Fig. 5 shows electron microscopic images of primary particles of medium high viscous plastisol with monomodal particle distribution (< 1 µm) and low viscous with bimodal distribution (particles ≥ 1 µm). In monomodal types, the structure of a three dimensional network, which results in high viscosity, is conceivable. In bimodal distribution, in general, low viscous pastes, their viscosity behaviour can be understood in such a way that small particles are bedded between large ones and so cause a ball bearing effect (Fig. 6). The large particles only have a lower activation threshold S to overcome in their change of position. In addition, it is conceivable that less space needs to be filled with softener in a bimodal distribution (according to Schulz and Herlinger as well as Knittel and Schollmeyer).

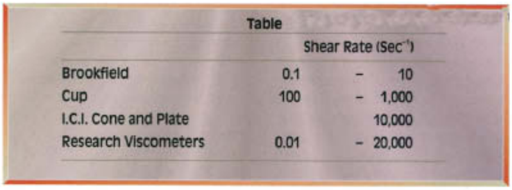
Rheology modifiers/thickeners Although viscosity is often treated as a constant, only a few materials such as water and some mineral oils possess a constant "Newtonian" viscosity. In most fluids, viscosity varies with shear stress or shear rate. To completely describe the rheology of a formulation, it is necessary to know how the formulation handles, pours, pumps, coats, penetrates and spreads. Therefore, the correct choice of a thickener or rheology modifier is an impor-

	Shear Rate (Sec^{-1})
Dispersion	100 - 10,000
Mixing	10 - 1,000
Pouring	1 - 10
Pumping	10 - 500
Spraying	1,000 - 50,000
Rolling	100 - 100,000
Rotary Printing	1,000 - 50,000
Knifing	100 - 50,000
Sagging	0.01 - 0.1
Levelling	0.01 - 0.1

Tab. 1: Typical ranges of shear rates for manufacturing and coating equipment.

tant one. The difficulty in making this choice is that the different processes involve different rates of shear. Generally, latex viscosities decrease with increasing rate of shear (pseudoplastic) and decrease with constant rate of mixing (thixotropic). However, every rheology modifier affects the overall viscosity profile differently. A useful principle for optimising performance of the latex is to test at the shear rates experienced during the course of processing and application. These operations occur over a wide range of shear rate which are shown in Tab.1.

Usually only research laboratories have equipment to measure all these flow situations. Typical plant viscometers, such as Brookfield or Cup (Ford, Zahn etc.) measure viscosity at low shear rates as shown in Tab. 2. This is adequate for pumping, pouring and possibly mixing, but it does not measure the flow characteristics of the coating in higher shear regimes where the system is less Newtonian. A simple tool recommended as a useful indicator to the coating chemist as well as for plant quality control is an I.C.I. Cone and Plate viscometer. When readings are coupled with those from a Brookfield viscometer, the rheological behaviour is seen over a much wider operating range. In these technical notes Brookfield readings are used to describe the handling characteristics of the product or formulation before application – the higher the number, the more viscous the product. Readings from the I.C.I. Cone and Plate viscometer are used to depict high shear behaviour such as those encountered during an application such as roller coating.



Table

	Shear Rate (Sec^{-1})
Brookfield	0.1 - 10
Cup	100 - 1,000
I.C.I. Cone and Plate	10,000
Research Viscometers	0.01 - 20,000

Tab. 2: Typical plant viscometers.

The wide variety of Rohm and Haas Acrysol thickeners and rheology modifiers that are available allow the formulator to choose the thickener that is ideal for his specific needs. Cellulosic materials like hydroxyethyl cellulose (HEC) do not offer the same wide range of products. The Acrysol thickeners provide improved rheological properties, handling chracteristics and resistance to microbial attack. In addition, the thickeners and rheology modifiers can be blended to get an optimal rheology for any application.

Alkali soluble or swellable emulsions: These Acrysol thickeners are acrylic polymers containing acid carboxyl functional groups that are designed either to dissolve or to swell when neutralised with a base. Compared to natural water-soluble thickeners, the Acrysol ASE family of polymers are considerably higher in molecular weight. Because they are produced by emulsion polymerisation, these polymers are present as dispersed particles (not in solution). They are therefore supplied and can be handled at low viscosity, and the shipment of viscous low solids solutions is avoided. These emulsions are much easier to use than conventional cellulosic and polyvinyl alcohol solutions. At the point of use, the Acrysol products are neutralised to produce clear, viscous solutions (Acrysol ASE-95) or clear, highly swollen dispersions (Acrysol ASE-60). These products can be incorporated directly into formulations to be thickened without any necessity for slow preliminary preparation of a separate thickener solution. This in-situ thickening is a marked advantage over procedures usually used with natural thickeners (e.g. alginates) or with semi-synthetic polymers (e.g. methyl cellulose, carboxy methyl cellulose). However, it is highly desirable to predilute the Acrysol emulsion with at least an equal amount of water and to keep the pH as low as possible until the Acrysol thickener has been thoroughly stirred in. Adjustment of the pH to swell or dissolve the thickener then brings the formulation to the desired viscosity smoothly and rapidly.

Associative thickeners (AT's) are water soluble/dispersible polymers containing hydrophobic groups which are capable of forming intermolecular associations and absorbing onto the surface of dispersed particle, thus providing thickening power much greater than unmodified polymers of similar molecular weight. Because AT's are capable of non-specific hydrophobic association similar to surfactants, they are sometimes referred to as polymeric surfactants. Just as surfactants are capable of absorbing onto both the latex binder and pigment particles in a formulation, the AT's can absorb onto these dispersed particles, both enhancing thickening efficiency and, in a properly formulated coating, assuring a stable, uniform dispersion. Emulsions thickened with these products are characteristically free from flocculation, and possess more nearly Newtonian rheology than comparable emulsions thickened with conventional water soluble polymers such as cellulosics. In practice, these features provide benefits of improved flow and firm build and improved film formation. The Acrysol associative thickeners can be broken down into two groups: the nonionic ethylene-oxide based urethane block copolymers and the anionic hydrophobically modified alkali-soluble acrylic copolymers. With these two classes, a growing number of products provide performance/cost benefits suited to a wide range of formulation types. The former provide the highest level of performance in terms of both rheology and film properties, but generally are more difficult to handle than the alkali-soluble associative thickeners. Films of emulsions thickened with the nonionic AT's have improved water and alkali resistance. The anionic AT's are supplied as low viscosity acidic latexes which can be added directly to the formulation and neutralised for in-situ thickening.

Effects on thickening efficiency: Since the hydrophobic association and absorption exhibited by these thickeners is non-specific, it is greatly influenced by the presence of surfactants and water miscible organic solvents. The hydrophobes of surfactants may compete for absorption sites on particle surfaces and can hinder or enhance associations between thickener hydrophobes, depending on the surfactant HLB (Hydrophile-Lipophile Balance). Nonionic AT's rely heavily on association to build low shear viscosity and are therefore very responsible to formulation modifications that have the effect of decreasing association between thickener molecules or with dispersed particles. Therefore, since the nonionic thickener is low in molecular weight, low shear viscosity can decrease rapidly as thickener is desorbed from the latex surface. Viscosity at high shear rates, where associations have less of a role, is essentially unaffected.

The choice of latex binder can have a major effect on interaction with the associative thickeners. This is not unexpected, since latexes vary in surface hydrophobicity due to their composition and the surfactants and stabilisers used in their preparation, and can vary in the surface available for associaton due to the wide particle range in which latexes are supplied. Type and particle size of pigments and extenders are not usually important, since these tend to be more hydrophilic. Choice of dispersing agent and the level used often have important effects, both by bringing the pigments into the interaction and by associating directly with the rheology modifier. Water-miscible solvents can modify the association by changing the solubility parameters of the aqueous continuous phase, relative to the dispersed phase of the coating.

Methods of thickening and formulating: It is helpful to understand the function of all three Acrysol ASE products as thickeners to consider their neutralisation analogous to a weak acid-base tritation. See Fig. 1 for Acrysol ASE-60 and Fig. 2 for Acrysol TT-615. Ammonia is the base employed in nearly all applications because it is fugitive and therefore does not harm the water resistance of the formulation after application and drying. A volatile base is also necessary when curing the conventional, acid-catalysed, self-crosslinking, acrylic chemistry. Thickening always occurs rapidly to the Acrysol ASE products. The time required is essentially the same as that necessary to obtain intimate mixture with the base solution. Often the Acrysol ASE acrylic thickeners can be added directly to a system without pre-neutralisation. This eliminates the handling of a highly viscous solution entirely. In these cases, the Acrysol emulsions should be pre-diluted with an equal weight of water being added to the sytem. The diluted emulsion should be dispersed quickly and uniformly to avoid localised concentration of acid polymer. This will prevent any undesirable "pH shocking" of the system which results in grit formation. Solubilisation and thickening will take place in-situ if the system contains enough free alkalinity. If it does not, alkali can be added to induce thickening. Thickener solutions are shear thinning and therefore easy to mix. When any of the Acrysol ASE products are added to formulations that are pre-neutralised or partially neutralised, good agitation is always necessary to ensure complete mix-

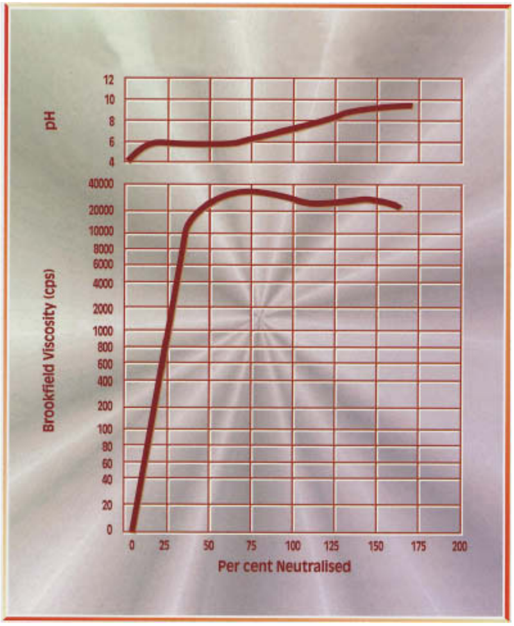


Fig. 1: Viscosity and pH change upon neutralisation of Acrysol ASE-60 with NH_4 OH at 5% polymer solids.

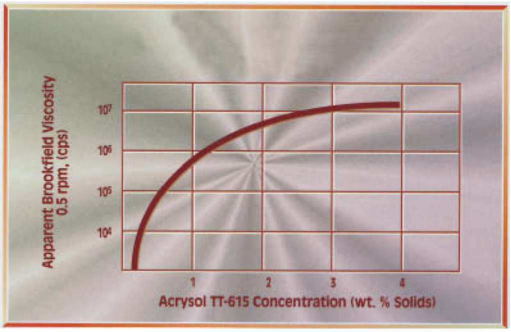

Fig. 2: Viscosity vs concentration for neutralised Acrysol TT-615.

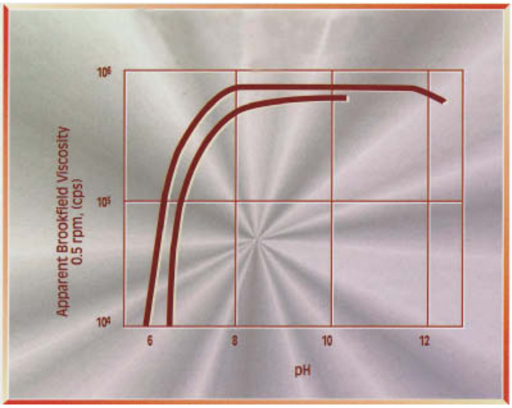

Fig. 3: Viscosity vs pH neutralised Acrysol TT-615 at 1% solids.

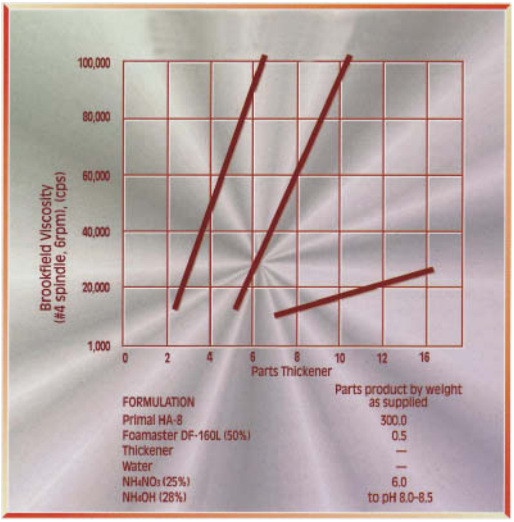
ing. However, a vortex should be avoided to prevent unwanted air entrapment. Once neutralised and put in soluble form, the emulsion thickeners cannot be reverted to emulsion form, as a reduction in pH will precipitate the polymer. The Acrysol ASE emulsions are completely neutralised at approx. pH 8.0. The polymer on which the formulation is based will affect the thickening efficiency of the Acrysol products.

Acrysol TT-615 is an alkali-swellable acrylic polymer emulsion. Viscosity is developed by neutralisation to a pH of 7 to 10. Its thickening efficiency is unmatched by any other polyacrylate thickener especially in formulations having a high electrolyte content. It is particularly suited for low solids formulations used in textile printing or highly filled and "difficult" formulations in addition to standard backcoating, flocking and laminating applications. The thickening efficiency is even greater when electrolytic catalysts, such as ammonium nitrate, are not used. Acrysol TT-615 thickener can be added to formulations on the acid side and the compound mix then thickened by the addition of base. The product contains functional groups that are designed to dissolve or swell when neutralised with a base. It should be pre-diluted with at least an equal weight of water before being added to the mix. The diluted emulsion should be dispersed quickly and uniformly to avoid localised concentration of acid polymer. Any base appropriate to the formulation can be used: ammonia, sodium, hydroxide, sodium carbonate, triethanol amine, etc. Alternatively, Acrysol TT-615 can be pre-neutralised; addition of base and alcohols yield a viscous syrup for use where the formulation is already at high pH. The effect of thickener concentration and pH on the viscosity of aqueous solutions of Acrysol TT-615 thickener is shown in Figs. 2 and 3. Fig. 4 compares the performance of Acrysol TT-615 with Acrysol ASE-60 and ASE-95 in a typical textile backcoating formulation.



FORMULATION	Parts product by weight as supplied
Primal HA-8	300.0
Foamaster DF-160L (50%)	0.5
Thickener	—
Water	—
NH_4NO_3 (25%)	6.0
NH_4OH (28%)	to pH 8.0-8.5

Fig. 4: Comparison of thickeners in a typical backcoating formulation.

Acrysol RM-825 is an efficient nonionic associative thickener. Because it is supplied at a low solids, it has a lower viscosity and is easier to handle. Its thickening efficiency is not sensitive to changes in pH. It is supplied as a pumpable liquid and should not require dilution. However, if dilution is desired, it should be done with a blend of 25 butyl Carbitol/75 water (the same solvent composition as in the thickener.) Diluting with butyl Carbitol alone offers no reduction in viscosity over the solvent blend and can cause flocculation of the thickener. On dilution with water, the viscosity of the solution will decrease to a minimum and then increase rapidly.

Rheometer Device for measuring rheological properties, consisting of two coaxially arranged movable cylinders.

Rheopexy (flow bonding), rheological property, which in the disperse system under isothermal, reversible and temporary conditions, results in an increase of the apparent → Viscosity under the influence of mechanical shearing strain (dilatancy). The → Thixotropy contrasting behaviour that solidifies a sol or a suspension during movement, e.g. through rhythmic beating or scutching, into a solid mass (e.g. gel), becomes liquid again immediately after the movement stops.

Rib fabrics Collective name for all materials, which have a ribbed appearance. The ribs may be in a longitudinal or transverse direction (longitudinal or transverse rib), in which the latter predominates; even diagonally in exceptional cases (inclined rib). For the transverse rib, in addition to the rib weave (→ Weave) the cloth weave is also considered, whereby the warp should have considerably more dense threads and the weft should be very coarse. Made from worsted and/or carded yarns, in which generally higher valency yarns are used for the outre thread system. Chiefly used for women's outerwear.

Ribbed spreader rollers On hank contacts for expanding work. Are provided with externally raised spiral ribs running from the centre to left and to right (Fig. 1), which stretch the fabric web through the gripping angle as the two ribbed spreader rollers of the same type rotate (Fig. 2).

Fig. 1: A ribbed spreader roller.

Fabric web correction is carried out using two swivel/slide rollers, driven by a d.c. motor. Scanning of the fabric web or edge is done by optoelectronic sensors. The controller transmits the signal to the actuator drive. The actuator speed is proportional to the deviation from the desired value in the corresponding sensors. Tracking using wide-angled light barriers is not applicable for different fabric widths.

Ribbon → Narrow fabric.

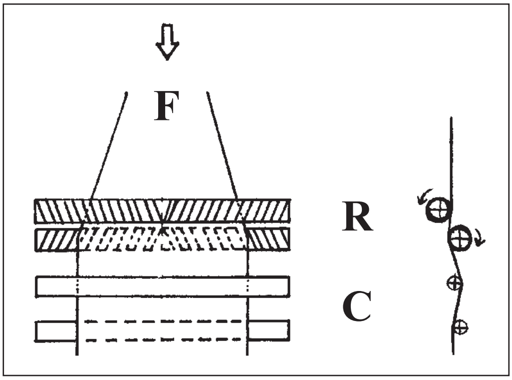


Fig. 2: Fabric feed when using two ribbed spreader rollers. F = fabric; R = ribbed spreader rollers; C = control rollers.

Ribbon cutter Textile or other stiff fabrics may be cut into ribbons using circular knives (see Fig.), electrically heated wires or by laser beams and/or ultrasound.

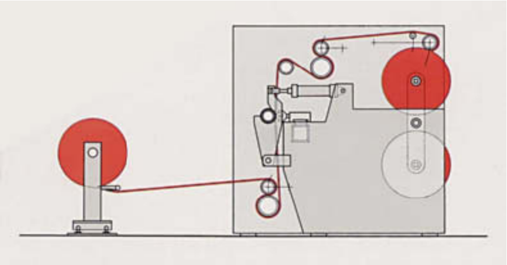

Fig.: Ribbon cutter (Menschner).

Rib-knit fabrics → Knitted fabrics which appear to have only plain stitches on both sides, although plain and reverse stitches alternate and in each wale there are only either plain or reverse stitches. They are described as double-face due to the fact that the look is the same on both sides. Two-way stretch and more elastic than (single face) plain knit goods. Use: for sweaters, jackets, knitted tops, sleeves, trouser leg cuffs, underwear.

Rice starch Crystal, lump, powder form. Pure white, similar to wheat starch; break and surface area are smooth; not yellowish. Handle smooth and supple. Water content 12–14%. Rarely adulterated. Heated bloating: swelling at 53.7°C, start of gelatinisation at 58.75°C and ends at 61.2°C. Paste: similar to wheat starch, hygroscopic; greatest adhesive strength of all the starch pastes. Finishing handle hard and robust. Used as starch.

Rigid foam → Foam.

Ring accumulator A dwell device (see Fig.) for

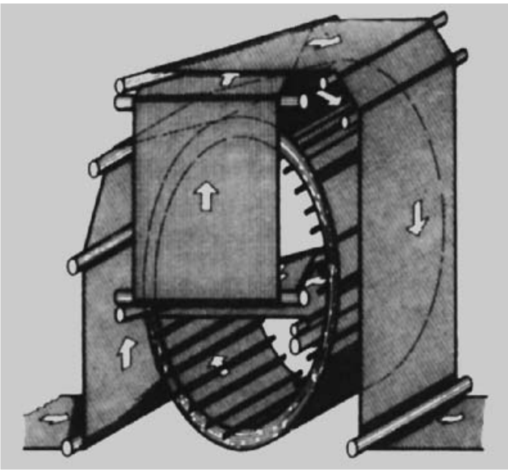

Fig.: A continuous reaction ring accumulator (Babcock-Artos).

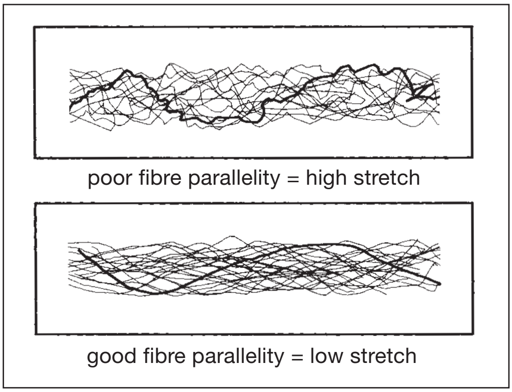

Fig. 1: Consequences of the different parallel layouts of the fibres in yarn and yarn twist.

advantages	disadvantages
– low yarn irregularity – reduced thin and thick points depending on the spinning machine – more favourable winding tension (less barriness in the weft) – higher extension coefficient – better abrasion resistance – better running	– yarn structure – harder, stiffer threads – dull appearance – strength

Tab. 1: The differences of rotor-spun yarn (compared with ring-spun yarn) from the point of view of finishing.

processes which require a set time for continuous implementation. The floor space for a corresponding steamer is considerably larger for the same output.

Ring dyeing Dyeing, in which the fibre cross-section is not completely dyed through. The dye is like a sheath on the outer periphery of the individual fibre; the fibre core is not stained or only stained to a slight degree. Depending on process, fibre type and dye, ring dyeing is a common occurrence, particularly for densely packed, crystalline fibre materials, for large molecular dyes and for short-time dyeing processes. In extreme cases, ring dyeing results in visually higher yields, in poor colour fastness to rubbing and in use in whitish worn areas (cut-pile carpets).

Ring main Main starting from the central supply system and leading back again with individual tappings at the point of consumption. Facilitates simultaneous supply of several machines or devices widely separate from each other.

Ring-spun/rotor-spun yarns, behaviour in finishing If the structures of two different yarns shown in Fig. 1 are considered, the correlation between yarn twist and fibre parallelism becomes clear. It is plausible that a yarn with a less parallel structure would have a higher elongation than a yarn with a higher fibre parallelism, as the fibres which are not lying parallel are firstly tightened and almost uncurled before higher tensile forces can be taken up. Such a confusing situation may however not be the aim of an optimised yarn design. A considerable increase in the parallel position of the fibres in the rotor ring has meanwhile been achieved through improving the spinning process in rotor spinning and influencing the spinning elements. This led both to a reduction in the elongation at break and to an increase in yarn strength. An important step towards having fewer fibres in the yarn cross-section was thereby made at the same time and to a reduction in the twist coefficient.

Another yarn structure (Tab. 1) is inevitably produced from the principle of different yarn production of rotor and ring-spun yarn. A lower reflection of light occurs in the rotor-spun yarn and items manufactured from this seem darker and more matt as a result (Tab. 2). In order to obtain more gloss, brighter shiny fibres may therefore be used by preference in the case of man-made fibres. Higher reflection values should only conditionally be obtained in cellulosic fibres using chemical processes so that you should fall back upon mechanical finishes and/or upon particular pre-treatment processes. The strengths of rotor-spun yarns are less than in ring-spun yarns, which has an effect on the finished article. The harder, stiffer thread, which is produced by the OE-spinning technique, eventually causes the main problem for rotor items, namely the tough and hard handle.

Rotor-spun yarns have fewer anti-slip problems due

Ring-spun/rotor-spun yarns, behaviour in finishing

a little higher	swelling number	a little lower
worse	emerizing and roughening	better
greater	volume	smaller
approximately the same	wash-and-wear effect	approximately the same
approximately the same	crumpling	approximately the same

Tab. 2: Finishing characteristics of fabrics woven from either ring-spun or rotor-sprun yarns.

to the stronger mechanical adhesion tendency. Poorer dry crease angles, but better wet crease angles are obtained with fabrics made from rotor-spun yarn (independent of the cellulose crosslinker type) than with ring-spun yarn. Ring-spun yarns have a more favourable reaction in the washing shrinkage test, which is possibly related to the lower source value. Water repellent effects are achieved on both yarn types in a similar order of magnitude.

There are problems with the handle of rotor-spun yarn items; such high softener additives are required, that tear resistance and seam strength suffer. The explanation for the poorer handle in rotor items can be found in the fact that on the one hand the processed rotor-spun yarn has a greater rigidity and lower flexibility. On the other hand, a rougher surface results because of the confused position of the fibres compared with the greater parallelism in the ring-spun yarn. In special cases where normal softener systems do not have any success, the use of microemulsions may be of help, as an optimum degree of distribution is achieved as a result of the smaller particle size and the desired "inner softness" occurs as a result.

The fabric handle consists of at least three individual characteristics as does the fabric optics:

– softness (flexural strength),
– surface roughness,
– knitted volume and/or fabric thickness.

The knitted volume is in turn determined by the thickness and compressibility of the knitting. Rotor-spun yarn knits are slightly thinner than ring-spun yarn knits with the same density factor (Fig. 2). This becomes particularly noticeable in the fabric handle. The yarn volume represented by the yarn hairiness can be established as the cause of the lower thickness. Despite worldwide efforts, no one has yet succeeded in recording by measurement techniques the differences, never-

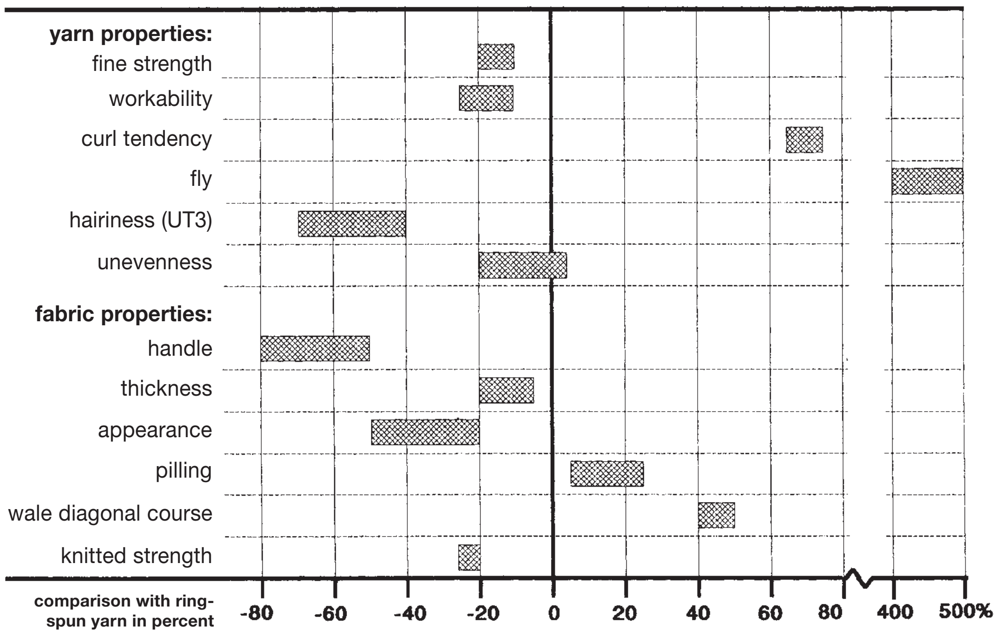

Fig. 2: The characteristics of rotor-spun yarn articles compared with ring-spun yarn articles, given in %.

	ring-spun yarn fabric	rotor-spun yarn fabric

Tab. 3: Differing characteristics of ring-spun yarn and rotor-spun yarn articles.

theless small, in flexural strength and surface roughness between ring-spun yarn and rotor-spun yarn items of the same yarn counts, sensed well by experienced and also by inexperienced test persons. The yarn parameters predominantly responsible for the fabric handle are hairiness (yarn volume) and twist (rotation coefficient).

There are cases where it is no longer possible to improve the handle with normal padder finishing. Even an extremely high amount of softeners brings no improvement in these cases. It is necessary to take measures to crush the fabric even before finishing. Mechanical processes (calendering, emerizing, crushing, microstretching processes [Raduner], etc.) are used for example and/or additional chemical finishing processes (caustic treatment, pre-scrooping agents, etc.). Microemulsions are chiefly used in the so-called pre-scrooping agents in order to obtain an optimum distribution. Drying then takes place and the actual finish recipe formulation is applied on the padder. The usual drying, condensing and final finish of the material follows. So considerable additional quantities of products used and/or process changes and thereby a rise in the cost of finishing are partly necessary for fabrics and knitgoods manufactured from ring-spun yarn. In many cases, however, as mentioned, no other possibility is available with regard to improving the handle and an increase in costs must therefore be accepted.

For a long time, rotor-spun yarns have been used chiefly for coarse to medium fine qualities, even finer yarns (up to approx. 14 tex) are manufactured cost-efficiently today and are, for example, used in the shirt, blouse and dress goods sector. This means a rethink for the finisher (Tab. 3), who has been used to expect rotor-spun yarns only in coarser fabrics and was not so strongly confronted with the problem of handle and strength. A hard, brittle handle and a too great loss of strength are chiefly the criteria on rotor-spun items, which are to be optimised in the finishing. In addition, a better gloss is often demanded whereby this is however of secondary importance. So the finisher must know whether the fabric to be finished is manufactured from ring-spun or rotor-spun yarn, as different treatment methods are necessary (in accordance with Tetzlaff as well as according to Schönung and Bay and according to Bühler and Haid and according to Brockmanns and Landwehrkamp).

Ring-spun/rotor-spun yarns, properties of The replacement of the relatively heavy spinning wings of the wing-spinning machine from Arkwright with a trailing circular slide was the birth of the ring-spinning machine. The crucial invention goes back to the Americans Thorp and Jenks from 1828 and 1830 (Fig. 1). Only towards the end of the 19th century did industrial installation take place as a continuously operating, universal spinning machine. The ring spinning process has in principle hardly changed today and still represents the dominant spinning process. The almost complete replacement of knot technology by splicing and the possible link of spinning and rinsing machines produced an increase in the efficiency of the spinning process besides an improvement in quality in the spun product.

In ring spinning, the relative strengths are as shown in Fig. 2 and the processes in the spinning delta as in Fig. 3.

In a 4 mm long spinning delta, 75% of all the fibres are merged between clamping line and yarn end in the conventional ring spinning process; 25% of the fibres "swim". If the spinning delta becomes larger at higher spinning rates, the percentage of "swimming" fibres increases, which worsens spinning stability. The traveller speed increases from 34-38 m/s (conventionally) by approx. 20% during heavy duty spinning. Considerably

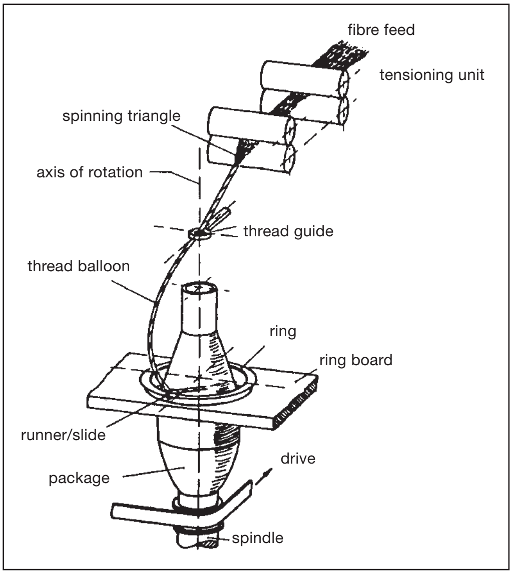

Fig. 1: The ring spinning principle.

Ring-spun/rotor-spun yarns, properties of

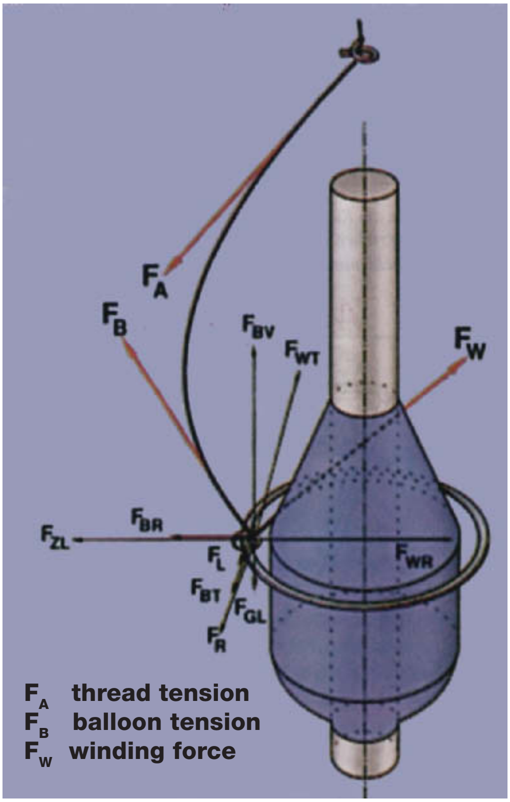

Fig. 2: Forces in the ring spinning process.

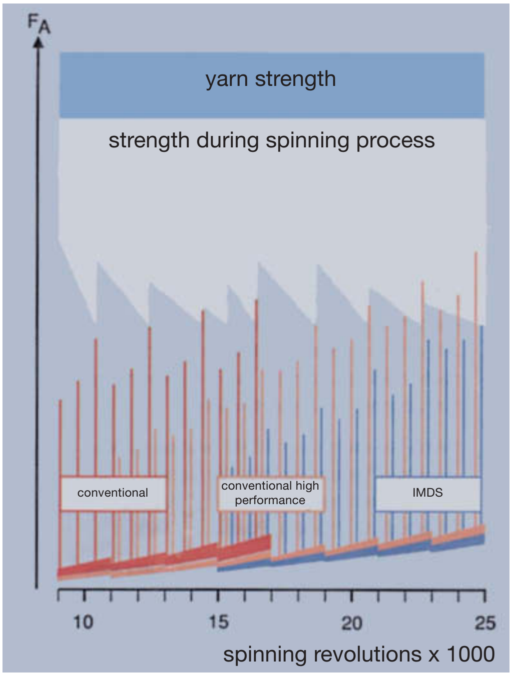

Fig. 4: Thread tension during ring spinning.

higher spindle speeds (up to 20 000 rpm) are achieved using individual spindle drive (IMDS), in which the thread tensile force F_A acting into the spinning delta is

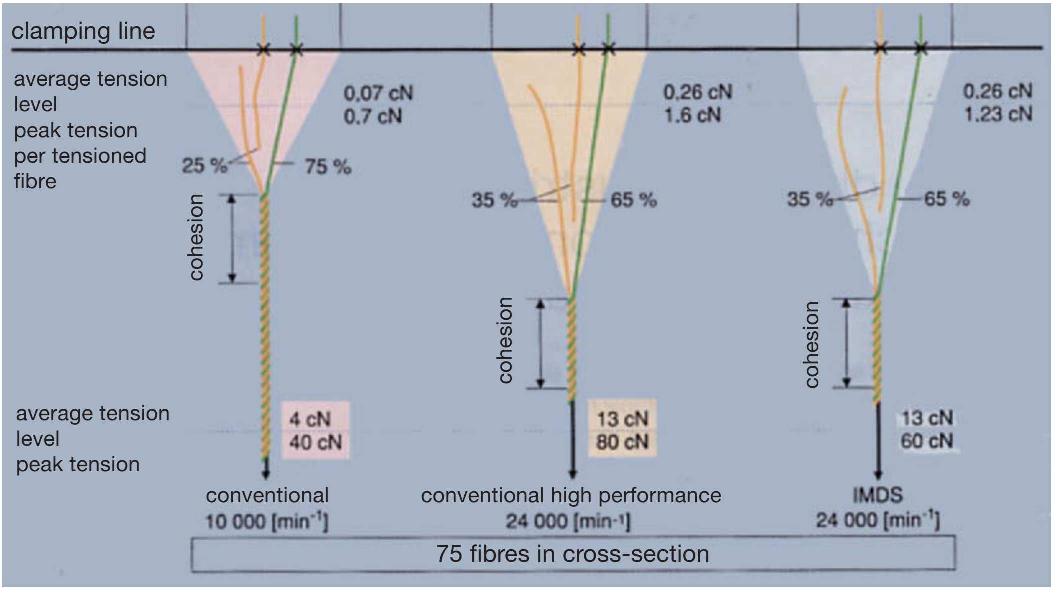

Fig. 3: The formation of yarn during ring spinning (spinning triangle).

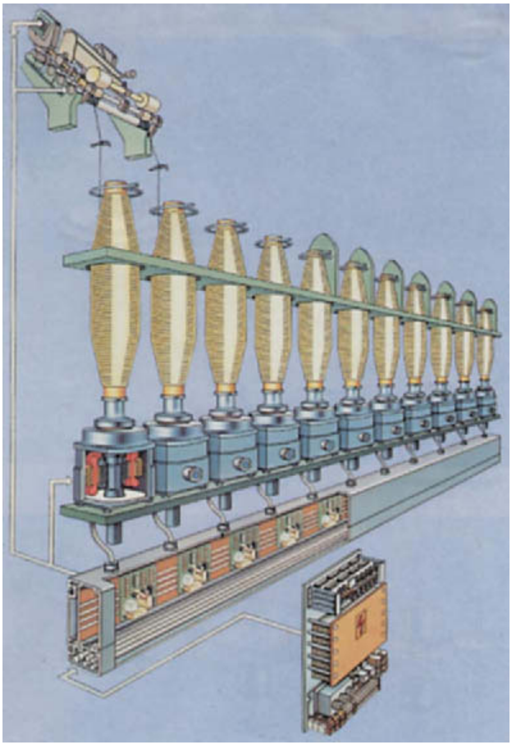

Fig. 5: The IMDS individual motor drive system on a ring spinning machine.

equal in heavy duty types (band drive in groups or individually; individual motor drive IMDS) (Figs. 3–5).

The demand of the ring spinning process for a combination yarn twist and yarn winding restricts the speed of the spindle and therefore the production speed as a result of the thread loads. The maximum possible rotor speed and the necessary power required furthermore restrict the format of the yarn carrier. The obligatory interruption of the spinning process, after filling the yarn carrier, and the desire for an increase in production speeds had already led to completely new thoughts on yarn formation and yarn bonding at the start of the 19th century.

The manufacture of a spun yarn with ring-like twist structure is thereby additionally possible in accordance with the classical principle by means of distortion of a fibre lattice and twist issue with the rotating yarn carrier on which isolated fibres on the free end of a thread are twisted (Fig. 6). This type of spinning is described as open-end spinning due to the necessary temporary loss of contact of individual fibres underneath each other. The big advantages of this process compared with ring spinning lie in:

- the considerable reduction in the rotary mass required for giving twist,

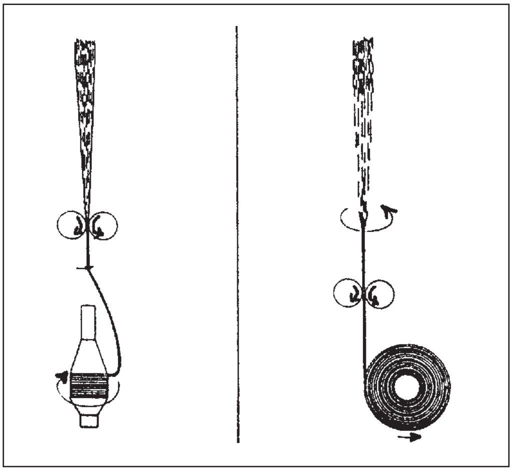

Fig. 6: Uninterrupted spinning (left) and spinning with an "open" yarn end (right).

- the independence from the reference format
- the independence from the format of the winding media.

In contrast to the ring-spinning process, the distortion mechanism and given twist are switched between the flow of material in the → OE-spinning process (Fig. 7). The yarn twist is hereby produced by rotating the bent yarn end around the yarn and/or rotor axis. The rotor groove picks up the yarn end and the distance of the rotor axis to the rotor groove represents the moment arm to produce a torque.

The counter-torque created in the finished yarn causes a twist in the piece of yarn within the rotor during each rotor revolution. The yarn rotation causes the

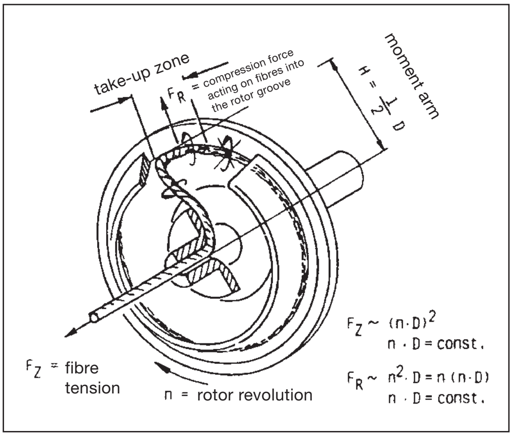

Fig. 7: The take-up zone and the relationship of forces during OE rotor spinning.

fibres built up in the rotor groove to interlink. The twist of the yarn is reproduced in the rotor rotational direction until the torque acting on the yarn is in equilibrium with the frictional force between yarn and rotor grooved wall. This zone is described as the merging zone and represents an important dimension as regards spinning technology. The longer the merging zone the more safely the spinning process runs in general. The advantage of higher spinning stability at longer merging zone length may however be faced with disadvantages as regards yarn technology.

An enhancement in performance of rotor spinning machines can be achieved to a certain degree via the reduction of the rotor diameter (Fig. 8).

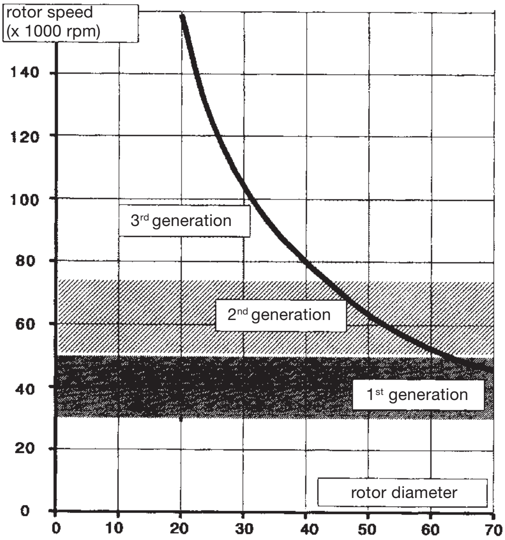

Fig. 8: Increasing the rotor revolution rate by reducing rotor diameter.

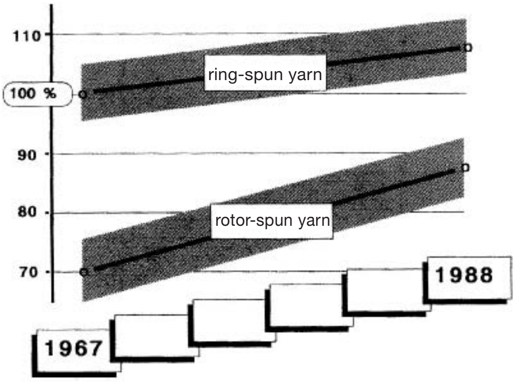

Fig. 9: Advancement in yarn tear resistance from 1967–1988 (Schubert and Salzer).

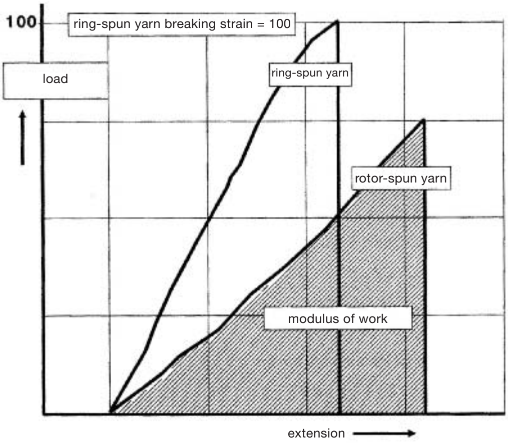

Fig. 10: Diagram showing the breaking strain, extension and workability of ring-spun and rotor-spun yarns.

In principle the tear strength of a ring-spun yarn is higher than that of a rotor-spun yarn (Fig. 9); however an improvement in tear strength by 20% could be achieved by enhancement of the ring-spun yarn strength by 10% as a result of machine construction improvements on ring-spinning machines at the same time through optimisation of the rotor spinning machines. The properties of ring-spun yarn and rotor-spun yarn prove to be considerably different in the force/extension curve (Fig. 10) as well.

Ring-spun yarn Yarn from the ring spinning frame.

Rinse liquors, economization Lowering the water consumption in machine dyeing through process controlled reduction of the amount of rinse liquors. Reduction in rub fastness, etc., is feared, for example, which is why rinsing is carried out for a longer time in case of doubt. A controlled delimitation of the amount of rinse liquors is offered to lower water consumption, as according to experience, the machine is filled 3–6 times for rinsing. If the rinsing process is regarded as a measure to be derived from laws of liquor dilution, it has the advantage that order of priority and effectiveness of water-saving measures during rinsing can be assessed more certainly and carried out in a more targeted way. Control of the rinsing is regarded as a favourable alternative, over remaining liquor concentration through inductive liquor conductance measuring systems, which are relatively insensitive to addition and coating influences and it also has a sufficiently broad effective range (→ Rinse water control systems). Convenient installation on the rinse liquor exit. Installation in the liquor circulation of the machine is recommended, principally in the supply to the circulating pump, as such current measurements also make the

process run more transparent; possibly practical with connection of a recording device (for process comparisons, item conversions and similar).

Rinse water control systems offer checked, controlled injection of fresh water required in accordance with the principle "in each rinsing phase of determinable electrolyte content" or using continuous colour measurement in accordance with the transmission principle.

Rinsing Thinning, washing out, rinsing away of substances attached to the surface or inside fibres with water or solvent.

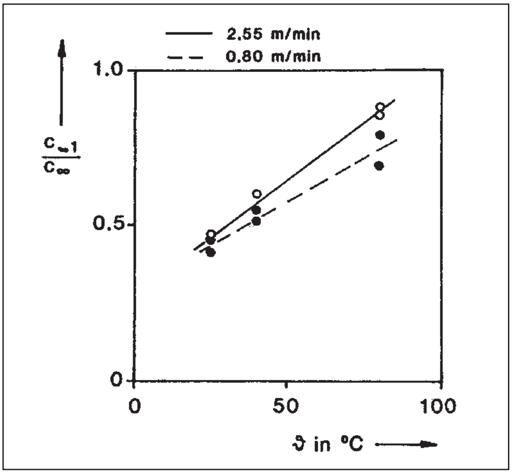

Fig. 1: Accessibility. A reactive dye hydrolysate on cotton (according to Heidemann and Schollmeyer).

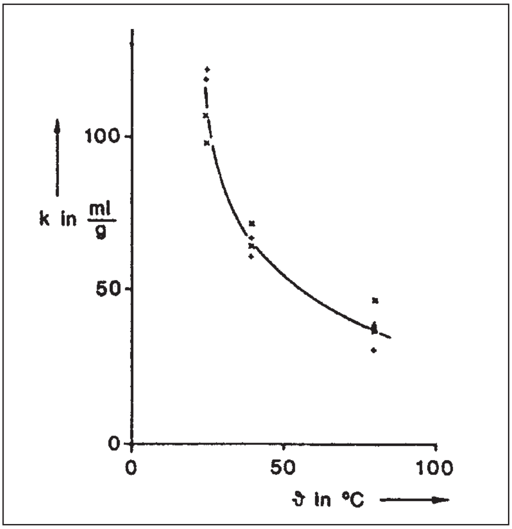

Fig. 2: Coefficient of distribution. A reactive dye hydrolysate on cotton (according to Heidemann and Schollmeyer).

In practice distinctions are made between the following:

- batch rinsing (15l/kg water consumption) and rinsing in the overflow (20l/kg water consumption),
- the counter current principle of rinsing in each individual wash compartment in continuous operation.

Apart from the time and the amount of water and besides the flow mechanisms in dyeing, temperature has an influence on the rinsing effect. The rinsing of a reactive dyeing (washing off of the hydrolysed dye), for example, comprises the influence of the temperature on

- the mass transfer coefficient, which is only slightly greater at a higher temperature because the diffusion coefficient of reactive dye hydrolysates does not increase so much with the temperature;
- the accessibility of cotton, which considerably increases with the temperature (Fig. 1);
- the distribution coefficient, which is reduced with increasing temperature (Fig. 2).

