a iron rod, it will melt off a part of it. Arſenic likewiſe eaſily mingles with iron, and has a ſtrong attraction for it; forſaking all the other metals to unite with this. It renders the iron white, very hard, and brittle.

1163 Pruſſian blue.

This metal is the baſis of the fine blue pigment, called, from the place where it was firſt diſcovered, *Berlin* or *Pruſſian* blue. This colour was accidentally diſcovered about the beginning of the preſent century, by a chemiſt of Berlin, who, having ſucceſſively thrown upon the ground ſeveral liquors from his laboratory, was much ſurpriſed to ſee it ſuddenly ſtained with a beautiful blue colour. Recollecting what liquors he had thrown out, and obſerving the ſame effects from a ſimilar mixture, he prepared the blue for the uſe of painters; who found that it might be ſubſtituted to ultramarine, and accordingly have uſed it ever ſince.

1164 Dr Woodward's recept for.

Several chemiſts immediately endeavoured to diſcover the compoſition of this pigment; and in the year 1724 Dr Woodward publiſhed the following proceſs, in the Philoſophical Tranſactions, for making it. "Alkalize together four ounces of nitre, and as much tartar as is directed for charcoal (nº 779). Mix this alkali well with four ounces of dried bullocks blood; and put the whole in a crucible covered with a lid, in which there is a ſmall hole. Calcine with a moderate heat, till the blood be reduced to a perfect coal; that is, till it emits no more ſmoke or flame capable of blackening any white bodies that are expoſed to it. Increaſe the fire towards the end, ſo that the whole matter contained in the crucible ſhall be moderately, but ſenſibly, red.

"Throw into two pints of water the matter contained in the crucible, while yet red, and gave it half an hour's boiling: decant this firſt water; and pour more upon the black charry coal, till it becomes almoſt inſipid. Mix together all theſe waters; and reduce them, by boiling, to about two pints.

"Diſſolve alſo two ounces of martial vitriol, and eight ounces of alum, in two pints of boiling water. Mix this ſolution when hot with the preceding lixivium alſo hot. A great efferveſcence will then be made: the liquors will be rendered turbid; and will become of a green colour, more or leſs blue; and a precipitate will be formed of the ſame colour. Filtrate, in order to ſeparate this precipitate; upon which pour ſpirit of ſalt, and mix them well together; by which means the precipitate will become of a fine blue colour. It is neceſſary to add rather too much of the ſalt than too little, and till it no longer increaſes the beauty of the precipitate. The next day waſh this blue, till the water comes off from it inſipid; and then gently dry it."

1165 Mr Geoffroy's theory.

Mr Geoffroy was the firſt who gave any plauſible theory of this proceſs, or any rational means of improving it. He obſerves, that the Pruſſian blue is no other than the iron of the vitriol revived by the inflammable matter of the alkaline lixivium, and perhaps a little brightened by the earth of alum; that the green colour proceeds from a part of the yellow ferruginous calx, or ochre, unrevived, mixing with the blue; and that the ſpirit of ſalt diſſolves this ochre more readily than the blue part; though it will diſſolve that alſo by long ſtanding, or if uſed in too large quantity. From theſe principles, he was led to increaſe the quantity of inflammable matter; that there might be enough to revive the whole of the ferruginous ochre, and produce a blue colour at once, without the uſe of the acid ſpirit. In this he perfectly ſucceeded; and found, at the ſame time, that the colour might be rendered of any degree of deepneſs, or lightneſs, at pleaſure. If the alkali is calcined with twice its weight of dried blood, and the lixivium obtained from it poured into a ſolution of one part of vitriol to ſix of alum, the liquor acquires a very pale blue colour, and depoſits as pale a precipitate. On adding more and more of a freſh ſolution of vitriol, the colour becomes deeper and deeper, almoſt to blackneſs. He imagines, with great probability, that the blue pigment, thus prepared, will prove more durable in the air, mingle more perfectly with other colours, and be

leſs

leſs apt to injure the luſtre of ſuch as are mixed with or applied in its neighbourhood, than that made in the common manner; the tarniſh to which common Pruſſian blue is ſubject, ſeeming to proceed from the acid, which cannot be ſeparated by any ablution.

1166 Amuſing phenomenon in the preparation.

He takes notice of an amuſing phenomenon which happens upon mixture. When the liquors are well ſtirred together; and the circular motion, as ſoon as poſſible, ſtopped; ſome drops of ſolution of vitriol, (depurated, by long ſettling), let fall on different parts of the ſurface, divide, ſpread, and form curious repreſentations of flowers, trees, ſhrubs, flying inſects, &c. in great regularity and perfection. Theſe continue 10 or 12 minutes: and on ſtirring the liquor again, and dropping in ſome more of the ſolution of vitriol, are ſucceeded by a new picture.

1167 Mr Macquer's theory.

This theory is confirmed by Mr Macquer, in a Memoir printed in the year 1752. He obſerves, that the quantity of phlogiſton communicated to the iron in this proceſs is ſo great, as not only to cauſe the metal reſiſt in a great meaſure the action of acids, and become totally unaffected by the magnet; but by a ſlight calcination it becomes entirely ſimilar to other iron, and is at once deprived of its blue colour. He further obſerves, that fire is not the only means by which Pruſſian blue may be deprived of all the properties which diſtinguiſh it from ordinary iron. A very pure alkali produces the ſame effect. He has alſo diſcovered, that the alkali which has thus deprived the Pruſſian blue of all the properties which diſtinguiſh it from ordinary iron, becomes, by that operation, entirely ſimilar to the phlogiſticated alkali uſed for the preparation of Pruſſian blue.

1168 Phlogiſticated alkali loſes its alkaline properties.

By a more particular examination, he found, that the alkali might become perfectly ſaturated with the colouring matter; ſo that, when boiled on Pruſſian blue, it extracted none of its colour. When the ſalt was thus perfectly ſaturated, it ſeemed no longer to poſſeſs any alkaline qualities. If poured into a ſolution of iron in any acid, a ſingle, homogeneous, and perfect precipitate, was formed; not green, as in Dr Woodward's proceſs, but a perfect Pruſſian blue; which needed no acid to brighten its colour. A pure acid added to the alkali was not in the leaſt neutralized, nor in the leaſt precipitated the colouring matter. From hence Mr Macquer concludes, that, in the making of Pruſſian blue, vitriol is decompoſed; becauſe the iron has a ſtrong attraction for the colouring matter, as well as the acid for the alkali; and the ſum of the attraction of the acid to the alkali, joined to that of the iron for the colouring matter, is greater than the ſingle attraction of the acid to the metal.

1169 Earths do not attract the colouring matter.

Another very important phenomenon is, that earths have not the ſame attraction for this colouring matter that metallic ſubſtances have. Hence, if an alkali ſaturated with this colouring matter be poured into a ſolution of alum, no decompoſition is effected, nor any precipitate formed. The alum continues alum, and the alkali remains unchanged. From this experiment Mr Macquer concludes that alum does not directly contribute to the formation of the Pruſſian blue. The purpoſe he thinks it anſwers is as follows. Fixed alkaline ſalts can never be perfectly ſaturated with phlogiſtic matter by calcination; alkalies, therefore, though calcined with inflammable ſubſtances, ſo as to make a proper lixivium for Pruſſian blue, remain ſtill alkaline. Hence, when mixed with a ſolution of green vitriol, they form, by their purely alkaline part, a yellow precipitate, ſo much more copious, as the alkali is leſs ſaturated with phlogiſton. But nothing is more capable of ſpoiling the fine colour of the Pruſſian blue, than an admixture of this yellow precipitate: it is therefore neceſſary to add a quantity of alum, which will take up the greateſt part of the purely alkaline ſalt, and of conſequence the quantity of yellow ferruginous precipitate is much diminiſhed. But the earth of alum, being of a fine ſhining white, does not in the leaſt alter the purity of the blue colour, but is rather neceſſary to dilute it. From all this it follows, that it is a matter of indifference whether the green precipitate is to be again diſſolved by an acid, or the alkaline part of the lixivium ſaturated with alum or with an acid, before the precipitate is formed. The latter indeed ſeems to be the moſt eligible method.

1170 Blue producible from other alkalies.

Moſt alkalies obtained from the aſhes of vegetables, being combined, by their combuſtion, with a portion of inflammable matter, are capable of furniſhing a quantity of Pruſſian blue, proportionable to the quantity of colouring matter they contain, even without the neceſſity of mixing them with a ſolution of iron; becauſe they always contain a little of this metal diſſolved, ſome of which may be found in almoſt all vegetables; therefore it is ſufficient to ſaturate them with an acid. Henckel obſerved the production of this blue in the ſaturation of the foſſile alkali, and recommended to chemiſts to inquire into its nature.

1171 Mr Scheele diſcovers the colouring matter of Pruſſian blue.

The theories of Geoffroy, Macquer, &c. however, with reſpect to Pruſſian blue, have now given place to that of Mr Scheele; who has examined the ſubſtance with the utmoſt care, and found the colouring matter to conſiſt of an extremely volatile ſubſtance, capable of uniting with and neutralizing alkalies, but eaſily expelled from them by any other acid, even by that of fixed air.

1172 Lixivium ſanguinis loſes its colouring property by expoſure to the air.

He begins his diſſertation on this ſubject by obſerving, that the ſolution of alkali calcined with dried blood, which he calls *lixivium ſanguinis*, by expoſure to the air, loſes its property of precipitating the iron of a blue colour; and that the precipitate thus obtained is entirely ſoluble in the acid. In order to determine whether the air had thus undergone any change, he put ſome newly prepared lixivium into a glaſs veſſel well ſealed with roſin; but after ſome time finding no change on the lixivium, or on the air contained in the veſſel, he began to think that this might be occaſioned by the abſence of fixed air, which always abounds in the open atmoſphere, though not in any confined portion of it, at leaſt in an equal proportion.

1173 Suppoſed to ariſe from the fixed air abſorbed from the atmoſphere.

Having therefore filled a glaſs veſſel with fixed air, he poured into it a little lixivium ſanguinis; and next day found, that it threw down from green vitriol a precipitate entirely ſoluble in acids. With other acids he obtained no precipitate.

1174 The matter fixed by the addition of ſome green vitriol to the lixivium.

On inverting the experiment, and mixing ſome green vitriol with lixivium ſanguinis, the mixture grew yellow; and he found this addition capable of fixing the colouring matter ſo that neither the acid of fixed air nor any other could expel it from the alkali. For having poured the mixture abovementioned into a ſolution of green vitriol, and afterwards ſuperſaturated the

the lixivium with acid, he obtained a conſiderable quantity of blue. To the ſame lixivium ſanguinis, in which a ſmall quantity of green vitriol was diſſolved, he afterwards added of the other acids ſomewhat more than was neceſſary for its ſaturation; and though this was done, a conſiderable quantity of Pruſſian blue was afterwards obtained.

1175 Calx of iron ſoluble in lixivium ſanguinis;

Again, having precipitated a ſolution of green vitriol with alkali, and boiled the precipitate for ſome minutes in lixivium ſanguinis, part of it was diſſolved: the filtered lixivium underwent no change when expoſed to the open air or to the aerial acid, and precipitated the ſolution of vitriol of a blue; and though the lixivium was ſuperſaturated with acid, and ſome green vitriol added, a very beautiful Pruſſian blue was obtained.

1176 But not when highly dephlogiſticated.

This, however, will not hold when a perfectly dephlogiſticated calx of iron is employed, of which none can be diſſolved by the lixivium ſanguinis; nor will any Pruſſian blue be obtained by precipitating with lixivium ſanguinis a perfectly dephlogiſticated ſolution of iron in nitrous acid.

1177 The colouring matter taken up by the air after it has been expelled by acids.

To determine what had become of the colouring matter in thoſe experiments where it ſeemed to have been diſſipated, ſome lixivium ſanguinis was poured into a veſſel filled with aerial acid. It was kept well corked during the night, and next day a piece of paper dipped in a ſolution of green vitriol was fixed to the cork, pencilling it over with two drops of a ſolution of alkali in water. The paper was thus ſoon covered with precipitated iron; and on being taken out two hours afterwards, and dipped in muriatic acid, became covered with moſt beautiful Pruſſian blue. The ſame thing happened when lixivium ſanguinis ſuperſaturated with vitriolic acid was employed; for in this caſe alſo the air was filled with the colouring matter capable of being in like manner abſorbed by the calx of iron. But though from theſe experiments it is plain that acids expel this colouring ſubſtance from the lixivium, a given quantity of air is only capable of receiving a certain quantity of it; for the ſame mixture removed into another veſſel imparts the colouring property to the air it contains according to its quantity. On putting perfectly dephlogiſticated calx of iron upon the papers, no Pruſſian blue was formed; but the muriatic acid diſſolved the calx entirely.

1178 The colouring matter expelled by diſtillation with vitriolic acid.

Our author having now aſſured himſelf that acids really attract the alkali more than the colouring matter, proceeded to try the effects of diſtillation. Having therefore ſuperſaturated ſome lixivium ſanguinis with vitriolic acid, he diſtilled the mixture in a glaſs retort with a gentle fire. When about one-third had paſſed over, he changed the receiver, and continued the operation till one-half was diſtilled. The firſt product had a peculiar taſte and ſmell; the air in the receiver was filled with colouring matter, and the aqueous fluid was alſo ſtrongly impregnated with it, as appeared by its forming a fine Pruſſian blue with phlogiſticated calx of iron. Part of it being expoſed to the open air for ſome hours, entirely loſt its power, and the product of the ſecond operation was no other than water mixed with a little vitriolic acid.

1179 Attemps to procure the colouring matter by itſelf.

The next ſtep was to procure, if poſſible, the colouring matter by itſelf; and this he attempted to obtain from the Pruſſian blue, rather than the lixivium ſanguinis, as he would thus not only avoid the troubleſome calcination of the alkali and blood, but obtain the colouring matter im much larger quantity than could be done from the lixivium. On examining ſeveral kinds of this pigment, he found in them evident marks of ſulphur, volatile alkali, vitriolic acid, and volatile ſulphureous acid; all of which ſubſtances are to be found in the lixivium ſanguinis as well as in that of ſoot, and adhere to the precipitate in the preparation of Pruſſian blue.

1180 Neutral ſalt for diſcovering iron in mineral waters.

Finding, however, that he could not obtain his purpoſe by any kind of analyſis of theſe by fire alone, he had recourſe to a neutral ſalt uſed by chemiſts for diſcovering iron in mineral waters. This is formed by digeſting cauſtic fixed alkali on Pruſſian blue, which effectually extracts the colour from it even in the cold, in a very ſhort time, and being neutralized, may eaſily be reduced into a dry form. But it is not entirely to be depended upon for this purpoſe; for it always contains ſome iron which indeed is the medium of its connection with the alkali. The lixivium ſanguinis is preferable, though even this contains ſome iron, as well as the lixivium of ſoot; our author's experiments, however, were made with the neutral ſalt, for the reaſon already mentioned.

1181 Effects of diſtilling this ſalt with oil of vitriol.

1 An ounce of the ſalt was diſſolved in a glaſs retort in four ounces of water, afterwards adding three drachms of concentrated vitriolic acid; and the mixture was diſtilled with a gentle fire. The maſs grew thick as ſoon as it began to boil; from a great quantity of Pruſſian blue, a quantity of the colouring matter appeared by the ſmell to penetrate the lute: and part of it was abſorbed by the air in the receiver, as in former experiments. The diſtillation was continued till about an ounce had paſſed into the receiver. The blue maſs remaining in the retort was put into a ſtrainer, and a piece of green vitriol put into the liquid which paſſed through; but by this laſt no Pruſſian blue was produced. The blue which remained in the filter was again treated with lixivium tartari: the ſolution freed from its ochre by filtration, and the clear liquor committed a ſecond time to diſtillation with vitriolic acid. Pruſſian blue was again ſeparated, though in ſmaller quantity than before, and the colouring matter came over into the receiver. After one third of the matter had paſſed over, that which had been obtained by the firſt diſtillation was added to it, the Pruſſian blue was ſeparated from the lixivium in the retort, and extracted a third time. Some Pruſſian blue was formed again, though in much ſmaller quantity; whence it is apparent that Pruſſian blue may at laſt be totally decompoſed by means of alkali. Lime, or terra ponderoſa, likewiſe extract the blue colour, and ſhow the ſame phenomena as alkali.

1182 Colouring matter unites with volatile alkali.

With volatile alkali a compound, conſiſting of the alkali, iron, and colouring matter, is formed, which ſhows the ſame phenomena with that formed with fixed alkali. By diſtillation *per ſe* after it has been diſſolved in water, the liquor grows thick in conſequence of a ſeparation of Pruſſian blue, and volatile alkali paſſes over into the receiver. This volatile ſpirit is impregnated with the colouring matter; it is not precipitated by lime water; but green vitriol is precipitated by it; and on adding an acid, Pruſſian blue is formed. If a piece of paper, dipped in a ſolution of green vitriol, be expoſed to the vapour of this alkali, it is ſoon decompoſed; and if the ſame bepencilled over with muriatic acid, it inſtantly becomes blue.

blue. On expoſing the liquor to the open air, it all evaporates, leaving pure water behind.

1183 How to free the colouring matter perfectly from its vitriolic taint.

As in all the operations with vitriolic acid hitherto related, ſome ſmall quantity of it paſſes into the receiver, our author ſhows how to deprive the colouring matter, of that vitriolic taint. For this purpoſe nothing more is neceſſary than to put a little chalk into the matter, and rediſtil it with a very gentle heat; the acid unites with the chalk, and the colouring matter goes over in its greateſt purity.

1184 How to prevent the eſcape of the colouring matter thro' the lute.

In order to hinder, as much as poſſible, the eſcape of the volatile colouring matter through the lute, he makes uſe of a ſmall receiver, putting into it a little diſtilled water, and placing it ſo that the greater part ſhall be immerſed in cold water during the operation. The water impregnated with this colouring matter has a peculiar but not diſagreeable ſmell, a taſte ſomewhat approaching to ſweet, and warm in the mouth, at the ſame time exciting cough.

1185 This matter neither acid nor alkaline.

When rectified as above directed, it appears to be neither acid nor alkaline; for it neither reddens paper dyed with lacmus, nor does it reſtore the colour of ſuch paper after it has been made red; but it renders turbid the ſolutions of ſoap and hepar ſulphuris. The ſame liquor mixed with fixed alkali, though it contains a ſuperabundance of colouring matter, reſtores the blue colour of paper reddened by an acid. By diſtillation to dryneſs, there goes over a part of the colouring matter which diſengages itſelf from the alkali; the reſiduum is ſoluble in water, and has all the properties of the beſt lixivium ſanguinis; but, like the true lixivium, it is decompoſed by all the acids, even by that of fixed air.

1186 Forms a kind of ammoniacal ſalt with volatile alkali.

With cauſtic volatile alkali it forms a kind of ammoniacal ſalt; which, however, always ſmells volatile, though the colouring matter be in ever ſo great proportion. By diſtillation the whole inſtantly riſes, and nothing but pure water is left in the retort.

1187 Diſſolves magneſia alba.

Magneſia precipitated from Epſom ſalt by cauſtic volatile alkali, was diſſolved in the colouring matter by allowing them to ſtand together for ſeveral days in a warm cloſe bottle. On expoſure to the open air, the magneſia ſeparated from it by its ſuperior attraction for aerial acid, and formed on the ſurface of the water a pellicle like that of cream of tartar. This ſolution was likewiſe decompoſed by alkalies and lime-water.

1188 Very little terra ponderoſa.

The colouring matter diſſolves but a very ſmall quantity of terra ponderoſa, which may be afterwards precipitated by vitriolic and even by aerial acid.

1189 Diſſolves lime, but not clay.

Pure clay, or the baſis of alum, is not attacked by it. Lime is diſſolved in a certain quantity. The ſuperabundant portion ſhould be ſeparated by filtration; and as the liquor contains, beſides the combined lime, the portion which water itſelf is able to take up, in order to free it from this, preciſely the ſame quantity of water impregnated with aerial acid is to be added as is requiſite for precipitating an equal quantity of lime-water. The colouring matter, thus ſaturated with lime, is to be filtered again, and then to be preſerved in a well cloſed bottle to prevent the acceſs of fixed air. This ſolution is decompoſed by all the acids, and by the pure or cauſtic alkalies. By diſtillation the colouring matter riſes, and nothing but pure lime is left in the retort.

1190 The ſolution of lime the moſt proper for experiments on metals.

This ſolution of lime appears to our author to be ſo perfectly ſaturated, that he employed it in preference to any other in the experiments he made on metals, and which we are now about to relate.

1191 Silver, quickſilver, and iron precipitated by the colouring matter.

From the trials made by Mr Scheele, it appears that the colouring matter has no effect upon any metal or metallic ſolution, excepting thoſe of ſilver and quickſilver in nitrous acid, and that of iron in fixed air. The firſt is precipitated in a white powder: the ſecond in a black one; and the third aſſumes a ſea-green colour, which afterwards turns to blue.

1192 Its effects on metallic calces;

With metallic calces it produces the following phenomena. 1. Gold precipitated by aerated alkali becomes white. 2. The fixed air is diſengaged from a precipitate of ſilver with a ſlight effervescence. 3. Calx of mercury is diſſolved, and yields cryſtals by gentle evaporation. 4. The calx of copper precipitated by aerated alkali effervеſces, and aſſumes a faint citron colour. 5. Calx of iron precipitated from its ſolution in the vitriolic acid by the ſame alkali, effervеſces, and aſſumes a dark blue colour. 6. Precipitated cobalt ſhows ſome ſigns of effervеſcence, and changes into a yellowiſh brown colour. The other calces are not acted upon.

1193 On metallic ſolutions.

The precipitating liquor abovementioned, poured into metallic ſolutions, produces the following appearances by means of double elective attraction. 1. Gold is precipitated of a white colour, but by adding a ſuperabundant quantity of the precipitating liquor the calx is rediſſolved. The ſecond ſolution is colourleſs as water. 2. Silver is precipitated in form of a white ſubſtance of the conſiſtence of cheeſe; by adding more of the liquor the precipitate is rediſſolved, and the ſolution is not decompoſed either by ſal ammoniac or marine acid. 3. Corroſive ſublimate apparently undergoes no change, though it is in reality decompounded; the calx being diſſolved in the colouring matter. Mercury diſſolved in the nitrous acid without heat, is precipitated in form of a black powder. 4. The ſolutions of tin and biſmuth are precipitated, but the calx is not acted upon by the colouring matter. 5. The ſame effects are produced on the ſolution of butter of antimony, as well as on that of well dephlogiſticated calx of iron. 6. Blue vitriol is precipitated of a yellow citron colour: if more of the precipitating liquor be added, the precipitate is rediſſolved into a colourleſs liquor and a colourleſs ſolution of the ſame calx is likewiſe obtained by volatile alkali. On adding more of the ſolution of blue vitriol, the ſolution likewiſe diſappears, and the liquor aſſumes a green colour. Acids diſſolve a portion of this precipitate, and the remainder is white. The muriatic acid diſſolves the precipitate completely, but lets it fall again on the addition of water. 7. The ſolution of white vitriol yields a white precipitate, which is not rediſſolved by addition of the precipitating liquor, but is ſoluble in acids. Theſe ſolutions ſmell like the colouring matter, which may be ſeparated from them by diſtillation. 8. Green vitriol is precipitated firſt of a yellowiſh brown colour, which ſoon changes to green, and then becomes blue on the ſurface. Some hours afterwards the precipitate ſubſides to the bottom of the veſſels, and then the whole mixture turns blue; but on adding any acid the precipitate becomes inſtantly blue. If a very ſmall quantity of green vitriol be put into the precipitating liquor, the

the precipitate is entirely diſſolved, and the whole aſſumes a yellow colour. 7. Solution of cobalt lets fall a browniſh yellow precipitate, which is not diſſolved by adding more of the precipitating liquor, neither is it ſoluble in acids. By diſtillation the colouring matter goes over into the receiver.

1194
Inveſtigation of the conſtituent part of the colouring matter.

Laſtly, our author undertook an inveſtigation of the conſtituent parts of the colouring matter itſelf; and in this he ſucceeded in ſuch a manner as muſt do honour to his memory, at the ſame time that it promiſes to be a real and laſting improvement to ſcience, by ſhowing a method of preparing this valuable pigment without that nauſeous and horrid ingredient, blood, which is now uſed in great quantities for that purpoſe.—His firſt hint concerning this matter ſeems to have been taken from an obſervation of the air in his receiver accidentally taking fire from the neighbourhood of a candle. It burned without any exploſion, and he was able to inflame it ſeveral times ſucceſſively. Wiſhing to know whether any fixed air was contained in the colouring matter, he filled a retort half full of the liquor containing the colouring matter, and applying a receiver immediately after, gave the retort a briſk heat. As ſoon as the receiver was filled with thick vapours of the colouring matter, he disjoined it, and, inflaming the vapour by a little burning ſulphur introduced into the cavity, found that the air which remained threw down a precipitate from lime-water. "Hence (ſays he) it may be concluded, that the aerial acid (A) and phlogiſton exiſt in this colouring matter."

1195
Inflammability of the colouring matter.

1196
Aerial acid and phlogiſton ſuppoſed to exiſt in it.

1197
Pruſſian blue yields volatile alkali by diſtillation.

It has been aſſerted by ſeveral chemiſts, that Pruſſian blue by diſtillation always yields volatile alkali.—To determine this, Mr Scheele prepared ſome exceedingly pure from the precipitating liquor abovementioned and green vitriol; diſtilling it afterwards in a glaſs retort, to which he adapted a receiver containing a little diſtilled water. The operation was continued till the retort became red-hot. In the receiver was found the colouring matter and volatile alkali, but no oil; the air in the receiver was impregnated with aerial acid, and the ſame colouring matter; the reſiduum was very black, and obeyed the magnet. On ſubſtituting, inſtead of the Pruſſian blue, the precipitates of other metallic ſubſtances precipitated by the Pruſſian alkali, the reſults were: 1. The yellowiſh brown precipitate of cobalt yielded the very ſame products with Pruſſian blue itſelf; the reſiduum in the retort was black. 2. The yellow precipitate of copper took fire, and emitted, from time to time, ſparks during the diſtillation. It produced little colouring matter, but a greater quantity of aerial acid and volatile alkali than had been obtained by the former precipitates. A ſublimate aroſe in the neck of the retort, but in too ſmall a quantity to make any experiment; the reſiduum was reduced copper. 3. The precipitate of zinc yielded the ſame with Pruſſian blue. 4. That of ſilver yielded likewiſe volatile alkali and fixed air, but chiefly colouring matter; a ſublimate containing ſome ſilver aroſe into the neck of the retort; the reſiduum was reduced ſilver. 5. Calx of mercury cryſtallized by means of the colouring matter, yielded ſome of that matter, but ſcarce any mark of volatile alkali. Some mercury, with a portion of the original compound, aroſe in the neck of the retort.

1198
Appearances on diſtilling other precipitates thrown down by Pruſſian alkali.

1199
Ingredients contained in the colouring matter.

From theſe experiments Mr Scheele concluded, that the colouring matter of Pruſſian blue was compoſed of volatile alkali and an oily matter. He was confirmed in his conjecture, by obtaining Pruſſian blue from green vitriol and ſpirit of hartſhorn recently diſtilled on the addition of muriatic acid. The ſame product was obtained by means of the volatile ſpirit drawn from ox's blood; ſo that nothing now remained, but to imitate theſe natural proceſſes by artificially combining the two ingredients together. For this purpoſe he diſtilled a mixture of volatile ſalt and unctuous oil; a mixture of the ſame alkali with animal fat, and with oil of turpentine; a mixture of quick-lime, ſal ammoniac, and axunge, with others of a ſimilar kind; but in vain. He began therefore to conclude, that as long as the volatile alkali contained any water, it could not enter into an union ſufficiently intimate with the other principles to form the colouring matter; and finding alſo that the coal of blood, mixed with ſalt of tartar, yielded very good lixivium ſanguinis, he concluded that no oily matter was neceſſary for the ſucceſs of the experiment.

1200
Unſucceſsful attempts to prepare it artificially.

1201
True method of forming it.

Thus was our author led to make the following deciſive trials, which at once accompliſhed his purpoſe, and ſhowed the truth of the principles he had aſſumed. Three table-ſpoonfuls of charcoal powder were mixed with an equal quantity of alkali of tartar, and the mixture put into a crucible. A ſimilar mixture was put into another crucible, and both put into a fire, and kept red-hot for about a quarter of an hour. One of them was then taken out, and the contents thrown, while perfectly red-hot, into eight ounces of water. At the ſame time he put into the other quantity an ounce of ſal ammoniac in ſmall pieces, agitating the whole briſkly together, and taking care at the ſame time to puſh the ſal ammoniac down towards the bottom of the crucible, which he replaced in the fire. Obſerving in two minutes after, that no ammoniacal vapours aroſe, the whole maſs was thrown, when red-hot, into eight ounces of water. The former lixivium, into which no ſal ammoniac had been put, yielded no Pruſſian blue; but the latter ſhowed the ſame phenomena with the beſt lixivium ſanguinis, and produced a great quantity of blue. By mixing plumbago with the alkali inſtead of charcoal, a tolerable lixivium was obtained.

1202
Volatile alkali capable of uniting with phlogiſton and fixed alkali, ſo as to ſuſtain a great degree of heat.

"From theſe experiments (ſays Mr Scheele), it appears, that the volatile alkali is capable of uniting with the carbonaceous matter, after it has been ſubtilized by a ſtrong heat; that it thus acquires the remarkable property of combining ſo firmly with ſalt of tartar as to be able to ſuſtain the moſt violent degree of heat; and when this lixivium is diſſolved in water, there is obtained lixivium ſanguinis, as it is called.—It is now eaſy to explain what happens in the diſtillation

---

(A) This reaſoning ſeems not to be ſufficiently concluſive; for late experiments have ſhown that inflammation is generally attended with the production of fixed air, which could not be proved to have an exiſtence either in the materials or common atmoſphere before.

1203 Appearances on diſtilling Pruſſian blue accounted for.

lation of Pruſſian blue, as well as that of the other abovementioned metallic precipitates.—In the diſtillation of Pruſſian blue, for inſtance, the calx of iron attracts a portion of phlogiſton from the colouring matter. The aerial acid being thus diſengaged, muſt go over into the receiver with the volatile alkali, which is ſet free at the ſame inſtant; but as the calx of iron in the heat of this diſtillation cannot unite with more phlogiſton, a portion of the colouring matter, not decompoſed, muſt likewiſe ariſe. If the calx of iron could combine with the whole of the phlogiſton, there would come nothing over into the reciever but aerial acid and volatile alkali. In order to prove this, I diſtilled a mixture of ſix parts of mangaueſe finely powdered, and one part of pulverized Pruſſian blue, and obtained nothing but aerated volatile alkali, without the leaſt mark of colouring matter."

1204 Colouring matter kept from riſing by mangaueſe.

1205 The colouring matter can ſeparate only mercury and ſilver from their ſolution in nitrous acid.

Mr Scheele further remarks, that this colouring matter may probably be obtained in an aerial form, though he had not been able to do ſo. It is alſo worth notice, that, excepting the ſolutions of ſilver and mercury in nitrous acid, the colouring matter of Pruſſian blue is not able to decompoſe any other by a ſingle elective attraction. Now, as we know that Pruſſian blue is not ſoluble in acids, it naturally follows, that the colouring matter has a greater affinity with iron than acids have, notwithſtanding there is no precipitation perceived when this matter is mixed with the ſolution of vitriol of iron. "It may not be eaſy (ſays Mr Scheele) to give a ſatisfactory explanation of this phenomenon."

1206 Nitre alkalized by iron.

Iron deflagrates with nitre, and renders the ſalt alkaline and cauſtic. A part of the iron is thus rendered ſoluble, along with the alkalized ſalt. A mixture of equal parts of iron filings and nitre, injected into a ſtrongly heated crucible, and, after the detonation, thrown into water, tinges the liquor of a violet or purpliſh blue colour. This ſolution, however, is not permanent. Though the liquor at firſt paſſes through a filter, without any ſeparation of the iron; yet, on ſtanding for a few hours, the metal falls to the bottom, in form of a brick-coloured powder. Volatile alkalies inſtantly precipitate the iron from this fixed alkaline ſolution.

1207 Iron filings and ſulphur take fire ſpontaneouſly.

Iron readily unites with ſulphur; and when combined with it, proves much eaſier of fuſion than by itſelf. A mixture of iron filings and ſulphur, moiſtened with water, and preſſed down cloſe, in a few hours ſwells and grows hot; and, if the quantity is large, burſts into flame.

By cementation with inflammable maters, iron imbibes a larger quantity of phlogiſton; and becomes much harder, leſs malleable, and more fuſible. It is then called *ſteel.* See METALLURGY, and STEEL.

§ 5. *LEAD.*

1208 Has very little tenacity.

LEAD is a pale or livid-white metal, ſoon loſing its brightneſs in the air, and contracting a blackiſh or greyiſh aſh-colour. It is the ſofteſt and moſt flexible of all metallic bodies; but not ductile to any great degree, either in the form of wire or leaf; coming far ſhort, in this reſpect, of all other metals. It has alſo the leaſt tenacity of all metallic bodies; a leaden wire of $\frac{1}{10}$ of an inch diameter being capable of ſupporting only 29$\frac{1}{4}$ pounds. Lead has, however, a conſiderable ſpecific gravity; loſing, when immerſed in water, between $\frac{1}{11}$ and $\frac{1}{12}$ of its weight. It is of all metals the moſt fuſible, excepting only tin and biſmuth. The plumbers caſt thin ſheets of lead upon a table or mould, covered with a woollen, and above this with a linen, cloth, without burning or ſcorching the cloths. The melted lead is received in a wooden caſe without a bottom; which being drawn down the ſloping table by a man on each ſide, leaves a ſheet of its own width, and more or leſs thin according to the greater or leſs celerity of its deſcent. For thick plates, the table is covered over with moiſtened ſand, and the liquid metal conducted evenly over it, by a wooden ſtrike, which bears on a ledge at each ſide.

1209 Sheet-lead.

1210 Advantages of milled lead precarious.

Some have preferred, for mechanic uſes, the milled lead, or flatted ſheets, to the caſt; as being more equal, ſmooth, and ſolid. But whatever advantage of this kind the milled ſort may appear to have at firſt, they are not found to be very durable. When the lead is ſtretched between the rollers, its cavities muſt neceſſarily be enlarged. The particles of metal that may be ſqueezed into them can have no union or adheſion with the contiguous particles; and of conſequence, muſt be liable, from bending, blows, jarrs, &c. to ſtart out again, and leave the maſs ſpongy and porous.

1211 Rendered ſonorous.

Lead yields the dulleſt and weakeſt ſound of all metallic bodies. Reaumer obſerves, that it is rendered ſonorous by caſting a ſmall quantity into a ſpherical or elliptical ſegment, as in the bottom of an iron-laddle; from hence he conjectures, that the ſound of the ſonorous metals might be improved for the bells of clocks, &c. by giving them a ſimilar form.

1212 Calcined.

Though this metal very ſoon loſes its luſtre, and tarniſhes in the air, it reſiſts much longer than iron or copper the combined action of air and water, before it is decompoſed or deſtroyed; and hence it is exceedingly uſeful for many purpoſes to which theſe metals can by no means be applied. When juſt become fluid, lead looks bright like quickſilver; but immediately contracts a variouſly coloured pellicle on the ſurface. If this is taken off, and the fire continued, a freſh pellicle will always be formed, till the metal is by degrees changed into a duſky powder or calx. The injection of a little fat, charcoal-powder, or other inflammable matter, prevents this change, and readily revives the calx into lead again. It is ſaid, that lead, recovered from its calces, proves ſomewhat harder and whiter than at firſt, as well as leſs ſubject to tarniſh in the air.

1213 Minium.

The blackiſh calx or aſhes of lead become of a very different appearance if the calcination is continued with a fire ſo moderate as not to melt them, and particularly if expoſed to flame. By this treatment it is ſaid that they become firſt yellow; then they are called *maſſicot* or *yellow lead.* This colour becomes gradually more and more intenſe, till at laſt the calx is of a deep red; and then is called *minium* or *red lead;* but it is certain, that by proper management this calx never becomes yellow, aſſuming a reddiſh colour from the beginning. Too great a heat makes it irrecoverably yellow. It can be more eaſily prepared without expoſure

expoſure to the flame. The degree of heat neceſſary for converting it into minium is between 600 and 700 of Fahrenheit.

1214 Litharge. If inſtead of keeping this calx in a continued moderate heat, it be ſuddenly fuſed, the matter then puts on a foliated appearance, changing to a dull kind of brick-colour when powdered, and is then called *litharge*. Moſt of this ſubſtance is produced by refining ſilver with lead (ſee Refining): and is of two kinds, white and red. Theſe two are diſtinguiſhed by the names of *litharge of gold*, and *litharge of ſilver*. The moſt perfect is that called *litharge of gold*: the pale ſort contains a conſiderable proportion of lead in its metallic ſtate; and even the higheſt coloured litharge is ſeldom free from a little metallic lead, diſcoverable and ſeparable by melting the maſs in a crucible; when the lead ſubſides to the bottom.

1215 Phenomena with other metals. Lead mingles in fuſion with all the metals except iron, with which it refuſes any degree of union as long as the lead preſerves its metallic form. On continuing the fire, the lead, ſcorifying or calcining, abſorbs the phlogiſtic principle of the iron, and conſequently promotes the calcination of that metal; both being at length reduced to calces. The fuſible calx of lead eaſily unites with the calx of iron, and both melt together into an opaque brown or blackiſh glaſs. Copper does not unite with melted lead till the fire is raiſed ſo high as to make the lead ſmoke and boil, and of a bright red heat. Pieces of copper, now thrown in, ſoon diſſolve and diſappear in the lead: the mixture, when cold, is brittle, and of a granulated texture. The union of theſe two metals is remarkably ſlight. If a mixture of copper and lead is expoſed to a fire no greater than that in which lead melts, the lead almoſt entirely runs off by itſelf; a ſeparation of which no other example is known. What little lead is retained in the pores of the copper, may be ſcorified, and melted out, by a fire conſiderably leſs than is ſufficient to fuſe copper. If any of the copper is carried off by the lead, it ſwims unmelted on the ſurface.

Gold and ſilver are both diſſolved by lead in a ſlight red heat. They are both rendered extremely brittle by the minuteſt quantity of this metal; though lead is rendered more ductile by a ſmall quantity of either of them. In cupellation, a portion of lead is retained by gold, but ſilver parts with it all. On the other hand, in its eliquation from copper, if the copper contains any of the precious metals, the ſilver will totally melt out with the lead, but the gold will not. The attraction of lead to copper, however ſlight, is greater than that of copper to iron: a mixture of copper and iron being boiled in melted lead, the copper is imbibed by the lead, and the iron thrown up to the top. Silver is in like manner imbibed from iron by lead; whilſt tin, on the contrary, is imbibed from lead by iron. If two mixtures, one of lead and tin, and another of iron and ſilver, be melted together, the reſult will be two new combinations, one of the tin with the iron at the top, the other with the lead and ſilver at the bottom: how carefully ſoever the matter be ſtirred and mixed in fuſion, the two compounds, when grown cold, are found diſtinct, ſo as to be parted with a blow.

1216 Soluble in alkalies and in oils. This metal is ſoluble in alkaline lixivia and expreſſed oils. Plates of lead boiled in alkaline lixivia, have a ſmall part diſſolved, and a conſiderable quantity corroded: the ſolution ſtains hair black. Lead, fuſed with fixed alkaline ſalts, is in part corroded into a dark-coloured ſcoria, which partially diſſolves in water. Expreſſed oils diſſolve the calces of lead, by boiling, in ſuch large quantities as to become thick and conſiſtent: hence plaſters, cements for water-works, paint for preſerving nets, &c. Acids have a greater affinity with leads than oils have. If the common plaſter, compoſed of oil and litharge, be boiled in diſtilled vinegar, the litharge will be diſſolved, and the oil thrown up to the top. The oil thus recovered, proves ſoluble like eſſential oils in ſpirit of wine; a phenomenon firſt taken notice of by Mr Geoffroy.

§ 6. *Tin*.

The colour of this metal reſembles ſilver, but is ſomewhat darker. It is ſofter, leſs elaſtic, and ſonorous, than any other metal except lead. When bent backwards and forwards, it occaſions a crackling ſound, as if torn aſunder. It is the lighteſt of all the malleable metals, being little more than ſeven times ſpecifically heavier than water. The tenacity of its parts alſo is not very conſiderable; a tin wire of $\frac{1}{10}$ of an inch diameter being able to ſupport only $49\frac{1}{2}$ pounds.

1217 Capable of being beat into thin leaves. Tin is commonly reckoned the leaſt ductile of all metals except lead; and certainly is ſo, in regard to ductility into wire, but not in regard to extenſibility into leaves. Theſe two properties ſeem not to be ſo much connected with one another as is generally imagined. Iron and ſteel may be drawn into very fine wire, but cannot be beat into leaves. Tin, on the other hand, may be beat into very thin leaves, but cannot be drawn into wire: gold and ſilver poſſeſs both properties in a very eminent degree; whilſt lead, notwithſtanding its flexibility and ſoftneſs, cannot be drawn into fine wire, or beat into thin leaves. It melts the moſt eaſily of all the metals; about the 430th degree of Fahrenheit's thermometer. Heated till almoſt ready to melt, it becomes ſo brittle that large blocks may be eaſily beat to pieces by a blow. The purer ſort, from its facility of breaking into long ſhining pieces, is called *grain-tin*. Melted, and nimbly agitated at the inſtant of its beginning to congeal, it is reduced into ſmall grains or powder.

1218 Calcined. With the heat neceſſary for fuſion, it may alſo be calcined; or at leaſt ſo far deprived of its phlogiſton as to appear in the form of a grey calx, which may be entirely reduced to tin by the addition of inflammable matter. The calcination of tin, like that of lead, begins by the melted metal loſing its brightneſs, and contracting a pellicle on its ſurface. If the fire is raiſed to a cherry-red, the pellicle ſwells and burſts, diſcharging a ſmall bright flame of an arſenical ſmell. By longer continuance in the fire, the metal is converted firſt into a greyiſh, and then into a perfectly white calx, called *putty*, which is uſed for poliſhing glaſs and other hard bodies.

The calx of tin is the moſt refractory of all others. Even in the focus of a large burning mirror, it only ſoftens a little, and forms cryſtalline filaments. With glaſs of biſmuth, and the ſimple and arſenicated glaſſes of lead, it forms opaque milky compounds. By this property it is fitted for making the baſis of the imperfect glaſſes called *enamels*; (ſee GLASS and ENAMEL). The author of the Chemical Dictionary relates, "that having expoſed very pure tin, ſingly, to a fire as ſtrong as that of a glaſs-houſe furnace, during two hours, under a muffle, in an uncovered teſt, and having then examined it, the metal was found covered with an exceedingly white calx, which appeared to have formed a vegetation; under this matter was a reddiſh calx, and an hyacinthine glaſs; and laſtly, at the bottom was a piece of tin unaltered. The experiment was ſeveral times repeated with the ſame ſucceſs."

1219 Affinity of tin with arſenic.

Nitre deflagrates with tin, and haſtens the calcination of this as well as of other imperfect metals. The vapours which riſe from tin, by whatever method it is calcined, have generally an arſenical ſmell. Tin melted with arſenic falls in great part into a whitiſh calx: the part which remains uncalcined proves very brittle, appears of a white colour, and a ſparkling plated texture, greatly reſembling zinc. The arſenic is ſtrongly retained by the tin, ſo as ſcarcely to be ſeparable by any degree of fire; the tin always diſcovering, by its augmentation in weight, that it holds a portion of arſenic, though a very intenſe fire has been uſed. Hence, as the tin ores abound in arſenic, the common tin is found alſo to participate of that mineral.

1220 Arſenic ſeparable from tin.

Henckel diſcovered a method of ſeparating actual arſenic from tin; namely, by ſlowly diſſolving the tin in eight times its quantity of an aqua-regia made with ſal ammoniac, and ſetting the ſolution to evaporate in a gentle warmth: the arſenic begins to concrete whilſt the liquor continues hot, and more plentifully on its growing cold, into white cryſtals. M. Margraaf, in the Berlin Memoirs for 1746, has given a more particular account of this proceſs. He obſerves, that the white ſediment which at firſt ſeparates during the diſſolution, is chiefly arſenical; that Malacca tin, which is accounted one of the pureſt ſorts, yielded no leſs than $\frac{1}{4}$th its weight of arſenical cryſtals; that ſome ſorts yielded more; but that tin extracted from a particular kind of ore, which contained no arſenic, afforded none. That the cryſtals were truly arſenical, and appeared from their being totally volatile; from their ſubliming (a little fixed alkaline ſalt being added to abſorb the acid) into a colourleſs pellucid concrete; from the ſublimate, laid on a heated copper-plate, exhaling in fumes of a garlic ſmell; from its ſtaining the copper white: and from its forming, with ſulphur, a compound ſimilar to the yellow or ſulphurated arſenic. He found that the arſenic was ſeparable alſo by means of mercury; an amalgam of tin being long triturated with water, and the powder which was waſhed off committed to diſtillation, a little mercury came over, and bright arſenical flowers aroſe in the neck of the retort.

1221 Dr Lewis's obſervation.

Dr Lewis obſerves, that the crackling noiſe of tin in bending may poſſibly ariſe from its arſenic; as thoſe operations which are ſaid to ſeparate arſenic from the metal, likewiſe deprive it of this property.

Tin may be allayed, in any proportion, with all metals by fuſion: but it abſolutely deſtroys their ductility, and renders them brittle, as in bell-metal; whence this metal has obtained the name of *diabolus metallorum*.

Mercury or quickſilver.

1222 Injurious to other metals.

Iron is diſſolved by tin in a heat far leſs than that in which iron itſelf melts; the compound is white and brittle. Iron added to a mixture of lead and tin, takes up the tin, leaving the lead at the bottom; and in like manner, if lead, tin, and ſilver, are melted together, the addition of iron will abſorb all the tin, and the tin only. Hence an eaſy method of purifying ſilver from tin.

1223 Not liable to ruſt.

Tin notwithſtanding it is, like lead, ſoon deprived of its luſtre by expoſure to the air, is nevertheleſs much leſs liable to ruſt than either iron, copper, or lead; and hence is advantageouſly uſed for covering over the inſides of other metalline veſſels. The amalgam of mercury and tin is employed to cover one of the ſurfaces of looking-glaſſes; by which they are rendered capable of reflecting the rays of light.

1224 Aurum moſaicum.

The amalgam alſo, mixed with ſulphur and ſal ammoniac, and ſet to ſublime, yields a ſparkling gold-coloured ſubſtance called *aurum moſaicum*; which is ſometimes uſed as a pigment. This preparation is commonly made from quickſilver and tin, of each two parts, amalgamated together; and then thoroughly mixed with ſulphur and ſal ammoniac, of each one part and a half. The mercury and ſulphur unite into a cinnabar, which ſublimes along with the ſal ammoniac; and, after ſublimation, the aurum moſaicum remains at the bottom.

Sulphur may be united with tin by fuſion; and forms with it a brittle maſs, more difficultly fuſible than pure tin. Sulphur has, in this reſpect, the ſame effect upon tin as upon lead. The allay of tin leſſens the fuſibility of theſe very fuſible metals, while it increaſes the fuſibility of other difficultly fuſible metals, as iron and copper.