A slow and quick process is evident (Fig. 3).

$$c_1 = c_{\infty 1}\,[1 - \exp(-\beta_1\, t)]$$
$$c_2 = c_{\infty 2}\,[1 - \exp(-\beta_2\, t)]$$

$$c = c_1 - c_2 = c_{\infty 1}\,[1 - \exp(-\beta_1\, t)] + c_{\infty 2}\,[1 - \exp(-\beta_2\, t)]$$

$$\frac{c}{c_\infty} = \frac{c_{\infty 1}}{c}\,[1 - \exp(-\beta_1\, t)] + (1 - \frac{c_{\infty 1}}{c_\infty})\,[1 - \exp(-\beta_2\, t)]$$

$\beta_1 >> \beta_2$, then the following applies for a large value of t

$$\ln(1 - \frac{c}{c_\infty}) = \ln(1 - \frac{c_{\infty 1}}{c_\infty}) - \beta_2\, t$$

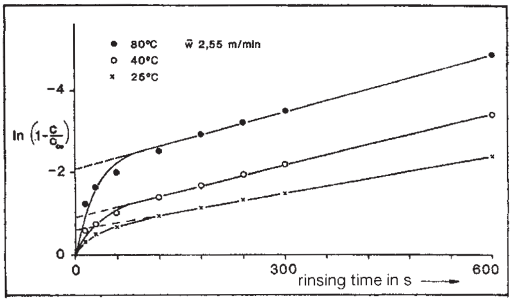

Fig. 3: Rinsing, reactive dyeing on cotton in a stationary bath (according to Heidemann and Schollmeyer).

When the first partial process has run, calculations can be made from the equation and the measured values for c for the times t using a compensating calculation c_∞, $c_{\infty 1}$ and β_2. β_1 can also be calculated from a measuring point with a small t.

process run more transparent; possibly practical with connection of a recording device (for process comparisons, item conversions and similar).

Rinse water control systems offer checked, controlled injection of fresh water required in accordance with the principle “in each rinsing phase of determinable electrolyte content” or using continuous colour measurement in accordance with the transmission principle.

Rinsing Thinning, washing out, rinsing away of substances attached to the surface or inside fibres with water or solvent.

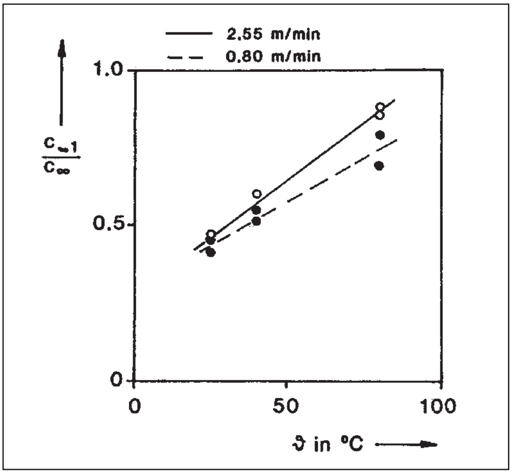

Fig. 1: Accessibility. A reactive dye hydrolysate on cotton (according to Heidemann and Schollmeyer).

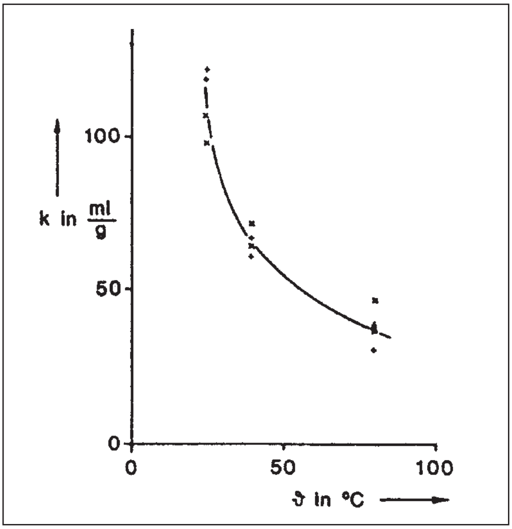

Fig. 2: Coefficient of distribution. A reactive dye hydrolysate on cotton (according to Heidemann and Schollmeyer).

In practice distinctions are made between the following:

- batch rinsing (15 l/kg water consumption) and rinsing in the overflow (20 l/kg water consumption),
- the counter current principle of rinsing in each individual wash compartment in continuous operation.

Apart from the time and the amount of water and besides the flow mechanisms in dyeing, temperature has an influence on the rinsing effect. The rinsing of a reactive dyeing (washing off of the hydrolysed dye), for example, comprises the influence of the temperature on

- the mass transfer coefficient, which is only slightly greater at a higher temperature because the diffusion coefficient of reactive dye hydrolysates does not increase so much with the temperature;
- the accessibility of cotton, which considerably increases with the temperature (Fig. 1);
- the distribution coefficient, which is reduced with increasing temperature (Fig. 2).

A slow and quick process is evident (Fig. 3).

$$c_1 = c_{\infty 1}\,[1 - \exp(-\beta_1 t)]$$
$$c_2 = c_{\infty 2}\,[1 - \exp(-\beta_2 t)]$$

$$c = c_1 - c_2 = c_{\infty 1}\,[1 - \exp(-\beta_1 t)] + c_{\infty 2}\,[1 - \exp(-\beta_2 t)]$$

$$\frac{c}{c_\infty} = \frac{c_{\infty 1}}{c}\,[1 - \exp(-\beta_1 t)] + \left(1 - \frac{c_{\infty 1}}{c_\infty}\right)[1 - \exp(-\beta_2 t)]$$

$\beta_1 >> \beta_2$, then the following applies for a large value of t

$$\ln\left(1 - \frac{c}{c_\infty}\right) = \ln\left(1 - \frac{c_{\infty 1}}{c_\infty}\right) - \beta_2 t$$

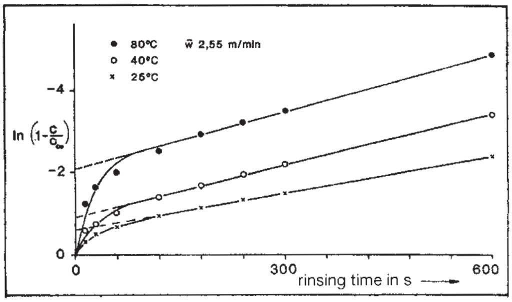

Fig. 3: Rinsing, reactive dyeing on cotton in a stationary bath (according to Heidemann and Schollmeyer).

When the first partial process has run, calculations can be made from the equation and the measured values for c for the times t using a compensating calculation c_∞, $c_{\infty 1}$ and β_2. β_1 can also be calculated from a measuring point with a small t.

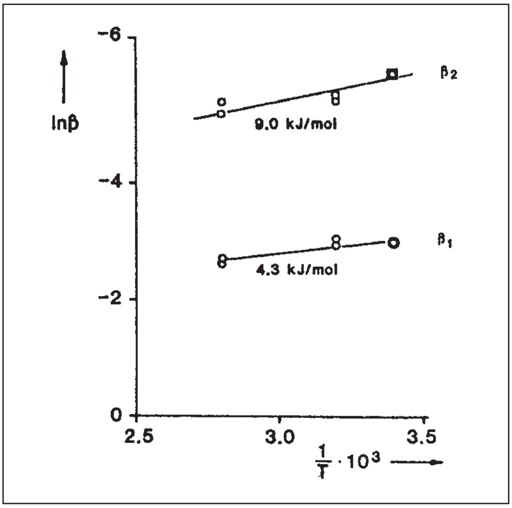

Fig. 4: The activation energy of desorption. A reactive dye hydrolysate on cotton (according to Heidemann and Schollmeyer).

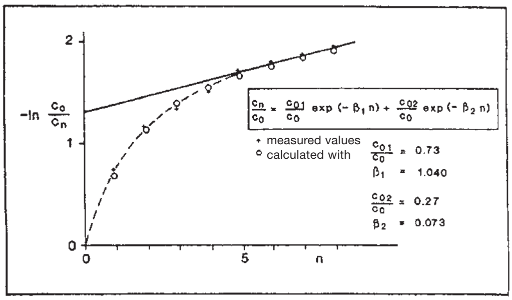

Fig. 5: Open width washing following reactive dyeing. Operational trial: 60 m/min of 165 g/m² cotton fabric (according to Heidemann and Schollmeyer).

An Arrhenius equation of the mass transfer coefficients (Fig. 4) produces very little activation energies for dye desorption, in which the lower accessibility of the ranges of the 2nd process also requires a higher activation energy. The distribution coefficient can be calculated from the equilibrium values calculated for the liquor and the quantity of dye hydrolysates padded on the fabric, which shows a distinct temperature dependency (Fig. 3). In summarising, it can be established that the rinsing of a reactive dyeing on cotton can be described using two desorption processes of pseudo 1st order running in parallel. The model can be converted freely in practice as the results described in Fig. 5 show, which were obtained on an open-width washing unit with eight compartments. The concentrations calculated in the individual wash compartments agree well with the measured values (Heidemann and Schollmeyer).

Rinsing contact Correct condition for optimum rinsing effect/time is the most rapid thinning possible of the substance sticking to the fabric surface. Can be achieved through intensive fabric movement, intensive air mixing, counter current or series rinsing in cascades. → Rinse water control systems.

Rinsing water is used for washing out (rinsing out) in accordance with the washing process. Important in all textile finishing processes in order to completely remove remains of textile auxiliary.

Rising roll batcher,

I. Batching device for open-width fabrics, operating at constant surface speed, with indirect drive. The batching roller lies on two driven rollers located horizontally adjacent to each other its axis is fitted laterally into vertical gliding rails. The roller rises in the rails as the diameter of the batching roller increases. The rising roll batcher is only suitable for smooth piece goods, as the whole weight of the yarn package constantly presses onto the fabric.

II. → Roll batcher in which the yarn package lies on one or two rollers, of which at least one is driven at constant speed. The winding spindle rises in a guideway as yarn package diameter increases. (→ Batching drives).

Rkm Tearing kilometre; → Breaking length.

Rn Element symbol for radon (86).

Roasted starch → Dextrines.

Roberto rolls Squeeze rollers, with a pressed steel core with porous natural/man-made fibre. 20–50% improvement in the squeezing effect compared with soft rubber roll. Action: firstly saturated with liquor, then squeezing as other squeeze rollers, at the same time the highly elastic, porous covering is compressed,

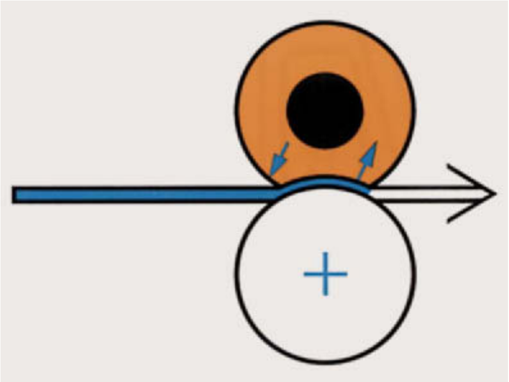

Fig.: The principle of the Roberto roll. The solid rubber roller (below) presses the fabric, from which water is to be removed, against the Roberto roll (above) which has an outer layer of deformable hygroscopic material and which removes additional water due to the capillary forces within this material.

and a portion of the moisture contained in the covering is pressed out in front of the nip (see Fig.). After the nip, the covering is opened again and thereby additional drawing out of moisture from the fabric takes place using capillary action. – Manuf.: Roberto.

Robotic systems Increasing → Automation is making a considerable contribution to the human welfare in the working world. Two things should be understood by this: on the one hand the human structure and on the other hand the organisational structure of work. The first case concerns the protection of staff from dangerous and burdensome work, the other the combat of monotony, as, for example, employees are freed from monotonous and extremely compartmentalised work by the use of robots. On the other hand the use of robots also results in rationalisation and thereby in the loss of jobs. In general, attempts should be made to get away from a course of action based on the division of labour and to increase the scope of decision-making and action for employees through the creation of more quality jobs per employee and through increased complete processing in the sense of “job enlargement” and “job enrichment”. With the aid of modern techniques such as flexible manufacturing systems and autonomous production islands, it is possible to meet these demands to a large extent.

One definition of the robot reads as follows: “programmable, multifunctional manipulator with the purpose of moving material, parts and tools”, or “a special device for the execution of a multitude of jobs by means of programmable movements”. The fundamental concepts from both these definitions are:

- programmable,
- multifunctional,
- manipulator.

Programming always means conditioning a device or a procedure to a particular, but replaceable purpose; so one aim lies in flexibility; but it also concerns the permissive detection and processing of information. Information is produced in a robot internally on the one hand, for example, about its present state of motion, about its mechanical loading, etc. On the other hand, information is produced from a perception of the environment, whether tactile, visual or acoustic components, which are to be detected. A comparison with the human nervous system including the sense organs and the central nervous system suggests itself. Information processing organs, which were summarised until now in machine technology in the term “logic controls”, are required to realise, control and master sequences of motions and forces.

Precursors are numerical or computer-controlled machine tools, i.e. automatons. There is therefore a fluid transition between automatons and robots, and it is largely a matter of opinion to which category products are regarded as belonging. An automaton is all the more a robot the more flexible and in particular the greater its capability for adaptation with regard to environmental

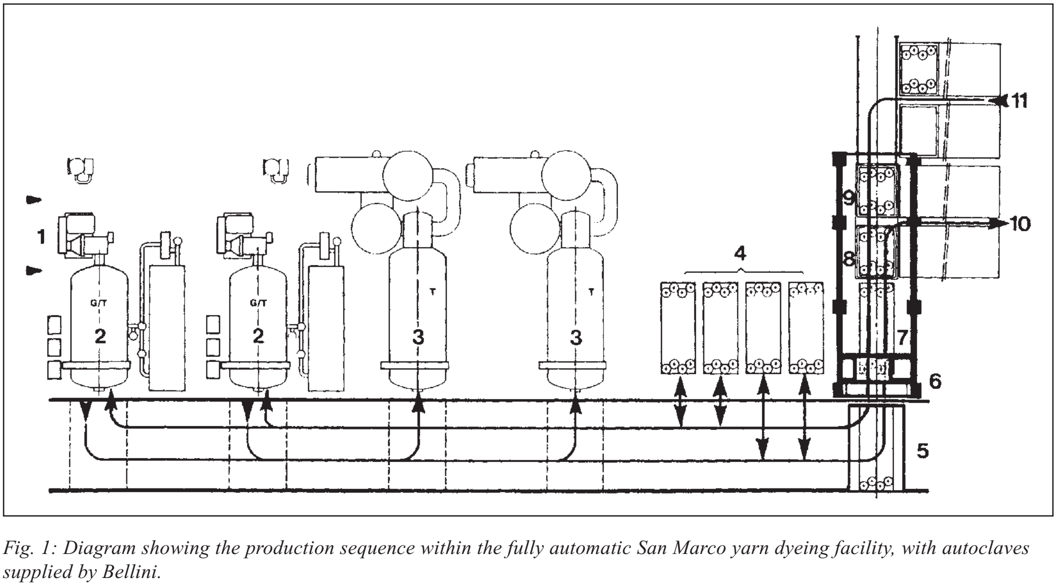

Fig. 1: Diagram showing the production sequence within the fully automatic San Marco yarn dyeing facility, with autoclaves supplied by Bellini.

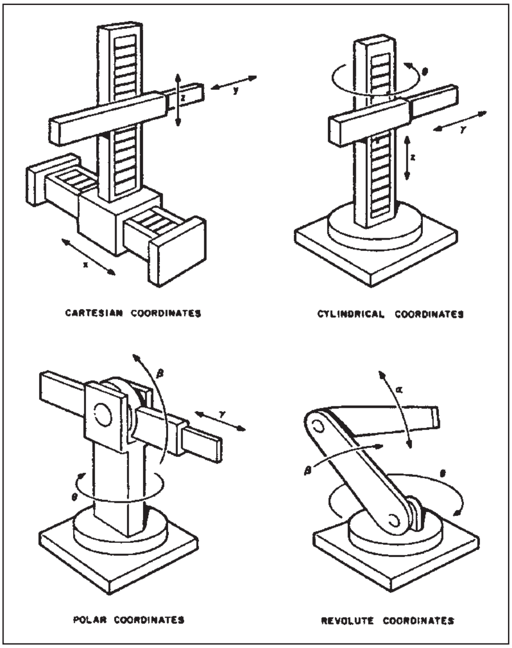

Fig. 2: "Playback" robots. Three degrees of freedom of movement are required in order to be able to reach any point within a defined radius. The most commonly used kinetic configurations are shown here. The "human" model is almost no longer recognisable.

information. In accordance with the Japanese Industrial Robots Association (JIRA), industrial robots should be divided into four classes:

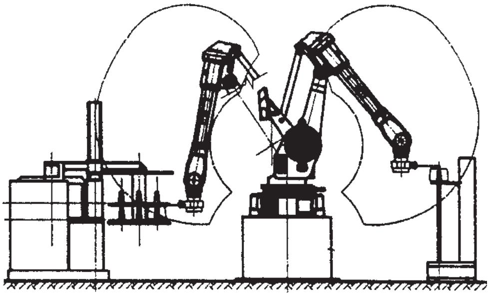

Fig. 3: A single-armed robot in different operating positions (left: filling material carriers; right: picking up a yarn package).

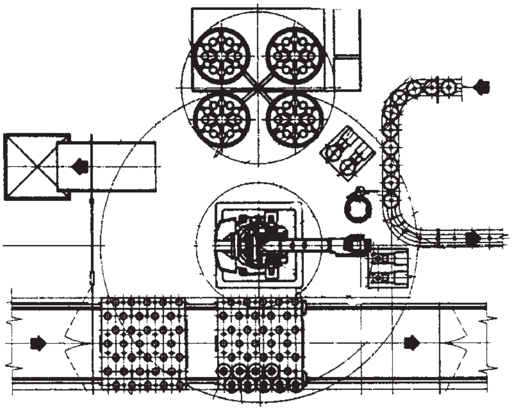

Fig. 4: The working radius of an all-round operating robot (ABB-Robotica) used for loading and unloading crosswound yarn packages.

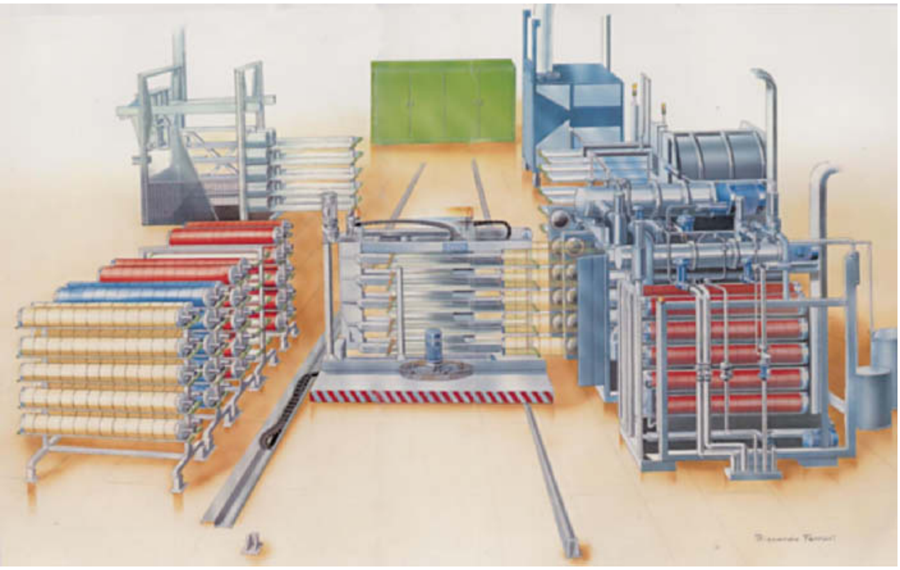

Fig. 5: A robot working in yarn dyeing (OBEM).

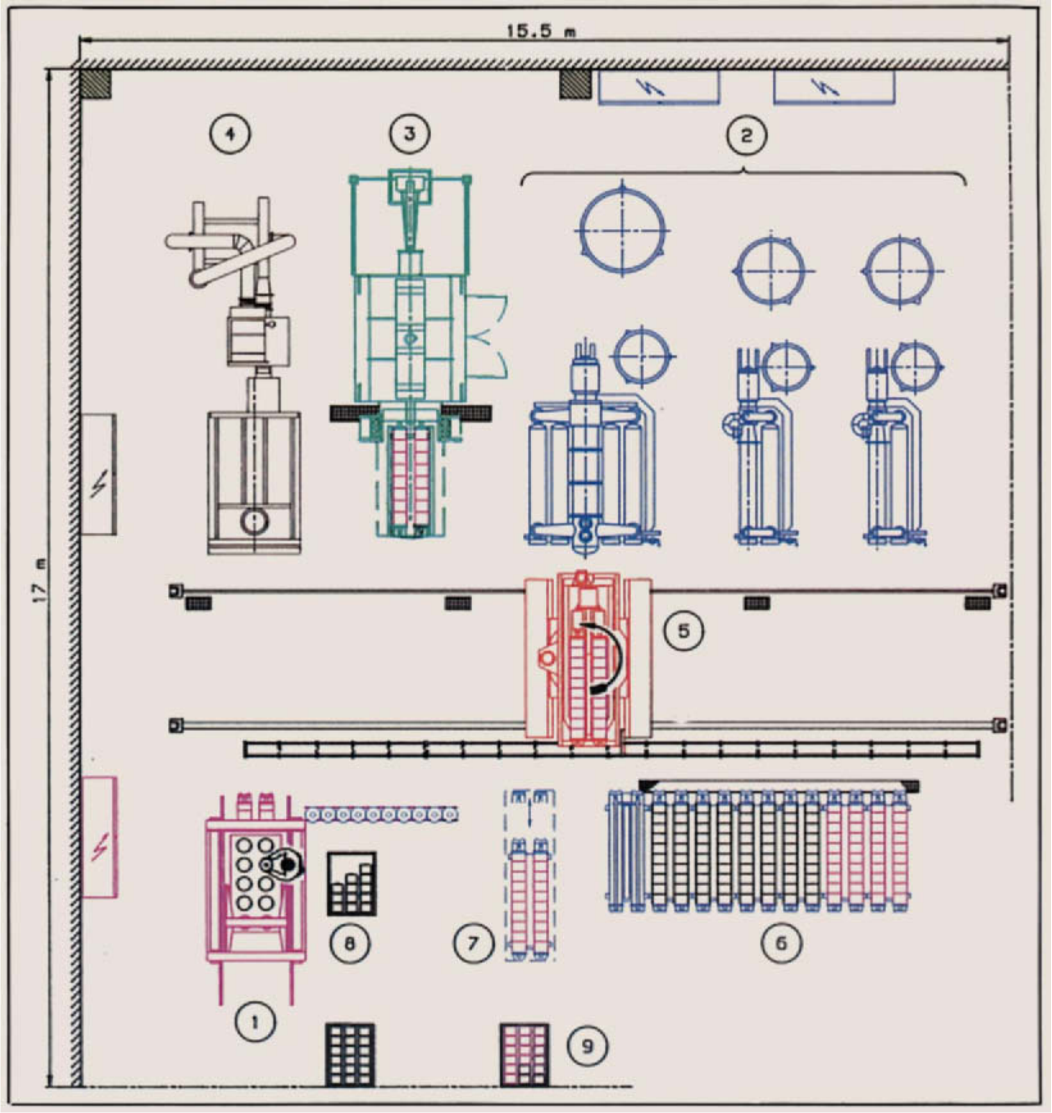

Fig. 6: The sequence of operations in yarn dyeing, automated by the use of robots (according to OBEM).

1. manual manipulators for fixed or specified sequences.
2. playback systems, which repeat fixed instructions.
3. NC robots, which execute operations on the basis of loaded programs.
4. intelligent robots with autonomous detection and environmental information.

Class 1 devices (Fig. 1) would no longer be assigned to robots (the high numbers of robots installed in Japan can be put down to the fact that these simple manipulators are also included). The class 3 robots come really close to conventional numerically controlled machine tools.

Classes 2 and 4 have typical, original and autonomous robotic characteristics at their disposal: in robotics "playback" means that, for example, the robotic arm is run at first by a worker corresponding to the work to be executed, whereupon it then often repeats the sequences of motions input into it (Fig. 2). A simple form of learning is established in the sense of simple imitation. More complex and more demanding forms of learning can be derived from this, for example, so that a

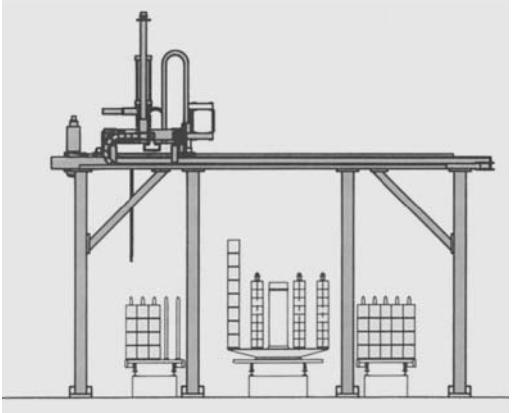

Fig. 7: *The filling of small batches by robot (Pozzi) in the process of yarn dyeing preparation.*

repeated sequence of motions is made dependent on momentary effective geometric ratios or force influences. These kinds of processes have been partly developed in perfection and were already familiar a long time ago from machine tool technology. The robots of class 4, which are also called "intelligent robots", are the really interesting ones. Their "intelligence" lies in the fact that they have diverse sensors at their disposal, which enable them to adapt jobs, which are given and/ or pre-programmed in their essentials, to given conditions. Combined with the "capability for learning", functional specimens result in high flexibility and efficiency (in accordance with Mey).

The use of robots in the field of yarn dyeing is considerably more advanced than in spinning (used for the handling of rinsing in this comparison). Italian firms gathered a lot of experience in this field early on. All round operating classic robots may probably use too much space in the necessary circular arrangement of the machines to be operated (ABB) (Figs. 3–4). Solutions in which the robot moves on rails (OBEM) (Figs. 5–6) or crane-like on racks (Figs. 7 + 8) (Bellini and Camel robot, chiefly for small batches as also with Pozzi) seem more sensible. The intermediate plate to stabilise the material carrier during centrifugation (Figs. 9–10) is essential in robotisation by Bellini.

Fig. 9: The stabilization of a yarn dyeing carrier suitable for manipulation by robot (Bellini).

Rocket packages (bottle packages). Rocket-shaped packages with an axial structure. Are used as dye packages, as opposed to normal crosswound yarn packages, for dyeing on special material carriers. Also as a reference package on shuttle-less weaving machines.

Rock salt Extracted from natural deposits, more or less pure → Sodium chloride. Is either extracted from

salt-works by miners (ground, recast, refined, etc.) or via evaporation from saline springs.

Rock wool → Mineral silicate fibres.

Rod squeegee → Doctor blade.

Rod teasel machine → Raising teasels.

Roll batcher Device for fabric batching for storage in → Package. Varieties: →: Paternoster batcher; Swivel batcher; Rising roll batcher; Surface batcher; Centre drive batcher. → Batching drives.

Roll batching machine Automatically operating machine made of two rising roll batchers acting in parallel (→ Rising roll batcher). If the desired diameter of a yarn package has been reached, the roll batching machine cuts through the fabric and lays the start on the following empty roller.

Roll carpets (carpets),

I. Carpets in roll make-up.

II. In accordance with DIN 61 151: only in the width, for example, machine-conditioned, measured carpets.

Roll Coater → Reverse roller coating.

Roll/er application in coating processes is carried out in accordance with melt coating. Fusible polymers are heated and sealed in a roller until a film from the roller grinding mill capable of application (top in Fig. 1) is applied to the fabric to be coated (e.g. in PVC coatings of car covers). Coating pastes can generally be applied with the aid of a spreader, sieve or roller application systems. Roller application technology includes

- reverse roll coater (Fig. 2),
- smooth roller coaters (Fig. 3),
- grid roller application devices (Fig. 4),
- nip padding machines (Fig. 5) and immersion impregnation (Fig. 6).

In the broadest sense, a roller bearing element for paste or substrate is also in the cylindrical spreading process,

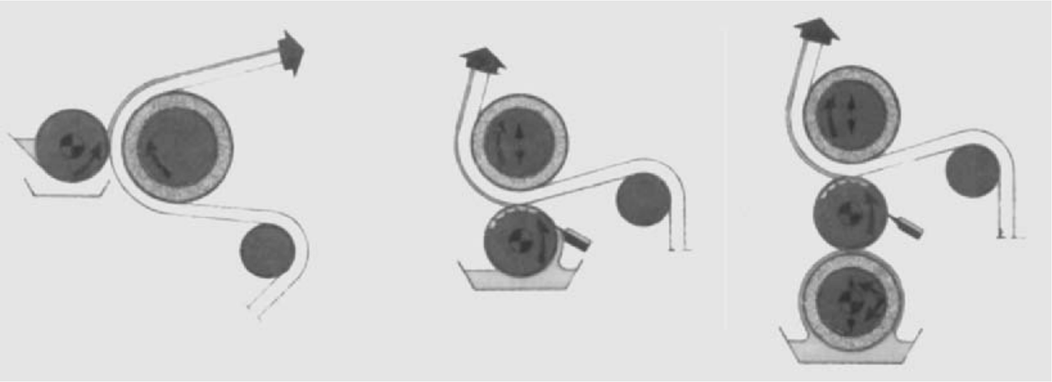

Fig. 4: Grid roller application devices (Kleinewefers KTM).

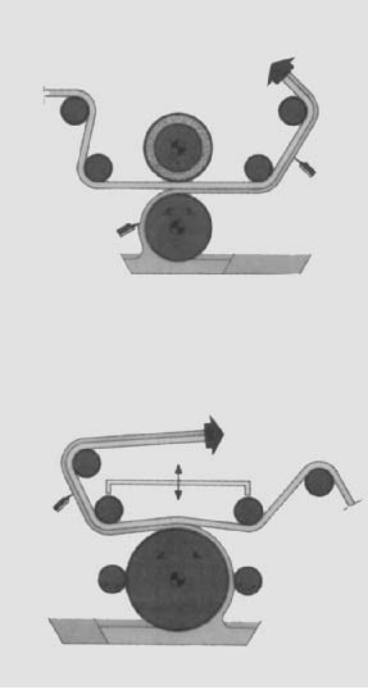

Fig. 5: Nip padding (Kleinewefers KTM).

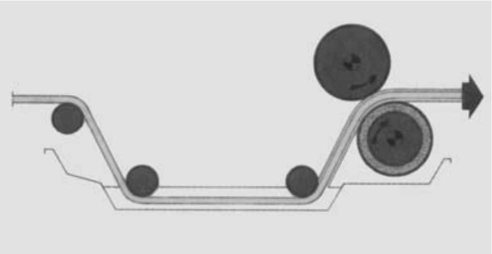

Fig. 6: Immersion impregnation (Kleinewefers KTM).

in the roller coating around a magnetic roller and in the reverse application system. The reverse roll coater has proven to be a versatile application system because it is applied independent of fluctuations in starch in the coating substrates of the mass film and not, as is usual in roller blade coating systems, do carrier substrate and coating starch have to run through a common gap. The applicable viscosity range is also broad provided that the coating pastes do not coagulate under the effect of the shear forces. The application polymer mixture should be stressed at the moment of the metering and levelling through shear forces so that the thixotropic pastes are converted into a homogenous, uniformly strong film of constant flow properties. The coating starches vary from insignificant dry application weights to high mass coatings and are a function of the viscosity and dye content of the coating paste. The coating starch is essentially determined by the gap between applicator roller and metering roller as well as by the speed ratio between applicator roller (operating in the opposite direction to the transmission roller and operating with a speed of rotation of 15% to +200% of the nominal speed of the plant) and substrate roller (the metering roller runs in the opposite direction to the applicator roller with a speed of rotation, which is different to the applicator roller by up to 10%).

The gap adjustment may be regarded as coarse metering and the variation of the applicator roller speed to the tool path feed rate as fine metering. It is thereby important that the path totally adsorbs the mass supplied and the applicator roller enters the metering gap cleanly. Rheological paste properties and speed ratios between metering roller, applicator roller and fabric transport as well as the metering gap width should be precisely co-ordinated with each other, if a smooth, thin film is to result (in accordance with Patermann).

Roller arrangement Depending on the functional principle of a machine, operating rollers are positioned together. When mercerizing (Fig. 1), the rollers

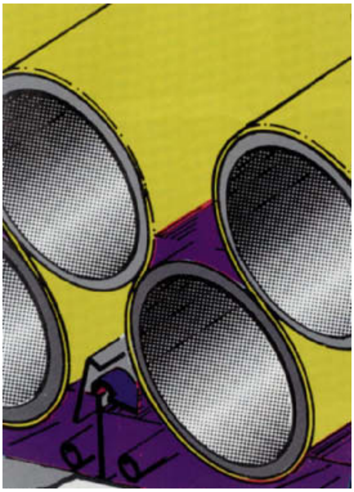

Fig. 1: Roller arrangement on a Goller mercerizing machine.

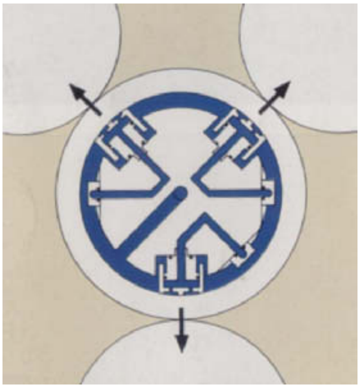

Fig. 2: Roller arrangement in the case of a Kleinewefers KTM calender.

are in a displaced arrangement so that the cloth under tension runs in a controlled manner. The L arrangement or the 3 zone arrangement may be of interest when calendering (Fig. 2).

Roller-bed steamer Broad steamer for continuous shock bleaching of cotton and polyester/cotton cloth. Fabric runs vertical via steam/air level (intensive heating from superheated steam), then falls onto a slowly driven roller bed (water spray system on top).

Roller card raising machine Roller card raising machines (→ Raising machines) have two central cylinders; one central cylinder rotates against the cloth run and the other with it. There are also machines with only one central cylinder, in which the piece has to be turned after several passages, i.e. raising of the number-free end of the piece firstly takes place and then with the number end forwards. The spindles used in card raising are secured on the central cylinder in rows and each individual card raising spindle is supported radially (see Fig.).

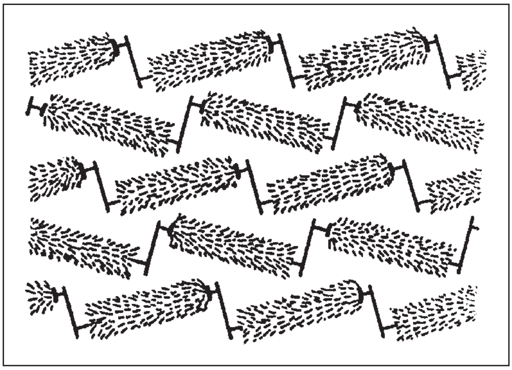

Fig.: Typical roller card raising machine arrangement.

Roller chisel is used for mill engraving (→ Pattern die) on printing rollers.

Roller defects in roller printing result from improper treatment of the printing roller, which has to be corrected or even engraved again.

Roller deformation When rollers are pressed together deformation can occur (Fig. 1) so that the linear pressure is unequal in the gap. Attempts are made to even out this roller deformation through specifically applied corrective forces (Fig. 2).

Roller systems with active bending correction operate

- with bending compensation by transposing the axes (axcrossing),
- with suspended hooks and bending moment (roll bending),
- with mechanically, pneumatically or hydraulically supported roll shells (Variflex-S roller from Babcock; floating roller from Küsters; Hydrein and Bicoflex roller from Kleinewefers KTM or Nippco roller from Sulzer Escher Wyss).

Monforts displaces both squeeze rollers side by side against each other in the Matex colour roller with a special S profile (Fig. 3) and so produces specific nip profiles.

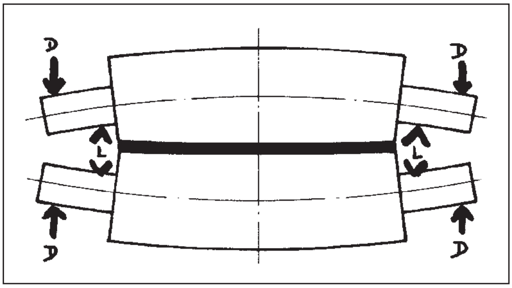

Fig. 1: Roller deformation. L = bearing; D = pressure.

Roller deformation

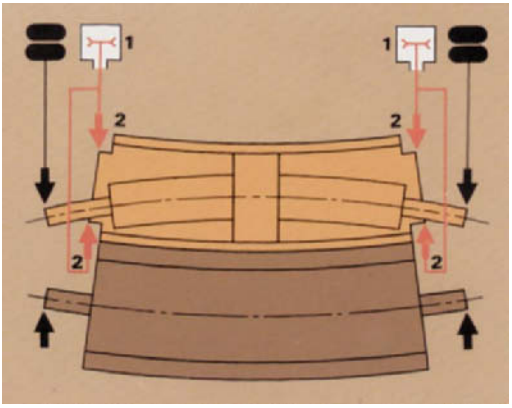

Fig. 2: Function principle of a correcting unit for roller deformation (Benninger).
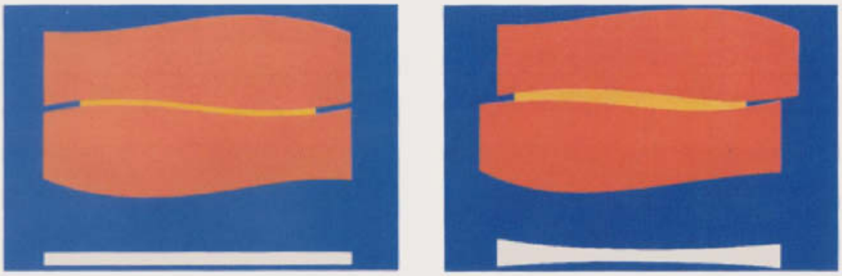
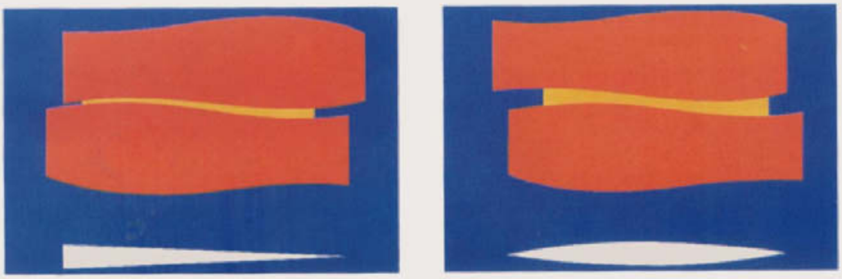
1 = correcting cylinder; 2 = correcting force.

A very even stress load characteristic (Fig. 4) can be achieved by using individually controllable pressure zones as normal in the Hydrein roller (Figs. 5 + 6). This functions as follows: across the entire operating range of linear loads from 1 : 10 (Thermo-Hydrein roller as an under roller), e.g. between 15 N/mm and 150 N/mm, the hydrostatic pressure in the bearing elements (c) is automatically set by the system so that an even clearance pressure exists across the entire roller width (Fig. 7). The oil is used as a coolant at the same time. The axial feed (d) causes the oil to reach the inside of the roller housing with practically no loss in temperature. The high oil velocity in the gap between the bearing elements and the inside of the roller housing causes turbulence, which ideally causes heat transmission to the roller housing (b).



nip pressure constant across full width of rollers

nip pressure greater at right and left than in centre



nip pressure greater at left than at right and at centre

nip pressure lower at right and left than in centre

Roller engraving Electronic: small bowls are cut with a sharp diamond chisel from the copper surface of the printing form in gravure printing cylinders. The diamond chisel is electronically controlled (electronic signals control position and depth of insertion of the chisel). The small bowls (which are pyramid shaped at the tip) have smooth walls due to the sharp cutting edges of the chisel, which has a positive effect on the transmission of the print paste to the printed goods. Chisel control signals are obtained through optical-electronic scanning of a black and white pattern (extract from a multicoloured design), which also contains developments as grey-scale values. → Engraving.

Roller fabric spreader → Expander.

Roller grinding and polishing Grinding and polishing of roller printing rollers is carried out on the polishing bench. This is a lathe-like device, in which the print roller rotates and is moved across a rotating disc. A water tank forms part of the polishing bench, in which the roller body is immersed by approx. 5–10 mm during the polishing process. The following are used as polishing materials: polishing stone, grinding stone, charcoal sized at approx. (5 x 12 x 25) cm^3 .

Roller grinding mill is used in printing for grinding print pastes. Chiefly for vat dyes, pigments or pigmented discharge print pastes.

Roller grinding of print paste causes finest grinding of the material, i.e. of dye, thickener, etc. Distinctions are made between roller grinding machines with one roller and one or two grinding bars and those with two rollers and three bars or three rollers. The grinding process results from differential speeds between rotating roller and fixed bars or between rollers running at different speeds. The grinding material is transmitted from one roller to the other in a three roller machine, whereby each subsequent roller circulates more quickly than the preceding one. The grinding material is wiped from the last roller by a doctor blade.

Roller hardness The description of the hardness and/or softness for companies at home and abroad is in accordance with different scales for rubber or plastic rollers for finishing machines amongst other items, whereby confusion continually arises. It should be especially emphasised that the terms → DVM softness and → Shore hardness conflict with each other and are handled differently to some extent.

Roller mangle → Mangle, which contains batch rolled piece goods in one and/or two magazines (double roller mangle).

Roller press (cylinder press) →: Rotary clothpress; Pressing.

Roller printing,

I. Distinctions are made according to the type of roller printing area:

1. Gravure printing using → Roller printing machines: almost exclusive mode of operation using gravure printing rollers, on which print paste is transferred from the print paste container (colour box) by a running roller (furnisher roller). Removal of the surplus print paste by a doctor blade moving to and fro at the side. Such print paste application devices are arranged around the printing cylinder corresponding to the number of print pastes. The fabric runs on a back grey (undercloth) with lappings and a continuous rubber cloth (printing blanket) between the elastic support and the engraved printing rollers. Joint drive of the printing rollers by a repeat wheel.

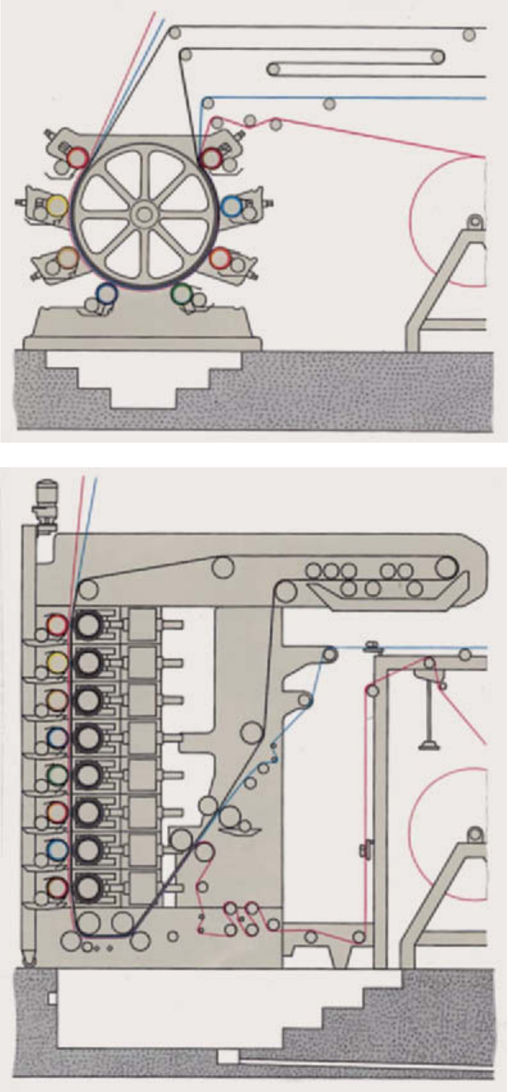

Fig.: Comparison of the run of material through a classical roller printing press (above) with that of a Saueressig-Portal roller printing press (below).

2. Relief roller printing (high pressure): of less importance. Printing rollers with raised samples (print paste application using continuous felt tapes for example) are used. Still used partly for carpet and wallpaper printing.
3. Mosaic printing, e.g. →: Conversion print; Orbis printing.

II. Regarding the type of print paste application through the print rollers, distinctions are made between deeply engraved pressure rollers, roller printing (see Fig.) and relief printed effects, in which the rollers contain the raised pattern. The latter may no longer be found in material printing. Only vigoureux and carpet printing machines still operate using relief rollers. Roller printing is a gravure printing. The sample is etched on the rollers made from copper, copper-plated steel and photo mechanical copper-plated light metal. The term "engraving" is no longer applicable. The transmission of the colour arrangement onto the rollers has been eased by electronics (scanning process). Roller printing machines are particularly suitable for the printing of large batches. They run at speeds of up to 100m/min.

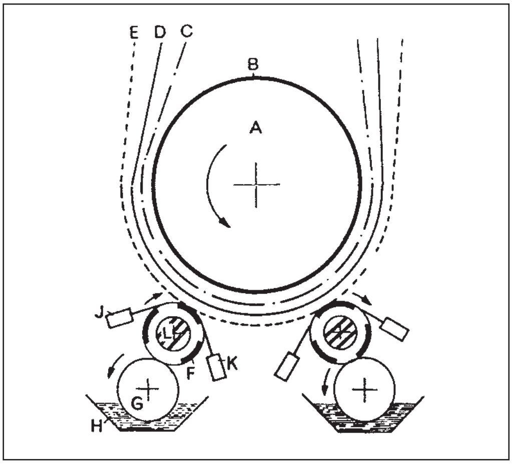

Fig. 2: Diagram of a two-roller printing press.
A = print cylinder; B = lapping; C = endless print blanket; D = back grey; E = goods; F = engraved zone; G = print paste feed roller; H = print paste trough; J = doctor; K = lint doctor; L = print spindle.

Roller printing machines The print paste applicator is composed of the print paste tank (colour box) and the tank in the rotating applicator roller, which transmits the print paste onto the engraved roller (printing roller) (Fig. 1). A doctor blade lying on top of the latter wipes off the surplus paste so that only the deep engravings still contain print paste and transmit this onto the material. The doctor blade has a moving capability of 5–25 mm and moves to and fro sideways 10–50 times per minute. The depth of the engraving is different. Shallow engraving up to 0.09 mm deep is sufficient for surface printing; this increases to 0.2 mm for good imprinting. The depth of the engraving is a criterion for the quantity of absorbed print paste and thereby a cost-determining factor. Shallow engravings give a rather smooth printing. For patterns, which go beyond the extent of fine lines or points, the doctor blade would remove the print paste. In order to prevent this, the figures are divided into fine grooves side by side, so-called hatching, which are at an oblique angle to the direction of motion of the fabric. The rollers corresponding to the colour number to be printed using the print paste application device are arranged on the perimeter of a large cylinder, of the print cylinder or printing cylinder (Fig. 2). They are pressed onto the cloth running between the printing cylinder and the engraved rollers by highly sprung spindles.

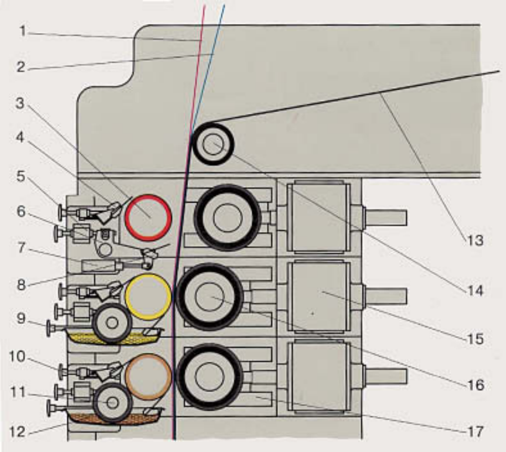

Fig. 1: The printing machinery in a Saueressig-Portal roller printing press.
1 = print material; 2 = back grey; 3 = printing roller; 4 = lint doctor; 5 = print paste doctor adjustment; 6 = print paste doctor bearing; 7 = doctor cylinder; 8 = print paste doctor; 9 = print paste roller adjustment; 10 = lint doctor adjustment; 11 = print paste application roller; 12 = print paste trough; 13 = printing blanket; 14 = deflecting roller; 15 = printing cylinder; 16 = printing roller; 17 = printing roller guides.