§ 7. *MERCURY or QUICKSILVER.*

1225 Heavier in winter than in ſummer.

MERCURY is a fluid metallic ſubſtance, of a bright ſilver colour, reſembling lead or tin when melted; entirely void of taſte and ſmell; extremely diviſible; and congealable only in a degree of cold very difficultly produced, in this country, by art (ſee COLD and CONGELATION). It is the moſt ponderous of all fluids, and of all known bodies, gold and platina excepted; its ſpecific gravity being to that of water nearly as 14 to 1. It is found to be ſpecifically heavier in winter than in ſummer by 25 grains in 11 ounces

Neither air nor water, nor the united action of theſe two, ſeem to make any impreſſion upon mercury: nor is it more ſuſceptible of ruſt than the perfect metals. Its ſurface, nevertheleſs, is more quickly tarniſhed than gold or ſilver; becauſe the duſt which floats in the air, quickly ſeizes on its ſurface. The watery vapours alſo, which float in the air, ſeem to be attracted by mercury.

1226 Purification.

From theſe extraneous matters, which only ſlightly adhere to it, mercury may be eaſily cleanſed by paſſing it through a clean new cloth, and afterwards heating it: but if mixed with any other metal, no ſeparation can be effected without diſtillation. In this proceſs, a ſmall portion of ſome of the metals generally ariſes along with the mercury. Thus, quickſilver

1227 Curious mercuries by Boyle.

ver diſtilled from lead, biſmuth, or tin, appears leſs bright than before; ſtains paper black; ſometimes exhibits a ſkin upon the ſurface; and does not run freely, or into round globules. Mr Boyle relates, that he has obſerved the weight of mercury ſenſibly increaſed by diſtillation from lead, and this when even a very moderate fire was made uſe of. By amalgamation with ſtellated regulus of antimony, and then being diſtilled after a few hours digeſtion, mercury is ſaid to become, by a few repetitions of the proceſs, more ponderous, and more active. The animated, or philoſophic mercuries of ſome of the alchemiſts, are ſuppoſed to have been mercury thus prepared. By the ſame, or ſimilar proceſſes, ſeem to have been obtained the curious mercuries which Boyle declared he was poſſeſſed of, and made himſelf; which were "conſiderably heavier in ſpecie than common quickſilver,—diſſolved gold more readily,—grew hot with gold, ſo as to be offenſive to the hand, and elevated gold in diſtillation." When quickſilver is to be diſtilled, it is proper to mingle it with a quantity of iron-filings; which have the property of making it much brighter than it can be otherwiſe obtained, probably by furniſhing phlogiſton.

1228 Mercurius precipitatus per ſe.

1229 Mercury unalterable by a gentle heat;

By digeſtion in a ſtrong heat for ſeveral months, mercury undergoes a conſiderable alteration, changing into a powder, at firſt aſh-coloured, afterwards yellow, at length of a bright red colour, and an acrid taſte; and is then called *mercurius precipitatus per ſe.* In this laſt ſtate it proves ſimilar to the red precipitate, prepared from a ſolution of mercury in nitrous acid. This calx proves leſs volatile in the fire than the mercury in its fluid ſtate. It ſupports for ſome time even a degree of red heat. In the focus of a burning mirror, it is ſaid to melt into glaſs when laid upon a piece of charcoal, and to revive into running mercury before it exhales. Evaporated by common fire, it leaves a ſmall portion of a light brown powder; which, Boerhaave relates, bore a blaſt-heat; ſwelled into a ſpongy maſs; formed with borax a vitreous friable ſubſtance; but vaniſhed in cupellation. By a long continued digeſtion in a gentle heat, mercury ſuffers little change. Boerhaave digeſted it in low degrees of heat, both in open and cloſe veſſels, for 15 years together, without obtaining any other reward for his labour than a ſmall quantity of black powder; which, by trituration, was quickly revived into running mercury. Conſtant triture, or agitation, produce a change ſimilar to this in a ſhort time. Both the black and red powders, by bare expoſure to a fire ſufficient to elevate them, return into fluid mercury. The red powder has been revived by ſimply grinding it in a glaſs mortar.

1230 Or by diſtillation.

1231 Exploſion by the vapours of mercury.

In like manner, quickſilver remains unchanged by diſtillation. Boerhaave had the patience to diſtil 18 ounces of mercury upwards of 500 times over, without obſerving any other change than that its fluidity and ſpecific gravity were a little increaſed, and that ſome grains of a fixed matter remained. The vapours of mercury, like thoſe of all other volatile bodies, cauſe violent exploſions if confined. Mr Hellot gives an account of his being preſent at an experiment of this kind: a perſon pretending to fix mercury, had incloſed it in an iron box cloſely welded. When the mercury was heated, it burſt the box, and diſſipated in inviſible vapours.

1232 Amalgamated with different ſubſtances.

Mercury diſſolves or unites with all metallic bodies, except three, *viz.* iron, arſenic, and nickel: in ſome caſes it will abſorb metals, particularly gold and ſilver, from their ſolutions in acids or alkalies; but does not act upon any metal when combined with ſulphur, nor on precipitates made by alkalies, nor on calces by fire. Whatever metal it is united with, it conſtantly preſerves its own white colour. It unites with any proportion of thoſe metallic ſubſtances with which it is capable of being combined; forming, with different quantities, amalgams of different degrees of conſiſtence. From the fluid ones, greateſt part of the quickſilver may be ſeparated by colature. Biſmuth is ſo far attenuated by mercury, as to paſs through leather with it in conſiderable quantity. It alſo promotes the action of quickſilver upon lead to a great degree; ſo that mercury united with $\frac{1}{4}$, $\frac{1}{8}$, or $\frac{1}{12}$ its weight of biſmuth, diſſolves maſſes of lead in a gentle warmth, without the agitation, triture, comminution, or melting heat neceſſary to unite pure mercury with lead. From theſe properties, this ſolution of biſmuth in mercury becomes a proper ſolvent for pieces of lead lodged in the human body.

1233 Separation of the amalgamated metal.

On triturating or digeſting amalgams for a length of time, a blackiſh or duſky-coloured powder ariſes to the ſurface, and may be readily waſhed off by water. Some of the chemiſts have imagined, that the amalgamated metal was here reduced to its conſtituent parts: but pure mercury is by itſelf reducible to a powder of the ſame kind; and the metallic particles in this proceſs, united with the mercury, are found to be no other than the metal in its entire ſubſtance. Some metals ſeparate more difficultly than others; gold and ſilver the moſt ſo. Boerhaave relates, that if the powder which ſeparates from an amalgam of lead be committed to diſtillation with vinegar in a tall veſſel, the mercury will ariſe before the vinegar boils; that, by a like artifice, quickſilver may be made to diſtil in a leſs degree of heat than that of the human body: but Dr Lewis, though he made many trials, was never able to ſucceed.

1234 Becomes fixed by amalgamation with gold.

By amalgamation with gold, mercury may become exceedingly fixed; ſo as not to be diſſipable by the greateſt heat. Concerning this, Dr Brandt relates the following curious experiment: "Having amalgamated fine gold with a large proportion of quickſilver, and ſtrained off the ſuperfluous mercury, he digeſted the amalgam in a cloſe ſtopped veſſel for two months with ſuch a degree of heat, that a part of the quickſilver ſublimed into the neck of the glaſs. The matter being then ground with twice its weight of ſulphur, and urged with a gradual fire in a crucible, a ſpongy calx remained; which being melted with borax, and afterwards kept in fuſion by itſelf for half an hour, in a very violent fire, ſtill retained ſo much of the quickſilver as to become brittle under the hammer, and appear internally of a leaden colour. The metal being again amalgamated with freſh mercury, the amalgam again ground with ſulphur, and expoſed to an intenſe fire, a ſpongy calx remained as before. This calx being digeſted in two or three freſh parcels of aqua-regia, a ſmall portion of whitiſh matter remained at laſt undiſſolved. The paper which covered the cylindrical glaſs wherein the digeſtion was performed, contracted, from the vapours, a deep-green circular ſpot in the middle, with a ſmaller one at the ſide; whereas the aqua-regia digeſted in the ſame manner by itſelf, or with gold, or with mercury, gave no ſtain. The firſt ſolution, on the addition of oil of tartar *per deliquium*, grew red as blood; on ſtanding, it depoſited, firſt, a little yellow calx, like aurum fulminans; afterwards, a bright matter like fine gold; and at laſt, a paler precipitate, inclining to green; its own deep red colour and tranſparency remaining unchanged. Being now committed to diſtillation, a colourleſs liquor aroſe; and the reſiduum, perfectly exſiccated, yielded, on edulcoration, a yellow calx of gold; which the alakaline lixivium had been unable to precipitate. The ſecond ſolution turned green on the admixture of the alkaline liquor, and let fall a white precipitate, which turned black and brown. The ſeveral precipitates were calcined with twice their weight of ſulphur, and then melted with four times their quantity of flint, and twelve of pot-aſh, in a fire vehemently excited by bellows. The ſcoria appeared of a golden colour, which, on pulverization and edulcoration, vaniſhed. At the bottom was a regulus, which looked bright like the pureſt gold; but was not perfectly malleable. Broken, it appeared internally white; and the white part amounted to at leaſt one-third its bulk Beſides this lump of metal, there were ſeveral others, white like ſilver, and ſoft as lead."

1235 Suppoſed to be convertible into water.

In Wilſon's chemiſtry, we have a proceſs for converting quickſilver into water, by dropping it by little and little into a tall iron veſſel, heated almoſt to a white heat in the bottom. Over the mouth of this veſſel were luted ſeven aludels; and on the top, a glaſs alembic head, with a beak, to which was fitted a receiver. The mercury was put in ſo ſlowly, that it required 16 hours for one pound. Every time that a little quantity of mercury was put in, it made a great noiſe, filling the aludel's head and receiver with white fumes. When the veſſels were cooled, a little water was found in each of the receivers, and in the firſt and ſecond ſome grains of crude mercury. The whole quantity amounted to 13 ounces and 6 drachms; which was expected to prove a powerful ſolvent of gold and ſilver: but, on trial, was found to be in no reſpect different from common water. On this experiment Dr Lewis has the following note.

1236 Dr Lewis's detection of the falſehood of this proceſs.

"The poſſibility of converting mercury into water, or at leaſt of obtaining a great quantity of water from mercury, has not only been believed by ſeveral great men in the chemical art, but ſome have even ventured to aſſert that they have actually made this change. Yet, neverthleſs, they have delivered the hiſtory of this affair with ſuch marks, as ſeem to make the reality of the change extremely doubtful. Mr Boyle (in his tract *of the producibleneſs of Chemical Principles*, annexed to *Scept. Chemiſt.* p. 235) ſays, "that he once obtained water from mercury without additament, without being able to make the like experiment ſucceed afterwards." M. Le Febure, who is generally looked upon as an honeſt practitioner, directs a proceſs ſimilar to that above (Wilſon's), for obtaining of this mercurial water. But it is to be ſuſpected, as Mr Hales very well obſerves (in his *Statical Experiments*, p. 200.), that Mr Boyle and others were deceived by ſome unheeded circumſtance, when they thought they obtained a water from mercury, which ſhould ſeem rather to have ariſen from the lute and earthen veſſels made uſe of in the diſtillation: for Mr Hales could not find the leaſt ſign of any moiſture upon diſtilling mercury in a retort made of an iron gun-barrel, with an intenſe degree of heat; although he frequently cohobated the mercury which came over into the recipient. "In a courſe of chemical experiments, I repeated Mr Hales's proceſs, and urged the mercury, which was let fall by little and little, through an aperture made in the gun-barrel, with a moſt intenſe degree of heat, without obtaining any water; but it being ſuſpected by a byſtander, that the mercury in this experiment came over before it had been ſufficiently acted upon by the fire, by reaſon of the lowneſs of the neck of the diſtilling inſtrument, the experiment was varied in the following manner. Sixteen ounces of mercury were heated in a crucible, in order to evaporate any moiſture that might have been accidentally mixed with it; and an iron gun-barrel of four feet in length, being placed perpendicularly in a good furnace, and a glaſs-head and recipient fitted to its upper part, the mercury was let fall by little and little into the barrel, and the fire urged with bellows. After each injection, the mercury made a conſiderable noiſe and ebullition, and aroſe into the head; where it ſoon condenſed and trickled down, in the common form of running mercury, into the recipient, without the leaſt perceptible appearance of any aqueous humidity."

1237 How to amalgate with regulus of antimony.

Mercury is difficultly amalgamated with regulus of antimony and copper; for which ſome particular manœuvres are required. Two of Dr Lewis's receipts for uniting quickſilver with copper, we have already given (n° 1153.): with regulus of antimony, mercury, he ſays, may be perfectly united, by pouring a ſmall ſtream of melted regulus into a conſiderable portion of mercury, made almoſt boiling hot. Another method directed by Henckel, is to put mercury into an iron mortar along with ſome water, and ſet the whole over the fire. When the water boils, a third or fourth part of melted regulus is to be poured in, and the maſs ground with a peſtle, till the amalgam is completed. The uſe of the water, as Dr Lewis obſerves, is to hinder the mercury from flying off by the heat of the regulus: but as the two are by this means not put together in ſo hot a ſtate, the union is more difficult, and leſs perfect. The loſs of the mercury, in the firſt proceſs, may be prevented by uſing a large veſſel, and covering it with a perforated iron-plate, through the hole in which the regulus is to be poured. This method is likewiſe applicable to the amalgamation of copper.

With ſulphur, mercury unites very readily, forming by trituration, or ſimple fuſion, a black powder or maſs, called *Ethiops mineral*; which, by careful ſublimation, becomes the beautiful red pigment called *vermillion*. (See SULPHUR, ſect. iv.).

1238 Preparations of mercurius dulcis in the moiſt way.

The extenſive uſe of mercurius dulcis in medicine has rendered it an object to chemiſts to find out ſome method of preparing it with leſs expence and trouble, and with more certainty of its effects, than it can be by the methods hitherto mentioned. This is now accompliſhed

pliſhed through the induſtry of Mr Scheele, to whom chemiſtry in general has been ſo much obliged. His method is as follows:

"Take half a pound of quickſilver, and as much pure common aquafortis. Pour it into a ſmall cucurbit with a pretty long neck, ſtop the mouth with a little paper, and put it into warm ſand. Some hours afterwards, when the acid appears no longer to act upon the quickſilver, the fire is to be augmented ſo as to make the ſolution nearly boil. This heat is to be continued for three or four hours, and the veſſel now and then to be ſhaken. Towards the end, regulate the heat in ſuch a manner that the ſolution ſhall gently boil for a quarter of an hour. In the mean time, diſſolve $4\frac{1}{2}$ ounces of pure common ſalt in ſix or eight pounds of water; pour this ſolution, ſtill boiling, into a glaſs veſſel, and immediately afterwards mix with it the abovementioned ſolution of quickſilver, which alſo muſt be boiling, in ſmall quantities at a time, with conſtant agitation. When the precipitate has ſettled, decant off the clear liquor, and pour hot water again on the precipitate, with which it is to be edulcorated till the water ſtanding upon it ſhall be entirely taſteleſs. Put the whole, obtained by theſe means, together, filter and dry it in a mild heat."

1239 How to obtain a perfectly ſaturated ſolution of quickſilver.

On this proceſs it is remarked, that when the quickſilver no longer effervesces with the acid, one would imagine that a ſaturation had taken place. But this is far from being the caſe. By increaſing the heat the ſolution is ſtill able to diſſolve a great quantity; with this difference, however, that, whereas the quickſilver in the beginning is calcined, a great deal of it afterwards, in a metallic form, is diſſolved, as appears from this, that not only no more elaſtic vapours aſcend; but alſo, that with fixed and volatile cauſtic alkalies, a black precipitate is obtained; otherwiſe, when the ſolution contains only calcined quickſilver, the precipitate is yellow. If the black precipitate be gently diſtilled, quickſilver ariſes, and there remains a yellow powder, which is that part of the metal that was calcined by the nitrous acid. The fire muſt at any rate be augmented, in order to keep the mercurial calx diſſolved, the compound of this metal and nitrous acid being extremely apt to cryſtallize even in the heat. There commonly remains ſome undiſſolved quickſilver; but it is always better to take too much than too little; for the more metal the mercurial ſolution contains, the more mercurius dulcis is obtained at laſt. The quantity here mentioned uſually produces $8\frac{1}{2}$ ounces of mercurius dulcis. The mercurial ſolution muſt be cautiouſly poured into that of ſea-ſalt, that no mercury may follow. Two ounces of ſalt would be ſufficient for the precipitation of all the quickſilver; but when ſo ſmall a quantity is uſed, it may eaſily happen, that ſome ſuperabundant corroſive ſublimate may adhere to the precipitate, which water alone is incapable of entirely ſeparating. Among other advantages this method of making mercurius dulcis poſſeſſes, it is none of the leaſt, that the powder is much finer than any to which it can be reduced in the common way by trituration, however long continued.

§ 8. *Zinc.*

This is a ſemimetal of a bluiſh white colour. It is the leaſt brittle of any of the ſemimetals; and when amply ſupplied with phlogiſton, which may be done by treating it in cloſe veſſels with inflammable matters, it poſſeſſes a ſemiductility, by which it may be flattened into thin plates. When broken, it appears formed of many flat ſhining plates or facets, which are larger when ſlowly than when haſtily cooled. When heated, it is very brittle; and crackles like tin, only londer, when bent. Expoſed to the air, it contracts in length of time a yellowiſh ruſt. 1240 Deflagration. Its ſpecific gravity, according to Dr Lewis, is to that of water as $7\frac{1}{10}$ to 1. It begins to melt as ſoon as red-hot; but does not flow thin till the fire is raiſed to a white heat. Then the zinc immediately begins to burn with an exceedingly bright and beautiful flame. Kept juſt in fuſion, it calcines ſlowly; not only on the upper ſurface, but likewiſe round the ſides, and at the bottom of the crucible. If ſeveral pieces are juſt melted together, the maſs, when grown cold, may be broken into the ſame number; their union being prevented by a yellowiſh calx, with which each piece is covered over. M. Malouin relates, in the French Memoirs for 1742, that a quantity of zinc being melted ſix times, and the fuſion continued fifteen hours each time, it proved, on every repetition, harder, more brittle, leſs fuſible, and leſs calcinable; that after the two firſt fuſions, its colour was grey; after the third, brown; and after the fourth, black; that the fifth rendered it of a ſlate-blue; and the ſixth of a clear violet.

1241 Flowers of zinc.

So violent is the deflagration of zinc, that the whole of its calx is ſublimed by it, in the form of light flocks of wool; which, however, are eaſily reduced to a fine powder. Theſe are uſed in medicine, and reckoned an excellent remedy in epileptic caſes. When once ſublimed, they are by no means capable of being elevated again by the moſt violent heat. In a heat far greater than that in which they firſt aroſe, they ſuffer no alteration; in a very vehement one, they melt, according to Henckel, into a ſemiopaque green glaſs. Vitrified with borax, they give a grey, or browniſh, glaſs. From the brightneſs of the flame of burning zinc, and the garlic ſmell which it is ſaid to emit, ſome have concluded that zinc contained the phoſphorine acid; which, from ſome other circumſtances, is not altogether improbable.

1242 Dr Lewis's method of reducing them.

The flowers of zinc have been thought very difficultly, or not at all, reducible to their metallic form by an addition of phlogiſton. But Dr Lewis obſerves, that this difficulty proceeds not from their unfitneſs to be reſtored into the form of zinc, but from the volatility of the ſemimetal, which occaſions its being diſſipated in fumes, if the common methods are made uſe of. All calces, theſe of iron excepted, require a greater heat for their fuſion than that in which the metal itſelf melts; and as a full melting heat is the greateſt that zinc can ſuſtain, it burns and calcines the inſtant of its revival, if the air is admitted; and in cloſe veſſels eſcapes, in part at leaſt, through their pores. On mixing flowers of zinc with powdered charcoal, and urging them with a ſtrong fire in a crucible, a deflagration and freſh ſublimation enſue: ſufficient marks that the zinc has been reduced to its metallic form; for as long as it remains in the ſtate of calx, neither of theſe effects can happen. If the veſſel is ſo contrived

trived as to exclude the air, and at the ſame time to allow the reviving ſemimetal to run off from the vehemence of the heat, into a receiver kept cool, the zinc will there concrete, and be preſerved in its metallic ſtate. It is ſtill more effectually detained by certain metallic bodies, as copper, or iron; with which the zinc, when thus applied, unites more readily and perfectly than it can be made to do by any other means.

1243 Oil from flowers of zinc by Mr Homberg.

Homberg pretended to obtain an oil from the flowers of zinc, by diſſolving them in diſtilled vinegar, and then diſtilling the ſolution in a glaſs retort. At firſt a quantity of phlegm aroſe; then the ſuperfluous acid; and at laſt an empyreumatic oil. This laſt, which Homberg imagined to proceed from the flowers of zinc, Newmann very juſtly attributes to the diſtilled vinegar.

1244 Another by Mr Hellot.

An oil of another kind was obtained by Mr Hellot from the above ſolution, by digeſting the aſh-coloured reſiduum, which remained after the diſtillation, with the acidulous phlegm which came over, for eight or ten days; diſtilling the tincture to dryneſs; and repeating the extraction with the diſtilled liquor, till the quantity of dry extract thus obtained was very conſiderable. This reſin-like matter, diſtilled in a retort with a ſtronger fire, yielded a yellowiſh liquor, and a white ſublimate. The liquor diſcovered no mark of oil; but, upon being paſſed upon the ſublimate, immediately diſſolved it, and then exhibited on the ſurface ſeveral drops of a reddiſh oil. Some of this oil was taken up on the point of a pencil, and applied to gold and ſilver-leaf. In twenty-four hours the parts touched appeared, in both, equally diſſolved.

1245 Zinc with other metals.

Zinc does not unite in fuſion with biſmuth, or the ſemimetal called *nickel*. It unites difficultly with iron; leſs ſo with copper; eaſier with the other metals. It renders iron or copper more eaſily fuſible; and, like itſelf, brittle whilſt hot, though conſiderably malleable when cold. 1246 Materials for ſpecula. It brightens the colour of iron almoſt into a ſilver hue, and changes that of copper into a yellow or gold colour. It greatly debaſes the colour of gold; and renders near an hundredth part of that moſt ductile metal brittle and untractable. A mixture of equal parts of each is very hard, white, and bears a fine poliſh; hence it is propoſed by Mr Hellot for making ſpecula. It is not ſubject to ruſt or tarniſh in the air, like thoſe metals whoſe baſis is copper. It improves the colour and luſtre of lead and tin, renders them firmer, and conſequently fitter for ſeveral mechanic uſes. Tin, with a ſmall proportion of zinc, forms a kind of pewter. Lead will bear an equal weight, without loſing too much of its malleability. Maoluin obſerves, that arſenic, which whitens all other metals, renders zinc black and friable; that when the mixture is performed in cloſe veſſels, an agreeable aromatic odour is perceived on opening them; that zinc amalgamated with mercury, and afterwards recovered, proves whiter, harder and more brittle than before, and no longer crackles on being bent.

1247 Deflagration of zinc with other metals.

Mixtures of zinc with other metals, expoſed to a ſtrong fire, boil and deflagrate more violently than zinc by itſelf. Some globules of the mixture are uſually thrown off during the ebullition, and ſome part of the metal calcined and volatilized by the burning zinc: hence this ſubſtance has been called *metallic nitre*. Gold itſelf does not entirely reſiſt its action. It very difficultly volatilizes copper; and hence the ſublimates obtained in the furnaces where braſs is made, or mixtures of copper and zinc melted, are rarely found to participate of that metal. 1248 Cannot be united with ſulphur. On melting copper and zinc ſeparately, and then pouring them together, a violent detonation immediately enſues, and above half the mixture is thrown about in globules.

Zinc does not unite in the leaſt with ſulphur, or with crude antimony, which ſcorify all other ſubſtances except gold and platina; nor with compoſitions of ſulphur and fixed alkaline ſalts, which diſſolve gold itſelf. With nitre it deflagrates violently. Its flowers do not ſenſibly deflagrate; yet alkalize double their weight of the ſalt more readily than the zinc itſelf. 1249 Nitre alkalized by flowers of zinc. The alkaline maſs appears externally greeniſh, internally of a purple colour. It communicates a fine purple to water, and a red to vinegar. The acetous tincture inſpiſſated, leaves a tenacious ſubſtance which ſoon runs in the air into a dark red cauſtic liquor, the alkaheſt of ſome of the pretended adepts.

§ 9. *BISMUTH.*

THIS ſemimetal, called alſo *tin-glaſs*, and by ſome naturaliſts *marcaſita officinarum*, is ſomewhat ſimilar to the regulus of antimony. It appears to be compoſed of cubes formed by the application of plates upon each other. Its colour is leſs white than that of regulus of antimony; and has a reddiſh tinge, particularly when it is expoſed to the air. In ſpecific gravity it approaches to ſilver; being nearly ten times heavier than water. It has no degree of malleability; breaking under the hammer, and being reducible by trituration to fine powder. It melts a little later than tin, and ſeems to flow the thinneſt of all metallic ſubſtances. Biſmuth is ſemivolatile, like all other ſemimetals. 1250 Convertible into litharge and glaſs. When expoſed to the fire, flowers riſe from it; it is calcined; and converted into a litharge and glaſs nearly as lead is; (See GLASS). It may even be employed, like that metal, in the purification of gold and ſilver by cupellation. (See REFINING). When in fuſion, it occupies leſs volume than in its ſolid ſtate: a property peculiar to iron among the metals, and biſmuth among the ſemimetals. It emits fumes in the fire as long as it preſerves its metallic form; when calcined or vitrified, it proves perfectly fixed.

1251 Promotes the fuſion of all the metals,

Biſmuth mingles in fuſion with all the metalline ſubſtances, except regulus of cobalt and zinc. The addition of nickel or regulus of antimony, renders it miſcible with the former, though not with the latter. It greatly promotes the tenuity as well as facility of the fuſion of all thoſe metals with which it unites. It whitens copper and gold, and improves the colour of ſome of the white metals: mixed in conſiderable quantity; it renders them all brittle, and of a flaky ſtructure like its own. If mixed with gold or ſilver, a heat that is but juſt ſufficient to melt the mixture, will preſently vitrify a part of the biſmuth; which, having then no action on thoſe perfect metals, ſeparates, and glazes the crucible all round.

§ 10. Regulus of Antimony.

1252 Appearance of a ſtar on its ſurface.

This ſemimetal, when pure, and well fuſed, is of a white ſhining colour, and conſiſts of laminæ applied to each other. When it has been well melted, and not too haſtily cooled, and its ſurface is not touched by any hard body during the cooling, it exhibits the perfect figure of a ſtar, conſiſting of many radii iſſuing from a centre. This proceeds from the diſpoſition that the parts of this ſemimetal have to arrange themſelves in a regular manner, and is ſimilar to the cryſtallization of ſalts.

1253 Sublimable.

Regulus of antimony is moderately hard; but, like other ſemimetals, it has no ductility, and breaks in ſmall pieces under a hammer. It loſes $\frac{1}{7}$ of its weight in water. The action of air and water deſtroys its luſtre, but does not ruſt it ſo effectually as iron or copper. It is fuſible with a heat ſufficient to make it red hot; but when heated to a certain degree, it fumes continually, and is diſſipated in vapours. Theſe fumes form what are called the *argentine flowers* of regulus of antimony, and are nothing but the earth of this ſemimetal deprived of part of its inflammable principle, and capable of being reduced to its reguline ſtate by an union with this principle.

1254 Separation of the ſulphur from antimony.

There are different methods of preparing the regulus of antimony; but all of them conſiſt merely in ſeparating the ſulphur which this mineral contains, and which is united with the regulus. It is plain, therefore, that regulus of antimony may be made by an addition of any ſubſtance to crude antimony in fuſion, which has a greater attraction for ſulphur than the regulus itſelf has. For this purpoſe, alkaline ſalts have been employed, either previouſly prepared, or extemporaneouſly produced in the proceſs, by a deflagration of tartar and nitre. By this means, the ſulphur was indeed abſorbed; but the hepar ſulphuris, formed by the union of the ſulphur and alkali, immediately diſſolved the regulus, ſo that very little, ſometimes none at all, was to be obtained diſtinct from the ſcoria. Metals are found to anſwer better than alkaline ſalts, but the regulus is ſeldom or never free from a mixture of the metal employed. The way of obtaining a very pure regulus, and in great quantity, is to calcine the antimony in order to diſſipate its ſulphur; then to mix the calx with inflammable matters, ſuch as oil, ſoft ſoap, &c. which are capable of reſtoring the principle of inflammability to it. This method was invented by Kunckel. Another, but more expenſive way of procuring a large yield of very pure regulus, is, by digeſting antimony in aqua-regis, which diſſolves the reguline part, leaving the ſulphur untouched, precipitating the ſolution, and afterwards reviving the precipitate by melting it with inflammable matters.

1255 Regulus eaſily miſcible with mercury.

There are conſiderable differences obſerved in the regulus of antimony, according to the different ſubſtances made uſe of to abſorb the ſulphur. When prepared by the common methods, it is found to be very difficultly amalgamated with mercury; but Mr Pott has diſcovered, that a regulus prepared with two or five parts of iron, four of antimony, and one of chalk, readily unites with mercury into an hard amalgam, by bare trituration with water. Marble and quicklime ſucceed equally well with chalk; but clay, gypſum, or other earths, have no effect.

1256 Extemporaneous regulus with cawk.

One earthy ſubſtance, found in lead-mines, and commonly called *cawk*, has a very remarkable effect upon antimony. This is found in whitiſh, moderately compact and ponderous maſſes; it is commonly ſuppoſed a ſpar; but differs from bodies of this kind, in not being acted upon by acids, (ſee nº 1068). If a lump of cawk, of an ounce or two, be thrown red hot into 16 ounces of melted antimony, the fuſion continued about two minutes, and the fluid matter poured off, "you will have 15 ounces like poliſhed ſteel, and as the moſt refined quickſilver." *Phil. Tranſ.* nº 110. Dr Lewis mentions his having repeated this experiment ſeveral times with ſucceſs: but having once varied it by mixing the cawk and antimony together at the firſt, a part of the antimony was converted into a very dark black vitreous matter, and part ſeemed to have ſuffered little change; on the ſurface of the maſs ſome yellow flowers appeared.

1257 Glaſs of antimony.

Regulus of antimony enters into the compoſitions for metallic ſpeculums for teleſcopes, and for printing-types. It is alſo the baſis of a number of medicinal preparations; but many of theſe, which were formerly much eſteemed, are found to be either inert, uncertain, or dangerous in their operations. When taken in ſubſtance, it is emetic and purgative, but uncertain in its operation; becauſe it only acts in proportion to the quantity of ſolvent matter it meets with in the ſtomach; and if it meets with nothing capable of acting upon it there, the regulus will be quite inactive. For theſe reaſons, the only two preparations of antimony now retained, at leaſt by ſkilful practitioners, are the infuſion of glaſs of antimony in wine and emetic tartar. For making the glaſs of antimony we have the following proceſs. "Take a pound of antimony; reduce it to fine powder, and ſet it over a gentle fire; calcine it in an unglazed earthen pan, till it comes to be of an aſh colour, and ceaſes to fume: you muſt keep it continually ſtirring; and if it ſhould run into lumps, you muſt powder them again, and then proceed to finiſh the calcination. When that is done, put the calcined antimony into a crucible; ſet it upon a tile in a wind-furnace; put a thin tile on the top; and cover it all over with coals. When it is brought into fuſion, keep it ſo in a ſtrong fire for an hour: then put into it an iron rod; and when the melted antimony, which adheres to it, is tranſparent, pour it upon a ſmooth, hot, marble; and when it is cold, put it up for uſe. This is *vitrum antimonii*, or *ſtibium*."

1258 Difference of ſtrength in emetic tartars.

This preparation is more violent in its effects than the pure regulus itſelf; becauſe it contains leſs phlogiſton, conſequenly is ſimilar to a regulus partially calcined, and ſo more ſoluble. Hence it is the moſt proper for infuſion in wine, or for making the tartar emetic. It is obviouſly, however, liable to great uncertainties in point of ſtrength; for as the antimony is more or leſs ſtrongly calcined, the glaſs will turn out ſtronger or weaker in its operation, and conſequently all the preparations of it muſt be liable to much uncertainty. This uncertainty is very apparent in the ſtrength of different parcels of emetic tartar: accordingly Mr Geoffroy found by examination of different emetic tartars, that an ounce of the weakeſt contain-

Rugulus of antimony.

ed from 30 to 90 grains of regulus; an ounce of moderate ſtrength contained about 108 grains; and an ounce of the ſtrongeſt kind contained 154 grains. For theſe reaſons, the author of the Chemical Dictionary recommends the pulvis algaroth as the moſt proper material for making emetic tartar; being perfectly ſoluble, and always of an equal degree of ſtrength. Emetic tartar, as he juſtly obſerves, ought to be a metallic ſalt compoſed of cream of tartar ſaturated with the regulus of antimony; and M. Beaumé has ſhown ſuch a ſaturation to be poſſible, and that the neutral ſalt cryſtallizes in the form of pyramids. They are tranſparent while moiſt; but by expoſure to a dry air, they loſe the water of their cryſtallization and become opaque. The preparation of this ſalt, according to M. Baumé, conſiſts in mixing together equal parts of cream of tartar, and levigated glaſs of antimony: theſe are to be thrown gradually into boiling water; and the boiling continued till there is no longer any efferveſcence, and the acid is entirely ſaturated. The liquor is to be filtered; and upon the filter is obſerved a certain quantity of ſulphureous matter along with ſome undiſſolved parts of the glaſs of antimony. When the filtered liquor is cooled, fine cryſtals will be formed in it, which are a ſoluble tartar perfectly ſaturated with glaſs of antimony. He obſerves, that the diſſolution is ſoon over if the glaſs is well levigated, but requires a long time if it is only groſsly pounded.

1259 Pulvis algaroth the moſt proper material for emetic tartar.

1260 Objection to its uſe.

The trouble of levigating glaſs of antimony, as well as the uncertainty of diſſolving it, would render *pulvis algaroth* much preferable, were it not on account of its price; which would be a temptation to thoſe in uſe to prepare medicines, to ſubſtitute a cheaper antimonial preparation in its place. This objection, however, is now in a great meaſure removed by Mr Scheele; who demonſtrated that the pulvis algaroth is no other than regulus of antimony half calcined by the dephlogiſticated marine acid in the corroſive ſublimate made uſe of for preparing the antimonial cauſtic. If therefore we can fall upon any other method of dephlogiſticating the regulus, we ſhall then be able to combine the marine acid with it; and by ſeparating them afterwards, may have the powder of algaroth as good as from the butter of antimony itſelf. One of the methods of dephlogiſticating the regulus is by nitre. Our author therefore gives the following receipt for the powder in queſtion.

1261 Scheele's theory of the nature of pulvis algaroth.

1262 His receipt for making it cheap.

"Take of powdered crude antimony one pound; powdered nitre, one pound and a half; which, after being well dried and mixed, are to be detonated in an iron mortar. The hepar obtained in this manner is to be powdered, and a pound of it to be put into a glaſs veſſel, on which firſt a mixture of three pounds of water and 15 ounces of vitriolic acid is to be poured, and afterwards 15 ounces of powdered common ſalt are to be added; the glaſs veſſel is then to be put in a ſand-bath, and kept in digeſtion for 12 hours, during which period the maſs is to be conſtantly ſtirred. The ſolution, when cool, is to be ſtrained through linen. On the reſiduum one third of the above menſtruum is to be poured, and the mixture digeſted and ſtrained. From this ſolution, when it is diluted with boiling water, the pulvis algarothi precipitates, which is to be well edulcorated and dried."

As regulus of antimony, like other metallic ſubſtances, is ſoluble in liver of ſulphur, it happens, that, on boiling antimony in an alkaline ley, the ſalt, uniting with the ſulphur contained in that mineral, forms an hepar ſulphuris, which diſſolves ſome of the reguline part. If the liquor is filtered, and ſaturated with an acid, the regulus and ſulphur will fall together in form of a yellowiſh or reddiſh powder, called *golden ſulphur of antimony*. If the ley is ſuffered to cool, a like precipitation of a red powder happens. This laſt is called *kermes mineral*.

Arſenic.

1263 Golden ſulphur of antimony and kermes mineral.

1263 Diaphoretic antimony.

Nitre deflagrates violently with antimony, conſuming not only its ſulphureous part, but alſo the phlogiſton of the regulus: and thus reduces the whole to an inert calx, called *antimonium diaphoreticum*. If equal parts of nitre and antimony are deflagrated together, the ſulphureous part is conſumed, as well as part of the inflammable principle of the regulus. The metalline part melts, and forms a ſemivitreous maſs of reddiſh colour, called *crocus metallorum*, or *liver of antimony*. It is a violent emetic, and was formerly uſed for making infuſions in wine ſimilar to thoſe of glaſs of antimony; but is now diſuſed on account of its uncertainty in ſtrength. It is ſtill uſed by the farriers: but the ſubſtance ſold for it is prepared with a far leſs proportion of nitre; and ſometimes even without any alkaline ſalt being added to abſorb part of the antimonial ſulphur. This crocus is of a dull red colour; and, when powdered, aſſumes a dark purple.

1265 Crocus metallorum.

§ II. *ARSENIC.*

This ſubſtance, in its natural ſtate, has no appearance of a metal, but much more reſembles a ſalt, which, as has been already obſerved, it really is when deprived of its phlogiſton. When united to a certain quantity of phlogiſton, it aſſumes a metallic appearance; and in this ſtate it is found, as Mr Bergman informs us, in Bohemia, Hungary, Saxony, Hercynia, and other parts; particularly at Alſatia in the mines called *St Marieux*. The maſſes in which it is found are frequently ſhapeleſs, friable, and powdery; but ſometimes compact, and divided into thick convex lamellæ, with a needle-formed or micaceous ſurface: it takes a poliſh, but ſoon loſes it again in the air. When freſh broken, it appears compoſed of ſmall needle-like grains of a leaden colour, ſoon becoming yellow, and by degrees blackiſh; exceeding copper in hardneſs, though as brittle as antimony.

1266 Arſenic found naturally in a metallic form.

1267 Regulus of arſenic eaſily converted into the common white kind.

Reguline arſenic, whether found naturally or prepared by art, very readily parts with as much of its phlogiſton as is ſufficient to make it fly off in a white ſmoke; but this ſtill retains a very conſiderable quantity of phlogiſtic matter, as is evident from its producing nitrous air by the affuſion of nitrous acid, and from the experiments already related of the preparation of the acid of arſenic. This calx indeed is the form in which arſenic is moſt commonly met with. It is leſs volatile than the regulus; and by ſublimation in a glaſs veſſel aſſumes an opaque cryſtalline appearance from becoming white on the ſurface; but that which cryſtallizes in the bowels of the earth does not appear to be ſubject to any ſuch change.

1268 White arſenic may be mixed with other metals.

White arſenic, though a true metalline calx, may be mixed in fuſion with the ſame metals which will unite with the regulus. This ſeems contrary to the general rule of other calces, which cannot be united with any metal in its metalline ſtate; but it muſt be remembered, that by this operation the arſenical calx is reduced to a regulus by the phlogiſton of the metal: whence, in all fuſions of this kind, ſome ſcoriæ riſe to the top, conſiſting of the calcined metal and part of the white arſenic.

1269 Solution of arſenic in water. Eight parts of diſtilled water diſſolve, by means of moderate heat, one part of calcined arſenic, and by boiling may be made to take up 15. The ſolution changes ſyrup of violet green, but the tincture of turnſole red. It is not changed by neutral ſalts, but ſlowly precipitates the ſolutions of metals, the arſenic united to the metallic calx falling to the bottom.—"It may be aſked (ſays Mr Bergman), whether the whole of the arſenic, or only the arſenical acid, unites with the metallic calx, yielding the phlogiſton to the menſtruum of the other metal?" Certainly ſuch a mutual commutation of principles does not appear improbable, if we conſider only thoſe caſes in which the menſtruum is vitriolic or nitrous acid: but as iron, for example, united with marine acid (which does not attract the phlogiſton of white arſenic), as well as when it is joined to the nitrous acid, is precipitated, it would appear that the whole of the arſenic is united, at leaſt in certain caſes, to the metallic calces.

1270 And in ſpirit of wine. One part of arſenic is diſſolved by 70 or 80 of boiling ſpirit of wine.

1271 In vitriolic acid. Arſenic diſſolves partially in concentrated vitriolic acid, but concretes in the form of cryſtalline grains on cooling. Theſe diſſolve in water with much greater difficulty than the arſenic itſelf. On the blow-pipe they emit a white ſmoke, but form into a globule by fuſion, which at firſt bubbles, but ſoon grows quiet, and is but ſlowly conſumed even in a white heat. This fixity is occaſioned by the acid carrying off the phlogiſton of the arſenic, and thus leaving a greater proportion of its peculiar acid than what it naturally contains; and therefore the more frequently the operation is repeated, the more fixed the arſenic becomes, though it is ſcarce poſſible to diſſipate the arſenical phlogiſton as perfectly with this acid as with the nitrous; the effects of which have been already particularly mentioned.

1272 In marine acid. The marine acid, which naturally contains phlogiſton, diſſolves about one-third of its weight of arſenic, a great part of which ſeparates ſpontaneouſly on cooling in a ſtate of ſaturation with the acid. This ſalt, which may be had in a cryſtalline form, is much more volatile than the former, readily ſubliming in a cloſe veſſel with a moderate heat; but is ſoluble with difficulty in boiling water. It is of a fine yellow colour, and ſcarcely differs from butter of arſenic, except in its degree of concentration. The nature of marine acid prevents it from diſengaging the arſenical acid from the phlogiſton of the ſemimetal, as will eaſily appear from what has been ſaid concerning that acid. The arſenical acid, however, is eaſily made to appear by the addition of that of nitre, as will be underſtood from the directions given by Mr Scheele for the preparation of the acid of arſenic.

1273 Phlogiſticated alkali cannot precipitate arſenic except from marine acid. Arſenic is not precipitated from its ſolution in vitriolic and nitrous acids by the phlogiſticated alkali, which yet very readily precipitates all other metals. From the marine acid, however, it is precipitated by its means of a white colour; but unleſs the ſolution be very acid, the addition of mere water will throw down a precipitate of the ſame colour.

1274 Decompoſed by dephlogiſticated marine acid. Dephlogiſticated marine acid deprives arſenic of its inflammable principle; ſo that in the diſtilling veſſel we find water, acid of arſenic, and marine acid, regenerated.

1275 Phenomena with other acids. Arſenic is diſſolved by its own acid, and forms cryſtalline grains with it as well as with that of fluor and borax. Saccharine acid diſſolves it likewiſe, and forms priſmatic cryſtals; and a ſimilar ſalt is alſo formed by the acid of tartar. Vinegar, and the acids of vinegar and phoſphorus, form with it cryſtalline grains, which are ſcarcely ſoluble in water.

1276 Liver of arſenic. Solutions of fixed alkali diſſolve arſenic; and, when loaded with it, form a brown tenacious maſs, called *liver of arſenic.* The arſenic is partly precipitated by mineral acids, though part of it gradually loſes its phlogiſton, and adheres more tenaciouſly. Solution made with volatile alkali ſeems to effect this decompoſition more readily, as no precipitation is made by acids. Limpid ſolution of ſaline hepar, dropped into a ſolution of white arſenic, floats upon the ſurface in form of a grey ſtratum, which at length diſturbs the whole liquor.

1277 Effects on metals. By the aſſiſtance of heat ſolutions of arſenic attack ſome of the metals, particularly copper, iron, and zinc; the ſolutions of the two laſt yielding cryſtals by evaporation. No alteration is made on theſe compounds by alkaline ſalts or by acids: volatile alkali does not diſcover the copper by changing the colour of the ſolution blue; nor does the phlogiſticated alkali throw down any blue precipitate from the ſolution of iron. The reaſon of this is the ſuperabundance of phlogiſton in the ſolutions; for the arſenical acid takes up all metals: when united with copper, it ſhows a blue colour with volatile alkali; and when united with iron, it lets fall a Pruſſian blue in the uſual way; but the quantity of phlogiſton which converts the acid into white arſenic, prevents the appearance of theſe phenomena when the latter is made uſe of.

1278 Unites eaſily with ſulphur. Arſenic, either in its calcined or reguline ſtate, may be united with ſulphur; in which caſe it appears either of a red or yellow colour, according to the quantity of ſulphur with which it is united. Theſe compounds are ſpontaneouſly produced by nature; both of them ſometimes pellucid and cryſtalline; with this difference, however, that the yellow ſeems to affect a lamellated, and the red a cryſtalline, form. 1279 Realgar and orpiment. Theſe are called *red and yellow orpiment*, or realgar and orpiment; the ſpecific gravity of realgar being about 3.225; of orpiment, 5.315. Both of theſe ſublime totally with a moderate heat, unleſs when they happen to be mixed with other ſubſtances. They readily unite with thoſe metals which form an union with the arſenic and ſulphur of which they are compoſed. Silver mineralized by fuſion with orpiment, forms a ſubſtance ſimilar to what is called the red ore of that metal. Iron, in conjunction with orpiment, aſſumes a white, poliſhed, and metallic appearance, ſimilar to that of the white or arſenical pyrites; and by various combinations of theſe ſubſtances with metals of different kinds, many of the natural metalline ores may be produced.

1280 Phenomena with nitrous acid. Nitre, when treated with mineralized arſenic, detonates

tonates partly with the ſulphur, and partly with the phlogiſton of the arſenic; the alkaline baſis of the ſalt either forming ſal polychreſt with the acid of the ſulphur, or uniting with the alkali, and forming the neutral arſenical ſalt. By the addition of fixed alkali in proper quantity, either to orpiment or realgar, and then expoſing the mixture to a ſubliming heat, nitre retains the ſulphur, but lets go the greateſt part of the arſenic; the hepatic maſs, however, retains a ſmall quantity of the latter; and if there is much alkali, ſcarce any of the arſenic ariſes.

1281 Butter of arſenic.

On diſtilling orpiment with twice or thrice it quantity of corroſive ſublimate, two liquids ariſe which refuſe to unite; and at length, on augmenting the heat, a cinnabar ariſes. A butter of arſenic is found at the bottom of the receiver, of a ferruginous brown colour, but pellucid: in the open air it firſt ſends forth a copious fume of a white colour, and then gradually attracts the moiſture of the atmoſphere, by which it is precipitated.

1282 Can ſcarce be made to unite with marine acid.

It is remarkable that it unites ſo ſlowly with marine acid, that they ſeem to repel one another; nor can they be made to unite beyond a certain degree. By the affuſion of diſtilled water, a white powder will be precipitated, which, though ever ſo well waſhed, retains ſome acidity; for a portion of butter of antimony is produced by diſtillation, as is likewiſe true of the pulvis algaroth. The ſmoke has a peculiar penetrating ſmell, ſomewhat ſimilar to that of phlogiſticated vitriolic acid, and lets fall white flowers.

1283 Oil of arſenic.

The liquor which ſwims above, and which, by chemical authors, has been compared to oil, is yellowiſh and pellucid, ſeparating a white arſenical powder by the addition of water and ſpirit of wine. It is not affected by the ſtronger acids; but effervesces, and lets fall a precipitate, with alkalies. On keeping it with a cucurbit with a long neck unſtopped, white flowers gradually concrete round the orifice, which are lax, and ſometimes approaching to a cryſtalline form. And laſtly, by ſpontaneous evaporation, pellucid cryſtals appear at the bottom of the liquor, which are ſoluble in water with great difficulty; but when diſſolved, precipitate ſilver from nitrous acid, and let fall ſome arſenic on the addition of an alkali. When put into lime-water, a cloud ſlowly ſurrounds them: on being expoſed to the fire, they totally ſublime without any arſenical ſmell, without decrepitation, or loſing their tranſparency; but if ignited phlogiſtic matter comes in contact with them, the arſenical ſmell inſtantly appears. No traces of mercury are to be found in this liquor by treating it either with alkali or copper; not the ſlighteſt precipitation is made by it on being dropped into a ſolution of terra ponderoſa in the marine acid: from all which it appears, that this liquor is only a very dilute butter of arſenic, containing leſs of the mercury on account of the quantity of water it has. The butter contains the acid in its moſt concentrated ſtate, and is therefore loaded with a larger quantity of arſenic: the former liquor will therefore be obtained in much larger quantity, by ſetting the mixture of corroſive ſublimate and arſenic to ſtand a night in a cellar, or moiſtened with water, before it be ſubjected to diſtillation. As the common marine acid can diſſolve only a determined quantity of the butter, it naturally follows, that what remains after complete ſaturation ſhould totally refuſe to mix. The acid, however, when too much diluted, precipitates the butter; but in proportion to its ſtrength it diſſolves a greater quantity.