It can easily be seen that a thixotropic behaviour of a print paste may be desired with rapid movements (particularly in roller printing). The thinner and lower its viscosity, the quicker the break contours run into a homogenous, smooth surface and the easier the penetration of the fabric surface will be. The following results in the adhesion of the print paste to the printing roller, i.e. in the hatching: The thinner the thickening, the less it sticks. The thickness of the remaining layer is a function of a suitable flow characteristic (with low, very possibly thixotropic viscosity and low adhesiveness). If the part already printed is now touched by another new surface, it is understandable that this part is the less sensitive to squeezing of prints

- the more thoroughly the fabric surface is already homogeneously penetrated by the print paste and
- the less print paste adheres to the new contact surface of the printing roller.

Seen physically, this fact is a function of the flow characteristics within parameters of surface tension and adhesiveness; thus, the adhesion forces between the contact media.

The Kauschka-Brückner roller printing machine system departs from the conventional design with a central printing cylinder and arranges the individual print paste plant, consisting of colour box, printing roller, doctor blade and printing cylinder, lying diagonally. The print paste plant is arranged vertically in the machine from Saueressig. The printing rollers do not have spindles. They are mounted directly and held in bearings by compressed air. The contact pressure is low compared with conventional machines. The “Sari Roller” printing machines built in England are a speciality for printing large registers. The design is distributed on three rollers in these machines, whereby two rollers print the middle section and the 3rd the border.

An elastic base should be available under the cloth during printing, which consists of a thick wool union material (lapping) and a rubber cloth continuously running across and protecting the lapping wound in several layers around the printing cylinder. Modern printing machines are provided with a rubberised printing cylinder. The continuous rubber cloth (printing blanket) then becomes no longer necessary. A cotton back grey absorbs the surplus print paste, which penetrates the material to be printed. In order to be able to use this on both sides without interrupting the printing function, a back grey turning device has been constructed. The continuous washing off on the printing machine can be carried out itself on existing roller printing machines with continuous rubber printing blanket using polyamide/cotton blend fabrics as continuous back grey. Küsters has constructed such a device, in which a special water calender (Aquaroll calender) de-waters the back grey so severely that it is unnecessary to dry it. The back grey is replaced by a continuous, ultrafine grooved plastic printing blanket in the “Darex” printing process. This is continually washed using a particular device. The washing off of print pastes with water-soluble thickenings does not cause any difficulties. The rotor should however be provided with a particular protective layer against solvents in pigment printing pastes and emulsions. The trend from fabric to knitgoods also becomes noticeable in printing. A roller printing machine was constructed in a portal type of construction (“tricot print”), on which tubular knitgoods can be printed.

The precise calibration of the register is a difficult job, especially for multicoloured printing. The printing rollers can be rotated forwards and backwards on their axis for this, moved to the side and also positioned higher and deeper on the sides. The repeat on modern printing machines can be adjusted electro-mechanically during printing by means of pushbutton control. In order to make the repeat easily visible for print pastes with a low natural colour, so-called sighting colours are added to them. These are dyes, which have no affinity to the fibres in question and can consequently be washed off again later. Compounds, which light up in ultraviolet light (fluorescent brighteners), can also be selected for this with the use of corresponding lamps.

The risk of spreading the printing dye pastes exists in wet-on-wet printing of multicoloured designs. The print pastes printed first stain off from the material onto the print cylinder below. The fitting of counter doctor blades or lint doctors or the insertion of non-engraved rollers, which are continuously washed (water rollers), has a counter-effect. In addition, the brighter, more delicate shades, i.e. in “forehand”, are printed first and the darker ones last (“the smallest colour in the first hand”).

A good printing result depends on many parameters in roller printing. The individual factors have hardly been recorded in detail in their effect until now. Even today experience therefore still plays an important role in printing. The relatively low number of installed roller printing machines is mainly due to the fact that engraving the rollers is a costly job. Only large firms have their own engraving department; the rest have the rollers engraved outside. The printing orders should reach a particular minimum quantity for the amortisation of the engraving costs; the metre lengths of the printing design become shorter and shorter however. Roller printing is still of interest chiefly for multicoloured discharge printing.

Roller printing preparation trolley facilitates the preparation of print paste units outside the printing machine, while the machine itself is still producing. Setting-up times can be reduced.

Roller printing, pressure adjustment is still used to adjust the printing pressure in older printing machines. It facilitates resetting of the contact pressure on both sides even during printing with the aid of pins. Frequently replaced by → Plate springs in roller printing.

Roller printing, quality parameters Amongst machine-independent parameters, which lie in the hands of the printer, the print paste dependent dimensions have particular practical significance, of which, it is known that this essentially concerns interface problems, i.e. the laws, which apply to water transport in fabrics/knits, should also be authoritative for the printing process. The following are important:

1. influence of the contact period and centrifugal acceleration (printing speed).

2. influence of isolation effects due to variably rapid migration of print paste components in the course of the printing process.

While the first dimension, and also initial and limit conditions, is influential to a certain extent, both effects govern the continued course of the transfer of thickeners and dye on fabric within a short contact period as well as during the subsequent drying. Knowledge of the rheological properties of thickeners alone is not sufficient, however, for the interpretation of complex dye transfer processes, in which threshold stress and surface tension play a no less important role. For the interpretation of phenomenological facts, mechanically conditioned factors should be just as carefully considered as fabric data and physical/chemical as well as rheological print paste properties.

Roller raising → Raising.

Roller recutting Repair work to the roller after mill, panto and photo-engraving (→ Ruling).

Rollers, rolls Rotatable cylindrical bodies.

I. For the guiding or transporting of cloth, either undriven or driven as → : Guide rollers; Draw rollers. Deflecting rollers may contain the roller pins sealed in a hollow cylinder as a simple equipment practice (Fig. 1).

Fig. 1: Roller pins with welded-in double bottoms.

There are various bracing measures, e.g. filling with expanded foam, if high working widths are to be handled by rollers (Fig. 2).

Fig. 2: Internal bearing method complete with special bearing.

If there are guide rollers in open-width washing machines, the rollers in the gusset as well may be regarded as washing or liquor exchange elements (Fig. 3).

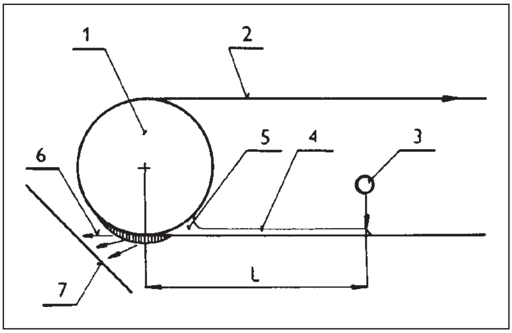

Fig. 3: Guide roller as a washing element.
1 = guide roller; 2 = textile fabric; 3 = liquor application unit; 4 = liquor film; 5 = liquor wall; 6 = spray;
7 = collector; L = distance between application point and tip of stuffer/compression wedge.

II. For the processing of cloth: squeezing rollers, pressure or calender rollers (→ Calender), →: Printing rollers; Applicator rollers.

Squeezing rollers are rubberised. The sequence of operations in Fig. 4 is the same for new or retreadings:

1. registration and initial inspection.
2. removal of an old coating possibly present.
3. sand rays: pretreatment to achieve a perfect adhesion. Covering all parts not to be rubberised such as spindle ends, etc.
4. application of the adhesive system: arranges the adhesion between rubber and metal; if the mixture is adapted, takes place in several machining operations.
5. application of the coating: by hand or on special machines, without bubbles.
6. tying with tape: prevents the running off of the rubber during subsequent vulcanising and ensures good adhesion.
7. vulcanisation: crosslinking of the rubber molecules under heat and pressure, approx. 145°C, 2–10 h. Transfer of the material texture from the plastic into the elastic state, physical/chemical connection with the core at the same time.
8. removal of the bandages.
9. processing of the coating: looping and/or rotating and attaching of possible structures.
10. check: inspection of the specification demanded such as diameter, roundness, hardness, surface quality and surface cleanliness, for example.

Fleece rollers produce special squeezing effects (Fig. 5). The lower the speed of a fabric guide roller (Fig. 6) in roller vats or in roll steamers, the lower is the risk of rope creases due to the fabric wrapping around the rolls in a semicircle. Increased fabric guide rollers with a large diameter are therefore used in these plants (Fig. 7).

Roller scratches in roller printing

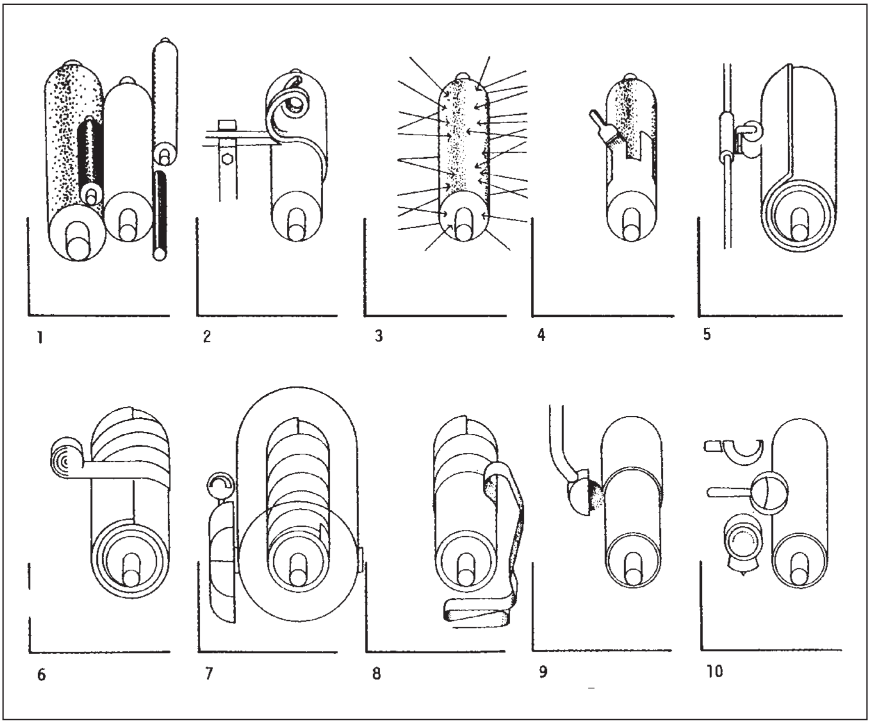

Fig. 4: The application of a rubber roller covering (Zeppernick).

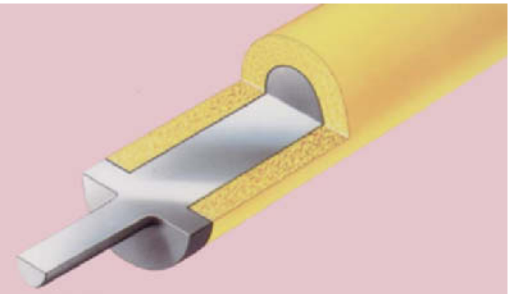

Fig. 5: Roberto roller with special adhesive.

Roller scratches in roller printing result from hard foreign bodies, which were usually only briefly jammed between doctor blade and printing roller and produce a more or less deep tear on the printer roller exterior. Also result if the grinding burrs of the doctor blade are not completely removed.

Roller storage in roller printing The printing rollers are normally stored horizontally on top of each other in several tiers in special shelves in the so-called roller store. On each shelf, a printing roller rests on three to four moving wooden rollers laid down to avoid scratches on the roller when being taken out and pushed

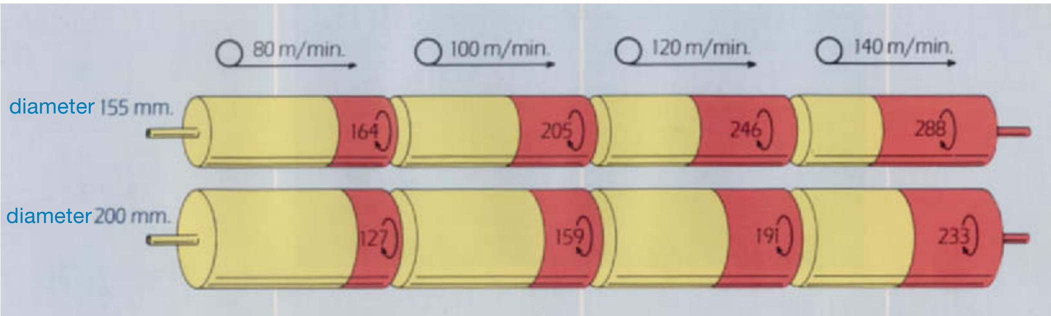

Fig. 6: The speed in revolutions per minute of guide rollers of different diameters for goods moving at different speeds.

Fig. 7: Fabric guide rollers in the Brugman steamer.

back in. Each roller must be numbered for filing and the shelf compartment correspondingly labelled as well.

Roller strike-off machine is used for production-independent design, for the testing of roller engravings and similar. The roller strike-off machine contains a printing station, on which the printing cylinder driven by the printing roller is started up. The printing cylinder is kept spindle-less by spindle sleeves. The repeat is precisely adjusted by means of a pitch pin. A filling doctor is used for the print paste feed. A water roller connected in series to the printing unit squeezes off the printed print paste.

Rollers, wrapped Elastic calender rollers made of paper, cotton, jute, special spiral fabric and similar. The elastic material is pushed onto a steel axis (sufficient diameter avoids bending of the wrapped roller) in the form of separate disks (e.g. approximately 20 000 per metre of roller), hydraulically pressed under high pressure (up to 100 t) and held together on the head ends by iron rim discs. Such wrapped roller surfaces are exceptionally tough and can only be re-surfaced to the desired diameter using diamonds (e.g. → Roberto rolls).

Roller vat, roller beck Basic form of all open-width washing machines. Principle (Fig. 1): Rectangular dyeing vats (approx. 1.1 m wide, 1.2 m deep, 3.5 m long) with guide roller system installed top and bottom, across which the piece good is carried in the zig zag by the liquor after passing an expander (speed of 15–100 m/min).

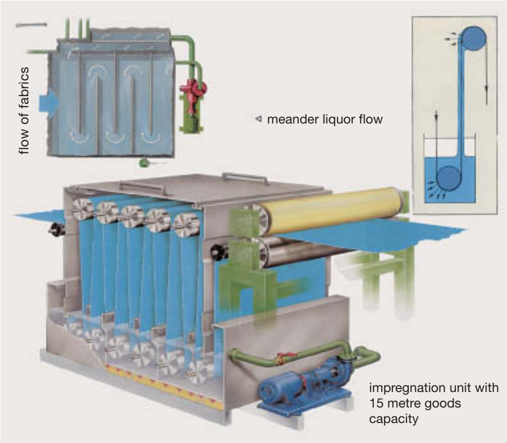

Fig. 1: Meander liquor flow in counterflow direction and throughflow of goods in a Brugman roller vat.

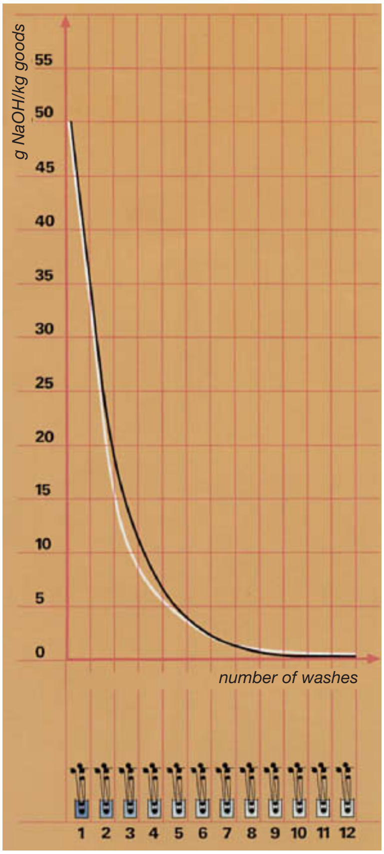

Fig. 2: Comparison of the calculated concentration curve with measurements obtained in practice during the washing out of mercerization liquor in twelve roller vats (black = calculated values; white = measured values).

3–8 such dyeing vats are arranged in combination as required. Large (diameter) deflecting rollers in the roller vat reduce the risk of rope creases. The efficiency of several roller vat washing steps shows the washing off curve of mercerized cotton fabric (Fig. 2). In order to optimise the liquor exchange and thereby increase the washing effect:

- double fabric thread-up (Fig. 3),
- supporting rollers (Fig. 3),
- mote rollers (Fig. 4),
- meander liquor guide (Fig. 1),
- counter current principle (Fig. 5)

can be used.

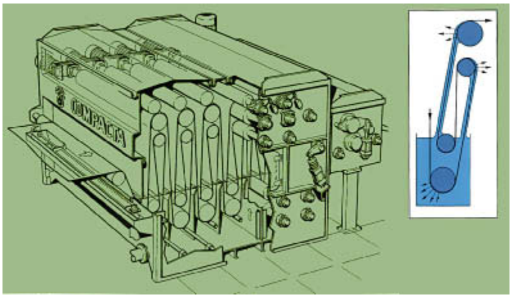

Fig. 3: *Increased liquor exchange by using double immersion of fabrics and supporting rollers in the Küsters roller vat.*

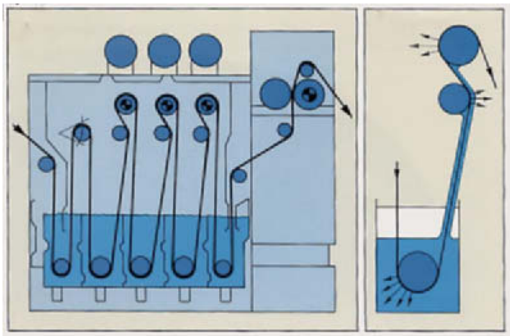

Fig. 4: *The Supra Nova roller vat with mote roller and the single immersion of fabrics, together with top roller drive and horizontal squeezer (Kleinewefers KTM).*

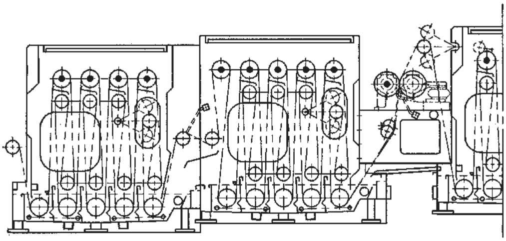

Fig. 5: *The flow of fabrics is from left to right, the flow of liquor from right to left: the principle of counterflow in a Babcock roller vat array.*

Rolling,

I. Drum movement on machines (e.g. washing machines) in one or both directions without stoppage, in contrast to → Reversing action.

II. Hemming of handkerchiefs, for example.

Rolling machine For the rolling of textile fabrics during storage, further transport (and also for their protection). Particularly for voluminous textiles or those of such large width, such as carpet lengths for example, special rolling machines are required for the rolling of a polished technique into shape, which form regular yarn packages kind to material on corresponding carriers (tubes).

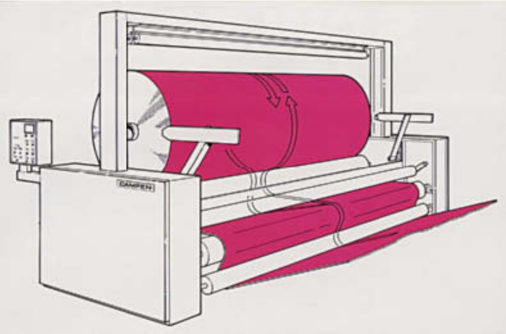

Fig. 1: *Carpet rolling machine SCW 5000 (Campen).*

The rolling unit from Campen shown in Fig. 1 shows the following features and working options:

- driven thread-up rollers (contact rollers) support the carpet from the dead centre to the rolling rollers;
- 2 tiltable driven roller guideways for carpet transport alternatively for exterior and interior pile;
- double dead centre device with rotating shearing blades;
- driven guide roller and 2 driven “rolling head rollers” for starting automatic rolling on cardboard tubes without staples, etc.;
- 2 rubber-coated rising rollers each with a separate drive for the setting of the desired roller strength;
- measuring system with electronic length counter with length preset;
- cardboard tube dispenser with automatic tube insertion;
- pneumatic roll ejector by means of lifting the rear, rising roller;
- seams can be cut out and expelled as required.

With a rolling machine for light, 150 cm wide outwear fabric (Fig. 2), the operator merely has to bring the

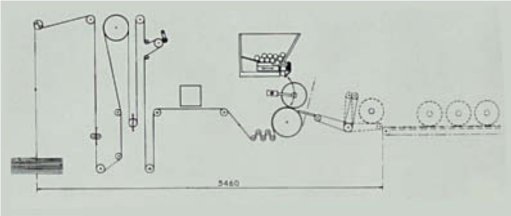

Fig. 2: Rolling machine for fabric (Biella Shrunk).

tubes and the material to be wound. The machine is controlled by a microprocessor. Many variants are possible for controlling the measuring and winding processes. The machine carries out the following machine operations without intervention from the operator (speed of 10–120 m/min, production: 50 rolls at 50 m/h):

- batching of the material into small and medium rolls (max. Ø 500 mm);
- measuring the length;
- readout of marked errors;
- print-out of weight and error marks on a label;
- attaching the label;
- cutting off the material in accordance with given length count;
- piling the roll onto a conveyor belt;
- insertion of a new tube;
- start of a new roll.

Roll test → Levelling property test.

Romaine raw wool weight loss in scouring Weight loss (= loss from washing) from → Raw wool in the laundry.

Röntgen Designation for the unit of ion dose until 1977, the SI unit valid from 1978 is Coulomb per kilogram C/kg: $1\ \text{R} = 2.580 \cdot 10^{-4}\ \text{C/kg} = 258\ \text{C/kg}$. For ion dose rate or output, the derived SI unit is correspondingly the ampere per kilogram A/kg:

$$\text{ion dose rate} = \frac{\text{ion dose by irradiation}}{\text{duration of irradiation}}$$

Roof heat recovery system Radial fan with integrated heat recovery (principle of regenerative heat exchange); as fresh air and exhaust air fan, a bladeless capillary blower, which transports the two separate air streams (fresh air and exhaust air) at the same time; the capillary heat exchange thus extracts approx. 50% of incoming external air from the used, warm, exhaust air. The power saving due to the use of accumulated heat is around 40%, and this figure is even higher where there are large internal heat sources (e.g. laundries).

Root-Tip-Levelling-Kinetics in wool dyeing Prevents skittery dyeing in wool. Sunlight-damaged wool fibres invariably dye first at the tips, probably because the hydrophobic scale layer becomes hydrophilised through cystine oxidation. In the dyeing process the tip and root colour gradually levels out, but can be accelerated by the use of amphoteric levelling agents based on ethoxylated fatty amines (dye and fibre affinity).

During dyeing, the dye needs to diffuse through the laminar boundary layer and the hydrophobic cuticula into the woollen fibres (Fig. 1).

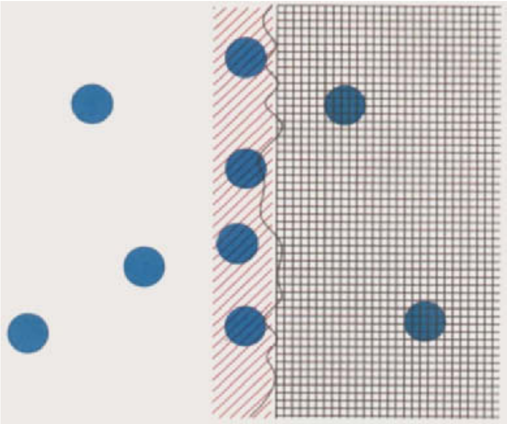

Fig. 1: The blue dye molecules diffuse through the laminar boundary layer (diagonally hatched in red), are adsorbed onto the hydrophobic cuticula and then diffuse into the cortex (cross-hatched) of the wool (by Ciba Geigy).

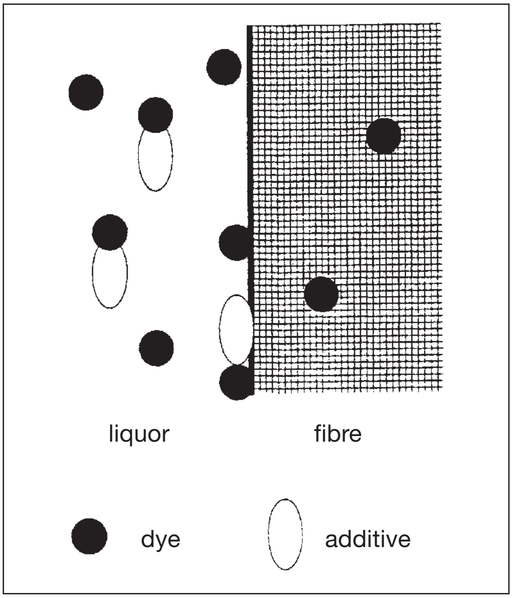

Fig. 2: Possible auxiliary exchange, particularly between additive and dye (by Ciba Geigy).

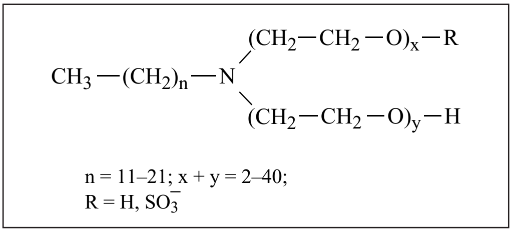
Root-Tip-Levelling-Kinetics in wool dyeing



$$CH_3-(CH_2)_n-N\begin{matrix}(CH_2-CH_2-O)_x-R\\(CH_2-CH_2-O)_y-H\end{matrix}$$

n = 11–21; x + y = 2–40;
R = H, SO_3^-

Fig. 3: The general formula for ethoxylated fatty amines as used in many levelling additives for wool. The nitrogen atom may be additionally quarternated.

In the dyebath, dyestuffs and auxiliaries can form a complex which has different properties (Fig. 2). The damaged tip is significantly more hydrophilic than the hydrophobic root. In the case of the auxiliary illustrated in Fig. 3, the resulting dye-auxiliary complex is more hydrophobic than the dye alone, and ought therefore to possess a higher root affinity, and therefore level the differences. An interesting question is why a substantially larger dye/auxiliary complex diffuses more quickly into the fibres than a smaller dye molecule.

The auxiliary surfactant is concentrated at the phase surfaces, thus enhancing the wetting properties of the wool (Fig. 4). As the wool fibre roots and tips have different hydrophilic properties, it is quite plausible to assume that auxiliaries are taken up in different amounts at the root and tip, thus changing the hydrophilic properties of the fibres. This change could result in improved dyeability levelling of fibre root and tip.

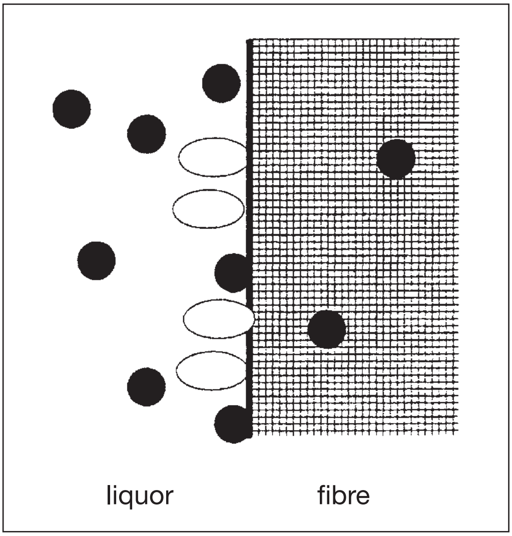


Fig. 4: Possible auxiliary exchange at the fibre surface (by Ciba Geigy).

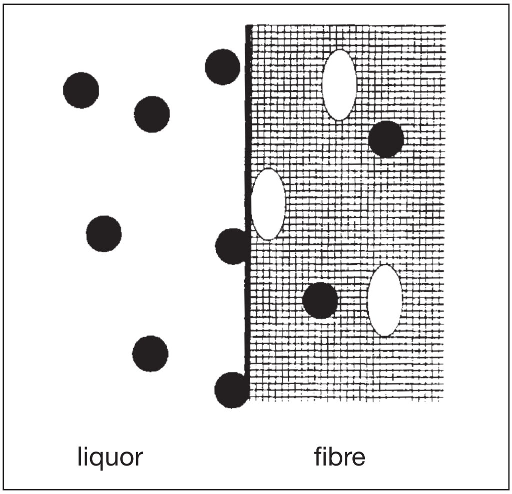

Fig. 5: Possible auxiliary exchange between additive and the interior of the fibre (by Ciba Geigy).

It is widely known that non-ethoxylated anion surfactants are taken up by the wool, enter the fibre and affect the fibre properties relatively quickly. Accelerated levelling of root/tip differences can be brought about by a change in the charge density, competition for bonding points or increased fibre swelling (Fig. 5).

Damaged wool fibre tips are always dyed first. Levelling from the tip to the root occurs during the dyeing process in the dyebath. With reactive dyes, this levelling process stops at a relatively early stage due to the chemical bonding of the fibres, resulting in skittery dyeing. As suitable levelling agents overcome skittery dyeing, the question is whether the auxiliary brings about even dyeing from root to tip from the outset, or whether it accelerates the process of levelling from root to tip, enabling more dye to diffuse to the root, before the reaction with the fibre takes place.

Chlorinated wool is damaged on the surface by chemical treatment, similarly to the way the wool tips are damaged by climatic influences. The simultaneous dyeing of chlorinated and untreated wool in a single dyebath (Fig. 6) is a system where the varying dyeability corresponds approximately to the root and fibre properties of a wool fibre.

Without auxiliaries the dye is taken up relatively quickly by chlorinated wool (tip model) with a damaged surface. Although there still is a slight redistribution of dye in favour of untreated wool (root model) at higher temperatures, the fundamental preference for damaged wool remains. However, with auxiliaries, the process of dyeing is different: although an initial preference for damaged wool is observed, it becomes less and less pronounced. At temperatures above 70°C the dye starts to re-distribute from the chlorinated to the

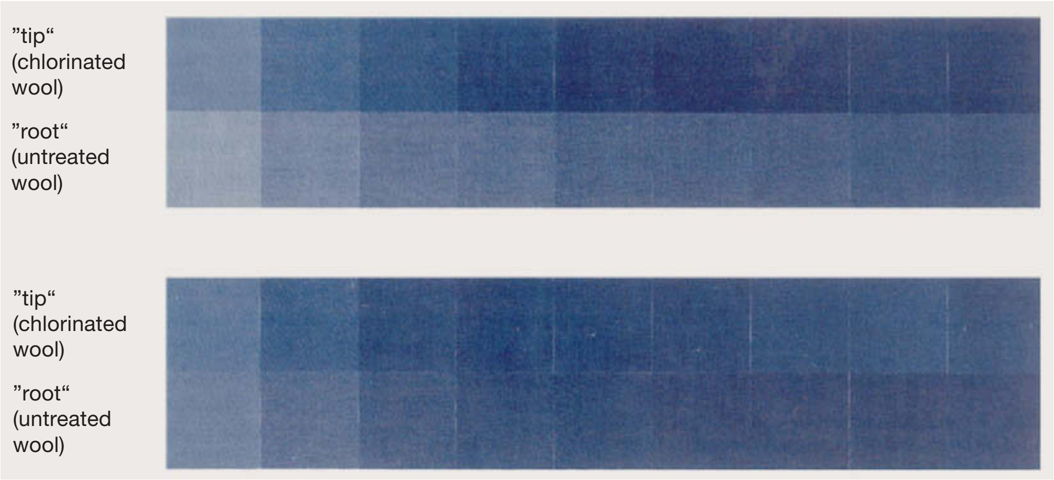

Fig. 6: Model system for correcting root/tip differences: dyeings of untreated and of chlorinated wool in the same dye bath with 1.5% Lanasol Blue 3G (Ciba Geigy). Above without and below with Albegal B (Ciba Geigy).

untreated wool. At this time the dyeing process is almost complete. When boiling point is reached, the process is largely finished, and the untreated wool is more strongly dyed. On the one hand, this reduces the preference for damaged wool at the beginning of the dyeing process, and the absolute colour intensity shows that the dye uptake of the chlorinated wool has not been influenced by the addition of the auxiliary, while the dye absorption rate into the untreated wool is markedly increased by the surfactant. On the other hand, the levelling agent ensures that after the dye has been taken up, it is re-distributed from the damaged to the untreated wool.

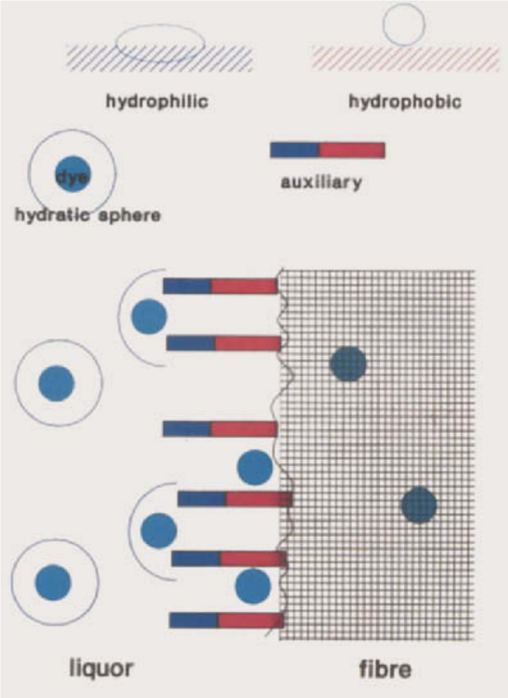

Fig. 7: Hydrophobic and hydrophilic exchanges as an explanatory model for the acceleration of dyeing (by Ciba Geigy).

The fibre levelling effect of formulated ethoxylated fatty amine derivative-based levelling agents of varying structure, charge and active substance content, when applied on a mass concentration scale, is directly dependent on the surfactant quantity taken up by the fibre (Fig. 7).

Studies of sorption using different fatty amine polyglycol ether derivatives, some using equal mass concentrations, others using molar initial concentrations, provide a fairly clear picture of the influence of the structure (hydrophile-lipophile balance (HLB), molecular weight, surface activity) on the exhaustion kinetics and the quantity of surfactants taken up by sorption. The number of monomeric surfactant molecules which can be taken up by sorption is determined by the surfactant’s critical micelle concentration (CMC) and its dependence on the outside electrolyte content (the amount of sodium sulphate in the dyebath during blank dyeing fluctuates during the adsorption of the electrolyte by the wool) and by the temperature. Hydrophobic surfactants (with a low HLB) have a tendency to more rapid sorption while having a lower CMC, i.e. a lower supply of monomers. Regardless of structural influences, at relative low temperatures (25–50°C), considerable quantities of the added surfactant (between 30 and

90%, depending on the initial concentration and structure) are absorbed. The potentially suppressive influence of these surfactants can be shown by velocity potential measurements. There is no simple correlation between the quantity of surfactants taken up by sorption or cation charge density (molecular weight) and the measurable zeta potential: the architecture of the surfactant layer taken up by sorption affects the shearability of the potential-defining ions (according to Hannemann).

Rope creases Disruptive, longitudinal marks; a problem that occurs in fabric and knitted goods finishing, particularly where dyeing takes place in rope form at higher temperatures. It has been shown in practice that crease inhibitors can minimise this fault. Where impregnation is carried out with plaiting, folds, creases occur either in the padder, when plaited, in the steamer or later during piling.

Rope detwister The product rope (Fig. 1) passes between two spring-loaded rollers of the detwister basket (1), the deflecting roller (2) and the two sensor rollers (3) before proceeding to the spreader. When the rope is opened, the torsion direction of the product causes a response in the sensor rollers, and their lateral position is sensed by a proximity actuator. The proportional output signal is amplified and passed on to the induction drive motor which rotates the detwister basket, thus unravelling the rope. The deflecting roller may be equipped with an additional drive or a pneumatic brake. This prevents tensile stress and run-on from developing in the product when the machine is shut down. Finally the system plaits down the product (Fig. 2).

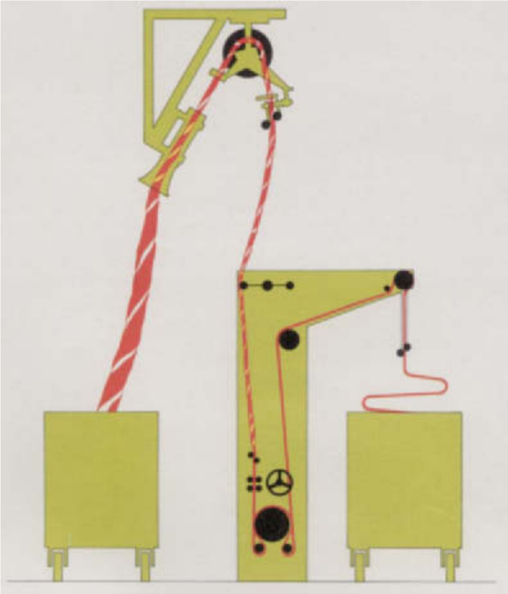

Fig. 2: A rope detwister system (Hemmer).

Rope dyeing machines Dyeing machines in which the textile product is dyed in the form of hanks or ropes, e.g. jet or overflow dyeing machines.

Rope form Textile fabric which has been gathered loosely into the form of a rope in the warpwise direction (woven fabrics) or wale direction (knitted

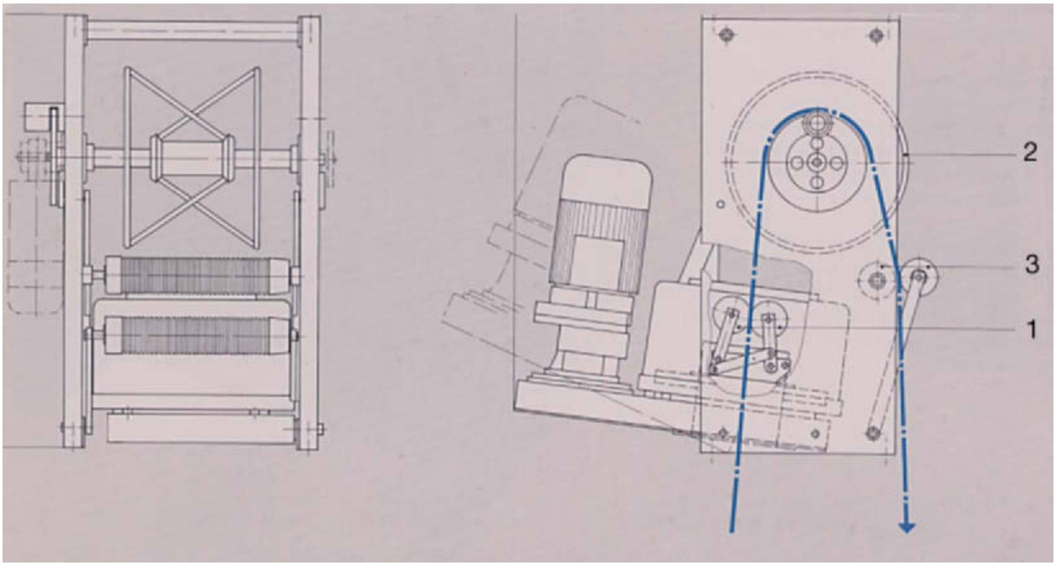

Fig. 1: Contact sensor (numbers explained in text) on the head of a rope detwister (Erhard and Leimer).

fabrics), usually by passage through a ring or pot-eye of suitable diameter for pretreatment and dyeing processes (as opposed to open-width processing).

Rope form handling Device for guiding goods in rope form →: Rope opener; Rope guide wheel; Rope ring.

Rope guide wheel A rotating element in → Rope form handling device which guides and supports rope piece fabric. It may or may not be driven.

Rope marks Bursts in the weft yarn during → Milling in tube form when selvedges which have been sewn together do not allow the air to leave the tube (hose) sufficiently quickly.

Rope opener This spreads all piece goods which are pre-treated in rope form by means of beater rollers, scrollers and spreader rollers.

Rope opening/plaiting device A device for unravelling, spreading and plaiting down fabric ropes.

Rope piler At the end of a wet rope treatment section the rope leaves the machine and is squeezed before being placed in intermediate storage (see Fig.).

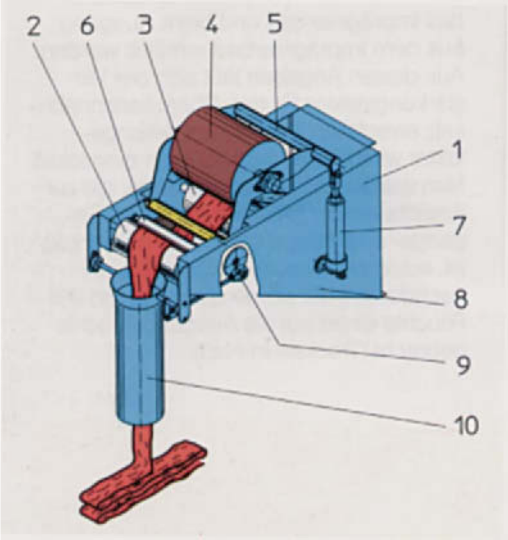

Fig.: Goods run-out with intensive squeeze rollers and a rope piler (Brückner).
1 = run-out housing; 2 = traction roller; 3 = deflection roller; 4 = Aeroflex squeeze roller with frame (5) and pneumatic cylinder (7); 6 = deflection roller; 8 = moving-magnet drive (not shown); 9 = crank drive for plaiting device; 10 = plait pipe.

Rope piler, trunk rope piler Device for feeding rope-form piece goods into bleaching vats. It is usually fed in together with a wetting-out liquor. Electric-hydraulic rope pilers have a telescopic tube which can be used for round bleaching vats. Even with varying product speeds from 30–150 m/min (infinitely variable) it ensures an even rope speed without twisting at a variety of rope speeds.

Rope plaiter Hydrodynamic piece rope plaiter which feeds the rope into the fabric accumulators by means of a rope piling device.

Rope ring (pot-eye). A ring-shaped component forming part of the → Rope form handling device for guiding and supporting the product rope.

Rope soaper (rope washer). Washing, rinsing and finishing device consisting of e.g. 3–5 adjustable pressure squeeze and guide rollers. As well as the washing, rinsing and blueing of bleached goods, it is also used in particular for the chlorine finishing of e.g. the Ce-Es bleaching of fabrics.

Rope squeezing machines (rope mangles). Are designed to extract water from piece goods treated in rope form. They can be incorporated into some manufacturing systems as intermediate devices (squeezing units), e.g. washers or autonomous devices (squeezing machines). In the latter case they are usually full-width squeezers.

Rope washing machines (rope scourers). Are washing machines for washing piece products in rope form. Unlike discontinuous rope washing machines, which consume large amounts of water, continuous rope washing machines operate with smaller amounts

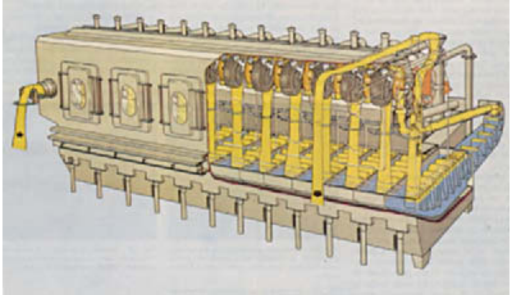

Fig. 5: The WR rope washing machine from MCS (Italy) for the continuous wet treatment of woven or knitted goods.

of liquid and a specific liquor flow. They almost invariably function on a counter-current basis.

In a continuous rope washing machine there needs to be a balance between the stationary product zone and the liquor interchange zones so that the arrival and departure of the laminar boundary layer and subsequent diffusion from the fibres into the laminar boundary layer are sequentially matched. Rope washing machines must be designed in order to make optimum use of available space. In the "Delphin" by Brückner this is achieved by positioning the stationary rope settlement area prependicular to the main product travel direction (Figs. 2 and 4). The liquor exchange zone in the Delphin consists of squeeze rollers (Figs. 1 and 3), while in the MCS rope washing machine (Fig. 5) it is made up of jet tubes. In this system the jet tube transports the rope from one chamber to the next (Figs. 6 and 7), thus enabling the goods to be passed through 8 settlement areas and 8 liquor exchange zones within a single machine. If different pretreatment stages are required, more settlement and liquor exchange zones are required (Fig. 8).

The advantages and disadvantages of rope washing machines produced both by machine manufacturers and by textile finishers are as follows:

Advantages:

- product width does not matter;
- ease of guiding ropes, even over long distances;
- higher product speeds possible than when in expanded state (150 m/min);
- the ability to keep large quantities of material in a small space, particularly in dwell processes;

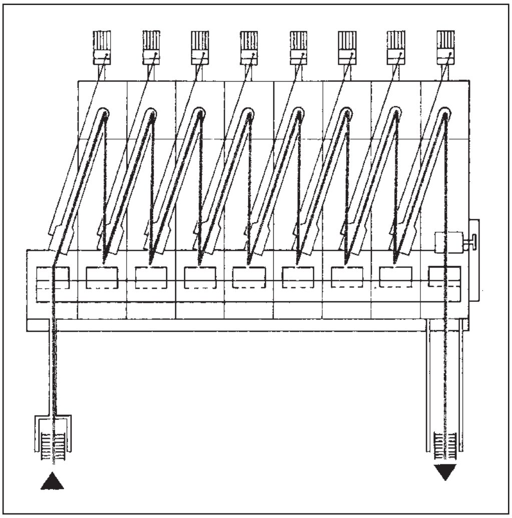

Fig. 6: The transport of goods in the Argathen rope washing machine, which has routing of goods typical for that type of system.

- less tension of goods than with open-width wash machines;
- less space requirements;

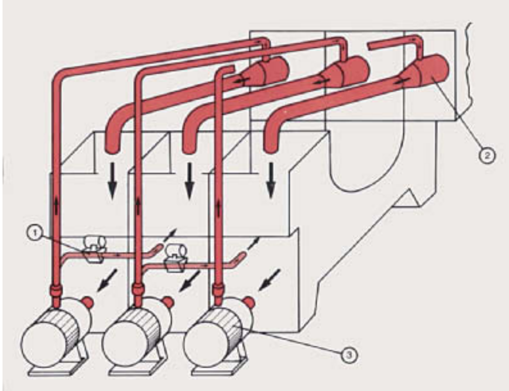

Fig. 7: The liquor interchange zone and the flow of liquor in the Argathen rope washing machine. 1 = counterflow; 2 = jet; 3 = circulation pump.

- reduced capital and maintenance costs;
- better relaxation of goods, a fuller and deeper handle, less pilling (depending on product);
- particularly good appearance for crêpe fabrics, in particular bark crêpe;
- saves time and water consumption, particularly when used with the consistent counterflow principle.