1284 Arſenic mineralized by ſulphur.

Arſenic mineralized by ſulphur is not diſſolved by water, but is affected by the different acids, according to the particular circuſtances of each. Nitrous acid and aqua-regia act moſt powerfully; the former ſoon deſtroys the red colour of the realgar, and converts it into yellow orpiment; its primary action being to calcine the arſenic, without affecting the yellowneſs of the ſulphur. It makes no change on the colour of orpiment. Aqua-regia, by long digeſtion, takes up the arſenic, and leaves the ſulphur at the bottom; and hence we may find out the proportions of the two ingredients. Some dexterity, however, is neceſſary in performing this operation with accuracy; for if, on the one hand, the menſtruum be too weak, part of the arſenic will remain undiſſolved; and if, on the other, it be too ſtrong, part of the ſulphur will be decompoſed; for ſtrong nitrous acid is capable of decompoſing ſulphur by long digeſtion, having a greater attraction for phlogiſton than the vitriolic acid itſelf. The colour of the reſiduum ought to be grey; for as long as any yellow particles remain, it is a ſign that ſome of the arſenic alſo remains. If any iron be preſent in the compound, it is all diſſolved, by reaſon of the ſuperior attraction of the acid for it, before any of the arſenic is taken up, unleſs it ſhall have been calcined either by the acceſs of air and heat employed in the operation, or by the too great power of the menſtruum.

1285 Pure regulus of arſenic, how prepared.

The pure regulus of arſenic may be obtained artificially from white arſenic, either by ſublimation with oil, black flux, or other phlogiſtic materials; or by melting it with double its weight of ſoap and potaſhes; or laſtly, by precipitation by means of ſome other metal, from orpiment or ſandarack melted with ſulphur and fixed alkali. By the firſt of theſe methods it is obtained in a cryſtalline form, octohedral, pyramidal, or even priſmatic.

1286 Miſpickel, a natural regulus of arſenic.

Mr Bergman mentions a natural regulus of arſenic, named *miſpickel*, which along with ſome ſulphur contains a large quantity of iron united with the regulus into a metallic compound; but tho' the iron ſometimes amounts to $\frac{2}{2}$ or even $\frac{2}{3}$ of the whole, it nevertheleſs remains untouched by the magnet. When ignited, it ſends forth an arſenical ſmell, and ſoon becomes obedient to the magnet, even though the operation be performed on a tile without any additional phlogiſton; it melts eaſily in an open fire, and in cloſe veſſels the greater part of the regulus ſublimes, leaving the iron at the bottom.

1287 Great volatility of this ſemimetal.

The pure regulus of arſenic is vaſtly more volatile than any other metal, and therefore cannot be melted. It begins to ſend forth a viſible ſmoke in 180° of the Swediſh thermometer, and is capable of inflammation; but in order to inflame it, it muſt be thrown into a veſſel previouſly heated to a ſufficient degree, otherwiſe it will be ſublimed. The flame is of an obſcure whitiſh blue, diffuſing a white ſmoke and garlic ſmell. In cloſe veſſels it retains its metallic form, and may be ſublimed of any figure we pleaſe.

1288 Effects of regulus of arſenic on other metals.

Regulus of arſenic unites with many of the metals, but deſtroys the malleability of thoſe with which it enters into fuſion. It renders thoſe more eaſy of fuſion which are melted with difficulty by themſelves; but tin, the moſt eaſily fuſible of all the metals, becomes

comes more refractory by being united with arſenic. This metal acquires a permanent and ſhining whiteneſs by its union with regulus of arſenic, and is able to retain half its own weight of the arſenical metal. The other white metals become grey by fuſion with this ſemimetal, platina only excepted. Gold fuſed in a cloſe veſſel with regulus of arſenic, ſcarcely takes up $\frac{1}{60}$ of its weight; ſilver $\frac{1}{4}$; lead $\frac{1}{6}$; copper $\frac{5}{6}$; and iron more than its own weight. The magnetic property of this laſt metal is deſtroyed by a large quantity of regulus, though the exact proportion which deſtroys it can ſcarcely be determined, as ſome of the iron is always taken up by the ſcoria; but according to Mr Bergman, leſs than an equal quantity is certainly ſufficient. Biſmuth retains $\frac{1}{15}$ of its weight; zinc $\frac{1}{5}$; regulus of antimony $\frac{1}{8}$; and manganeſe an equal quantity. Nickel and regulus of cobalt take up a large quantity; but how much cannot be determined, as it is next to impoſſible to procure any of thoſe metals in a ſtate of perfect purity. In a ſufficient degree of heat, and by a triture of ſeveral hours, regulus of arſenic takes up about $\frac{1}{6}$ of its own weight of mercury, forming an amalgam of a grey colour.

1289 May be expelled by heat from all the metals with which it is united.

Regulus of arſenic, by reaſon of its volatility, may be expelled from all the metals with which it is united; but, in flying off, it generally carries along with it ſome of the metals with which it is united, gold and ſilver not excepted, if the degree of heat be great and very ſuddenly applied. Platina, however, perfectly reſiſts the volatilization; and by reaſon of its refractory nature, even retains a portion of the arſenic.

1290 Effects of it upon alkaline ſalts and nitre.

This ſemimetal cannot be united by fuſion with alkaline ſalts until the phlogiſton is conſiderably diminiſhed, and the regulus approaches to the nature of pure arſenical acid. By adding regulus therefore to nitre in fuſion, a detonation enſues, the phlogiſton of the former is totally deſtroyed, and the acid uniting with the alkali of the nitre forms a neutral arſenical ſalt, ſimilar to that made with white arſenic and nitre. By diſtillation with dry acid of arſenic, the regulus ſublimes before it can be acted upon by the acid; but when thrown into the acid in fuſion, ſoon takes fire, and ſends forth a white ſmoke: for the acid, being in this inſtance deprived of its phlogiſton, ſeparates that principle from the regulus, and unites with it in ſuch quantity as to regenerate white arſenic; while on the other hand, the regulus, by this operation, is ſo far deprived of its phlogiſton as to appear in the form of a calx. 1291 Decompoſes corroſive ſublimate. By diſtillation with corroſive ſublimate, a ſmoking butter, and ſmall quantity of mercurius dulcis and running mercury, are procured; which happens in conſequence of a double elective attraction; the regulus of arſenic yielding its phlogiſton to the baſe of the corroſive ſublimate, which being thus really calcined, reduces the former to perfect mercury, while the marine acid takes up the calx of arſenic. The regulus of arſenic readily unites with ſulphur, and forms the ſame red and yellow compounds that have already been mentioned when ſpeaking of white arſenic; it is ſoluble in hepar ſulphuris, but may be precipitated by every other metal which can unite with the hepar.

1292 Converted into white arſenic by the vitriolic acid.

Regulus of arſenic is not affected by the vitriolic acid, unleſs when concentrated and aſſiſted by heat. The inflammable part of the regulus which phlogiſticates the acid flies off, ſo that the remainder aſſumes the nature of white arſenic, and exhibits the ſame properties with menſtrua as any other metallic calx: the ſame holds good with nitrous acid, except that it attracts the phlogiſton more vehemently. Marine acid has little or no effect except when boiling.

1293 Effects of it on metallic ſolution.

Regulus of arſenic precipitates certain metals diſſolved in acids, ſuch as gold and platina, diſſolved in aqua-regia, as well as ſilver and mercury in vitriolic and nitrous acids. Silver generally appears in beautiful poliſhed ſpiculæ, like the arbor Dianæ; but if the arſenic be ſuffered to ſtand long in the nitrous ſolution but little diluted, the ſilver ſpiculæ are again diſſolved, the arſenic in the mean time being dephlogiſticated. Solutions of biſmuth and antimony are ſcarcely rendered turbid. Iron may be ſeparated from regulus of arſenic by digeſtion with marine acid, or with aqua-regia; neither of which will touch the arſenic, as long as any iron remains; but in order to ſucceed in this operation, ſubtile pulveriſation is neceſſary as well as a juſt quantity and ſtrength of the menſtruum. Heat muſt alſo be carefully avoided. The regulus is alſo diſſolved by hepar ſulphuris and by fat oils, the latter forming with it a black maſs like plaſter.

§ 12. *Cobalt.*

Regulus of cobalt, or more properly pure cobalt itſelf (what we have under the name of *cobalt* being only a calx of the regulus), is a ſemimetal of a reddiſh white colour, cloſe-grained, ſo as to be eaſily reducible to powder, about 7.7 of ſpecific gravity, and forming itſelf into maſſes of a needle-like texture, placed upon one another. It is ſeldom or never found native, but almoſt always calcined and united with arſenic, the arſenical acid, ſulphur, iron, &c. 1294 Zaffre, a calx of cobalt. The zaffre uſed in commerce is an impure and grey calx of cobalt. When mixed with three times its weight of pulveriſed flints, and expoſed to a ſtrong fire, it melts into glaſs of a dark blue colour, called *ſmalt*, uſed in tinging other glaſſes, and in painting. 1295 Smalt, how produced. With three times its weight of black flux, a ſmall quantity of tallow and marine ſalt, it affords the ſemimetal known by the improper name of *regulus of cobalt*; but the reduction is very difficult. 1296 Regulus of cobalt difficult to reduce. For this purpoſe a large quantity of flux muſt be made uſe of, and the crucible kept a conſiderable time in a white-red heat, that the matter may become very fluid, and that the ſcoria may be completely fuſed into a blue glaſs, at which period the cobalt ſinks in the form of a button to the bottom.

1297 Properties of cobalt when expoſed to heat.

Cobalt melts in a ſtrong red heat, is very fixed in the fire, and it is uncertain whether it can be volatilized in cloſe veſſels. When ſuffered to cool ſlowly, it cryſtallizes in needle-ſhaped priſms, placed one upon the other, and united in bundles, having a conſiderable reſemblance to maſſes of baſaltes ſeparated from each other: in order to ſucceed in this cryſtallization, however, the cobalt muſt be melted in a crucible till it begins to boil, and, when the ſurface of the metal becomes fixed on being withdrawn from the fire, the veſſel is then to be inclined; that which ſtill remains fluid runs out, and the portion adhering to the lumps formed by the cooling of the ſurface is found covered with cryſtals.

1298 Calcines ſpontaneouſly in the air.

This ſemimetal, expoſed to the atmoſphere, becomes covered with a dull pellicle, and undergoes a ſpontaneous calcination; but it may eaſily be calcined

1299 Its calx forms a beautiful blue glaſs.

in any quantity by expoſing it in powder in a ſhallow veſſel, under the muffle of a cupelling furnace, and ſtirring it now and then to expoſe freſh ſurfaces to the air. After being kept red hot for ſome time, this powder loſes its ſplendor, increaſes in weight, and becomes black, the calx being convertible, by a moſt violent heat, into a blue glaſs. By fuſion it combines with vitrifiable earths, forming with them a beautiful bule glaſs extremely fixed in the fire; whence it is of the greateſt uſe in enamel-painting, porcelain-painting, &c. The action of terra ponderoſa, magneſia, and lime, on cobalt, is not known. Alkalies manifeſtly alter it; but in what reſpect is not known.

1300 Phenomena with vitriolic acid.

Cobalt diſſolves in concentrated vitriolic acid, when aſſiſted by a boiling heat; the acid evaporating almoſt entirely in the form of ſulphureous gas. The reſiduum is then to be waſhed; a portion of it diſſolves in the water, and communicates a greeniſh colour to it when warm, which changes to a roſe colour when cold. M. Beaumé affirms, that by ſufficiently evaporating the vitriolic ſolution of cobalt, two ſorts of cryſtals are obtained; one white, ſmall, and cubical; the other greeniſh, quadrangular, ſix lines in length, and four in breadth. Theſe laſt he only conſiders as the true vitriol of cobalt; the former being produced by certain foreign matters united to it. The cryſtals moſt commonly obtained have the form of ſmall needles, and may be decompoſed by fire, leaving a calx of cobalt not reducible by itſelf. They may likewiſe be decompoſed by all the alkalies, by terra ponderoſa, magneſia, and lime. According to Fourcroy, 100 grains of cobalt, diſſolved in the vitriolic acid, afford, by precipitation with pure mineral alkali, 140 grains of precipitate; by the ſame alkali aërated, 160 grains. Diluted vitriolic acid acts on zaffre, and diſſolves a part, with which it forms the ſalt already deſcribed.

1301 With nitrous acid.

Nitrous acid acts upon the ſemimetal with that violence which is its general characteriſtic; and the ſolution, when nearly ſaturated, appears either of a roſy brown or bright green colour. By ſtrong evaporation it yields a ſalt in ſmall needles joined together; which is very deliqueſcent, boils upon hot coals without detonation, and leaves a calx of a deep red colour. It is decompoſed by the ſame ſubſtances as the former, and by exceſs of alkali the precipitate diſappears.

1302 With marine acid.

Muriatic acid, aſſiſted by heat, diſſolves cobalt in part, but has no effect upon it in the cold. It acts more ſtrongly on zaffre, forming a ſolution of a reddiſh brown, which becomes green by being heated. By evaporation it yields a very deliqueſcent ſalt in ſmall needles, which becomes green when heated, and is ſoon after decompoſed. Aqua-regia diſſolves the metal more eaſily than the marine acid, but leſs ſo than the nitrous. The ſolution has been long known as a *ſympathetic Ink*.

1303 With the acid of borax.

Cobalt is not diſſolved directly by the acid of borax; but when a ſolution of this ſalt is mixed with a ſolution of cobalt in any of the mineral acids, a double decompoſition takes place; the alkaline baſis of the borax uniting with the acid which held the cobalt in ſolution; and the calx, combining with the ſedative ſalt, falls to the bottom in form of an inſoluble precipitate.

1304 With ſal ammoniac.

1305 With ſulphur.

This ſemimetal is calcined by being heated to ignition with nitre. One part of cobalt, and two or three of dry nitre, well powdered and mixed, when thrown into a red-hot crucible; produce ſmall ſcintillations; a portion of the cobalt being converted into a calx of a red colour, more or leſs deep, and ſometimes of a green. Sal ammoniac is not decompoſed, by reaſon of the little attraction there is between the metal and muriatic acid. M. Bucquet, who made the experiment with great care, could not obtain a particle of volatile alkali. Sulphur does not unite with it but very difficultly, and the combination is promoted by liver of ſulphur. Thus a kind of artificial one may be produced, the grain of which will be finer or cloſer, and its colour whiter or yellower, in proportion to the quantity of ſulphur in the mixture. M. Beaumé obſerves, that this compound cannot be decompoſed by acids, and that fire cannot deſtroy all the ſulphur.

§ 13. *Nickel.*

1306 Diſcovered by Mr Cronſtedt.

This was firſt diſcovered to be a ſemimetal of a peculiar kind by Cronſtedt, in the years 1751 and 1754, who procured it in the form of regulus from its ore, but without being able to reduce it to a ſufficient degree of purity; which indeed has not yet been done by any chemiſt. M. Bergman has laboured moſt in this way, though even he has not reduced it to the purity of other metallic ſubſtances. His experiments were made with ſome regulus made by M. Cronſtedt, and whoſe ſpecific gravity was to that of water exactly as 7.421 to 1. His attempts to purify it were made,

I. By Calcination and Scorification.

1307 Effects of calcination with a violent heat.

Nine ounces of powdered nickel were expoſed for ſix hours, in ſeveral portions, to a moſt violent heat, under the dome of an aſſay furnace. Thus the arſenic was firſt diſſipated with a fetid ſmell, after which the odour of ſulphur became perceptible; after this a white ſmoke aroſe without any ſmell of garlic, and which, according to our author, aroſe probably from the more dephlogiſticated part of the arſenic which now began to ſublime. The heaps (we ſuppoſe after the matter had been poured out of the diſhes, and yet retaining a great deal of heat), when hot, began to ſwell, and green vegetations aroſe from all the ſurface, reſembling ſome kinds of moſs, or the filiform lichen; a ferruginous aſh-coloured powder remained at bottom; and 0.13 of the whole were diſſipated during the operation. Half an ounce of this calx fuſed in a forge for four minutes, along with three times its weight of black flux, yielded a regulus reticulated on the ſurface; the areola of a hexangular figure, with very ſlender ſtriæ, diverging from a centre, full of little tubercles; it weighed 0.73 of half an ounce; was obedient to the magnet; and, when ſcorified with borax, left a blackiſh glaſs.

By a ſecond roaſting the regulus again emitted a garlic ſmell; afterwards a viſible fume without any ſmell, with vegetations as before. The roaſted powder, reduced with black flux as before, ſtill emitted a ſmell of arſenic; but on repeating the fuſion with the calx and borax, nothing but ſome obſcure ſigns of cobalt appeared. A third calcination ſeemed to have much diſſipated the arſenic, as it now emitted but little of that kind of ſmell; the vegetations were alſo gone; and the matter had rather a ferruginous than a green

green colour. Nearly the ſame phenomenon appeared after reduction in a fourth operation.

On performing the reduction with lime and borax, the regulus, when firſt melted, loſt much of its ferruginous matter, which adhered to the black ſcoriæ; it ſoon acquired an hyacinthine colour, without any remarkable mixture of cobalt, was little obedient to the magnet, and its ſpecific gravity was ſomewhat diminiſhed, being now only 7.0828.

By a fifth calcination, gradually adding a quantity of powdered charcoal while the matter continued red hot, a prodigious quantity of arſenic, imperceptible before, flew off in the form of vapour; the arſenical acid being thus furniſhed with as much phlogiſton as was neceſſary to make it riſe in fume. The regulus was treated in this manner until no more arſenical ſmoke could be perceived; it was now of a lamellated and tenacious texture when reduced, but ſtill diffuſed the arſenical odour on being removed from the fire. The roaſting was therefore repeated a ſixth time, and continued for ten hours; the addition of powdered charcoal continued to diſſipate the arſenic in inviſible vapours which yet were perceptible by the ſmell; the colour of the metallic calx was obſcurely ferruginous, with a mixture of green ſcarcely viſible. On reducing the regulus with equal parts of white flux, lime and borax, a ſemiductile regulus was obtained, highly magnetic, and ſoluble in nitrous acid, to which it communicates a deep green colour; a blackiſh maſs remained, which afterwards become white, and when laid on a burning coal, flies off without any remarkable arſenical ſmell. The regulus being then ſix times fuſed with lime and borax, the ſcoriæ reſembled the hyacinth in colour, and the metallic part was ſurrounded with a green calx. The regulus, as before, was magnetic and ſemi-malleable. Laſtly, it was expoſed for 14 hours to a very ſtrong heat; when the powdered charcoal was added by degrees without any diſſipation of arſenic or loſs of weight; the colour of the roaſted powder was ferruginous, with a very ſlight tinge of green. On reduction, a very ſmall globe, ſtill magnetic, was found among the ſcoriæ.

II. By Sulphur.

1308
Effects of ſulphur and borax.

Eight hundred parts of Cronſtedt's regulus of nickel, fuſed with ſulphur and a ſmall quantity of borax, yielded a mineralized maſs of a reddiſh yellow, whoſe weight amounted to 1700. On expoſing one half of this to the fire, it began to grow black; on which the heat was augmented until vegetations appeared; the remaining calx weighed 652. Melting this part with borax, and the other which had not been expoſed to the fire, a ſulphurated regulus of a whitiſh yellow colour was obtained, weighing 1102. The ſame regulus, calcined for four hours, was firſt covered with vegetations, and then, on the addition of powdered charcoal, diffuſed an arſenical odour; the metallic calx was green, and weighed 1038. A whitiſh yellow regulus was obtained ſemiductile, highly magnetic, and extremely refractory, weighing 594. By fuſion with ſulphur a ſecond time, it weighed 816; one half of which roaſted to greenneſs, united by means of fire to the other half ſtill ſulphurated, weighed 509, and was almoſt deprived of its magnetic quality. A calcination of four hours, during which phlogiſton was added, diſſipated a conſiderable quantity of arſenic; the powder put on an aſh-colour, ſomewhat greeniſh, was in weight 569; and by reduction yielded a regulus whoſe ſurface was red, and which, on breaking, appeared of a white aſh-colour, very friable, and weighing 432; the ſpecific gravity 7.173.

On mineralizing the regulus a third time with ſulphur, adding charcoal as long as any veſtige of arſenic remained, which required a violent calcination of 12 hours, the remaining powder was of an aſh-green colour, and weighed 364; but the regulus obtained by means of a reduction effected by the moſt violent heat in a forge for three quarters of an hour, was ſo refractory that it only adhered imperfectly to the ſcoria, which were of a diſtinct hyacinthine colour; nor could it be reduced to a globule by means of borax, though urged by the ſame vehemence of fire. The abſolute gravity of this regulus was 180; its ſpecific gravity 8.666. Its magnetic virtue was very remarkable; for it not only adhered ſtrongly to the magnet, but to any other piece of iron; and the ſmall pieces of it attracted one another. It had a conſiderable ductility, was of a whitiſh colour, mixed with a kind of glittering red; diſſolved in volatile alkali, yielding a blue ſolution, and a green one in nitrous acid.

An hundred parts of the ſame regulus, beaten out into thin plates, were covered by a calcination of four hours, with a cruſt apparently martial, having under it a green powder, and within it a nucleus conſiſting of reguline particles ſtill unchanged; the weight being increaſed by 5. The friable matter, reduced to powder, put on a browniſh-green colour; and after a calcination of four hours more, concreted at the bottom in form of a friable black cruſt, ſtrongly magnetic, and weighing 100: No veſtiges of arſenic were diſcovered by a ſucceeding operation, in which charcoal was added; nor was the magnetic powder deſtroyed, but the weight was increaſed to 105, and the colour ſomewhat changed. By fuſion for an hour with lime and borax, this powder yielded a regulus of an angular ſtructure, red, ſemiductile, and altogether magnetic; the ſpecific gravity being 8.875. The ſame globule diſſolved in aqua-regia, was precipitated by green vitriol, as if it had been loaded with gold; but the precipitate was readily ſoluble in nitrous acid. Moſt of the reguli ſhowed no ſigns of precipitation with green vitriol.

III. With Hepar Sulphuris.

1309
Effect of hepar ſulphuris.

Fifty-eight parts of regulus of nickel, which had been ſulphurated before, being fuſed with 1800 parts of ſaline hepar ſulphuris, then diſſolved in warm water, filtered through paper, and precipitated by an acid, yielded a powder, which, by calcination till the ſulphur was driven off, appeared of an aſh-colour, and weighed 35. The inſoluble reſiduum, deprived of its ſulphur by means of fire, was likewiſe of an aſh-colour, and weighed 334. On reducing this regulus by means of the black flux, a friable regulus was obtained, which had a very weak magnetic property; but, on fuſion with borax, this quality was augmented. On mixing and melting together equal parts of calx of nickel, gypſum, colophony, and white flux, a powdery, ſquamous, and reguline maſs was produced; which, by fuſion with borax, afforded a regulus poſſeſſing the properties

perties of nickel, but not entirely deſtitute of cobalt, which obeyed the magnet, and did not part with its iron even after two ſolutions in the nitrous acid, and various reductions by fuſion with borax; the ſulphur was alſo retained with great obſtinacy.

On diſſolving regulus of nickel by fuſion, in hepar ſulphuris made with fixed alkali, adding a quantity of nitre ſufficient only to deſtroy a ſmall part of the hepar, the regulus which had been ſuſpended by it was ſeparated, and fell to the bottom. On examining this regulus, it appeared more pure, and generally deprived of cobalt, but ſtill containing iron. In like manner nickel is always very diſtinctly precipitated by regulus of cobalt, as this latter is attracted more powerfully by the hepar ſulphuris. When diſſolved by fuſion with hepar ſulphuris, this ſemimetal may be precipitated by adding iron, copper, tin, or lead, and even by cobalt: the regulus obtained is indeed ſcarcely ever attracted by the magnet; but we are not from thence to conclude that it does not contain any iron; for when the heterogenous matters, which impede its action, are properly removed, it then acknowledges the power of the magnet very plainly.

IV. By Nitre.

1310
Of nitre.

One part of Cronſtedt's regulus was added to twelve of nitre ignited in a crucible, and kept red-hot for about an hour. Some weak flaſhes appeared firſt; then a large quantity of arſenic was emitted; and, laſtly, the ſides were covered with a blue cruſt occaſioned by the cobalt, a green matter remaining at bottom. This, fuſed again for an hour, with twelve parts of nitre, tinged the internal ſides of the veſſel of a green colour; and, laſtly, a browniſh green maſs, much leſs in quantity than in the former operation, was left at the bottom. This green matter, treated in the ſame way for two hours a third time, left a grey ſcoria at the bottom, which yielded no regulus with black flux.

Another portion of the ſame regulus, treated in the ſame way with nitre, was diſſolved, and became green; yet on being freed by ablution from the alkaline ſalt, it yielded no regulus with black flux, but only ſcoria of an hyacinthine colour mixed with blue, tinging nitrous acid of a green colour, concreting into a jelly, and on evaporation leaving a greeniſh calx behind.

Another portion of Cronſtedt's regulus was kept ſome hours in the crucible with 16 parts of nitre; by which means all the arſenic was firſt ſeparated; then the phlogiſticated nitrous acid; and, laſtly, the ſides of the veſſel were penetrated by a kind of green efflo-reſcences. The maſs, after being waſhed with water, was of a dilute green colour, and tinged borax of a greeniſh brown. A green powder was ſtill yielded, after treating this in the ſame manner with 12 parts of nitre; and on reducing it with one-half black flux, one-eighth borax, and as much lime, a yellowiſh white regulus, both magnetic and malleable, was obtained, poſſeſſing all the properties of nickel. Its ſpecific gravity was 9.000; the phlogiſtic ingredient was uſed in ſmall quantity, that the iron might, if poſſible, enter the ſcoria.

1311
Nitre capable of ſeparating all the cobalt from nickel.

It having appeared from this and ſome other experiments, that nitre was capable of diſcovering the ſmalleſt quantity of cobalt contained in nickel the products of the former operations were now ſubjected to its action. The regulus produced by repeated ſcorification thus became a little blue; that diſſolved in volatile alkali (to be afterwards particularly mentioned) diſcovered a conſiderable quantity of cobalt; nor was there any one which did not thus diſcover more or leſs of that ingredient by this trial.

V. By Sal Ammoniac.

1312
Effect of ſal ammoniac

A calx of nickel, ſo much freed from cobalt that it did not tinge borax in the leaſt, mixed with twice its weight of ſal ammoniac, yielded by ſublimation with a ſtrong red heat, two kinds of flowers; one, which roſe higher than the other, was of an aſh colour; the other white. The bottom of the glaſs was ſtained of a deep hyacinthine colour; the reſiduum was divided into two ſtrata; the upper one yellow, ſcaly, and ſhining like moſaic gold. With borax it afforded an hyacinthine glaſs, but not regulus; and in a few days liquefied in the air, acquiring a green colour and the conſiſtence of butter. The reſiduum ſhowed the ſame properties with calx of nickel; and the green ſolution ſhowed no veſtiges of iron with galls, but became blue with volatile alkali; which was alſo the caſe with the flowers. The lower ſtratum contained a calx, blackiſh on the upper part, but of a ferruginous brown in the under, with a friable and ſcarcely magnetic regulus, of a reddiſh white. The blackiſh calx yielded an hyacinthine glaſs with borax. Part of this ſtratum ſublimed with twice its quantity of ſal ammoniac; and with the ſame degree of heat as before, yielded flowers of a very fine white, with a reſiduum of ferruginous brown, greeniſh on the upper part towards the ſides of the veſſel, the bottom being ſtained of an hyacinthine colour as before. Twenty parts of ſal ammoniac being added to a part of the inferior ſtratum reduced, the whole was ſublimed in a retort; a blackiſh powder remained, which became green by calcination, and of an hyacinthine colour by ſcorification, as did alſo the bottom of the containing veſſel. The ſublimation being twice repeated, uſing a double quantity of ſal ammoniac each time, the calx became at length very green, diſſolving with the ſame colour in the nitrous acid, and yielding by reduction a white, brittle, and very little magnetic regulus. In all theſe ſublimations, it was obſerved, that the volatile alkali roſe firſt; then ſal ammoniac; and, laſtly, a part of the marine acid was forced over by the violence of the heat.

VI. With Nitrous acid.

1313
Effects of antimony.

Having obtained a ſalt by cryſtallization from nickel diſſolved in nitrous acid, part of this was calcined with charcoal duſt in a proper veſſel, and during the operation a large quantity of arſenic was diſſipated; a grey, ſemiductile, and magnetic regulus being obtained after reduction. A brittle regulus was obtained after a ſecond ſolution, precipitation, and reduction; but by a third operation it became again ſemiductile and magnetic. By repeating this proceſs a fourth and fifth time, the quantity became ſo much diminiſhed that it could no longer be tried. In all theſe ſolutions a blackiſh reſiduum appeared; which, when ſuffered to remain in the acid, grew white by degrees; but when edulcorated and laid on a burning coal, exhaled a ſulphureous ſmoke, and left a black powder ſoluble in the nitrous acid.

VII. By volatile Alkali.

1314 Volatile alkali.

Four hundred and eighty-ſeven parts of a calx of nickel, produced by diſſolving Cronſtedt's regulus in nitrous acid, and precipitating the ſolution by a fixed alkali, being immerſed for 24 hours in a quantity of volatile alkali, yielded a reſiduum of fifty, having a blackiſh green colour. The ſolution, which was blue, by filtration and inſpiſſation yielded a powder of a light blue colour, weighing 282; which, reduced with black flux, produced a white, ſemiductile, and highly magnetic regulus, weighing 35, whoſe ſpecific gravity was 7.000. The ſcoriæ were of a light red: but when mixed with borax, put on an hyacinthine colour, and yielded a regulus weighing 30. The two reguli united together proved very refractory; ſo that the maſs could not be melted by the blow-pipe, even with the addition of borax. It ſent forth neither an arſenical nor ſulphureous ſmell on the addition of charcoal-duſt; but, on a ſucceeding reduction, yielded hyacinthine ſcoriæ; and the remaining flocculi, diſſolved in nitrous acid, affording a very green ſolution, which, on the addition of volatile alkali, yielded a powder of the ſame colour.

From 50 parts of the blackiſh green reſiduum, 13 of a clear white, brittle, ſquamous, and little magnetic regulus, were obtained, the ſpecific gravity of which was 9.333. At the bottom of the veſſel was found a ſcoria of an obſcurely blue colour, with the upper part hyacinthine. It was eaſily fuſed; and tinged borax, firſt blue, then of a hyacinth colour, upon which it became more ſtrongly magnetic. By the aſſiſtance of heat it diſſolved in nitrous acid, forming a ſolution of a beautiful blue colour. A black powder at firſt floated in the liquor, but became white, and fell to the bottom. After edulcoration it was for the moſt part diſſipated, with a ſulphureous ſmell, on being expoſed to the fire; a little brown-coloured maſs, ſoluble in volatile alkali, remaining at bottom. This ſolution was precipitated by phlogiſticated alkali, and a powder thrown down of the colour of calx of nickel, which ſoon grew blue with volatile alkali.

1315 Nickel cannot be obtained in a ſtate of purity.

From all theſe experiments it appears, that nickel cannot be obtained in a ſtate of purity by any means hitherto known. From every other ſubſtance, indeed, it may be ſeparated, except iron; but this reſiſts all the operations hitherto deſcribed, and cannot be diminiſhed beyond certain limits. The magnet not only readily diſcovers its preſence, but ſome portions of the regulus itſelf becomes magnetic; but the tenacity and difficulty of fuſion, which increaſe the more in proportion to the number of operations, plainly ſhow that there is no hope of ſeparating the whole quantity, unleſs we ſuppoſe the regulus of nickel itſelf to be attracted by the magnet; and there is certainly a poſſibility that one other ſubſtance beſides iron may be attracted by the magnet. The great difficulty, or rather impoſſibility, of obtaining it in a ſtate of purity, naturally raiſes a ſuſpicion of its not being a diſtinct ſemimetal, but a mixture of others blended together; and on this ſubject our author agrees in opinion with thoſe who ſuppoſe it to be a compound of other metals. Indeed, Mr Bergman is of opinion, that "nickel, cobalt, and manganeſe, are perhaps no other than modifications of iron." And in order to aſcertain this, he made the following experiments.

1316 Bergman's opinion of the compoſition of nickel.

1317 Experiments to compoſe nickel artificially.

1. Equal parts of copper, of the gravity of 9.3243, and iron of 8.3678, united by fuſion with black flux, yielded a red maſs, whoſe ſpecific gravity was 8.5441; and which tinged nitrous acid firſt blue, then green, afterwards yellow, and at laſt of an opaque brown. 2. Two parts of copper and one of iron had a ſpecific gravity of 8.4634; the mixture yielding firſt a blue, and then a green ſolution. 3. Equal parts of copper and iron, of the ſpecific gravities already mentioned, with another part of cobalt whoſe gravity was 8.1500, yielded a metal of the gravity of 8.0300, imparting a brown colour to the ſolution. 4. Two parts of arſenic of 4.000, added to one of copper and another of iron, gave a brittle metal of 8.0468, which formed a blue ſolution. 5. One part of copper, one of iron, two of cobalt, and two of white arſenic, gave a brittle regulus of 8.4186; the ſolution of which was browniſh, and ſeparated in part ſpontaneouſly. 6. One part of copper, one of iron, four of cobalt, and two of white arſenic, formed a maſs of 8.5714. The ſolution was ſomewhat more red than the former; and a ſimilar effect took place on repeating the experiment, only that the ſpecific gravity of the metal was now 8.2941. 8. One part of iron and four of white arſenic formed a metal which diſſolved with a yellow colour; and, on the addition of Pruſſian alkali, immediately let fall a blue ſediment. 9. One part of copper, eight of iron, ſixteen of white arſenic, and four of ſulphur, united by fire, on the addition of black flux, yielded a maſs which, though frequently calcined and reduced, produced nothing but brown or ferruginous calces. It acquired a greenneſs with nitrous acid; but on the addition of phlogiſticated alkali depoſited a Pruſſian blue. 10. One part of iron was diſſolved in ſix of the nitrous acid, and likewiſe ſeparated by one part of copper and one of the calcined ore of cobalt, in the ſame quantity of the ſame acid. The whole of the ſolution of iron was then mixed with five parts of the ſolution of copper, whence a green and ſaturated nickel colour was produced; which, however, on the addition of three parts of the ſolution of cobalt, became evidently obſcured. The alkaline lixivium dropped into this threw down at firſt a ferruginous brown ſediment, the ſolution ſtill remaining green: afterwards all the blue was precipitated; by which at firſt all colour was deſtroyed, but afterwards a red appeared, occaſioned by the cobalt diſſolved in the alkaline ſalt. The ſediment, when reduced, yielded a regulus ſimilar to copper, and at the ſame time ductile, which tinged both glaſs and nitrous acid of a blue colour. If a ſaturated ſolution of nickel be mixed with half its quantity of ſolution of cobalt, the green colour is much obſcured; but four parts of the former, on the addition of three of the latter, put off all appearances of nickel. See the article NICKEL.

§ 14. *Of* PLATINA.

1318 The heavieſt of all metals.

THE properties of this metal have not as yet been thoroughly inveſtigated by chemiſts, and there is therefore ſome diſagreement concerning them. Formerly it was ſuppoſed to be inferior in ſpecific gravity to gold;

gold; but now is generally allowed to be ſuperior in that reſpect by little leſs than a fourth part; being to water in the proportion of 23 to 1 when perfectly freed from all heterogeneous matters. Mr Bergman ſays that its colour is that of the pureſt ſilver. The very ſmall globules of it are extremely malleable; but when many of theſe are collected together, they can ſcarcely be ſo perfectly fuſed as to preſerve the ſame degree of malleability. They are not affected by the magnet in the leaſt, nor can they be diſſolved in any ſimple menſtruum excepting dephlogiſticated marine acid. As it is commonly met with, however, platina has the form of ſmall grains, its plates of a bluiſh black, whoſe colour is intermediate betwixt thoſe of ſilver and iron. Theſe grains are mixed with many foreign ſubſtances, as particles of gold, mercury, and blackiſh ferruginous, ſandy grains, which by the magnifier appear ſcorified. The grains themſelves, when examined by a magnifying glaſs, appear ſometimes regular, ſometimes round and flat, like a kind of button. When beat on the anvil, moſt of them are flattened and appear ductile; ſome break in pieces, and on being narrowly examined appear to be hollow, and particles of iron and a white powder have been found within them: and to theſe we muſt attribute the attraction of platina by the magnet; ſince, as we have already obſerved, pure platina is not attracted by it.

1319
Inſoluble except by dephlogiſticated marine acid.

1320
Found in ſmall grains intermixed with foreign ſubſtances.

1321
Mr Bergman's experiments on this metal.

Mr Bergman, who carefully examined this metal, diſſolved it firſt in aqua-regia compoſed of the nitrous and marine acid. The ſolution at firſt exhibits a yellow colour, but on approaching to ſaturation became red, and the redneſs increaſes as the liquor becomes more loaded with metal. Cryſtals are produced by evaporation of a deep red colour, generally in ſmall angular and irregular grains, whoſe true ſhape cannot be diſcovered. Their appearance is ſometimes oqaque and ſometimes pellucid. After theſe are once formed, they are extremely difficult of ſolution, requiring much more water than even gypſum itſelf for this purpoſe.—The ſolution is not precipitated by vegetable fixed alkali, nor does the latter affect the cryſtals, except very faintly by digeſtion with them in a cauſtic ſtate. Aerated mineral alkali takes them up and grows yellow, but without depoſiting any thing, though it decompoſes them at laſt by evaporating to dryneſs.

1322
Cryſtals of platina may be decompoſed by mineral but not vegetable fixed alkali.

On the addition of a ſmall quantity of vegetable fixed alkali, either mild or cauſtic, ſmall red cryſtals ſoluble in water, and ſometimes of an octohedral figure, are depoſited. They are decompoſed with difficulty by the mineral alkali, but not at all by the vegetable. If a larger quantity of ſalt is added at firſt, an inſoluble ſpongy matter of a yellow colour is precipitated. Cryſtalline particles of the ſame kind are thrown down by an alkali ſaturated either with the vitriolic, nitrous, marine, or acetous acids, though all the platina cannot thus be ſeparated from the menſtruum.

1323
Solution in aqua-regia made with nitrous acid and that of ſea-ſalt.

Aqua-regia, compoſed of nitrous acid and common ſalt, diſſolved the metal with equal facility as the former; only the ſolution was more dilute, and a yellow powder floated on the ſurface, a larger quantity being found at the bottom. On adding vegetable fixed alkali to the clear ſolution, a copious yellow powder, ſoluble in a large quantity of water, was depoſited. A powder, of a ſimilar kind, was precipitated, tho' more ſlowly, and more of a cryſtalline nature; but mineral alkali, though uſed in much larger quantity, did not make any alteration. The collected powder was yellow, and agreed in property with that ſeparated ſpontaneouſly in a former experiment.

1324
In a liquor compoſed of nitre and ſpirit of ſalt.

On repeating the experiment with nitre and depurated ſpirit of ſalt, inſtead of nitrous acid and ſea-ſalt, the platina was diſſolved into gold-coloured liquor, a greeniſh coloured granulated matter falling to the bottom, and the finer part of the ſame riſing to the top. After ſaturating the ſuperfluous acid, a metallic calx, inſoluble in water, was thrown down by the vegetable alkali. The green powder is ſoluble in water, and is of the ſame nature with the precipitate thrown down by the vegetable alkali.

1325
Cryſtalline powder precipitated by vegetable alkali from ſolution of the calx in marine acid;

Platina precipitated from aqua-regia by a ſufficient quantity of mineral alkali, the precipitate waſhed and diſſolved in marine acid, on the addition of vegetable alkali immediately lets fall a cryſtalline powder, as it does alſo with nitre and other ſalts, having the vegetable alkali for their baſis. The caſe is the ſame with calx of platina, diſſolved in vitriolic acid. Nitrous acid alſo diſſolves the calx of platina, but does not yield any diſtinct ſaline precipitate without the aſſiſtance of marine acid.—The above phenomena are likewiſe produced by the precipitate thrown down by the vegetable alkali after the ſaline powder has been depoſited.

1326
But not from the ſolution in nitrous acid.

1327
This precipitate a kind of triple ſalt.

From theſe experiments our author concludes, 1. That the precipitate which is firſt thrown down, on the addition of vegetable alkali to ſolutions of platina, is a ſaline ſubſtance, and different from the calx of the metal. 2. That this ſaline precipitate is compoſed of calcined platina, marine acid, and vegetable alkali. 3. By means of vitriolic acid, a precipitate analogous to this may be obtained, compoſed of calcined platina, vegetable alkali, and vitriolic acid. 4. The whole ſolution of platina cannot be precipitated by vegetable alkali in form of a triple ſalt; but after paſſing a certain limit, a metallic calx in the uſual way is produced.

1328
Whether mineral alkali can ſeparate platina from its ſolvent.

As it has been denied by Margraaf and Lewis that mineral alkali is capable of ſeparating platina from its acid, our author was induced to attend particularly to this circumſtance. Having therefore tried the common ſolution with mineral alkali, he found that each drop excited a violent effervescence, and at laſt that a yellow ſpongy matter, affording a genuine calx of platina, was precipitated: this was more ſpeedily effected by uſing the dry mineral alkali, which had fallen to powder of itſelf. To determine, however, the difference betwixt the two alkalies in a more accurate manner, he divided a very acid ſolution of platina into two equal parts. To one of theſe, he added ſmall portions of the vegetable, and to the other an equal weight of pieces of mineral alkali, waiting five minutes after every addition, till the effervescence ſhould fully ceaſe. After the firſt addition, ſmall cryſtals appeared; in the former partly on the ſurface, and partly in the bottom; but in the latter no precipitate could be obſerved until 56 times the quantity of vegetable alkali had been added. The difference, however, was even greater than what appears from this experiment; for the vegetable alkali was cryſtallized, and therefore charged with the water neceſſary to its cryſtalline form;

1329
Fifty-ſix times as much mineral alkali required to precipitate platina as of vegetable alkali.

form; whereas the mineral alkali was ſpontaneouſly calcined: and though, in equal quantities of theſe two alkalies, the purely alkaline parts are as 3 to 2, yet three parts of vegetable alkali ſaturated only 1.71 of this aqua-regia, while two of the mineral alkali took up about 2.6.

1330
Effects of the volatile alkali.

The volatile alkali firſt throws down this metal in a ſaline form; the grains ſometimes diſtinctly octohedral. Their colour is red when that of the ſolution is ſo, but yellow when the ſolution is more dilute. After ſaturating the ſuperabundant acid, the ſame alkali precipitates the platina truly calcined. This precipitate is diſſolved in water, though with difficulty, and may be reduced to more regular cryſtals by evaporation. Theſe are diſſolved by the mineral alkali; but hardly any ſigns of decompoſition are to be obſerved, unleſs the yellow ſolution, evaporated to dryneſs, be again diſſolved in water; for then the metallic calx reſts at the bottom, and the ſolution is deprived of its yellow colour. The vegetable alkali has ſcare any effect in this way; for, after repeated exſiccation, the ſolution remains clear and yellow: but here probably the fixed alkali takes the place of the volatile; for in larger quantities, and eſpecially when the cauſtic vegetable alkali is made uſe of, the mixture ſmells of volatile alkali.

1331
Platina partly precipitated by neutral ſalts.

The volatile alkali, ſaturated with any acid, precipitates the platina in the ſame manner as the vegetable alkali in combination with acids: but theſe neutral ſalts precipitate only a determined quantity of platina; for after their effect has ceaſed, the liquor lets fall a pure calx of platina on the addition of vegetable or volatile alkali.

1332
Triple ſalts formed by this metal.

The calx of platina precipitated by mineral alkali, and then diſſolved in any ſimple acid, ſhows nearly the ſame phenomena with volatile alkali as with the vegetable alkali. "Whence (ſays Mr Bergman) we may conclude, that platina diſſolved in acids forms at firſt, both with the volatile and fixed vegetable alkali, a triple ſalt, difficult of ſolution, and which therefore almoſt always falls to the bottom unleſs the quantity of water be very large." Calcareous earth, whether aerated or cauſtic, produces the ſame phenomena as the mineral alkali, without any cryſtalline appearance.

1333
Platina the moſt infuſible ſubſtance in the world.

Platina has been remarkable ever ſince its firſt diſcovery for being the moſt infuſible ſubſtance in the world. Meſſrs Macquer and Beaumé kept it in the moſt violent heat of a glaſs-houſe furnace for ſeveral days without perceiving any other alteration than that its grains adhered ſlightly to each other; but the adheſion was ſo ſlight that they ſeparated even by touching. In theſe experiments the colour of the platina became brilliant by a white heat, but acquired a dull grey colour after it had been heated for a long time. They obſerved alſo, that its weight was conſtantly increaſed; which undoubtedly aroſe from the calcination of the iron it contained. Dr. Lewis, after various attempts to fuſe platina, found himſelf unable to ſucceed even in a fire which vitrified bits of glaſs-houſe pots and Heſſian crucibles.

1334
Firſt melted by a burning mirror.

Meſſrs Macquer and Beaumé firſt melted this refractory metal with a large burning-glaſs, 22 inches diameter and 28 inches focus. The power of this ſpeculum was almoſt incredible, and far exceeded what is related of the lens of Tſchirnhauſen or the mirror of Villette. Its general effects are related under the articl *Burning-Glaſs*. And as platina reſiſted this intenſe heat more than ſix times as long as the moſt unfuſible ſubſtances formerly known, it appears to require a fire as many times ſtronger to melt it.

1335
May be vitrified by electric fire.

It has been found, however, capable not only of fuſion but of vitrification by the electric fire; and that it may alſo be melted by fire excited by dephlogiſticated air:

1336
Its precipitate fuſible in a common forge.

but M. de Liſle was the firſt who was able to melt it with the heat of a common forge when expoſed to the blaſt of a double bellows in a double crucible. Thus its real ſpecific gravity began firſt to be known. It muſt be obſerved, however, that this fuſion was not performed on common platina, but on ſuch as had been diſſolved in aqua-regia and precipitated by means of ſal ammoniac. M. Morveau repeated the experiment, and from 72 grains of platina obtained a regulus weighing 50½; which ſeemed to have undergone a very imperfect fuſion; for it did not adhere to the crucible or take its form, but ſeemed to be merely platina revived. Its ſpecific gravity was alſo found to be no more than 10.045; but it was nearly as malleable as ſilver; and when it had been ſufficiently hammered, its ſpecific gravity was augmented to no leſs than 20.170, which is more than that of gold itſelf.

1337
This precipitate, or even crude platina, fuſible by the aſſiſtance of fluxes.

M. Morveau found that he could melt the precipitate with different fluxes, ſuch as a mixture of white glaſs, borax, and charcoal, and a mixture of white glaſs and neutral arſenical ſalt: and that the regulus thus obtained was more completely fuſed, but was not malleable, and obeyed the magnet; but the regulus obtained without addition did not ſhow this mark of containing iron. He alſo found, that by means of the abovementioned flux of white glaſs, borax, and charcoal, he could melt crude platina. Since that time the fuſion of platina has been accompliſhed by various chemiſts, and with different fluxes; and in proportion to the degree of purity to which the metal has been reduced, its ſpecific gravity has alſo increaſed; ſo that it is now ſettled at 23, that of fine gold being 19.

1338
Alloyed by Dr Lewis with other metals.

Though Dr Lewis could not accompliſh the fuſion of platina by the methods he attempted, he was nevertheleſs able to alloy it with other metals. Equal parts of gold and platina may be melted together by a violent fire, and the mixed metal formed into an ingot by pouring it into a mould. It is whitiſh, hard, and may be broken by a violent blow; but when carefully annealed, is capable of conſiderable extenſion under the hammer.

1339
With gold.

Four parts of gold with one of platina form a compound much more fuſible than the former, and likewiſe more malleable; ſo that it may be extended into very thin plates without being broken or even ſplit at the edges. Dr Lewis remarks alſo, that though in this caſe it be alloyed with ſuch a quantity of white metal, it nevertheleſs appears no paler than guineas uſually are, which contain only one-twelfth of ſilver.

1340
With ſilver.

Equal parts of ſilver and platina melted together with a violent fire, form a much harder and darker-coloured maſs than ſilver, which has alſo a large grain, though it preſerves ſome ductility. Seven parts of ſilver with one of platina form a compound much more reſembling ſilver than the other; but ſtill coarſer-grained and leſs white. From the experiments made on ſilver, however, it appears that no perfect union is formed betwixt the two; for after the mixture has been kept in fuſion for a conſiderable time, moſt of the platina ſeparates and falls to the bottom. Lewis obſerved that ſilver melted with platina was thrown up with an exploſion againſt the ſides of the crucible.

1341 Copper conſiderably improved by union with platina.

Silver did not appear to be in any degree meliorated by its union with this metal, excepting by the ſuperior hardneſs communicated to it; but copper ſeemed to be conſiderably improved. A large proportion of platina, indeed, as two-thirds or equal parts, produced an hard, brittle, and coarſe-grained compound; but when a ſmaller quantity of platina is added, as from $\frac{1}{6}$ to $\frac{1}{25}$, or even leſs, a golden-coloured copper is produced, very malleable, harder, ſuſceptible of a finer poliſh, ſmoother-grained, and much leſs ſubject to calcination and ruſt than pure copper.

1342 Unites moſt readily with zinc;

Of all metallic matters, however, zinc moſt readily unites with platina, and is moſt effectually diſſolved by fuſion. When the proportion of platina is conſiderable, the metal is of a bluiſh colour, the grain cloſer, without tarniſhing or changing colour in the air, and they have not even the malleability of the ſemimetal.

1343 And with the compound metals.

Platina unites readily with the compound metals, braſs formed of copper and zinc, and bronze made of copper and tin. In the latter it was remarkable, that the compound metal took up more platina than both its ingredients ſeparately can do. This compound was hard and capable of receiving a fine poliſh, but is ſubject to tarniſh.

1344 The compound of braſs and platina a proper material for ſpeculums.

Equal parts of braſs and platina formed a compound very hard, brittle, capable of receiving a fine poliſh, and not ſubject to tarniſh. It is poſſible therefore that it might be uſed to advantage as a material for ſpeculums; all materials for which, hitherto diſcovered, have the great inconvenience of tarniſhing in the air, and that very quickly.

1345 Can ſcarce be united with mercury.

Platina amalgamates with mercury, but with much greater difficulty than gold, which will alſo ſeparate the quickſilver after it has been united with the platina. The amalgamation of platina does not ſucceed but by very long trituration of the metals with water, as for inſtance a week; but if the trituration be performed with a mixed metal compoſed of gold and platina, the mercury ſeizes the gold, and leaves the platina untouched. Dr Lewis propoſes this as a method of ſeparating gold from platina; and it is that uſed in Peru, where gold and platina are ſometimes naturally mixed in the ore; but we do not know whether this ſeparation be quite complete.

1346 Mercury leaves platina to unite with gold.

1347 May be united with forged and caſt iron;

Mr Morveau ſucceeded in uniting iron with platina, though Dr Lewis could not accompliſh this. The latter ſucceeded, however, in uniting it with caſt iron. The compound was much harder and leſs ſubject to ruſt than pure iron. It was alſo ſuſceptible of a much finer poliſh.

1348 And with tin, lead, or biſmuth:

Platina may be alloyed with tin, lead, or biſmuth, but without any advantage. To lead and tin it gives the property of aſſuming blue, violet, or purple colours, by being expoſed to the atmoſphere.

Dr Lewis could not ſucceed in uniting platina with arſenic; but M. Scheffer affirms, that if only one twentieth of arſenic be added to platina when red hot in a crucible, the two ſubſtances will be perfectly fuſed and united into a brittle grey maſs. This experiment did not ſucceed with Mr Margraaf; for he, having expoſed to a violent fire during an hour a mixture of an ounce of platina with a fuſible glaſs, compoſed of eight ounces of minium, two ounces of flints, and one ounce of white arſenic, obtained a regulus of platina well united and fuſed, weighing an ounce and 32 grains; the ſurface of which was ſmooth, white, and ſhining, and the internal parts grey; but which nevertheleſs appeared ſufficiently white when filed. The experiment ſucceeded imperfectly alſo in the hands of Dr Lewis; but M. Fourcroy informs us, that "it has ſince been repeated, and that platina is in fact very fuſible with arſenic, but that it remains brittle. In proportion as the arſenic is driven off by the continuance of the heat, the metal becomes more ductile; and by this proceſs it is that M. Achard and M. de Morveau ſucceeded in making crucibles of platina by melting it a ſecond time in moulds." (A)

1349 May be melted by means of arſenic.

1350 Fourcroy denies that platina can be united with mercury.

M. Fourcroy ſeems to deny that platina can be united with mercury, contrary to what is mentioned above. "Platina (ſays he) does not unite with mercury, though triturated for ſeveral hours with that metallic fluid. It is likewiſe known, that platina reſiſts the mercury uſed in America to ſeparate the gold. Many intermediums, ſuch as water, uſed by Lewis and Beaumé, and aqua-regia by Scheffer, have not been found to facilitate the union of theſe two metals. In this reſpect platina ſeems to reſemble iron, to whoſe colour and hardneſs it likewiſe in ſome meaſure approaches." This laſt ſentence, however, ſeems very little to agree with what he himſelf had before told us of M. Macquer's experiment of melting platina. "The melted portions (ſays he) were of a white brilliant colour, in the form of a button; they could be *cut to pieces* with a knife." This ſurely was a very ſmall approach to the hardneſs of iron; and gives us an idea rather of the conſiſtence of tin or lead. "One of theſe maſſes was flattened on the anvil, and converted into a thin plate without cracking or breaking, but it became hard under the hammer." In another experiment indeed the button of platina was brittle, and ſufficiently hard to make deep traces in gold, copper, and even iron; but this was obtained from precipitated platina urged for 35 minutes by a ſtrong blaſt furnace. In an experiment of this kind M. Beaumé even ſucceeded in melting the precipitate along with certain fluxes, into a vitriform ſubſtance by two different proceſſes. The precipitate of platina, mixed with calcined borax, and a very fuſible white glaſs, was expoſed, for 36 hours, in the hotteſt part of a potter's furnace; and afforded a greeniſh glaſs, inclining to yellow, without globules of reduced metal. This glaſs, treated a ſecond time with cream of tartar, gypſum, and vegetable alkali, was completely melted, and exhibited globules of platina diſperſed through its ſubſtance. M. Beaumé ſeparated them by waſhing, and found them ductile. The ſame chemiſt afterwards, together

1351 Inconſiſtent in his account of its hardneſs.

1352 Precipitated platina vitrified by M. Beaumé

(A) For a particular account of this proceſs ſee before n° 587.

gether with M. Macquer, expoſed precipitate of platina to the ſame burning mirror with which they had fuſed the metal: the precipitate exhaled a very thick and luminous fume, with a ſtrong ſmell of aqua-regia: it loſt its red colour, reſumed that of platina, and melted into a perfect brilliant button, which was found to be an opaque vitreous ſubſtance, of an hyacinthine colour at its ſurface, and blackiſh within; and may be conſidered as a true glaſs of platina. It may however be obſerved, that the ſaline matters with which it was impregnated contributed doubtleſs to its vitrification.

1353 Precipitate by ſal ammoniac fuſible in a ſtrong forge heat.

1354 This fuſion ſuppoſed by Macquer not to be perfect.

“ The orange-coloured precipitate obtained by pouring a ſolution of ſal ammoniac into a ſolution of platina, appears to be a ſaline ſubſtance entirely ſoluble in water. This precipitate has a valuable property, diſcovered by M. de l'Iſle, viz. that it is fuſible without addition in a good furnace or common forge-heat. The platina melted by this proceſs is a brilliant, denſe, and cloſe-grained button; but it is not malleable unleſs it has been expoſed to a very ſtrong heat. Macquer thinks that this fuſion, like that of the grains of platina alone, expoſed to the action of a violent fire, conſiſts only in the agglutination of the ſoftened particles; which being exceedingly more divided and minute than the grains of platina, adhere to and touch each other in a greater number of points than the grains; and in that manner render the texture of the metal much more denſe, though no true fuſion may have taken place. It ſeems, however, that if platina in grains be capable of fuſion by the burning-glaſs, and of becoming conſiderably ductile, the precipitate of this metal, formed by ſal ammoniac may likewiſe be fuſed on account of its extreme diviſion; and that its not being as ductile as the button of platina fuſed by the ſolar heat, may perhaps depend on its retaining a part of the matter it carried down with it in precipitation, of which it may be poſſible to deprive it by fire.”

1355 Attempts to purify platina by cupellation

It being ſo extremely difficult to bring platina itſelf into fuſion, one of the firſt attempts to purify it was by cupellation with lead. Thus the baſer metals would be ſcorified; and, running through the crucible along with the lead, leave the platina in as great purity as though it had been melted by itſelf. This operation, however, was found almoſt equally difficult with the fuſion of the metal by itſelf. Lewis failed in the experiment, though he applied the moſt violent heat of the ordinary cupelling furnaces. The vitrification and abſorption of the lead indeed took place as uſual; but in a ſhort time the platina became fixed, and could not by any means be rendered fluid. Meſſrs Macquer and Beaumé ſucceeded by expoſing an ounce of platina with two ounces of lead in the hotteſt part of a porcelain furnace, where the fire is continued for 50 hours without intermiſſion. At the end of the operation the platina was flattened in the cupel; its upper ſurface was dull and rough, and eaſily ſeparated; but its under ſurface was brilliant, and it was found eaſily to extend under the hammer; and on every chemical trial was found to be perfectly pure without any mixture of lead. M. de Morveau likewiſe ſucceeded in cupelling a mixture of one drachm of platina and two drachms of lead in M. Macquer's wind-furnace. The operation laſted eleven or twelve hours, and a button of platina was obtained which did not adhere to the cupel, was uniform, though rather rough, and of a colour reſembling tin. It weighed exactly one drachm, and was not at all acted upon by the magnet. Thus it appears that platina may be obtained in plates or laminæ, which may be forged, and conſequently may be employed in making very valuable utenſils; and this the more eſpecially as Mr Beaumé has obſerved that different pieces of it may be welded and forged like iron. After having heated two pieces of pure cupelled platina to whiteneſs, he placed them one upon the other, and ſtriking them briſkly with a hammer, found that they united together as quickly and firmly as two pieces of iron would have done.

1356 Of the poſſibility of adulterating gold with platina.

1357 Methods of detecting this fraud if it ſhould be practiſed.

The great ſpecific gravity of platina has rendered it a very deſirable matter for ſuch as wiſh to adulterate the precious metal, and can procure the platina eaſily. This, however, can only be done in South America, where platina is met with in plenty. In Europe the ſcarcity of platina renders it a more valuable object than even the gold itſelf. Fears of this fraud, however, have undoubtedly given occaſion to the prohibition of exporting it. There are great differences among chemiſts concerning the quantity of platina that can be mixed with gold without deſtroying the colour of the latter. Dr Lewis, as has already been obſerved, informs us, that four parts of platina may be mixed with one of gold, and yet the mixture be no paler than that for guineas; while Fourcroy aſſerts, that “it greatly alters the colour of the metal, unleſs its quantity be very ſmall: thus, for example, a 47th part of platina, and all the proportions below that, do not greatly affect the colour of the gold.” But whether this be the caſe or not, chemiſtry has afforded various ways of ſeparating even the ſmalleſt proportion of platina from gold; ſo that there is now no reaſon to prohibit the importation of it to Europe, more than that of any other metal with which gold can be alloyed. The following are the methods by which the platina may be moſt readily diſcovered: 1. By amalgamating the ſuſpected metal with mercury, and grinding the mixture for a conſiderable time with water; by which the platina will be left, and the gold remain united with the quickſilver. 2. By diſſolving a little of it in aqua-regia, and precipitating with alkaline ſalt; the remaining liquor, in caſe the metal has been adulterated with platina, will be ſo yellow, that it is ſuppoſed a mixture of one thouſandth part would thus be found out. 3. By precipitation with ſal ammoniac, which throws down the platina but not the gold. If mineral alkali be uſed, the gold will be precipitated, but not the platina, unleſs the precipitant is in very large quantity. 4. By precipitation with green vitriol, which throws down the gold, and leaves the platina united with the menſtruum.

1358 Platina moſt eaſily diſcoverable by its great ſpecific gravity.

All theſe methods, however, are not only attended with a conſiderable deal of trouble, but in ſome caſes, for inſtance in ſuſpected coin, it might not be eligible to uſe them. The hydroſtatic balance alone affords a certain method of diſcovering mixtures of metals without hurting the texture of their parts. The great ſpecific gravity of platina would very readily diſcover it if mixed with gold in any moderate quantity; and even in the ſmalleſt, the gravity of the maſs could never be leſs than that of the pureſt gold: which circumſtance

cumſtance alone, as gold is never worked without alloy, would be ſufficient to create a juſt ſuſpicion; after which ſome of the methods already mentioned might be tried. It is poſſible, however, that the hardneſs and ductility of platina might render it more proper for alloying gold than even copper or ſilver, uſually made uſe of for this purpoſe.

§ 15. *Of Manganese.*

1359 New ſemi-metal afforded by manganeſe.

This ſubſtance is now diſcovered to afford a ſemi-metal different from all others, and likewiſe to poſſeſs ſome other properties of a very ſingular kind. Mr Scheele has inveſtigated its nature with the utmoſt care; and the reſult of his inquiries are as follows:

1360 Properties of the common manganeſe treated with vitriolic acid.

1. Two drachms of levigated manganeſe, digeſted for ſeveral days in a diluted vitriolic acid, did not appear to be diſſolved or diminiſhed in quantity; nevertheleſs a yellowiſh white precipitate was procured by ſaturating the acid with fixed alkali. The remaining manganeſe was not acted upon by more of the ſame acid, but the addition of another half ounce nearly deſtroyed the acidity of the menſtruum when boiled upon it.

2. With concentrated vitriolic acid an ounce of manganeſe was reduced to a maſs like honey, and then expoſed to the fire in a retort till it became red-hot. Some vitriolic acid came over into the receiver; and after breaking the retort, a maſs was found in it weighing 12½ drachms, hard and white in the inſide, but red on the outſide. A great part of it diſſolved in diſtilled water, on the affuſion of which at firſt it became very hot. The reſiduum after edulcoration weighed a drachm and an half, and was of a grey colour. Being calcined in a crucible with concentrated vitriolic acid till no more vapours aroſe, it was all diſſolved by water excepting one drachm; which being again calcined with the ſame acid, an inſoluble reſiduum of a white colour, and weighing only half a drachm, remained. This white reſiduum efferveſced with borax, and melted into a tranſparent brown glaſs; it likewiſe efferveſced with fixed alkali, changing into a brown maſs, which yielded an hepatic ſmell with acids, and became at the ſame time gelatinous. The ſolution obtained by calcination was evaporated and ſet to cryſtallize. A few ſmall cryſtals of ſelenite were firſt depoſited, and afterwards ſome very fine large cryſtals of an oblique parallelopiped form, whoſe number increaſed as long as there was any liquid left. They taſted like Epſom ſalt, and Mr Weſtfeld ſuppoſes them to be alum; but according to Mr Scheele, they have no other reſemblance to alum than that they contain the vitriolic acid.

1361 Entirely diſſolved by phlogiſticated vitriolic acid.

3. By phlogiſticated vitriolic acid the manganeſe was entirely diſſolved. To procure this acid in purity, Mr Scheele dipped ſome rags in a ſolution of alkali of tartar, and after ſaturating them with the fumes of burning brimſtone, put them into a retort, pouring on them ſome diſſolved acid of tartar, luting on a receiver which contained levigated manganeſe and water. After a warm digeſtion of only one day, the liquid of the receiver had become as clear as water, and a little fine powder, conſiſting principally of ſiliceous earth, fell to the bottom.

4. Two drachms of levigated manganeſe, digeſted for ſeveral days with an ounce of pure colourleſs acid of nitre, did not appear to have deprived the menſtruum of its acidity, or to have been affected by it in any degree. The liquor being diſtilled off, and the product of the diſtillation poured back on the reſiduum, a ſmall quantity of it was diſſolved. By a third diſtillation, and pouring back the liquor on the reſiduum, a complete ſolution was effected; and this quantity of acid appeared capable of diſſolving nine drachms of the powder.

1362 Precipitate and cryſtals obtained from the ſolution.

5. The ſolution of manganeſe thus ſaturated, was filtered and divided into two equal portions. Into one of theſe ſome drops of vitriolic acid were poured, by which a fine white powder was thrown down, which, however, did not ſettle to the bottom for ſome hours. It was ſoluble neither in boiling water nor in acids. The limpid ſolution, by evaporation, yielded ſome ſmall cryſtals of ſelenite or gypſum.

6. From the other half of this ſolution, after evaporation by a gentle heat, about ten grains of ſmall ſhining cryſtals of a bitter taſte were obtained. On pouring ſome drops of vitriolic acid into the ſolution inſpiſſated by gentle heat, no precipitation, excepting of a little ſelenite, enſued; but as ſoon as it was inſpiſſated to the conſiſtence of honey, ſome fine acicular cryſtals, verging towards the ſame centre, began to form, but grew ſoft, and deliqueſced in a few days after.

1363 Manganeſe diſſolved by phlogiſticated nitrous acid.

7. Phlogiſticated nitrous acid diſſolves manganeſe as readily as the phlogiſticated vitriolic. A little levigated manganeſe mixed with ſome water was put into a large receiver, to which a tubulated retort was luted. Some ounces of common nitrous acid were put into the retort, to which ſome iron-filings were added, taking care always to cloſe the orifice with a glaſs ſtopple. The phlogiſticated nitrous acid thus paſſed over into the receiver, and diſſolved the manganeſe in a few hours: the ſolution was as limpid as water, excepting only a little fine ſiliceous earth. Another white precipitate, ſimilar to that produced by adding vitriolic acid to the ſolution in pure nitrous acid now began to fall; but in other reſpects this ſolution agreed with the former.

1364 Effects of it on ſpirit of ſalt.

8. An ounce of purified muriatic acid was poured upon half an ounce of levigated manganeſe; which, after ſtanding about an hour, aſſumed a dark brown colour. A portion of it was digeſted with heat in an open glaſs veſſel, and ſmelled like warm aqua-regia. In a quarter of an hour the ſmell was gone, and the ſolution became clear and colourleſs. The reſt of the brown ſolution being digeſted, to ſee whether the muriatic acid would be ſaturated with manganeſe, an efferveſcence enſued, with a ſtrong ſmell of aqua-regia, which laſted till next day, when the ſolution was found to be ſaturated. Another ounce of acid was poured upon the reſiduum, which was followed by the ſame phenomenon, and the manganeſe was entirely diſſolved, a ſmall quantity of ſiliceous earth only remaining.

1365 Entirely diſſolved by this acid.

The ſolution, which was yellow, being now divided into two portions, ſome drops of vitriolic acid were poured into the one, by which it inſtantly became white, and a fine powder, inſoluble in water, was precipitated. Some ſmall cryſtals of ſelenite were formed by evaporation, and the reſiduum exhibited the ſame phenomenon with thoſe abovementioned with nitrous

trous acid, by evaporating the other half, ſome ſmall ſhining angular cryſtals were obtained, ſimilar to thoſe procured by means of the nitrous acid.

1366
Scarce ſoluble in fluor acid,

9. Very little manganeſe was diſſolved by fluor acid, even after ſeveral days digeſtion. A great quantity was required to form a ſaturated ſolution. It had very little taſte, and gave a ſmall quantity of precipitate with fixed alkali. But if a neutral ſalt, compoſed of fluor acid and ſal ammoniac, be added, a double decompoſition takes place, and the manganeſe is precipitated along with the fluor acid.

1367
Or in phoſphoric acid.

10. A drachm of phoſphoric acid, digeſted with as much powdered manganeſe, diſſolved but litle of it; and, though evaporated to dryneſs, the reſiduum taſted very acid; but by adding more manganeſe the acid was at laſt ſaturated. On adding microcoſmic ſalt to a ſolution of manganeſe, a decompoſition takes place ſimilar to that effected by the combination of fluor acid and volatile alkali.

1368
Partly ſoluble in acid of tartar.

11. Pure acid of tartar diſſolved manganeſe partly in the cold, and more effectually by means of heat. The whole, however, could not be diſſolved, though the acid was at laſt ſaturated by adding a great quantity of the mineral. On adding a ſolution of ſoluble tartar, a double decompoſition took place.

1369
With difficulty in the acetous.

12. Little was diſſolved by diſtilled vinegar, though boiled on manganeſe; but after diſtilling ſpirit of verdigris ſeveral times upon it, the acid at laſt became ſaturated. The ſolution, evaporated to dryneſs, left a deliqueſcent maſs. Little or none of the remaining manganeſe was diſſolved by concentrated vinegar, though repeatedly diſtilled upon it.

1370
Entirely diſſolved by acid of lemons;

13. With acid of lemons the whole was diſſolved with efferveſcence, excepting only ſome white earth.

1371
And by water impregnated with fixed air.

14. Water impregnated with fixed air likewiſe diſſolved manganeſe, but parted with it on the addition of alkali, or ſpontaneouſly by expoſure to the air.

1372
Has a ſtrong attraction for phlogiſton.

1373
Becomes white by ſaturation with phlogiſton.

From theſe experiments Mr Scheele concludes, that manganeſe has a ſtrong elective attraction for all phlogiſtic ſubſtances; and that this attraction becomes ſtronger, if there be preſent a menſtruum which can unite with the phlogiſticated manganeſe. Thus it attracts phlogiſton more powerfully than even the nitrous acid itſelf in the moiſt way. By ſaturation with phlogiſton, manganeſe has the property of loſing its black colour, and aſſuming a white one, which is unuſual, the phlogiſton generally communicating a black or dark colour to the ſubſtances with which it was united.

1374
Contains ſome phlogiſton naturally.

That manganeſe naturally contains ſome phlogiſton, though but in ſmall quantity, appears from evaporating a ſolution of it in vitriolic acid to dryneſs, and then diſtilling the maſs in a glaſs retort in an open fire. When the retort begins to melt, the acid parts fly off from the manganeſe in a ſulphureous ſtate, leaving the former of its natural black colour. By diſtilling the maſs remaining after evaporation of the nitrous ſolution, a green volatile nitrous acid remains, and the black calx of manganeſe remains as before. A ſolution of this mineral in vitriolic or nitrous acid, precipitated by fixed alkali, retains its colour; but when calcined in the open fire, again becomes black.

1375
Becomes inſoluble in pure acids by loſing its phlogiſton.

By loſing its phlogiſton, manganeſe becomes inſoluble in pure acids; and therefore the reſiduum of the abovementioned diſtillations cannot be diſſolved by adding more of the vitriolic or nitrous acids: but if that which has come over into the receiver be poured back into the retort, a ſolution will again take place by reaſon of the manganeſe reaſſuming the phlogiſton it had parted with to the acid.

1376
Partial ſolutions of manganeſe explained on this principle.

On this principle our author explains the reaſon of the partial ſolutions of this mineral abovementioned. Part of it is diſſolved, for inſtance, in the vitriolic acid, while the remainder is found inſoluble. This happens (ſays he), "becauſe the undiſſolved portion has parted with the little phlogiſton it naturally poſſeſſed to that portion of manganeſe which is taken up by the vitriolic acid during the firſt digeſtion; for without that principle it is inſoluble."

Manganeſe attracts phlogiſton more ſtrongly when combined with ſome acid than by itſelf, as appears from the following experiments.

1377
Strong attraction of manganeſe when combined with acids for phlogiſton.

1378
Why the concentrated acid of vitriol diſſolves manganeſe without addition.

1. Levigated manganeſe, digeſted or boiled with a ſolution of ſugar, honey, gum arabic, hartſhorn, jelly, &c. remains unchanged; but on mixing the pounded mineral with diluted vitriolic, or pure nitrous acid, and then adding ſome of theſe ſubſtances, the whole is diſſolved, the black colour vaniſhes by degrees, and the ſolution becomes as limpid as water. So ſtrong is the attraction of manganeſe for phlogiſton in theſe circumſtances, that metals, the noble ones not excepted, render it ſoluble in theſe acids in a limpid form. Concentrated vitriolic acid, indeed, diſſolves manganeſe entirely without any phlogiſton. "It would be difficult (ſays Mr Scheele) to comprehend whence the phlogiſton in this caſe ſhould come, if we were not certain that ſeveral ſubſtances, which have a great attraction for phlogiſton, can attract it in a red heat. Quickſilver and ſilver, when diſſolved in the pureſt nitrous acid, really loſe their phlogiſton, which is a conſtituent part of theſe metals. This appears from the red vapours in which the acid ariſes; and the diſſolved metallic earth cannot be again reduced to its metallic form, till it has acquired the loſt phlogiſton, which is effected either by precipitation with complete metals or by heat alone. Thus manganeſe can attract the quantity of phlogiſton neceſſary for its ſolution by means of concentrated vitriolic acid from heat. It is not probable that the concentrated acid undergoes a decompoſition in this degree of fire; for if you ſaturate half an ounce of this acid with alkali of tartar, and afterwards calcine in a retort, with a receiver applied, an ounce and a half of powdered manganeſe, with an equal quantity of the ſame vitriolic acid, then diſſolve the calcined maſs in diſtilled water, and likewiſe waſh well the receiver, which contains ſome drops of vitriolic acid, which are alſo to be added to the ſolution, and laſtly, add the ſame quantity of alkali, there will be no mark of ſuperabundant acid or alkali. Thence it may be concluded, that the phlogiſton in the vitriolic acid, if there really exiſts any in it, contributes nothing to the ſolution. But the manganeſe precipitated by alkali, contains a conſiderable quantity of it; in conſequence of which it is afterwards entirely ſoluble in acids without any addition.

1379
Why the volatile ſulphureous acid diſſolves it.

"The effects of volatile ſulphureous acid on manganeſe, clearly prove what has been aſſerted. The manganeſe attracts the phlogiſton contained in this acid, which is the cauſe of its great volatility, and which renders the former ſoluble in the new pure vitriolic acid. If this ſolution be mixed with concentrated vitriolic acid and diſtilled, no volatile ſulphureous acid is obtained; and if it be precipitated by means of fixed vegetable alkali, vitriolated tartar is obtained; which proves that manganeſe has a ſtronger attraction than vitriolic acid for phlogiſton in the moiſt way.

1380
Effects of nitrous acid on mangeneſe explained.

"The effects of nitrous acid on this ſubſtance are ſimilar to thoſe of vitriolic acid. Could ſpirit of nitre ſuſtain as great a degree of heat as the concentrated vitriolic acid, it would alſo entirely diſſolve the manganeſe by means of the phlogiſton attracted by heat; but as this is not the caſe, it is neceſſary to add phlogiſton in the manner abovementioned. The manganeſe decompoſes phlogiſticated nitrous acid, for the ſame reaſon that it does the volatile ſulphureous acid; and that the phlogiſton of this acid really combines with manganeſe, is manifeſt from this, that the affuſion of vegetable acid produces no ſmell of aquafortis by diſplacing the phlogiſticated acid of nitre. By diſtillation with pure vitriolic acid alſo, the nitrous acid is expelled, not in a ſmoking ſtate, and of a yellow colour, but pure and colourleſs.

"In the ſolution of manganeſe by means of gum arabic or ſugar, a very conſiderable effervеſcence takes place, owing to the extrication, or probably rather the production, of fixed air from the mixture; but with phlogiſticated acid of nitre no ſuch phenomenon takes place, becauſe the manganeſe is combined with pure phlogiſton; and if this ſhould be again ſeparated, there is no cauſe for the production of fixed air. This mineral is alſo diſſolved without effervеſcence, by uniting it with nitrous acid and metals, arſenic or oil of turpentine."

1381
Exiſtence of phlogiſton in the muriatic acid proved

As muriatic acid diſſolves manganeſe without addition, Mr Scheele is of opinion that this proves the exiſtence of phlogiſton in that acid, as has already been taken notice of. The manganeſe digeſted in the cold with ſpirit of ſalt aſſumes a dark brown colour; for it is a property of this ſubſtance that it cannot be diſſolved into a colourleſs liquor without phlogiſton, but has always a red or blue colour; but with ſpirit of ſalt the ſolution is more brown than red, on account of the fine particles of the manganeſe floating in the liquid. Here the mineral adheres but looſely to the acid, ſo that it may be precipitated by water.

1382
Explanation of the action of acid of tartar and acid of lemons.

The effects of acid of tartar and acid of lemons upon manganeſe are likewiſe explained on the principle already laid down, *viz.* the extreme attraction this ſubſtance has for phlogiſton. Thus it attracts part of that naturally contained in theſe acids, decompoſing one part of them, and being diſſolved by the other. This deſtruction of the acid is ſimilar to that of the ſugar, gum arabic, &c. which render it ſoluble in nitrous acid; for if a proper quantity of theſe are added, the manganeſe will be diſſolved, without a poſſibility of recovering the ſmalleſt particle of the vegetable ſubſtance employed; and if the ſolution be ſlowly evaporated and calcined, there will not remain the ſmalleſt mark of burned ſugar or gum. During this decompoſition, a pungent vapour ariſes, which, being collected, appears to be true vinegar. It is obtained in its pureſt ſtate from diluted vitriolic acid, ſugar, and manganeſe.

1383
Of fluor acid.

Fluor acid diſſolves but very little manganeſe, owing to its precipitating ſalt which envelopes the particles of manganeſe, and prevents the further action of the menſtruum. In all precipitations of manganeſe, however, by means of mild fixed alkalies, the full quantity is not procured; becauſe the fixed air, detached from the mineral, diſſolves part of it.

1384
Effects of manganeſe on nitre.

Though manganeſe decompounds nitre, yet this does not happen till the mixture becomes red hot. If phlogiſticated manganeſe be mixed with an equal quantity of nitre, and diſtilled in a glaſs retort, the mixture begins to grow black before the retort becomes red-hot, but no nitrous acid goes over. By lixiviation, no mark of uncombined alkali is met with; but phlogiſticated nitrous acid is extricated by the application of tamarinds, or any vegetable acid. Three parts of phlogiſticated manganeſe, mixed with one part of finely pounded nitre, yields no nitrous acid, though the nitre is alkalized as ſoon as the mixture becomes black in the retort.

1385
Experiments on manganeſe united with phlogiſton.

Mr Scheele proceeds now to another ſet of experiments upon manganeſe united with phlogiſton. In order to procure it in this ſtate, the beſt method is to diſſove in diſtilled water, and cryſtallize the ſalt obtained by ſolution of manganeſe in vitriolic acid, and then precipitate it with vegetable fixed alkali. In this ſtate it is white like chalk; but by calcination in an open fire, the ſuperfluous phlogiſton flies off, and the calx regains its uſual black colour. This change of colour likewiſe happens when the precipitation is made with cauſtic alkalies, whether fixed or volatile. The precipitate, indeed, in this caſe, is white when kept cloſe from the air, but aſſumes a brown colour when expoſed to it for any time: But when the precipitation is made by mild alkali, the white colour is preſerved by the fixed air, which in this caſe it alſo contains. By diluting the ſolution with a conſiderable quantity of water, and precipitating with cauſtic alkali, the precipitate is brown from the very beginning, owing to the air in the liquid attracting the phlogiſton from the manganeſe. The precipitate formed by lime-water is alſo brown; but on adding more of a ſtrong ſolution of manganeſe, and afterwards precipitating with cauſtic alkali, the powder falls of a white colour; becauſe the air, being already ſaturated with phlogiſton, cannot take up any more. The reſults of Mr Scheele's experiments on this phlogiſticated manganeſe are,

1386
By diſtillation *per ſe.*

1. An ounce of this ſubſtance diſtilled by itſelf in a glaſs retort, with a ſtrong fire, yielded a great quantity of fixed air with ſome drops of water. The reſiduum poured warm out of the retort grew red-hot, and ſet the paper on fire.

2. On repeating the experiment with only a drachm of phlogiſticated manganeſe, and tying a bladder to the neck of a retort, three ounce-meaſures of air came over: the reſiduum was of a light grey colour; diſſolved in acids without addition of any more phlogiſton; and took fire in that degree of heat in which ſulphur ſmokes, but does not burn. From theſe experiments, ſays Mr Scheele, it is evident, that phlogiſton does not ſeparate from manganeſe if the acceſs of air be prevented.

1387
Boiled with oil olive.

3. One part of finely powdered manganeſe boiled in four of oil-olive, effervеſced violently, and diſſolved into a kind of ſalve.

1388
By diſtillation with charcoal.

4. On diſtilling a mixture of finely powdered manganeſe and charcoal, with an empty bladder tied to the mouth of the retort, a quantity of fixed air was extri-

cated when the retort began to melt and diſtended the bladder. The reſiduum was moſtly ſoluble in diluted vitriolic acid.

1389 With ſulphur.

5. On diſtilling half an ounce of powdered manganeſe with two drachms of ſulphur, the latter partly roſe into the neck of the retort, and ſome volatile acid vapours penetrated through the lute. The diſtillation was continued till the retort began to melt; and, on cooling, the reſiduum was found to weigh $5\frac{1}{2}$ drachms. It was of a yellowiſh-grey colour; and diſſolved in ſpirit of vitriol with effervefcence, yielded an hepatic ſmell, ſome ſulphur being alſo precipitated at the ſame time. By calcination in the open air, the ſulphur was diſſipated; but great part of the maſs was rendered ſoluble on account of its having been penetrated by the acid vapour, and ſhot into cryſtals as though it had been formally diſſolved in volatile ſulphureous acid; and by repeating the calcination with more ſulphur, the whole became at laſt entirely ſoluble, and was reduced to cryſtals.

1390 By calcination with nitre.

Finely powdered mangaueſe, triturated with nitre and ſtrongly calcined in a crucible, unites with the alkali of the nitre, while the acid is diſſipated in the air. The maſs formed by the union of the manganeſe and alkali is of a dark green colour, and ſoluble in water, communicating alſo a green colour to the liquid; but in a ſhort time a fine yellow powder (an ochre of iron) falls to the bottom, leaving the liquor of a blue colour. By the addition of water, this ſolution firſt aſſumes a violet colour, grows afterwards red, and a precipitation of the manganeſe takes place, which reſumes its natural colour as ſoon as it has fallen. The ſame precipitation takes place on the addition of a few drops of acid, or by expoſure for ſome days to the open air. As for the dark red colour aſſumed by the ſolution when the precipitate is about to fall, Mr Scheele conjectures that the particles of manganeſe may naturally have a red colour, which becomes viſible when the ſubſtance is diſperſed through a menſtruum without being perfectly diſſolved.

1391 With the addition of arſenic.

7. By the addition of finely powdered white arſenic to the alkaline maſs of nitre and manganeſe, the green colour diſappears, and the whole becomes white; phlogiſticated manganeſe being alſo precipitated on the addition of water. This ariſes from the more powerful attraction of manganeſe for the phlogiſton of the arſenic than that of the arſenical acid itſelf; and for the ſame reaſon, if the maſs be calcined with charcoal, or any other phlogiſtic ſubſtance, a colourleſs ſolution will be obtained.

1392 By diſtillation with ſal ammoniac.

8. Half an ounce of phlogiſticated manganeſe, diſtilled in a retort with an equal quantity of powdered ſal ammoniac, yielded firſt a concrete volatile ſalt, after which ſome ſal ammoniac undecompoſed aroſe in the neck of the retort. Half an ounce of pure dephlogiſticated manganeſe, mixed with two drachms of powdered ſal ammoniac, yielded alkali in its cauſtic ſtate. Both reſiduums were ſoluble in water; which ſhows that manganeſe attracts phlogiſton from the volatile alkali.

1393 By diſtillation with pure nitrous acid.

9. On digeſting finely powdered manganeſe for ſome weeks with pure nitrous acid and ſome volatile alkali, a great number of air-bubbles riſe to the top, and the volatile alkali is entirely decompoſed: for though the mixture be afterwards diſtilled in a retort with the addition of quicklime, not the leaſt urinous ſmell can be perceived. This decompoſition is effected by the manganeſe attracting the phlogiſton of the volatile alkali; for that the nitrous acid has no ſhare in this, is proved by the following experiment.

1394 Volatile alkali deſtroyed by manganeſe attracting its phlogiſton.

10. An ounce of well triturated manganeſe was diſtilled with half an ounce of ſal ammoniac; and a liquid alkali, ſuch as that obtained from ſal ammoniac and quicklime, was procured. On repeating this experiment, with the variation only of a bladder inſtead of a receiver, the ſame kind of air was obtained as that which riſes to the top of the nitrous mixture. Though the emiſſion of this air indicated a deſtruction of the volatile alkali, our author explains the reaſon of its being ſtill obtained in a cauſtic ſtate by the phlogiſton taken from the alkali being more than ſufficient to render the alkali ſoluble in muriatic acid; in conſequence of which, the ſuperfluous quantity combines with the manganeſe, and enables it to decompoſe the ſal ammoniac in the ordinary way. It muſt be owned, however, that his reaſoning on this ſubject is not entirely ſatisfactory, nor does the account he gives of his experiments ſeem entirely conſiſtent with itſelf. See *Scheele's Chem. Eſſays*, Eſſay V. § xxxix.

1395 By diſtillation with arſenic.

11. Powdered manganeſe, diſtilled with an equal quantity of white arſenic, underwent no change, the arſenic flying off in its proper form; but with an equal quantity of yellow orpiment, ſome volatile ſulphureous acid came over firſt, then a yellow ſublimate, and at laſt a little red ſublimate aroſe. On augmenting the fire by degrees, the orpiment remained obſtinately attached to it. Similar effects enſued on treating manganeſe with an equal quantity of antimony; which likewiſe yielded a pungent ſulphureous acid, but no ſublimate. By calcination in the open air theſe compounds are decompoſed; and the manganeſe, united with vitriolic acid, becomes ſoluble in water.

1396 With cinnabar.

12. On diſtilling manganeſe with an equal quantity of finely pounded cinnabar, a volatile ſulphureous acid came over firſt; then a little cinnabar was ſublimed into the neck of the retort; and at laſt the quickſilver, which had been the baſis of the cinnabar, began to diſtil: the reſiduum, being a combination of manganeſe and ſulphur, was ſimilar to the compounds already deſcribed.

1397 With corroſive ſublimate.

13. With an equal quantity of corroſive ſublimate, manganeſe underwent no change; but when ſublimed with an equal quantity of mercurius dulcis, a corroſive ſublimate, and then mercurius dulcis, aroſe into the neck of the retort. The reaſon of this is, that the mercurius dulcis contains a portion of phlogiſton; by being deprived of which it ceaſes to be mercurius dulcis, and becomes corroſive ſublimate: but by reaſon of the ſtrong attraction of manganeſe for phlogiſton, the mercurius dulcis parts with that portion which is neceſſary to keep it in its mild ſtate, and thus is converted into corroſive mercury.

SECT. IV. *Inflammable Subſtances.*

1398 General diviſion.

THESE may be divided into the following claſſes: 1. Sulphurs. 2. Ardent ſpirits. 3. Oils and fats. 4. Reſins. 6. Bitumens; and, 6. Charcoal.

§ 1. SULPHURS.

1399 Sulphur.

1. *Common ſulphur.* For the extraction of this ſubſtance from its ores, ſee Sulphur. The artificial compoſition of it we have already related, n° 715; and have now only to take notice of a very few of its properties, which come more properly under this ſection.

Sulphur, as commonly uſed in commerce and the arts, is of a pale yellow colour, of a diſagreeable and peculiar ſmell, which is rendered more ſenſible when it is heated or rubbed. By rubbing, it receives very curious electrical qualities: (See Electricity.) Its ſpecific gravity is conſiderably greater than that of water, though leſs than earths or ſtones. In cloſe veſſels, ſulphur is incapable of receiving any alteration. It melts with a very gentle heat; and then is ſublimed, adhering to the capital in ſmall, very fine, needle-like cryſtals, called *flowers of ſulphur*. It may thus be ſublimed many times without alteration. 1400 Cryſtallization. If ſulphur is expoſed to a heat barely ſufficient to melt it, and very ſlowly cooled, it cryſtallizes in form of many needles croſſing one another. Some of theſe pointed cryſtals may alſo be obſerved in the interior parts of the lumps of ſulphur which have been melted, and caſt into cylyndrical moulds, as they are commonly ſold; becauſe the centre of theſe cylindrical rolls is more ſlowly cooled than the ſurface. Sulphur alſo gives this needle-like form to cinnabar, antimony, and many other minerals containing it. Sulphur may be decompoſed in ſeveral ways. The moſt ſimple is by burning; which we have already taken notice of, n° 623. It may alſo be very effectually decompoſed by mixing it with iron filings and water. In this caſe the phlogiſton is diſſipated, and the acid uniting with the iron forms a green vitriol.

1401 Decompoſed by a ſuperabundance of phlogiſton.

It is very remarkable, that though ſulphur is compoſed of vitriolic acid and phlogiſton, yet the addition of more inflammable matter, ſo far from making the union ſtronger, weakens it to a great degree: and hence we have another method of decompoſing this ſubſtance; namely, by combining it with a large quantity of oil, and diſtilling the compound.

Sulphur is capable of being eaſily diſſolved in expreſſed oils, but very difficultly in eſſential ones. Theſe compoſitions are called *balſams of ſulphur;* and are ſometimes employed in medicine, but are found to be of a very heating nature. They are much uſed by farriers. According to Mr Beaumé, ſulphur cannot be diſſolved in oil, without a heat ſufficient to melt it. A larger quantity is kept diſſolved when the mixture is hot, than when cold; and conſequently the ſulphur, eſpecially if it has been diſſolved in a thin eſſential oil, cryſtallizes on cooling the mixture. The ſulphur, thus ſeparated from the oil, is found not to be altered in any reſpect from what it formerly was; but if the mixture is expoſed to a degree of heat capable of entirely decompoſing the oil, the ſulphur is decompoſed along with it, and the ſame products are obtained by diſtilling this mixture to dryneſs, as if a mixture of pure oil of vitriol and oil were diſtilled. Theſe products are, firſt a portion of oil, when an eſſential oil was made uſe of in the compoſition of the balſam; then ſome volatile ſulphureous acid, which is at firſt watery, and afterwards becomes ſtronger; along with this acid more oil ariſes, which becomes more and more thick towards the end of the diſtillation; and laſtly, when the retort has been made red hot, nothing remains but a fixed coal.

In this proceſs we find, that both the ſulphur and oil are decompoſed. The acid of the ſulphur ſeems to attack the watery principle of the oil, while its phlogiſton remains confounded with that of the oil, or is diſſipated in vapours. Hence, though the vitriolic acid in ſulphur is concentrated to the utmoſt degree, and perfectly free from water, what riſes in this diſtillation is very aqueous, by reaſon of the water which it attracts from the oil.

1402 How ſoluble in ſpirit of wine.

Spirit of wine does not ſenſibly act upon ſulphur in its liquid ſtate; but if both the ſpirit of wine and ſulphur meet in the ſtate of vapour, they will then unite, and a perfect ſolution will take place. By methods of this kind, many combinations might be effected, which have been hitherto thought impoſſible.

1403 Its union with metals.

Pure ſulphur unites eaſily with all metals; gold, platina, and zinc, excepted. The compounds, except that with mercury, poſſeſs a metallic luſtre without any ductility. The ſulphur may be ſeparated by expoſing the mixture to a ſtrong fire. (See Metallurgy,) or by diſſolving the metalline part in acids. The ſulphur, however, defends ſeveral of the metals from the action of acids; ſo that this diſſolution ſucceeds but imperfectly. The reguline part of antimony is more eaſily ſeparated from ſulphur by means of acids than by any other metalline ſubſtance. Alkaline ſalts will ſeparate the ſulphur from all metals in fuſion, but they unite with it themſelves, and form a compound equally capable of diſſolving the metal.

1404 Vermilion

Sulphur united with quickſilver forms the beautiful pigment called *cinnabar*, or *vermilion;* which is ſo much uſed in painting, that the making of it is become a diſtinct trade. Neumann relates, that in the making of cinnabar by the Dutch method, ſix or eight parts of quickſilver are made uſe of to one of ſulphur. The ſulphur is firſt melted, and then the quickſilver is ſtirred into it; upon which they unite into a black maſs. In this part of the proceſs the mixture is very apt to take fire; of which it gives notice by ſwelling up to a great degree. The veſſel muſt then be immediately covered. The maſs being beaten to powder, is afterwards to be ſublimed in large earthen jars almoſt of an equal wideneſs from end to end; theſe are hung in a furnace by a ſtrong rim of iron. When the matter is put in, the mouth of the veſſel is covered, the fire increaſed by degrees, and continued for ſeveral hours, till all the cinnabar has ſublimed; care being taken to introduce at times an iron rod to keep the middle clear; otherwiſe the cinnabar concreting there, and ſtopping up the paſſage would infallibly burſt the veſſels.

The quantity of ſulphur directed in the common receipts for making cinnabar is greatly larger than the above; being no leſs than one-third of the quantity of quickſilver employed: accordingly it has been found, that the ſublimate, with ſuch a large quantity of ſulphur, turned out of a blackiſh colour, and required to be ſeveral times ſublimed before it became perfectly red; but we cannot help thinking, that by one gentle

ſublimation

ſublimation the ſuperfluous ſulphur might be ſeparated, and the cinnabar become perfectly pure the ſecond time. Hoffman gives a curious method of making cinnabar without ſublimation: by ſhaking or digeſting a little mercury with volatile tincture of ſulphur, the mercury readily imbibes the ſulphur from the volatile ſpirit, and forms with it a deep red powder, not inferior in colour to the cinnabar prepared in the common manner. Dr Lewis has found the common ſolutions of ſulphur by alkalies, or quicklime, to have a ſimilar effect. This cinnabar will likewiſe be of a darker or lighter colour, according as the ſolution contains more or leſs ſulphur.

1405 Pulvis fulminans. Sulphur is a principal ingredient in gun-powder, (ſee GUN-POWDER.) It alſo enters the compoſition of the *pulvis fulminans*. This conſiſts of three parts of nitre, two of the dry alkali of tartar, and one part of ſulphur, well ground together. If a little quantity of this powder is laid on an iron-ſpoon or ſhovel, and ſlowly heated, it will explode, when it arrives at a certain degree of heat, with aſtoniſhing violence and noiſe. The moſt probable opinion concerning this is, that the fixed air contained in the alkali is, by the acid vapours acting upon and endeavouring to expel it all at once, driven off with ſuch force, that a loud exploſion is produced.

1406 Phoſphorus of urine. 2. *Phoſphorus of Urine*. This is a very inflammable ſubſtance, compoſed of phlogiſton united with a certain acid, the properties of which we have already taken notice of, n° 904 *et ſeq*. The preparation of it was long a ſecret, and only perfectly diſcovered by Mr Margraaf, who publiſhed it in the Berlin Memoirs in 1743. This proceſs being by far the beſt and moſt practicable, we ſhall content ourſelves with inſerting it alone.