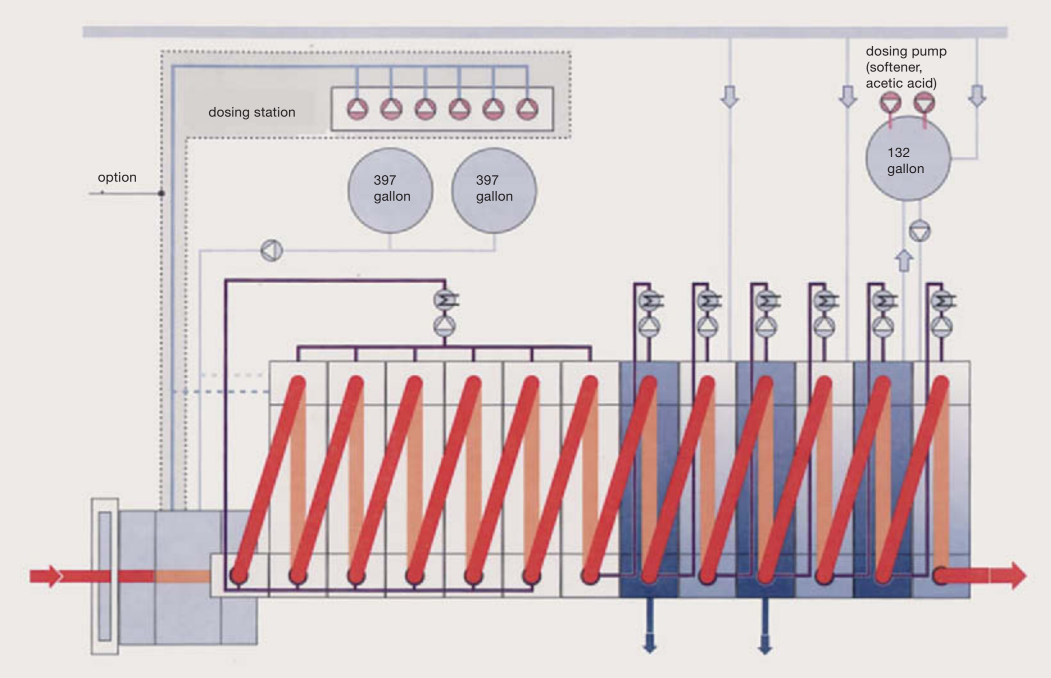

Fig. 8: The twelve compartment "Edelweiß" rope washing machine based on a Rotostream (Thies) for the continuous rope bleaching of cotton.

Disadvantages:

- not every product (due to construction and weight) can be rope-treated for reasons of unlevel dyeing, breaks or fold marks; unsuitable for pure synthetic woven fabrics;
- the product needs to be re-opened after rope treatment;
- danger of ghost prints during the after-treatment of printed goods;
- danger of skewing product;
- fluffy product appearance depending on goods;
- uneven flow of thin articles, occasional knotting;
- idling of individual sections due to incorrect adjustment.

Rosaceae rubber → Vegetable gums from cherry, plum, almond and other trees. Often in large, luminescent lumps, which look red or amber against the light. It contains gum arabic and about one-third ceresine which accounts for its inability to be diluted evenly and fully in water. Although when dissolved it consists of a thick mucilage, it has a lower viscosity than solutions of → Gum arabic. Pulvarised rosaceae rubber can be dissolved in water in the following manner, similar to gum arabic: soften by soaking in water (remove impurities) and then leave to swell for 36 h; then heat the mucilagenous mass for 2 h in autoclaves at 3.0199 bar, leave to cool, filter and if required concentrate by evaporation. Rosaceae rubber from almond trees and wild plum trees is usually used to imitate tragacanth. Decomposed cherry gum is used as → Industrial gums and sometimes as a thickener for printing.

Rosaniline → Fuchsin dyes.

Rosella A bast fibre originating in South-East Asia and similar to → Kenaf. The length of the basic fibre is about 2–5 mm; its per hectare yield is higher than jute, but it requires more processing. Used as a packaging material.

Ross-Miles method (modified) →: Foam test methods; Foam evaluation criteria.

Rot Rot is chemical decomposition with a mainly alkaline reaction (in contrast to → fermentation) and unpleasant odour. It encompasses a variety of indeterminate chemical reactions with the formation of intermediates and soluble end products, which are also released by aerobic and anaerobic bacteria. Putrefactive agents include in particular unstable, easily decomposable proteins, the rotting of which introduces enzymes which dissolve peptide bonds (peptidases). The next stage is the formation of albumoses, peptones or simple amino acids (leucine, tyrosine etc.). As the process progresses, other enzymes (carboxylases) cause CO_2 to split off from the amino acids. Successive splitting-off of CO_2 causes a progressive shortening of the carbon chain. The sulphur contained in sulphurous amino acids (cystine) is released as foul-smelling hydrogen sulphide. The final stage of the rot is mineralization, i.e. decomposition to water-soluble minerals (nitrates, chlorides, phosphates). In comparison with proteins, pure celluloses, fats, resins, waxes and related substances are much less prone to rot. The bacterial or enzymatic decomposition of carbohydrates (sugars, starches, celluloses) gives rise to particularly acid-reacting decomposition products (lactic, butyric and acetic acids), which in the presence of protein lead to the neutralization of the ammonia formed during decomposition of the protein, thus prolonging the rotting process. If dry substances contain a lot of carbohydrates and few proteins, there is only a low level of decomposition under the influence of simple mould fungi. Fats are also much more resistant to bacteria if, for example, they are decomposed by lipases in glycerine (often decomposes quickly) and fatty acids (often resistant to decomposition or only slightly susceptible).

Rotary cloth-press It should theoretically be possible to achieve a press effect in wool fabrics during continuous processing using calenders that are used in cotton finishing. However, rotary cloth-presses are predominantly employed in the continuous dry finishing of wool (see Fig.), in order to compress fabrics. The aim of pressing is to smooth the surface of the fabric. The rotary cloth-press, the Contipress (Menschner) and the flat press are suitable for this purpose; mangles can also be used to smooth fabric surfaces. With the rotary cloth-press, the product is passed without creases between a heated steel roller and a trough. The roller draws the product in and pulls it over the trough, which is held in place by means of hydaulic devices or spindles.

The rotary cloth-press consists of a rotating heated cylinder and a static heated trough which is pressed against the cylinder; care needs to be taken when seams are passed through. The pressure is adjustable. Although this system means that some pressure is exerted on the surface, the area pressed is relatively small and the exposure time is short. Cylinder diameters range from 400 to 800 mm depending on the machine, with a similar pressing surface. In order to avoid excessive loss of product moisture during pressing, the trough and the cylinder are heated at 0.2–0.3 MPa, corresponding to a steam temperature of 120–134°C. If the product moisture is reduced excessively, the product quality deteriorates, and a slight alteration in hue also occurs. Rotary cloth-presses also stretch the material slightly lengthwise, thus reducing its breadth. This occurs more where a rigid pressure is applied to the trough than if flexible pressure is applied. On the other hand, sliding the product over the trough surface results in a delaying friction which the highly-polished nickel silver turning does to some extent reduce, but it cannot be completely eliminated. Rotary cloth-presses are fitted with a momentum raising device allowing the trough to be promptly lowered when folding or other disruptions occur.

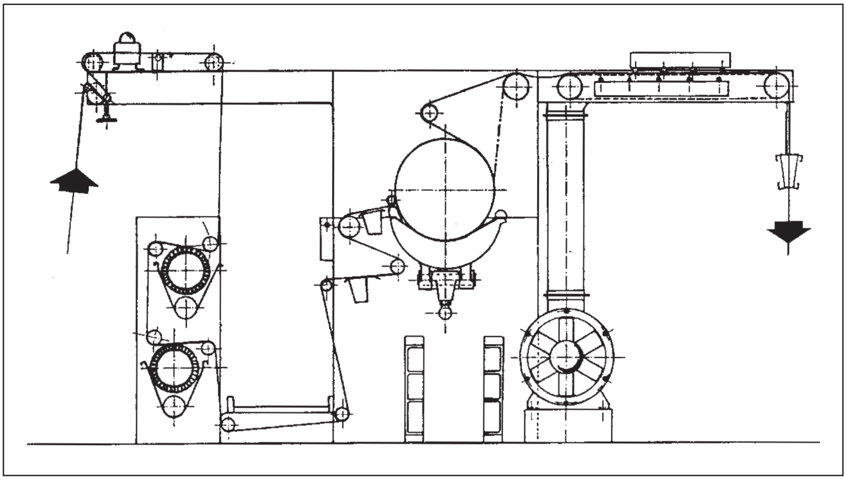

Fig.: A typical rotary cloth pressing machine.

Rotary drum drier A sieve-drum drier where the fabric is guided almost all the way around the drum, for the dry treatment and/or thermal treatment of tubular and/or web qualities. Their compact, high-productivity design with little space requirements make them particularly suitable for small and medium-sized shops.

Rotary irons A further development of → Ironing machines and steam ironing dummies used for finishing outerwear in one fully automated process (→ Steam ironing dummy).

Rotary milling machine → Cylinder rolling milling machine.

Rotary press A combination of 4 ironing presses for transfer printing. The transfer printing processes are cyclic, and hence continuous. There are 4 stations: 1. uptake of the material; 2: uptake of the thermal transfer paper; 3. transfer; 4. cooling and removal of the transfer material.

Rotary screen coating machine A device to provide an even coat of screen lacquer to rotary screens. The lacquer is applied in a single process using a variety of different lacquer types on rotary screens from the top downwards with the help of a rubber doctor roll.

Rotary screen printing The process of → Screen printing using rotary screens. The screen is not placed flat in a frame, but takes the form of a hollow roller. The advantage over automatic → Flat screen printing is a substantially higher level of continuous production (similar to → Roller printing). The advantage over roller printing is greater ease of changing dye and design, as rotary screens can be inserted and removed by hand, without the need for lifting blocks.

Rotary screen printing machines Design features:

I. Stork rotary screen printing machine (Fig. 1): During printing the cylindrical screens are supported by rollers, over which runs an endless printing blanket. The squeegee, which is fitted with a flexible coating blade, is inside the screen. The continuous adjustment of the squeegee pressure makes precision adjustment of the print paste coating possible for each individual screen without making it necessary to stop the printing machine. For long-pile fabrics requiring complete print penetration, an “air blade” which increases the penetrating pressure three-fold has been developed.

II. Zimmer rotary screen printing machine: this uses a magnet roll squeegee, which guarantees steady rolling of the screens and also makes it possible to use a screen stretching device which is independent of the machine. This makes it possible to fit narrow screens for narrow printing widths on wide rotary printing machines without the need to fit additional units.

III. Buser rotary screen printing machine: a significant design feature of this machine is the product feed. The Buser feed stand makes it possible to process fabrics of different qualities. Buser also supplies combined

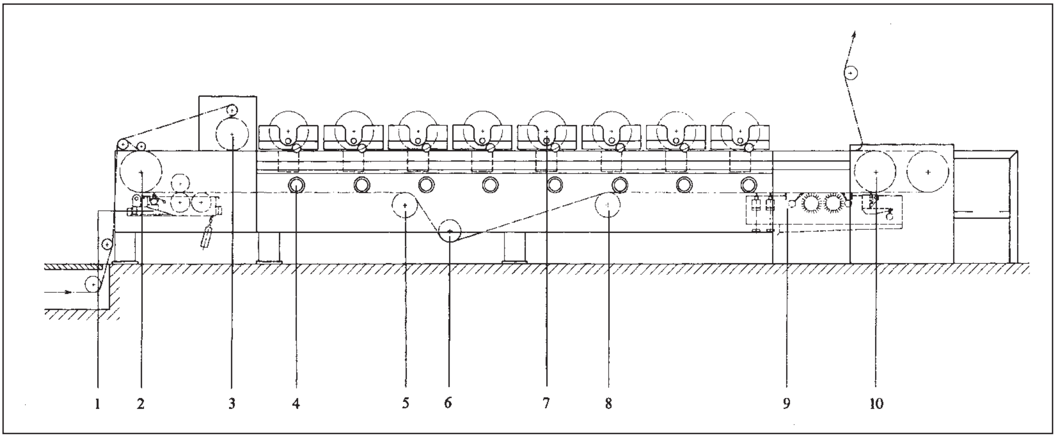

Fig. 2: An MKB rotary screen printing machine.
1 + 3 = gluers; 2 = deflection roller; 4 = pattern repeating wheel; 5 + 8 = supporting rollers; 6 = control roller; 7 = printing system; 9 = printing blanket washer; 10 = drive and tensioning rollers.

rotary screen printing machines, i.e. a flat screen printer with a rotating part.

IV. Aljaba rotary screen printing machine: unlike other rotary screen printing machines, its design is similar to the roller printing machine. However, unlike roller printing, it is the printing cylinder that is driven, while the rotary screens revolve only with slight pressure. They are stabilised and adjusted at the ends by a free-running cog. The product, together with the back cloth, is fed in at a constant tension, but not stuck on.

V. In the MKB machine, the rotary screens can be inserted neatly into the open guide units (Fig. 2).

VI. Reggiani's Futura rotary screen printing machines make it easy to observe products running at a speed of 25–50 m/min between the rotary screens, which is important for ensuring quality control on the part of the printing machine operator (Fig. 3).

Rotary screen printing of carpets → Carpet printing machines.

Rotary screens for screen printing are metal

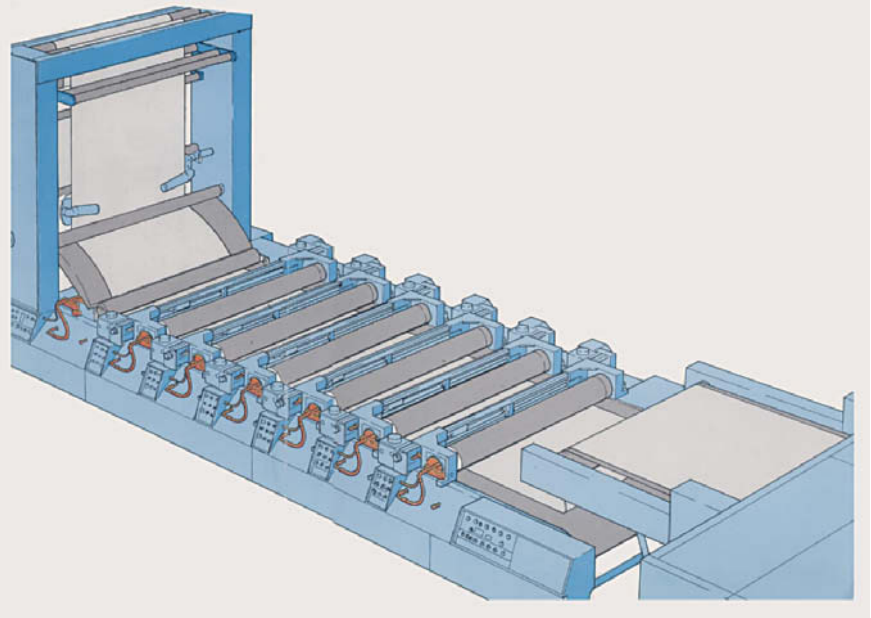

Fig. 3: The Reggiani Futura screen printing machine for circular screens.

cylinders containing fine pores whose walls have a thickness of 0.08–0.15 mm and which can be more than 3 metres in length.

I. Perforated lacquer screens: engraving lacquer screens is one of the classical methods of creating rotary screens. They are based on a seamless perforated cylinder on to which the design is transferred by photomechanical means. After cleaning, a photosensitive coating is applied to the screen, and the positive image is copied to the rotary screen. This is then developed, dried and baked. Finally the end rings are inserted into the engraved rotary screen.

II. Directly patterned galvanised screens: with this other classical method the screen is also produced by galvanisation, but it is engraved at the same time. This is done by transferring a negative film of the grid design, which is prepared and transferred to the master roller. The grid points then remain open or closed depending on the hue in the galvanised nickel coating. A 150-mesh rotary screen with a wall thickness of 0.085 mm and a length of 3 500 mm produced by galvanisation (matrix produced electronically) makes it possible to print half-tones.

III. Discharge screens: another possibility that rotary screen production offers is transferring the screened design to un-perforated nickel cylinders and etch them on, which again makes it possible to achieve screened printing. This process is rarely used.

IV. Laser engraving: this process dispenses with the exposure, development and polymerisation stages needed for other processes. The engraving only needs a time of 15–30 minutes.

Rotary screen printing was first developed at the turn of the century, and perfected in the 1930s. This can be seen from early patents. However, it was only put into practice in the 1950s by Almerindo Barros of Portugal (Aljaba). In the early 1960s, the Stork company was the first to employ galvanisation to manufacture good quality rotary screens in sufficiently large numbers. It was this, rather than the design of the first rotary screen printing machine which was presented in 1963, that was the real technical breakthrough. The rotary screens are the medium for the printing pattern. As such, the size of the perforations determines the graphic resolution, and this decides what the image to be printed will be. The fineness of the perforations, combined with the open perforated surface, also doses and distributes the print paste. The quality of coverage and the levelness depend on them. However, the screen also has mechanical functions. The evenness of the circumference, the torsion strength and flexural resistance of the rotary screen all help to determine the register. The latter two are particularly important when blade squeegees are used. Finally, the screen is also subjected to chemical and mechanical stresses during operation and handling.

The galvano procedure makes use of the ability to produce perforated hollow cylinders through electrodeposition of metal. In galvanoplasty (also known as electroforming), the electro-deposition of metal on suitable bases makes it possible to produce relatively thick metal layers. These tend to be self-supporting and make it possible to produce complex hollow cylinders. Typical of galvanoplasty is the exact reproduction of the surface structure of the medium, which gets lost increasingly as the thickness of the metal wall increases. A metal tube forms the basic element, which is normally electrolytically copper-plated and turned on a lathe so that the outside diameter has as fine a tolerance as possible. In the next stage the copper surface of the tube, which is known as the master roller or die, is mill engraved. The copper coating of the tube is ideally suited, as it is a metal that is easy to emboss. At the same time, unlike steel, a copper coating can be renewed and re-embossed. This is necessary when a master roller has reached the end of its life, for example. Mill engraving is a process in embossing engraving which originally was used in the manufacture of textile gravure cylinders. It involves rolling the relief, an embossing tool which is cylindrical and small in relation to the master roller, and which is prepared in special processes, on to the drive master roller under mechanical pressure (Fig.1). The relief resembles a hedgehog, as it is fitted with a multitude of seamless miniature embossing elements (needles) which are geometrically equal. Often the embossing elements resemble small skittles or pyramids, with a height of approximately 40 µm.

In practice the term → Pattern die-mill engraving is often mistakenly used in place of relief; Jakob and Weissberger summarised the issue: in mill engraving (which is used primarily in preparing rollers for roller

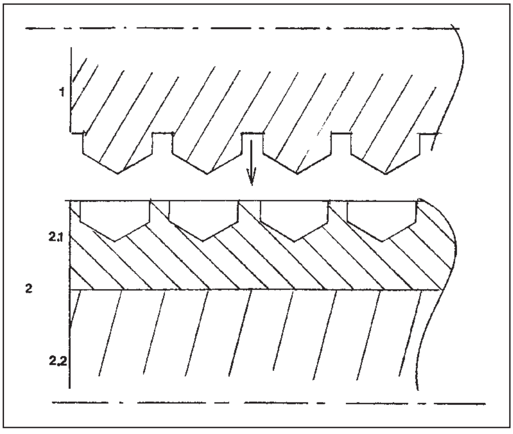

Fig. 1: Embossing the master drum.
1 = embossing tool (relief); 2 = master drum with copper sheath (2.1) and steel core (2.2).

printing), which is suitable for (low-pitch) and geometrical designs, the design is engraved into a small soft steel roller. All production stages that (in mill engraving) involve the creation of deep-set pictorial elements come within the concept of mill engraving. When it has set, the pattern die, i.e. the relief die or “relief”, is rolled at high pressure onto a soft steel roller. The relief therefore has the imprint of the pattern die, the pictorial elements being raised. All processes in mill engraving that create raised pictorial elements are therefore reliefs. When the relief has hardened, it can be transferred, i.e. mill engraved, on to the copper roller or the master roller, resulting again in inset pictorial elements.

The way in which this embossing procedure is able to transfer an almost totally uniform embossed image all the way around the roller, and along its entire length (which can be over 3 m) is as follows: when it is engraved on the outside edge of the master roller the first time around, the relief is embossed on to the roller surface. Here the transfer from the “end” to the “beginning” of the embossed pattern is vital. It must be ensured that the embossed elements of the relief coincide exactly at either end. If this has been achieved, the non-driven embossing of the relief into a forced rolling is a process which can be compared with the intermeshing of two cogs. Due to the extremely small picture pitch (i.e. the distance from one element to the next), the master roller circumference does not need to be a complete multiple of the relief circumference.

All the requirements for fitting the embossed image on the roller circumference also applie to the width. The relief is embossed in such a way that its pattern does not only match the circumference of the master roller, but also the width of the roller parallel to itself. This is achieved by slightly inclining the relief, which means it has a very slight spiral pattern, which is also “force-fed”. When embossing is complete, various processing stages are carried out, which vary from one manufacturer to another – for instance, the nickel-plating of the master roller in order to give stability to the copper margins around the inset picture elements. The next stage involves filling the inset picture elements with a material that does not conduct electricity. At this stage there is hardly any difference between the different processes. However, the coating process and the choice of filler material is one of the best-kept secrets of every manufacturer of rotary screens. They use artificial resins that are liberally applied, and which, when set, are removed (ground off) until the margins are blank metal and the inset picture elements remain filled with plastic and have an even surface (Fig. 2).

Other stages may follow to ensure the mechanical stabilisation of the entire structure, but these are insignificant for the manufacturing process of rotary screens. The master roller, once processed, proceeds to the nickel plating bath. The electrochemical process that takes place here deposits nickel at all parts of the master roller which conduct electricity and therefore permit a current to be created between the electrolyte and the master roller at this point. It is now obvious how the two-dimensional configuration of the master roller creates a three-dimensional screen. This screen wraps around the surface of the master roller and gets thicker and thicker during the electrolytic process (Figs. 3–4).

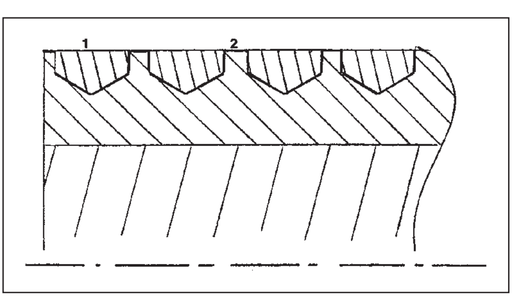

Fig. 2: The low-relief picture segments are filled with plastic (1) and then the ridges are exposed by grinding (2).

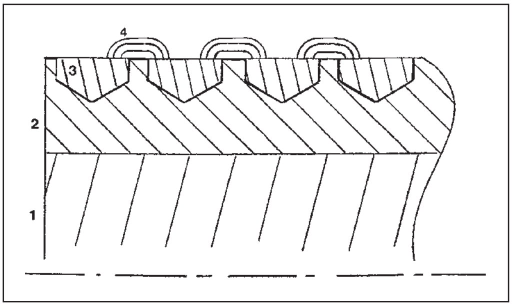

Fig. 3: The build-up of a rotary screen by galvanizing the surface of the master drum.
1 = steel core; 2 = copper sheath; 3 = plastic-filled pattern elements; 4 = the rotary screen, whereby the “contours” indicate progressive deposition with time and also the increase in width of the nickel ridges that is unavoidable under this procedure.

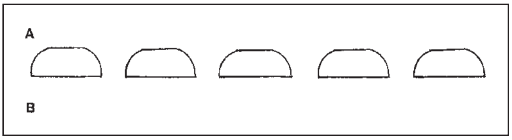

Fig. 4: Section through a first-generation rotary screen after the master drum has been removed. A = the outer surface; B = the inner surface of the screen.

In the past attempts have been made to use plating materials other than nickel to create rotary screens. However, none of these have proved suitable in practice. This is because the metallurgical and chemical properties of nickel make it best suited to the purpose, it is relatively inexpensive and can be galvanised onto thick walls in a relatively short time. The only question is which chemical composition of nickel electrolytes should be chosen. The choice is between sulphamate electrolytes and sulphate nickel electrolytes. The former creates a highly ductile (i.e. flexible, non-brittle) form of nickel, which can almost be classed as soft, whereas sulphate nickel ensures rigidity while ensuring a high level of ductility.

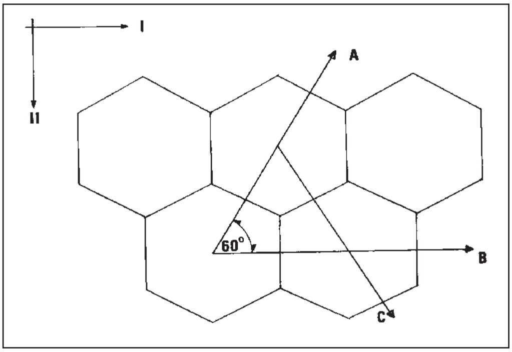

Fig. 5: The basic geometry of a rotary screen (first and second generation). The mesh index is determined by measuring out the screen perforations using a Piece glass. Only the counting axes A, B and C are used. Use of other axes leads to deviations in the result; it must be noted that the mesh index represents a nominal value which may vary. I = orientation of the longitudinal axis of the screen; II = direction of the screen circumference.

The relief is generally applied in such a way that a honeycomb pattern forms which is also imprinted in the rotary screen (Fig. 5).This geometry is both a technical and a historical development. The hexagonal apertures form an equal border width on the master roller and rotary screen in the "metering direction", which applies equally to "metering directions" in square patterns. This means that the screen can take mechanical loads in those directions (which it cannot in other directions). If the openings were circular, for instance, nickel borders of unequal width would form in the metering directions, which in theory would mean a disparate load capability.

Stork's → Penta-Screens are second-generation rotary screens. The word "Penta", derived from the Greek for "five", denoted the change from an increment of 10, which started off as 20, down to an increment of 5. The new screen type is based on the same master roller as the lacquer screen, as is the fact that it uses the hexagonal embossing method. However, it differs from the conventional process in the following way: whereas in the conventional process the rotary screen is deposited on the master roller until it has reached the required thickness, in the new process the galvanisation process is carried out in two stages. In the first stage, a skeleton screen is deposited with a wall thickness of about 30–40 µm. This screen is then removed from the master roller with extreme care, as it is highly delicate, and then increased to the required wall thickness in a second nickel plating process. What distinguishes this process is that the screen margins increase in size both from the outside and the inside of the screen simultaneously (albeit at different rates). This results in a significant decrease in the increase in breadth, which is vital for increased screen fineness with sufficient wall strength. If certain additives are added to the electrolyte in the secondary nickel plating process, and its currents are properly guided, the increase in breadth is limited even further. This makes it possible to produce screen materials of e.g. 300 mesh. However, these are not used in textile printing, but have found their application in technical screen printing.

The second galvanising process "rounds off" the originally precise hexagonal structure of the screen skeleton. It is scarcely recognisable as such, having instead a circular aperture shape. The process makes it possible to achieve a screen fineness of 125, 155, 185, 215 and higher mesh. The new second-generation screens are further distinguished by an enhanced wall thickness accompanied by a greater open screen area. As far as the extreme fineness of this type of screen is concerned, 185 mesh is very rarely used, and higher meshes are almost never used. With an open screen surface of 11.5%, 185 mesh offers a mesh width of 46 µm, while 215 mesh with an open screen surface of 9.5% offers a mesh width of 36 µm. Both these widths hinder the flow of print paste, and tend to cause dye loss during printing. 125 mesh (breadth d_1 with an open surface of 15% 79 µm, compared with 80 mesh with a d_1 of 95 µm with an open surface of 9%) has become the standard for screens. It allows an adequate flow of print paste, has advantages as regards micro-evenness, has a higher graphic resolution than 100 mesh, is more stable and does not tend to cause dye loss during printing.

Rotary screen washing is carried out in a screen washing cabinet by means of a spray ring on the outside and a spray head fitted with a nozzle on the inside. The washing operations in the system illustrated in the Fig., which can either be additionally installed in a printing machine or is already fitted in new machines, are made up in the main of the following stages: at the end of printing the print paste tube has to be detached and cleaned as usual. Then, by pressing a button on the main control system, all screens are washed in parallel, after which the print paste tube has to be re-fitted. The next printing operation can now be carried out. In a special process the doctor removes about 95% of the residual print paste from the surface of the screen into the trough of the internal cleaning device without the need for water. This leaves only a small residual amount of print paste that requires washing, thus economising on water. The main advantage of automatically washing all screens simultaneously is the time saving involved. It also simplifies operation of the machine and helps prevent screen breakages due to handling during removal and insertion.

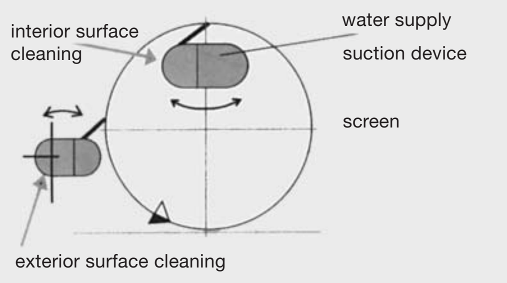

Fig.: The RSR stationary rotary screen cleaning device (Hassler HWB Textile Machines).

In the majority of systems rotary screens are removed and cleaned in the conventional manner using detergents. This involves trained staff, the use of large amounts of water, and associated equipment. On the other hand, cleaning is carried out in the printing machine itself, where the print paste tube and screen are cleaned by more or less the same method as when they have been removed; however, this entails "flooding" the machine.

Rotating rod drier A continuous hank yarn drier with rotating yarn rods which rotate while passing through the machine and which are closely spaced and allow air to flow between them so that the circulated air is fully utilised and the yarn is well aired. Dry treatment in a misty atmosphere at stepped temperatures up to the infeed of the wet product (resulting in the maximum possible protection, easy handling yarn with an even residual moisture content and low vapour consumption).

Rotating rod drier for hanks A continuous drier for drying hanks in a thermal chamber. The hanks of yarn are supported on rods which rotate slowly during their passage through the drier so that the position of contact with the hanks changes constantly. This type of drier is similar to the → Rotation rod drier.

Rotation (Lat. rota = wheel), revolution, turning.

Rotor atomizer This coating system basically consists of a rotor support, hydraulic control device, liquor container unit and centrifugal pump. The rotors turn at approximately 5000 rpm and distribute the treatment liquid over the product with droplets of approximately 30 µm (see Fig.).

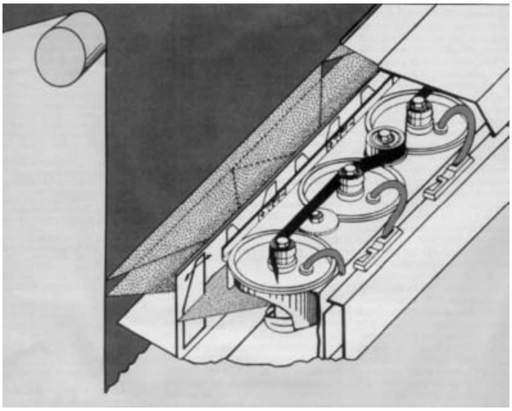

Fig.: Rotor atomizers (WEKO) for dampening a material across its width as it travels past.

Rotor damping A method for damping fabric and for → Low wet pick-up. It operates without jet nozzles. The equipment consists of a rotor support, a hydraulic control unit, liquor container and centrifugal pump (Fig. 1). The liquor is finely dosed. The rotors (approx. 500 rpm) spray a part of the liquor as very flat spray in the form of tiny droplets (diameter approx. 30 µm) at a vertical sheet of fabric. The spray width is approximately 100–400 mm (Fig. 2). The staggered sprays and overlapping zones result in a spray width of 180–280 mm for approximately 800 ml/m/min. Higher application levels are possible by having several rotor sup-

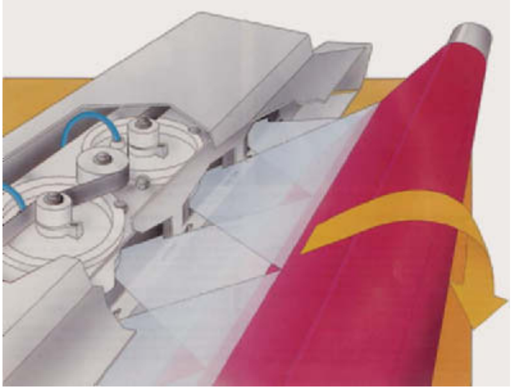

Fig. 1: The WEKO rotor dampening system.

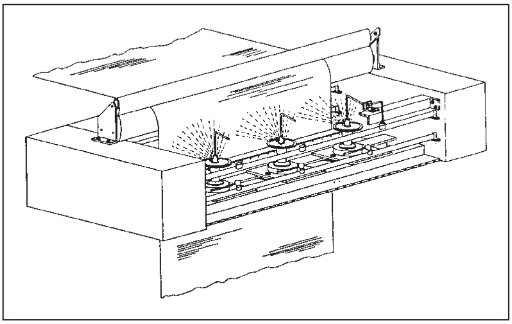

Fig. 2: The Proeco rotor dampening system.

ports, either on one or both sides. The wet absorption depends on the speed, and can be 0–25%, allowing for the product weight. Rotor damping can, because of its convenient size, be integrated into existing machines without much trouble, e.g. into the entry and exit of stretching machines, calenders, pole rotors, sanforising machines, etc. Wet-in-wet application is possible.

Rotor-spun yarn (OE yarn). Fibre yarn produced by means of rotor or turbine spinning process (→ OE spinning process). Individual fibres are removed from slubbings and are continuously added to a spinning open yarn end by an air current from a rotating turbine. This method of spinning results in carded -type yarn with typical qualities differing from those of ring-spun yarn → Ring-spun/rotor-spun yarns, properties of.

Rotor washing machines Washing machines with a divided inner drum uni-directional. Used in the multi-bath or → Flow washing process. Advantages: idle time for reversal of drum rotation is eliminated, thus ensuring a shorter washing process (= levelling for compression treatment reduces washing requirements) and smooth inner drum rotation.

Rot-protective finishing →: Fungicidal finishes; Antimicrobial finishes.

Rottability of textiles Refuse (wet household refuse). Rotting is done on an industrial scale in composting plants by the following heat process: 36 hours heating at a temperature of 70°C; 4 weeks of additional rotting with aeration (and eventual rotting of residual waste). This involves aerobic and anaerobic bacteria, which break down the waste product with the help of enzymes. Synthetic materials such as polyester, polyamide, polyacrylnitrile or polyolefins, however, are not broken down. What is important in the rottability of textiles, is that only cellulose fibres or protein-based fibres rot during composting. A year-long rotting test revealed the following order of textile degradability:

- wool > cotton > viscose > linen > polyamide > polyester > polyacrylnitrile > polyurethane > polyvinylchloride.
- natural/synthetic fibre mixes > synthetic fibres > reinforced rubber.
- carton/packing card > polythene bags > polypropene bags.

The DIN 53 933/part 1 test is the measure of rottability for these textiles. In this test, the criterion is 80% loss of the sample's initial maximum tensile strength (Fig. 1).

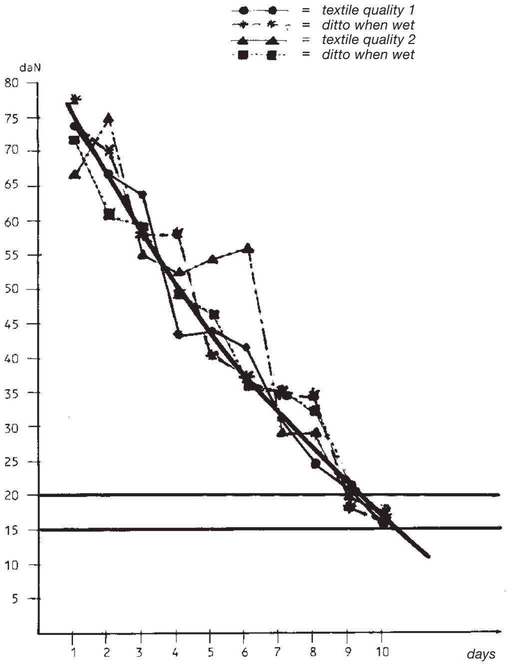

Fig. 1: The strength performance of unfinished cotton fabric in the burial test (DIN 53 933/part 1); drop in maximum tensile force of 80% with respect to the initial maximum tensile force (according to Hemmpel).

If a fall in maximum tensile strength of a cellulose textile product is taken as the criterion for the final rotting point, dependent on the action of the soil, a certain rotting period in days until the final point is reached is designated by f_1.

If a non-finished textile product is used to obtain the starting and reference values, the drop in the maximum tensile strength in a comparative tear strength test according to DIN 53 857 provides a fairly precise indication of the rottability that can be expected of a textile product.

It should basically be assumed that a non-chemically finished cellulose textile product will rot to 80% of its original (maximum) tensile strength within 5–8 days under the test conditions defined in DIN 53 933. Multiples of the rotting time f_1, $f_2 - f_5$, are only important in testing the durability of textiles treated against rotting according to DIN 53 933/part 2 (in preparation).

To rot a product until it loses more than 80% of its maximum tensile strength is pointless, as a tensile strength loss of over 80% is impossible to differentiate exactly. If total rotting (100% tensile strength loss) were used it would no longer be possible to establish the required time factor f_1 for later tests with treated material.

The time it takes for a textile product to rot completely in composting depends on the composting method. Untreated cellulose fibre can be composted in the same time scale as ordinary wet refuse.

If the basic value for the drop in the maximum tensile strength of untreated fabrics is given as 80%, and the product is described as "100% rottable", where a specified number of days until this is achieved is given for the burial test, then with treated fabrics the effect of the treatment can be shown by the reduction in this rottability under the same test conditions (same number of days in burial test according to DIN 53 933 (Fig. 2).

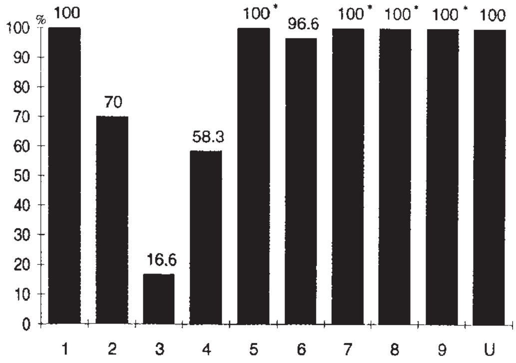

Fig. 2: The influence of finishing agents on the rottability of cotton (tested similarly to DIN 53 933).
1 = water-repellent finishing agent (fluorocarbon and silicon based); 2 = water-repellent finishing agent (paraffin based); 3 = curing agent; 4 = flame retardant agent; 5 = nonconserved softening agent; 6 = conserved softening agent; 7 = anti-electrostatic agent; 8 = handle improving starch; 9 = anti-slip finishing agent; U = untreated goods.
**improves rottability (according to Hemmpel).*

Textile finishing processes affect the rottability of cellulose textiles as follows:

a) Antimicrobial finishing: up to 5% of the rottability of an untreated sample in 7–12 days.
b) Vat dyeing, reactive dyeing, direct dyeing: no reduction in rottability.
c) Resin finishing materials reduce the rottability to zero, depending on the amounts of resin used:
  - modified dimethyldihydroxyethyleneurea: 100 g/l.
  - N-methylol compounds (which below 1500 ppm formaldehyde is not subject to labelling under the German Directive for Use of Dangerous Substances (GefStV – Gefahrstoffverordnung), according to DIN 54 260): 150 g/l,
  - self crosslinkers modified as methylolurea: 100 g/l.
d) Flame-proof materials behave differently according to type, but as wash-fast crosslinking finishes are no longer rottable.

Other finishing agents, e.g. softeners, antistatics, handle modifiers or anti-slip agents appear to accelerate rotting in the burial test (reaching 80% tensile strength loss in less than 8 days). If the finishing agents used in the cellulose textiles contain preservatives, the rottability is reduced (according to Hemmpel).

Rotting resistance test A method of determining the tensile (tear) strength of a textile sample either by the →: Soil burial enzyme test; Soil burial test or by inoculating (infecting) the sample with the spores of one or more moulds in a test chamber where tropical humidity and temperature levels are maintained.

Roughness is understood as the unevenness of a surface. It can be described geometrically by the size of the roughness elements, or mechanically by the friction coefficient. When touched with a finger, the roughness is not noticeable. However, if a finger is moved across the surface at a constant speed (approx. 3–4 cm/s), the movement receptors in the finger are rhythmically stimulated. These groups of impulses are perceived as roughness, the time between the individual impulses reproducing the roughness. The contact pressure is close to the contact threshold so that the roughness is identified from the friction caused.

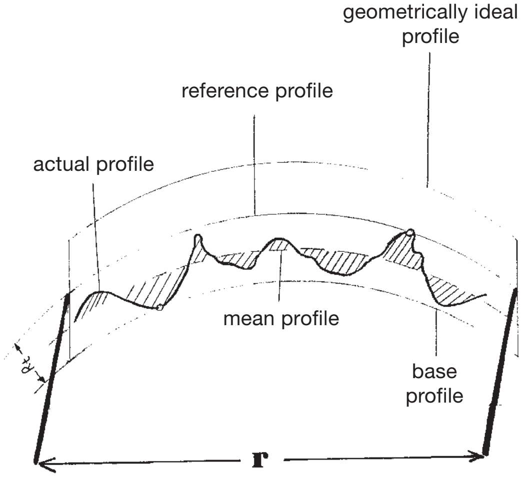

Fig.: Roughness: the relation of the reference profile to the actual profile.
Mean profile, roughness depth R_t (r = roughness reference length).

“Raising” is the processing stage where roughness is achieved. The result is a surface which is distinct from smooth surface of a solid, both regularly and irregularly. In mechanically produced items, roughness affects the appearance (visual surface) and function (surface resistance). It is the result of the production process. The surface structure can be grooved, hollowed, spongy or scaly. In textiles processing, → Raising means bringing fibre ends out of the fabric to the surface in order to obtain a fluffy surface.

Roulette The upper pressurised milling cylinder on a → Cylinder rolling milling machine.

Roving Condenser cable, usually of doubled spun glass yarn, but also of other fibres, e.g. woven and pieced together, for industrial matting. Rovings can, for example, be used as reinforcment in cylindrical composites (see Fig.) and are therefore used as semi-finished products in non-steel constructions, e.g. bicycle frames.

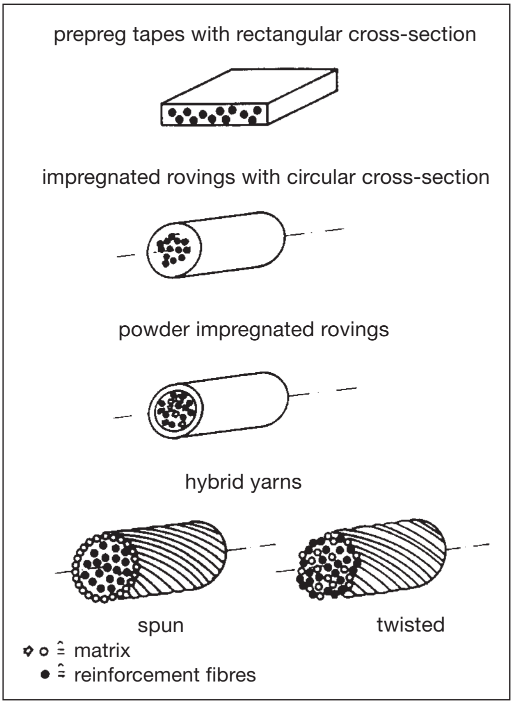

Fig.: Rotationally symmetrical composites as semifinished products; roving reinforced thermoplastics.

Royal-Axminster carpet A velvet pile machine-woven carpet. The pattern does not penetrate to the back of the carpet.

Ru Symbol for ruthenium (44).

Rubber →: Caoutchouc; Vegetable gums.

Rubber covered rollers for textile finishing The problem is to find the right rubber quality to match the particular finishing processes in each textile finishing machine. Selecting the correct rubber quality requires details on the type and concentration of chemical agents used in the process, the bath temperature and mechanical load. The chemicals to which the rubber is exposed are of particular importance. Even small amounts of chemical additives and traces of certain substances can play a role.

Rubber fibres (rubber threads, latex threads), are latex fibres with the elasticity of rubber: they either have a circular cross-section (extruded) or a square cross-section (cut from rubber sheets). The properties of cut threads are: density 0.92–1.05; strength 25–30 N/mm^2 (injected 35–45 N/mm^2), elongation at break 700–900%. They are susceptible to damage (softening and brittleness) from: atmospheric oxygen, ozone, sunlight (10 h of intensive solar radiation degrades elasticity), dry heat (should not be dried at high temperatures or shaped in dry heat), rubber toxins, oils, fats, protective skin creams, dry cleaning solvents, many spotting agents (including benzine, benzol, chlorinated hydrocarbons, etc.). Modern alternatives are → Elastomer fibres. They are dyed with pigment dyes. Not all rubber fibres are resistant to boiling. Treatment liquors should be alkali-free (permutit water can cause damage).

Rubberizing,

I. Sometimes used to describe the application of finishes.

II. Coating a fabric with rubber, on one or both sides, either in a solution of benzol and other hydrocarbons, or as an emulsion. Coating is applied in several layers on a coating machine; finally it is hot or cold vulcanized. Fabrics to be rubberized must be free of acids, fats and metals (rubber poisons), as these cause premature ageing and tackiness of the coating. Synthetic rubber can be used in place of natural rubber. However, nowadays rubberizing has largely been replaced by the use of film-forming plastics.

Rubber-metal connection Bearing elements of rubber and metal which are tightly bonded together chemically at contact points. The binding strengths in respect of tear strength are at the level of the quality of the rubber used (natural rubber or synthetic rubber). The soft rubber element between metal parts functions as a vibration and sound damping elastic shock absorber, which means that with proper application they can provide great stability for machine beds and damping for couplings, joints, buffers, etc. Rubberized metal is also widely used for finishing machines, as well as for centrifuges, washing, printing and raising machines, for electric motors, sensitive lamps, ventilators, switches, testers, etc. For heavier machines, rubberized metal rails are usually used, with a U-profile to provide vertical suspension, and buffers for parts subjected to pressure and shear forces. Special suspension elements are used to support sensitive instruments and devices, which feature rubberized metal dome nuts. Also of importance are various kinds of rubberized metal buffers and couplings.

Rubber thread inlay Rubber thread threaded between textile stitch courses.

Rubber threads → Rubber fibres.

Rubber varnish → Shellac.

Rubbing fastness, wet Tests were carried out with a crockmeter to investigate the force required when rubbing. The rubbing strength for dry rubbing fastness depends more on the fibre material than the profile of the fabric. With cotton textiles the spread of results obtained is significant, while the spread is less with woollen textiles and negligible with man-made fibres. With wet rubbing fastness, almost double the rubbing force is required as with dry rubbing fastness across all fibre types. With wet, in contrast to dry, rubbing fastness, the spread of results is remarkably low, although again it is highest with cotton textiles.

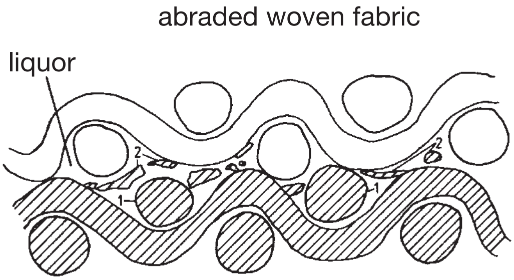

Fig.: Possibilities of dye extraction in the event of wet rubbing:
1 = from the damaged woven fabric; 2 = form abraded fibre fragments.

Microscopic examination has shown that during wet rubbing tests, cotton fabrics are significantly damaged (see Fig.). The cause of this damage is the rubbing coefficient, which is almost twice as high. This means that a significant part of the mechanical work done causes damage to the material.

Rubbing reaction (from P.-A. Koch) used to identify types of polyamide fibre. → Rubbing reagents I and II cause extremely characteristic swelling of the polyamide fibre. At first, fine fibre lacing occurs (name of reaction), which merges again as the depth increases until deliquescence occurs in the final stages, similar to the melting process. The difference between polyamide 6 differs and polyamide 6.6 is due to rubbing reagent II.

Rubbing reagents For polyamide fibre verification using → Rubbing reaction.

1. Rubbing reagent I: 5 parts by volume of zinc chloride solution (from 100g of water-free zinc chloride and 50 ml of water, density adjusted to 1.9) is mixed with a proportion by volume of methanol.
2. Rubbing reagent II: 5 parts by volume of zinc chloride (from 100g of water-free zinc chloride and 100 ml of water, density adjusted to 1.566) is mixed with a proportion by volume of methanol.

Rub fastness testing (crock fastness testing). A test to check the resistance of textiles and their dyes against soiling and crocking during use; in accordance with DIN 54 021. The guidelines apply to all fibre types. For dry fastness, dry dye is rubbed with dry cotton fabric; for wet rub fastness, dry dye is rubbed with wet cotton fabric; it can be carried out with a special rub tester (crockmeter). The fabric is rubbed to and fro 10 times over 10 cm for 10 seconds, at a load of approximately 1000 g. The staining of the cotton rubbing cloth is then compared against the grey scale/stain.

Rub off, to (crock, to). Transfer of dye to white fabric, which often happens with saturated colours, in particular naphthol and pigment dyes, and with some dyes it is practically unavoidable. This rubbing off (dry rubbing) is not colour loss in the sense of fading or insufficient dye; it is rather due to superfluous dye particles (excessive dyeing).

Ruby number A value used for protective colloid effects of textile auxiliaries. It is based on protection against precipitation of a sodium chloride solution, with a solution of Congo ruby A being used as a indicator. The ruby number is the protective colloid in mg, which is just able to prevent the colour change to violet after 10 minutes.

Ruling After precutting in mill engraving, the pattern die is coated with a thin layer of acid-resistant asphalt varnish, into which the → Hatching is scratched on the ruling machine. Finally the pattern die surfaces lying outside the pattern contours are additionally coated with asphalt varnish (reinforced) and the hatching is etched in with nitric acid. The varnish is then washed off with solvents, the pattern die is re-cut, ground, polished and finally hardened. In this way the master pattern is ready. → Engraving.

Rumal An old Indian art still practiced today, where fine cotton headscarves and wedding cloths are silk embroidered with figures.

Run American numbering system for carded woollen yarns. 1 run = 1 hank of 100 yards/oz.

Runic coating The addition of modified rune-type points (point coating) with polyamide paste which is beneficial in preventing mock moiré effects in outer material. Runic coating when applied in even quantities (20 g/m^2), in contrast to dot coating, ensures softness of nonwovens which have been coated, thus reducing the danger of breaking through with a thinner coating of the adhesive mass.

Running creaser Permanent creases in wool products occurring during washing, dyeing and milling in longer runs along the same fold length, and which can only be partially removed by crabbing and decatizing.

Running speed The speed at which a textile product being treated passes through a section, e.g. a finishing machine. It is measured in m/min, while the rotational speed is given in rpm; in weaving machines running speed is measured by weft insertions/min.

Run-off control A program control whereby the unit being controlled relies on certain process parameters. The operating program, which depends on parameters entered by a programmer, follows a pre-set procedure in which each stage is dependent on the process stage reached (feedback system). → Process control engineering.

Russian hemp Identical to Pita fibre; → Mauritius hemp.

Rust consists of iron (III) oxide Fe_2O_3 or iron oxide hydrate (hydroxide) $Fe_2O_3 \cdot H_2O$. The coating is typically red to red-brown. It occurs through the attack of atmospheric oxygen, hydrogen and carbonic acid and is aggravated by acidic vapour, ammoniac, flue gas, etc. It does not occur in alkaline water.

Rust forms according to the following formula:

$$Fe + {}^{1}/{}_{2}\, O_2 \rightarrow FeO$$
$$2\, Fe + {}^{3}/{}_{2}\, O_2 \rightarrow Fe_2O_3$$

This corresponds to an iron pipe that corrodes after a few weeks in a damp atmosphere. Rust forms in the following stages: 1. Adsorption of oxygen (from the air). 2. Iron atoms migrate to the surface, forming oxide, which causes gaps in the crystal lattice of the metal. 3. Further rust forms on the surface. In this way the originally compact crystal structure gradually dissolves (according to Fornelli).

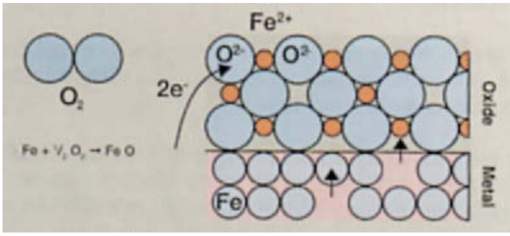

Fig.: The mechanism by which rust is formed (Sandoz).

Rust, laminar →: Keratin sheet structure; Pleated sheet structure.

Rust remover stick Usually → Oxalic acid in stick form for removing rust stains.

Ruthenium red solution 0.02–0.05 g of ruthenium red (ruthenium ammoniumoxychloride) is dissolved in 9 ml of water, 1 ml of ethylenediamine and 10 ml of concentrated glycerine is added. Uses: in microscopy and for fibre testing. It results in a red colour with lignified membranes, resins, pectins, fibroin, chlorinated wool and solids. Silk (sericin) and flax acquire a pink colour, while jute and hemp acquire a pink-red colour.

Rutile A modification of → Titanium dioxide. Used as a white pigment in textile pigment printing.

Rya carpet Scandinavian long-pile carpets in characteristic colours and patterns. They were originally hand-knotted from rough wool (genuine Rya). They are now machine-woven by various processes.

S

S The chemical symbol for sulphur (16).

SABS South African Bureau of Standards → Technical and professional organizations.

Saccharides → Carbohydrates.

Saccharification Saccharification is the process of starch decomposition during desizing. End products: starch sugars (maltose, glucose), which can be removed by washing as they are easily water soluble, and therefore enable starches to be removed from fabrics.

Saccharomycetes → Yeasts.

SAD SAD is a measure for soil pick up which is obtained by reflection measurement (→ Soil adhesion).

$$\mathrm{SAD} = \log \frac{R_{\mathrm{unsoiled}}}{R_{\mathrm{soiled}}}$$

R = reflection according to the wavelength.

Safety belts → Automobile safety belts.

Safety data sheets (SDS). The ecological behaviour of commercial products, together with aspects relating to application, are playing an increasingly important role for manufacturers, processors and consumers, as legislation and authorities are increasing pressure to use environmentally friendly products. On the other hand, however, this is clearly accepted, as individuals are taking measures on their own initiative in order to minimise the impact on the environment by converting to other products and/or altering processes. The ETAD (Ecological and Toxicological Association of the Dyestuffs Manufacturing Industry) has been issuing safety data sheets to affiliated dyestuff manufacturers since 1974 in order to support these efforts and to provide information on the regulations to be complied with, details of the physical, toxicological and ecological properties, together with handling, transport, storage and safety aspects. In the meantime, the ETAD data sheet has been superseded in the dyestuffs sector by the German DIN safety data sheet (SDS)[the German DIN Sicherheitsdatenblatt (SDB), i. e. SDS], which has resulted in a higher intensity of information. Methods to establish the necessary data, which are influenced, amongst other things, by chemical legislation, are also increasingly being normalized or standardized. The ecological details are listed under point 8 in the SDS, i.e. whether substances are biodegradable, toxic to fish, harmful to waste water bacteria, and details of the water pollutant toxicity classification of the product. More information concerning the exact chemical composition of the products, proper disposal and the by-product level present will be desired in future. According to the Directive for Use of Dangerous Substances the manufacturer, importer or marketer has a duty to supply the recipient with a safety data sheet with the first delivery. If the content of the safety data sheet should change within twelve months of delivery, the supplier must automatically forward the client an updated version of the safety data sheet.

Safety signs With the ever increasing risk of litigation, the need for state-of-the-art safety signs and labels has become virtually mandatory for equipment manufacturers. Lawsuits based on “inadequate warnings” have become the predominate form of product liability litigation in the United States. The fact is, if a personal injury occurs during the use or service of equipment and it did not have a state-of-the-art safety sign, there is a significant chance that the equipment manufacturer will be brought into a product liability lawsuit. To prevent this from happening, the best remedy is to design the hazard out of the product or environment. If this cannot be done, effective guarding is the second option. Often guards are removed or circumvented. Using warnings under guards acts as a second line of protection, both for the product user and for the equipment manufacturer. Designing out of guarding hazards should always be the first choice, but because of its function some equipment can be dangerous. Blades cut, gears crush, heated surfaces are hot. Such equipment can have hazards associated with its use and/or service. This is where warnings become an integral part of the product’s design. Safety signs can serve to warn about residual risks, thereby helping to prevent accidents from occuring. If an accident does occur, warnings can provide an equipment manufacturer with a better defence in court. Safety signs and labels should be located in the appropriate place to alert persons to the hazard in time for them to take proper evasive action to avoid the hazard. Sometimes this location is at the point of control for equipment and other times it is

Fig.: Safety signs.

immediately near the potential hazard. In some cases, the hazard does not exist while a guard or protective door is in place. But once the guard is removed or door opened, a possible hazard exists. In this instance, a safety sign or label is often placed on or next to the guard or door and another label is placed on the equipment under the guard or door to alert people to the fact that a hazard exists (Fig.).

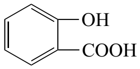
Sail test Combined wear and laboratory test for → Static charge. A test subject wearing a waist slip made from the fabric to be tested passes a polyester sail fixed in an air conditioning chamber. The slip rubs against the sail and is charged. A second person assesses and records the charging and discharging per unit of time.

Sailcloth (canvas, duck). Dense and tight, impregnated heavy fabric (linen, cotton, hemp, synthetic fibres) in plain weave. Used for tarpaulins, awnings, sails, window blinds, etc.

Sakellaridis Valuable Egyptian → Maco cotton.

Sal-ammoniac → Ammonium chloride. A term used commonly in practice, yet incorrectly, for → Ammonium hydroxide.

Salicylic acid (o-oxy-benzoic acid), C_6H_4OH COOH. Density 1.443; melting point 156°C. White crystal needles, sweet and sour to the taste, strong acid, sublimates when heated gently, decomposes (into phenol and carbon dioxide) when heated rapidly. Soluble in fatty oils, alcohol, ether, hot water, barely soluble in cold water. Inhibits the growth of bacteria. Use: as a preservative (coloured ferrous salts), carrier, to increase light fastness of direct vat printing (aftertreatment with 10 g/l).



Salt accumulation When recycling e.g. rinsing water which is sometimes still cleaned in in-house waste water treatment plants, the salts remain dissolved in the water and are not removed. When the recycled water is reused as process or rinsing water, more salt is added to the salt concentration already present from the first use of the water. If part or all of the water is used several times, the salt water concentration continues to increase imperceptibly and may become a source of interference.

Salt addition in dyeing This is used for the following:

I. Dyeing cellulosic fibres with direct dyestuffs: Addition of salt (sodium sulphate or sodium chloride) increases the affinity of the dyestuffs to the cellulosic fibres. The salt affects the agglomeration of the dyestuff molecules in the liquor and the fibre, displacing the equilibrium to the fibre.

II. Dyeing protein fibres: the addition of salt is used to dye the fibre evenly in the acid medium. Due to its negative charge, the dyestuff has a high affinity to the positively charged wool fibre. The essentially smaller anions of the salts also invade the positive areas of the wool, preventing the dyestuff molecules from being absorbed. As the affinity of the dyestuff molecules to the fibre is higher than that of the anions, the dyestuff is absorbed slowly. The slow ion exchange results in an even dyeing.

Salt content monitor Electrical monitoring device to check the salt content of solutions, e.g. bleaching liquors, washing water. The high measuring accuracy is only slightly affected by deviations in temperature. The salt content can be kept constant by means of control equipment.

Salt dyes → Direct dyes.

Salting out This refers to incorrect precipitation of dissolved dyestuffs or textile auxiliaries as a result of excessive addition of electrolytes which results in bronzing and insufficient fastness to crocking.

Salt linkages (salt bridges) → Wool chemistry.

Salt on dyed goods as a source of fibre damage Viscose which has been badly rinsed after dyeing and immediately dried can suffer losses in strength when residues of sodium sulphate (Glauber's salt) from the dyeing process crystallize out on and in the fibre thereby causing some mechanical fibre breakage through pronounced swelling.

Salt resins → Cationic resin.

Salts Reaction products from acids and bases (alkalis) with removal of water; e.g. hydrochloric acid and sodium hydroxide solution form sodium chloride and water. Salts dissociate in electropositive base radicals or metal cations and negative acid radicals or non-metallic anions. Depending on the number of hydrogen atoms exchanged, polyvalent acids form a) neutral salts: all hydrogen atoms are replaced by metal ions; b) acid salts: only a portion of the hydrogen atoms present are replaced by metal ions, e.g. sulphuric acid H_2SO_4, sodium sulphate $NaHSO_4$ (→: Primary salts; Secondary salts; Tertiary salts); c) basic salts: only a portion of the OH-ions present are replaced by acids, e.g. basic chromium chloride $CrCl(OH)_2$, instead of $CrCl_3$; d) double salts: by mixing different salts or by H atom exchange using different metals e.g. sodium potassium sulphate $NaKSO_4$; complex salts, e.g. chromium potassium sulphate $KCr(SO_4)_2 \cdot 12\,H_2O$.

Salts for dyeing applications →: Aluminium chlorate; Aluminium ammonium sulphate; Aluminium potassium sulphate; Calcium carbonate; Potassium dichromate; Sodium acetate; Sodium bisulphite; Sodium chloride; Sodium hexametaphosphate; Sodium nitrite; Sodium phosphate; Sodium silicate; Sodium sulphate, (beta-naphthol), (copper sulphate), (mordanting), (oxygen products), (zinc oxide).

Salt wash (salting out process). Washing process for wool fibres, also removal of mineral oil lubrication stains; whiteness degree and handle are extremely good. Corrosion of iron parts possible. Carried out using non-ionic detergent and sodium sulphate, 10–20 g/l at 25°C liquor temperature, approx. 10 g/l at 45°C. Cold fresh water below the wash temperature is added for rinsing.

Sal volatile → Ammonium carbonate.

Sample Samples in textile testing, in the form of an individual or collective sample, should correspond to the representative section of the goods to be tested in terms of composition and properties. →: Random sampling; Technical textile sampling.

Sample cutter A sample cutter is used to take samples from the fabric.

Sample drier Cabinet drier for textile samples.

Sample dyeing Preparing a colour which, to a large extent, matches a colour sample under various sources of light (day light, artificial light). Assessing a shade or whether it matches the sample and any adjustment using the eye are subjective processes and can be influenced by various factors. Assessment of compatibility with or deviation from the sample for adjustment is therefore carried out using colour measuring devices.

Sample lengths Small quantities are required for dyeing or printing when preparing collections. The relevant sampling machines should anticipate the production ratios as accurately as possible so that the samples manufactured can be reproduced if the client places an order.

Gali manufactures a screen-printing machine to print small sample lengths. The short printing background is bonded to a rotating steel belt (Fig. 1). The next colour is printed with a new screen for each precise repeat cycle. Minox produces a sample overflow dyeing machine with a liquor capacity of 60 l for 5 kg of fabric (Fig. 2).

Fig. 1: A short-run rotary printing machine using an endless steel band (Gali).

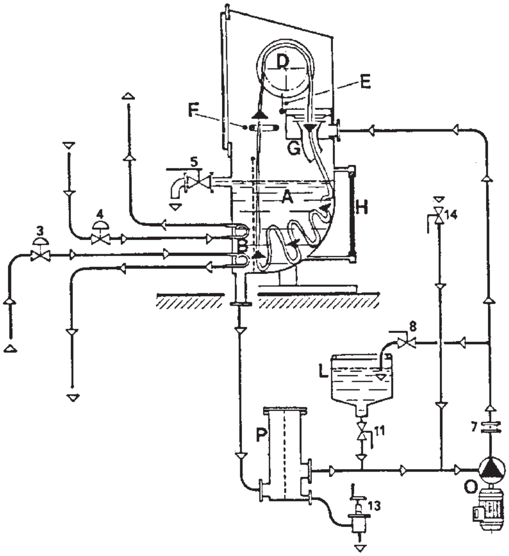


Fig. 2: Minox Overflow, a sample dyeing machine. A = dye liquor; B = heat exchanger; D = transport winch; E = goods sensor; F = goods guide; G = overflow system; H = filling level indicator; O + P = liquor circulation system.

Sampling controller A sampling controller is a discontinuous, scanning or analogue controller which contains a sampling element in the input channel which samples deviations at specific time intervals and provides a specific signal.

Sampling lock E.g. the patterning attachment on a HT yarn beam dyeing autoclave with which it is possible to insert small quantities of yarn or piece goods into the dye and extract them during the matching process by means of a twin lock without altering the treatment conditions (see Fig.).

Sampling vessel This is a small vessel attached to the dyeing machine, in which quantities of sample are switched to the secondary liquor cycle. These are connected to the dyeing machine so that the test specimens (samples) can be incorporated into the liquor circulation during dyeing. The interconnecting valves between the dyeing machine and the sampling container should be closed to remove the sample. The liquor should then be drained off from the sampling vessel and this must also be vented if necessary.

As with many dyeing machines, it is possible to open the sampling vessel even without taking these measures, and then scalding often occurs. According to

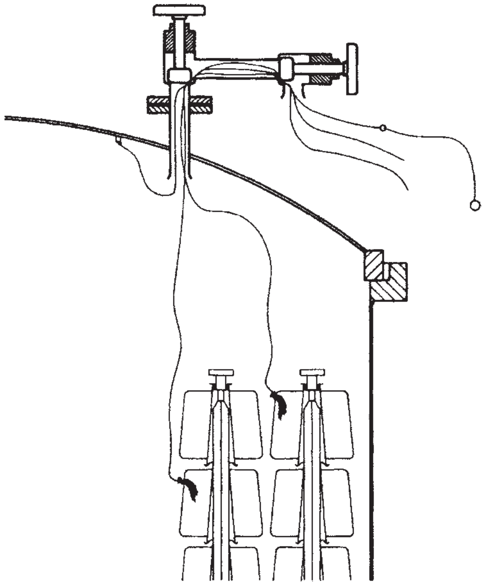

Fig.: A sampling lock on a yarn dyeing autoclave.

the draft of the future European and international safety standard for textile machinery, sampling vessels must be constructed in such a way that it is not possible to open the cover before the feed and outlet connections are closed and the vent is open. It is possible to achieve this using a single shaft connected to the cover which activates the interconnecting valves together with the vent connection (see Fig.).

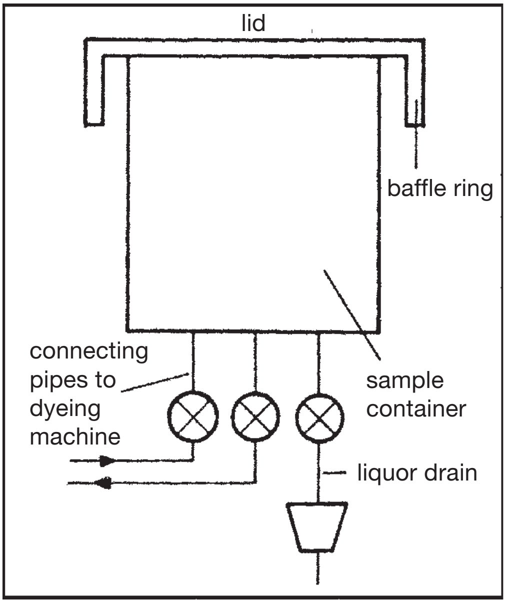

Fig.: A sampling vessel with a safety device to avoid danger when opening.

Sancowad-Process Short liquor dyeing process (Sandoz) for fully fashioned articles, stockings, socks, etc. with liquor-to-goods ratios of 1 : 1 to 1 : 2, using special textile auxiliaries which produce microfoam.

Sandarac gum Natural → Resin from the bark of a North African cypress. Lemon yellow pieces, powdery, fresh surface fracture with glassy lustre. Melting point approx. 135°C. Soluble in alcohol, chloroform, distilled oils. Only used occasionally for silk ribbon finishes and lacquers.

Sand crêpe → Crêpe Jersey.

Sanding Sanding is distinguished from → Emerizing in that only one roller is used as a tool per machine, whereas several rollers work on the fabric in emerizing. A guide roller advances the fabric as close as possible to the abrasive roller which operates at high speed (Fig. 1). The distance determines the sanding effect and must therefore be accurately adjusted. The resultant frictional forces are discharged in the abrasive grinder by cooling the roller. The effect can be intensified, as shown in Fig. 2, by looping the abrasive grinder more.

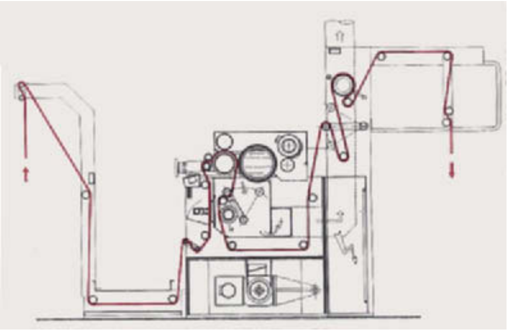

Fig. 1: The Sperotto Rimar SM1 sanding machine.

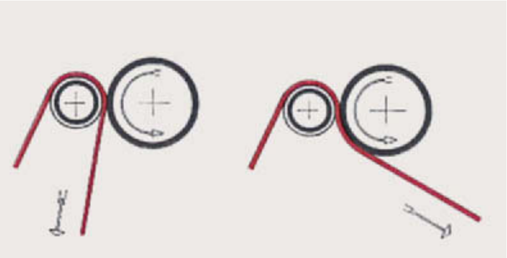

Fig. 2: Two ways of introducing goods to the grinding roller. Left: proximity; right: tangential.

Sandwash silk The sandwash finish of silk fabrics was launched as a response to the fashionably successful "peach-skin" articles made from polyester microfibres. Firstly, the silk is treated with an enzyme (protease) in the drum washing machine in a weak alkali bath with a low liquor-to-goods ratio. This causes the fabric to peel slightly and at the same time, the mechanical strains on the fabric cause a slight napping of the silk fibres. Together with the appropriate final finish, this achieves the characteristic sandy soft handle. Sandwash fabrics display a faded character in contrast to machine wash finishes and have (intentional) white marks (extremely napped, lighter areas, generally lengthways and in folds). Ready-to-wear items are often finished in this way.

Sandwich In sandwich structures, the filling is found between the two layers. Sandwich structures arise e.g. macroscopically, if a fabric which is to be treated enters between a printing belt and a cylinder (Fig. 1). Sandwich structures on a textile basis (Figs. 2–3) may reduce the weight of a fibre-reinforced synthetic material e.g. as a nonwoven.

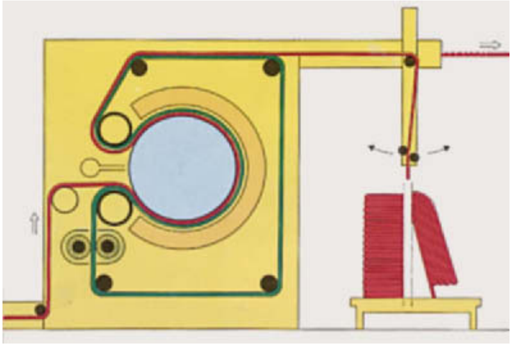

Fig. 1: A typical sandwich working method: the goods (red) are fed between the heated cylinder (blue) and the pressure band (green) in the Sperotto Rimar Multidecat 2.

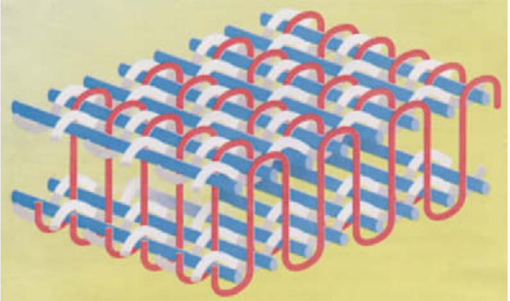

Fig. 2: A textile constructed with a sandwich structure to serve as the core for lamination.

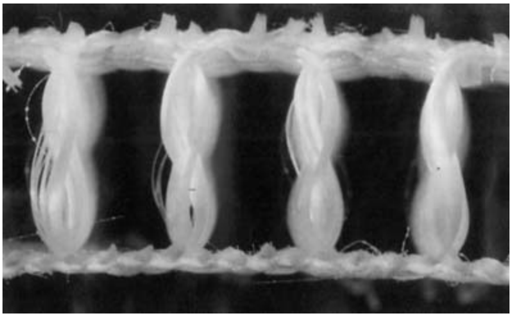

Fig. 3: A three dimensional fabric seen in warp section.

Sandwich structures are also formed in → Laminating, with e.g. an "inner sandwich" (lining inside, top cloth outside) or an "outer sandwich" (lining outside, top cloth inside) being formed. When transport tarpaulins are laminated, the sandwich structure is as follows:

outside	lacquer coat
	top coat
	base coat
inside	fabric

In transfer printing, the paper and the polyester material between the heated pressure plate and base (discontinuous) or in the calender between the roller and belt form a sandwich themselves to enable the disperse dyestuff to sublimate well.

Sandwich dyeing Method of impregnating used predominantly for synthetic fibrous material, mainly to dye light shades whereby the material, rather than being fed through the liquor and squeezed, passes in close contact between two endless absorbent cloths which constantly absorb liquor. Dyestuff from these liquors is thus transferred to the material to be dyed.

Sandwich effects in dyeing (greyness) A dye migration phenomenon in continuous dyeing. The dye migrates from the surface to the interior of the textile material or the dye is washed off the textile surface. As a result, the textile material only appears to be dyed in the middle whilst the surface has a whitish appearance which is often referred to as "greyness". The problem can be remedied or prevented by using appropriate dyeing systems.

Sandwich laminating → Laminating an expanded sheet between two textile webs.

Sanforize A no longer protected brand name for cotton and cotton-mix textiles with shrink-proof finishes made by specific mechanical processes, e.g. shirts, pyjamas, workwear, etc. with a shrink resistance of max. ± 1% tested according to prescribed standard regulations → Compressive shrinkage processes.

Sanforizing oils Sanforizing oils are finishing oils used to provide the fabrics to be sanforized with sliding properties on the shoes of the progressive shrinkage device. Sanforizing oils must not become resinous, and must have good rewetting properties and act as softeners at the same time.

Sanfor-Knit Brand name, which is no longer protected and which is a control standard, relating to cotton knitwear. The standard is achieved by → Compressive shrinkage with additional light synthetic resin finish.

Sanfor-Set Brand name which is no longer protected which is a control standard. Limited to effects of textiles which have been finished using the → Liquid ammonia process and are characterized by good shrink resistance under drying conditions in a tumbler drier. This process can also be used for lighter cotton qualities.

Sanitary wear In the broadest sense, sanitary wear refers to so-called anti-rheumatic clothing. The alleviating effect is provided in conjunction with electrostatic properties and high thermal retention (heat retention). Woollen items are one example, as are particularly air-permeable woollen blankets, continental quilts, travel rugs which are also widely commercially available e.g. polyvinylchloride fibres. Medical aspects of such clothing: has the effect of promoting perspiration and the release of other toxins, encourages the skin to breathe and cleanse itself, guarantees healthy perspiration, removal of grease and salt and has the effect of accelerating the neuronal response time, i.e. it activates a neutral reaction, and therefore prevents colds, rheumatism, inflammation and is prophylactic. Angora underwear is also recommended for rheumatic illnesses.

Sanitation Process to control the germ count with the aim of avoiding the risk of undesired germs spreading, achieving an inhibiting effect and/or counteracting damage to material caused by microbes. →: Antimicrobial finishes; Sanitized finishing.

Sanitized chemical cleaning Complete chemical cleaning and disinfection process in the solvent bath with the addition of bactericidal agents.

Sanitized finishing (→ Antimicrobial finishes). Protects textiles against the growth of bacteria and mycotoxins, achieving a deodorizing effect at the same time (sanitized finish). Currently used for lining fabrics, stockings, socks, etc. Sanitized finishing is achieved using e.g. quaternary ammonium compounds, halogenated phenols, salicylanilide derivatives, neomycin sulphate, etc. To disinfect cotton items following a hypochlorite wash, zinc fluosilicate is used in the USA, for example. The intensive strain on functional clothing such as cycling shorts or body suits results in increased deposits of excrement such as perspiration, fat and traces of faeces and urine. These can form an ideal breeding ground for micro-organisms found on the skin. The high degree of moisture and body heat provide optimal conditions for growth for most micro-organisms. They can double in number every 20–30 minutes. When oxygen is present, i.e. in aerobic conditions, the nutrients (perspiration, soil) and the textile itself oxidize to form carbon dioxide and water. Nitrogentated nutrients (urea, skin particles) decompose to form ammonia. Where oxygen is not present, i.e. in anaerobic conditions, the bacteria are not able to oxidize the nutrients sufficiently to form carbon dioxide. In this case, acids such as lactic acid, acetic acid and butynic acid (odour of perspiration) may be produced. Certain micro-organisms such as the mould fungus aspergillus niger form pigments in addition to carbon dioxide, water, ammonia and acids (black-brown specks in the case of aspergillus niger).

Now that synthetic fibres are used, washing practices have also changed fundamentally. Washing at high temperatures, which has a germicidal effect, has been replaced by washing at low temperatures. Mild, alkali-free detergents are also used which do not substantially increase the death rate of bacteria. Often the laundry is hung up while still wet, esp. items which have a wash-and-wear finish. Due to the almost ideal conditions, the bacteria may increase during drying, in particular in the area of the shoulders and the crotch. All this leads to a deterioration in the standard of hygiene, unpleasant odours resulting from microbial metabolic products and, in the case of sports socks and shoes, athlete’s foot. Permanence must be guaranteed in order to ensure sustained hygienic freshness and the desired material protection. Moreover, it must not be too high due to excessive fixing of the antimicrobial active substances, as they are only effective if there is a certain migration of a minimal concentration in the surface moisture film. The antimicrobial finishing agent must be simple to apply and must be able to be combined with other materials such as softeners, antisoiling agents and water repellents, etc. Fastness to colour, perspiration, ironing, etc. must be preserved. The entire microbial spectrum normally present when using functional clothing must be covered with minimal additive concentration. If a standard concentration of a monosubstance is used as an antimicrobial finish, individual types of bacteria may survive and reproduce all the more quickly. With an optimal combination of carefully selected monosubstances, the individual additive concentrations can be kept low and the entire spectrum is nevertheless efficiently covered by the bacteriostatic and fungistatic effect. Ready-made combination formulae offer the most practical solution. The finish should be kind to the skin, non-toxic as far as possible and environmentally friendly. Pentachlorophenol, for example, which is repeatedly found in imported articles (e.g. sports socks) and products containing arsenic, for example, should not, therefore, be used. A wide range of ready-made formulae are commercially available. These enable an antimicrobial finish which is simple to apply and permanently effective and is also kind to the skin and the environment (according to Kehrli and Mebes).

Sansevieria fibre → Hard fibres similar to manila fibre (tropical Africa, Ceylon). The sansevieria fibre from Ceylon is finer than the African equivalent, similar to Mauritius hemp. Use: for string, matting and coarse cloths.

SANZ New Zealand. Standards organization; → Technical and professional organizations.

Saponide Term used abroad, especially in France, to refer to anionic organic detergent base materials, with the exception of soaps.

Saponification,

I. → S-Finish.

II. Chemical reaction to convert fats into → Soap by a base reaction. With fatty acids, saponification is in the form of simple neutralization. When neutral fat is saponified, glycerine is also produced.

Saponification dyeing process This is used for acetate/cellulose mixes. The aim is to achieve simultaneous → Saponification and dyeing with direct dyestuffs, vat dyestuffs, etc. Disadvantage: more difficult to achieve uniformity of shade (higher dye affinity of cellulose fibre), encourages uneven dyeings where there are different acetate grades (colour stripes).

Saponification number The saponification number indicates how many mg of potassium hydroxide are required to saponify 1 g fat. Using the equation

$$C_3H_5(COO–C_{17}H_{35})_3 + 3\ KOH =$$
$$3\ C_{17}H_{35}–COOK + C_3H_5(OH)_3$$

3 mol KOH (= 168 g) are required for 1 mol tristearine (= 891 g), i.e. approx. 0.189 g pure KOH is required to saponify 1 g tristearine. The saponification number provides an indication of the average molecular size (molecular weight) of the fatty acids involved in forming fat. From this, the → Fats are divided into those with very low saponification numbers (80–130 = beeswax, spermaceti, wool fat), low saponification numbers (171–181 = castor oil, rapeseed oil), those with average saponification numbers (approx. 193 = olive oil, groundnut oil, palm oil, cotton oil, poppy seed oil, hempseed oil, neat's foot oil, bone oil, beef dripping, whale oil, etc.; most fatty acids with 18 C-atoms) and those with high saponification numbers (205–290 = coconut oil, palm nut oil, japan wax, certain train oils). Paraffin oil or mineral oils or fats have a saponification number of 0. Adulterated or diluted fats can therefore be recognised by decreasing saponification numbers.

Saponification of acetate fibres As acetate fibres are esters of cellulose, they are easy to saponificate. This process gives rise to hydrocelluloses. Advantages: improved dyeing properties of regenerated cellulose which may now be dyed using direct dyestuffs, unlike acetate. Disadvantages: reduced brightness and reduced breaking strength. Saponification is nevertheless common where necessary. Principle: partial saponification (unmodified core of acetate cellulose and a saponified surface layer of hydrocellulose which is as fine as possible) with alkali and levelling agent and fibre preserving agent if necessary.

Saponification value (ester number) → Acid value (for fats and oils).

Saponin Pulverised, evaporated aqueous extract from soaproot or → Panama soap. Non-alkali detergent. Group of complex plant glucosides of tigogenine, gitogenine, etc. in Panama soap, soaproot or Senegal root, horse chestnut, etc. Contain amongst other things the particularly toxic sapotoxins which can be separated using a special process. Saponins provide colloidal, foaming solutions, similar to soap. Adding approx. 1% saponin when dry-cleaning with white spirit acts as an anti-static agent.

Saprogenous system → Water quality classification.

Saprophytes Dead organic matter. The term saprophytic bacteria (putrefactive bacteria) is used.

SAQ Swiss Association for the Promotion of Quality, Zurich; → Technical and professional organizations.

Sarcina Sarcina are earth- and air-borne bacterial microbes (in coccus or cuboidal form, sporadically forming spores). Also occur in perspiration (up to 45% on the upper arm). Sarcina can be harmless but also pathogenic.

Sarcosine → Methylaminoacetic acid.

Sari A sari is a wrap-around robe native to India which is often printed with large patterns.

Sarong A Sarong is a Malaysian item of clothing for women which often has large characteristic batik patterns.

SARTEX SARTEX is a Swiss association for textile labelling. Office based at the Gesamtverband der schweizerischen Bekleidungsindustrie [General Association of the Swiss Clothing Industry] (GSBI), Zurich; → Technical and professional organizations.

Satin,

I. Name derived from atlas or satin weave. Generic term for various, mainly lustrous materials, predominantly manufactured using 5-weave satin. Worsted satins are either napless (e.g. satin de Chine) or finished with a fine nap; carded satins almost always have a napped finish. Fabrics with a particularly napped finish have an intense shine which is further emphasised by the weave.

II. Smooth fabric (silk, viscose, wool, flax, cotton, etc.) with high sheen, in atlas or satin weave, e.g. → Duchesse satin, cloth; liberty, etc., see I.

Satinette Satinette is a combination of → Satin and finette (cotton twill napped on one side in linen goods). The warp consists of lustrous viscose filament, the weft is cotton; the weave is in the form of 5-weave warp satin. The lustrous warp is generally found on the fabric face, whereas the cotton warp on the reverse side of the fabric is very napped. Used for night-shirts and pyjamas.

Satin weave → Weave.

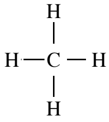
Saturated hydrocarbons Methane hydrocarbons, paraffins, alkanes, saturated aliphatics, of the form C_nH_{2n+2}, characterized by the final syllable -ane, e.g.

methane	CH_4	butane	C_4H_{10}
ethane	C_2H_6	pentane	C_5H_{12}
propane	C_3H_8	hexane	C_6H_{14}, etc.

These are saturated to the limit of their chemical absorbency by hydrocarbons, hence the name saturated hydrocarbons (contrast → Olefins). Together with basic substances, they form aliphatic compounds which arise by substitution and can be recognised as such by their altered final syllables. E.g. the following derived alkyl radicals, each having one H fewer, enabling bonding with other elements of equivalent valency:

methane	CH_4	→	ethane	C_2H_6
methyl	$–CH_3$	→	ethyl	$–C_2H_5$ (alkyls)
methene	$–CH_2–$	→	ethene	$–C_2H_4–$
			(alkylenes or olefins)	

Saturated organic compounds These are compounds where all available bonds (corresponding to their valencies) of the atoms are mutually saturated, e.g. methane:



$$\begin{array}{ccc} & H & \\ & | & \\ H— & C & —H \\ & | & \\ & H & \end{array}$$

Contrast: → Unsaturated organic compounds.

Saturated solution → Solution.

Saturated steam → Steam at a temperature corresponding to a water boiling point of 101°C and there is no water present in the vapour.

Saturated steam fixation (Saturated atmospheric pressure steam fixation). Saturated steam (e.g. in printing steamers, see Fig.) is 100% water vapour at atmospheric pressure with a temperature of 101°C. When the dry and cool fabric reaches the steamer (1), the steam condenses on it, and the energy released (heat of condensation) warms the fabric (2). The absorption phase (3) begins at the same time as the condensation phase. The absorption phase lasts until a physical equilibrium between the moisture content of the fabric and the moisture in the steamer has been reached. The heat of condensation and absorption released together with the exothermal reaction increase the temperature of the fabric to above the temperature of the fixation atmosphere (4). The fixation medium is thereby heated above saturation temperature: the steam is superheated. As the steam is superheated, the absorbing ability of the fabric decreases as the moisture content of the superheated steam is reduced (5). The moisture content of the steam decreases with superheat. As optimal fixation is only achieved when the steam is saturated, the effect of superheating must be nullified (6). In the steamer, this occurs with the minimum possible energy costs as the steam is circulated in combination with a water injection system. The large difference in the dyestuff concentration between the fibre and printing paste causes the dyestuff to diffuse under the influence of saturated steam in the direction of the fibre (7) until a diffusion equilibrium has been reached. The dyestuff is then fixed (8).

Saturated vapour pressure → Steam pressure.

Saturation,

I. → Solution.

II. The so-called saturation of a colour (in contrast to the so-called → Whiteness index) i.e. the extent to which a body colour differs from an equally bright → Achromatic. This is also referred to as depth of shade or grey scale (→ Grey series) and corresponds to Ostwald's black component. Physically obtained indirectly as spectral colour density from the CIE tristimulus values. Also colour saturation (→ Colorimetric measures) as a difference of the → Type of colour from the → Achromatic point. The lower the saturation, the duller/flatter the coloration at the same lightness and the same shade, and the higher the saturation, the brighter/more brilliant the coloration.

Saturation, degree of → Saturation point.

Saturation factor The saturation factor is a constant which is specific to the dyestuff used to calculate the → Saturation value (principally for cationic dyestuffs).

Saturation point Also known as saturation value S_{max}. Particularly important for synthetic fibres. Expresses the maximum dyeing potential of the fibre. If more dyestuff is added to the bath, then either the fibre is no longer able to absorb any more dyestuff or blocking effects arise. Alternatively, non-fast dyeing may occur. The saturation point may vary from dyestuff to dyestuff for any given fibre type.

Saturation value Max. absorption of dyestuff and/or levelling agent by a fibre.

Saturator → Impregnating machine (saturator also padder with large liquor bowl) for intensive wetting with treatment liquor in continuous open-width bleaching, mercerization, etc.

Saueressig printing machine The Saueressig machine represents one of the most popular developments of → Roller printing machines in the 20th century. In this machine, the printing heads are arranged vertically one above the other, unlike conventional roller printing machines where they are positioned around a central

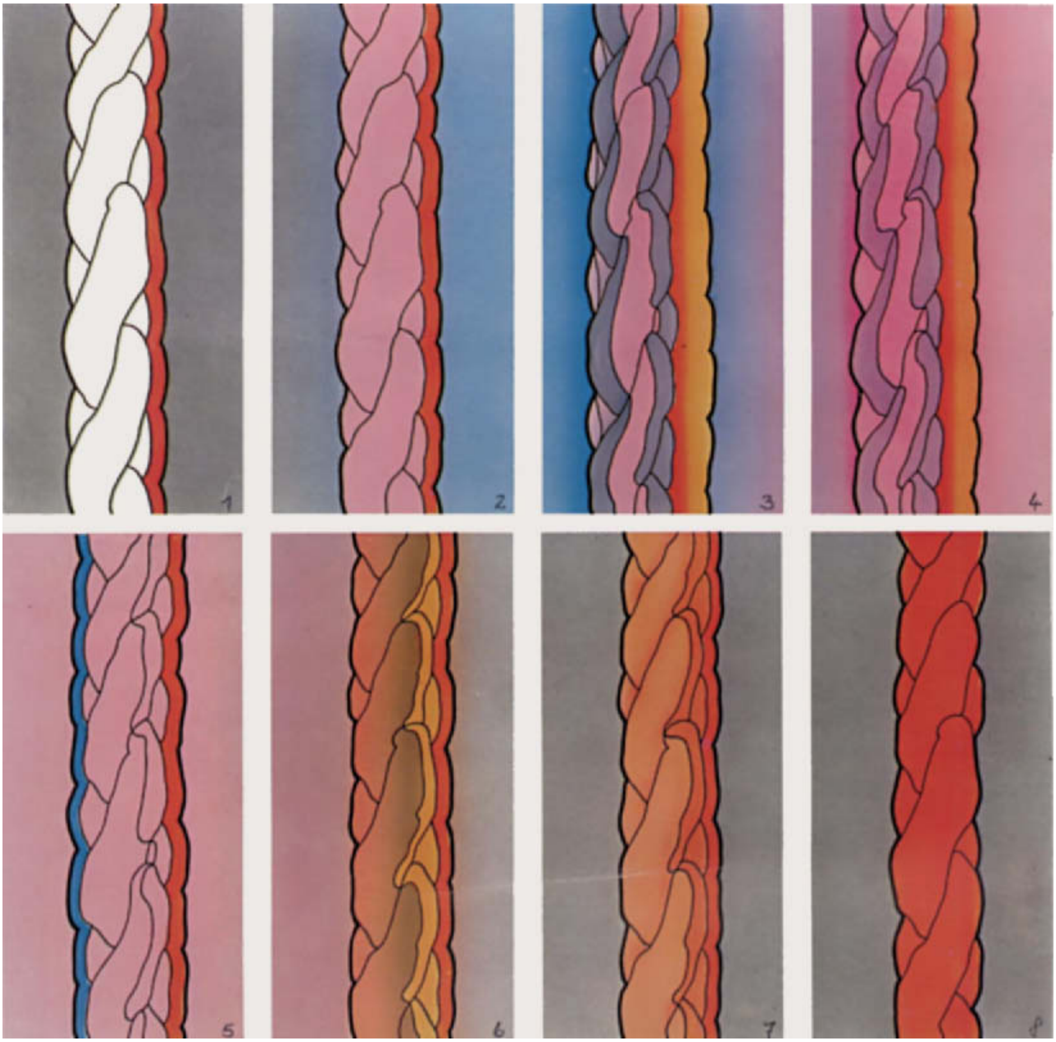


Fig.: Saturated steam fixation in a printing steamer (by Babcock).

cylinder. The colour boxes, doctor blades and furnisher rollers are all mounted on a hinged sub-frame which can be swung to one side of the Saueressig roller printing machine to facilitate the changing of printing rollers. This arrangement allows more rapid colour and design changes than conventional roller printing machines.

Saueressig roller printing machine Roller printing machines in which the central cylinder is replaced by individual cylinders for each printing roller.

Saw-tooth effect Defect in screen printing in the form of graduated (stepped) repeated profiles of fine pattern details which run askew; particularly undesirable with fine floral designs or figured patterning, etc. Correction: e.g. by using even finer gauze screen, use of photosensitive screen coatings with a crossed mesh effect and by correctly developing illuminated screens.

SAWTRI (South African Wool Textile Research Institute) → Technical and professional organizations.

Saxony Woollen cloths made from high quality fine merino carded yarn with soft, flannel-like handle. Predominantly in sporty patterns (e.g. shepherd’s check, glen-check). Finish varies between smooth and a slight melton finish. Used for ladies’ and men’s suits and lightweight coats.

Saybolt Universal viscosity American measure of → Viscosity.

Sb The chemical symbol for antimony (51).

Sc The chemical symbol for scandium (21).

Scaffolding effect A mixed fabric sample (e.g. cotton and polyester) has different burning properties (e.g. in a vertical flammability test) than a corresponding sample made from one of the pure fibre components. Therefore the fibre portion made from polyester fibre for example promotes better burning of the associated cotton as it is worked and spun into the blended yarn almost as a stable scaffold. The scaffolding effect therefore benefits the relative low combustibility of the polyester fibres (at best melting), whereas the relative high flammability of the cotton is increased still further by the "loose" distribution in the scaffolding, which increases the oxygen available.

Scala d'Oro Italian → Quality symbols which covers Rhodiatoce quality testing on finished goods and ready-made garments made from cellulose acetate, polyamide and polyester fibres for in-house products.

Scale structure of wool The scale structure of the outer covering layer of wool has an effect on the felting and dyeing behaviour. If the wool fibres are non-felted, the original hydrophobic scales are either rendered hydrophilic by a polymer or by oxidation (or a combination of the two in the Hercosett process) in such a way that a water film significantly alters the friction between the fibres (Fig. 1).

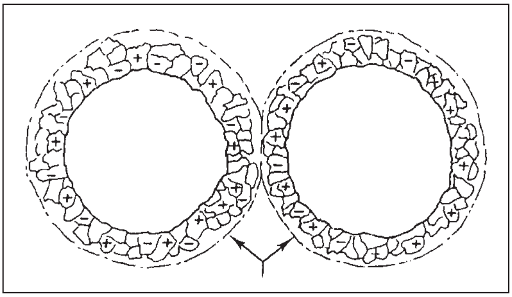

Fig. 1: Hydrophilically treated wool fibres (through felt-free finishing), each with an adhered water film (arrows) at the fibre surface (according to Meichelbeck).

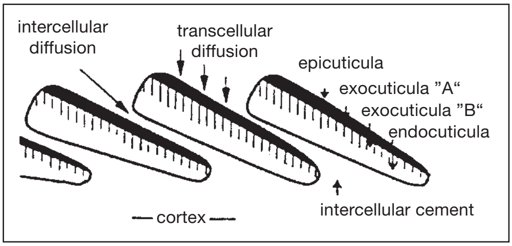

Fig. 3: Diffusion routes into a wool fibre (according to Zollinger).

The scale layer consists of (Fig. 2)

1. The outer epicuticle: hydrophobic, low cystine content, i.e. low degree of crosslinking.
2. Exocuticle: hydrophobic, high cystine content or degree of crosslinking, division into a-layer (extremely high in cystine) and b-layer (high in cystine).
3. Endocuticle: low in cystine, i.e. low degree of crosslinking.
4. Intercellular cement: globular proteins, low in cystine.

The high sulphur content of keratins, i.e. a high cystine content and high degree of crosslinking, in addition to the increased content of hydrophobic amino acids, is regarded as a cause for the hydrophobic nature of the scales. For this reason, the exocuticle (with approx. 35% cystine content) is regarded as a diffusion barrier for dyestuff molecules during the dyeing process. The high sulphur content causes reduced swelling capacity of this layer of fibres. Consequently, changes to the wool fibre by splitting the cystine links causes acceleration of the dye absorption. If the wool is untreated, the dyestuff does not diffuse vertically (Fig. 3) through the exocuticle (so-called "transcellular diffusion") into the wool fibre, but migrates via the intercellular cement/cellular membrane complex (Fig. 2), i.e. between the scales, into the fibre (so-called "intercellular diffusion"). This intercellular diffusion path can be observed at the beginning of the dyeing process.