1407 Mr Margraaf's proceſs for making. Two pounds of ſal ammonaic are to be accurately mixed with four pounds of minium, and the mixture diſtilled in a glaſs retort; by which means a very penetrating, cauſtic alkaline ſpirit will be obtained. The reſiduum, after the diſtillation, is a kind of *plumbum corneum*; n° 812. This is to be mixed with nine or ten pounds of extract of urine, evaporated to the conſiſtence of honey. (Seventy or eighty gallons of urine are required to produce this quantity of extract.) The mixture is to be made ſlowly in an iron pot ſet over the fire, and the matter frequently ſtirred. Half a pound of powdered charcoal is then to be added, and the evaporation continued till the whole is reduced to a black powder. This powder is to be put into a retort, and urged with a graduated heat, till it becomes red hot, in order to expel all the volatile alkali, fetid oil, and ammoniacal ſalt, that may be contained in the mixture. After the diſtillation, a black friable reſiduum remains, from which the phoſphorus is to be extracted by a ſecond diſtillation and a ſtronger heat. Before it is ſubjected to another diſtillation, it may be tried by throwing ſome of it upon hot coals. If the matter has been well prepared, a ſmell of garlic exhales from it, and a blue phoſphorical flame is ſeen undulating along the ſurface of the coals.

The matter is to be put into a good earthen retort, capable of ſuſtaining a violent fire. Three quarters of the retort are to be filled with the matter which is to yield the phoſphorus, and it is to be placed in a furnace capable of giving a ſtrong heat. Mr Margraaf divides the matter among ſix retorts, ſo that if any accident happens to one, the whole matter is not loſt. The retorts ought to be well luted to a receiver of a moderate ſize, pierced with a ſmall hole, and half full of water; and a ſmall wall of bricks muſt be raiſed between the furnace and receiver, in order to guard this veſſel againſt heat as much as poſſible. The retorts are to be heated by ſlow degrees for an hour and an half; then the heat is to be increaſed till the veſſels are red hot, when the phoſphorus aſcends in luminous vapours. When the retort is heated till between a red and white, the phoſphorus paſſes in drops, which fall and congeal in the water at the bottom of the receiver. This degree of heat is to be continued till no more comes over. When a retort contains eight pints or more, this operation continues about five hours.

1408 Rectification of phoſphorus. In the firſt diſtillation, phoſphorus never paſſes pure, but is always of a blackiſh colour, by reaſon of its carrying along with it ſome part of the coal. From this, however, it may be purified by rectification in a ſmall glaſs-retort, to which is luted a receiver half full of water. A very gentle heat is ſufficient; becauſe phoſphorus, once formed, is very volatile; and as the fuliginous matter was raiſed probably by the fixed air emitted by the charcoal in the inſtant of its union with the phoſphorine acid, none of it can ariſe in a ſecond diſtillation.

The phoſphorus is then to be divided into ſmall cylindrical rolls, which is done by putting it in glaſs-tubes immerſed in warm water; for the phoſphorus is almoſt as fuſible as ſuet. It takes the form of the glaſs-tubes; from which it may be taken out, when it is cold and hardened. This muſt be done under water, leaſt the phoſphorus ſhould take fire.

1409 Proceſs ſometimes dangerous. This concrete continually appears luminous in a dark place; and by a very ſlight heat takes fire, and burns far more vehemently than any other known ſubſtance. Hence it is neceſſary to be very cautious in the diſtillation of it; for if the receiver ſhould happen to break while the phoſphorus is diſtilling, and a little flaming phoſphorus fall upon the operator's legs or hands, it would burn its way to the bone in leſs than three minutes. In this caſe, according to Mr Hellot, nothing but urine will ſtop its progreſs.

Though phoſphorus takes fire very readily by itſelf, it does not inflame at all by grinding it with other inflammable bodies, as camphor, gun-powder, or eſſential oils. In grinding it with nitre, ſome luminous flaſhes are obſerved; but the mixture never burns, unleſs the quantity of phoſphorus be large in proportion to the nitre: rubbed pretty hard on a piece of paper or linen, it ſets them on fire if they are rough, but not if they are ſmooth. It fires written paper more readily than ſuch as is white, probably from the former having more aſperities. On grinding with iron-filings, it preſently takes fire.

1410 Liquid phoſphorus. Oils ground with phoſphorus appear, like itſelf, luminous in a temperately warm place; and thus become a liquid phoſphorus, which may be rubbed on the hands, &c. without danger. Liquid phoſphorus is commonly prepared by grinding a little of the ſolid phoſphorus with oil of cloves, or rubbing it firſt with camphor, and this mixture with the oil. A luminous *amalgam*, as it is called, may be obtained, by digeſting a ſcrua ſcruple of ſolid phoſphorus with half an ounce of oil of lavender, and, when the phoſphorus begins to diſſolve and the liquor to boil,' adding a drachm of pure quickſilver; then briſkly ſhaking the glaſs for five or ſix minutes till they unite.

1411 Experiments on phoſphorus with ſpirit of wine.

Rectified ſpirit of wine, digeſted on phoſphorus, extracts a part of it, ſo as to emit luminous flaſhes on being dropt into water. It is computed that one part of phoſphorus will communicate this property to 600,000 parts of ſpirit. The liquor is never obſerved to become luminous of itſelf, nor in any other circumſtance except that abovementioned. By digeſtion for ſome months, the undiſſolved phoſphorus is reduced to a tranſparent oil, which neither emits light nor concretes in the cold. By waſhing with water, it is in ſome meaſure revived; acquiring a thicker conſiſtence, and becoming again luminous, though in a leſs degree than at firſt. During this digeſtion, the glaſs is very apt to burſt.

1412 With eſſential oils and acids.

Phoſphorus is partially diſſolved by expreſſed oils; and totally, or almoſt ſo, in eſſential oils and ether. When eſſential oils are ſaturated with it by heat, a part of the phoſphorus ſeparates, on ſtanding in the cold, in a cryſtallize form. Concentrated ſpirit of ſalt has no action on it. In diſtillation, the ſpirit riſes firſt, and the phoſphorus after it unchanged. Spirit of nitre diſſolves it, and the diſſolution is attended with great heat and copious red fumes; ſo that great part of the ſpirit diſtils without the application of any external heat, and the phoſphorus at laſt takes fire, explodes, and burſts the veſſels. Oil of vitriol likewiſe diſſolves phoſphorus, but not without a heat ſufficient to make the acid diſtil. The diſtilled liquor is white, thick, and turbid; the reſiduum is a whitiſh tenacious maſs, which deliquates, but not totally, in the air. Phoſphorus itſelf is reſolved into an acid liquor on being expoſed two or three weeks to the air, its inflammable principle ſeeming by degrees to be diſſipated.

Phoſphorus has been reported to produce extraordinary effects in the reſolution of metallic bodies: but from the experiments that have been made with this view, it does not appear to have any remarkable action on them; at leaſt on the precious ones, gold and ſilver, for the reſolution or ſubtilization of which it has been chiefly recommended. The following experiments were made by Mr Margraaf.

1413 Mr Margraf's experiments with metals.

1. A ſcruple of filings of gold were digeſted with a drachm of phoſphorus for a month, and then committed to diſtillation. Part of the phoſphorus aroſe, and part remained above the gold, in appearance reſembling glaſs: this grew moiſt on the admiſſion of air, and diſſolved in water, leaving the gold unaltered. Half a drachm of fine ſilver, precipitated by copper, being digeſted with a drachm of phoſphorus for three hours, and the fire then increaſed to diſtillation, greateſt part of the phoſphorus aroſe pure, and the ſilver remained unchanged Copper filings being treated in the ſame manner, and with the ſame quantity of phoſphorus, the phoſphorus ſublimed as before; but the remaining copper was found to have loſt its metallic brightneſs, and to take fire on the contact of flame. Iron filings ſuffered no change. Tin filings run into granules, which appeared to be perfect tin. Filings of lead did the ſame. The red calx of mercury, called *precipitate per ſe*, treated in the ſame manner, was totally converted into running quickſilver. 2. Regulus of antimony ſuffered no change itſelf, but occaſioned a change in the conſiſtence of the phoſphorus; which, after being diſtilled from this ſemimetal, refuſed to congeal, and continued, under water, fluid like oil-olive. With biſmuth there was no alteration. A drachm of phoſphorus being diſtilled and cohobated with an equal quantity of zinc, greateſt part of the zinc ſublimed in form of very light pointed flowers of a reddiſh-yellow colour: theſe flowers, injected into a red hot crucible, took fire, and run into a glaſs reſembling that of borax. White arſenic, ſublimed with phoſphorus, aroſe along with it in form of a mixed red ſublimate. Sulphur readily unites with phoſphorus into a maſs which ſmells like *hepar ſulphuris*. This does not eaſily take fire on being rubbed; but expoſed to a moderate dry heat, it flames violently, and emits a ſtrong ſulphureous fume. If phoſphorus is burnt in an open veſſel, a quantity of acid remains behind; and if a glaſs bell is held over it, an acid likewiſe ſublimes in the form of white flowers.

1414 Mr Canton's phoſphorus.

3. *Mr Canton's phoſphorus*. This is a compoſition of quicklime and common ſulphur. The receipt for making it is as follows. "Calcine ſome common oyſter-ſhells, by keeping them in a good coal-fire for half an hour; let the pureſt part of the calx be pulverized and ſifted. Mix with three parts of this powder one part of flowers of ſulphur. Let this mixture be rammed into a crucible of about an inch and a half in depth till it be almoſt full; and let it be placed in the middle of the fire, where it muſt be kept red hot for an hour at leaſt, and then ſet by to cool: when cold, turn it out of the crucible; and cutting or breaking it to pieces, ſcrape off, upon trial, the brighteſt parts; which, if good phoſphorus, will be a white powder. This kind of phoſphorus ſhines on being expoſed to the light of the ſun, or on receiving an electrical ſtroke.

1415 Homberg's phoſphorus or pyrophorus.

4. *Phoſphorus of Homberg*. This ſubſtance, which has the ſingular property of kindling ſpontaneouſly when expoſed to the air, was accidentally diſcovered by Mr Homberg, as he was endeavouring to diſtil a clear flavourleſs oil from human excrements. Having mixed the excrement with alum, and diſtilled over as much as he could with a red heat, he was much ſurpriſed at ſeeing the matters left in the retort take fire upon being expoſed to the air, ſome days after the diſtillation was over. This induced him to repeat the operation, in which he met with the ſame ſucceſs; and he then publiſhed a proceſs, wherein he recommended alum and human excrement for the preparation of the phoſphorus. Since his time, however, the proceſs has been much improved; and it is diſcovered, that almoſt every vitriolic ſalt may be ſubſtituted for the alum, and moſt other inflammable ſubſtances for the excrement; but though alum is not abſolutely neceſſary for the ſucceſs, it is one of the vitriolic ſalts that ſucceed beſt. The following proceſs is recommended in the Chemical Dictionary.

1416 Beſt method of preparing.

Let three parts of alum and one of ſugar be mixed together. This mixture muſt be dried in an iron ſhovel, over a moderate fire, till it be almoſt reduced to a blackiſh powder or coal; during which time it muſt be ſtirred with an iron ſpatula. Any large maſſes muſt be be bruiſed into powder; and then it muſt be put into a glaſs matraſs, the mouth of which is rather ſtrait than wide, and ſeven or eight inches long. This matraſs is to be placed in a crucible, or other earthen veſſel, large enough to contain the belly of the matraſs, with about a ſpace equal to that of a finger all round it. This ſpace is to be filled with ſand, ſo that the matraſs ſhall not touch the earthen veſſel. The apparatus is then to be put into a furnace, and the whole to be made red hot. The fire muſt be applied gradually, that any oily or fuliginous matter may be expelled; after which, when the matraſs is made red hot, ſulphureous vapours exhale: this degree of heat is to be continued till a truly ſulphureous flame, which appears at the end of the operation, has been ſeen nearly a quarter of an hour: the fire is then to be extinguiſhed, and the matraſs left to cool, without taking it out of the crucible; when it ceaſes to be red hot, it muſt be ſtopped with a cork. Before the matraſs is perfectly cold, it muſt be taken out of the crucible, and the powder it contains poured as quickly as poſſible into a very dry glaſs phial, with a glaſs ſtopper. If we would preſerve this phoſphorus a long time, the bottle containing it muſt be opened as ſeldom as poſſible. Sometimes it kindles while it is pouring into the glaſs phial; but it may be then extinguiſhed by cloſing the phial expeditiouſly. A ſmall quantity of this pyrophorus laid on paper, and expoſed to the air, immediately takes fire, becomes red like burning coals, and emits a ſtrong ſulphureous vapour greatly reſembling that which ariſes on decompoſing liver of ſulphur.

1417 Is not injured by mere expoſure to light.

It has been generally alleged, that the common black phoſphorus is impaired by being expoſed to the light; but Mr Cavallo has diſcovered the fallacy of this ſuppoſition by the following experiment. Some portions of the ſame pyrophorus were incloſed in three glaſs tubes, and immediately ſealed up hermetically. On the 22th of May 1779, two of them were ſuſpended from a nail out of a window, and the third was wrapped up in paper and incloſed in a box, where not the leaſt glimmering of light could enter. In this ſituation they were left for more than a year; after which one of thoſe that had been kept out of the window was broke, along with that which had been kept in the dark, in the preſence of Mr Kirwan; when the pyrophorus ſeemed to be equally good in each tube, taking fire in about half a minute after it was taken out of the tubes, and expoſed to the air on a piece of paper.

1418 Cauſe of the accenſion.

There are many different kinds of pyrophori: ſome of the moſt remarkable of which are deſcribed under the article Pyrophorus. Many theories have been invented to ſolve the phenomenon of their accenſion on the contact of air. This has been thought owing to the converſion of the earth of alum into lime, or to a remainder of the vitriolic acid attracting moiſture from the atmoſphere; but the formation of pyrophorus without either alum or vitriolic acid, ſhows that neither of theſe opinions can be juſt. It is more probable, therefore, that, the heat is occaſioned by the total diſſipation of that aqueous part which is eſſential to the conſtitution of terreſtrial ſubſtances. In conſequence of this, the water contained in the atmoſphere is not only attracted with avidity, but decompounded by the matter reduced to ſuch a ſtate of extreme dryneſs. By theſe operations it gives out the latent heat contained in it, and this produces the accenſion in queſtion.

§ 2. *Ardent Spirits.*

See Fermentation and Distillation.

§ 3. *Oils.*

1419 Eſſential oils.

1. *Eſſential Oils.* Thoſe oils are called *eſſential* which have evidently the ſmell of the vegetable from which they are drawn. For the method of procuring them, ſee Distillation. They are diſtinguiſhed from all others by their ſuperior volatility, which is ſo great as to cauſe them riſe with the heat of boiling water. All theſe have a ſtrong aromatic ſmell, and an acrid, cauſtic taſte; in which reſpect alſo they differ from other oils. This taſte is thought to proceed from a copious and diſengaged acid, with which they are all penetrated. The preſence of this diſengaged acid in eſſential oils, appears from the impreſſion they make upon the corks of bottles in which they are kept. Theſe corks are always ſtained of a yellow colour, and a little corroded, nearly as they are by nitrous acid. The vapour of theſe oils alſo reddens blue paper, and converts alkalies into neutral ſalts.

1420 Suppoſed cauſe of their taſte.

1421 Of their ſolubility in ſpirit of wine.

This acid is likewiſe ſuppoſed to be the cauſe of their ſolubility in ſpirit of wine. They are not all equally ſoluble in this menſtruum, becauſe they do not all contain an equal quantity of acid. As this acid is much diſengaged, they loſe a great deal of it by repeated diſtillations, and therefore they become leſs and leſs ſoluble on being frequently diſtilled. By evaporation they loſe their moſt volatile and thin part, in which the ſpecific ſmell of the vegetable from which they are extracted reſides; by which loſs they become thick, and acquire the ſmell and conſiſtence of turpentine, and even of reſins. In this ſtate they are no longer volatile with the heat of boiling water; and, if diſtilled with a ſtronger fire, they give over an oil which has neither ſmell nor taſte of the vegetable whence they were extracted, but is entirely empyreumatic, and ſimilar to thoſe oils procured by diſtilling vegetable or animal ſubſtances with a ſtrong fire. See Distillation.

1422 Camphor.

To the claſs of eſſential oils, the volatile concrete called *camphor* ſeems moſt properly to belong. With them it agrees in its properties of inflammability, ſolubility in ſpirit of wine, and a ſtrong aromatic flavour. The only differences between them are, that camphor is always in a ſolid ſtate, and is incapable of decompoſition by any number of ſublimations.

1423 Decompoſed by diſtillation with bole.

It has, however, been found poſſible to decompoſe it by diſtillation with certain additions. By diſtilling it ſeveral times along with bole, we obtain a fluid having the properties of an eſſential oil, ſoluble in water, and ſeparating again on the the addition of ſpirit of wine. On diſtilling it eight times with dephlogiſticated nitrous acid, we obtain a ſalt having the form of a parallelopiped, of an acid and bitter taſte, and changing the juice of violets and turnſole red. This has the properties of a true acid; combines with fixed and volatile alkalies into neutral ſalts capable of being cryſtallized; diſſolves copper, iron, biſmuth, arſenic, and cobalt.

1424 With dephlogiſticated nitrous acid.

cobalt. With magneſia it forms regular cryſtals, in ſome meaſure reſembling baſaltes. It is diſtinguiſhed from the acid of ſugar by not precipitating lime from its ſolution in marine acid, and by forming with magneſia a white powder ſoluble in water.

According to Neumann, all the camphor made uſe of is the produce of two ſpecies of trees; the one growing in Sumatra and Borneo, the other in Japan. Of theſe, the Japan kind is the only one brought into Europe. The tree is about the ſize of a large lime, the flowers white, and the fruit a ſmall red berry. All parts of the tree are impregnated with camphor; but the roots contain moſt, and therefore are chiefly made uſe of for the preparation of this commodity: though, in want of them, the wood and leaves are ſometimes mixed.

The camphor is extracted by diſtillation with water in large iron pots filled with earthen heads ſtuffed with ſtraw; greateſt part of the camphor concretes among the ſtraw, but paſſes down into the receiver among the water. In this ſtate it is found in ſmall bits like gray ſalt-petre, or common bay-ſalt; and requires to be purified either by a ſecond ſublimation, or by diſſolution in ſpirit of wine, filtration, and exſiccation. If the firſt method is followed, there will be ſome difficulty in giving it the form of a perfect tranſparent cake. A difficulty of this kind indeed always occurs in ſublimations; and the only way is to keep the upper part of the glaſs to ſuch a degree of heat as may keep the ſublimate in a half-melted ſtate. Dr Lewis recommends the depuration of camphor by ſpirit of wine, and then melting it into a cake in the bottom of a glaſs.

Camphor poſſeſſes conſiderable antiſceptic virtues; and is a good diaphoretic, without heating the conſtitution; with which intention it is often uſed in medicine. It is likewiſe employed in fire-works and ſeveral other arts, particularly in making varniſhes. See VARNISH.

1425 Soluble in ardent ſpirits and oil.

This ſubſtance diſſolves eaſily and plentifully in vinous ſpirits and in oils; four ounces of ſpirit of wine will diſſolve three of camphor. On diſtilling the mixture, the ſpirit riſes firſt, very little camphor coming over with it. This ſhows that camphor, however volatile it may ſeem by its ſmell, is very far from having the volatility of ether, and conſequently is improperly claſſed with ſubſtances of that kind.

1426 Empyreumatic oils.

2. *Empyreumatic Oils.* Under this name are comprehended all thoſe oils, from whatever ſubſtance obtained, which require a greater heat for their diſtillation than that of boiling water. Theſe are partially ſoluble in ſpirit of wine, and becomes more and more ſo by repeated diſtillations. The empyreumatic oils obtained from animal ſubſtances are at firſt more fetid than thoſe procured from vegetables; but by repeated diſtillations, they become exceedingly attenuated and volatile, becoming almoſt as white, thin, and volatile, as ether. They then acquire a property of acting upon the brain and nervous ſyſtem, and of allaying its irregular movements, which is common to them with all other inflammable matters when highly attenuated and very volatile; but this kind of oil is particularly recommended in epileptic and convulſive affections. It is given from 4 to 10 or 11 drops: but, though prepared with the utmoſt care, it is very ſuſceptible of loſing its whiteneſs, and even its thinneſs, by a ſhort expoſure to air; which proceeds from the almoſt inſtantaneous evaporation of its more thin and volatile parts, and from the property which the leſs volatile remainder has of acquiring colour. To avoid this inconvenience, it muſt be put, as ſoon as it is made, into very clean glaſs bottles with glaſs ſtoppers, and expoſed to the air as little as poſſible.

1427 How rectified.

The moſt important obſervations concerning the method of making the pure animal oils are, firſt to change the veſſel at each diſtillation, or at leaſt to make them perfectly clean; for a very ſmall quantity of the thicker and leſs volatile part is ſufficient to ſpoil a large quantity of that which is more rectified. In the ſecond place, Mr Beaumé has obſerved, that this operation may be greatly abridged, by taking care to receive none but the moſt volatile part in each diſtillation, and to leave a large reſiduum, which is to be neglected, and only the more volatile part to be further rectified. By this method a conſiderable quantity of fine oil may be obtained at three or four diſtillations, which could not otherwiſe be obtained at fifty or ſixty.

1428 Animal fats.

3. *Animal Fats.* Though theſe differ conſiderably from one another in their external appearance, and probably in their medicinal qualities, they afford, on a chemical analyſis, products ſimilar in quality, and differing but inconſiderably in quantity. They all yield a larger portion of oil, and no volatile ſalt; in which reſpect they differ from all other animal ſubſtances. Two ounces of hogs's lard yielded, according to Neumann, two drachms of an empyreumatic liquor, and one ounce five drachms and 50 grains of a clear brown-coloured oil of a volatile ſmell, ſomewhat like horſe-radiſh. The *caput mortuum* was of a ſhining black colour, and weighed 10 grains.

1429 Tallow.

Tallow being diſtilled in the ſame manner, two drachms of empyreumatic liquor were obtained from two ounces of it; of a clear brown oil, ſmelling like horſe-radiſh, one ounce ſix drachms and 12 grains. The remaining coal was of a ſhining black colour, and weighed 18 grains. A particular kind of acid is now found to be contained in it.

1430 Marrow.

The marrow of bones differs a little from fats, when chemically examined. Four ounces of freſh marrow, diſtilled in the uſual manner, gave over three drachms and a ſcruple of a liquor which ſmelled like tallow; two ſcruples and an half of liquor which had more of an empyreumatic and a ſouriſh ſmell; two ounces and an half of a yellowiſh-brown, butyraceous oil, which ſmelled like horſe-radiſh; and ſix drachms and an half of a blackiſh-brown oil of the ſame ſmell. The *caput mortuum* weighed four ſcruples.

1431 Rancid oils purified.

All animal fats, when perfectly pure, burn totally away without leaving any feces, and have no particular ſmell. In the ſtate in which we commonly find them, however, they are exceedingly apt to turn rancid, and emit a moſt diſagreeable and noxious ſmell; and to this they are peculiarly liable, when long kept in a gentle degree of heat. In this ſtate, too, an inflammable vapour ariſes from them, which when on fire is capable of producing exploſions. Hence, in thoſe works where large bellows are uſed, they have been often ſuddenly burſt by the inflammable vapours ariſing from the rancid oil employed for ſoftening the leather

leather. The expreſſed unctuous oils of vegetables are ſubject to the ſame changes; but from this rancidity they may all be freed moſt effectually, by the ſimple proceſs of agitating them well with water: which is to be drawn off, and freſh quantities added, till it comes off at laſt clear and inſipid, without any ill ſmell. The proper inſtrument for performing this operation in large is a barrel-churn, having in it four rows of narrow ſplit deals, from the centre to the circumference, each piece ſet at obtuſe angles to the other, in order to give different directions to the oil and water as the churn turns round, thereby to mix them more intimately. The churn is to be ſwiftly turned round for a few minutes; and muſt then be left at reſt, till the oil and water have fully ſeparated; which will be in 15 or 20 minutes, more or leſs, according to the ſize of the churn. When this water is drawn off, freſh water is to be put in, and the churn again turned round, and this continued till the oil is perfectly ſweet. If the oil and water are allowed to ſtand together for ſome days, a gelatinous ſubſtance is found between them, which is not very eaſily miſcible either with oil or water. Chalk, quicklime, and alkaline ſalts, are found alſo capable of taking off the rancidity from oils and fats; but have the inconvenience of deſtroying a part of their ſubſtance.

§ 4. RESINS and BALSAMS.

THESE are commonly reckoned to be compoſed of an eſſential oil thickened by an acid; as the eſſential oils themſelves are found to be convertible into a ſimilar ſubſtance, by the exhalation of their more volatile parts. True reſins are generally tranſparent in a conſiderable degree, ſoluble in ſpirit of wine, and poſſeſſed of a conſiderable degree of flavour.

1432 Whence procured.

Reſins are originally produced by inſpiſſating the natural juices which flow from inciſions made in the ſtems of growing vegetables, and are in that ſtate called *balſams*. The balſams may be conſidered as eſſential oils thickened by loſing ſome of their odoriferous principle, and of their fineſt and moſt volatile parts. There are ſeveral kinds of balſams, which, however, differ from each other only in the ſmell and degree of conſiſtence; and therefore all yield ſimilar products on diſtillation. An analyſis of turpentine therefore will be ſufficient as an example of the analyſis and natural properties of all the reſt.

1433 Turpentine Chio.

The true turpentine-tree is found in Spain and the ſouthern parts of France, as well as in the iſland of Chio and in the Indies. It is a middling-ſized evergreen-tree, with leaves like thoſe of the bay, bearing purpliſh, imperfect flowers; and on ſeparate pedicles hard unctuous berries like thoſe of juniper. It is extremely reſinous; and unleſs the reſin is diſcharged, decays, produces fungous excreſcences, ſwells, burſts, and dies; the prevention of which conſiſts wholly in plentiful bleeding, both in the trunk and branches. The juice is the *Chio* or *Cyprus turpentine* of the ſhops. This ſort is quite of a thick conſiſtence, of a greeniſh white colour, clear and tranſparent, and of ſcarcely any taſte or ſmell.

1434 Venice.

The kind now called *Venice turpentine*, is no other than a mixture of eight parts of common yellow or black roſin with five parts of oil of turpentine. What was originally Venice turpentine is now unknown. Neumann relates, that the Venice turpentine ſold in his country was no other than that prepared from the larix tree, which grows plentifully in ſome parts of France, as alſo in Auſtria, Tyrol, Italy, Spain, &c. Of this there are two kinds; the young trees yielding a thin limpid juice, reſembling balſam of copaiba; the older, a yellower and thicker one.

1435 Straſburg.

The *Straſburg turpentine* is extracted from the ſilver-fir. Dr Lewis takes notice that ſome of the exotic firs afford balſams, or reſins, ſuperior to thoſe obtained from the native European ones; as particularly that called *balm of Gilead fir*, which is now naturalized to our own climate. A large quantity of an elegant reſinous juice may be collected from the cones of this tree: the leaves alſo, when rubbed, emit a fragrant ſmell; and yield, with rectified ſpirit, an agreeable reſinous extract.

1436 Common.

The common turpentine is prepared from different ſorts of the pine; and is quite thick, white, and opaque. Even this is often counterfeited by mixtures of roſin and common expreſſed oils.

1437 Phenomena on diſtillation.

All the turpentines yield a conſiderable proportion of eſſential oil. From ſixteen ounces of Venice turpentine, Neumann obtained, by diſtillation with water, four ounces and three drachms of oil. The ſame quantity diſtilled, without addition, in the heat of a water-bath, gave but two ounces and an half; and from the reſiduum treated with water, only an ounce could be obtained. The water remaining in the ſtill is found to have imbibed nothing from the turpentine; on the contrary, the turpentine is found to imbibe part of the water; the reſiduum and the oil amounting to a full ounce on the pound more than the turpentine employed. When turpentine is diſtilled or boiled with water till it becomes ſolid, it appears yellowiſh; when the proceſs is further continued, of a reddiſh brown colour: in the firſt ſtate, it is called *boiled turpentine*; and in the latter, *colophony*, or *roſin*.

On diſtilling ſixteen ounces of turpentine in a retort with an open fire, increaſed by degrees, we obtain firſt four ounces of a limpid colourleſs oil; then two ounces and two drachms of a yellowiſh one; four ounces and three drachms of a thicker yellow oil; and two ounces and one drachm of a dark browniſh red empyreumatic oil, of the conſiſtence of balſam, and commonly called *balſam of turpentine*.

1438 Eſſential oil difficult of ſolution.

The limpid eſſential oil called *ſpirit of turpentine*, is exceedingly difficult of ſolution in ſpirit of wine; tho' turpentine itſelf diſſolves with great eaſe. One part of the oil may indeed be diſſolved in ſeven parts of rectified ſpirit; but on ſtanding for ſome time, the greateſt part of the oil ſubſides to the bottom, a much greater proportion of ſpirit being requiſite to keep it diſſolved.

1439 Benzoin.

2. *Benzoin.* This is a very brittle browniſh reſin, of an exceedingly fragrant ſmell. The tree which produces benzoin is a native of the Eaſt Indies; particularly of Siam and the iſland of Sumatra. It is never permitted to exceed the ſixth year; being, after this time, unfit for producing the benzoin. It is then cut down, and its place ſupplied by a young tree raiſed commonly from the fruit. One tree does not yield above three pounds of benzoin.

A tree ſuppoſed to be the ſame with that which affords

fords benzoin in the Eaſt Indies, is plentiful alſo in Virgina and Carolina; from whence it has been brought into England, where it grows with vigour in the open ground. The bark and the leaves have the ſmell of benzion; and yield with rectified ſpirit a reſin of the ſame ſmell; but no reſin has been obſerved to iſſue from it naturally in England, nor has any benzoin been collected from it in America.

1440 Soluble in ſpirit of wine. Benzoin diſſolves totally in ſpirit of wine into a blood-red liquor, leaving only the impurities, which commonly amount to no more than a ſcruple on an ounce. To water, it gives out a portion of ſaline matter of a peculiar kind, volatile and ſublimable in the fire. See 984 *et ſeq.*

The principal uſe of reſins is in the making of lacquers, varniſhes, &c. See VARNISH.

§ 5. *Bitumens.*

THESE are inflammable mineral bodies, not ſulphureous, or only caſually impregnated with ſulphur. They are of various degrees of conſiſtency; and ſeem, in the mineral kingdom, to correſpond with the oils and reſins in the vegetable.

1441 Origin of bitumens. Concerning the origin of bitumens, chemiſts are not at all agreed. Some chemical writers, particularly Mr Macquer, imagine bitumens to be no other than vegetable reſins altered in a peculiar manner by the admixture of ſome of the mineral acids in the earth; but Dr Lewis is of a contrary opinion, for the following reaſons.

"Mineral bitumens are very different in their qualities from vegetable reſins; and, in the mineral kingdom, we find a fluid oil very different from vegetable oils. The mineral oil is changed by mineral acids into a ſubſtance greatly reſembling bitumens; and the vegetable oils are changed by the ſame acids into ſubſtances greatly reſembling the natural reſins.

"From bitumens we obtain, by diſtillation, the mineral oil, and from reſins the vegetable oil, diſtinct in their qualities as at firſt. Vegetable oils and reſins have been treated with all the known mineral acids; but have never yielded any thing ſimilar to the mineral bitumens. It ſeems, therefore, as if the oily products of the two kingdoms were eſſentially and ſpecifically different. The laws of chemical inquiries at leaſt demand, that we do not look upon them any otherwiſe, till we are able to produce from one a ſubſtance ſimilar to the other. When this ſhall be done, and not before, the preſumption that nature effects the ſame changes in the bowels of the earth, will be of ſome weight."

1442 Naphtha. There is a perfectly fluid, thin bitumen, or mineral oil, called *naphtha*, clear and colourleſs as cryſtal; of a ſtrong ſmell; extremely ſubtile; ſo light as to ſwim on all known liquors, ether perhaps excepted: ſpreading to a vaſt ſurface on water, and exhibiting rainbow colours; highly inflammable: formerly made uſe of in the compoſition of the ſuppoſed inextinguiſhable greek fire.

1443 Petroleum. Next to this in conſiſtence is the *oleum petræ*, or *petroleum;* which is groſſer and thicker than naphtha, of a yellowiſh, reddiſh, or browniſh colour; but very light, ſo as to ſwim even on ſpirit of wine. By diſtillation, the petroleum becomes thinner and more ſubtile, a groſs matter being left behind; it does not, however, eaſily ariſe, nor does it totally loſe its colour by this proceſs, without particular managements or additions.

Both naphtha and petroleum are found plentifully in ſome parts of Perſia, trickling through rocks or ſwimming on the ſurface of waters. Kempfer gives an account of two ſprings near Baku; one affording naphtha, which it receives in drops from ſubterraneous veins; the other, a blackiſh and more fetid petroleum, which comes from Mount Caucaſus. The naphtha is collected for making varniſhes; the petroleum is collected in pits, and ſent to different places for lamps and torches.

Native petrolea are likewiſe found in many different places, but are not to be had in the ſhops; what is ſold there for petroleum, being generally oil of turpentine coloured with alkanet root. The true naphtha is recommended againſt diſorders of the nerves, pains, cramps, and contractions of the limbs, &c. but genuine naphtha is rarely or never brought to this country.

There are ſome bitumens, ſuch as amber, ambergris, pit-coal, and jet, perfectly ſolid; others, ſuch as Barbadoes tar, of a middle conſiſtence between fluid and ſolid. Turf and peat are likewiſe thought to belong to this claſs.

1. *Amber.* This ſubſtance melts, and burns in the fire, emitting a ſtrong peculiar ſmell. Diſtilled in a ſtrong heat, it yields a phlegm, an oil, and a particular ſpecies of acid ſalt. The diſtillation is performed in earthen or glaſs retorts, frequently with the addition of ſand, ſea-ſalt, coals, &c. which may break the tenacity of the melted maſs, ſo as to keep it from ſwelling up, which it is apt to do by itſelf. Theſe additions, however, make a perceptible difference in the produce of the diſtillation: with ſome the ſalt proves yellowiſh and dry; with others, browniſh or blackiſh, and unctuous or ſoft like an extract: with ſome, the oil is throughout of a dark brown colour; with others, it proves externally green or greeniſh; with elixated aſhes, in particular, it is of a fine green. The quantity of oil and phlegm is greateſt when coals are uſed, and that of ſalt when ſea-ſalt is uſed. 1444 Amber.

The moſt advantageous method of diſtilling amber, however, is without any addition; and this is the method uſed in Pruſſia, where the greateſt quantities of ſalt and oil of amber are made. At firſt a phlegmatic liquor diſtils; then a fluid oil; afterwards one that is thick and more ponderous; and laſt of all, an oil ſtill more ponderous along with the ſalt. In order to collect the ſalt more perfectly, the receiver is frequently changed; and the phlegm, and light oil, which ariſe at firſt, are kept by themſelves. The ſalt is purified, by being kept ſome time on bibulous paper, which abſorbs a part of the oil: and changing the paper as long as it receives any oily ſtain. For the further depuration as well as the nature of this ſalt, ſee SUCCINUM. 1445 Moſt advantageouſly diſtilled without addition.

2. *Ambergris.* This concrete, which is only uſed as a perfume, yields, on diſtillation, products of a ſimilar nature to that of amber, excepting that the volatile ſalt is in much leſs quantity. See AMBERGRIS. 1446 Ambergris.

3. *Pit-coal.* See the articles COAL and LITHANTHRAX 1447 Pit-coal.

THRAX. This ſubſtance yields by diſtillation, according to the tranſlator of the Chemical Dictionary, 1. phlegm, or water; 2. a very acid liquor; 3. a thin oil, like naphtha; 4. a thicker oil, reſembling petroleum, which falls to the bottom of the former, and which riſes with a violent fire; 5. an acid, concrete ſalt; 6. *an uninflammable earth* (we ſuppoſe he means a piece of charred coal, or cinder) remains in the retort. The fluid oil obtained from coals is ſaid to be exceedingly inflammable, ſo as to burn upon the ſurface of water like naphtha itſelf.

1448 Peat.

4. *Peat.* There are very conſiderable differences in this ſubſtance, proceeding probably from the admixture of different minerals: for the ſubſtance of peat is plainly of vegetable origin; whence it is found to anſwer for the ſmelting of ores, and the reduction of metallic calces, nearly in the ſame manner as coals of wood. Some ſorts yield, in burning, a very diſagreeable ſmell, which extends to a great diſtance; whilſt others are inoffenſive. Some burn into grey or white, and others into red, ferruginous aſhes. The aſhes yield, on elixation, a ſmall quantity of alkaline, and ſome neutral ſalts.

1449 Phenomena on diſtillation.

The ſmoke of peat does not preſerve or harden fleſh like that of wood; and the ſoot into which it condenſes is more apt to liquefy in moiſt weather. On diſtilling peat in cloſe veſſels, there ariſes a clear inſipid phlegm; an acid liquor, which is ſucceeded by an alkaline one; and a dark-coloured oil. The oil has a very pungent taſte, and an empyreumatic ſmell; leſs fetid than that of animal ſubſtances, but more ſo than that of mineral bitumens. It congeals, in the cold, into a pitchy maſs, which liquefies in a ſmall heat: it readily catches fire from a candle; but burns leſs vehemently than other oils, and immediately goes out upon removing the external flame. It diſſolves almoſt totally in rectified ſpirit of wine, into a dark, browniſh-red liquor.

§ 6. CHARCOAL.

1450 Differences between the coals of different ſubſtances.

THIS is the form to which all inflammable matters are reducible, by being ſubjected to the moſt vehement action of fire in cloſe veſſels; but though all the coals are nearly ſimilar to one another in appearance, there is nevertheleſs a very conſiderable difference among them as to their qualities. Thus the charcoal of vegetables parts with its phlogiſton very readily, and is eaſily reducible to white aſhes: charred pitcoal, or, as it is commonly called, *coak*, much more difficultly; and the coals of burnt animal ſubſtances, far more difficultly than either of the two. Mr Macquer acquaints us, that the coal of bullock's blood parts with its phlogiſton with the utmoſt difficulty. He kept it very red, in a ſhallow crucible ſurrounded with charcoal, for ſix hours and more, ſtirring it conſtantly that it might be all expoſed to the air, without being able to reduce it to white, or even grey aſhes. It ſtill remained very black, and full of phlogiſton. The coals of pure oils, or concrete oily ſubſtances, and ſoot, which is a kind of coal raiſed during the inflammation of oils, are as difficultly burnt as animal coals. Theſe coals contain very little ſaline matter, and their aſhes furniſh no alkali. Theſe coals, which are ſo difficultly burnt, are alſo leſs capable of inflaming with nitre than others more combuſtible; and ſome of them, in a great meaſure, reſiſt even the action of nitre itſelf.

1451 Charcoal perfectly refractory.

Charcoal is the moſt refractory ſubſtance in nature; no inſtance having been known of its ever being melted, or ſhowing the leaſt diſpoſition to fuſion, either by itſelf, or with additions: hence, charcoal is found to be the moſt proper ſupport for ſuch bodies as are to be expoſed to the focus of a large burning glaſs. The only true ſolvent of charcoal is *hepar ſulphuris*. By the violent heat of a burning-glaſs, however, it is found to be entirely diſſipable into inflammable air, without having any reſiduum. See AEROLOGY, n° 129. and CHARCOAL.

The different ſubſtances mixed with different coals, render ſome kinds of charcoal much leſs fit to be uſed in reviving metals from their calces, or in ſmelting them originally from their ores. The coals of vegetable ſubſtances are found to anſwer beſt for this purpoſe. See METALLURGY.

SECT. V. *Vegetable and Animal Subſtances.*

THE only ſubſtances afforded by vegetables or animals, which we have not yet examined, are the mucilaginous, or gummy; and the colouring parts obtained by infuſion, or boiling in water; and the calculous concretions found in the bodies of animals, chiefly in the human bladder. The colouring matter is treated of under the article *COLOUR-Making*, to which we refer; and in this ſection ſhall only conſider the nature of the others.

§ 1. *MUCILAGE or GUM.*

1452 Mucilage.

THE mucilage of vegetables is a clear tranſparent ſubſtance, which has little or no taſte or ſmell, the conſiſtence of which is thick, ropy, and tenacious, when united with a certain quantity of ſuperabundant water. It is entirely and intimately ſoluble in water, and contains no diſengaged acid or alkali.

When mucilage is diſſolved in a large quantity of water, it does not ſenſibly alter the conſiſtence of the liquor: but, by evaporation, the water grows more and more thick; and, at laſt, the matter acquires the conſiſtence of gum arabic, or glue; and this without loſing its tranſparency, provided a heat not exceeding that of boiling water has been uſed.

1453 Phenomena on diſtillation.

Gums, and ſolid mucilages, when well dried and very hard, are not liquefied in the fire like reſins, but ſwell, and emit many fumes; which are, at firſt, watery: then oily, fuliginous, and acrid. Diſtilled in cloſe veſſels, an aqueous acid liquor comes over along with an empyreumatic oil, as from other vegetable ſubſtances; a conſiderable quantity of coal remains, which burns to aſhes with difficulty.

Mucilages and gums are not ſoluble either by oils, ſpirit of wine, alkalies, or acids, except in ſo far as they diſſolve in theſe liquors by means of the water in which the alkali or acid are diſſolved. They are, however, the moſt effectual means of uniting oil with water. Three parts of mucilage, poured upon one part of oil, will incorporate with it by trituration or agitation; and the compound will be ſoluble in water. Vegetable gums are uſed in medicine, as well as the mechanic arts; but the particular uſes to which each of them is applicable, will be mentioned under the name of each particular gum.

1454 Jelly and glue.

The mucilage obtained from animal ſubſtances, when not too thick, is called *jelly*, or *gelatinous matter*; when further inſpiſſated, the matter becomes quite ſolid in the cold, and is called *glue*. If the evaporation is ſtill further continued, the matter acquires the conſiſtence of horn.

This gelatinous ſubſtance ſeems to be the only true animal one; for all parts of the body, by long continued boiling, are reducible to a jelly, the hardeſt bones not excepted. Animal jelly, as well as vegetable mucilage, is almoſt inſipid and inodorous; but, though it is difficult to deſcribe the difference betwixt them when apart, it is very eaſily perceived when they are both together. Acids and alkalies, particularly the latter, diſſolve animal jellies with great eaſe; but the nature of theſe combinations is not yet underſtood. The other properties of this ſubſtance are common to it with the vegetable gums, except only that the animal mucilage forms a much ſtronger cement than any vegetable gum: and is therefore much employed for mechanical purpoſes, under the name of *glue*. See Glue and Isinglass.

§ 2. *Of the Human Calculus.*

1455 Scheele's experiments on the human calculus.

This ſubſtance has been repeatedly examined by the moſt eminent chemiſts. Mr Scheele, as has been related n° 982, *et ſeq.* has been able to extract an acid from it. His account of it in other reſpects is to the following purpoſe.

1. All the calculi examined, whether flat and poliſhed, or rough and angular, were of the ſame nature, and conſiſted of the ſame conſtituent parts.

2. The diluted vitriolic acid has no effect upon the calculus, but the concentrated acid diſſolves it, and by abſtraction from it is converted into the ſulphureous kind, leaving a black coal behind.

3. Neither diluted nor concentrated ſpirit of ſalt had any effect upon it.

4. By means of nitrous acid, a new one was produced, and which is poſſeſſed of ſingular qualities, as already mentioned.

5. The ſolution of calculus in nitrous acid is not precipitated by ponderous earth, nor are metallic ſolutions ſenſibly altered by it.

6. It is not precipitated by alkalies, but grows ſomewhat yellower by a ſuperabundance of the latter. In a ſtrong digeſting heat the liquor becomes red, and tinges the ſkin of the ſame colour. It precipitates green vitriol of a black colour; vitriol of copper, green; ſilver, grey; corroſive ſublimate, zinc, and lead, white.

7. The ſolution is decompoſed by lime-water, and lets fall a white precipitate, ſoluble in the muriatic acid without any efferveſcence: but though there be an exceſs of precipitate, the liquor ſtill remains acid; which happens alſo with animal earth, and that of fluor diſſolved in the ſame acids. On evaporation to dryneſs, the matter will at laſt take fire; but when heated only to a dull red heat in a cloſe crucible, it grows black, ſmells like burnt alum, and efferveſces with acids; being convertible before the blow-pipe into quicklime.

8. Neither this ſolution, nor the alkaline mixture, is changed by the acid of ſugar.

9. The calculus is not changed by acid of tartar, though it is diſſolved even in the cold by alkali, when reduced to ſuch a ſtate of cauſticity as not to diſcover the leaſt mark of aerial acid. The ſolution is yellow and taſtes ſweetiſh; and is precipitated by all the acids, even by the aerial. It decompoſes metallic ſolutions, but does not precipitate lime-water; and a ſmell of volatile alkali is produced by a little ſuperabundance of alkali in the ſolution. Dry volatile alkali has no effect upon the calculus; but cauſtic volatile alkali diſſolves it, though a pretty large quantity is required for this purpoſe.

10. Calculus is likewiſe diſſolved by digeſting in lime-water; and for this purpoſe four ounces of lime-water are required to twelve grains of the calculus; but the latter is partly precipitated by adding acids to the ſolution. By this union the lime-water loſes its cauſtic taſte.

11. Calculus is alſo diſſolved entirely by pure water; but for this purpoſe a large quantity of fluid is required. Eight grains of calculus in fine powder will diſſolve by boiling for a ſhort time in five ounces of water. The ſolution reddens tincture of lacmus, but does not precipitate lime-water; and when it grows cold, the greateſt part of the calculus ſeparates in fine cryſtals.

12. On diſtilling a drachm of calculus in a glaſs retort, a volatile liquor was obtained reſembling hartſhorn, but without any oil; and in the neck of the veſſel was a brown ſublimate. On heating the retort thoroughly red hot, and then leaving it to cool, a black coal was left, weighing 12 grains, which retained its black colour on a red hot iron in the open air. The ſublimate, which had ſome marks of fuſion, weighed 28 grains, and became white by a new ſublimation. Its taſte was ſomewhat ſouriſh, but it had no ſmell; it was ſoluble both in water and in ſpirit of wine; but a larger quantity of ſpirit than of water was requiſite for this purpoſe. It did not precipitate lime-water, and ſeemed in ſome reſpects to agree with the ſal ſuccini.

1456 His concluſions concerning its compoſition.

From theſe experiments our author concludes, that the human calculus is neither calcareous nor gypſeous; but conſiſts of an oily, dry, volatile acid, united with ſome gelatinous matter. The calculus is an oily ſalt, in which the acid prevails a little, ſince it is ſoluble in pure water; and this ſolution reddens the tincture of lacmus. That it contains phlogiſton, appears from its ſolution in cauſtic alkalies and lime-water, but eſpecially from the effect of the nitrous acid, by which it acquires quite different properties than from ſolution in alkalies; nor can it be precipitated from this ſolution. The animal gelatinous ſubſtance appears on diſtillation, by which a liquor is obtained reſembling ſpirit of hartſhorn, and a fine coal is left behind.

1457 Is found univerſally in urine.

13. Calculus is found diſſolved in all urine, even in that of children. On evaporating four kannes of freſh urine to two ounces, a fine powder is depoſited as it cools, and a part firmly adheres to the glaſs. The precipitated powder readily diſſolves in a few drops of cauſtic fixed alkali; and has in other reſpects all the properties of calculus. Of the ſame nature is the lateritious ſediment depoſited by the urine of thoſe who labour under an ague. Mr Scheele ſuſpected at firſt, that there was in this urine ſome unknown menſtruum which kept ſuch a quantity of powder diſſolved, and which might afterwards evaporate by expoſure to the air; but altered his opinion on perceiving that the ſediment was equally depoſited in cloſe veſſels.