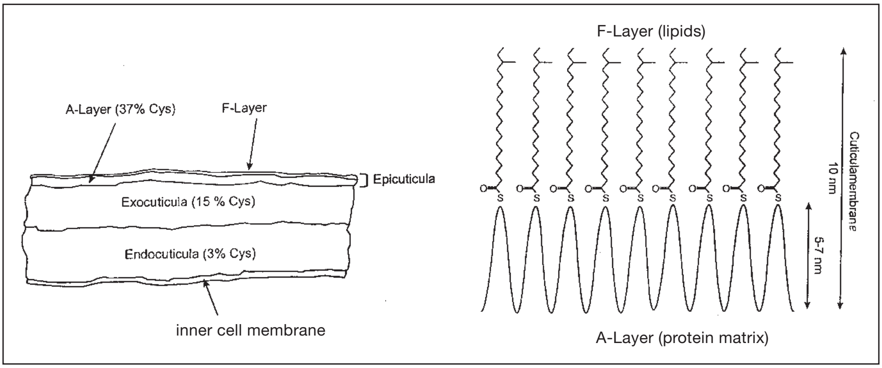

Fig. 2: Scale structure of wool.

Scanner Sensor in electronics, e.g. for colour measuring instruments. Important for electronic sample preparation, electronic colour separation and colour correction devices to make colour separations for multicolour textile printing (transfer printing).

Scanning In contrast to integral imaging using photography, scanning consists of linear recording, with the image elements forming consecutively.

Scanning drum The scanning drum is an integral part of a scanner. The colour transparency is found by the transparent, rotating scanning drum. Focused light is irradiated axially onto the drum and deflected by 90° using a mirror so that the light penetrates both the scanning drum and the colour transparency.

Scanning Electron Microscope (SEM). An electron microscope, which linearly scans the surface to be inspected using a sharply focused electron beam. During this process, electrons are emitted from the object which are collected using an electron collector. The electron flow of these secondary electrons controls the intensity of the electron beam of a television monitor, so that there is an enlarged image of the surface on the monitor. SEM images are characterised by a particular definition and plasticity. The electron beam of the device releases x-rays as well as electrons from the surface. X-ray fluorescent analyses make it possible to define the material of the object being examined (Figs. 1–2).

The development of an electron microscope is based on the 1924 discovery (de Broglie) that electron beams can be assigned a wavelength. The wave describes the periodic movement which radiates from a transmitter, e.g. an electron source, in a specific direction. The wavelength indicates the distance between two successive points in the same phase, i.e. if a rope is swung periodically to and fro, a wave runs across it, and the amplitude creeps along the entire rope until it reaches the end, where it is reflected and creeps back. By taking a photograph of such a wave, it can be seen that the amplitude of the rope is repeated at specific distances. These distances are the wavelength. The same applies to the electron source - according to de Broglie, electrons and protons behave as if they are waves.

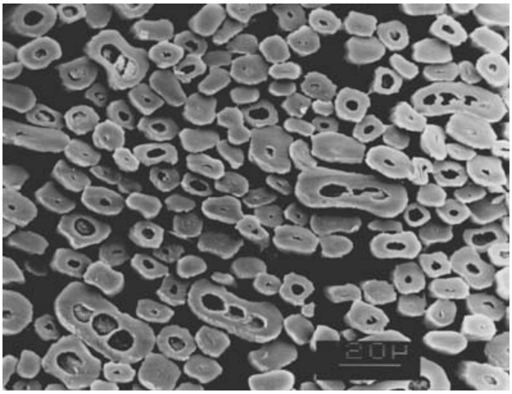

Fig. 1: A scanning electron microscope image of angora fibres in cross-section.

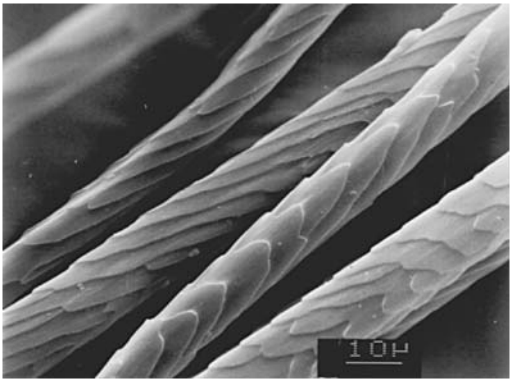

Fig. 2: A scanning electron microscope image of angora fibres in side orientation for the purpose of comparing several fibres of the same type.

The wavelength of the electron beam (0.004 nm at a beam potential of 100 kV) cannot be compared with the wavelength of visible light. The extremely short wavelength of the electron beam enables better definition or greater enlargement compared with a normal optical microscope. With the SEM, the surface of the sample is bombarded by a small (narrow) electron beam. This causes secondary electrons to be released from the surface of the sample, i.e. the sample used must be conductive, otherwise it is not possible to carry out the experiment. The intensity of the secondary electrons is dependent amongst other things on the inclination of the surface in question to the primary beam. The secondary electrons are collected by a detector (rectifier for electron beams), amplified and displayed on a screen. The fine electron beam only reaches one point of the sample at each moment, therefore the beam must be passed across the sample in a fine grid pattern in order to record the entire surface of the sample line by line. In this way, the finished image of the surface of the sample is formed on the screen. The intensity of the secondary electrons gives the brightness.

The principal elements of a scanning electron microscope can be seen in Fig. 3. The electromagnetic lenses are not only used for the imaging, but also as condenser lenses (focusing lenses) to produce the extremely finely focused electron beam on the sample surface. Deflection points for scanning are integrated into the second condenser lens. As mentioned earlier, samples which are not conductive cannot be used and must therefore be specially prepared. In order to conduct the electric charge which arises on the non-con-

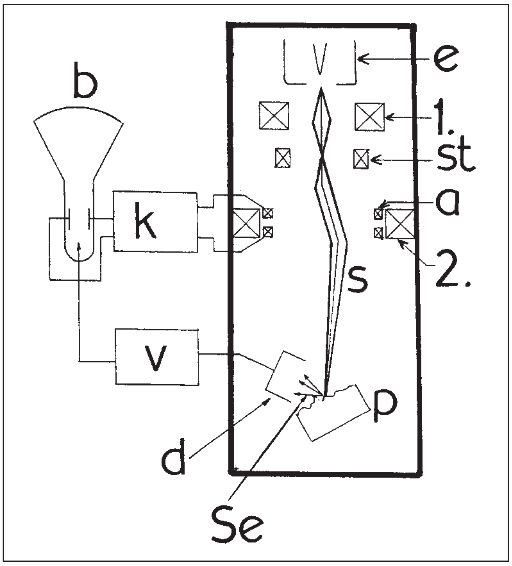

Fig. 3: A simplified diagram of a SEM.

ductive samples, they are vacuum coated (sputtered) with a thin contact plating (using a conductive metal like gold). The advantages of the SEM are improved resolution and therefore better enlargement and enhanced definition in comparison to the optical microscope.

Scanning element A transmission element which transmits an input signal at irregular time intervals (during the scanning period) and, by this means, delivers a sequence of impulses as a signal.

Scanning in photo-engraving This process refers to the breaking up of coloured areas into colour points of varying sizes, which when observed give the optical impression of different colour intensities due to blending of the colour lying between the points on the printbase.

Scanning, optoelectronic Optoelectronic scanning causes colour separation (in automatic electronic production of colour separations for textile printing by a scanner) using a scanning drum. Next, the particle beams are converted into signals using electron multipliers. The signals are then sent to the colour computer for the shade and tristimulus values to be corrected. The master copies are illuminated by the optical head which intercepts the reflected light. Further processing is then carried out in the same way as with transparencies.

Scanning process This is a printing method in which a multicoloured design is directly transferred electronically using film or paper copies without the need for screens or printing blocks. The scanning process (as a natural process in image generation) consists of linearly scanning a copy, with the entire image being sampled at close linear intervals which can be selected within limits. This can be carried out continuously, with the copy (image) being fastened around a cylinder and scanning along a spiral by advancing the optical head, with the cylinder turning. Discontinuous scanning uses parallel lines which are staggered at the reverse point by the linear interval selected. A distinction is made between → Colour scanner for paper printing and typical → Textile scanner.

Scarf cutting machine After the fringes of scarf fabric have been twisted and set, the individual scarves must be cut longitudinally or transversely along the unwoven warp or weft thread (see Fig.).

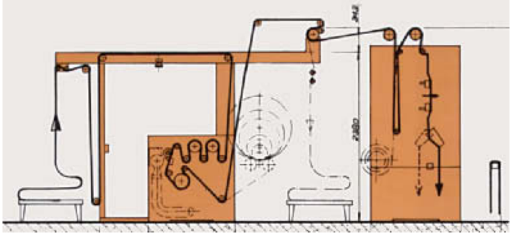

Fig.: Scarf cutting machine by Lafer.

Scarlet →: Kermes; Cochineal.

Scatter coating (Scatter granules coating). Procedure used for interlinings. The granular adhesive (polyamide or polyethylene) is irregularly scattered on the base material and then heated until the granules sinter to form beads (see Fig.). Alternative → Powder-dot coating.

Scatter coating is also used in the manufacture of formed mats for automobile inner fittings to laminate a decorative polyester fabric using the copolyester powder coating with polyester fibre web. Only recyclable polymers are therefore used so that the moulded formed mats can be shredded after the used car has been recycled. The resultant polyester agglomerates can be recycled, i.e. a portion can be added when manufacturing new formed mats.

Scattered light measurement Where dyestuff has been dispersed, a certain portion of the measured extinction is always caused by scattered light. For particle sizes with a radius of r < λ/20, the scattering intensity can be described:

$$l_s = l_0 c r^6/\lambda^4$$

l_s = intensity of scattered radiation,
l_0 = intensity of incident radiation,
c = concentration of scattered particles,

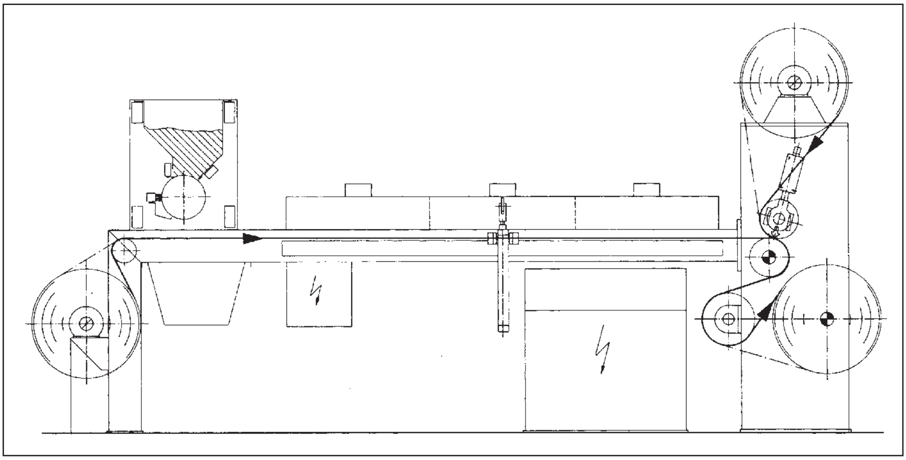

Fig.: A compact scatter coating machine.

r = radius of the scattered particles,
λ = wavelength.

Shortwave radiation is therefore scattered to a greater extent than longwave radiation. For larger particles of radii in the range of the wavelength of the incident radiation, the scattering intensity increases and spatially becomes particularly anisotropic. The ratio of forward to backward scattering increases. Commercial dyestuffs generally have particle sizes in the range of 0.1–1 µm diameter. Their dispersions spatially scatter the light extremely anisotropically and predominantly in a forward direction. For extraction measurements on dyestuff dispersions, this does not have a negative effect on the validity of the measurement of scattered light as long as the distribution of particle sizes of a dispersion is not dependent on concentration. The relative number of agglomerates with larger diameter at increased concentration, for example, may therefore increase. To a remarkable degree of accuracy, dyestuff dispersions act in line with Lambert-Beer's law (→ Extinction). When measuring transmission of dispersions with defined, close particle size fractions, it has been seen that there are different gradients in the extinction-concentration diagram for the same dyestuff depending on the particle size fraction, although the relationship remains linear. For a mix with constant portions of the different fractions which are not dependent on concentration, a linear relationship can also be expected.

Schappe (silk) (Chappe, Floret silk). This is taken from the beginnings and ends of the cocoon which can no longer be unwound after the vegetable glue has been decomposed in a putrefaction process. The schappe undergoes further processing in a similar spinning process to that used for worsted yarn. The comber waste which falls away provides → Bourette. Schappe is used e.g. for machine sewing silk and for strong silk fabrics. → Silk.

SCHEK, SEK Swiss fastness commission → Technical and professional organizations.

Schiff's Reagent Colourless aqueous solution:

I. Fuchsine with some sodium sulphite, sodium disulphite or potassium metadisulphite and the addition of a little hydrochloric acid or sulphuric acid. In this state, the fuchsine is reduced to a colourless compound. Use: as a test for aldehyde (acetaldehyde), formaldehyde: after the addition of aldehyde, there is an immediate or gradual red violet colouring.

II. Sulphur dioxide in 1% fuchsine solution results in an almost colourless solution. Damaged cellulose turns red.

Schreiner calender A Schreiner calender is a 2-roller calender with 30–50 t printing capacity consisting of an upper engraved steel roller (fluted roller) and an elastic roller positioned beneath (hard-pressed covering made from special paper, or very occasionally a cotton roller) (see Fig.), whereas the 3-roller calender has an additional printing roller for printing with 50, 80, 120 t. The heatable fluted roller contains numerous fine grooves (8–22/mm) which run at angles. These, together with the combination of a high heating temperature, 100–200°C depending on the quality of the material, and pneumatically adjustable pressure, produce the silky lustre on moist cotton fabrics. Heating is generally a combination of steam/electricity or gas. Multi-purpose Schreiner calender with exchangeable rollers include the 2-roller embossing silk finishing and chintz calender, the 3-roller silk finish and simili mercerizing calender. The position of the grooves in the fluting is important as the warp and weft twist need to have uniform direction so the fluting doesn't run at an angle through the fibre lay and cut into the fibres. Depending on the direction of the fluting, a distinction is made between: 1) Cross fluting parallel to the roller axle; no longer common due to excessive wear;

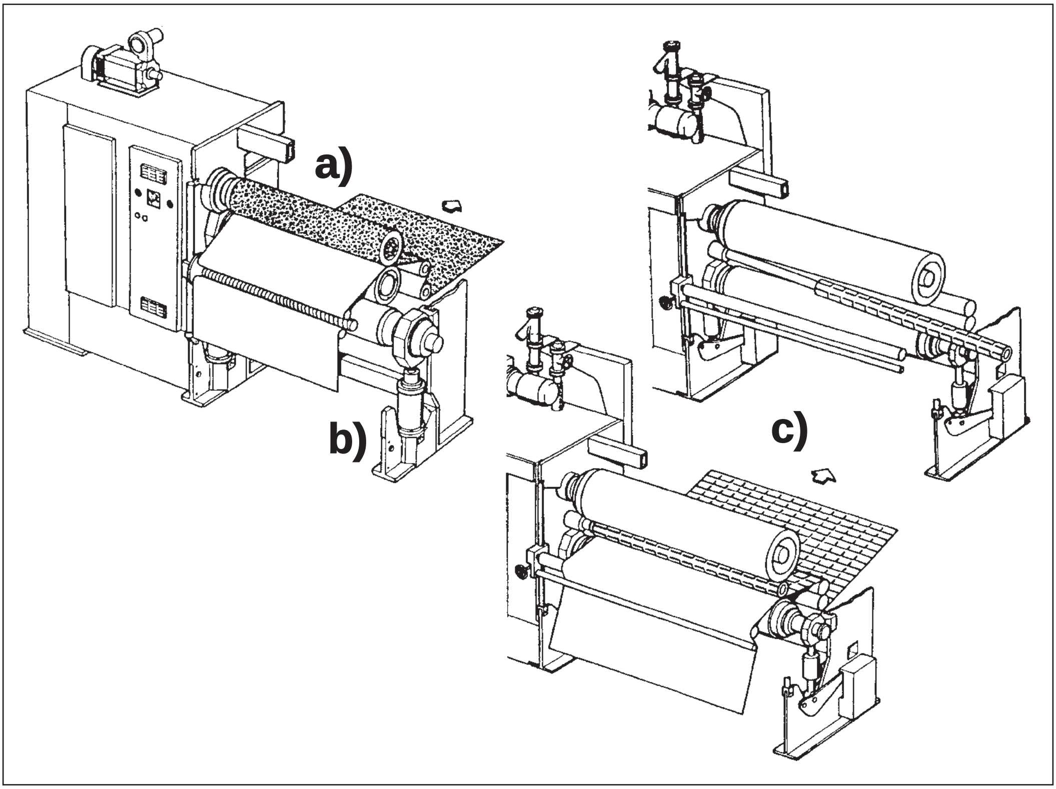

Fig.: Küster's three-roller multi-application calender.
a) upper gap = Schreiner finish or other effects; b) lower gap = matt, rolled, smooth, glossy or chintz effects; c) auxiliary roller with quick change for embossing.

2) Round fluting: grooves around the roller, e.g. silk finish on warp satin; 3) Diagonal fluting: grooves running from the bottom left to top right (when looking at the roller from above). As regards the diagonal gradient, for fabric surfaces with dominant weft yarns (weft satin), gradients of 12–25° are selected, and gradients of 70–80° are selected for fabrics with dominant warp yarns. It is necessary to resharpen the fluting after approx. 6–9 months assuming 8 h daily use.

Schreiner effect, Schreiner calender → Schreiner calender.

Schweizerischer Verein der Chemiker – Colorist (SVCC), similar function as the → SVF, therefore joint efforts to merge the associations.

Schweizerische Vereinigung von Färbereifachleuten (SVF), Basle; task: Intensive promotion of the chemical/technical and professional endeavours of experts in dyeing and the entire textile finishing, for the good of the profession and advance of its members, for the benefit of the textile industry. Members of all countries with significant textile industries belong to the SVF. Principal divisions of the association are the general assemblies and the executive committee. Publishing division: textile finishing. → Technical and professional organizations.

Scleroprotein →: Keratin; Fibre proteins.

Scorch test American test method (AATCC) to determine the amount of damage to hardenable synthetic resin finishes due to → Chlorine retention on cellulose textiles. Also records the specific buffer capacity for each synthetic resin and each catalyst. Working principle: chlorine treatment (2.5 g/l active chlorine, liquor ratio 1 : 50, 25°C, pH 9.5, 15 min), rinse, dry, condition, scorch or press between two metal plates with constant pressure and temperature (185°C, 30 s), condition. Assess by comparing the percentage average decrease in breaking strength and any yellowing which may occur.

Scouring of cellulose fibres and their blends (Scouring of cotton with alkaline boiling). Preparative process for bleaching and dyeing, esp. for cotton, to remove the primary wall of cotton. Can be used for cotton and cotton/synthetic blends both in long liquor (→ Kier-boiling) and in the continuous process (→: Alkali shock process; Extraction scour/extraction bleach). Pretreating with weak acids, e.g. acetic acid, to remove alkaline earth pollutants is not necessary when the extraction method is used. Alkaline boiling is increasingly concentrating on saving time, energy and water in the subsequent rinsing. Polyester/cotton fabrics are boiled in rope form or open-width, depending on the quality, with the tendency being towards open-width treatment. Efforts are increasingly being made to combine desizing, boiling and bleaching in one process. Shock methods at high alkali concentrations are not recommended for polyester/cotton fabrics as this would have a negative effect on the polyester portion.

Boiling and scouring should

- saponify fats and waxes (0.4–1%);
- split proteins and pectins (1.1–1.9%; 0.7–1.2%);
- complex mineral substances with Ca, Mg, Fe, Cu (0.7–1.6%, more in some cotton derivatives), to avoid these reacting with saponification products;
- prevent the formation of oxycellulose and associated damage;
- increase the absorptive capacity (test using capillary rise method);
- improve the degree of whiteness and reduce the seed husk content;
- extract reaction and by-products after impregnation and following the reaction phase at a high temperature where suitable dispersing agents are used and intensive liquor exchange takes place;
- prevent fold marks if strong swelling process occurs.

For this, the following are required:

- up to 25°Bé NaOH (20–80g/l);
- the addition of a reducing agent;
- an anionic surfactant with wetting and detergency power, expressed as a HLB value (hydrophile-lipophile balance which states whether the surfactant tends towards an oil-in-water emulsion or a water-in-oil emulsion; the higher the HLB value, the higher the oil/water ratio with good detergency power; the lower the HLB value, the higher the water/oil ratio with good wetting effect);
- a complexing agent (electron donator) to sequester the metallic cations (electron acceptor). The resulting complex is characterized by its pK

$$pK = -\log K;\ K = \frac{[M^{+n}] \cdot [L^{-m}]}{[ML^{+n \cdot -m}]}$$

The aim of alkali scouring is to produce an absorbent material with an average degree of whiteness and extremely low mechanical and chemical damage for textile dyeing and finishing. To achieve this aim, the substances used on the fibre must be removed as completely and as quickly as possible.

During the impregnation process, the alkali initially moves towards the textile surface by convective diffusion. It is assumed that the liquor then diffuses into the pores filled with air. As this process involves a pure exchange of concentration between the pores of the fibre which are filled with air and the alkali liquor, the process is extremely slow without any external effect. If the liquor is diffused into the fibres, the substances used are partially emulsified (chemical reaction). Next, the extraction of the hydrolized substances from the fibre into the liquor takes place. This diffusion takes place as rapidly as the exchange between fresh, unused and used liquor. It is not clear whether this is a reaction controlled by diffusion in which the speed of the reaction is only dependent on the diffusion of the liquor into the fabric and back out again. In the case of a reaction which is self-controlled, its rate is only dependent on the speed of the reaction between the primary wall of cotton and caustic soda liquor. In order to increase the reaction rate of a diffusion-controlled reaction, the flow-rate must be increased (Fig. 1). In addition to this increase, the following influencing variables have an effect on the extraction rate of the alkali scouring:

- temperature,
- concentration of soda liquor (Fig. 2),
- time,

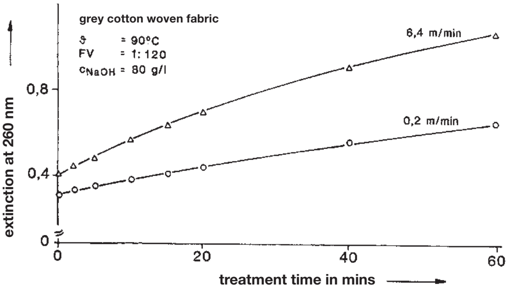

Fig. 1: Effect of liquor exchange on alkaline cotton boiling speed (0.2 m/min = inferior liquor exchange; 6.4 m/min = intense liquor exchange).

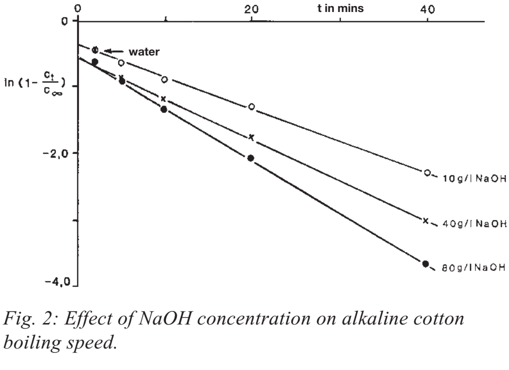

Fig. 2: Effect of NaOH concentration on alkaline cotton boiling speed.

- auxiliary,
- pretreating the cotton with acid.

On the assumption that this is a chemical reaction of the 1st order (rate dependent on the concentration of the starting material, as well as on the temperature), the reaction rate of the boiling and scouring process is as follows:

$$\frac{dc}{dt} = \beta^* (c_\infty - c).$$

If the concentration at the time t = 0 is defined as the initial concentration $c = c_0$ and the concentration at the time t is defined as c_1, the rate of the boiling and scouring process can be derived from:

$$\ln \frac{c_\infty - c_t}{c - c_0} = -\beta^* \cdot t$$

$$\ln\left(1 - \frac{c_t}{c_\infty}\right) = \ln\left(1 - \frac{c_0}{c_\infty}\right) - \beta^* \cdot t.$$

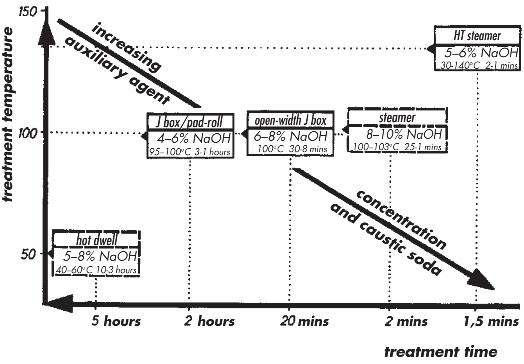

Fig. 3: Standard formulation for alkali treatment with Lufibrol KB and Leophen U (BASF).

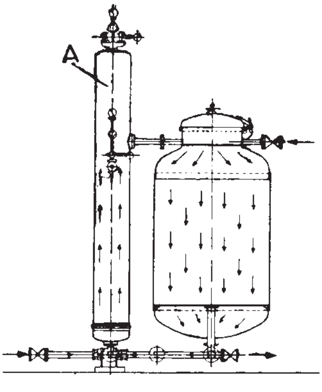

Fig. 4: Kier for alkaline high pressure boiling and scouring (A = lye heater).

The quickest boiling and scouring results are therefore achieved when diffusion is used (Fig. 3) as a result of:

- high temperatures,
- high alkali concentration,
- rapid material flow.

A distinction is made between the two processes: discontinuous boiling and scouring (kier boiling) (Fig. 4) and continuous boiling and scouring (mainly with steamers). The alkali-shock process is used under extreme conditions in terms of soda liquor concentration, temperature and time (Fig. 5).

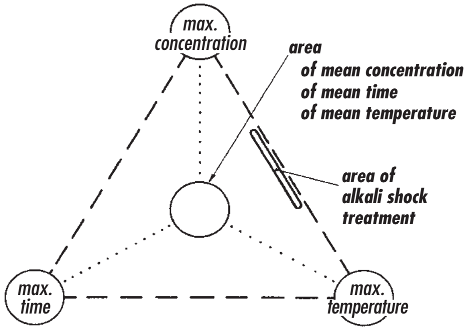

Fig. 5: Alkali shock stage: dependent on concentration, temperature and time.

Screen Grid system of points or lines which intersect at right angles. If a photograph is taken of an original image through this type of screen which is located at a certain distance from the photographic plate, the light spreads conically behind the screen. This causes a dissection of the image or dispersion of the brightness on the plate in the form of numerous points. Using this principle of dissecting extremely small areas, photographic negatives are produced which are copied onto a metal plate and then etched, used as so-called autotypes in paper printing and similarly for → Half-tone printing on textiles.

Screen coating The rotary printing screen system (see Fig.) is based on seamless rotation screens (2). A doctor blade (1) presses the print or coating paste (5) into the screen through the perforated screen wall onto the substrate (4). A pump and level control guarantee constant supply of paste. If the perforations in the rotary screen are sealed in places using a spec. lacquer (the rotary screen is then engraved) the coating unit can be used as a single-colour printing unit for a pattern. Light squeegee pressure makes it possible to apply a small amount of paste for vertical passage of the cloth. The quantity applied to the substrate can be increased by increasing the squeegee pressure or if the doctor blade applies pressure behind the centre of the counter roller (3). Fabric may also be introduced horizontally. This

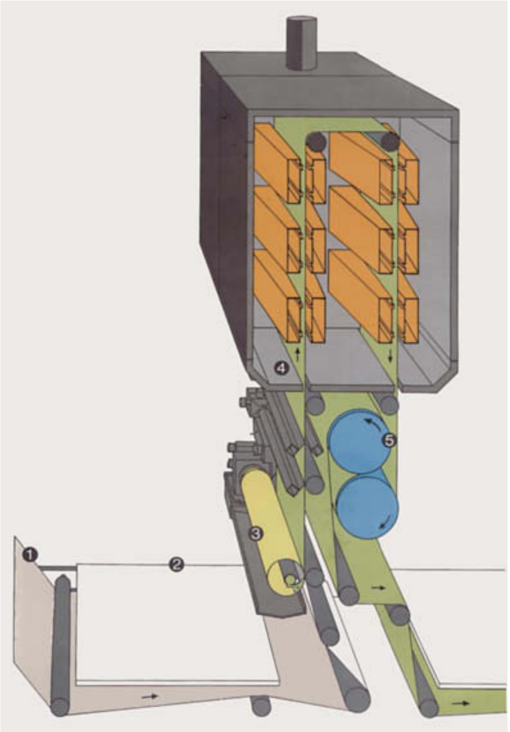

Fig.: A rotary screen coating system (Stork).

may be necessary if the substrates are inflexible and cannot be bent. The wide coating unit has a horizontal fabric feed system as the material and the screen must be well supported. Stork X-cels technology makes a new development in coating processes possible: coating both sides of an open fabric in one passage through the machine using only one screen. In this process, the counter roller operates at a variable speed in relation to the substrate, so the paste which remains on the roller is applied to the reverse of the substrate. The substrate is then guided across a double levelling blade (both on the fabric face and the reverse) which smoothes the surface. Next, non-contact gelling takes place in the vertical drier. The advantage of screen coating for this application, compared with a dip coating process, e.g., is that the amount applied can be accurately controlled. The substrate (1) to be coated or printed passes under the platform (2) through the coating/printing unit (3); this is generally a rotary printing unit which is suitable for both printing and coating processes as well as for partial coatings. The non-stop screen alternating system can be used for short lengths. Additional finishing techniques can also be integrated into the plant if necessary. In this case, the coated material is dried in the vertical drier (4). These driers are also used as intermediate driers in multicolour printing machines, e.g. when manufacturing floor or wall coverings. The drier generally comprises one section for each coating or printing station. A second drying section can be used for particular applications, whereby the length of the drying path is doubled in each section. The substrate is drawn through the drier by means of a pair of cooling rollers (5). After cooling, the substrate is coated or printed.

Screen engraving for printing The textile industry has seen many changes over the years but one constant has been the continued pressure to get new designs printed quickly and economically. One basic reason for this situation is that once the screen is on the printing machine there is very little one can do to increase productivity. Thus, the design and screen imaging area are where savings must be made. The most significant technical innovation introduced in the mid-1980’s was laser engraving of lacquer screens, offering substantial reductions in the production process steps required to achieve a print-ready screen. Coupled with this, the more recent introduction of computer generated design and graphic creation systems based on personal computers has brought great creative and production advantages over conventional methods. In the future textile designers will be able to make rapid design changes to meet market pressures with laser engraving, providing accurate, repeatable and fast, print-ready rotary screens. Some early investors into this technology are now well on the way to their second (or third) engraving machine, and with hardware and software enhancements to generate half-tone screens from continuous tone inputs, the days of Galvano engraving are numbered. Considerable advantages are realised over conventional film engraving, and some of the total system advantages are outlined as follows:

1. Pre-coating: As laser engraving does not require photo sensitive coatings, numerous screens can be coated and baked. The blank screen can be inspected for pinholes prior to engraving, then stored ready for instant engraving when required.

2. End-rings: Engravings may now be made with end-rings already glued in place. Coupled with pre-coating, this can save an enormous amount of down-time on a printing machine. Glueing the end-rings takes up to 30 minutes per screen. It is common for a printer to order a set of remakes with an original set of engravings in anticipation of screen breakage. If the printer has his own laser he can engrave the original set and bypass the remakes. Should he have a screen break, and as he has a coated, end-ringed screen ready, the only time lost will be engraving time. The screen is ready to print straight out of the laser.

3. Film elimination: Film is expensive and it can physically distort over time. Wrinkles, due to handling, are likewise inevitable. As the laser’s powerful computer holds a motif in digitised form, not only costs, but most problems associated with film disappear, includ-

ing step and repeat machines, contact frames, cameras, processing units, etc., all of which take up expensive floor space. The major savings day-by-day through the elimination of colour separation films cannot be overemphasised. Additionally, the creative designer is allowed to concentrate on texture, shapes, colours and text. Tones need only be represented as continuous tone values, not dots. Corrections and amendments are also greatly simplified by the ability to trap, retouch, edit, merge and engrave line and tone files.

4. Seamless designs: Join lines no longer exist.

5. Instant precise remakes: All engraving parameters are stored together with the motif, ensuring that a precise remake can be made at a later date. Archiving can take the form of print-outs, optical disc, floppy disc, half-inch tape or tape cassette.

6. Memory factor: A single motif, once scanned from Zedco's scanner or received from a design computer (Scitex, Hell, Epicad, etc.), can be manipulated (stretched, distorted, jointed, stepped and repeated) in many different ways without re-scanning or returning to the design computer. For example, a motif can be stepped and repeated twice around the circumference of a 640 mm screen and say 72 inches engraving width. Then after suitable distortions, 3 times onto a 860 screen, any engraving width is feasible. These parameters can be changed in seconds. Using this technique memory space is relatively small compared to the storage requirements of a full stepped and repeated design. Registration marks, legends, etc., can be engraved in the selvedge as a separate procedure or engraved automatically with the motif. A job number can be typed directly onto the rotary screen from one of the computers.

7. Continuous tones: By reading a grey wash from the scanner or directly from an imaging system (Hell, Scitex, etc.) either a random stipple or a conventional regular screen can be computer generated at any screen count at any percentage at selectable angles. The engraver can change the gradation curve without going back to the original design or artwork. This is particularly useful for creating platforms. These changes can be made in seconds, then laser engraved immediately. Simulation of a Galvano screen is achieved by using the above method.

The impression has arisen in recent years that the laser technique is dominant as far as direct engraving is concerned. The units for laser erosion rotary screen engraving (ZED, Baasel Scheel, CST, Stork-STK) and for the laser exposure of rotary or flat screens (Stork-STK, MS) seemed to be the only solution. At the last ITMA, the Swiss Lüscher AG showed in fact that, in addition to the laser technique, there is another suitable process for producing economic and environmentally conscious, high quality rotary and flat screens: the ink-jet technique. With the use of the ink-jet technique in "JetScreen" type equipment, Lüscher has been successful with a development which is worth presenting in detail, and can be compared with the laser technique. With the "JetScreen", rotary screens or flat screens are patterned without the use of transparencies, the producer combining familiar, tried and tested processing elements with new ones. The units operate in conjunction with a CAD system. The colour separation to be transferred to the screen is therefore produced in the Lüscher "ImagBox" CAD unit in the form of a graphics file or is available as the compatible or convertible data file of another CAD system.

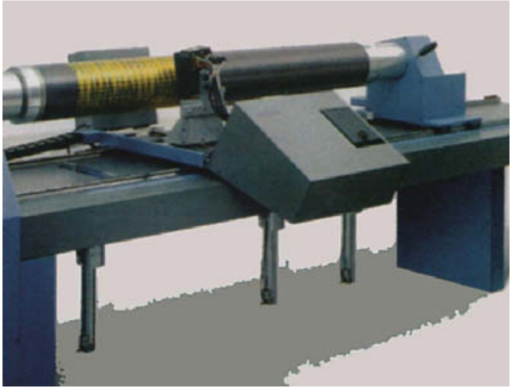

Fig. 1: The parallel layout of 96 spray jets in the "JetScreen" for rotary screens results, with high definition, in short engraving times (Lüscher AG).

The screen is first of all conventionally photosensitively coated, the familiar engraving units, photoelectric layers and coating processes being usable. Instead of the then subsequent film montage with subsequent exposure, the flat or rotary screen is 'shot' according to pattern with the finest wax droplets with the aid of the ink-jet technique. In the case of the rotary screen, this is done with a cylinder rotating about its longitudinal axis, along which the ink-jet head is guided (Fig.1). Flat screens on the other hand are inserted in a vertical machine frame, and the ink-jet head "removes" the screen areas to be engraved line by line (Fig. 2). The graphics file, which is retrieved directly from the CAD machine via a LAN or by an integral computer, serves as the control data file. The spray technique used is the so-called "Drop-On-Demand" process where the droplet is expelled only when it is needed in accordance with the pattern. The wax particles adhere to the screen surface, forming a layer impervious to light. It assumes the function of the transparency. It is then exposed in the "JetScreen", developed away from the machine, and finally produced in the familiar engraving environment.

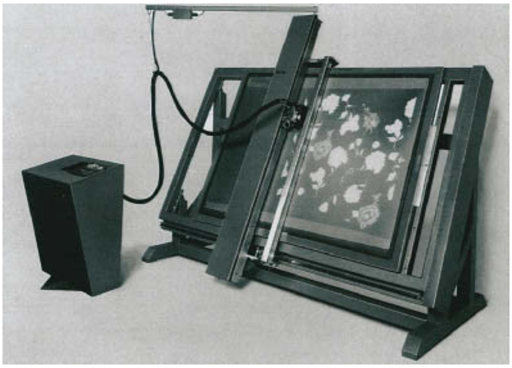

Fig. 2: In the "JetScreen" for flat screens, the spraying head scans the screen surface line by line (Lüscher AG).

The printing head does not spray aqueous dyestuff, for example, but wax. This material is thermoplastic. To prepare it for spraying, it is heated in the printing head. The heated wax has a higher viscosity than a dyestuff formulation dissolved in water or solvent for example. While a less viscous drop would flow in undefined form over the screen surface on impact, the wax droplet changes its round shape very little in cross-sectional terms; it just becomes bigger. Its viscosity is already increasing in the flight stage as it begins to cool, finally hardening in contact with the screen surface. Actinic light absorbent additives, which reliably prevent irradiation of the wax particle, can be introduced into wax. Currently used waxes have 10^4 opacity, which reduces light penetration to 0.01%. There is a further aspect for material choice. Wax can in fact cool down and harden in the spray jet, but does not dry in, since it is composed of 100% solids. Its extrudability is achieved via thermoplasticity. There are therefore no clogged nozzles, even when a nozzle expels no droplet over a long period. Dirt in the nozzle piping system is insignificant, since filters there ensure exceptional wax purity. Furthermore, the wax recommended by the "JetScreen" manufacturer is an environmental-friendly material, which can easily be filtered out of the effluent. The wax develops natural adhesion to all known photoelectric layers, without "sticking" too hard. In this way, it adheres securely to the screen photoelectric layer on the one hand, and on the other can be washed off easily enough in the developing process.

The ink-jet technique imposes minimal requirements on screen positional accuracy, because, in contrast to the laser technique, no focal range has to be adhered to. For this reason, the "JetScreen" for rotary screens has a simply designed screen mounting (cone), and requires no specialised screen guides such as air bearings or guide rings in the working area. The screen is very simply pneumatically stabilised with a minimum overpressure of 0.02 bar. In contrast, the flat screen is brought into the plane position by means of a partial vacuum. Screen positional tolerance has very little effect on picture detail representation. This is due to the very favourable relationship between droplet flight speed and screen rotational speed and spraying head feed speed. The bigger the difference between the two speeds, the smaller the representational error resulting from positional tolerance. A rotary screen running at a relatively low speed or a relatively slow spraying head feed with the flat screen prolong engraving times in principle of course. The current ink-jet technique however permits the parallel layout of a large number of nozzles. There are 96 in the "JetScreen" unit. The number of nozzles more than offsets the low rotary or feed speed relative to engraving time. In contrast to this, a rotary screen laser engraving unit, for example, operates in fact at a high screen speed (400 rpm and above), but only with a focal ray. This can of course be multiplied, but the process founders on cost grounds. With the ink-jet technique on the other hand, the already large number of nozzles can easily be increased as part of the further development of this technique (and retrofitted). The ink-jet technique produces no seam, as is familiar from conventional film engraving, and is dreaded with certain patterns. This process can produce no 'hollow copies', another difficulty not always to be avoided with the conventional process. Another interesting new test and correction process, the "JetScreen" units produce on the screen an image (graphic) almost identical with the subsequent print with this screen. Therefore when in doubt about the resultant print of a critical half-tone, for example, it can be printed out on paper which has been laid on the screen by way of a proof. Since the engraving unit is linked with the design computer, corrections are made in a very short time. This is therefore a significant checking and correction possibility for the engraver, which has not been provided in this form up to the present time.

Basically, "JetScreen" units only apply to the screen the conventional engraving transparency, though by a new method. All other processing stages, i.e. exposure, development, thermal or chemical hardening if necessary, through to retouching, remain unchanged. For this reason, all photoelectric layers are immediately usable whatever the make. How appropriate this concept is, is proved by comparing the ink-jet technique with the laser exposure technique for rotary or flat screens. The short-wave laser sources used there are low in performance, and therefore need extremely sensitive photoelectric layers. Their development is only in the initial stages. Thus, there is of course already a series of "ultra-fast" photoelectric layers on the market, but many limitations are apparent in practice. Apart from the fact that these layers need extremely subdued light for processing, there are still difficulties as regards durability in printing. Moreover, the fast photoelectric layers have to be applied within strict limits as regards layer thickness (which also applies to laser erosion engraving units, so that, basically, exclusively mechanised application processes come in question). If the layer thickness is exceeded, full hardening suffers in laser exposure, or the layer is not completely burned off. All these limitations, which of course seem individually controllable, but can as a whole represent troublesome fault sources, are excluded from the onset with the ink-jet technique.

Laser engraving	"JetScreen"

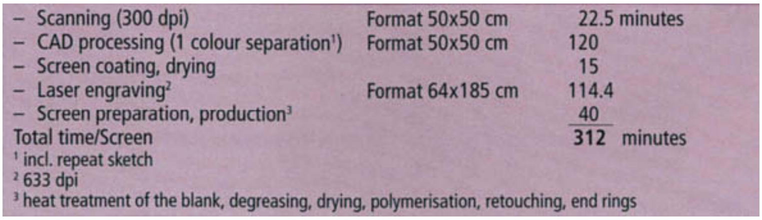
Fig. 3: Comparison of processing cycles with laser engraving and the "JetScreen" (Lüscher AG).

Laser/ink-jet comparison: Apart from the technical differences in the systems, the practical man is interested above all in the performance aspects. In Fig. 3 the (erosion) laser engraving process and the "JetScreen" are compared for rotary screen patterning. In addition to the colouristic configuration of a textile design, print quality means above all the graphic harmony of colour separation and resultant print. Engraving affects this harmony primarily with its graphic definition capacity. Fineness of contour and screen, freedom from moiré or from "saw toothing" in figure outlines are criteria which, in addition to the photoelectric layer and the screen gauge used, are determined by the engraving process and equipment definition capacity. Thus one would expect better engraving and printing results from the process offering higher effective definition. In this connection, effective means the relationship between graphic definition and engraving time. Higher definition is unusable or less usable, for example, if it leads to unreasonable engraving times. With both processes, therefore, picture definition in printing depends on scanner definition capacity, on the photoelectric layer, and ultimately on mesh count and screen model. These influencing parameters are assumed to be identical in the comparison: identical datafile, identical photoelectric layer and screen.

The lengthy time requirements for laser engraving needs brief explanation (Figs. 4 and 5).The engraving time results from screen speed (403 rpm) and horizontal definition (633 dpi), which is equivalent to an engraving head feed of 40 µm per screen revolution. Under these conditions, the total engraving time is 114.4 minutes. This time requirement is too high in practice. In order to keep engraving time within limits, a compromise is made, definition being reduced in the horizontal engraving direction, while it can be selected at a high level in the vertical direction within the bounds of the possible. With a horizontal definition of 245 dpi, for example, (this is equivalent to a feed of 104 µm per revolution), the engraving time is 44 minutes at a speed



– Scanning (300 dpi)	Format 50x50 cm	22.5 minutes

of 403 rpm. With a horizontal definition of 200 dpi, the engraving time is then about 36 minutes. In this way, practicable engraving times are achievable. Presupposing suitable designs, the engraving result is acceptable. If of course highly detailed designs are to be produced with large half-tone areas or other difficult parameters, this process cannot meet requirements without having to take account of loss of quality or longer engraving times. (according to M. Klemm and W. J. Burrow).

Screen films in photo-engraving These are used:

I. In film printing to copy texture or grid effects into the sample pattern.

II. In photo-engraving for printing rollers to copy the → Hatching into the negatives of the colour separations by contact printing.

Screen frames (film screen frames). The screen gauze is supported by the screen frame. Wood, metal, plastics and combinations of the above, e.g. metal/plastic, are suitable for the production of screen frames.

Screen frames in screen printing In contrast to rigid frames (as used in yuzen, spray and brush stencil printing), various special materials are used as film bases in screen printing. These are supported by a stable screen frame. Types of screen frame include: wooden frames, metal frames, plastic frames and combined frames (e.g. metal and plastic).

Screen gauze → Screen mesh, screen gauze.

Screening test OECD 301 E This test is used as an initial test of the biodegradability of a textile auxiliary (→ Surfactant biodegradability, evaluation of) and should be regarded as a particularly stringent test as it simulates the conditions of river water, rather than those of a biological waste water treatment plant. This test is described in the form of a diagram in Fig. 1.

The substance to be tested is added to an open container, together with nutrient salt solution and a bacterial suspension from a municipal waste water treatment plant with approx. 1 mill. germs/ml. This container is shaken at room temperature for 28 days in a shaking device and a sample is tested for its rate of biodegradability (reduction in DOC) every 7 days. It is, of course, also possible to test the reduction in BiAS analytically, but this gives higher values. If the limit values (DOC 60%) are not achieved, a continuous test is prescribed (Fig. 2). This test is also known as the "confirmatory test". In this, the substance to be tested is tested in an

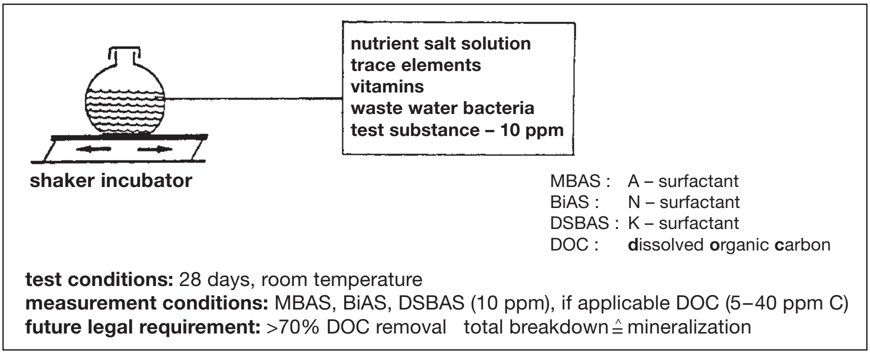

Fig. 1: Test methods for the selection test – screening test OECD 301 E.

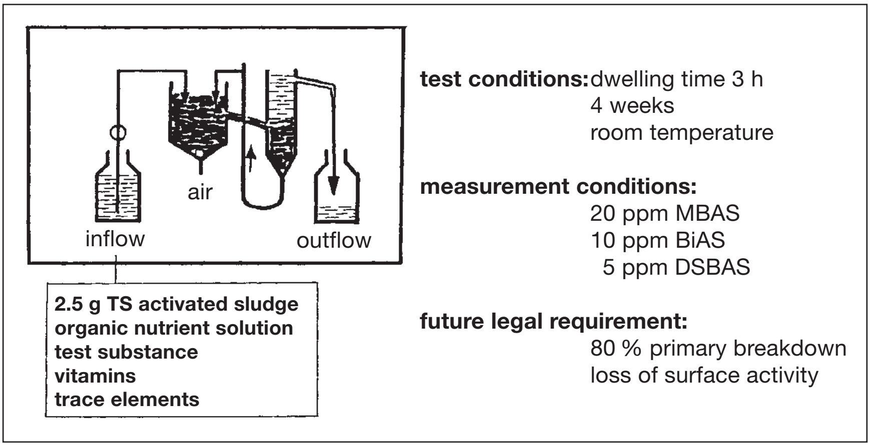

Fig. 2: Test methods for the confirmation test – confirmatory test without OECD number.

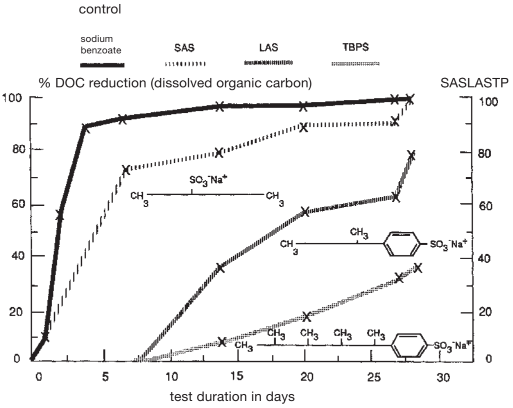

Fig. 3: The total breakdown of anionic surfactants, sec. alkane sulphonate SAS, alkylbenzene sulphonates LAS, TPBS, total breakdown according to modified OECD screening test 301 E.

activated sludge device in which the conditions are adapted to those in a waste water treatment plant. Nutrient salt solution is continuously added to the test substance in an aeration tank. This is where the essential biodegradation takes place. The required 2.5 g solid matter/l activated sludge comes from the municipal waste water treatment plant. The bacterial sludge migrates into a sedimentation tank, where it is pumped back into the aeration tank. At the infeed, approx. 5–20 mg/lxh of anionic surfactant or 5–10 mg/lxh non-ionic surfactant is allowed to flow through the device. The biodegradation can be calculated taking into consideration the concentration of the surfactant at the infeed/outflow. Using this method, the primary degradation should be 80% and above. The biodegradability of the surfactants which are generally used in pre-treatment can be described as good, as shown in the examples in Fig. 3.

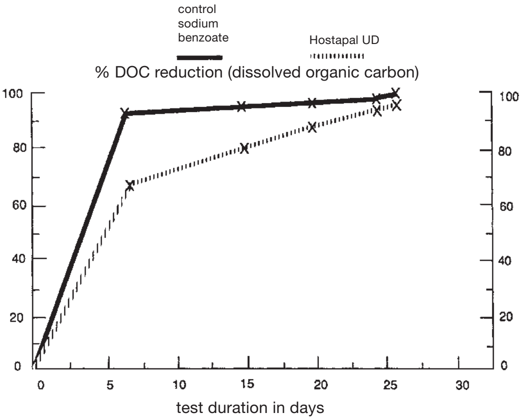

Fig. 4: The total breakdown of nonionogenic surfactants, alkyl (C 16-C 18)-polyethylene glycol ether (11 EO), total breakdown according to modified OECD screening test 301 E.

With SAS, it is extremely easy for the bacteria to carry out biodegradation (Fig. 3). The LAS will exceed the 60% limit after a sufficiently long adaptation time. The delayed degradation could be due to the structure of the benzene ring. Fig. 4 shows the biodegradation of nonionogenic surfactants.

Screen lacquer This is used for prelacquering (preparation) in → Screen making, as a support for photosensitive layers and as a reinforcement coating.

Screen magazine for screen printing Screen magazines were placed to the side of or in front of the printing table in the first screen printing machines (Hikisch, Teximpex). They are divided into sections which can be raised and lowered in order to bring the desired screen to printing table height. Before printing, the movable screen frame is removed from the screen magazine and is slid back into the same compartment afterwards.

Screen making The repeat must be specified before the screens are made. Flat or rotary screens are manufactured by specialist companies or in separate departments within printing works. After the printing repeat has been designed and the colour separation has been produced, a flat screen is manufactured using the photochemical method, or alternatively a rotary screen is manufactured using the galvano-plastic method (or less often using the photosensitive lacquer process). The photochemical method is based on the fact that gelatine together with chromium salts forms water-insoluble compounds (chrome gelatine) when subjected to intensive exposure. The carrier layer is formed by coating with gelatine, which contains ammonia and potassium dichromate. During exposure, the unexposed layers may continue to swell and can be rinsed out at a later stage.

The galvano-plastic method to manufacture rotary screens uses seamless, thin nickel foil cylinders which are perforated and must be of uniform thickness. There is a sealed nickel layer on the areas which are not printed, while the screen is located on the patterned area. The sequence of procedures in the galvano-plastic method is such that a light-sensitive layer must be applied to the carrier roller. A negative film with screen resolution is then copied onto the carrier roller. The photosensitive layer must be developed and hardened before a separation layer is applied to the carrier roller (see Fig.). In the galvanising process, the cylinder is nickel-plated using nickel sulphate before the nickel screen is separated from the carrier roller. Nickel foil cylinders can also be patterned using → Laser screen engraving. →: Engraving; Positive process for screen making.

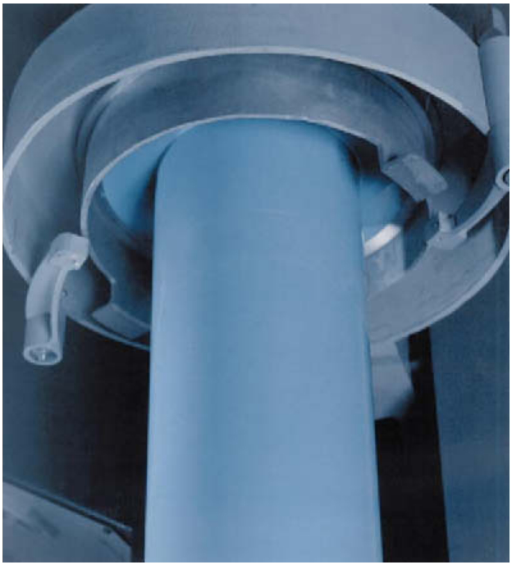

Fig.: Coating a rotary screen by dipping (Stork).

Screen mesh, calendered Crossover points are flattened during calendering and the thickness of the fabric is reduced, while the stitch width remains more or less unchanged. The volume of print paste in the dye paste channel and therefore the quantity of print paste applied is thereby decreased.

Screen mesh materials (→ Screen mesh, screen gauze), a) Silk: elastic, insensitive to pressure and impact, durable, sensitive to strong alkalis; b) Phosphor bronze (alloy consisting of 93% copper, 6.75% tin, 0.25% phosphorous): extremely fine wires (0.09–0.03 mm), high resistance to alkalis and acids, low elasticity gives high accuracy of registration, sensitive to pressure and impact (bulges); c) Polyamide, polyester: fine, even and durable fabric, resistant to chemicals, low moisture absorption, sensitive to highly concentrated caustic soda solutions.

Screen mesh, precleaning In → Screen making, the mesh must be cleaned of dirt, grease, etc. before the cover layer is applied. There are various methods available: for meshes made of silk or synthetic fibres, the screen is merely brushed down with hot water. Metallic meshes must be cleaned using chemicals. The screen can be cleaned with 10% sodium carbonate solution, diluted ammonia or caustic soda solution. However, the cleanest screens are obtained by using diluted organic acids or brushing down with 10% chromic-sulphuric acid (10 parts sulphuric acid, 20 parts water, 1 part potassium or sodium dichromate) followed by thorough rinsing.

Screen mesh, screen gauze (screen-printing fabric). Fabric covering for the screen frame which also serves to support the printing pattern in → Screen printing. Materials used include synthetic monofilaments and fine wires.

Screen plates in screen production These are required when producing → Half-tone autotype screens to help divide an image with differences in shade into a grid network of different sized dots.

Screen print This term is used instead of → Screen printing predominantly in the graphics industry. Screen print denotes the printing process in which the dye paste is pressed through the substrate as through a sieve.

Screen printing (film printing, correct: film screen printing, silk-screen printing). Printing process for textiles, etc. in which the printing block consists of patterned areas which are permeable to print paste, whereas the areas which do not have a design are impermeable to print paste. A distinction is made between → Flat screen printing and → Rotary screen printing. The screens consist of screen mesh (with recessed patterns) which is coated (on both sides) with lacquer, and which is mounted in the screen frame (wood, light metal). The print paste is poured into this and is pressed through the patterned areas which are free from lacquer onto the substrate below (which is fastened to the screen printing table) using the → Doctor blade. Repeat printing is used. The screens, which are generally each used for one print paste (i.e. there is generally one screen for each colour used) are positioned according to the repeat. This simplifies the repeat device which is applied along the screen printing table (bars with pins, etc.). Use: in particular for high quality novelty prints, for rapid colour matching with frequent colour changes and a large number of patterns and for suitable, especially smaller, yardage. → Roller printing and → Rotary screen printing are cheaper, however, especially for large print runs.

Screen printing adhesives When bonding the fabric, the printing table must be covered with a width of rubber, synthetic or wax cloth. Dextrines, gum solution, cellulose derivatives, starch ethers, alginates and even suitable combination detergents are used as adhesives. The adhesive application requires particular care as the adhesive coating must be completely even. The fabric should also be placed on the table as soon as possible after the adhesive has been applied. A glueing carriage has been developed for this in table printing. On screen printing machines, the adhesive is applied using a glueing unit.

Screen printing carriage This was the first step in the partial mechanisation of the printing process in screen printing. Printing table on each side with sliding bars as the contact surface for the screen printing carriages. In principle, this is a rigid frame with four runners which are positioned in such a way that the frame can be raised vertically to a height of approx. 100 mm by operating levers. During printing the screen printing carriage is moved along the table with the screen until the repeat device locks into place. After this has engaged, the carriage and screen are lowered so the screen lies against the goods to be printed. After printing, the screen is lifted off again by operating the lever and the carriage is moved to the next repeat or the next repeat but one.

Screen printing carriage for rotary and flat screens Automatic printing table for either rotary or flat screens to accurately print awkward fabric qualities. The printer moves along with the production carriage which is fitted with a platform (monitoring, exact adjustments).

Screen printing carriage, lever-controlled The first construction of a screen printing carriage occurred in 1935 during the course of the partial mechanisation of hand screen printing. The printing table has sliding bars on each side which form the contact surface for the screen printing carriages. In principle, this carriage consists of a rigid frame with four runners. These are positioned in such a way that the frame can be lifted vertically to a height of approx. 100 mm by operating levers attached to the runners. The frame also has locking devices which lock onto the bars at appropriate repeat limit stops and therefore guarantee accurate repeats. This frame supports the screen. During printing the screen printing carriage is moved along the table with the screen until the repeat device locks into place. The carriage and screen are then lowered so the screen lies against the goods to be printed. Printing takes place using double tilting or double rod squeegees. After the screen has been lifted again by operating the lever, the carriage is moved to the next repeat or the next repeat but one and the printing process is repeated. With the original printing carriages, it was necessary to raise and lower the carriage using two levers with both hands. The development of the lever-controlled screen printing carriage enables the working speed to be increased as the printer does not have to change grip from the lever to the doctor blade handle. Instead, the lever is left in position as the carriage moves forward enabling doctor blade movement to be initiated immediately after the screen has been lowered.

Screen-printing fabric → Screen mesh, Screen gauze.

Screen printing machine, automatic These are machines which carry out the entire printing process automatically when the screens are fixed in a stationary position while the fabric moves. Goods to be printed are affixed to an endless rubber blanket using a gumming device and are moved over the printing table. Screens are arranged next to each other above the table and are raised and lowered at the same time. Doctor coating takes place mechanically, either in the direction of the warp or the weft depending on the design of the machine. This doctor coating process can be carried out once or several times. After the screens have been raised, the fabric is moved forward by one repeat. A washing device, which is used to clean the printing blanket, is located beneath the machine. At the end of the machine, the fabric, which is moist from printing, is fed into a drying chamber, dried and cuttled down as it exits the chamber. The machines can be designed for 12 colours, for example, if there is sufficient space. In 8h, production is between 3000–4000 m, if the colour design for the pattern to be printed remains the same over 1000 m (totally independent of the number of screens). Colour design refers to the colour combination of a pattern which can be modified as required without changing the number of screens.

Screen printing squeegees →: Doctor blade; Squeegee systems in printing.

Screen printing table The table, in hand screen printing, on which the item to be printed is affixed, whilst with screen printing machines, the endless printing blanket runs over the screen printing table, on which the piece good, with a backing cloth if necessary) is affixed. Wool felt is often used under the printing blanket as an flexible layer.

Screen print steamer Designs follow the principle of fabric circulation, with only the reverse of the fabric sitting close to the guide rollers (to prevent haloing effects and smudging). Fabric always guided in a spiral, either a) in the Krostewitz steamer from the outside to the inside, with the fabric being turned by 90° in the centre of the steamer and being delivered at the side or b) in the Gerber or spiral high-speed steamer, with the fabric being guided in the same way, but with the fabric passing in the opposite direction through the tunnel, i.e. from the inside to the outside or c) in the double spiral steamer with the fabric firstly passing at the bottom from the outside to the inside, then turned by 90° and guided upwards, followed by another 90° turn and guided at the top from the inside to the outside. As in cases a) and b) it is always only the unprinted side of the fabric which comes into contact with the guide rollers, there is absolutely no risk of haloing. Other designs include: → Universal loop steamer and the → Continuous steamer.

Screen roller in screen printing These are used to facilitate the transport of screens on the printing table.

Screens, dimensional stability This depends on the material used for the → Screen frames, the type and tension of the screen gauze, → Screen making, environmental conditions in the preparation and printing rooms, treatment and care of the screens. Strong metal frame profiles are useful in providing the required cloth tension. To reduce fluctuations where the frame is permanently bowed, the following is recommended:

– Frame should be sufficiently bowed into a convex form before the fabric is affixed.
– When the frames are being manufactured, the trans-

verse leg (or also the broad leg) may each be bent convexly by approx. 4mm/m and be welded together at this angle which is slightly above 90°.

→ Stretching frames for screen making.

Screen sequence in screen printing Particular care should be taken with the sequence of screens or print pastes as this can have a major influence on the printing result, especially if fine outlines, overlaps or resists are being printed.

Screens for screen printing (film screens). Continuous, fine screens made from → Screen mesh which contain the desired patterning and therefore act as a carrier for the printing pattern. → Screen making.

Screens, fully lacquered → Screens produced using the → Negative process. The face and reverse of the screen are lacquered with a spec. appropriate coating. The advantage of the fully lacquered screens is that it is possible to produce extremely precise designs and that the screens are particularly simple to make.

Screen silk Spec. → Screen meshe, in screen printing is referred to as screen silk to distinguish them from standard → Bolting cloth. They are characterised by more careful selection of material, material treatment, control, particularly good and even material penetration and low swelling capacity when strong alkali print pastes are used. In places, guide threads are woven into the warp and weft at intervals of approx. 20–25 cm. These serve to ensure the mesh is fixed evenly in line with the threads on the screen frame. Mesh count is mainly between 6–16; 6–9 for blotch prints, pigment colours and bronze prints; 4–16 for finer outlines, streaks and screen effects.

Screens, stencils (design, form). Patterned support to enable reproduction of textile fabric patterning. Printing screens consist of the → Screen mesh and the → Screen frames.

I. Metal screens where the designs have been punched out are laid on the untreated material and enable the fabric to be partially brushed.

II. Paper screens where the designs have been cut out are laid on a fabric, and pigment dyestuff dispersions and binders are sprayed onto the fabric to form designs (→ Yuzen printing).

III. Negative films are screens which allow partial light transmission onto the printing screens which are to be exposed.

IV. Gauze cloths, which are stretched on frames and stopped with lacquer as per the design, and allows print paste to permeate the open area of the screen in → Flat screen printing using a doctor blade.

V. Rotary nickel screens, the perforations of which are partially blocked electrochemically with another metal or in which the completely sealed perforations have been previously opened using lacquer treatment in line with the design are used as → Rotary screens for screen printing.

Screen storage in screen printing To prevent damage, it is important that screens are stored in separate compartments, either one above the other, or next to each other (upright). For upright storage, small rollers are fixed in the floor in order to make it easier to manoeuvre the screens. The frames can also be suspended for storage. Rotary screens are kept horizontally in cardboard tubes, or upright if they are oversized.

Screens, subdivided (partitioned). This is used in screen printing to print several colours at the same time using a limited number of screens. To achieve this, the screen frame has a series of cross strips and the mesh is fastened as tightly as possible to the external frame and to the cross links to create individual fields which are totally separate from one another. A comb-type device with notches is used as a doctor blade.

Screen to screen coating A double foam application station can apply the same or, if preferred, different finishes (either wet-on-dry or wet-on-wet as preferred) to both sides of the fabric in a single process. In addition to foam application, paste coatings are, of course, also possible.

The horizontal design (Fig. 1) is used for double-sided coatings and finishes and operates with enclosed doctor blades, Drying takes place in a stenter or conveyor drier. This model can be used for combined use if the lower screen is operated using an enclosed doctor blade; it is therefore possible to combine paste coating on the upper side with impregnation on the underside, for example.

The vertical design (Fig. 2), in which the material is guided upwards, is used for paste coatings, which are dried using infra-red plates, and is used, e.g. with PVC

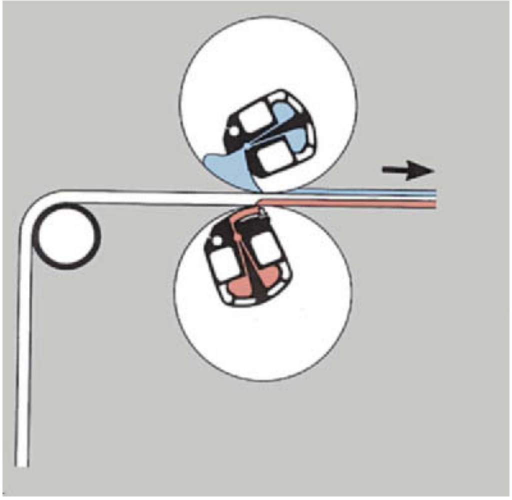

Fig. 1: Screen to screen coating in horizontal layout (STS by Stork).

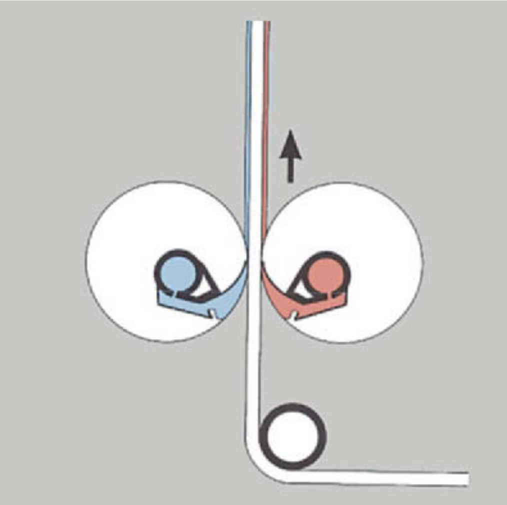

Fig. 2: Screen to screen coating in vertical layout with goods moving upwards (STS by Stork).

coatings for tarpaulins and nets. It can also be used for combined treatments with a stenter, conveyor drier or infrared drier positioned above. The vertical design in which the material is guided downwards is generally used for impregnating textiles/nonwovens and to chemically bond nonwovens. This version of the vertical design can also be used for combined treatments, although it must always be noted that the impregnated side of the material needs to be turned and should be dried in a stenter.

The principle element in screen to screen coating systems is the seamless rotary screen. The doctor blade presses the paste through the perforated screen onto the fabric which has an open fabric structure. A pump and a level controller ensure the paste is applied uniformly. The quantity of print paste applied on the substrate can be altered by choosing a different type of screen or altering the doctor blade pressure. The substrate then passes a double levelling blade (with a face and reverse side) which smoothes the surface.

Screen washing Rotary screens are generally cleaned in the vertical position. The outer screen wall is cleaned using a spray ring, and the inside is cleaned with a spray head with jets (see Fig.). Another possibility is the turbo spray washer which is attached to the central wash water feed on the inside of the screen: there are polyamide fibres on the rotating part which are hydroextracted on the screen wall due to the rotating centrifugal force in order to mechanically intensify the washing effect of rinsing with water.

Scroller → Selvedge uncurler.

Scrooping agents,

I. Common as a finishing agent on fibres to produce

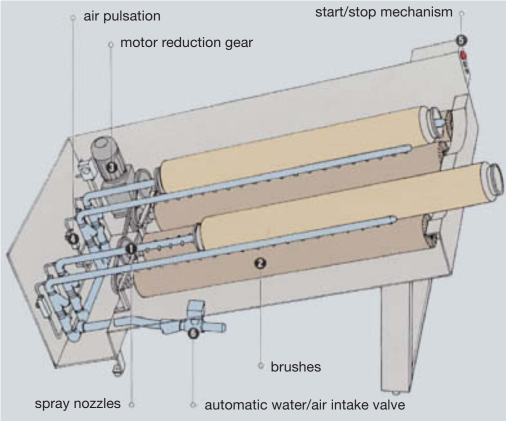

Fig.: A screen washing facility (Stork).

specific finishing effects. Different types of scrooping agents are available to take into account water, fibre, type of fabric and intended use. → Softening of textiles.

II. These are used to produce a scroopy handle (craquant, → Silk scroop). The textile fabric is treated with Marseilles soap, followed by an aftertreatment with lactic or tartaric acid. More recent methods are based on the use of ethoxylated fatty acids or paraffin emulsions.

Scroopy handle → Silk scroop.

Scrubbers for exhaust air For systems dealing with → Exhaust air, cleaning of using scrubbers, a distinction is made between:

a) Scrubbers: centrifugal washer, Prött system (Fig. 1); vortex chamber, Babcock system (Fig. 3); spray absorber (Fig. 2).
b) Heat exchangers (indirect cooling process): Lamella heat exchanger, alternatives between air/air and air/water, Behr system; bare-tube heat exchanger with mechanical tube cleaning, air/water, Radscan system; plate heat exchanger with wet cleaning of the plate, air/water, DEG system.

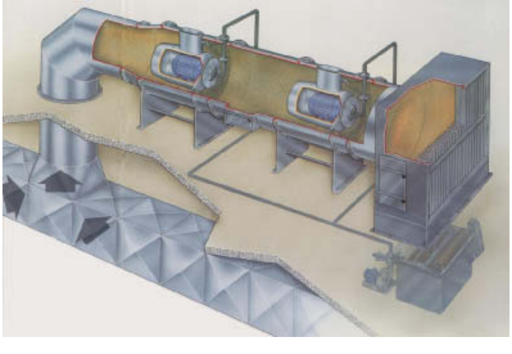

Fig. 1: Section through a Prött exhaust air scrubber.

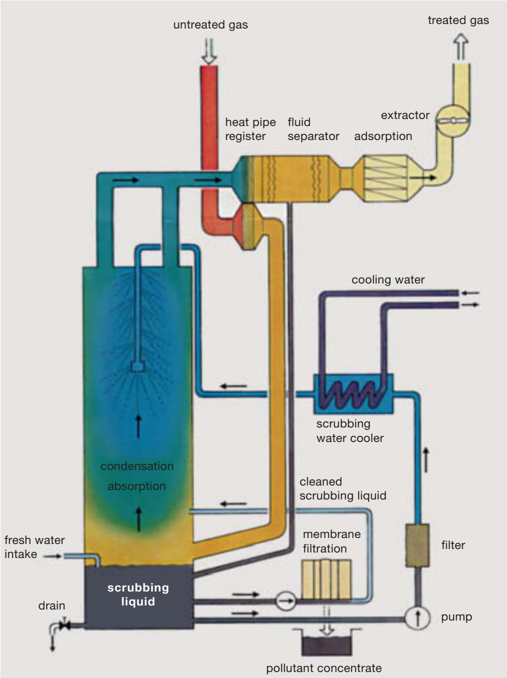

Fig. 2: Heraeus spray absorber.

c) Combination of scrubber and heat exchanger, Behr system.

In Prött's centrifugal washer (Fig. 1), the exhaust air is conveyed through the water curtain in a cross current. The exhaust air is thereby cooled to approx. 50°C, causing the pollutant vapours to condense, thus absorbing the pollutants, e.g. the odorous substances, to a certain extent. Soluble pollutants are partially dissolved in the water droplets. The air is fed to a mist eliminator after it has flowed through the water curtain. Droplets of water, condensation products and pollutants are here separated out. A water reservoir with a filter is used to separate the non-soluble pollutants back out of the water. If necessary, these must be disposed of as special category waste. The cleaned water is then fed back to the atomiser as part of the cycle. It is also possible for the atomised water to be removed from wet treatment machines and fed into the exhaust air cleaning systems.

The pollutants which are separated out are fed into the plant's waste water. This necessitates either a special treatment or transfers the problem to either the in-house or municipal waste water treatment plant.

Prött has a make-up water requirement of 700–5000 l/h with a max. air volume of 32 000 m^3/h for the two-stage system. The two centrifugal discs operate at 4700 l/h and 15 000 l/h; the pump motor capacity is 2 · 18.5 kW.

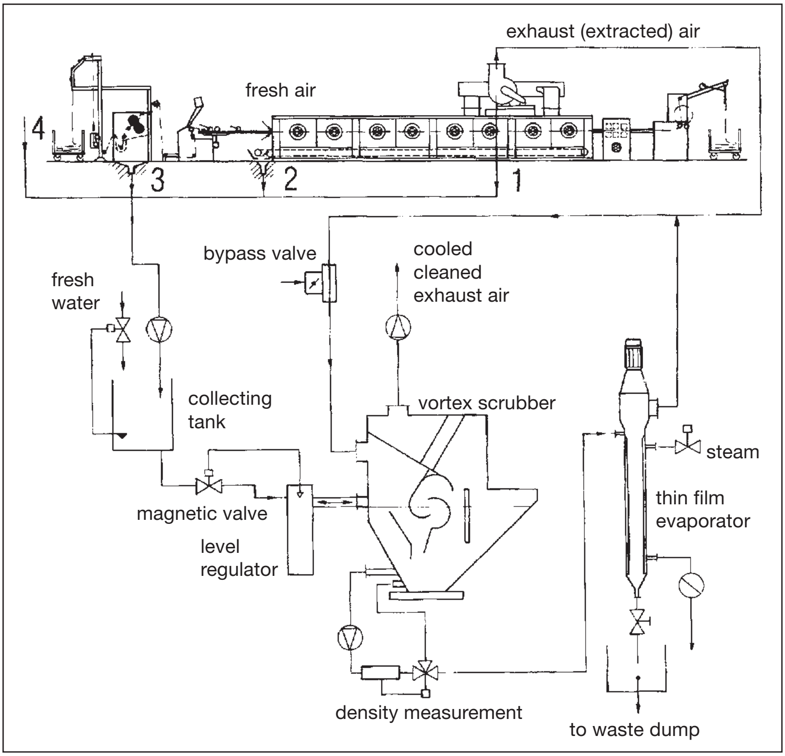

Fig. 3: Exhaust air cleaning system with the evaportion of residual liquor and waste water in a vortex scrubber (Babcock). 1 = water from the automatic cleaning system for a heat exchanger wheel or other recovery devices; 2 = water from automatic screening belt cleaning; 3 = residual liquor and pad cleaning water; 4 = other waste water arising, e.g. from washing or dyeing.

The figures for a two-stage Krantz system of the same size are 700 l/h make-up water at 13 200 l/h and 26 400 l/h water spray for both centrifugal discs. The max. airflow is 35 000 m³/h. Babcock produces a vortex scrubber which has a vortex chamber in the place of one or two centrifugal discs. The waste air is thoroughly mixed with water in this chamber, thus cleaning the air. It is configured directly on a stenter. The max. air volume is 10 000 m³/h. Its method of operation is explained in Fig. 3.

The exhaust air from the stenter is fed into a vortex scrubber where it is cleaned in a rotating air/water vortex and the ensuing water curtain (Fig. 4).

- particles, lints and aerosols are surrounded by water droplets which precipitate as they become heavier.
- water-soluble gases and vapours are absorbed into solution.
- cooling the exhaust air to wet bulb temperature, i.e. to 50–65°C causes the majority of the vapours to condense into fine droplets.

Mist eliminators are provided after the vortex chamber so that no water from the air stream is entrained into a subsequent electrostatic precipitator (Fig. 5). The energy extracted from the exhaust air by cooling can be used to evaporate the wash water. Two examples are given to explain the extent of this: the first example is for a drying process, and the second for a setting process. Example 1: the drying process (assumed figures):

Fig. 4: View of the interior of the swirl chamber of the Babcock exhaust air scrubber.

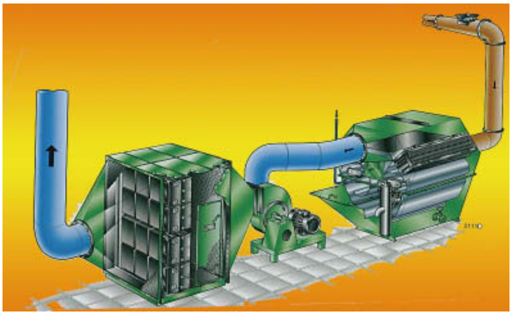

Fig. 5: Exhaust air purification system (right side: scrubber; left side: electrostatic precipitator).

- exhaust air temperature 130°C,
- exhaust air moisture 100 g/kg,
- exhaust air volume 10 000 m³/h = 8759 kg/h.

This gives a wet bulb temperature in the washer of 57°C and exhaust air moisture of 132 g/kg. According to the i-x diagram, 32 g of water/kg air and thus 280 kg water/h are therefore evaporated. Fig. 6 shows the progression in the i-x diagram.

Example 2: the setting process (assumed figures):

- exhaust air temperature 160°C,
- exhaust air moisture 30 g/kg,
- exhaust air volume 7000 m³/h = 5706 kg/h.

This gives a wet bulb temperature of 48°C and an exhaust air moisture of 75 g/kg. According to the i-x diagram, 47.5 g of water/kg air and thus 271 kg water/h are therefore evaporated.

The liquid level of the vortex scrubber is controlled by a level controller and the amount of water evaporated from the reservoir is replaced. The wash water may originate from the residual liquor in the padder or from the dyehouse, for example.

Processes with heat exchangers: in a similar way to the process using washers, cleaning of exhaust air with heat exchangers is based on the reduction of the exhaust air flow temperature, which causes condensable materials to separate out. In comparison to direct washers, the filtration efficiency for dust-like or fibrous pollutants is lower, thus generally necessitating a filter to be provided in addition to the heat exchangers required. The type of heat exchanger (recuperative or regenerative) can vary; whether air/air or air/water exchangers are used is dependent on the operating conditions. With these methods, it is important that attempts are always made to make use of the exhaust heat in order to achieve economic efficiency.

The principle of the washer is shown in Fig. 7: the exhaust air is cooled in an air/air or air/water heat exchanger. This causes fresh air to be heated on the secondary side of the heat exchanger. This air is fed to the thermal treatment machine. This enables heat to be recovered. By cooling the exhaust air in the heat exchang-

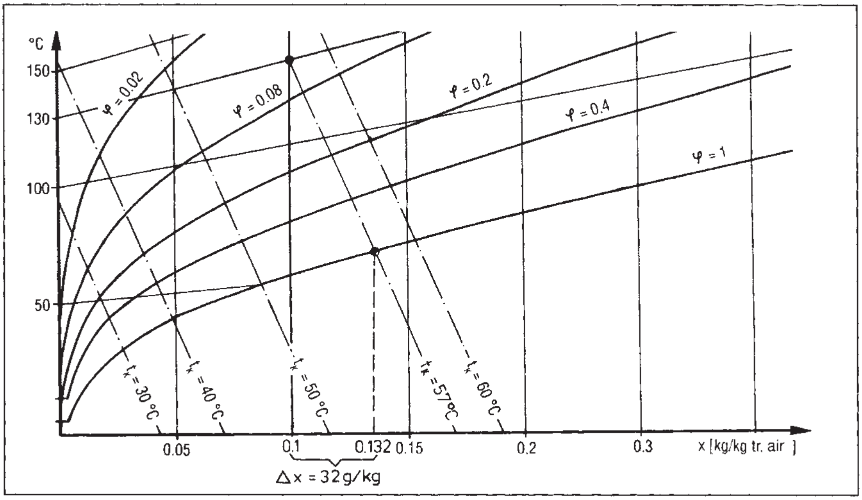

Fig. 6: i-x diagram (example illustrated: drying process).

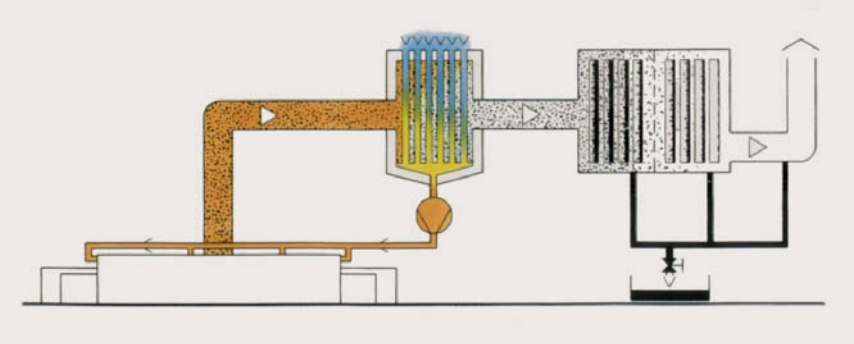

Fig. 7: Diagram of a washer with heat exchange facility (cooling principle).

er to below 60°C, the pollutant vapours are condensed. The condensed pollutants are then filtered out of the exhaust air using mechanical or electrical filters. Heat exchangers and filters must be cleaned with water. The water washes the condensed pollutants off the filter surface and the surfaces of the heat exchanger. The polluted water is collected in containers and must be disposed of in waste water treatment plants. In contrast to exhaust air scrubbers, water-soluble substances and odorous substances cannot be removed from the exhaust air using this system. It is possible, however, to combine this system with the exhaust air scrubber system.

A general problem with this process is the formation of deposits on the elements of the heat exchanger, which necessitates cleaning, and thus indirectly results in further pollution of the effluent. Three variations of the process represent the current practical situation. Behr produce aluminium air/air heat exchanger modules in plate form in addition to stainless steel air/water heat exchangers. Cleaning aluminium heat exchanger elements which have stubborn stains poses a problem. Using aggressive alkali cleaners which are probably used at too high a concentration or for too long a period, causes damage to aluminium parts. It is therefore recommended that more resistant materials are used. This increases the cost of the system. Behr produce aluminium/stainless steel elements which are identical in construction at a price ratio of $^{1}/3$ (DM 850 : 2500).

Radscan's cleaning system allows deposits to be abraded during operation. These cleaning systems have annular scrapers which are positioned around each individual tube in the heat exchanger and which can be moved vertically along the tubes. This can result in contact between the elements and the tubes, as there is naturally no real symmetry to the deposits. Damage to individual tubes also occurs gradually and it is then necessary to plug them to prevent cooling water passing into the airflow. The life-span of a heat exchanger is given at approx. 10 years due to this phenomenon.

A system which originated in the chemical industry is used by DEG-Engineering for heat exchanger elements. Fig. 8 shows these elements in a plate heat ex-

Scrubbers for exhaust air

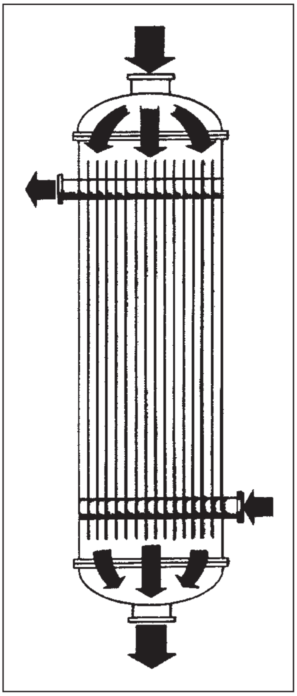

Fig. 8: Plate heat exchanger (DEG).

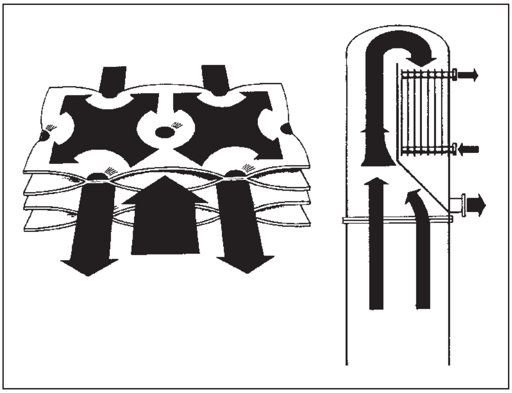

Fig. 9: Plate heat exchanger surfaces (DEG).

changer. It is important that the surfaces are relatively smooth (Fig. 9) and therefore easy to clean and that stainless steel is used. According to the manufacturers, cleaning can be carried out during operation by spraying with a cleaning fluid. As this is sprayed on by jets, there is no risk of mechanical damage. DEG provides for a transfer of energy from the exhaust air to the fresh air. An internal water cycle is set up for this; the heat exchanger on the fresh air side should be designed in a copper/aluminium alloy. The filtration efficiency of the heat exchangers will not be higher than when using a scrubber; as long as efforts are made to achieve comparable reductions in the temperature of the exhaust air (50–60°C). A better effect can be achieved using the scrubber because soluble gases or condensates can also be separated off in the water. This is not possible with a heat exchanger.

Combination scrubber/heat exchanger: the exhaust air passes through a distributor box in the Behr system. It is then routed via a spray system which is fed by circulating water, via packed heat exchangers. The exhaust air is therefore brought into extensive contact with the wash water. At the same time, the exhaust air temperature is reduced in the air/air heat exchanger and the wash water is kept at a lower temperature. After leaving the heat exchanger, the exhaust air is diverted by 90° and passes into the open air through a mist eliminator via a stainless steel filter and an exhauster. Condensate and wash water are collected in the settling basin and are then conveyed to the spray system via a pump (Figs. 10 and 11). By condensing the water vapour in the exhaust air in the scrubber or heat exchanger, approx. 150 kg of condensate/h are collected in the system collecting tank. A second pump conveys the excess scouring solution into an emulsion separating plant for further disposal. The cooling air is extracted by a dust filter. The cooling air then passes into the air/air cross flow plate heat exchanger where it is heated by the exhaust air or the wash water before being blown

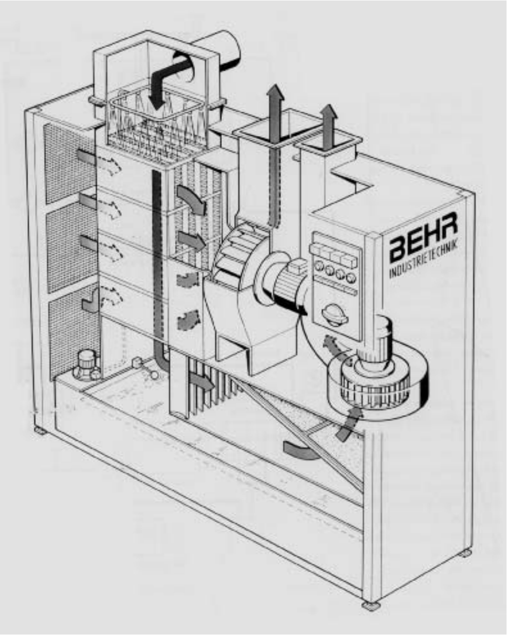

Fig. 10: Exhaust air scrubber for yarn finishing machines (Behr).

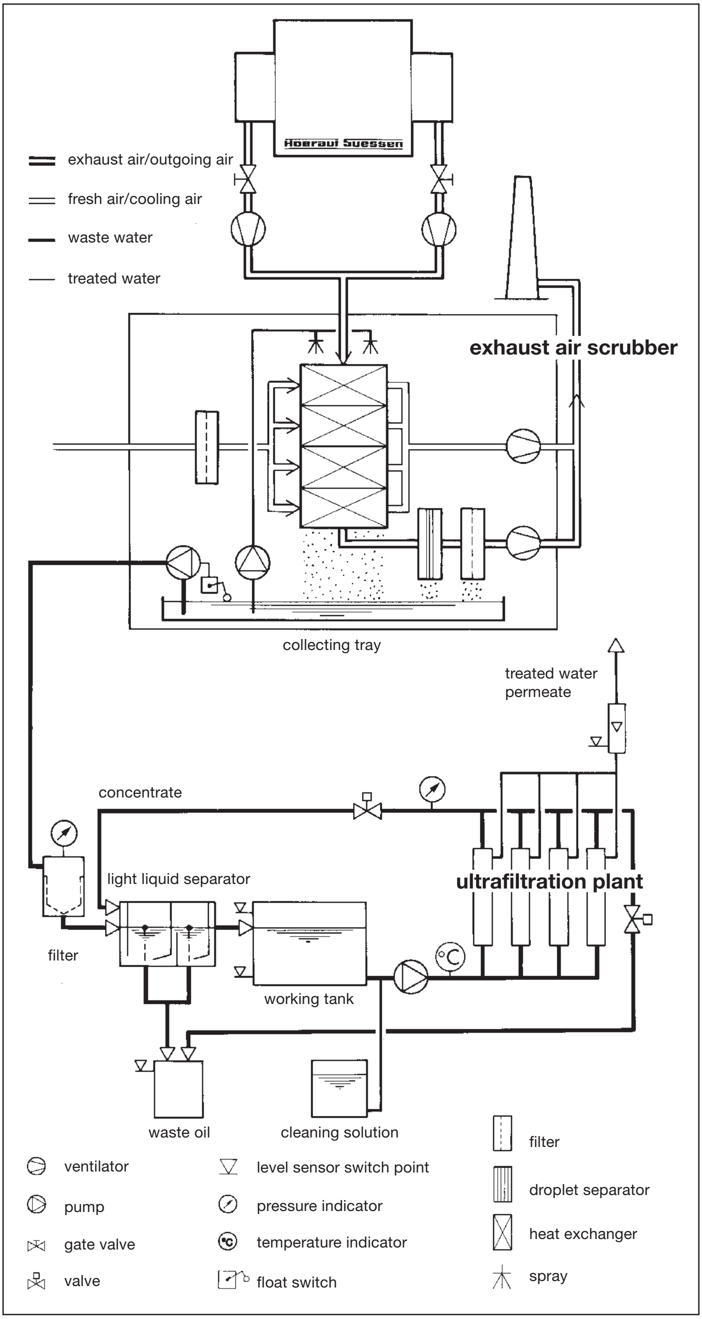

Fig. 11: A yarn finishing facility with exhaust air scrubber and an ultrafiltration plant (Behr).

into the open air by a radial fan. The heated cooling air and the exhaust air emerging from the washer can be collected in the system casing and released into the open air via a collecting main. If the energy from the heated cooling air is to be reused, this is possible by means of a separate channel.

Biowashers: if the exhaust air contains strong odours, it is recommended that it is washed with water which contains bacteria to break down the odorous substances (Fig. 12).

Scutched flax → Scutching.

Scutcher Also known as a stamping machine, used for → Engraving grooved rollers. Using a scutcher, the → Hatching is imprinted into the coat of lacquer on the master mill before the acid-resistant lacquer in which this is coated has fully hardened.

Scutcher oils → Textile lubricants.

Scutchers, breaking machines → Mechanical breaking.

Scutching Scutching is the second stage in preparing flax stems after retting, drying and breaking (flax scutching). The purpose is to separate the wood shavings as much as possible, a process which gives rise to tow in the form of short, snarled fibres. It can be carried out either manually or on a machine (scutching turbines). Scutched or swingled flax (approx. 15–25 % from flax straw, depending on source) are the coarsest long-fibre flaxes which can actually be spun. It is followed by the hackling process. → Flax processing.

Scutching (flax) (breaking). This is the first stage in → Flax processing after retting and drying, and involves breaking down the brittle woody tissue into shavings. It can be carried out either manually or mechanically using a pair of fluted rollers. It is followed by the scutching process.

SDC dyeing control system (Synchron Dyeing Control). As sensitive fabric surfaces can be damaged in rope dyeing if the mechanics (reel, liquor circulation) in the liquor exchange zone of a jet dyeing machine are too high, it is possible to optimise the number of passages through the nozzle system based on the length of

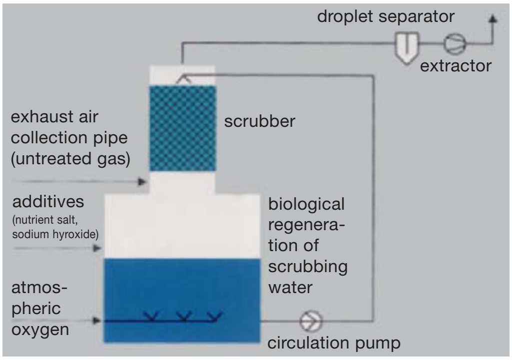

Fig. 12: The principle of a bio-scrubber. The exhaust air is sprayed with scrubbing liquid which dissolves the odorous substances; the scrubbing liquid is then regenerated biologically and returned to the process.

the hank per jet by using appropriate control programs (see Fig.). The reeling speed and the pump capacity should always be adjusted to the current dyeing conditions (affinity of the dyestuffs at the acute dyeing temperature) so that uniform absorption is guaranteed. On the other hand, max. reeling speed in the migration and fixation phase is not necessary. The "Synchron Dyeing Control" system therefore allows the fabric speed to be adjusted to the dyeing process by reducing the number of passes through the nozzle systems and the capacity of the circulating pump to be optimised in each case. Not only does this protect the fabric, it also reduces energy consumption by savings on electricity.

SE → Silk (mulberry silk), → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Se The chemical symbol for selenium (34).

Sea jute A brown, brittle fibre composed principally of lignocellulose (→ Lignin) and similar to → Peat fibres and being obtained from dead plant material on the Southern Australian coast, where it is obtained in great quantities.

Used mainly for insulation and packing. Its utilization in textiles is of secondary importance, though it

used to be mixed with wool in the manufacture of cheap carpets.

Seal → Heat sealing.

Sealskin (musquash). An imitation sealskin. Fur-like plush consisting of a backing fabric with pile on one side, 3-5 mm thick, extremely lustrous, made from Tussah or Schappe silk.

Seam detector This is a mechanically or electrically controlled automatic device to monitor and control the passage of cloth at seam points at machine bottlenecks, e.g. in calenders, rotary cloth presses and shearing machines. As the hank of cloth passes through the annular sensor (inside the dyeing machine), a small, Teflon-cased magnet (which has previously been sewn onto the seam point) in a pouch causes an induced voltage in the toroidal coil as it passes over the seam point. This is processed into an output signal using amplifiers and interference blanking and enables the circulating hank of cloth to be stopped exactly at the seam points for sampling or for seam unpicking when emptying the machine. Also used to display the rotational frequency and cycle time to monitor the dyeing cycle.

Seam detector for jet dyeing machines This is used for fabric control (monitoring the dyeing process), to stop the passage of the cloth (for sampling), to count the piece cycle and to determine the cycle time. The seam detector consists of a sampling probe, electronic kit and a display unit. As the sampling probe passes the jet pipe (secondary cradle mounting also possible), through which the goods are being transported in rope form in the liquor, the premarked seam (marked using a ferromagnetic body Ø 50 mm, 0.1 mm thick) causes the impulse which controls the passage of the goods and stops the piece circulation.

Seam protection If a fabric with a seam is passed through the cutting device of a shearing machine, the shearing blade will destroy the fabric along the seam. The cutting device therefore raises up from the shearing table (or preferably vice-versa). As the seam passes through, a seam protection plate automatically slides between the fabric and the cutting device and covers the shearing point until the seam has passed. Only a minimal length remains unsheared on either side of the seam. The function of the seam protection device is adjusted to the rate of the passage of the goods (see Fig.).

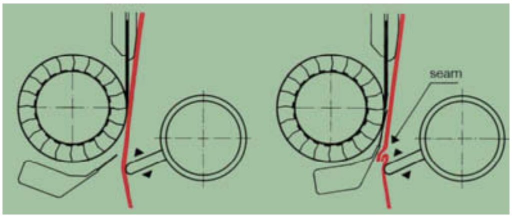

Fig.: Seam protection (Monforts).

Seam welding → Fusible seaming.

Sea silk → Mussel silk.

Sea water salt content Important information for the critical assessment of → Fastness to sea water for (export) swimwear, particularly in view of the increasing trend towards long distance travel to destinations with low and high sea water salt content. The sea water salt content is defined as the total amount of salts/kg sea water. Reference values given in g/l:

The Baltic Sea	8–10
The Caspian Sea	13
The Black Sea	22
The North Sea	28–35
The Adriatic	30–38
The Atlantic	35–37
The Mediterranean Sea	41
The Red Sea	41
The Persian Gulf	39–42
The Dead Sea	250–275

1 kg of ocean water contains on average (in wt.%):

$NaCl$	77.93
$MgCl_2$	5.59
$MgSO_4$	6.12
$CaSO_4$	4.03
KCl	2.11
$MgBr_2$	0.22

Sebacic acid, $HOOC(CH_2)_8COOH$. Starting material for plastics, synthetic fibres (e.g. polyamide 6.10). Used in England and the USA to produce castor oil.