14. All urine contains ſome animal earth combined with phoſphoric acid; by the ſuperabundance of which acid,

1458 Why freſh urine reddens lacmus.

acid, the earth is kept diſſolved; and by reaſon of this ſuperabundant acid freſh urine communicates a red colour to lacmus. By ſaturation with cauſtic volatile alkali a white powder is precipitated; of which three drachms and an half are obtained from four kannes of urine. It is ſoluble in nitrous acid; and on adding the vitriolic, ſome gypſum is precipitated. On evaporating the nitrous acid, another remained, which precipitated lime-water; and when mixed with lamp-black, afforded phoſphorus by diſtillation; whence it is evident, that the white powder juſt mentioned contained lime and phoſphoric acid.

1459 Salts, &c. contained in urine.

15. From theſe experiments Mr Scheele concludes, that all urine contains, beſides the ſubſtances already known (*viz.* ſal ammoniac, common ſalt, digeſtive ſalt, Glauber's ſalt, microcoſmic ſalt, ſal perlatum, and an oily extractive matter), a concrete acid, or that of calculus, and animal earth. It is alſo remarkable, that the urine of the ſick is more acid, and contains more animal earth than that of healthy perſons. With regard to the ſal perlatum, it was afterwards diſcovered by Mr Scheele not to be a peculiar acid, but only a phoſphoric acid diſguiſed by a ſmall quantity of foſſil alkali united with it. The analyſis is confirmed by ſyntheſis; for, by combining foſſil alkali with phoſphoric acid, our author obtained a true perlate acid.

1460 Bergman's account of the calculus.

In a ſupplement to Mr Scheele's diſſertation on the calculus, Mr Bergman obſerves, that he could not ſucceed in diſſolving it entirely either in pure water or in the nitrous acid, though the undiſſolved part was the leſs in proportion to the fineneſs of the powder to which the calculus was reduced. The undiſſolved part appears moſt conſpicuous, when ſmall pieces, or ſmall calculi of a few grains weight only, are put into a ſuperabundant quantity of menſtruum, and kept in a degree of heat very near to that which makes water boil. Here it will be obſerved, that the greateſt part of the piece is diſſolved; but that at the ſame time ſome ſmall white ſpongy particles remain, which are not affected either by water, ſpirit of wine, acids, or cauſtic volatile alkali. If the liquor be made fully to boil, theſe particles divide into white rare flocculi, and become almoſt imperceptible, but without any entire diſſolution. Mr Bergman could not collect a ſufficient quantity of them to determine their nature with accuracy; only he obſerved, that when expoſed to a ſtrong heat, they were reduced to a coal which burns ſlowly to aſhes, and is not ſoluble in diluted nitrous acid.

“When calculus veſicae (ſays he) is diſſolved in nitrous acid, no precipitation enſues on adding the acid of ſugar; whence one is readily induced to conclude, that there is no calcareous earth preſent, becauſe this experiment is the ſureſt way to diſcover it. But I have found, in the variety of experiments concerning elective attractions, that the addition of a third ſubſtance, inſtead of diſuniting two already united, often unites both very cloſely. That the ſame thing happens here I had the more reaſon to believe, becauſe the acid of ſugar contains ſome phlogiſtic matter, though of ſuch a ſubtle nature, that, on being burned, it does not produce any ſenſible coal; and the event of my experiment has ſhown, that I was not miſtaken in my conjecture. In order to aſcertain this point, I burned coals of the calculus to aſhes, which were quite white, and ſhowed in every reſpect the ſame phenomena as lime; cauſed ſome efferveſcence during their ſolution in acids, united with vitriolic acid into gypſum, were precipitated by the acid of ſugar, and were partly ſoluble in pure water, &c. Notwithſtanding this, there remains about one-hundredth part of the aſhes inſoluble in aquafortis; being the remainder of the ſubſtance abovementioned, which, together with the concrete acid, conſtitutes the calculus. If the calculus be diſſolved in nitrous acid, the ſolution filtered and evaporated to dryneſs, and the dry maſs calcined to whiteneſs, a calcareous powder is thus likewiſe obtained.”

1461 Calcareous earth ſeparated from it by vitriolic acid.

As pure vitriolic acid contains no phlogiſton, our author ſuppoſed, that by dropping it, in its concentrated ſtate, into a ſolution of calculus in nitrous acid, the calcareous earth, if any exiſted in it, would be diſcovered. In this he was not diſappointed; for when the ſolution was ſaturated, ſome ſmall cryſtals were thus immediately ſeparated. Theſe, on examination, were found to be gypſum; and, after being diſſolved in diſtilled water, were precipitated by acid of ſugar. When the ſolution of calculus was very much diluted, no change appeared at firſt on the addition of oil of vitriol; but after a little evaporation, the abovementioned cryſtals began to appear. Some calculi of the bladder or kidneys at leaſt certainly contain lime, but ſeldom more than one half in an hundred parts, or one in 200 parts.

By the aſſiſtance of heat, concentrated vitriolic acid diſſolves the calculus with efferveſcence, and the ſolution is of a dark brown colour. On adding a little water, a kind of coagulation takes place; but by adding more, the liquor again becomes clear, and aſſumes a yellowiſh colour. Mr Bergman agrees with Mr Scheele in ſuppoſing that the muriatic acid has no effect upon the calculus; but he is in no doubt whether it may not extract ſome part of the calcareous earth.

1462 Red colour of the nitrous ſolution accounted for.

The red colour aſſumed by the ſolution of calculus in aquafortis is remarkable. A ſaturated ſolution diſcovers no ſmell of nitrous acid, and if evaporated by itſelf in a large open veſſel, the liquor aſſumes at laſt a deep red colour, and ſcarcely contains any nitrous acid: for, on the one hand, paper tinged with lacmus ſcarce ſhows any redneſs; and, on the other, the colour is deſtroyed irrecoverably by the addition of any acid. By quick evaporation the ſolution at laſt ſwells into innumerable bubbles; the foam grows redder and redder, and at laſt becomes dark red after it is quite dry. This dry maſs communicates its colour to a much larger quantity of water than before, and diſſolves very readily in all acids, even ſuch as have no action on the calculus; but they entirely deſtroy the colour, and that the more quickly in proportion to their degree of ſtrength; even alum has this effect on account of the ſmall quantity of looſe acid it contains. Cauſtic alkalies alſo diſſolve the colouring matter, and deſtroy it, but more ſlowly.

Our author endeavours to account for this red colour produced by the nitrous acid, from the peculiar nature of that acid and the effect it has upon phlogiſton. In order to obtain it, a proportionable quantity of acid muſt be made uſe of, and it ought to be diluted, that there may be no danger of going beyond the neceſſary limit. If too much be uſed, it will not produce the proper effect; but, by reaſon of its ſuperabundance, more or leſs, or even the whole, will be deſtroyed in proportion to the quantity. By pouring it in an undiluted ſtate on powdered calculus, it is converted in a few moments into mere foam. The acid of calculus is the more eaſily ſeparated from the aquafortis by evaporation, as the latter is rendered more volatile by the inflammable particles of the former: alkali added to them both united does not produce any precipitation; a circumſtance generally obſerved where two acids are united. In this caſe both the acids unite with the alkali, according to the different laws of their attraction. The red maſs obtained after deſiccation is, however, very different from the concentrated acid, ſuch as is contained in the calculus; for it is of a darker colour, and very deliqueſcent: the leaſt particle gives a roſe colour to a very conſiderable quantity of water; but the muriatic and other ſtrong acids always certainly deſtroy it; and, in a longer or ſhorter time, produce a colourleſs ſolution. This remarkable change depends, according to our author, more on the action of the nitrous acid upon the inflammable part, than upon any thing remaining behind.—Such red ſpots as are produced upon the ſkin by the ſolution, are likewiſe produced upon bones, glaſs, paper, and other ſubſtances; but more time is required for their becoming viſible, though this too may be a little accelerated by means of heat.

1463
Experiments of Mr Higgins on this ſubject.

The following is an abſtract of Mr Higgins's experiments upon this ſubject.

1. Eight hundred and forty grains of dry and well powdered calculus were introduced into a glaſs retort. It was taken from a laminated ſtone with a ſmall nucleus, which was likewiſe laminated. The outward cruſt appeared very porous, but increaſed in denſity towards the centre. By the application of heat, an elaſtic fluid was firſt ſlowly extricated; and which, on examination, appeared to be compoſed of equal parts of fixed and phlogiſticated air. The laſt portions came over very faſt, and were attended with an urinous ſmell; and, by continuing the diſtillation, it became evident that fixed and alkaline air came over together without forming any union, as they ought, on the common principles of chemiſtry, to have done; though our author is at a loſs to know why they did not unite, unleſs they were prevented by the ſmall quantity of inflammable air which came over along with them.

From the beginning of the 10th meaſure, a black, charry, and greaſy matter began to line the conical tube and air-veſſel adapted to the retort; and as the proceſs went on, the proportion of alkaline air decreaſed, while that of the inflammable air was augmented, until towards the end, when the laſt nine meaſures were all inflammable; after which no more would come over, though the retort was urged with a white heat. On breaking the diſtilling veſſel, a black powder weghing 95 grains was found in it. On digeſting this for an hour in ten ounces of diſtilled water, and then filtering and evaporating it to two ounces, a yellowiſh powder was precipitated, but no cryſtals were formed after ſtanding a whole night. This powder was then ſeparated by filtration, and the liquor evaporated to one ounce; during which time more powder was precipitated. It was then filtered a ſecond time, and the liquor evaporated to half an ounce; when it began to depoſit a white powder, and to emit a ſubacid aſtringent vapour, not unlike that of vitriolic acid. This white precipitate, when waſhed and dried, amounted only to one grain, had a ſhining appearance, and felt very ſoft, not unlike mica in powder. It was not changed, but rather looked whiter by expoſing it to a fierce heat for ten minutes. It diſſolved in diſtilled water without being precipitated by cauſtic volatile alkali. Mineral alkali, acid of ſugar, and nitrated terra ponderoſa, rendered the ſolution turbid; whence our author inferred, that the powder in queſtion was ſelenite.

After the ſeparation of this powder, the remaining ſolution was evaporated to dryneſs with a gentle heat. During the evaporation it continued to emit ſubacid vapours, leaving eleven grains of powder of a dirty yellow colour, having an aluminous taſte. To this powder he added as much diſtilled water as was nearly ſufficient to diſſolve it; after which it was ſet by for three weeks. At the expiration of this term ſeveral ſmall, tranſparent, and cubical cryſtals appeared on the ſide of the veſſel above the ſurface of the ſolution; and theſe likewiſe had an aluminous taſte. The whole was then diſſolved in diſtilled water, and the ſolution filtered. Acid of ſugar produced no change in the liquor for at leaſt five minutes, but an immediate cloudineſs took place on a mixture with volatile alkali; and on filtering the liquor it was again rendered turbid by mineral alkali, though the cauſtic alkali already predominated. Nitrated terra ponderoſa threw down a copious precipitate, and Pruſſian alkali diſcovered a ſmall quantity of iron. This aluminous ſolution left a yellow ſubſtance on the filter; which, when collected and dried, weighed only half a grain: it diſſolved without efferveſcence in nitrous acid; acid of ſugar cauſed no precipitation, but cauſtic volatile alkali threw down a precipitate which diſſolved in diſtilled water. This ſolution was rendered turbid by the acid of ſugar and muriated terra ponderoſa, but no effect was produced by cauſtic volatile alkali or lime-water.

The yellow powder firſt depoſited by the ſolution weighed two grains and a half, and by expoſure to a ſtrong heat acquired a deep orange colour. On digeſtion with diſtilled water, the inſoluble part was reduced to three-fourths of a grain, and appeared to be iron: while the ſoluble part was found to be nothing elſe but gypſum. Our author, however, is of opinion, that this iron is impregnated with a ſmall portion of vitriolic acid, though not in ſuch quantity as to render it ſoluble.

The charred matter remaining in the retort was reduced by lixiviation with water to 80 grains. Theſe were calcined with a red heat in an open fire, but could not be reduced to a grey powder in leſs than three quarters of an hour. When thoroughly calcined and cold, it weighed only 21 grains, which communicated to hot diſtilled water a limy taſte, and gave it the property of turning ſyrup of violets green. Diluted vitriolic acid had no effect upon it, but it was rendered turbid by aerated volatile alkali and acid of ſugar. The remainder when well dried weighed 16 grains, which diſſolved in nitrous acid at firſt with a little efferveſcence; and when this ceaſed, the ſolution went on very ſlowly, until the whole was taken up. Acid of ſugar made no change in the liquid, but the whole was precipitated by cauſtic volatile alkali. Pruſſian alkali threw down a grain, or perhaps more, of blue;

1464 His account of its component parts.

blue; the precipitate digeſted with diſtilled vinegar loſt a grain and an half, which was thrown down by cauſtic volatile alkali. The inſoluble part being waſhed and digeſted in diſtilled water for half an hour, was partly diſſolved; the ſolution was not affected by cauſtic volatile alkali, but acid of ſugar and nitrated terra ponderoſa cauſed an immediate cloudineſs. Seven grains and an half of the powder, which was inſoluble both in acetous acid and diſtilled water, were readily taken up by diluted vitriolic acid, and precipitated by cauſtic volatile alkali: the 16 grains laſt treated, therefore, appeared to contain, of clay $7\frac{1}{2}$ grains; of ſelenite, ſix grains; magneſia, one and a half; and of iron, one grain. The proportions of the different ingredients in the whole calculus, therefore, according to Mr Higgins, are as follows:

	Grains.
Iron - -	$2\frac{1}{9}$
Selenite - -	11
Clay - -	$7\frac{1}{2}$
Alum - -	8
Pure calcareous earth -	5
Aerated magneſia - -	$1\frac{1}{2}$
Charry combuſtible ſubſtance -	59
In all	$94\frac{1}{9}$

1465 Experiments on the ſublimate ariſing from it on diſtillation.

In this experiment, a darkiſh yellow ſublimate adhered to the neck of the retort; the inner part next the retort more compact, but the reſt of a lamellar ſpongy texture. This ſublimate, when carefully collected, was found to weigh 425 grains, and readily diſſolved in eight ounces of hot diſtilled water. A coaly ſubſtance was ſeparated from this ſolution by filtration, which, when waſhed and dried, weighed ten grains, and when expoſed to a red heat burned with a greeniſh flame, emitting white fumes, which ſmelled like vitriolic ſal ammoniac: the reſiduum after calcination weighed half a grain, and was of a whitiſh colour: appearing inſoluble in diſtilled water, but diſſolving with efferveſcence in nitrous acid. Acid of ſugar cauſed a very ſmall precipitation, which did not take place until the mixture had ſtood for ſome time; but cauſtic volatile alkali inſtantly threw down a precipitate, which was taken up, when waſhed, by the acetous acid. The quantity was too ſmall to be examined with greater accuracy; but it ſeemed to poſſeſs the properties of magneſia. The ſaline ſolution had the colour of ſmall beer; and, when evaporated to two ounces, did not depoſit any ſediment, or yield any cryſtals. The black matter with which the conical tube and air veſſel were lined, weighed 28 grains, and adhered ſo faſt to the glaſs, that it was impoſſible to collect the whole from the fragments of the glaſs. When diſſolved in diſtilled water and filtered, four grains of coals, ſimilar to that obtained from the former, were procured; but no ſigns of cryſtallization were obſerved after evaporation to one ounce, and ſuffering the liquor to ſtand all night.

By this treatment the ſolution acquired the conſiſtence of treacle; ſo that it was plainly not cryſtallizable, and therefore its analyſis was plainly to be attempted after a different method. It was now put into a tubulated glaſs retort, together with ſix ounces of diſtilled water to waſh it down. By diſtillation in a ſand-bath three ounces of water were procured, which differed in nothing from common diſtilled water, but in being coloured with a ſmall quantity of the ſolution from the neck of the retort. On changing the receiver, about half an ounce of liquor of the ſame kind came over, after which the diſtillation began to be attended with an urinous ſmell. This continued barely perceptible for ſome time; but when about an ounce and an half had paſſed over, it became ſo very pungent, that our author could no longer doubt of its being in a cauſtic ſtate. A ſmall quantity of mild alkali, however, adhered to the lower part of the neck of the retort, ſome of which was waſhed down by the diſtillation; ſo that the proportions betwixt the two could not be aſcertained. The volatile alkaline ſolution in the retort had the colour of ſpirit of hartſhorn, and like it became darker coloured by the contact of air; on account of the evaporation of part of the alkali, and the reſt becoming leſs capable of ſuſpending the coaly matter mixed with it.

After all the liquor had paſſed over, and nothing remained in the retort but a ſmall quantity of black matter, the fire was raiſed; and, as the heat increaſed, this black ſubſtance acquired a white colour, with a kind of arrangement on the ſurface, which was occaſioned by the heat applied to the bottom of the retort being only ſufficient to raiſe the ſalt to the top of the matter in the retort; but as the ſand became nearly red-hot, white fumes began to appear, which condenſed on the upper part of the retort, and a little way down the neck. The proceſs laſted until the matter was nearly red-hot, when the fumes ceaſed, and nothing more paſſed over. The ſublimate, when collected, was found to weigh 72 grains, a black porous brittle ſubſtance remaining on the bottom of the retort, which weighed 12 grains. This reſiduum, when expoſed to a ſtrong heat, emitted white fumes, with a ſlight alkaline ſmell; by which proceſs it was reduced, with very little appearance of combuſtion, to a grey powder weighing three grains, which was accidentally loſt.

Five grains of this purified ſublimate, mixed with as much quicklime, emitted no ſmell of volatile alkali; and, when thrown upon a red-hot iron, emitted white fumes. The ſame effect was produced by a mixture of equal quantities of vegetable alkali and ſublimate. The remainder, conſiſting of 62 grains, was divided into two equal parts; the one of which was mixed with two ounces of diſtilled water, and on the other was poured 60 grains of vitriolic acid diluted with half an ounce of water. Theſe two mixtures being ſuffered to remain for ſix weeks, ſeemed to be but little acted upon. That with vitriolic acid was then put into a ſmall matraſs, and boiled on ſand for half an hour with two ounces of diſtilled water, when the whole was taken up. The ſolution looked clear, and depoſited nothing on ſtanding. Mild mineral alkali had no effect upon it; but mild vegetable alkali threw down a copious ſediment in white flocculi, which was rediſſolved by cauſtic alkali, lime-water, and partly by mild mineral alkali. Phlogiſticated alkali, acid of ſugar, and acid of tartar, had no effect upon it. The other portion of ſublimate, which had been mixed with diſtilled water, was very little diſſolved; but in pouring it into a matraſs ſome ſmall round lumps were obſervable on the bottom of the glaſs. Theſe were ſix or ſeven in number, ſome weighing a whole grain, others not more than one-half. They were very hard and compact, with a ſmooth ſurface, and in figure reſembling the nucleus of the original calculus. The whole was then put into a matraſs with about three ounces of water. On boiling it on ſand for three quarters of an hour, about one-half, of it was taken up: the ſolution paſſed the filter very clear whilſt hot; but on cooling became turbid, and at laſt depoſited white flocculi, which were rediſſolved on the addition of cauſtic volatile alkali and lime-water. It turned ſyrup of violets green; which, however, our author thinks might have been occaſioned by its retaining volatile alkali, though it had not the ſmalleſt appearance of any ſuch impregnation. He has nevertheleſs frequently obſerved, that ſometimes the pureſt vegetable alkali contains volatile alkali, notwithſtanding the various operations and degrees of heat it undergoes before it can be brought to the degree of purity at which it is called ſalt of tartar.

On filtering the ſolution to ſeparate what had been depoſited by cooling, no change was produced in the filtered liquor by mineral alkali; but mild vegetable alkali produced a cloudineſs, which was inſtantly taken up on adding mineral alkali and lime-water. Neither Pruſſian alkali, nor the acids of arſenic, tartar, ſugar, or borax, nor any of the three mineral acids, had any effect upon it.

1466 Experiments with nitrous acid.

2. An hundred and twenty grains of the ſame calculus were put into a tubulated glaſs retort, and half an ounce of ſtrong nitrous acid poured upon it. An effervescence immediately enſued; and ſome part of the extricated aerial fluid being perſerved, appeared to be fixed air mixed with a ſmall quantity of nitrous air. When the effervescence ceaſed, a quarter of an ounce more of nitrous acid was added. On digeſting the mixture upon hot ſand for an hour, it emitted nitrous vapour and nitrous air; but the latter in very ſmall proportion. When the ſolution was completed, the whole was poured into a ſmall matraſs, and gently boiled till the ſuperabundant nitrous acid was nearly expelled. The ſolution was of a deep yellow colour and turbid; but on adding five ounces more of water, and digeſting it for a quarter of an hour longer, it acquired the colour and conſiſtency of dephlogiſticated nitrous acid. On cooling it became ſomewhat turbid, and in a few days depoſited a darkiſh yellow powder; which, when ſeparated, waſhed, and dried, weighed little more than a quarter of a grain, and, on examination, was found to be a calx of iron.

1467 Cryſtallizes on expoſure to the ſun.

Our author being deſirous to know what effect the ſun would have upon it, placed it in a window where the ſun ſhone full upon it for four hours every day. Here a little moiſture ſeemed daily to exhale from it, the weather being hot, and the matraſs, which had a ſhort wide neck, being only covered, with bibulous paper to keep out the duſt. In this ſituation, in the courſe of a week, a few very ſmall cryſtals appeared to float upon the ſurface. Theſe in time fell to the bottom, where they adhered together ſo as to form a hard concretion, ſtill retaining a cryſtalline appearance, but ſo ſmall and confuſed, that it was impoſſible to diſtinguiſh their figure; and this depoſition of cryſtals continued for a month, after which it ſeemed to ceaſe. The ſolution was then filtered to ſeparate the ſalt; after which one-half of the liquor was evaporated away, and the reſt ſet in the uſual place for a fortnight longer, but no more cryſtals appeared. The ſalt, which weighed three grains, was then digeſted in four ounces of diſtilled water; but no part ſeemed to be diſſolved. Three ounces of the water were then decanted off, and ſix drops of vitriolic acid added to the remainder, which by the help of digeſtion ſeemed to diſſolve the ſalt ſlowly; but on adding half an ounce more diſtilled water, the whole was readily taken up. Acid of ſugar had no effect on this ſolution; but lime-water rendered it turbid. The whole was then precipitated with cauſtic volatile alkali, and the ſolution filtered, which likewiſe threw down the lime from lime-water. The precipitate was then waſhed, and diſtilled vinegar poured upon it, which did not take it up; but it was diſſolved by marine acid. Phlogiſticated alkali had no effect upon it; and the acid of ſugar occaſioned very little cloudineſs after ſtanding three or four hours; from which our author ſuppoſed that the matter was phoſphorated clay.

The ſolution, being now free from iron and phoſphorated clay, had a ſubacid taſte, and looked clearer, though ſtill retaining a yellow caſt. Acid of ſugar had no effect upon it; but nitrated terra ponderoſa threw down a precipitate, as did likewiſe the cauſtic volatile alkali. Mild vegetable alkali cauſed no precipitation; which our author attributed to the ſolution of the manganeſe and clay by the fixed air extricated from the alkali. Two-thirds of the ſolution were then put into a ſmall glaſs retort, and two ounces diſtilled off, which had no taſte, but ſmelled very agreeably, and not unlike roſe-water. After all the liquor had paſſed over, white fumes appeared in the retort, and theſe were ſoon followed by an aerial fluid. On collecting ſome of this, a candle was found to burn in it with an enlarged flame. Nitrous air did not diminiſh it in the leaſt; and it ſeemed to be that ſpecies of air into which nitrous ammoniac is convertible. No more than 13 or 14 inches of this kind of air could be obtained; and as ſoon as it ceaſed to come over, cryſtals were obſerved in the lower part of the neck of the retort. On augmenting the heat, a white ſalt began to ſublime and adhere to the upper part of the retort; the operation was continued until the retort was red-hot; but, on breaking it, the quantity of ſublimate was ſo ſmall, that very little of it could be collected; though, from the ſmall quantity obtained, our author was convinced of its being the ſame in quality with what was obtained in the former analyſis. The ſalt which cryſtallized in the neck of the retort was nitrous ammoniac, as appeared from its detonation *per ſe*, &c. A grey powder was left in the bottom of the retort, which hot diſtilled water partly diſſolved; muriated terra ponderoſa, acid of ſugar, and vegetable alkali, rendered this ſolution turbid: but cauſtic volatile alkali had no effect upon it. The remaining part of the powder which was left by the diſtilled water, readily diſſolved with effervescence in the marine acid, and was precipitated by cauſtic volatile alkali; the part ſoluble in diſtilled water appearing to be gypſum, and that ſoluble in marine acid to be magneſia.

From all theſe experiments, Mr Higgins concludes the compoſition of the human calculus to be vaſtly different

1468
Higgins's account of the conſtituent parts of calculus.

ferent from what either Mr Scheele or Mr Bergman have ſuppoſed it to be. "It appears (ſays he), that the calculus was compoſed of the following different compounds blended together; *viz.* ſelenite, alum, microcoſmic ſalt, mild volatile alkali, lime, and cauſtic volatile alkali, combined with oil, ſo as to form a ſaponaceous maſs; calx of iron, magneſia combined with aerial acid, clay enveloped by a ſaponaceous and oily matter, and the ſublimate already deſcribed." Conſidering this to be the true ſtate of the calculus in the bladder, the ſmall proportions of clay, ſelenite, magneſia, and iron, which are the moſt inſoluble of the ingredients; the great ſolubility of microcoſmic ſalt and alum, and the miſcibility of lime, volatile alkali, and oil, in water; tend to ſhow, that the ſublimate is the cementing ingredient. Indeed, its inſolubility in water, and property of forming nuclei out of the body, as above obſerved, leave no room to doubt it. The proportion of the other ingredients, and very likely their preſence, depend upon chance, volatile alkali and oil excepted; therefore this ſublimate ſhould be the object of our inveſtigation.

1469
Remarks on the remedies proper for diſſolving it.

Mr Higgins concludes his diſſertation with ſome practical remarks concerning the remedies proper for diſſolving the ſtone, for counteracting that diſpoſition in the body which tends to produce it, and concerning the regimen proper for thoſe who are to undergo the operation of cutting for it. "The effect of mild mineral alkali (ſays he) on the ſublimate, is well worth the attention of thoſe who may have an opportunity of trying its efficacy. Mild mineral alkali may be taken in large doſes, and continued for a length of time with impunity to the moſt delicate conſtitutions, only obſerving a few circumſtances; but this alkali, in a cauſtic ſtate, muſt very often be attended with miſchievous conſequences. Beſides, if we conſider that it muſt enter the maſs of blood before any part can reach the bladder, and the ſmall portion of the doſe taken ſecreted with the urine, and, laſtly, the action of cauſtic alkali upon animal ſubſtances; we ſhall be at a loſs to know on what principle cauſtic alkalies have been recommended in preference to mild. Soap itſelf might as well be recommended at once; for ſoon after cauſtic alkali is taken, it muſt be in a ſaponaceous ſtate. Fixed vegetable alkali ſhould be avoided, and the perference given to the other two alkalies. As it is evident that alkalies have no real action on the ſtone in the bladder, though their efficacy has been experienced in alleviating the diſeaſe when timely adminiſtered, their mode of action is only explicable in the following manner: They either prevent the generation of the ſublimate in the ſyſtem, or elſe keep it in ſolution in the maſs of fluids: and being in the utmoſt degree of diviſibility, its ultimate particles are capable of paſſing through the moſt minute emunctories; by which means it is carried off by other ſecretions as well as the urinary. Thus urine, not being ſaturated with this matter, acts as a ſolvent on the ſtone; and as the moſt ſoluble parts are firſt waſhed away, it falls through time into fragments of irregular ſurfaces, which by their friction irritate and inflame the bladder, as has been obſerved by ſeveral practitioners.

"Allowing that the ſublimate is the cementing ſubſtance in the calculus, and judging, from the effects of alkalies upon it, their *modus operandi* in the conſtitution, it remains now to inquire into the origin of the calculus. Mr Scheele has found this ſublimate in the urine of different perſons; and hence inferred, that it was a common ſecretion; but it ſtill remains to be aſcertained, whether there be a greater quantity of it procured from the urine of patients who labour under this diſorder than in thoſe who do not? If this ſhould not be the caſe, may not a deficiency of volatile alkali in the conſtitution be the cauſe of the concretions in the kidneys, bladder, &c.; or, which muſt have the ſame effect, too great a proportion of acid, which, uniting with the alkali, may take up that portion which would have kept the ſublimate in ſolution until conveyed out of the ſyſtem by the urinary and other ſecretions; and may not this be the phoſphoric acid? If this latter ſhould be the caſe, an increaſe of microcoſmic ſalt muſt be found in the urine; but if the former, a decreaſe of the volatile alkali, and no increaſe of the neutral ſalt. The ſmall quantity of phoſphoric acid found in the calculus proceeds from the ſolubility of microcoſmic ſalt. Do not volatile alkali and phoſphoric acid conſtitute a great part of the human frame? and is their not a proceſs continually carried on to generate theſe in the ſyſtem? and is not this proceſs liable to be retarded or checked by intemperance, &c. which may vary their quantities and proportions? and may not a due proportion of theſe be neceſſary to a vigorous and ſound conſtitution? If ſo, no wonder that an increaſe or deficiency in either or both of theſe ſhould be productive of ſeveral diſorders."

1470
Sublimate of calculus found in conſumptive and gouty people.

On this ſubject, however, our author has not had ſufficient leiſure to make the experiments neceſſary for its elucidation. Indeed, it ſeems not eaſy to do ſo; as, in his opinion, at leaſt 500 would be required for the purpoſe. "That the urinary ſublimate is preſent in tubercles found in the lungs of perſons who die of pulmonary conſumptions, and likewiſe in what are vulgarly called *chalk ſtones*, is what I have experienced: but in what proportion, or whether in quantities ſufficient to cauſe the concretion, is what I cannot ſay; for I have had but a few grains of each to examine. I have every reaſon to ſuſpect, that conſumptions and ſcorbutic complaints very frequently ariſe from a ſuperabundance of this ſublimate in the ſyſtem; and that it is chiefly the cauſe of the gout and rheumatiſm, and ſolely the cauſe of the ſtone in the bladder. I make no doubt but theſe diſorders generally proceed from obſtructions: and it is probable, that either a precipitation of this ſublimate in the ſyſtem, or elſe a deficiency of ſome other ſecretion, which would hold it in ſolution until conveyed out of the body, may be the chief cauſe of thoſe obſtructions; and likewiſe, that different degrees of precipitation may produce different ſymptoms and diſorders.

"That mineral or volatile alkali and bark have been uſeful in the above diſorders, has been affirmed by experienced phyſicians; and I know an inſtance myſelf of mineral alkali and nitrous ammoniac being ſerviceable in a pulmonary complaint of ſome ſtanding.

"With reſpect to the ſtone, when it acquires a certain magnitude, it is abſurd to attempt to diſſolve it in the bladder, it waſtes ſo very ſlowly; and during this time the patient muſt ſuffer vaſt pain, particularly when

when the ſtone acquires a rugged ſurface: therefore cutting for it at once is much preferable.

“ Mineral alkali taken in the beginning of the complaint, and before the ſtone accumulates, will no doubt check its progreſs, and may in time change that diſpoſition in the habit. Patients who are cut for the ſtone ſhould, I think, take mineral alkali for ſome time when the wound is healed, but not before, for fear of bringing on a mortification.”

APPENDIX;

Containing ſuch DISCOVERIES as have appeared ſince the Compilation of the Article, and which could not be inſerted in their proper Places.

I. *VITRIOLIC ETHER.*

1471 Various methods of rectifying vitriolic ether.

M. PELLETIER formerly propoſed a method of rectifying this fluid by putting mangancſe into the veſſels; but as the vitriolated manganeſe might perhaps communicate ſome injurious quality, another method is propoſed by M. Tingry. After firſt drawing off the ether, he adds a diluted ſolution of volatile alkali, and avoids as much as poſſible the diſſipation of the vapours: the ether is then rediſtilled. It may afterwards in this way be waſhed more ſafely, and with leſs loſs. The little proportion of the ether which is ſeparated in the water, may be again recovered, or the water may be again employed for the ſame purpoſe. M. Lunel propoſes calcined magneſia for this purpoſe, as its ſalt is not ſoluble; though perhaps pure terra ponderoſa might be better.

II. *NITROUS ACID.*

1472 Mr Higgins's obſervations.

ON this ſubject Mr Higgins has ſeveral curious and intereſting obſervations. “ It is not an eaſy matter (ſays he), to aſcertain exactly the greateſt quantity of dephlogiſticated air, which a given quantity of nitrous acid may contain. I always found nitre to vary, not only in its product of phlogiſticated and dephlogiſticated air, but likewiſe in their proportion to one another. The pureſt nitre will yield, about the middle of the proceſs, dephlogiſticated air ſo pure as to contain only about $\frac{1}{13}$ of phlogiſticated air. In the beginning, and nearly about the latter end of the proceſs, air will be produced about twice better than common air. On mixing the different products of a quantity of pure nitre, it was found that, by expoſure to liver of ſulphur, $\frac{1}{6}$ part was left unabſorbed; and this was the utmoſt purity in which I obtained dephlogiſticated air from nitre.

1473 Account of its conſtituent parts by M. Lavoiſier.

“ According to M. Lavoiſier, 100 grains of nitrous acid contain $79\frac{1}{2}$ of dephlogiſticated air, and $20\frac{1}{2}$ of phlogiſticated air, which is not quite four to one. But his experiments contradict this; for whatever mode he adopted to decompoſe nitrous acid, it appeared that the proportion of dephlogiſticated air was nearly as five to one of phlogiſticated air.

1474 By Mr Cavendiſh.

“ Mr Cavendiſh has proved, that nitrous acid may be formed by taking the electric ſpark in a mixture of three parts of phlogiſticated air, and ſeven of dephlogiſticated air, which is but $\frac{1}{7}$ more of dephlogiſticated air than nitrous air contains; which may apparently contradict M. Lavoiſier's, as well as my own, eſtimation of the proportion of the conſtituent principles of nitrous acid, when in its perfect ſtate. The red nitrous vapour contains three parts of nitrous air and one of dephlogiſticated air, or one of phlogiſticated and three of dephlogiſticated air; but nitrous vapour may be formed with a leſs proportion of dephlogiſticated air; and which, though it may not be ſo condenſible as a more perfect nitrous vapour, yet will, when in contact with pure alkali, unite with it, and form nitre, as was the caſe in the experiment of Mr Cavendiſh. The common ſtraw-coloured nitrous acid contains more dephlogiſticated air than the red nitrous acid or vapour; the proportion appears to be about four to one; but the colourleſs contains about five of dephlogiſticated to one of phlogiſticated air.

1475 Method of obtaining colourleſs nitrous acid.

“ Having once a charge of nitrous and vitriolic acid in a green glaſs retort, I put it in a ſand-pot to diſtil; but the pot being ſmall, the edge came too near the retort, about a quarter of an inch or more above the charge; which, before the proceſs commenced, and when it acquired more than the heat of boiling water, cracked it all round in that direction. Being thus ſituated, I was obliged to withdraw the fire, and, before the charge got cold, to ladle it into an earthen pan. On introducing it into a freſh retort, I obtained from it nitrous acid nearly as colourleſs as water. The vitriolic acid uſed in this proceſs not being very perfect, the goodneſs of the nitrous acid was attributed to the purity of the nitre from whence it was diſtilled; but in another proceſs, though the ſame nitre was uſed with much purer vitriolic acid, the produce was of an high ſtraw colour. On recollecting the abovementioned circumſtance, the vitriolic acid and nitre were next mingled in due proportion, and expoſed in an earthen pan ſet in ſand, to nearly the heat of boiling water, for half an hour or more, continually expoſing freſh ſurfaces to the air. When the charge was quite cold, I introduced it into a retort, and diſtilled as colourleſs nitrous acid as the former. As no nitrous air was emitted during digeſtion, it muſt have imbibed dephlogiſticated air from the atmoſphere.”

1476 How to ſet charcoal on fire by means of nitrous acid.

Mr Prouſt found, that ſtrong nitrous acid will ſet fire to charcoal if it be rendered very dry. He likewiſe remarked, that charcoal expoſed to the air a few hours after calcination, was unfit for the experiment. Charcoal, he obſerves, attracts moiſture very forcibly. The firſt effect of the charcoal on the nitrous acid, he obſerves, is to withdraw a portion of its water from it; by which it is rendered highly concentrated, at the ſame time that the condenſation of the water heats the charcoal in a ſmall degree, but ſufficiently to volatilize a nitrous vapour; which, as ſoon as it reaches that portion of dry charcoal next the humid part, is condenſed

denſed by it, and generates heat enough to promote the decompoſition of the nitrous acid. Hence we ſee why the experiment will not ſucceed if the acid be poured on the ſurface of the charcoal.

1477 Effect of nitrous acid on blood.

The effect of nitrous acid on blood, according to Mr Higgins, is very ſingular. Two parts of blood procured freſh at the butchers, one of ſtrong nitrous acid, and about one fifth of the whole of water, were digeſted in the heat nearly of boiling water (freſh portions of water being occaſionally added until the whole of the acid was expelled), when it acquired almoſt the colour, and exactly the taſte, of bile. When mixed with a large quantity of water, it acquired a fine yellow colour; and, on ſtanding, depoſited a ſubſtance of a brighter yellow, though the ſupernatant liquor ſtill retained a yellow colour and bitter taſte, but not ſo intenſely as when the precipitate was ſuſpended in it. The different ſtages of this proceſs were well worthy of obſervation. No nitrous air was produced, and the acid was expelled in the ſtate of a white vapour. The liquor was found to increaſe in bitterneſs as the acidity vaniſhed. About the middle of the proceſs, the ſolution firſt taſted acid, but was quickly ſucceeded by a bitter ſenſation. It appears that the nitrous acid took dephlogiſticated air from the blood; for though red nitrous acid was uſed, it was expelled in a perfect ſtate.

III. *Nitre.*

1478 Nitre generated without putrefaction.

Though the artificial generation of the nitrous acid, from a mixture of dephlogiſticated and phlogiſticated air, is now ſufficiently underſtood, yet we do not well know in what manner nature performs the operation. Some chemiſts, particularly M. Thouvenal, have found, that putrefaction favours the production of nitrous acid. All animal ſubſtances, during their decay, give out a vaſt quantity of phlogiſticated air; therefore, if dephlogiſticated air be preſent, it will unite to the phlogiſticated air in its naſcent ſtate, and form nitrous acid: but Mr Higgins has obſerved, that nitrous acid may be generated in plenty where there is no putrid proceſs going on. "The chemical elaboratory at Oxford (ſays he) is near ſix feet lower than the ſurface of the earth. The walls are conſtructed with common limeſtone, and arched over with the ſame; the floor is alſo paved with ſtone. It is a large room, and very lofty. There are ſeparate rooms for the chemical preparations, ſo that nothing is kept in the elaboratory but the neceſſary implements for conducting experiments. There is an area adjoining it on a level with the floor, which, though not very large, is ſufficient to admit a free circulation of air. The aſhes and ſweepings of the elaboratory are depoſited in it. There is a good ſink in the centre of this area, ſo that no ſtagnated water can lodge there. Notwithſtanding all this, the walls of the room afford freſh crops of nitre every three or four months. Dr Wall, who paid particular attention to this circumſtance, and who told me it contained fixed vegetable alkali, requeſted I would analyſe it, and let him know what it contained. I found that two ounces of it contained ſix drachms of nitrated fixed vegetable alkali, and three of calcareous nitre. The nitre firſt appears in ſmall whitiſh filaments as fine as cob-web, which, when they get a little larger, drop off; ſo that they never acquire ſufficient growth to diſtinguiſh their figure to a naked eye. On finding that they contained fixed vegetable alkali, I concluded that it proceeded from minute vegetation; but in this I was miſtaken; for I found that they were ſoluble in water, and that they detonated with charcoal at every ſtage of their growth. Having ſwept this ſaline efflореſcence from the wall, I dug deep into it, but could not obtain nitre from it. When a part had been white-waſhed, it yielded nitre, but not ſo abundantly as a neighbouring ſpot which had not been treated in the ſame manner. Hence it is evident, that nitrous acid may be formed without the aſſiſtance of putreſcent proceſſes in a ſtill damp air, where there is a ſubſtance to attract it when half formed, whereby it is in time brought to perfection. The above facts moreover prove, that fixed vegetable alkali is a compound."

IV. *Marine Acid.*

1479 Unſucceſsful attempts to decompoſe ſea-ſalt.

Mr Higgins informs us, that he has, with a view to decompoſe ſea-ſalt, mixed it with mangan eſe in various proportions, and expoſed them in a reverberating furnace in a well cloſed crucible for three hours, to a heat nearly ſufficient to melt caſt iron. In the ſame manner he treated manganeſe, ſalt, and charcoal, as well as clay, ſalt, and charcoal, and ſalt and clay alone, with very little ſucceſs. He treated calcined bones, ſalt, and charcoal, and calcined bones and ſalt, as well as lime and ſalt, in the ſame manner, without effecting any apparent change in the ſalt. He was informed, however, by Mr Robertſon, apothecary in Biſhopsgate-ſtreet, that he had partially alkalized it, by expoſing it with clay to a fierce heat; but that ſoon after it got into contact with air, it became neutral again. "If common ſalt and litharge be fuſed (ſays Mr Higgins), it is in part decompoſed; the acid ſuffers no decompoſition, but unites with the lead; whereby it acquires, when the ſaline matter is waſhed away, a yellow colour. It is evident (adds he) from theſe facts, that the baſis of marine acid is a combuſtible body, and quite different from light inflammable air, charcoal, or any known inflammable ſubſtance; and that it attracts dephlogiſticated air with greater force than any ſubſtance hitherto diſcovered. Though charcoal will decompoſe all other acids, except a few, when united to bodies which will fix them until they acquire a ſufficient degree of heat, yet it has no effect upon marine acid."

According to Fourcroy, if alkaline air be confined by mercury, and dephlogiſticated marine acid air be added to it (which muſt be done quickly, as the acid air would diſſolve the mercury), each bubble produces a ſlight detonation, and furniſhes a very amuſing ſpectacle.

1480 Method of diſtilling ſpirit of ſalt with clay.

Though in Britain the diſtillation of the ſpirit of ſalt with clay has long been entirely laid aſide for the proceſs with oil of vitriol, yet it is ſtill practiſed in other countries, and may be effected in the following manner: Having previouſly decrepitated the ſalt, and dried the clay, they are then to be ground, mixed, and ſifted together. The mixture is next to be worked with a ſpatula, and then with the hands, until it is brought into a moderately ſtiff and uniform maſs.

This is to be divided into balls about the ſize of a pigeon's egg, ſo that they can paſs through the neck of the retort; but before they are put into the diſtilling veſſel, it is proper to dry them thoroughly. The retorts muſt be of ſtone-ware, and carefully coated, in order to prevent them from breaking with the intenſe heat to which they are expoſed. They are to be filled two-thirds full of materials, and the diſtillation muſt be performed in a reverberatory furnace. The receiver at firſt is not luted on, becauſe that which riſes in the beginning of the diſtillation, being very aqueous, is to be put by itſelf. When this has come over, another receiver is then to be applied, and cemented with fat lute, and covered with a cloth daubed with a mixture of lime and the whites of eggs. The heat is to be raiſed until the retort is red-hot, and continued in this degree until the diſtillation ceaſes.

Various proportions of clay and ſalt have been recommended for this proceſs; but it ſeems probable that not leſs than ten parts of clay to one of ſalt, as Pott has directed, will be found neceſſary. Inſtead of the clay, ſome direct the uſe of bole; but this is inconvenient on account of the iron it contains. Powdered talc has alſo been recommended, but this is not always free from iron; and where a very pure ſpirit is wanted, there is a neceſſity for having recourſe to oil of vitriol, and glaſs or ſtone-ware veſſels. As the marine acid cannot be ſeparated from the earthy mixtures abovementioned, but by means of moiſture, M. Beaumé adviſes to moiſten the reſiduum, and repeat the diſtillation, by which more acid will be obtained.

1481
Effect of marine acid upon phlogiſtic matters.

As the marine acid has very little action upon phlogiſtic matters, it cannot therefore affect oils, either expreſſed or eſſential, in a manner ſimilar to the vitriolic or nitrous. M. Marges, however, has obſerved yellow cryſtals reſembling amber formed in bottles, containing a mixture of oils and marine acid of moderate ſtrength, which had ſtood for ſeveral months. The little effect which the marine acid has upon theſe ſubſtances was firſt ſuppoſed to be owing to its want of phlogiſton in itſelf; but when it was afterwards found, that, by the application of certain ſubſtances which have a great attraction for phlogiſton, the marine acid was rendered capable of uniting very readily with inflammable matters, the former theory was abandoned. It was now aſſerted, that the acid, inſtead of containing no phlogiſton, was naturally endowed with a very conſiderable quantity; and that, in its new ſtate, it was dephlogiſticated by the ſubſtances applied. On the other hand, the antiphlogiſtians aſſerted, that no change was thus made upon it, farther than adding a quantity of pure air, which they ſuppoſe to be the baſis of all acids. On this ſubject, however, M. Cornette maintains, that the marine acid ſeems to have ſo little action upon inflammable ſubſtances, merely becauſe it is weaker than the reſt; and likewiſe that it is often previouſly combined with ſome inflammable matter, by which its attraction is prevented. He maintains, that if the marine acid be concentrated in ſuch a manner as to render its ſpecific gravity to that of water as 19 to 16, it will then act upon oils with heat and efferveſcence, reducing them to a black and thick ſubſtance, and even burning them to a kind of coal. Some experiments have been made by Mr Haſſe, with a view to inveſtigate the action of the marine and vitriolic acids upon balſams and oils; for which purpoſe he mixed two drachms of ſmoking ſpirit of ſalt with one of each of the oily ſubſtances to be tried. The reſults were, that Canada balſam gained one ſcruple in weight; balſam of capivi 19 grains; ſtorax, and Venice turpentine, each one ſcruple; aſphaltum 18 grains; but the eſſential oils of aniſe-ſeed, benzoin, bergamot, coriander, and many others, were not altered in any degree. The action of this acid upon inflammable matters, however, is augmented by its being reduced into the form of air.

Gmelin relates, that, by diſtilling a mixture of five parts of ſalt, twelve of ſpirit of wine, and four of vitriolic acid, to which he had previouſly added one or two parts of water, he obtained a completely dulcified ſpirit of ſalt, and an imperfectly dulcified ſpirit of vitriol, upon rectifying the liquor.

1482
Glaſs corroded by it.

Homberg found, that glaſs was corroded by the marine acid: and his obſervation has been confirmed by Dr Prieſtley; who finds that its corroſive power is augmented by confining the acid in tubes hermetically ſealed. Its power is exerted not only on flint-glaſs, but even on common green glaſs; though more powerfully on the former, where it chiefly attacks the red-lead uſed in its compoſition. By incloſing marine acid gas for ſome weeks in a glaſs tube expoſed to heat, an incruſtation was formed on the inſide, while the air was diminiſhed to $\frac{1}{8}$ of its original bulk, one half of which was abſorbed by water; the other was phlogiſticated air.

1483
Cauſe of the yellow colour of marine acid.

The marine acid is generally met with of a yellow or reddiſh colour, which by Macquer is given as one of its characteriſtic marks. In general, however, this colour is thought to proceed from iron; but Dr Prieſtley has found that it may be produced by many different ſubſtances; and his obſervations have been confirmed by Scheele and other chemiſts. The Doctor is of opinion that it is occaſioned for the moſt part, if not always, by a mixture of earth; and he was able to communicate it by means of calcined oyſter-ſhells, calcined magneſia, pipe-clay, or pounded glaſs; but not by wood-aſhes, from whence the air had been expelled by heat. It was effectually diſcharged by flowers of zinc, a coal of cream of tartar, and by liver of ſulphur; but he found that the colour which had been diſcharged by liver of ſulphur, would return by mere expoſure of the acid to the atmoſphere, but not that which had been diſcharged by flowers of zinc.

Dephlogiſticated ſpirit of ſalt.

1484
Expeditious method of bleaching linen.

When the action of this vapour upon any thing is to be examined, the ſubſtance muſt be put into a bottle in ſuch a manner as to remain in contact with it; or it may be put into a glaſs tube, which is ſuſpended and fixed to the ſtopper, and thus introduced into the bottle.—From its property of deſtroying all vegetable colours, it promiſes to be of very conſiderable uſe in the arts, provided it could be had in ſufficient quantity, and cheap. It bleaches yellow wax, and when properly applied to linen, will whiten it ſufficiently, and without injury in a few hours. This may be effected by ſteeping the linen for that ſpace of time in water impregnated with the dephlogiſticated marine gas. It unites with this fluid rather more eaſily than fixed air.

Ber-

Berthollet, in order to impregnate water with it without expoſing the operator to the fume, which is extremely diſagreeable, put the mixture of marine acid and manganeſe into a retort. To this he applied firſt an empty bottle, and then ſeveral others filled with water, and communicating with each other by means of bent tubes; ſurrounding the whole with ice. When the water in the bottles was ſaturated, the gas became concrete, and fell to the bottom; but with the ſmalleſt heat it aroſe to the top in bubbles. The ſpecific gravity of the ſaturated water was to that of diſtilled water, when the thermometer was only five degrees above the freezing point, as 1003 to 1000. This impregnated water is not acid, but has an auſtere taſte, and has the ſame action as the gas, though in a weaker degree. Mr Berthollet has obſerved, that the addition of alkalies does not prevent, but rather promotes, the diſcharge of colours; for which reaſon he directs to add a fixed alkali to the impregnated water in which linen is to be ſteeped for bleaching. This is the expeditious method hinted at under the article BLEACHING; but which has not hitherto come into uſe, principally through the high price of the dephlogiſticated gas.

The dephlogiſticated marine acid does not diſcharge all colours with equal eaſe. Thoſe of litmus and ſyrup of violets are entirely deſtroyed, and turned white. The colouring matter of Brazil-wood, and ſome green parts of plants, retain a yellow tint. The leaves of evergreen plants reſiſt its action for a long time, and at laſt only acquire the yellow colour which they aſſume by long expoſure to the air; and in general the changes of colour which vegetable matters ſuffer from this gas, are ſimilar to thoſe which take place on long expoſure to the air; and by this operation the gas is converted into common marine acid.

1485
Effect of the dephlogiſticated acid on phlogiſtic matter, &c.

Oils and animal fats are thickened by this gas; and by theſe and other inflammable ſubſtances it is reduced to the ſtate of common marine acid. Light is ſaid to produce the ſame effect. It unites with fixed alkalies and calcareous earths, but without any ſenſible effervеſcence; and thus they loſe their peculiar taſte and colour. M. Berthollet having boiled in a retort, to which a pneumatic apparatus was affixed, ſome of the dephlogiſticated marine acid liquor with mineral alkali, thus obtained a conſiderable quantity of elaſtic fluid, compoſed partly of fixed air, partly of the air contained in the veſſels, and partly of air conſiderably purer than that of the atmoſphere. The reſult of the combination was common ſalt. On repeating the experiment with lime, no fixed air was obtained; but that which came over became gradually more and more dephlogiſticated. Volatile alkali, even when cauſtic, occaſioned an effervеſcence, and emitted a peculiar kind of air, which was neither fixed nor dephlogiſticated, but of a peculiar kind.

Green vitriol is changed to a red by the dephlogiſticated gas, but the colour of blue and white vitriol is not affected. By the aſſiſtance of light, it acts upon phoſphorus, and the reſult is phoſphoric and common marine acids. It does not diſſolve ice nor camphor; in which reſpects it differs from the common marine acid gas.

1486
Marine ether.

On mixing marine acid, manganeſe, and ſpirit of wine, and diſtilling them with a very gentle heat, little air of any kind is produced, but a quantity of ethereal liquor very ſlightly acid. The proportion uſed by Pelletier were an ounce and a half of manganeſe, five ounces of concentrated marine acid, and three ounces of ſpirit of wine. "In this proceſs (ſays Mr Kier), the whole of the dephlogiſticated acid ſeems to have united with the ſpirit of wine, and to have formed ether. The difficulty of combining marine acid with ſpirit of wine, ſo as to form an ether, is well known, and though there have been ſome approximations to it, yet the only inſtances in which it has been completely effected, have ſucceeded in conſequence of the marine acid being dephlogiſticated; by which its action on ſpirit of wine, as well as on all inflammable matters, is greatly increaſed."

1487
Method of procuring a detonating ſalt from the acid in quantity.

M. Pelletier has obſerved, that when we put a bit of phoſphorus into dephlogiſticated marine gas, the former is immediately diſſolved, and a light is perceived, the veſſel being filled at the ſame time with white vapours. He has likewiſe obſerved, that ſea-ſalt, with an exceſs of pure air, thrown into heated vitriolic acid produces a ſmall detonation. To make this ſalt in quantity, take, for inſtance, ten pounds of ſea-ſalt, mixing it with from three to four pounds of manganeſe, pour on the mixture ten pounds of vitriolic acid, and diſtil with Woulfe's apparatus. Paſs the diſengaged acid through a ſolution of fixed vegetable alkali, either cauſtic or otherwiſe. A little more than ten ounces of the new marine ſalt with exceſs of pure air is obtained, and a quantity of ſalt of Sylvius, or digeſtive ſalt. The ſalt with exceſs of pure air cryſtallizes firſt, and by means of repeated cryſtallizations, is entirely diſengaged from the other.

V. *AQUA REGIA.*

1488
Various ways of preparing aqua-regia.

THIS acid, which is named from its property of diſſolving gold, is compounded of the nitrous and marine acids. Gold and platina cannot be diſſolved in any other menſtruum, nor can regulus of antimony and tin be ſo eaſily diſſolved by any other as aqua-regia. It may be made various ways. 1. By adding the two acids to each other directly. 2. By diſſolving in the nitrous acid ſome ſalt containing marine acid, particularly ſal ammoniac and common ſalt. 3. By diſtilling nitrous acid from either of theſe ſalts. And, 4. In Dr Prieſtley's method of impregnating marine acid with nitrous acid vapour.

1489
Differences between theſe acid liquors.

The only difference between thoſe liquors prepared by the methods abovementioned is, that when ſal ammoniac or ſea-ſalt are diſſolved in the nitrous acid, the aqua-regia contains a quantity of cubic nitre, or nitrous ammoniac, which, tho' it cannot much affect the acid as a ſolvent, may make a conſiderable difference in the nature of the precipitate. Thus, gold precipitated from an aqua-regia formed by the pure nitrous and marine acids, does not fulminate, though it does ſo when precipitated from one made with ſal ammoniac. There are no eſtabliſhed rules with regard to the proportions of nitrous and marine acids, or of nitrous acid and ſal ammoniac, which ought to be employed for the preparation of aqua-regia. The common aqua-regia is made by diſſolving four ounces of ſal ammoniac in 16 ounces of nitrous acid; but theſe proportions muſt be varied, according to the nature of the intended ſolution.

tion. Platina, for inſtance, is diſſolved in the greateſt quantity by equal parts of the two acids; regulus of antimony by four parts of nitrous acid to one of marine; and, in general, the greater the quantity of marine acid employed in the mixture, the leſs are the imperfect metals, particularly tin, calcined or precipitated by it. A mixture of two parts of ſpirit of nitre, and one of ſpirit of ſalt, diſſolves nearly an equal weight of tin into a clear liquor, without forming any precipitate; but, for this purpoſe, the operation muſt be conducted ſlowly, and heat avoided as much as poſſible.

VI. *Borax.*

1490 Methods of purifying borax.

In a memoir in Crell's Chemical Annals, by M. Tychſon, the author ſhews, by different experiments, that it may ſometimes be purified by ſolution, filtration, and evaporation only; but that ſometimes the operation is more eaſy and effectual by previous calcination; but then the product is a little leſſened, eſpecially if the calcined maſs be not well powdered, and then boiled ſufficiently in water. Powder of charcoal, he ſays, may be ſometimes advantageouſly employed in the purification; but in general there is no difference between the crude and purified borax, except in the addition of extraneous matters; at leaſt, as the quantity of acids is the ſame, the addition of mineral alkali is uſeleſs: theſe extraneous matters are an animal fat, and a ſand compoſed of clay, lime, and a martial earth. If the oily matter of tartar be ſeparated by paſſing the lixivium through a ſtratum of clay, as is ſuppoſed in the preparation of the cryſtals at Montpelier, it would ſuggeſt a method of greatly abridging the proceſs of the purification of borax.

VII. *Acid of Borax, or Sedative Salt.*

1491 Methods of preparing the ſedative ſalt from borax.

On the preparation of this ſalt Mr Beaumé obſerves, that a little more acid ought to be added to the borax than what is juſt ſufficient to ſaturate its alkaline baſis. Unleſs this be done, the ſedative ſalt remains confounded with the other ſaline matters in the ſolution, and of conſequence the cryſtallization muſt be diſturbed. The ſalt, though formed in an acidulated liquor, is eaſily deprived of its ſuperfluous acid by draining upon paper. It does not cryſtallize as ſoon as the ſtronger acid ſeparates it from its baſis, even tho' the ſolution of borax had been previouſly made as ſtrong as poſſible; but this delay is occaſioned by the heat of the liquor; for as ſoon as it cools, a conſiderable quantity of cryſtals is formed.

1492 Its properties.

The acid of borax does not fall into powder when expoſed to the air, but rather attracts a little moiſture from it. Its taſte is at firſt ſomewhat ſouriſh, then cooling and bitteriſh; and laſtly, it leaves an agreeable ſweetneſs on the tongue. It makes a creaking ſound, and feels a little rough between the teeth; and when vitriolic acid is poured upon it, exhales a tranſient odour of muſk. It is ſoluble, according to ſome chemiſts, in the proportion of one to 20 in cold water, or of one to eight in boiling water. Wenzel informs us, that 960 grains of boiling water diſſolve 434 of the ſalt; while, on the other hand, Morveau aſſerts, that he could diſſolve no more than 183 grains in a pound of diſtilled water. Rouſs informs us, that fixed air prevents the ſolution of the ſalt in water; and Morveau, that its ſolubility is much augmented by cream of tartar. When previouſly made red hot, it diſſolves in water with a ſmell of ſaffron, and a grey powder of an earthy appearance is precipitated, which is ſoluble in vitriolic and marine acids, and may be again precipitated in the form of ſedative ſalt.

Acid of borax and its combinations.

Phlogiſticated alkali makes no change on ſedative ſalt in ſolution; but paper dipped in a ſolution of it in vinegar, and afterwards dried, burns with a green flame. It is capable of vitrification, though mixed with fine powder of charcoal; and with ſoot unites into a black maſs like bitumen; which, however, is eaſily ſoluble in water, and can ſcarce be reduced to aſhes, but partly ſublimes. By the aſſiſtance of heat it diſſolves in oils, eſpecially thoſe of the mineral kind; and with theſe it yields ſolid and fluid compounds, which gives a green colour to ſpirit of wine. Rubbed with phoſphorus it does not prevent its inflammation; but a yellow earthy matter is left behind. It ſeems alſo to give to white and red arſenic a great degree of fixity, ſo as even to become vitreſcible in the fire; and this property it communicates alſo to cinnabar. When mixed and heated with powder of charcoal, it forms no liver of ſulphur.

Sedative Salt COMBINED,

1. *With volatile alkali.* The produce of this is a peculiar ammoniacal ſalt, which does not evaporate when thrown on burning coals, or otherwiſe intenſely heated, but melts into glaſs of a greyiſh colour, but tranſparent, which cracks when expoſed to the air; and, on diſſolution in water, ſhoots into ſmall cryſtals, which appear to have loſt none of their alkaline baſis. It may be decompoſed by the acetous as well as the mineral acids, and by fixed alkalies and lime.

2. *With magneſia* this acid ſhoots into irregular cryſtalline grains ſoluble in vinegar and acid of ants; in which liquids they cryſtallize like ſmall needles joined together at right angles. They are decompoſed by all other acids, and likewiſe by ſpirit of wine. In the fire, however, they melt eaſily without any decompoſition; and in the dry way ſedative ſalt decompoſes all the earthy ſalts formed by magneſia and any of the volatile acids.

3. *With pure earth of alum,* ſedative ſalt forms a ſalt very difficult of ſolution, when one part of earth is ground with four times its weight of ſedative ſalt and water. The ſame kind of earth, mixed with half its weight of ſedative ſalt, forms a hard grey maſs, reſembling pumice ſtone; part of which is ſoluble in water, and yields a mealy ſediment, together with ſome ſedative ſalt unchanged.

4. *With ſiliceous earth* the ſedative ſalt does not unite in the moiſt way; but, on melting one part of acid with two of this earth, we obtain a frothy, hard, greyiſh-white maſs, from which, however, the acid may be again procured.

5. *Gold* is not acted upon in the wet way by acid of borax; nevertheleſs Rouſs obſerved, that when ſedative ſalt was melted with gold-leaf, it did not vitrify, but became frothy and hard, did not colour the flame of ſpirit of wine, and only a little of it was ſoluble in water in which ſedative ſalt had been cryſtallized.

A ſolution of borax in which ſedative ſalt was diſſolved, did not precipitate gold.

6. *Platina* is not precipitated from aqua-regia by ſedative ſalt.

7. *Silver* is not affected by melting with an equal quantity of ſedative ſalt; but the latter is vitrified in ſuch a manner as to become inſoluble in water.

8. *Mercury* is not diſſolved either in the dry or wet way; but a ſolution of borax ſaturated with ſedative ſalt precipitates it in a yellow powder from nitrous acid.

9. *With copper.* On this metal ſedative ſalt acts but weakly, even when the ſolution is boiling hot; nevertheleſs, as much of the metal is diſſolved, as gives a little white precipitate on the addition of fixed alkali; but volatile alkali does not throw down a blue precipitate, nor turn the ſolution of that colour. The ſolution of borax precipitates all ſolutions of copper in acids, and then the ſedative ſalt unites with the copper in form of a light green jelly, which, after drying, is of very difficult ſolution in water. Bergman ſays, it is of an agreeable green colour, which it preſerves after being dried; and that, when expoſed to the fire, it melts into a dark-red vitreous ſubſtance. Wenzel aſſerts, that by long continued trituration of copper filings with ſedative ſalt he obtained a ſolution of the metal, which yielded cryſtals on being evaporated. With twice its weight of copper in a covered crucible, an inſoluble vitreous maſs was obtained.

10. *Tin* is not apparently acted upon by boiling with ſedative ſalt; nevertheleſs, the ſolution becomes turbid on the addition of an alkali. By melting the calx with half its weight of ſedative ſalt, we obtain a black maſs like the dark coloured tin ore. By rubbing for a long time filings of tin with ſedative ſalt and water, and afterwards digeſting the mixture with heat for one day, an hard, ſandy, and irregularly ſhaped ſalt was obtained, which, by diſſolution in water, yielded tranſparent, white, polygonous cryſtals; and a ſalt of of the ſame kind was obtained from the ſlag produced by melting equal parts of ſedative ſalt and tin filings.

11. *Lead* is not acted upon directly; but, on adding a ſolution of borax to ſolutions of the metal in vitriolic, nitrous, marine, or acetous acids, the ſedative ſalt unites with the lead. One part of ſedative ſalt with two of minium gives a fine, greeniſh-yellow, tranſparent, and inſoluble glaſs.

12. *With iron.* The acid of borax diſſolves this metal more eaſily than any other. The ſolution is amber-coloured, and yields an ochry ſediment, with cluſters of yellow cryſtals containing a little iron. The metal is precipitated by borax from its ſolutions in vitriolic nitrous, marine, and acetous acids, and the precipitates are ſoluble in ſedative ſalt. A ſolution of iron may alſo be obtained by melting this ſalt with iron filings, and lixiviating the maſs.

13. *Zinc* communicates a milky colour by digeſtion with ſolution of ſedative ſalt. By evaporation it affords a confuſed ſaline maſs, and a white earthy powder by precipitation with alkali. Flowers of zinc, melted with ſedative ſalt, form a light green inſoluble ſlag.

14. *Biſmuth,* in its metallic ſtate, is not acted upon by ſedative ſalt, but is precipitated by borax from a mixture of vitriolic and marine acids, in form of a very white powder, which keeps its colour when expoſed to air, and melts in the fire to a white, tranſparent, and permanent glaſs.

15. *Regulus of antimony* is not acted upon directly, but its calx is diſſolved when precipitated by borax from a ſolution in aqua-regia.

16. *White arſenic* unites with ſedative ſalt either in the dry or moiſt way, and forms a cryſtallizable compound, forming either pointed ramifications, or white, greyiſh, and yellowiſh ſaline powder.

17. *On regulus of cobalt* the acid has no direct action; but borax precipitates it from its ſolution, and the calx melts with the ſalt into a ſlag of a bluiſh-grey colour; and this, by lixiviation and evaporation, affords a ſedative ſalt impregnated with cobalt, of a reddiſh white colour, and of a ramified form.

18. *Nickel* is precipitated from its ſolution, and the ſedative ſalt unites with it into a ſaline ſubſtance difficult of ſolution.

1493
Experiments made to determine the nature of the ſedative ſalt.

A variety of opinions have been formed concerning the nature of ſedative ſalt. M. Beaumé and M. Cadet particularly have made a great number of experiments on the ſubject; but as none of theſe have led to any certain concluſion, we forbear to mention them at preſent. Thoſe of Meſſrs Exſchaquet and Struve have indeed eſtabliſhed ſome kind of relation between the acids of borax and phoſphorus, and they have made ſeveral attempts to analize the former, but with little ſucceſs. The moſt remarkable of theſe experiments are the following. 1. They diſtilled, with a ſtrong heat, two parts of phoſphoric acid evaporated to the conſiſtence of honey, one of ſedative ſalt, and two of water. Towards the end of the diſtillation a very acid liquor was obtained; and the reſiduum was a white earth, in quantity above three-fourths of the ſedative ſalt employed, and which, on examination, was found to be the ſiliceous earth; the liquor which paſſed over into the receiver being found to be the volatile phoſphoric acid. If, in this experiment, too much phoſphoric acid be added, a greaſy matter remains; and, if too little, a part of the ſedative ſalt will remain undecompoſed. In their attempts to compoſe borax, they combined phoſphoric acid with mineral alkali, the reſult of which was a compound reſembling borax in many reſpects. When expoſed to the fire it melts into a very fuſible glaſs, which has a mild taſte, and ſeems neutral, but on expoſure to the air, becomes moiſt and acid. On being ſaturated with alkali a ſecond time and vitrified, it again deliqueſces and becomes acid; and the more frequently this operation is repeated, the greater is the reſemblance it bears to borax. In this experiment they ſuppoſed that the alkali was decompoſed, and converted into an earth ſimilar to that of ſedative ſalt.

With earthy ſubſtances the reſults were very remarkable. With earth of alum a cryſtallizable ſalt was obtained, which made paper burn with a green flame. Fixed alkali added to a ſolution of this ſalt precipitates an earth, and the ſalt then formed by cryſtallization reſembles borax in ſeveral properties.—In the dry way the earth of alum, with the phoſphoric acid, melts into a glaſs of the ſame fuſibility as that of borax, and like it is fixed in the fire. The ſolution of this glaſs did not cryſtallize. Common clay

Acid of amber.

clay digeſted with phoſphoric acid produces ſilky cryſtals reſembling ſedative ſalt. When dried with their mother-water, theſe give a clear glaſs, which when united with mineral alkali, has the taſte of borax, ſmells in the ſame manner, and has the ſame effect upon metals. With lime, magneſia, and terra ponderoſa, this acid produces fuſible glaſſes, inſoluble in water, and which communicate a green colour to flame. Earth of bones and ſelenite mixed with the acid give a white, hard, ſhining glaſs, like the beſt cryſtal, but fuſible as the glaſs of borax, and which continued flexible after it had ceaſed to be red-hot. Two parts of gypſum, with one of phoſphoric acid, gave a milk white glaſs fit for ſoldering metals and enameling. In theſe experiments, however, it muſt be remembered, that unleſs the heat be raiſed very quickly, the phoſphoric acid will be evaporated before any fuſion takes place.

VIII. *Acid of Amber.*

It was known to Agricola, that a particular kind of ſalt could be obtained from amber by diſtillation; but neither he, nor any ſucceeding chemiſt for ſome time aſcertained its acid properties. On the contrary, ſome erred ſo far as to imagine that it was a volatile alkali; but, about the beginning of the preſent century, its acidity began to be generally acknowledged. This property indeed diſcovers itſelf by the taſte, which is manifeſtly acid and empyreumatic, along with the peculiar flavour of amber. According to Scheele, alſo, the aqueous fluid which paſſes over in the diſtillation of amber, is an acid reſembling vinegar both in taſte and chemical properties; and which of conſequence ought not to be confounded with the true acid of amber, which manifeſts qualities of a very different kind.

1494 Methods of purifying the ſalt of amber.

The properties of ſalt of amber can hardly be inveſtigated until it has been purified; for which, of conſequence, various methods have been propoſed. Pott recommends cryſtallization, after having filtered the ſolution through cotton-wool, in order to retain the oil. Cartheuſer attempts the purification by diſſolving the impure ſalt in ſpirit of wine, then diluting with ſix times its quantity of water, and cryſtallizing the ſalt. Others recommend ſublimation with common ſalt or ſand, and Bergman with pure clay.

The ſalt of amber diſſolves, by the aſſiſtance of heat, in nitrous and marine acids, and in the vitriolic without heat. In none of theſe combinations, however, does it either alter the diſſolving acids, or ſuffer any alteration itſelf, except that it becomes whiter; with nitre it detonates and flies off; and if the quantity of ſalt of amber has been greater than that of nitre, the latter is alkalized. Stockar informs us, that it expels the marine acid from ſal ammoniac, and ſublimes before that ſalt; with which it does not form any union. When ſublimed from common ſalt, it does not alter the latter in any other reſpect than giving it a darker colour. It precipitates calcareous earth from its ſolution in vinegar; and it decompoſes ſugar of lead; but the precipitate differs from plumbum corneum. It does not prevent the ſolution of lead in the acids of ſea-ſalt and nitre; nor does it produce any ſulphureous ſmell by calcination with charcoal. Hence it appears that it is neither a vitriolic, nitrous, nor marine acid; and M. Bourdelin muſt have been miſtaken, when he affirms, that, after detonation of this ſalt with nitre, he obtained a reſiduum, which taſted like common ſalt, decrepitated in the fire, yielded cryſtals of a cubical form, precipitated ſilver and mercury from the nitrous acid; and thence concluded that it was the ſame with acid of ſea-ſalt. It is very dear, as only about half an ounce can be obtained from a pound of amber.

Acid of amber and its combinations.

Acid of Amber COMBINED,

1. *With fixed vegetable alkali.* By ſaturating ſalt of amber with the fixed vegetable alkali, and then ſlowly evaporating the ſolution, we obtain, according to Wenzel, a light deliqueſcent ſaline maſs; but, according to Stockar, whoſe experiments are confirmed by thoſe of Mr Keir, the ſolution abovementioned affords ſhining white tranſparent cryſtals of a triangular priſmatic figure, with the terminating points truncated. Theſe cryſtals readily diſſolve in water, deliqueſce in the air, and have a peculiarly bitter ſaline taſte. In the fire they decrepitate, melt, and remain neutral; though Wenzel has obſerved, that with an intenſe heat they are decompoſed and become alkaline. Theſe cryſtals do not change aquafortis into aqua-regia; and though they precipitate both the ſolutions of lead and ſilver, the precipitates are neither plumbum corneum nor luna cornea.

2. *With Mineral alkali.* This combination produces long three-ſided columnar cryſtals, intermixed with ſome that are foliated. Theſe cryſtals do not deliqueſce in the air, and have a ſaline, bitter, and ſmoky taſte. They are leſs ſoluble than common ſalt, and melt with more difficulty than nitre. They do not become alkaline on burning coals, and, in their other properties, reſemble the former.

3. *With volatile alkali.* This ſalt ſhoots into acicular cryſtals, having a ſharp, ſaline, bitter, and cooling taſte; when heated in a ſilver ſpoon, they melt and evaporate entirely; in cloſe veſſels they ſublime. They do not precipitate ſolution of ſilver, nor change ſpirit of nitre into aqua-regis. A powerful antiſpaſmodic remedy is prepared from rectified ſpirit of hartſhorn and ſalt of amber.

4. *With lime.* This ſhoots into oblong pointed cryſtals, which do not deliqueſce in the air, and are ſoluble with difficulty even in boiling water; nor, according to Mr Stockar de Neuforn, can they be decompoſed by diſtillation either with acetous or marine acids. They detonate by diſtillation with nitrous acid; and are decompoſed, either in the moiſt or dry way, by the vitriolic. When mixed with common ſal ammoniac in the dry way, they ſuffer a decompoſition; the ſuccinated ammoniacal ſalt flying off and the combination of marine acid with lime remaining behind.

5. *With magneſia.* This yields a white, gummy, frothy, ſaline maſs, which acquires a yellowiſh colour when dried by the fire; and, when cool, deliquates in the air. It is decompoſed by alkalies and lime, as well as by the vitriolic acid.

6. *With clay.* By uniting the acid of amber with an edulcorated precipitate of alum with vegetable alkali, Wenzel obtained priſmatic cryſtals, which could not be decompoſed by alkalies.

7. *With ſilver.* The acid of amber has no effect on
ſilver

Acid of amber and its combinations.

ſilver in its metallic ſtate ; but with its precipitate forms thin oblong cryſtals, radiated and accumulated upon one another, from which the ſilver may be ſeparated by alkalies, by quickſilver, and by copper.

8. *With copper.* By a long digeſtion of copper with acid of amber a green ſolution is obtained, which by mixture with common ſalt is rendered turbid, by vitriolic acid white, and lets fall a green precipitate on the addition of fixed alkali. Wenzel, however, could not obtain this precipitation by alkalies. His ſolution yielded groups of green cryſtals, gave a cruſt of copper to zinc, and was precipitated by liver of ſulphur.

9. *With iron.* Wenzel diſſolved a precipitate of this metal in acid of amber, and from the ſolution obtained ſmall, brown, tranſparent, and ſtellated cryſtals. Zinc precipitated the metal, but not alkalies. From a ſlightly coloured ſolution of metallic iron, Pott obtained, by means of alkali, a white precipitate, which ſoon became yellow, and at length green, by pouring water upon it.

10. *With tin.* Acid of amber diſſolves tin when precipitated by a fixed alkali ; and the ſolution yields thin, broad, and foliated tranſparent cryſtals. Alkalies throw down but little from this ſolution ; liver of ſulphur more ; and lead, iron, or zinc, nothing.

11. *With lead.* Acid of amber whitens the ſurface of lead in its metallic ſtate, but does not diſſolve it ; neither can lead be precipitated from its ſolutions in nitrous and marine acids by ſalt of amber, though this is denied by Pott. According to Stockar, however, it forms a white precipitate with ſugar of lead. This metal precipitated by an alkali, and diſſolved in acid of amber, forms long foliated cryſtals lying upon one another ; from the ſolution of which the lead may be precipitated by alkalies in the form of a grey powder, and by zinc in its metallic ſtate.

12. *Zinc*, in its metallic ſtate, is readily diſſolved by the acid of amber ; and by a combination with the precipitate formed by fixed alkali, we obtain long, ſlender, foliated cryſtals, lying upon one another. The ſolution lets fall a white precipitate on the addition of fixed alkali ; but this is denied by Stockar, who ſays that volatile alkali produces a red precipitate.

13. *Biſmuth.* By means of heat, Stockar obtained a ſolution of this ſemimetal in acid of amber, which was decompoſed by alkalies. Wenzel obtained, from a precipitate of biſmuth prepared by means of fixed alkali, ſmall, ſlender, foliated, and yellow cryſtals; which alkalies cannot decompoſe, though black precipitates are thrown down by lead and zinc.

14. *Regulus of antimony.* Little or none of this ſemimetal, in its reguline form, is diſſolved in the acid of amber ; but it attacks the precipitate made with fixed alkali. This ſolution is very copiouſly precipitated by liver of ſulphur, but not by alkalies.

The combinations of this acid with gold, platina, nickel, arſenic, and manganeſe, have either been found impracticable, or not yet attempted ; all thoſe above deſcribed are non-deliqueſcent, and part with their acid when expoſed to the fire. The elective attractions of this acid, according to Bergman, are ſingular, as it adheres more ſtrongly, not only to terra ponderoſa and lime, but to magneſia, than to fixed alkali.

Acid of amber and its combinations.

1495
On the nature of the acid of amber.

On the origin of ſalt of amber, Mr Keir remarks, that "it deſerves to be conſidered as a pure and diſtinct acid. No proofs have been adduced of its being a modification either of the marine or vegetable acids, as Mr Cornette and M. Hermbſtadt have ſuppoſed. The former, having diſtilled ſpirit of ſalt with oil of lavender, obtained an acid which ſmelled like ſalt of amber, but on examination was found to retain the properties of the muriatic acid. He alſo relates, that, when purifying a conſiderable quantity of the ſalt of amber which he had prepared himſelf, ſome ſea-ſalt was ſeparated, which in the diſtillation had ariſen along with it. But this obſervation cannot be juſtly applied to ſhow any reſemblance betwixt theſe two, any more than the ſmell in the former caſe could ſhow an analogy betwixt it and oil of lavender. This mixture of ſea-ſalt with acid of amber, however, may readily explain the miſtake of M. Bourdelin already mentioned. M. Weſtrumb and M. Hermbſtadt have both laboured in vain to convert the acid of amber into acids of ſugar and tartar by frequent diſtillations with ſpirit of nitre ; and their want of ſucceſs confirms the account already given, that the acids of nitre and amber have no action upon each other, farther than that the former is phlogiſticated or changed into red fumes, and the latter becomes whiter. Nevertheleſs, if Mr Scheele's obſervation of the identity of the acid liquor, which comes over in the diſtillation of amber with acetous acid, holds good, we ſhall have the beſt reaſon yet given to aſcribe the origin of this acid to the vegetable kingdom ; and when we conſider the very different properties that are aſſumed by the vegetable acids, which, however, are convertible into one another, no reaſon can be drawn from the diverſity of its properties with thoſe of other vegetable acids, againſt its having a common origin with them. Indeed the natural hiſtory of amber, its ſimilarity to gums and reſins, and its involved inſects, afford other arguments in favour of the opinion.

IX. *Acid of Arsenic.*

1496
M. Pelletier's method of procuring the arſenical acid.

M. Berthollet remarks upon Mr Scheele's proceſs, that during the operation a great quantity of dephlogiſticated air is expelled from the acid. M. Pelletier has found another method of procuring the arſenical acid. He mixes common white arſenic with nitrous ammoniac, and diſtils the mixture. At firſt phlogiſticated nitrous acid paſſes over, then the volatile alkali, and laſtly the arſenical acid remains in the retort in form of a vitreous maſs, which deliqueſces into a very denſe acid liquor, reddening ſyrup of violets, and effervеſcing with alkalies. Mr Macquer had formerly deſcribed this proceſs, and obſerved, that the nitrous acid paſſes over firſt, and then the volatile alkali ; but was of opinion that the reſiduum was nothing but arſenic. He mentions a detonation which took place in his experiment ; but nothing of this kind was obſerved by M. Pelletier: he only informs us, that the nitrous acid was driven over with great violence, while that of arſenic united with the volatile alkali. M. Berthollet, who has endeavoured to aſcertain the weight gained by the converſion of ſulphur, phoſphorus, and arſenic, into acids, determines that of arſenic to be about one-ninth of the whole. At the ſame time he obſerves, that this additional weight does not diſcover the whole weight of the air contained in

the

the arſenic, as it had that neceſſary to convert it into calx before the operation of converting it into an acid was begun. On the other hand, M. Bergman aſſerts, that one-fifth of white arſenic is phlogiſton, and that this calx is converted into acid merely by being deprived of its phlogiſton. Thus the *facts* related by theſe two celebrated chemiſts differ enormouſly from one another; M. Berthollet affirming that the arſenic *gains* a ninth of its original weight in the proceſs of acidification; and M. Bergman, that it *loſes* a fifth part of the ſame. M. Berthollet endeavours to reconcile this, by ſuppoſing that Bergman had employed marine acid for the preparation of his arſenical acid, which is well known to cary off with it ſome part of moſt of thoſe ſubſtances with which it is capable of combining; and to this he attributes the loſs of weight in Bergman's proceſs.

IX. *Acid of Molybdæna.*

1497 M. Pelletier's experiments.

The opinion of M. Bergman concerning the metallic nature of the acid of molybdæna has obtained ſome confirmation from the experiments of M. Pelletier. He was not able indeed to obtain any regulus; but by means of oil alone he procured, by two hours vehement heat, a ſubſtance ſlightly agglutinated with a metallic luſtre, containing ſmall round grains of a grey metallic colour, very viſible by the help of a magnifier. Theſe he ſuppoſes to have been a true regulus of molybdæna; which he found to poſſeſs the following properties. 1. It is calcinable by fire into white calx. 2. It detonates with nitre, and the reſiduum is a calx of molybdæna united with the alkali of the nitre. 3. It is converted into a white calx by means of nitrous acid. 4. It yields inflammable air when treated with alkalies in the dry way, and forms peculiar compounds with them. 4. It forms regenerated molybdæna with ſulphur. 6. It unites, and forms peculiar ſubſtances with metals. By uniting it with ſilver, iron, and copper, we have friable reguline maſſes; and refractory powders with lead and tin.

Our author, in conſequence of his experiments, conſiders molybdæna as a metallic ſubſtance mineralized by ſulphur; and the earth called the acid of molybdæna as a calx much dephlogiſticated, which has retained part of the air contained in the nitrous acid. He obſerves likewiſe an analogy betwixt molybdæna and antimony in their chemical reſults. Both of them yield vitrifiable argentine flowers by ſimilar operations, and both are changed into white earths by nitrous acid; but they differ in the two following reſpects. 1. The latter eaſily gives a fuſible regulus; but the molybdæna ſeems to be the moſt refractory of all the ſemimetals. 2. The calx of regulus of antimony is ſoluble by alkalies in the moiſt way, but that of molybdæna is not.

X. *Acid of Tungsten or Wolfram.*

1498 Properties of tungſten.

Mr Luyart, who has examined this mineral, gives the following account of it. 1. It is infuſible by the blow-pipe, though the angles of the pieces into which it is broken are thereby rounded. 2. It efferveſces with microcoſmic ſalt, and melts before the blow-pipe into a reddiſh glaſs. 3. With borax it efferveſces; and by the outward flame of the blow-pipe is changed into a reddiſh glaſs; by the internal flame into a greeniſh one. 4. Heated by itſelf in a crucible, it ſwelled, became ſpongy, ſemivitrified, and was attracted by the magnet. 5. With an equal part of nitre it detonated, or boiled up with a blue flame round the edges, and nitrous vapours aroſe. The maſs was ſoluble in water, and let fall a white precipitate with acid. 5. It melted readily with fixed alkali, leaving a kind of black matter in the crucible, and a ſmaller quantity of lighter coloured ſubſtance on the filter. Theſe reſiduums ſhowed a mixture of iron and manganeſe. 6. With nitrous acid the filtered ſolution let fall a white precipitate, at firſt ſweet, but afterwards bitteriſh and ſharp, and which cauſed a diſagreeable ſenſation in the throat; and the acidity of the ſolution of it was manifeſt, by its turning the tincture of turnſole red.

Having examined the ſubſtance by means of liquids in Mr Scheele's way, they obtained the ſame yellow powder which he had characterized as the acid of tungſten, along with a very ſmall reſiduum, which appeared to contain a mixture of tin. Proceeding farther in the analyſis, they found that wolfram is compoſed of manganeſe, calx of iron, the yellow matter called the *acid of tungſten* by Bergman and Scheele, with a very little mixture of quartz and tin, and which they conſidered as accidental.

1499 Of the yellow matter, called its acid by Mr Scheele.

They now proceeded to examine the yellow matter, ſuppoſed by the two celebrated chemiſts juſt mentioned to be a ſimple acid ſalt, but which turned out very different on their inquiries. In order to procure a quantity of it, they melted ſix ounces of wolfram with as much vegetable alkali, diſſolved the mixture in diſtilled water, filtrated the liquor, and evaporated it to dryneſs. Thus they obtained a white ſalt; upon which, when dry, they poured nitrous acid, and ſet it to boil in a ſand-bath; by which operation it became yellow. They then decanted the liquor, pouring freſh acid upon the reſiduum; and repeated the operation a third time in order to deprive it of all the alkali. The remaining powder was then calcined in a cupelling furnace under a muffle, when it came out quite pure and yellow. The properties of it were then found to be as follow. 1. It is entirely inſipid, and of the ſpecific gravity of 6.12. 2. Before the blow-pipe, it continues yellow in the exterior flame even though put on charcoal; but grows black and ſwells, though it does not melt, in the internal flame. 3. In the internal flame it forms a blue tranſparent glaſs with microcoſmic ſalt. The colour vaniſhes in the external flame, but appears again in the internal one; but by a continuance of this operation, it at laſt loſes its colour ſo much that it cannot be recovered. 4. It efferveſces, and forms a browniſh yellow tranſparent glaſs with borax, which keeps its colour in both flames. 6. When triturated with water, it forms an emulſion which paſſes through filters without becoming clear, and continues a long time without any depoſition. 7. It is inſoluble in acids, but diſſolves readily in the vegetable alkali both in the moiſt and dry way; though the produce has always an exceſs of alkali. 8. On adding nitrous acid in greater quantity than what is neceſſary to ſaturate this exceſs, a white powder falls, which is the ſame with the acid of tungſten diſcovered by Mr Scheele; but which Meſſrs Luyarts will

1500 No ſimple acid procurable from tungſten.

not allow to be a ſimple acid, though they admit that it contains one; and affirm, that its properties are various according to the circumſtances of its precipitation. The properties of it, as deſcribed by them, are the following. 1. It is fuſible before the blow-pipe, exhibiting the ſame phenomena as the yellow matter. 2. By calcination in a little pot or teſt, it emits the ſmell of nitrous acid, and turns yellow; but, on cooling, remains white, inſipid, and inſoluble; and this reſiduum melts by itſelf before the blow-pipe. 3. A yellow colour is produced either by vitriolic or marine acids; and the filtrated liquor affords a neutral ſalt with baſis of fixed alkali, according to the nature of the acid employed. If the vitriolic acid is employed, and the operation performed in a retort, a quantity of nitrous acid paſſes over. 4. If, inſtead of pouring the acid on the ſalt, it be poured upon its ſolution, no precipitate will be formed, not even by making the liquor boil, if the quantity of acid is ſmall; only the ſolution loſes its ſweet taſte, and acquires more bitterneſs. On pouring on a large quantity of acid, and cauſing the liquor boil, a yellow precipitate is formed in every reſpect ſimilar to the yellow matter ſo often mentioned. 5. This ſalt is completely diſſolved by the boiling with vinegar. On leaving the ſolution to cool, a white waxy matter adheres to the ſides of the veſſel; which being waſhed and kneaded with the fingers, forms an adheſive maſs like bird-lime, having a fat and greaſy taſte. By expoſure to the air it acquires a dark grey colour, loſes its adheſive property, and becomes bitter. It diſſolves in water; and gives at firſt a ſweet, then a bitter taſte, making the tincture of turnſole red. 6. On evaporating the alkaline ſolution to dryneſs, pouring acetous acid upon the reſiduum, and then making it boil, the greater part of the reſiduum, was diſſolved, and on cooling afforded feathery cryſtals. Theſe when edulcorated had a ſweet taſte, though leſs ſtrong than that of the former ſalt, which afterwards became bitter. Their ſolution turned blue paper red; was precipitated, and became like an emulſion with ſpirit of wine; and the reſiduum, which did not diſſolve, appeared to be of the ſame nature. The cryſtals diſſolved in freſh acetous acid, and communicated a blue colour to the acid; but this gradually diſappeared on cooling, and a glutinous matter was depoſited on the ſides of the veſſel, which had the properties of the former ſubſtance of that ſort. If, in place of letting the ſolution cool, it ſhould be kept boiling, the blue colour diſappears, and nothing is precipitated. By adding ſpirit of wine when the liquor is almoſt evaporated to dryneſs, a white powder is precipitated; which after being edulcorated with freſh ſpirit of wine, taſtes exceedingly bitter, and is very ſoluble in water. This ſolution, however, does not redden blue paper, nor make a blue with vinegar. With vitriolic acid its ſolution is blue; with vitriol of copper it forms a white precipitate. All theſe ſalts, by calcination, firſt become blue, then yellow, and laſtly white. 7. On pouring a quantity of lime-water upon the ſolution of the precipitate formed by the nitrous acid, as well as on thoſe obtained by the acetous acid, white precipitates were formed, all of which were a true regenerated tungſten. Having afterwards impregnated the liquors with fixed air, and boiled them in order to precipitate the lime more completely, they found in the ſolutions, after they were filtrated and evaporated to dryneſs, neutral ſalts formed of the precipitating acids, joined with alkaline and calcareous baſes. This proved, that both alkali and acid were concerned in the precipitation. 8. On pouring the vitriolic ſolutions of iron, copper, and zinc, as well as that of marine mercurial ſalt, alum, and Pruſſian alkali, upon the ſolution of the precipitate formed by the nitrous acid, no precipitation enſues, and the acetous ſalts of copper and lead give white precipitates; but the Pruſſian alkali forms no precipitate with the acetous ſalts. Hence it appears that this ſalt is not a ſimple acid, but rather a ſalt compoſed of the yellow matter, fixed alkali, and the precipitating acid; and its compoſition appears more fully from the following experiments with the volatile alkali.

1. The yellow powder diſſolves entirely in volatile alkali, but without any perfect ſaturation taking place; and the alkali always prevails. 2. The ſolution being ſet in a ſand-bath, produced needle-like cryſtals, which had a ſharp bitter taſte, exciting a diſagreeable ſenſation in the throat. Their ſolution turned the tincture of turnſole red, and the liquor from which they were cryſtallized had the ſame properties. 3. Having repeated this operation with different quantities of the ſame cryſtals, leaving ſome longer on the fire than others, ſolutions were obtained, whoſe acidity was in proportion to the time they had remained on the fire; but during the operation they all emitted the ſmell of volatile alkali. By calcination this alkali was entirely diſſipated, and the reſiduum was a yellow powder, perfectly ſimilar to that with which the operation was begun. On making uſe of a retort for the operation, the remaining powder was blue. 4. This ſalt precipitates the vitriolic ſalts of iron, copper, zinc, and alum, calcareous nitre, marine mercurial ſalt; the acetous ſalts of lead and copper; and with lime-water regenerates tungſten. The vitriolic acid decompounds it, and forms a blue precipitate; the nitrous and marine acids produce a yellow; but no precipitate is occaſioned by the Pruſſian alkali.

Having poured nitrous acid upon a portion of the ſolution with exceſs of alkali, a white powder was precipitated, which, after edulcoration, had a taſte at firſt ſweet, but afterwards ſharp and bitter, and its ſolution turned the tincture of turnſole red. This, on examination, appeared to be a triple ſalt formed of the yellow powder, volatile alkali, and the precipitating acid.

1501 A kind of ſemimetal procurable from tungſten.

The following experiments realize the conjecture of Bergman, that the acid of tungſten is the baſis of a particular ſemimetal.

1. “ Having kept 100 grains of the yellow powder (ſays M. Luyart) in a Zamora crucible well covered, and ſet the whole in a ſtrong fire for half an hour, it became a ſpongy maſs of a bluiſh black colour, the ſurface of which was cryſtallized into fine points, like plumoſe antimony, and the inſide compact, and of the ſame colour. It was too hard to be broken in pieces by the fingers; and, when ground, was reduced to a dark-blue colour.

2, “ Having mixed 100 grains of the ſame powder with 100 of ſulphur, and put the mixture in a Zamora crucible on a ſtrong fire for a quarter of an hour, it came out a dark-blue maſs, which was eaſily broke by the fingers; and the inſide preſented a cryſtallization like needles as the laſt, but tranſparent, and of the colour of a dark lapis lazuli. This maſs weighed 42 grains, and when placed on burning coals yielded no ſmell of ſulphur.

3. "Having put another 100 grains of this powder into a Zamora crucible, provided with charcoal, and well covered, and placed it in a ſtrong fire, where it remained an hour and a half, we found, on breaking the crucible after it was cool (A), a button, which fell to powder between the fingers. Its colour was dark brown; and on examining it with a glaſs, there was ſeen a congeries of metallic globules, among which ſome were the bigneſs of a pin's head, and when broke had a metallic appearance at the fracture in colour like ſteel. It weighed 60 grains: of courſe there was a diminution of 49. Its ſpecific gravity was 17.6. Having calcined part of it, it became yellow, with $\frac{24}{100}$ increaſe of weight. Having put one portion of this ſubſtance powdered, in digeſtion with the vitriolic acid, and another with the marine acid, neither of them ſuffered more diminution than $\frac{2}{100}$ of their weight; then decanting the liquor, and examining the powder with a glaſs, the grains were ſtill perceived of a metallic aſpect. Both the acid liquors gave a blue precipitate with the Pruſſian alkali, which let us know that the ſmall diminution proceeded from a portion of iron which the button had undoubtedly got from the powder of the charcoal in which it had been ſet. The nitrous acid, and aqua-regia extracted likewiſe from two other portions the ferruginous part; but beſides, they converted them into yellow powder, perfectly ſimilar to that which he uſed in this operation.

4. "Having put 100 grains of gold and fifty of the yellow powder in a Zamora crucible furniſhed with charcoal, and kept in a ſtrong fire for three quarters of an hour, there came out a yellow button which crumbled in pieces between the fingers; the inſide of which ſhowed grains of gold, ſeparated from others of a dark-brown colour. This demonſtrated there had not been a perfect fuſion and likewiſe that this ſubſtance was more refractory with gold, ſince the heat which it endured was more than ſufficient to have melted it. The button weighed 139 grains; of courſe there was a diminution of 11 grains. Having put this button with lead in the cupelling furnace, the gold remained pure in the cupel; but this operation was attended with conſiderable difficulty.

5. "Having made a mixture of platina and yellow powder in the preceding proportions, and expoſed it to a ſtrong fire, with the ſame circumſtances, for an hour and a quarter, it produced a button which crumbled with eaſe between the fingers, and in which the grains of platina were obſerved to be more white than uſual, and ſome of them changed ſenſibly in their figure. This button weighed 140 grains, and of conſequence there had been a loſs of 10 grains. When calcined, it took a yellow colour, with very little increaſe of weight; and after waſhing it to ſeparate the platina, there remained 118 grains of a black colour. Having placed this portion again to calcine over a ſtrong fire in a muffle, it ſuffered no ſenſible alteration in weight or colour; for it neither grew yellow, nor took the brown colour of the platina, but kept the ſame blackneſs as before it was calcined. It muſt be attended to, that in the waſhings there was not ſo much care taken to collect all the platina as to deprive it of the yellow colour, and for this reaſon the water carried off part of the fine black powder: and conſequently the increaſe which the platina preſerved, after being waſhed and calcined the ſecond time, ought to be computed more than the 18 grains which it ſhowed by its weight.

"Having mixed the yellow powder with other metals in the preceding proportions, and treated them in the ſame manner, the reſult was as follows:

6. "With ſilver it formed a button of a whitiſh-brown colour, ſomething ſpongy, which with a few ſtrokes of a hammer extended itſelf eaſily, but on continuing them ſplit in pieces. This button weighed 142 grains, and is the moſt perfect mixture we have obtained, except that with iron.

7. "With copper it gave a button of a copperiſh red, which approached to a dark brown, was ſpongy, and pretty ductile, and weighed 133 grains.

8. "With crude or caſt-iron, of a white quality, it gives a perfect button, the fracture of which was compact, and of a whitiſh brown colour: it was hard, harſh, and weighed 137 grains.

9. "With lead it formed a button of a dull dark-brown, with very little luſtre; ſpongy, very ductile, and ſplitting into leaves when hammered: it weighed 127 grains.

10. "The button formed with tin was of a lighter brown than the laſt, very ſpongy, ſomewhat ductile, and weighed 138 grains.

11. "That with antimony was of a dark-brown colour, ſhining, ſomething ſpongy, harſh, and broke in pieces eaſily: it weighed 108 grains.

12. "That of biſmuth preſented a fracture, which, when ſeen in one light, was of a dark-brown colour, with the luſtre of a metal; and in another appeared like earth, without any luſtre: but in both caſes one could diſtinguiſh an infinity of little holes over the whole maſs. This button was pretty hard, harſh, and weighed 68 grains.

13. "With manganeſe it gave a button of a dark bluiſh-brown colour and earthy aſpect; and on examining the internal part of it with a lens, it reſembled impure drops of iron: it weighed 107 grains."

XI. *Acid of Ants.*

Etmuller is among the firſt authors who mentions the exiſtence of this acid, and ſpeaks of obtaining it by diſtillation. Nothing of its properties, however, was known, until Margraaf undertook to examine it; of whoſe experiments we have an account in the Memoirs of the Berlin Academy for 1749. Since his time a number of chemiſts have proſecuted the ſubject to

---

(A) "The firſt time we made this experiment, we broke the crucible without letting it cool entirely; and as ſoon as the matter was in contact with the air, it took fire, and its dark brown colour turned inſtantly yellow."

to a conſiderably greater length ; but Mr Keir prefers the reſearches of Arvidſon, Bucholtz, and Hermbſtadt, to the reſt.

The acid in queſtion is a natural juice which the inſects diſcharge when irritated, and which is very pungent to the ſmell as well as taſte. Thus it may inſtantly be perceived on turning up an ant-hill in ſpring or ſummer. The *formicæ rubræ* of Linnæus are thoſe inſects which have hitherto ſupplied this acid. Mr Arvidſon adviſes to collect them in the months of June and July, by laying ſome ſmooth ſticks upon an ant-hill; which being then diſturbed, the ants will run upon the ſticks in great numbers, and may then be ſwept off into a veſſel containing water until it be full. Hermbſtadt collects them in the ſame manner, but into a dry bottle, to avoid the evaporation of the ſuperfluous liquid. Bucholtz having moiſtened the inſide of a narrow necked glaſs bottle with honey and water, ſunk it into a diſturbed ant-hill until the mouth was level with the ground ; on which the inſects, allured by the ſmell of the honey, went into the bottle, and could not get out.

1502
Different methods of obtaining this acid.

For obtaining the acid, Margraaf employed diſtillation, with the addition of freſh water. Thus he obtained, from 24 ounces of freſh ants, 11 ounces and two drachms of acid, ſome volatile alkali, empyreumatic oil, and a reſiduum containing earth and fixed ſalt. Arvidſon made uſe of two methods : One conſiſted in diſtilling the ants when dry ; from a pound of which, in this ſtate, he obtained eight ounces of acid beſides the empyreumatic oil. His other method was to incloſe, in a piece of linen, the ants previouſly cleaned by waſhing in water, then to pour boiling water upon them, and to repeat the operation until it could extract no more acid ; which is then obtained by ſqueezing the linen, mixing all the liquors, and filtering them. Thus from a pound of ants he obtained a quart of acid liquor, which taſted like vinegar, but was ſpecifically heavier. By diſtillation Hermbſtadt obtained from a pound of dry ants ten ounces and a half of yellow empyreumatic liquor, which did not taſte more ſtrongly acid than the ſpirit obtained by diſtilling wood, on which ſwam three drachms of a brown fetid oil, in all reſpects like that of hartſhorn. In the retort was left a black reſiduum weighing one ounce ſix drachms, which exhibited ſigns of containing volatile alkali. By diſtilling a pound of ants with three of water, according to Mr Margraaf's method, he obtained an acid liquor and ſome oil in the receiver ; and from the ſurface of that which remained undiſtilled, he collected a drachm and an half of fat oil.

The ſpecific gravity of the acid liquor obtained by Mr Arvidſon's maceration was 1,0011 ; that of the ſame liquor, when diſtilled, 1.0075 ; and of the acid concentrated by freezing, 1.0453. According to Bucholtz, the acid liquor thus obtained by maceration did not grow in the leaſt mouldy in the ſpace of four weeks ; during which it was allowed to reſt in order to free itſelf perfectly from the impurities it contained. Mr Hermbſtadt, however, prefers Margraaf's method of diſtillation to that of Arvidſon's macerations, not only as being a more perfect analyſis, but as leſs laborious ; though he finds fault alſo with Margraaf's method, as diluting the acid too much, and altering it ſo that it has not the ſmell of living ants. He totally diſapproves of the method of diſtilling dried ants, as the acid is thus in a great meaſure decompoſed, and the remainder united with much oil. To avoid all theſe inconveniences, he contrived another method, namely, to expreſs the juice of the inſects ; by which means he obtained at once a concentrated liquor fit for diſtillation. In this way he obtained from two pounds of dried ants 21 ounces and two drachms of juice, which had a pungent and highly acid ſmell, reſembling the vapours of fluor acid ; in taſte reſembling concentrated vinegar and acid of tartar ; to which laſt it might be compared for ſtrength of acidity. By diſtilling eight ounces of this expreſſed liquor, he obtained ſix ounces and a half of clear acid, equal in ſtrength to a very concentrated vinegar.

1503
Properties of the pure acid.

The acid, when thus procured in purity, has a pungent, not unpleaſant ſmell, a ſharp, cauſtic taſte, and an agreeable acidity. It reddens blue paper, ſyrup of violets, and litmus ; blackens the vitriolic acid, and converts part of it into a ſulphureous vapour. It is alſo decompoſed by diſtillation with nitrous acid. Spirit of ſalt likewiſe, when dephlogiſticated, decompoſes it, but not in its ordinary ſtate. It does not form ſulphur by an union with phlogiſton, but produces inflammable vapours by diſſolving iron or zinc. By the aſſiſtance of a gentle heat it diſſolves ſoot, but oils with much more difficulty, and powder of charcoal not at all. It does not unite with vitriolic ether ; but in diſtilling a mixture of this acid with ſpirit of wine, Mr Arvidſon ſaw ſome traces of an ether, and M. Bucholtz perfectly ſucceeded in making an ether by means of it. It unites with fixed alkali, forming, according to M. Margraaf, a neutral ſalt, conſiſting of oblong deliqueſcent cryſtals, from which very little acid could be procured by diſtillation *per ſe*, but on adding concentrated oil of vitriol, a very ſtrong and pure acid was obtained ; from a mixture of which with ſpirit of wine, M. Bucholtz readily obtained a true ether. With mineral alkali it forms deliqueſcent foliated cryſtals of a ſaline bitter taſte, and ſoluble in twice their weight of water. With volatile alkali it forms an ammoniacal liquor ; which, according to Arvidſon, cannot be brought into a dry ſtate ; but Mr Arvidſon ſays he has obtained cryſtals from it, though very thin and deliqueſcent. Margraaf obtained dry cryſtals by uniting this acid, with chalk or coral ; and Arvidſon obſerves that this ſalt is tranſparent, cubical, or rhomboidal, nondeliqueſcent, ſoluble in eight parts of water, of a bitter taſte, and inſoluble in ſpirit of wine. No acid can be obtained from it by diſtillation *per ſe*. From a ſolution of magneſia in this acid, Mr Arvidſon obtained ſome ſaline particles by depoſition, and afterwards an effloreſcence of tranſparent ſalt riſing round a ſaline maſs. This ſalt had ſcarcely any taſte, was ſoluble in 13 parts of water, and inſoluble in ſpirit of wine. With ponderous earth the acid formed a cluſter of bitter needle-like cryſtals, which did not deliqueſce, were ſoluble in four times their quantity of water, inſoluble in ſpirit of wine, and when burnt gave out a ſmell like that of burnt ſugar, leaving a coal which efferveſced with acid. It unites with difficulty to the earth of alum, and can ſcarcely be ſaturated with it. It does not precipitate ſilver, lead, or mercury, from their ſolution in nitrous acid ; whence it ſeems to have no affinity to the marine acid: and as it does not precipitate lime from the marine acid, it ſeems to have as little with the vitriolic.

1504 Has an affinity with the acetous acid.

From his experiments, however, Margraaf concluded, that the acid of ants, in many reſpects, though not in all, has a great affinity with the acetous acid. From this it is diſtinguiſhed by forming different compounds, and likewiſe by having different affinities. It diſlodges the acetous acid alſo in all inſtances, and the arſenical acid from cobalt and nickel. It has a greater attraction for fixed alkalies than for lime.

1505 Its effects on metals.

As a ſolvent it acts but weakly upon copper; not at all, or very little, on ſilver, lead, tin, regulus of antimony, or biſmuth, but ſtrongly on iron or zinc. It diſſolves, however, the calces of copper, ſilver, zinc, and lead, without affecting thoſe of tin, regulus of antimony, or biſmuth. The calx of quickſilver, according to Margraaf, is revived by it. According to Arvidſon, it cryſtallizes with iron, zinc, or lead; does not act upon the regulus of antimony, of arſenic, cobalt, or nickel; though it diſſolves their calces as well as the precipitate of mangaueſe. Gold, mercury, and the calx of platina, are not affected by it; but it cryſtallizes with thoſe of copper, ſilver, lead, biſmuth, and mercury.

In its ſtrength of attraction, the acid of ants exceeds thoſe of vinegar, borax, and the volatile ſulphureous and nitrous acids.

1506 Acid procured from various inſects.

Inſects armed with ſtings, as bees, waſps, and hornets, are likewiſe ſaid to diſcharge a very acid juice when irritated; and Mr Bonnet has obſerved a very ſtrong acid ejected by a caterpillar which he diſtinguiſhes by the name of *grande chenille du ſaule a queu fourchue*. None of theſe, however, have been as yet particularly examined.

XII. *Acid of Apples.*

That the juices of unripe fruits contain ſome kind of acid has been univerſally known, and attempts to inveſtigate the nature of it have been made ſome time ago: but it is to Mr Scheele that we owe the diſcovery of the particular acid now treated of.

1507 Acid of citrons how procured.

He had obſerved that the juice of citrons contained a particular acid; which, by being united with lime, formed a ſalt very inſoluble in water; and which therefore by means of lime could be readily ſeparated from the mucilaginous part of the juice. By adding vitriolic acid to this compound of lime with the acid juice, almoſt in the ſame manner in which he uſed to procure the acid of tartar, the lime was again ſeparated, and the pure acid of citrons obtained. Proceeding in the ſame manner with other fruit, he found that an acid, agreeing in every reſpect with that of citrons, could be procured from the juice of the *ribes groſſularia*.

1508 Another acid procured from the juice of fruits.

Examining the juice which remained after the ſeparation of the former acid from the citrons, he found that it ſtill contained another acid; which being ſaturated with more calcareous earth, formed a ſalt eaſily ſoluble in water, and therefore remained ſuſpended in the juice. To ſeparate this new ſalt, he added ſome ſpirit of wine, by which the ſalt was precipitated; but finding that it ſtill contained much gummy matter, he judged that it would be proper to attempt a ſeparation of this gum before he precipitated the ſalt. For this purpoſe he evaporated ſome of the juice of the ribes groſſularia to the conſiſtence of honey, diſſolving the maſs afterwards in ſpirit of wine. Thus the acids, which are ſoluble in the ſpirit, were eaſily ſeparated by filtration from the inſoluble gum. He then evaporated the ſpirit, adding to the remainder twice its quantity of water, with as much chalk as was neceſſary for the ſaturation. The liquor was next boiled for two minutes; during which the inſoluble ſalt was precipitated, and the liquor ſeparated from it by filtration contained the ſolution of chalk in the new acid. To this ſolution he added ſpirit of wine, which again precipitated the ſalt, while ſome ſaponaceous and ſaccharine matters remained diſſolved in the ſpirit.

1509 Its properties.

Having thus at laſt obtained the ſalt in a ſtate of purity, he proceeded to examine its nature; and found, 1. That ſome of it, ſpread on his nail, ſoon dried, and aſſumed the appearance of varniſh. 2. It was very ſoluble in water, and turned litmus red. 3. When the ſolution had ſtood ſome days expoſed to air, it was found to have depoſited a number of ſmall cryſtals, which could only be diſſolved by a quantity of boiling water; and this ſalt was alſo found to be completely neutralized, ſo that, it yielded its calcareous earth to a fixed alkali. 4. The ſalt was decompoſed by heating *per ſe* in a crucible, and left a mild calcareous earth. 5. The acid was ſeparated from the earth by adding oil of vitriol diluted with water until gypſum was no longer precipitated, and the new acid was left diſengaged, ſo that it could be ſeparated by filtration. 6. By this operation, however, all the lime was not precipitated; ſo that the ſeparation of the acid was not complete. 7. He obſerved that the acid had a greater attraction for lead than for lime; and therefore made uſe of the method he had formerly diſcovered for ſeparating the acid of ſorrel. To the acid he added a ſolution of ſugar of lead; by which the acid was precipitated along with the lead, and the vinegar was left in the liquor.

1510 How procured in perfect purity.

To this precipitate, cleaned from the acetous acid by filtration, he added vitriolic acid, which expelled the weaker vegetable one, and thus left it quite pure and free from any heterogeneous mixture.

The juice of apples, either ripe or unripe, was found to contain no acid of citrons, but a large quantity of the new acid; which, being thus alone, he could more eaſily procure by a ſingle operation. The beſt method of procuring this he found to be by ſaturating the juice of the apples with a ſolution of fixed vegetable alkali, and pouring a ſolution of ſugar of lead to that of the ſalt juſt mentioned. The effect of this was a double decompoſition, and a precipitate of lead combined with the new acid. To the edulcorated precipitate he then added a dilute vitriolic acid till he could no longer perceive any ſweet taſte in the liquor; for the firſt portions of the vitriolic acid diſſolve a part of the calx of lead, and impart a ſweetiſh taſte to the liquor, which is ſenſible, notwithſtanding its acidity; but when the quantity of vitriolic acid is ſufficient to ſaturate the whole of the calx, all the metal falls to the bottom, and the ſweetneſs ceaſes; ſo that the acid is at once obtained pure.

1511 Properties of it when obtained from the juice of apples.

The acid of apples is poſſeſſed of the following properties. 1. It cannot be cryſtallized, but always remains in a liquid ſtate; or, if much evaporated, attracts the moiſture of the air. 2. With fixed alkalies of all kinds it forms deliqueſcent ſalts. 3. With calcareous earth it forms ſmall irregularly ſhaped cryſtals, which cannot be diſſolved but in a large quantity of boiling water; but if the acid is ſuperabundant, the ſalt readily diſſolves in lime-water. 4. It is effected by ponderous, earth in the ſame manner as by lime. 5. Earth of alum forms, with the acid of apples, a ſalt not very ſoluble in water. 6. With magneſia the acid forms a deliqueſcent ſalt. 7. Iron is diſſolved into a brown liquor, which does not cryſtallize. 8. The ſolution of zinc affords fine cryſtals. 9. On other metals it has no remarkable effects. From the acid of citrons it differs. 1. The acid of citrons ſhoots into fine cryſtals. 2. The acid of apples can be eaſily converted into that of ſugar, which Mr Scheele could not accompliſh with that of citrons; though Mr Weſtrumb has ſince done it. 3. The ſalt formed with the citron acid and lime is almoſt inſoluble in water; but that with acid of apples and lime is eaſily ſoluble. 4. Acid of apples precipitates mercury, lead, and ſilver from their ſolution in nitrous acid, and likewiſe the ſolution of gold, when diluted with water; but the acid of citrons does not alter any of theſe ſolutions. 5. The acid of citrons ſeem to have a greater attraction for lime than that of apples.

1512
Produced from ſugar by means of nitrous acid.

It is remarkable that this acid is the firſt produced in the proceſs for making ſugar. If a diluted acid of nitre be drawn off from a quantity of ſugar until the mixture becomes a little brown, which is a ſign that all the nitrous acid is evaporated, the ſyrup will be found to have acquired a ſouriſh taſte; and if, by means of lime, we next ſeparate all the acid of ſugar, another will ſtill remain, which diſſolves the calcareous earth. When this acid is ſaturated with chalk, and the ſolution filtered and mixed with ſpirit of wine, a coagulation takes place. On ſeparating the curdled part by means of a ſieve, diſſolving it in water, and then adding ſome vinegar of lead, the calx of lead will be precipitated; and if the new acid is then ſeparated from the metal by means of diluted oil of vitriol, it will be found to poſſeſs all the properties of the acid of apples, and is indeed the ſame. The ſpirit of wine, which has been employed to precipitate the calcareous ſalt, leaves on evaporation a reſiduum of a bitter taſte, very deliqueſcent, and ſimilar to the ſaponaceous extract of the citron.

1513
Experiments with nitrous acid on various ſubſtances.

The following are the reſults of Mr Scheele's experiments with the nitrous acid upon different ſubſtances. 1. From gum arabic he obtained both the acid of apples and of ſugar. 2. The ſame products were obtained from manna. 3. From ſugar of milk he obtained not only its own peculiar acid, but thoſe of apples and ſugar. 4. Gum tragacanth, during its ſolution in nitrous acids, lets fall a white powder, which was found to be the acid of the ſugar of milk. This gum contained alſo the acid of apples and of ſugar, and a ſalt formed from lime and the acid of apples. 5. Starch left an undiſſolved matter; which being ſeparated by filtration, and waſhed, reſembled a thick oil like tallow, which, however, was found to be very ſoluble in ſpirit of wine. By diſtillation he obtained from this oily matter an acid ſimilar to that of vinegar, and an oil which has the ſmell of tallow, and congeals by cold; and, beſides theſe ſubſtances, he found that ſtarch yielded the acids of apples and ſugar. 6. From the root of ſalep he obtained the acid of apples, with a large quantity of calcareous ſaccharine ſalt. 7. Extract of aloes indicated the exiſtence of the acids of ſugar and apples, and loſt the greateſt part of its bitter taſte. During the digeſtion a reſinous matter was ſeparated, which ſmelled like flowers of benzoin, and took fire on being heated in a retort. 8. Extract of colocynth was converted by nitrous acid into a reſinous ſubſtance, and ſhowed ſome ſigns of containing acid of ſugar. 9. The extracts of Peruvian bark and of the other plants examined by Mr Scheele, gave both the acids of apples and ſugar. 10. Theſe two acids were likewiſe obtained from an infuſion of roaſted coffee, evaporated to the conſiſtence of a ſyrup. 11. The ſame products were obtained from an extract of rhubarb, which yielded alſo a reſinous matter. 12. Juice of poppies afforded the ſame reſults. 13. Extract of galls did the ſame. 14. The eſſential oils afforded little or none of the acids; but the oil of parſley-ſeeds ſeemed to be entirely convertible into them. 15. With a very concentrated acid he was able alſo to decompoſe animal ſubſtances. From glue he thus obtained fine cryſtals of acid of ſugar, and afterwards acid of apples. Iſinglaſs, whites and yolks of eggs, afforded the ſame products. From all theſe ſubſtances, eſpecially the laſt, a fat matter was ſeparated: but it was remarkable that the gas, expelled during the proceſs, was compoſed of a little fixed air, a great quantity of phlogiſticated air, and very little nitrous air, whereas no phlogiſticated air is obtained in the uſual proceſs for preparing acid of ſugar. He obſerved alſo that in the proceſs for this acid, a ſmall quantity of vinegar is found in the receiver. He could not obtain the acid of ſugar from the ſaponaceous extract of urine; but got inſtead of it a ſalt, which, when completely purified, reſembled exactly the flowers of benzoin. The ſame ſalt is precipitated in abundance by adding to the extract of urine a little vitriolic or marine acid; and Mr Scheele had already remarked that the ſame ſalt is obtained in the diſtillation of ſugar of milk.

1514
Of the nature of this acid.

From the various experiments which have been made on this acid, it ſeems, according to Mr Keir, to be in an intermediate ſtate betwixt acid of tartar and acid of ſugar. This, however, ought not to prevent it from being accounted a ſeparate and diſtinct acid, otherwiſe we might confound all the vegetable acids with one another. It approaches more nearly to the nature of acid of milk than of any other. From this alſo, however, it is diſtinguiſhed, becauſe the ſalt formed by the union of acid of milk with lime is ſoluble in ſpirit of wine, but not that from lime and the acid of apples. According to Mr Hermbſtadt, if three parts of ſmoking nitrous acid be abſtracted from one part of ſugar, and if the brown acid maſs which remains in the retort be diluted with ſix times its weight of diſtilled water, and ſaturated with chalk, two compounds will be formed; one conſiſting of the acids of tartar and lime, which will precipitate; and the other of lime and the acid of apples, which will remain ſuſpended. If the calcareous earth be precipitated from this latter ſolution by adding acid of ſugar, a pure acid of apples will be left in the liquor: and

and he further informs us, that this acid of apples may be changed entirely into thoſe of ſugar and vinegar, by means of ſtrong nitrous acid.

XIII. *Acetous Acid.*

1515 How to cryſtallize ſpiritus Mindereri.

It is generally believed, that the combination of this acid with volatile alkali is altogether incapable of cryſtallization; but Scheffer and Morveau inform us, that it may be reduced into ſmall needle-ſhaped cryſtals, when the ſpiritus Mindereri is evaporated to the conſiſtence of a ſyrup, and left expoſed to the cold. The ſalt has a very ſharp and burning taſte, but a conſiderable quantity is loſt during the evaporation. Weſtendorf, by adding his concentrated vinegar to volatile alkali, obtained a tranſparent liquor which did not cryſtallize. By diſtillation it went over intirely into the receiver, leaving a white ſpot on the retort. A ſaline tranſparent maſs, however, appeared in the receiver under the clear fluid. On ſeparating it from the liquid, and expoſing it to a gentle heat, it melted, threw out white vapours, and in a few minutes ſhot into ſharp cryſtals reſembling nitre. Theſe remained unchanged in the cold; but when melted with a gentle warmth, ſmoked and evaporated. Their taſte was firſt ſharp and then ſweet.

1516 Salt from the acetous acid combined with calcareous earth.

The ſalt formed by uniting acetous acid with calcareous earth has a ſharp bitter taſte, and ſhoots into cryſtals ſomewhat reſembling ears of corn. Theſe do not deliquate in the air, unleſs the acid has been ſuperabundant. They are decompoſed by diſtillation *per ſe*, the acid coming over in white inflammable vapours ſmelling like acetous ether, ſomewhat empyreumatic, and condenſing into a reddiſh brown liquor. By rectification this liquor becomes very volatile and inflammable; on adding water, it acquires a milky appearance, and drops of oil ſeem to ſwim upon the ſurface; a reddiſh brown liquor, with a thick black oil, remain after rectification in the retort. On mixing this calcareous ſalt with that of Glauber, a double decompoſition takes place; we have a gypſum and the mineral alkali combined with acetous acid. By calcination, the mineral alkali may be obtained from this ſalt in a ſtate of purity. This acetous calcareous ſalt is not ſoluble in ſpirit of wine.

1517 With magneſia.

On ſaturating this acid with magneſia, and evaporating the liquor, we obtain a viſcid ſaline maſs like mucilage of gum arabic, which does not ſhoot into cryſtals, but deliqueſces in the air. It has a ſweetiſh taſte at firſt, but is afterwards bitter. It is ſoluble in ſpirit of wine, and parts with its acid by diſtillation without addition.

1518 With zinc.

Acetous acid diſſolves zinc both in its metallic and calciform ſtate, and even when mixed with other metals. By concentrated vinegar the zinc is diſſolved with great heat, ſulphureous ſmell, and exhalation of inflammable matter. By this union we obtain a congealed maſs, which on dilution with water ſhoots into oblong ſharp cryſtals at the firſt cryſtallization, and afterwards into cryſtals of a ſtellated form. From this liquor indeed cryſtals of various forms have been obtained by different chemiſts. Monnet obtained from it a pearl-coloured ſalt in friable talky cryſtals; which when thrown on the coals, fulminated a little at firſt, and gave a bluiſh flame, and then melted, letting its acid eſcape, while a yellow calx remained. Hellot informs us, that this ſalt by diſtillation *per ſe* in water, affords an inflammable liquor, and an oil at firſt yellow and then green, with white flowers burning with a blue flame. Weſtendorf obtained no oil in this diſtillation, but ſome acetous acid; a ſweet-taſted empyreumatic liquor impregnated with zinc; ſweet flowers, or ſublimate, ſoluble in water, and burning with a green flame. On applying a ſtronger heat, the zinc was ſublimed in its metallic form, leaving a ſpongy coal at the bottom of the retort. The ſolution gives a green colour to ſyrup of violets, lets fall a white precipitate on the addition of alkalies or an infuſion of galls. It is not precipitated by common ſalt, vitriolated tartar, vitriolic or marine acids, blue vitriol, or corroſive ſublimate; but forms a red precipitate when added to a ſolution of gold; a white precipitate with ſolution of ſilver; a cryſtalline pearly precipitate with ſolution of mercury; and cryſtalline precipitates with ſolutions of biſmuth and tin. According to Bergman, it is decompoſed by acid of arſenic.

1519 Its phenomena with arſenic.

Though regulus of arſenic is not ſoluble in this acid, its calx may be diſſolved either in common or diſtilled vinegar. M. Cadet obtained a ſmoking liquor by diſtillation from a mixture of white arſenic and terra foliata tartari. This experiment has been repeated by the chemiſts of Dijon, and attended with the following curious circumſtances. "We digeſted (ſay they), in a ſand-bath, five ounces of diſtilled vinegar on white pulverized arſenic; the filtrated liquor was covered, during evaporation, with a white ſaline cruſt. Of this ſubſtance were formed 150 grains; on which fixed alkali appeared to have no effect, and which was at firſt conſidered as pure arſenic. However, a cat, which had ſwallowed 72 grains of it, was only affected with vomitings that day and the next, and afterwards perfectly recovered. A ſimilar doſe was given to a little dog; but as he ran away, the effect it had upon him could not be diſcovered; but he returned afterwards in good health, and never ſhowed any uneaſineſs: whence it may be concluded, that vinegar is in ſome meaſure an antidote againſt the pernicious qualities of arſenic.

1520 Vinegar ſuppoſed to be an antidote againſt arſenic.

"On rediſſolving this ſaline cruſt in pure water, filtering and mixing it with liquid alkali, an irregularly cryſtallized ſalt was formed in it after a few days ſtanding. By this ſalt a yellow precipitate was thrown down from the nitrous ſolution of ſilver; whereas the ſolution of arſenic and terra foliata tartari threw down a white one.

"Equal parts of terra foliata tartari and arſenic, diſtilled in a retort, gave firſt a ſmall quantity of limpid liquor with a penetrating ſmell of garlic, and which had the property of reddening ſyrup of violets; while ſolution of arſenic in water turns that ſyrup green. The vinegar which now aroſe was not ſaturated when arſenic, but effervеſced ſtrongly with fixed alkali, with which it became turbid, but did not let fall any precipitate. On changing the receiver, there came over a reddiſh brown liquor, accompanied with thick vapours, diffuſing an intolerable ſmell, in which that of arſenic could ſcarcely be diſtinguiſhed. On continuing the operation, a black powder ſublimed into the neck of the

the retort, together with a little arſenic in its metallic form, and a matter which took fire by a lighted candle like ſulphur.

“ The red liquor ſtill preſerved its property of ſmoking though cold; diffuſing at the ſame time its peculiar and abominable fetor, from which the apartment could ſcarcely be freed in ſeveral days. This liquor does not alter the colour of ſyrup of violets, but efferveſces ſlightly with fixed alkali, letting fall at the ſame time a yellow precipitate, which, however, diſappeared on an attempt to ſeparate it by filtration.

1521 **Curious phoſphoric liquor.**

“ M. Cadet had obſerved, that the ſmoking liquor of arſenic did not kindle at the approach of a lighted candle; but that, on pouring it from the receiver into another veſſel, it had kindled the fat lute with which the junctures had been cloſed, and which had been dried during the operation: but we, being deſirous of examining more fully the nature of the red liquor which collects at the bottom, and has the appearance of oil, having decanted that which ſwims on the top, and poured the remainder on a filter of paper, before many drops had paſſed, there aroſe a thick ſmoke forming a column from the veſſel to the ceiling; a ſlight ebullition was perceived at the ſides of the veſſel, and a beautiful roſe-coloured flame appeared for a few moments. The paper filter was burnt at one ſide, but moſt of it was only blackened. After the flame was extinguiſhed, a fat reddiſh matter remained: which being melted on burning coals, ſwelled conſiderably, emitting a white flame. It then ſunk, and left on the coal a black ſpot, which could not be effaced but by the moſt vehement fire.

“ At the time theſe obſervations were made, the liquor had been diſtilled for three weeks, and the bottle frequently opened. The inflammability could not proceed from the concentration of the vinegar: for the roſe-colour of the flame, the precipitation of the ſublimate, and the fixity of the ſpot remaining on the coal, evidently ſhowed that the two ſubſtances were in a ſtate of combination; which is alſo further evinced by the loſs of the inflammable property when the liquor was decompoſed by fixed alkali.—The ſmell of the liquor, however, though ſo intolerably fetid, was attended with no other inconvenience than a diſagreeable ſenſation in the throat, which further ſtrengthens the ſuſpicion that vinegar is an antidote againſt arſenic.

“ The ſaline brown maſs remaining in the retort was partly diſſolved by hot water; and the filtrated lixivium was very limpid, but emitted the peculiar ſmell of the phoſphoric liquor. By evaporation it yielded a ſalt which did not deliqueſce in the air, of an irregular ſhape; and which being put on burning coals, did not ſmell ſenſibly of arſenic; loſt its water of cryſtallization; and became mealy and white without being diſſipated by heat. On expoſing the reſiduum to the air, it was found next day reſolved into a liquor; whence it is probable that moſt of it was compoſed of cryſtallized alkali, having received from the decompoſition of the vinegar as much fixed air as was neceſſary for its cryſtallization.”

1522 **Effect of the acetous acid on mercury.**

This acid does not act upon mercury in its metallic ſtate, but diſſolves the mercurial calces, as red precipitate, turbith mineral, and the precipitate formed by adding fixed alkali to a ſolution of mercury in nitrous acid; with all which it forms white, ſhining, ſcaly cryſtals, like thoſe of ſedative ſalt.

1523 **On ſilver.**

Vinegar does not act upon ſilver in its metallic ſtate, but readily diſſolves the yellow calces precipitated from its ſolution in nitrous acid by microcoſmic ſalt and volatile alkali. By the help of a boiling heat alſo it very copiouſly diſſolves the precipitate obtained by means of a fixed alkali. The laſt mentioned ſolution yields ſhining, oblong, needle-ſhaped, cryſtals, which are changed to a calx by means of ſeveral acids, eſpecially the muriatic. The ſilver is thrown down in its metalic form by zinc, iron, tin, copper, and quickſilver.

1524 **On gold.**

Though the acetous acid has no effect upon gold in its metallic ſtate, yet a ſolution of this metal is decompoſed by crude vinegar, which produces both a metallic precipitate and dark violet-coloured powder. Diſtilled vinegar throws down the gold in its metallic form. The precipitate by fixed alkali digeſted with acetous acid is of a purple colour. This, as well as fulminating gold, is diſſolved by Weſtendorff's concentrated vinegar; the fulminating gold very eaſily. The ſolution is of a yellow colour; and with volatile alkali affords a yellow precipitate; with lixivium ſanguinis, a blue one; both of which fulminate. The dry ſalt of gold diſſolves in the acetous acid, and produces oblong yellow cryſtals.

1525 **On inflammable ſubſtances.**

This acid has no effect on fat oils, farther than that when diſtilled together, ſome mixture takes place, as the Abbé Rozier has obſerved. Neither does diſtilled vinegar act upon eſſential oils, though M. Weſtendorff's diſtilled vinegar diſſolved about a ſixth part of oil of roſemary, and about half its weight of camphor. The latter ſolution was inflammable, and let fall the camphor on the addition of water. The acid diſſolves all the true gums, and ſome of thoſe called gum-reſins, after being long digeſted with them. By long boiling, Boerhaave obſerves, that it diſſolves the bones, cartilages, fleſh, and ligaments of animals.

1526 **Concentration of the acetous acid.**

The concentration of this acid may be effected by combining it with alkalies, earths, and metals. By combining it with copper, and then cryſtallizing and diſtilling the compound, we obtain the acid in the higheſt ſtate of concentration in which it is uſually met with. To produce this ſtrong acid, we have only to diſtill verdegris, or rather its cryſtals in a retort. The operation muſt be begun by a very gentle fire, which brings over an aqueous liquor. This is to be ſet aſide, in order to procure the more concentrated acid, which comes over with a ſtronger fire. On changing the receiver, and augmenting the heat, we obtain a very ſtrong acid which comes over partly in drops, and partly in white vapours. It is called radical vinegar, or ſometimes ſpirit of Venus, and has a very pungent ſmell, almoſt as ſuffocating as that of volatile ſulphureous acid. As the laſt portions of it adhere pretty ſtrongly to the metal, we are obliged to raiſe the heat to ſuch a degree as to make the retort quite red in order perfectly to ſeparate them. Hence ſome part of the metal is raiſed along with the acid, which, diſſolving in the receiver, gives the liquor a greeniſh colour; but from this it may be eaſily freed by a ſecond diſtillation, when it riſes with a very gentle heat, and

and becomes extremely white. Cryſtals of verdegris afford about one half their weight of radical vinegar; but verdegris itſelf much leſs, and of a more oily quality.

1527 Of its cryſtallization.

If this acid be heated in a wide-mouthed pan, and fire applied to it, it will burn entirely away like ſpirit of wine. This obſervation we owe to the count de Lauragais, who has likewiſe obſerved, that it is capable of cryſtallization. This, however, takes place only with the laſt portions which came over, and the cryſtals appear in the form of plates or needles. The marquis de Courtrivon, who has repeated and confirmed the experiment of the count de Lauragais, ſuppoſes this phenomenon to be owing to a ſulphur-like mixture of acetous acid and phlogiſton. Leonhardi ſuppoſes an analogy between theſe cryſtals and the white ſalt of copper expelled at the end of the operation by the count de Laſſone. This ſalt was at firſt very white, and fixed on the neck of the retort pretty thick; but unleſs quickly collected, was ſoon deſtroyed by the ſucceeding vapours. When expoſed to the air, it attracts moiſture, and runs into a greeniſh liquid. It is uncommonly light, and in ſuch ſmall quantity, that ſcarce five or ſix grains can be collected from a pound of verdegris. Its taſte is acid, auſtere, very unpleaſant and permanent. It readily and totally diſſolves in water, and partially in ſpirit of wine, leaving a yellow powder totally ſoluble in volatile alkali, and which burns with a green flame. From this ſalt, volatile alkali acquires a blue colour, and litmus a red one; and thus it diſcovers itſelf to be compoſed of acetous acid and copper.

1528 Difference between radical vinegar and common acetous acid.

Experience has ſhown that radical vinegar differs conſiderably in its properties from the common acid. It has a greater attraction for alkalies, forms with them more perfect combinations, and is leſs volatile. M. Berthollet obſerves, that when vinegar concentrated by froſt and radical vinegar, are reduced to equal denſities, by adding water to the heavier of the two, they differ very much both in ſmell and taſte. Laſſone found, that radical vinegar formed a cryſtallizable compound with volatile alkali; and Berthollet has obſerved the ſame with regard to fixed vegetable alkali. The cryſtals of the latter with radical vinegar were flat, tranſparent, and flexible, ſlowly deliqueſcent in the air. On comparing the ſalts formed by the two acids, he found, that the acetous ſalt rendered the ſyrup of violets green; but its colour remained unaltered with that made with radical vinegar. The latter alſo required a ſtronger fire to expel part of its acid; it was alſo whiter, and had a leſs acid taſte. On pouring radical vinegar on the acetous ſalt, the ſolution afforded, by evaporation and cryſtallization, a ſalt perfectly ſimilar to that procured directly from radical vinegar and fixed alkali. On diſtilling the mixture, the radical vinegar appeared to have expelled the common acetous acid, as the liquor which came over efferveſced with vegetable alkali, and formed with it a terra foliata tartari.

“It ſeems probable (ſays Mr Keir), that the radical vinegar contains a larger portion of the aerial principle than the common acetous acid; by which it undergoes a change ſimilar to that of marine acid, when brought into that ſtate in which it is ſaid to be dephlogiſticated. This air it may acquire from the metallic calx, which being deprived of its air is reduced to its metallic ſtate. Thoſe who believe in the phlogiſton of metals, may ſay that the acid is dephlogiſticated by imparting its phlogiſton to the metal, which is thereby metallized. It appears, however, to be very diſtinct from common acetous acid, and deſerves to have its properties and compounds farther inveſtigated.”

1529 How to obtain it pure from terra foliata tartari.

Concentrated acetous acid, of a great degree of ſtrength may alſo be obtained by diſtilling terra foliata tartari with vitriolic acid; but Leonhardi obſerves, that the acid thus obtained is always more or leſs contaminated with the volatile acid of ſulphur. He obſerves alſo, that the method propoſed of ſeparating the ſulphureous acid by a ſecond diſtillation from ſalt of tartar is not effectual, becauſe the ſulphureous acid has leſs attraction for alkalies than the acetous. Weſtendorf recommends the neutral ſalt formed by acetous acid and mineral alkali, inſtead of the terra foliata tartari. Thus, in the firſt place, we readily obtain cryſtals free from the inflammable matter of the vinegar; and, in conſequence of this, though we diſtil it afterwards with concentrated oil of vitriol, no ſulphureous taint can be produced. Even ſuppoſing this to be the caſe (he ſays), it may be removed by a ſecond diſtillation from ſome mineral alkali. Mr Keir, however, obſerves, that “probably all the acids diſtilled from acetous ſalts by means of the vitriolic, partake of the property of that procured by diſtilling cryſtals of verdegris; and none of them can compare with that from which Mr Louitz obtained acetous ether without addition, as a pure concentrated and unaltered vinegar.”

XIV. *Acid of Benzoin.*

1530 M. Lichtenſtein's account of its properties.

The properties of this acid have been inveſtigated by M. Lichtenſtein, and are as follow. 1. Expoſed to the heat of a candle in a ſilver ſpoon, it melts as clear as water, without burning, though it is deſtroyed by contact of flame. 2. When thrown upon coals, it evaporates, without reſiduum, in a thick white ſmoke. 3. It is not volatile without a conſiderable degree of heat. 4. By very ſlow cooling its aqueous ſolution yields large cryſtals, long, thin, and of a feathery ſhape. 5. It is ſoluble in the concentrated acids of nitre and vitriol, but ſeparates from them, without decompoſition, on the addition of water. 6. By the other acids it cannot be diſſolved without heat, and ſeparates from them alſo without any change, merely by cooling. 7. It is copiouſly diſſolved by ſpirit of wine, and precipitated from it on the addition of water. 8. With alkalies it forms neutral ſalts, very ſoluble in water, and of a ſharp ſaline taſte. With vegetable alkali it forms cryſtals of a pointed feathery form: with mineral alkali it yields larger cryſtals, which fall into powder on being expoſed to the air; and with volatile alkali it is difficultly cryſtallizable into ſmall, feathery, and deliqueſcent cryſtals. It is ſeparable from alkalies by the mineral acids. 9. With calcareous earth it forms white, ſhining, and pointed cryſtals, not eaſily ſoluble, and which have a ſweetiſh taſte without any pungency. 10. With magneſia

Acetous acid.

ſmall feathery cryſtals are formed, of a ſharp ſaline taſte, and eaſily ſoluble in water. 11. An aſtringent ſalt is formed with earth of alum.

All theſe earthy ſalts are eaſily decompoſed by the mineral acids as well as by alkalies. The acid of benzoin itſelf reddens litmus, but has little effect upon ſyrup of violets.

1531
Effects of nitrous acid upon it.

Meſſrs. Hermbſtadt and Lichtenſtein have both tried the effects of nitrous acid upon that of benzoin. In this operation, however, a great obſtacle aroſe from the volatility of the acid of benzoin, which prevented it from bearing any conſiderable heat without paſſing over into the receiver. By repeated diſtillations, however, the acid of benzoin, diminiſhed in its volatility, aſſumed a darker colour, and acquired a bitteriſh taſte. A coal was alſo left at the bottom; and, at the end of the third operation, when the nitrous acid had been all drawn off, M. Hermbſtadt obſerved that ſome brown drops came over which had the appearance of a dark-coloured tranſparent oil, ſoluble in diſtilled water, emitting acrid fumes, and having a very cauſtic taſte. On diſtilling this acid liquor a ſecond time, a yellow ſaline maſs was obtained, which, when diſſolved in diſtilled water, formed a fluid acid, which precipitated a ſolution of ſugar of lead and lime-water. On examining the charred reſiduum left in the retort, he obſerved, that, after calcination, ſome of the earth had been vitrified, while another was of a ſoft conſiſtence, and had acquired a cauſtic taſte. From a mixture of the abovementioned dark-brown acid and ſpirit of wine, he obtained an ether, which differed from the nitrous in being much leſs volatile, and ſmelling like bitter almonds.

From this reſiduum Mr Lichtenſtein obtained a reſinous ſubſtance, to which he aſcribes the volatility of the acid of benzoin, as well as the ſmell of bitter almonds already mentioned.

Scheele failed in his attempt to obtain ether from flowers of benzoin and ſpirit of wine; but, by adding a little ſpirit of ſalt, he obtained a kind of ether which fell to the bottom. On diſſolving this in alkalized ſpirit of wine, and drawing off the latter by diſtillation, he obtained from it a quantity of flowers of benzoin.

1532
Acid of benzoin procurable from Peruvian balſam and urine.

From Peruvian balſam alſo Lehman obtained a quantity of the acid of benzoin. It may alſo be procured from urine, either by precipitation, from the ſaponaceous extract (A), or by repeatedly diſtilling from it ſpirit of nitre, as in the preparation of acid of ſugar. In the urine it is found combined with volatile alkali, by which it becomes ſoluble in ſpirit of wine.

XV. *Sebaceous Acid.*

This is ſaid to have been firſt diſcovered by Mr Gruitzmacker, who publiſhed an account of it in 1748. It was afterwards more accurately treated of by Mr Rhades in 1753. Its properties were inveſtigated by Meſſrs Segner and Knappe in 1754; and afterwards more fully by Dr Crell, of whoſe diſcoveries an account is given in the Philoſophical Tranſactions for 1780 and 1782. It is found not only in the fat of all animals, but in ſpermaceti, the butter of cocoa, and probably in other vegetable oils.

Sebaceous acid.

1533
Sebaceous acid procurable from various ſubſtances.

In ſeveral reſpects it ſeems analogous to the marine acid; but in others it is remarkably different, particularly in precipitating a ſolution of corroſive ſublimate. It is probable, however, that is principles are the ſame with thoſe contained in all other vegetable and animal acids; and this opinion is ſupported by what happens on treating tallow in the uſual manner for obtaining acid of ſugar; for thus, not the ſebaceous, but the ſaccharine acid is found to be produced.

1534
Has a remarkable power of attraction.

It has a very great ſtrength of attraction, and by means of heat decompounds even the vitriolic ſalts themſelves; but in the moiſt way is expelled by the three mineral acids, though it expels all the vegetable ones, as well as thoſe of fluor and arſenic.

1535
Remarkable effect on tin.

Its moſt remarkable property is its effect on tin. The filings of this metal, eſpecially with the aſſiſtance of heat, are corroded by it into a yellow powder, and at the ſame time give out a very fetid ſmell. The ſolution, though filtered, ſtill continues turbid, and depoſits more yellow powder, acquiring at the ſame time a fine roſe-red colour. By adding water to this yellow powder, a white deliqueſcent ſalt may be obtained, and a ſimilar one obtained by diſſolving a yellow powder precipitated by this acid from ſolution of tin in aqua-regia.

1536
Its effects on other ſubſtances.

It corrodes lead rather than diſſolves it; but diſſolves a conſiderable quantity of minium, and changes the reſt to a white powder. This ſolution is ſweetiſh, and is not precipitated by common ſalt. The metal is precipitated by ſebaceous acid from the nitrous, in white needle-like cryſtals, eaſily ſoluble in water. A like precipitation takes place in ſolution of ſugar of lead; but the precipitate is ſtill ſoluble in ſtrong vinegar, provided it be not adulterated with oil of vitriol. In its elective attractions it agrees with the acids of apples and of fluor, preferring magneſia to fixed alkali.

XVI. *Acid of galls.*

Though it has for a long time been known that the infuſion of galls has the property of reddening vegetable juices, diſſolving iron, and decompoſing liver of ſulphur, theſe effects were generally aſcribed to its aſtringency. Of late, however, it has been found, that beſides this aſtringent principle a true acid exiſts in galls; and to this, rather than to the aſtringent principle, are we to aſcribe the properties of galls in ſtriking a black with ſolution of vitriol, &c.

1537
Method of ſeparating the acid.

To ſeparate the acid from the other matters contained in the galls, we muſt add fixed alkali to a decoction of them; by which means the aſtringent matter will be thrown down, and the acid remain in the liquor joined to the alkali, the precipitate, waſhed with clean water, dried, and rediſſolved, blackened a ſolution of vitriol but faintly, and no more than what may be ſuppoſed to proceed from ſome remaining acid, which could not be abſtracted. This is proved by di-

---

(A) By this is meant urine evaporated to a thick conſiſtence, and deprived of moſt of its ſalts by ſolution in ſpirit of wine.

Acid of galls.

1538 An acid obtained from galls by diſtillation.

ſtilling the aſtringent matter in queſtion, when an acid liquor comes over, which has the property of blackening ſolution of vitriol. Scheele has obſerved, that when galls in ſubſtance are expoſed to diſtillation, an acid liquor riſes of an agreeable ſmell, without oil, and afterwards a kind of volatile ſalt, which is the true acid of the galls. Hence he infers, that this ſalt is contained ready formed in the galls themſelves; but ſo much involved in ſome gummy or other matter, that it cannot be eaſily obtained ſeparately.

1539 Properties of this acid.

The acid of galls is capable of being ſeparated by cryſtallization. In an infuſion made with cold water, Scheele obſerved a ſediment which appeared to have a cryſtalline form, and which was acid to the taſte, and had the property of blackening ſolution of vitriol. By expoſing the infuſion for a long time to the air, and removing from time to time the mouldy ſkin which grew upon it, a large quantity of ſediment was formed. On rediſſolving this in warm water, filtering and evaporating it very ſlowly, an acid ſalt was obtained in ſmall cryſtals like ſand, which had the following properties: 1. It taſted acid, effervеſced with chalk, and reddened litmus. 2. Three parts of boiling water diſſolved two of the ſalt; but 24 parts of cold water were required to diſſolve one. 3. It is likewiſe ſoluble in ſpirit of wine; four parts of which are required to diſſolve one of the ſalt when cold, but only an equal quantity when aſſiſted by a boiling heat. 4. The ſalt is deſtructible by an open fire, melts and burns with a pleaſant ſmell, leaving behind a hard inſoluble coal, which does not eaſily burn to aſhes. 5. By diſtillation an acid water is firſt obtained without any oil: then a ſublimate, which remains fluid while the neck of the retort is hot, and then cryſtallizes. This ſublimate has the taſte and ſmell of flowers of benzoin; is ſoluble in water and in ſpirit of wine; reddens litmus; and precipitates metallic ſolutions of the following colours, viz. gold of a dark brown; ſilver of a grey colour; copper of a brown; iron of a black; lead of a white colour; mercury of an orange; biſmuth, lemon-coloured. The acid of molybdæna became yellow coloured, but no precipitate enſued. Solutions of various kinds of earths were not altered; but lime-water afforded a copious grey-coloured precipitate. 6. By treating this acid with that of nitre, in the manner directed for producing acid of ſugar, it was changed into the latter.

XVII. *Identity of the Vegetable Acids.*

1540 Mr Keir's objections to the opinions on this ſubject.