Secondary acetate fibre → Acetate fibres (2 $^1/_2$ acetate).

Secondary backing (carpets) These are used in particular to improve the dimensional stability of tufted carpets (body and border carpets). Polyester spunbonded fibres, e.g., are used for initial base material and secondary backing (see Fig.); the secondary backing is bound to the undercoat which is bonded to the tufts by a polyester spun bonded fabric. Method: pad the laminating compound on the carpet backs from the undercoat chassis and in the same step, feed the laminate material, press together between calender rollers, drying process in the coating machine.

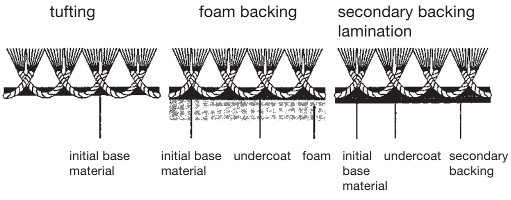

Fig.: Constructional elements in tufted pile carpets.

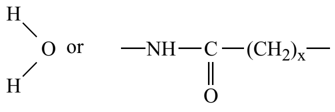
Secondary raw material This is a term applied to waste from spinning, weaving, garment manufacturing, the manufacturing of nonwovens, used textiles, etc. which is reused for fibre extraction, e.g. → Reclaimed wool.

Secondary salts Acid salts of polybasic acids where two hydrogen atoms are replaced by metal; e.g. secondary acid sodium phosphate Na_2HPO_4, derived from phosphoric acid H_3PO_4. →: Primary salts; Tertiary salts.

Secondary valency forces (intermolecular forces, intermolecular attraction forces, cohesive forces). Adhesive forces between molecules acting as → Co-ordinate atomic bond, which is generally liable to dissociation, which is not the case with → Principal valency. According to current opinion, secondary valency forces form a complex group of forces with interactions (micellar forces) for the lateral cohesion of principal valency chains (strength and elasticity properties), in the broadest sense as a group of additional linkage forces, for example in finishing processes. This relates to → Van der Waals forces and → Hydrogen bonds for example. The range of secondary valency forces is approx. 0.5 nm (the range of principal valency forces is approx. 10nm). They are defined and divided into: ε = potential energy; α = polarizability; I = ionizability; r = distance between the molecules; μ = permanent dipole moment.

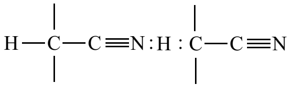
a) Dipole forces: orientation forces between two dipole molecules with permanent dipole moment. These are proportional to the fourth power of the dipole moment and inversely proportional to the absolute temperature.

$$\varepsilon = -\frac{2\,\mu 4}{3\,r^6\,kT} \quad \text{e.g.}$$



$$-NH-\underset{\underset{O}{\|}}{C}-(CH_2)_x-$$

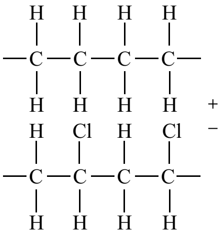
b) Hydrogen bonds: Special case of a) if dipoles come particularly close together so that the H-atoms oscillate to and fro, for example in the polyacrylonitrile molecule:



$$H-\underset{|}{\overset{|}{C}}-C\equiv N:H:\underset{|}{\overset{|}{C}}-C\equiv N$$

c) Induction forces occur as small additional forces if one of the molecules has a permanent dipole and the other is covalent. They increase in proportion to the second power of the dipole moment and are not dependent on temperature.

$$\varepsilon = -\frac{2\alpha\mu^2}{r^6} \quad \text{e.g.}$$

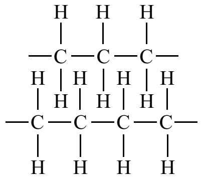


$$-\underset{H}{\overset{H}{C}}-\underset{H}{\overset{H}{C}}-\underset{H}{\overset{H}{C}}-\underset{H}{\overset{H}{C}}- \quad +$$
$$-\underset{H}{\overset{H}{C}}-\underset{H}{\overset{Cl}{C}}-\underset{H}{\overset{H}{C}}-\underset{H}{\overset{Cl}{C}}- \quad -$$

(polyethylene/polyvinyl chloride)

d) Dispersion forces (London forces) create the cohesion between covalent, identical or similar molecules. They are, independent of temperature, linked with the number of electrons and electron dissociation via the ionization constant:

$$\varepsilon = -\frac{3\alpha^2 I}{3r^6} \quad \text{e. g.}$$



(polyethylene)

It can be seen from this that the potential energy of two molecules located at a distance decreases much more quickly related to the distance than to the coulomb force:

$$K = -\frac{e_1 \cdot e_2}{r^2}$$

The secondary valency forces above, which have been intentionally schematized are in practice difficult to distinguish from one another. Therefore dispersion and induction forces arise between polyamide chains in addition to pure dipole forces. The relative proportion of these three forces will therefore vary from case to case. The relative size and importance of these types of orientation and dispersion forces varies; in contrast, induction forces may be disregarded.

Second order transition temperature This is the term used to denote the temperature under defined pressure conditions at which a material changes totally from one phase or state into another.

Sectional warp beams Ready warped beams supplied by the chemical fibre manufacturer, for chain effect and raschel machines as well as for strip looms.

Sectional warping The parallel winding of several warp threads to produce the warp beam. The yarn is stretched on large frames and guided through grid-like devices in such a way that the threads are wound parallel to one another on the warp beam. For particularly high warp settings and fine material, cone sectional warping machines are used. In sectional warping, it is important to achieve an absolutely uniform tension when winding the individual warp threads. → Warping.

Sediment Deposit, precipitate. The sedimentation of solid, suspended particles follows the law of gravity, with the coarsest particles being deposited first, extremely quickly, and the finest particles being deposited the most slowly at the end. The particle size of sediments can be determined in the sedimentometer (turbidity meter) from the turbidity and rate of settling.

Sedimentation This refers to the concentration of dispersed particles (sediment) in a liquid medium due to the effect of gravity or centrifugal force.

Seed fibres → Fruit wall hairs.

Seed hair fibres → Vegetable hair fibres, which can be found on the seed husks of various plants. These include → Cotton and → Akund.

Seepage propagation This is the difference between the level reached and the original position given in cm in → Chromatography.

$$R_f = \frac{\text{dyestuff seepage propagation}}{\text{mobile solvent seepage propagation}} \qquad (0 \le R_f \le 1)$$

Integer values only, especially in → Thin layer chromatography.

$$hR_f = 100 \cdot R_f$$

Seepage wash Cold pad batch bleaching process where the bleach liquor is transferred by pumping (see Fig.). The subsequent rinsing process pumps fresh rinsing water through the perforated beam. The rinsing liquor from the rotating package is drained away in contrast to conventional bleaching, where the liquor is pumped back into the cycle.

Seersucker,

I. Cotton crimp crêpe with vertical stripes, also → Craquelé. Fabric with linear or continuous bark – like effects. Genuine seersucker gets its puckered appearance from warp threads which are stretched tightly or loosely; the loosely stretched threads provide the effect. To achieve a varied tension, two warp threads are necessary. The crease effect is permanent.

II. From synthetic fibres, e.g. patterned interwoven, shrinkable synthetic spun yarns with different shrinkage properties. At increased temperatures, the high-shrinkage material shrinks and creates the embossed design together with the more shrink-resistant adjacent material.

III. Similar nonfast effects can also be obtained by

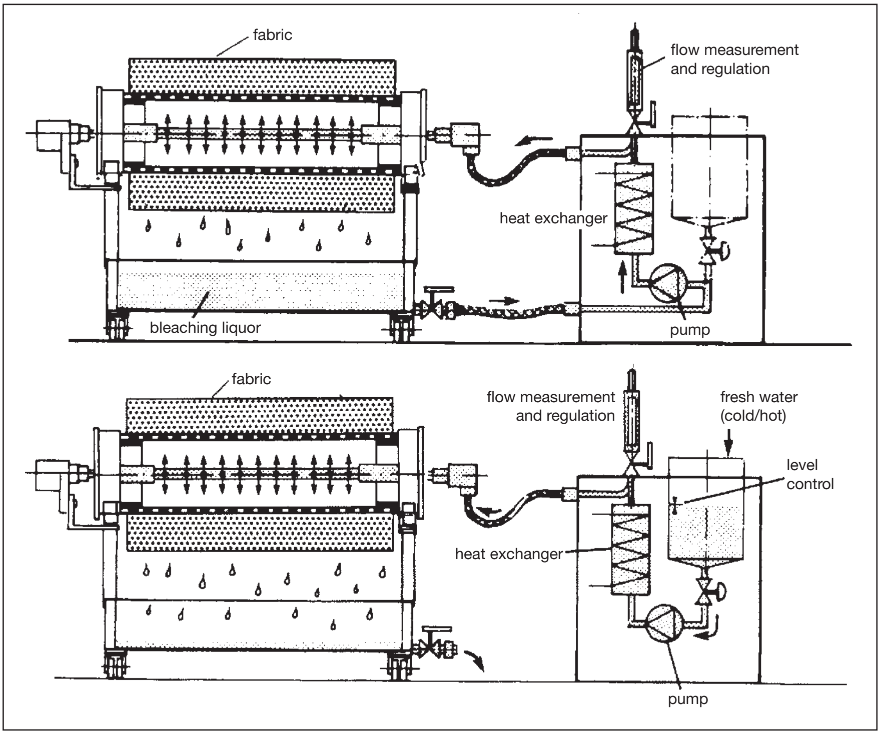


Fig.: Perfo-Roll liquor control (according to Schuierer) in the dwell process (top) and liquor control in rinsing (bottom).

local application of substances which cause the fibres to swell. When producing a garment made from → Crêpe prepared by steeping in caustic soda, a resist print paste which contains a water repellent agent is overprinted in the direction of the warp (as the crêpe effect is only possible in the direction of the warp). The garment is then padded using caustic soda liquor. During this process, a distance of 1–1.5 m should be maintained between the trough and the padding roller so that the caustic soda solution can create a water repellent effect on the areas for resist printing.

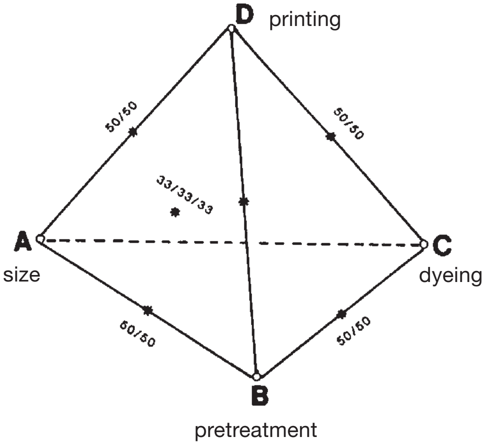
Segregated stream The definition of a segregated stream is controversial. The textile refinement industry has proposed a definition which defines segregated streams as waste from integrated production areas, e.g. from dye-works apparatus or finishing process facilities. The production area should be determined in individual cases and the parameters specific to the particular operation, such as use of systems, production sequence, changes in use of substances, etc., need to be taken into account. However, removal of harmful substances from waste is only economically justifiable from polluted segregated streams.

If the pollution carried by individual segregated streams resulting from textile production is analysed, it will be found that plain pre-treatment waste, for example, carries a high polysaccharide load which constitutes the pre-condition for anaerobic processes. Exactly the same goes for many printing plants. In the reactive printing process, alginates are used almost exclusively as thickening agents, which can be disposed of biologically. The task is therefore to modify the processing techniques within the framework of process-integrated environmental technology with a view to minimizing unnecessary, non-decomposable COD loads and to replacing inhibiting or toxic substances by bio-compatible ones.

The complexity of bio-technical problems demands solution strategies which can represent multi-dimensional variables in such a way that the problem remains adequately transparent. Experience shows that statistical models are very well suited to acquiring the basic knowledge for improved and possibly physical models. For this reason a four-dimensional vertex space was set up which is defined by the four segregated streams (option ranges):

X_1 = plain waste flow,
X_2 = pretreatment waste flow,
X_3 = dye-works waste flow,
X_4 = printing plant waste flow.

The trial vertex represents a tetrahedron (Fig. 1) whose corners correspond to 100% of a segregated stream in each case. The trials at the edges of the tetrahedron are mixtures of segregated streams which flow together at the edges. The boundary surfaces of the tetrahedron contain mixtures of three components of the appropriate waste streams while the interior of the tetrahedron contains a mixture of the four component segregated streams.



e.g.				
point	x_1	x_2	x_3	x_4
A	100	–	–	–
B	–	100	–	–
C	–	–	100	–
D	–	–	–	100

it is true that: $\sum_{i=1}^{i=4} x_i = 100$

Fig. 1: Diagram of the test space (according to Marte and Keller).

One of the significant results of the calculation model is the “screening” parameter which represents a relative measure of the influence of the individual segregated streams on the overall anaerobic decomposition process. The relative impact of the printing plant and the dye-works of 10% and 12% respectively points to considerable non-decomposable and inhibiting pollutants. The pretreatment flow of 27% and the plain flow of 51% have an even greater impact on the overall decomposition process.

Fig. 2 shows the high bio-compatibility of the sizing waste flow (left-hand corner of the phase diagram). The degree of decomposition, measured by the COD-relief of the pure sizing waste, is 75%. The pretreatment flow shows a maximum decomposition rate of approx. 40% (right-hand corner of the phase diagram). This is due on the one hand to a considerable surplus load of surfactants and on the other hand to the surplus peroxide remaining from the bleaching stage. As far as the overall achievable decomposition quota of approx. 17% is concerned, the dye-works flow is problematical. As it will scarcely be possible to increase the bio-compati-

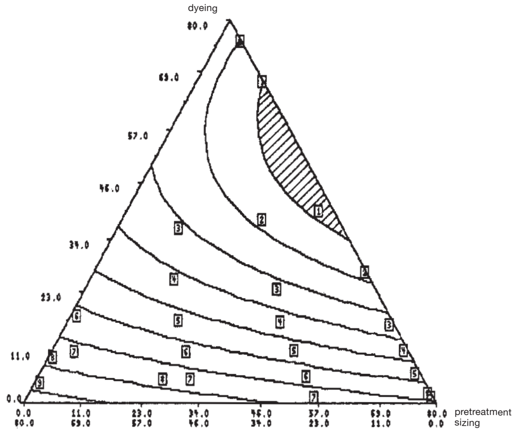


Fig. 2: The anaerobic breakdown of the segregated streams from pretreatment, sizing and dyeing (the COD demand contributed by the stream from printing is 20%) (according to Marte and Keller).
Isoline diagram for the quantity COD-AB. Isolines: 1 = 0.0; 2 = 5.0; 3 = 10.0; 4 = 15.0; 5 = 20.0; 6 = 25.0; 7 = 30.0; 8 = 35.0; 9 = 40.0. Minimum = –3.6278 at 0.0/50.4663; maximum = 42.4915 at 80.0/0.0.

bility of the dye-works flow significantly in the near future, precipitate and flotation techniques should be given preference. If it is assumed, for example, that the sizing and pre-treatment waste flow contains approx. 65% of the COD load of a textile refinement plant and that this load can be pre-purified at a decomposition rate of 80% in an anaerobic stage, this already represents a COD-reduction of approx. 52% of the overall flow of waste to the waste purification plant. It is necessary to revise the pretreatment techniques in order to achieve this goal. The printing-works flow could also be improved significantly if emulsion thickeners were replaced by alginate thickeners and the recipes were reviewed with regard to improved bio-compatibility (according to Marte and Keller).

Segregated stream treatment The continuing increase in the stringency of environmental legislation is having its impact on the textile refinement industry. Appendix 38 of the German Water Management Legislation demands a significant reduction of polluting waste substances. It prescribes limits for COD and BOD values, concentrations of heavy metals and halogenized hydro-carbons. When certain limit values are exceeded, segregated stream disposal is specified. However, the concept of the segregated stream has not as yet been adequately defined. It leaves open the question of whether a segregated stream is the total waste from a facility (e.g. dyeworks apparatus) or whether it means the waste from all existing similar production systems in a plant. All known techniques of waste cleansing can be used for treating the segregated streams if they lead to a reduction of the concentration of the harmful substance which exceeds the permitted limits.

Microbe decomposition of harmful substances can also be executed in segregated streams. Another possibility is to reduce the quantities of textile aids used or to use more easily biologically decomposable substances with low COD values. This was investigated thoroughly using the example of sizing. Cyclodextrines are being considered as a possible substitute for surfactants in washing and dyeing processes. They are easily biodegradable as sugar molecules. As they are similar in effect to micelles, composed of 80–100 surfactant molecules, they can be used in lower concentrations as a surfactant which has a favourable effect on the COD value of the waste.

Due to the high extinction coefficients of many dyestuffs, their presence in the waste can be established by visual means, even if their concentrations are low. Also the degradability of some dyestuffs is low and they are therefore, at worst, absorbed in sludge from the waste when treated in sewage plants.

Physical and chemical techniques are proposed for removing dyestuffs from waste. In some cases it is possible to separate the dyestuffs by means of ultra-filtration. They can also be absorbed by active carbon. If the absorbed dyestuffs are bio-degradable, appropriate biochemical treatment can be carried out. The harmful substance can be destroyed reductively by means of chemical reaction. However, this process is not successful with every dyestuff. This also results in sulphate pollution of the waste with constant COD values. Destruction of dyestuffs by oxidation results in reduction of the COD values as well as in reduction of dye. A disadvantage of this technique is that the oxidation strength of hydrogen peroxide is not adequate to destroy dyestuffs. Destruction of dyestuffs by oxidation is

segregated stream		
residual liquor + 1st rinsing bath + 1st hot bath 3 baths with > 80 % of total hydrolysate		
colour stripping	auxiliary agent/kg of dyestuff used	problem

	ozone, H_2O_2, Fenton's reagent	cost
reductive	1 to 2 kg of sodium dithionite	COD, sulphate
precipitation	0.3 to 0.6 kg of cationic special flocculation	sludge

Tab. 1: Segregated stream treatment for reducing the colour in reactive dye effluent.

only possible using Fenton's reagents (iron(II) salts) (Tab. 1). By attaining an optimum pH value using calcium carbonate, a precipitate of iron hydroxide and calcium carbonate is created in the form of sludge. This absorbs organic compounds and dyestuff molecules and therefore has to be disposed of separately, possibly as hazardous waste. Another possibility of destroying dyestuffs consists of using oxygen for oxidation. This reaction can be catalysed by the presence of poly oxadiazol; otherwise catalysis takes place through ultra-violet light. This process also destroys other organic compounds in the waste so that a significant reduction of the COD values can be expected. Ozone can be used as a suitable oxidation agent.

Waste can also be cleansed by using organic precipitate and flocculation agents. Dyestuffs can be removed from the waste in this manner. However, it must be seen as a disadvantage that this results in voluminous foam which contains up to 70% water and has to be disposed of as hazardous waste. Under these circumstances the percentage of dyestuff in the precipitate is low. Also some of the precipitate and flocculation agents are toxic to fish. As a certain quantity of precipitate and flocculation agents remain in the waste, the COD values of the waste are also increased. An overdose of the organic precipitate and flocculation agents in some cases results in the dyestuff dissolving again which means it cannot be removed.

The heavy metals which occur in the waste of the textile refinement industry are restricted to cobalt, nickel, copper, chrome and zinc. These heavy metals are contained in metal complex dyestuffs and reduction agents or they get into the waste during the after chroming of wool. The removal of heavy metals from waste is mainly carried out by precipitating as hydroxides. The remaining residue concentration in the waste depends on the pH value of the solution. The solubility of the hydroxides increases again in strong alkaline solution due to the formation of hydroxo complexes. At low heavy metal concentrations flocculation materials have to be added to the waste in order to separate the hydroxide precipitate. When complex organic forms are present a hydroxide precipitate is not possible. As most metals form sulphides which are difficult to dissolve, they can always be separated in this manner. Hydrogen sulphide and sodium sulphide are highly toxic, however, and surpluses have to be removed from the water after precipitation. Trimercaptotriazine also forms compounds which are difficult to dissolve. Among other things it is used in the metal processing industry. To improve sedimentation flocculation materials frequently have to be used. The resulting sludge is classified as hazardous waste, as its reuse is prohibited due to its heavy metal content. Only in the case of silver precipitates is reprocessing carried out to reclaim the pure metals.

Electrochemical methods of separating heavy metals with ion exchangers are possible. If the ion exchanger has chelate forming groups, it binds multi-value ions with high affinity and is particularly suited to binding heavy metals. For example, it is possible to separate copper from waste during copper fibre production by using ion exchangers in the presence of sodium and ammonium ions. It is possible to extract organic metals into an organic phase by means of polymer-bound and water-soluble complexes. Re-extraction results in an enriched solution of heavy metals. This technique is also suitable for waste cleansing. The selectivity of complexes is intensified considerably in comparison with the chelate forms by the use of macrocyclic (crown ether) and macrobicyclic ligands (cryptands). This is particularly significant with regard to recycling of the separated heavy metals. If the ligand used is not water-soluble, it can be used as an extraction agent. Polymer fixing of these ligands is, however, also possible. Due to the high complex image constants, it is possible to remove even the slightest trace of heavy metals. Heavy metals from dye-works waste can also be removed selectively by means of polymer-fixed crown ethers.

The occurrence of organic compounds containing halogen in waste produced by the textile refinement industry can mainly be attributed to the following causes:

- use of carriers containing chlorine during dyeing,
- use of dyestuffs containing chlorine,
- chlorinated pretreatment of wool
- chlorine bleaches.

Carriers containing chlorine are, however, only used in rare cases. Some dyestuff molecules contain halogen atoms. As the dyestuffs only enter the waste in relatively low concentrations, they scarcely increase the concentration of compounds containing halogen in the waste. If the dyestuff molecules are destroyed by chemical reaction, fragments of chlorine remain in the waste. Chlorinated pre-treatment of wool is important for felt free equipment and for printing pre-treatment. Bleaching processes based on hypochlorite result in more hydro-carbons containing halogen than with chloride bleach. In addition, the degree of pre-treatment when bleaching cotton has an important impact on the quantity of hydro-carbons containing halogen which are formed. In addition to other organic compounds containing halogen, hypochlorite bleaching produces mainly chloroform. As the current state-of-the-art does not allow all textile refinement processes to be carried out in such a way that no volatile hydro-carbons containing halogen result, their removal from the waste adopts a particular significance. A possible means of separation is to absorb them using active carbon. However, all other non polar compounds in the waste are absorbed simultaneously by the active carbon. This technique is very unspecific.

hydrolysate quantities as a % of total hydrolysate				
	on the fabric	In the bath	In the effluent	In the carry-over

Tab. 2: Breakdown of unfixated dye (hydrolysate) in washing.

Several chemical and physical techniques are available for dye removal from waste segregated streams from a dye-works. It is possible to separate wastes from reactive dye works in such a way that approx. 80% of the non-fixed dyestuff (hydrolyse) are contained in only three treatment baths, i.e. in less than a third of the dye-works waste (Tab. 2). The residual liquor, the 1st rinsing bath and the first bath have to be collected and the dye removed at almost boiling point. Concentrations of 100–200 mg/l are to be expected in the separated segregated stream. Depending on the liquor to goods ratio, in which the dyeing and rinsing processes are carried out, the water quantity is 20–40 l/kg of fabric.

The rejected, strongly-dyed waste is transferred to a suitable system of mixing and treatment tanks where the dye is removed and then returned to the remaining waste (see Fig.). The dimensions of the tanks depend in the first instance on the volumes of segregated streams expected. There are various possibilities for the design depending on the structure of the plant and the dye removal agents used. For small dye-works in which strongly varying segregated stream volumes are expected, it is advisable to use a large mixing tank for at least four hours at maximum input and a treatment tank, the minimum volume of which corresponds to the maximum segregated stream during the necessary treatment time in addition to the filling and emptying times. Large tanks with mixing facilities (circulation pumps but no ventilation) are useful as far as dosage and impact of dye removal agents are concerned as well as short filling and emptying times. For largely automated plants in which a large number of baths take place regularly during the main operational period (e.g. 5 or more baths per hour), dosage is particularly simple if the baths are collected and mixed in the treatment tank. Treatment begins when the tank is full. There is no intake to the tank for the duration of the treatment. The baths occurring during this period are transferred into an appropriately proportioned storage tank. After completion of the treatment the treated waste flows out and the treatment tank is again filled with new baths from the preliminary tank. A large mixing tank then becomes unnecessary (according to Beckmann, Sewekow, Schollmeyer).

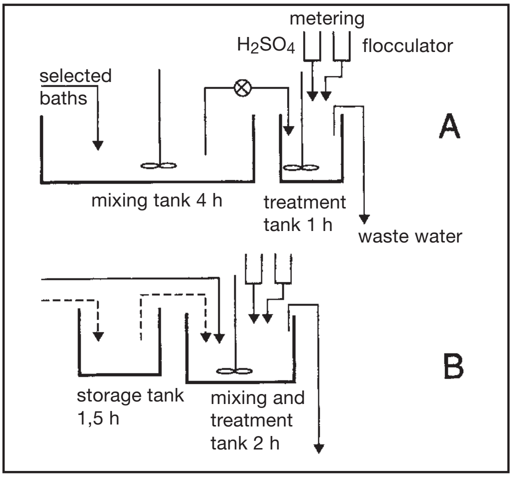

Fig.: Possibilities of the automatic segregated stream colour stripping of effluent from a reactive dyehouse, tank size after effluent accumulation during the times indicated.
A = for small dyehouses with widely changing segregated streams, B = for uniformly accumulating types of segregated streams.

Selection criteria for dyes and dyeing method These criteria provide guidance based on the requirement profile which defines the dyestuff and the fastness requirements needed to select (see Fig.) the possible dyestuff group or groups. It is then possible, paying particular attention to economic factors, to define the application method to be used (in particular also from an ecological viewpoint).

Tab. 2: Processing costs (machine occupation, water, energy, chemicals) without dye costs (Sandoz).

Tab. 1 is used as the basis for a decision in the initial stage of selection. Based on the specific requirements of the article in question, i.e. the shade, depth of shade, wear fastness properties and fastness requirements in manufacturing, it is possible to determine which dyestuff category should be used to fulfil the given requirements. In practice, this Tab. will differ especially with respect to the definition of the colour spaces and the relationship of fastness to concentration, but in future also in terms of environmental compatibility. If several possibilities are given, the costs of the procedures and the reliability of the method will be used as the decisive selection criteria. The costs of the dyeing processes are shown in Tab. 2. The machine utilisation times, bath contents and chemical costs listed are based on typical operating conditions and can be compared with each other (this includes the time required for loading and unloading and filling and emptying the baths). If these conditions are altered, the absolute figures may vary, although the ratios remain unchanged. The cost factors listed in the last column of Tab. 2 indicate the extent of the cost differences between the individual processes and the importance of selecting the optimal application process in each instance.

– machine occupation time:	dyeing process 7.30 hours loading and unloading 0.30 hours 8 h x 96.00	768.00
– water cost:	7 bath fillings 7 x 5 m^3 = 35 m^3 à 2.50	87.50
– steam cost:	$\frac{5000 \times 4.19 \times 270}{2400 \times 1000} \times 51$	120.20
– cooling water:	$\frac{5000 \times 110}{30\,000} \times 0.5$	9.20
– electricity:	0.12 x 30 x 7.5	27.00
		1011.90
– cost for 1 kg of fabric		2.02
– chemical cost: sodium sulphate calc. (60 g/l)		92.00
– sodium carbonate (2.5 g/l)		5.00
– others (3 %)		75.00
– (dispersing agents, lubricants, pH setting)		60.00
		232.00
– cost for 1 kg of fabric		0.46

Tab. 3: Procedural costs (1 batch of 500 g fabric).

When stipulating the various stages, the modular principle should be followed as far as possible, so that the same modular elements are always used for procedural sections which occur equally in several stages. This should ensure comparability. The overall procedural costs are composed of the machine costs together with the variable, process-specific expenditure on water, steam and electrical energy (Tab. 3). The assumed machine costs per hour are 96.00 monetary units.

Using this selection mechanism factor 0.4 would be chosen, for example, as the most cost effective dyeing method (according to Jakob and Tiefenbacher).

Selectivity Limited to preferred selection. Selective membranes are, for example, permeable for specific substances, and impermeable for others (→ Semipermeable). When dyeing polyamide fibres, selective absorption occurs if monosulphonic acids are absorbed by preference due to the displacement of disulphonic acids (→ Blocking effect in the dyeing of polyamide).

Selective separation of fibres from fibre blends by working methods which use solvents or release agents for individual components. Selective bleaching of black hairs in wool: premordanting with ferrous salts which are chemically bound to melamine pigment, rinsing; peroxide bleach catalyses in the black hairs without any effect worth mentioning on the colourless wool.

Selenium (Se). Atomic weight 79.2. Present in sulphur ores. Grey metallic selenium is a poor conductor of electricity, but its conductibility is increased when illuminated by approx. one thousand times, decreasing to its original value again in the dark. Used as selenium cells, bridges, barriers, photoelectric cells, etc.

Self-bonding fibres → Bicomponent fibres consisting of polymers with different melting points. If they are heated to the temperature corresponding to the fibre with the lowest melting point, this acts as an adhesive for the other components.

Self-cleaning Rotating filter basket with a rinsing self-cleaning effect to discharge any lint present.

Self-cross-linker In contrast to reactive resins, which tend to react more with cellulose and crosslink these, self-cross-linkers tend to react more with themselves and form resin deposits in the pores of the fibre which promote crease resistance. → Self crosslinking resins.

Self crosslinking →: Crosslinking; Self crosslinking resins.

Self crosslinking resins Resin finishing agents which predominantly react with themselves under specific crosslinking conditions (self crosslinkers, self

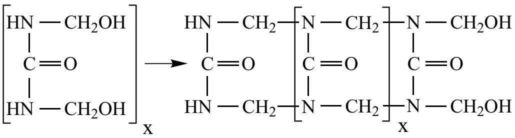

Fig.: Resin former self crosslinking mechanism in resin finishing.

crosslinking agents; see Fig.), which therefore also only enter into low crosslinking reactions with cellulose (in contrast to → Reactive resin) such as → Urea and → Melamine-formaldehyde compound. → Cross-linkers.

Self-extinguishing Term used in the → Flammability test: after the ignition flame has been removed, the test fabric continues to burn for a short time, although the charred area does not increase significantly. The flame extinguishes itself, although there is still non-burned test fabric which could fuel the flame.

Selfil yarn This is a single yarn consisting of fibre slubbing (e.g. wool) and two fine synthetic filament threads which loop in alternating directions offset phase around the yarn compound which has been subsequently formed, and thus has the effect of strengthening the yarn.

Properties: overall, fewer areas of yarn defects than with conventional spun yarns, tighter, more elastic, finer yarn, has relatively higher strength than coarser yarn, higher shrinking properties (generally 5–8%). Use: predominantly for fine knitwear. Selfil yarn no longer needs to be after twisted, steamed or respooled before dyeing. For light and mid-shades spin top-dyed wool with unbleached polyamide fibres. Yarn-dyed selfil yarn has a low tendency to relaxation due to the dyeing process. Garments made from selfil yarn can be dyed perfectly on the beam.

Self-polymerization → Self crosslinking resins.

Self shade (solid dyeing, plain dyeing). Monochromatism; occurs in fibre blends as → Tone-in-tone dyeing.

Self-smoothing fabrics Fabrics with an → Anticrease finish.

Selvedge,

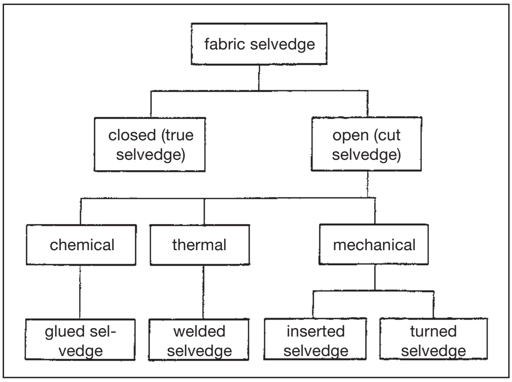

Fig. 1: A systematic classification of the possible methods of forming selvedges using the bonding principle.

I. With the introduction of shuttleless → Weft insertion systems it was necessary to adapt spec. mechanisms to fasten the → Selvedge on the looms in order to ensure the ground warp thread was firmly fixed. Numerous devices are available for this which differ in terms of the fastening principle and construction.

Fig. 1 shows a systematic classification of the possible methods of forming selvedges.

a) Fabrics produced on looms with shuttles have a closed selvedge which is formed by the continuous to and fro motion of the weft yarn.

b) Due to their nature, welded selvedges are limited in terms of the warp and weft material used. For fastening using a resistance wire, the warp and weft material must be made of thermoplastic materials, and when the selvedge is to be fastened using ultrasound, the fabric must have a thermoplastic content of at least 50%.

c) Laid-in selvedges are characterised by high stability. However, due to their complex mechanical structure, laying-in devices are expensive and limited in

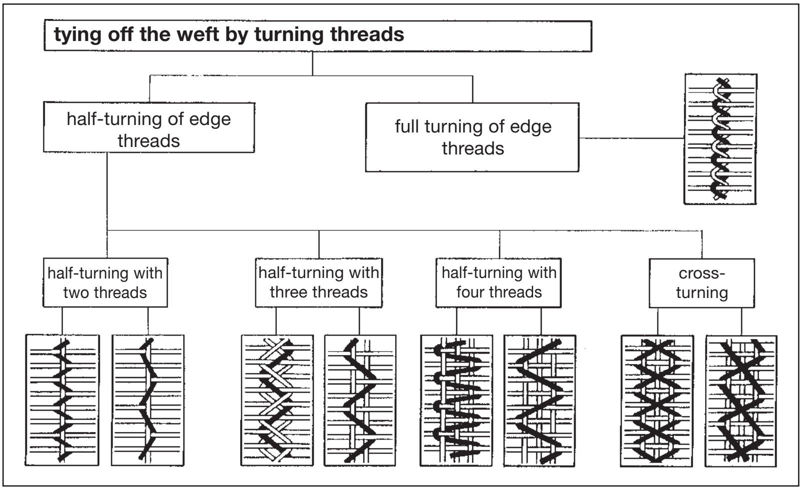

Fig. 2: Creating selvedge by means of turning threads (according to Wulfhorst et al.).

terms of the number of twists that can be made. For closely-woven fabrics, the principle reaches its technological limits as the procedure involves doubling the weft density in the area of the selvedge. For this reason, laid-in selvedges are predominantly used where this is necessary for stability reasons or where the selvedges are being made up during the garment-making process.

d) The turned selvedge is the most commonly found selvedge structure due to its high flexibility and to the comparatively cheap price of the turned selvedge device. These devices can be adapted to almost any loom and can be used for almost any type of fabric due to the variety of weaves. Fig. 2 shows a systematic classification of the different leno weaves. The weaves differ in terms of the number of crossing threads and stationary threads used and the type of tie thread. The most common are devices for two and four-thread half-cross turned weaves and those for full cross turned weaves. (Maetschke, Obolenski, von Thenen, Wulfhorst).

II. (edge, selvage). A distinction is made between the edge selvedge (list, selvage) and the centre selvedge (inside selvedge, split selvedge). The first is formed on the loom by reversing the shuttle or on shuttleless looms, by twisting or laying-in devices. The centre selvedge is formed similarly in the centre of the fabric (if several fabrics are being produced next to one another at the same time, which are later to be cut). The selvedge area is generally reinforced by regulating the relevant warp threads more closely, through tighter warp threads and/or another weave.

Selvedge cutting device This is a device which is used to cut the selvedges and remove the edge waste.

Selvedge feeler Non-contact scanning device which operates mechanically or photoelectrically to guide the cloth, particularly on stenters.

Selvedge gassing machine This is used to remove loose threads on the selvedge by gas singeing.

Selvedge guider → Expander.

Selvedge monitor This is a safety device which switches the machine off if one or both of the selvedges is no longer held by clips or the needle bar.

Selvedge printing machines (selvedge printers). These are generally combined with inspection machines on measuring machines, or less commonly with fabric batching machines. Company logos or advertising slogans are printed on the selvedges using heat transfer printing units.

Selvedge trailers Floating threads on fabric selvedges (→ Selvedge trimming machine).

Selvedge trimming machine This is used to remove from the selvedges loose, overhanging non-bound selvedge trailers which occur in weaving. The thread ends are cut off using a special shearing tool and extracted.

Selvedge uncurler (scrollers). This is a device to uncurl, unfold and stretch fabric and knitwear selvedges which have been rolled or turned up. Generally fluted metal or plastic fingers arranged in pairs, rotating rapidly in opposite directions, between which the fabric is guided. Selvedge uncurlers on stenters are generally combined with cloth guidance devices. Rolled selvedges in knitwear and folded edges in woven textiles are normally opened by selvedge uncurlers with motor driven spindles. Where these are not sufficiently effective, it is necessary to "intervene" from time to time and smooth out the selvedges manually as the fabric advances. This gives rise to the risk of injuries to fingers or hands by the operating spindles. On the other hand, there is no risk of injury or becoming caught in the device when a mechanical → Selvedge unroller is used. These smooth out the selvedges using fixed metal strips arranged helically at an angle to the direction of the cloth. Pneumatic selvedge unrollers, which use air nozzles to smooth out the selvedges, have no danger points either. These are suitable due to their high smoothing effect and low material strain, especially for sensitive fabrics.

Selvedge unroller These are used to open, unroll and stretch surface sensitive wovens and knitwear with folded edges or rolled selvedges. The operation involves no contact whatsoever (regardless of whether the fabric is dry, moist or wet). The nozzles are arranged in such a way in relation to the surface of the cloth guide that the stream of air emitted optimally smoothes out the rolled selvedges. This creates an insulating air cushion which guides the batch of cloth forward which has been unrolled without contact.

SEM → Scanning Electron microscope.

Semi-automatic Certain machine work stages are initiated manually but run automatically. Only part of the processes are automatic.

Semi-circle tester → Flammability test.

Semi-continuous bleach Open-width boiling and bleaching process for larger batches of cotton and cotton/synthetic blends which are uneconomical for continuous plants. Device: impregnating device, Benteler batching device and open-width scouring machine.

Semi-continuous bleaching → Semi-continuous bleach.

Semi-continuous operation If sections of a production line (e.g. washing ranges) need to operate discontinuously due to the nature of the process being carried out (e.g. rope washing machines for woollens to achieve sufficiently long washing time) it is sensible to use machines which allow at least semi-continuous operation.

An example of a semi-continuous operation is the high-capacity washer for rope washing fabrics with wool content (Fig. 1); it is equipped with a spec. rope handling device which helps to improve the performance of the washing system. Instead of feeding the hanks individually, positioned next to each other, and

Semi-continuous operation

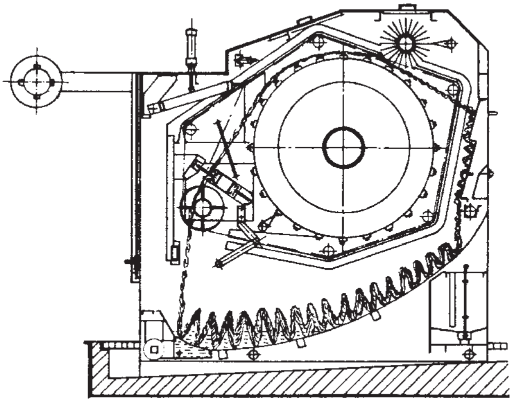

Fig. 1: A rope washing machine (the Menschner Lavarapid) with rope guide systems for semi-continuous operation.

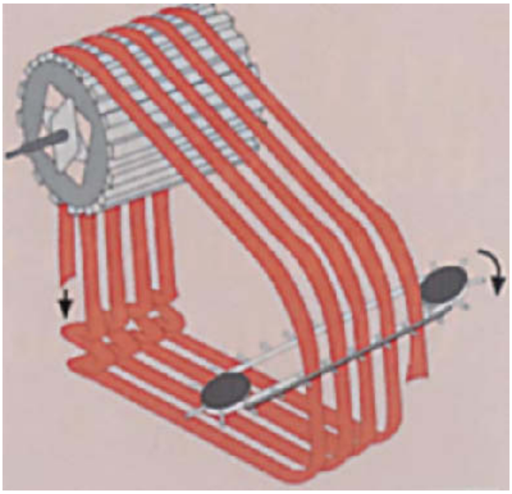

Fig. 2: Three-dimensional diagram showing the rope guiding system inside the Menschner "Lavarapid" washing machine.

sewing the hanks separately, this device feeds the fabric into the machine as one single rope which has been previously sewn together. The rope handling device moves the hank which has been sewn together along a helical line across the washing cylinder and finally through the entire machine (Fig. 2). Using this device, the hank is transported along in such a way that it is necessary to carry out any winding required in confined spaces. It is sensible to integrate this machine into a process such as that shown in Fig. 3.

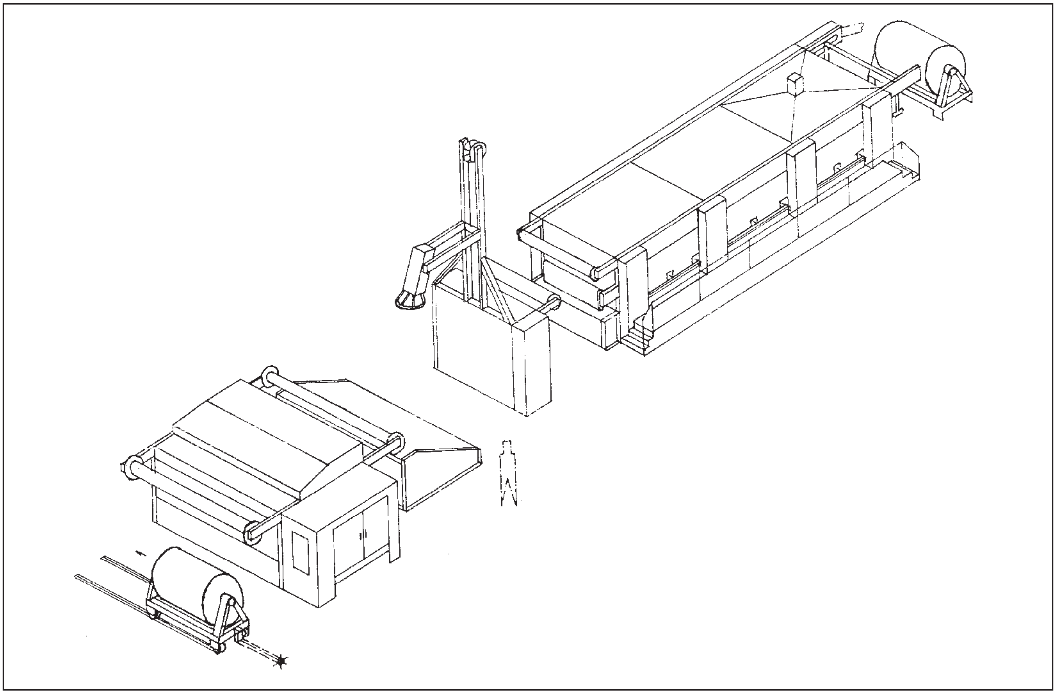

Fig. 3: Semi-continuous operation in wool fabric washing with rope (left) and open width (right) washing machines together with a rope opener (centre) from Hemmer-Menschner.

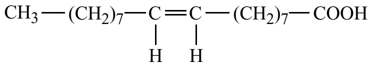
Semi-decatizing (semi-decating). A milder finishing process than full decatizing applied to wool and worsted piece goods to improve the lustre, handle and finish. The process involves crabbing followed by steaming of the goods wound on a perforated cylinder.

Semi-drying oils These include → Cottonseed oil, rapeseed oil, colza oil and soybean oil. They consist in particular of oleic acids and (to a lesser extent) linoleic acids. Due to the presence of unsaturated fatty acids with double bonds which are capable of oxidation and which are of the oleic acid type.



$$CH_3-(CH_2)_7-\underset{\underset{H}{|}}{C}=\underset{\underset{H}{|}}{C}-(CH_2)_7-COOH$$

Their drying power is significantly higher than that of → Nondrying oils.

Semi-felting raising machine → Wire raising machine which guides the napping cylinder in the opposite direction to that of the direction of the cloth by moment reversal.

Semipermeable This refers to the characteristic of a membrane which is permeable to specific molecules or ions, and to be impermeable to others. →: Osmotic pressure; Diffusion.

Semi-pigmentation dyeing process → Vat dyeing.

Semi-pigmentation process for vat dyes Principle: the dyebath is prepared cold with finely dispersed dyestuff, alkali and sodium dithionite and then heated slowly to vatting temperature, if necessary later to temperatures above 100°C (HT process) after reducing agents have been added.

Semipolar bond A co-ordinate bond which plays a particular part in → Chelation.

Semi-solid fats Bone fat, palm oil, also hardened fats (e.g. caster oil and coconut oil) and train oils. Obtained synthetically by reducing (hardening) unsaturated fluid oleic acids (by the catalytic hydrogenation of fats) in saturated solid stearic acid. Used as a basis for soaps, give more viscous working solution (preferred in milling for example), particularly effective at temperatures of 60°C. Glycerides from oxy fatty acid (caster oil) have similar properties.

Semi-solvent Mixtures of solvents whose individual components do not dissolve certain substances, but which together have the effect of a solvent; e.g. benzene and alcohol on acetate-cellulose. Particularly important in textile printing and stain removal.

Semi-worsted yarn,

I. This refers to soft, full-bodied yarn, loosely or tightly twisted, produced in the semi-worsted spinning process for weaving, knitting, warp-knitting. Intermediate stage between → Worsted yarn and → Carded yarn. Is fuller bodied, but less strong than worsted yarn, as the short fibres are not separated using combs. Semi-worsted yarn is stronger, but less full-bodied than carded yarn, on the other hand; clear finish.

II. Fabric with a) a worsted warp and a carded weft or b) twisted carded and worsted yarn, in the warp and the weft or c) alternate worsted and carded yarns in the warp and the weft.

Senegal gum African → Vegetable gums with predominant acacia content. Properties similar to those of kordofan gum, described under → Gum arabic, but with less adhesive strength. Main varieties: poorest qualities: pador gum, (dark amber to brown, often contaminated with sand and vegetable matter). Galam gums are purer and more water-soluble. The best qualities are found in salabreda gums which can be ground (most similar to kordofan, the purest form, colourless or slightly coloured).

Senneh carpets (Senna carpets). The finest and most well-known → Knotted carpets from Iran. Extraordinarily finely linked patterning in finely graduated, modest colours. 250 000–600 000 Turkish knots/m^2.

Sensor (Lat.: sensus = feeling, perception), measuring device (sampling probe, electronic sensor, signal measuring device, detectors) for physical values which are to be passed on for evaluation. Important in process control engineering, e.g. simple on/off contacts, water meter flow impulses, residual moisture measurement, etc. Used in computer-controlled finishing processes.

Sensor engineering International specialist designation for the field of generating process signals. → Sensor is another word for the terms measuring probe, measuring head, detector, transmitter, probe. Sensor engineering is the method of obtaining readings and both preparing signals and converting them into standard interface properties. Monitoring analysis with redundant measurements has taken the place of representative individual experiments, enabling an analysis of trends to be carried out and meaningful prognoses to be made. A chemical measuring technique in the reaction vessel (the “in process control”, “in-line” analysis and chemical process and quality control) is therefore possible, increasingly negating the need for quality control of the end product which is based on a deeper technical and scientific level, and which is therefore more complicated.

Until now, electricity has been the only technology of any importance in measuring and control technology when transmitting a signal. Optical fibres and other energy carriers, as well as fluid material systems are becoming increasingly important in analysis. They help to shift the analytical test methods out of the specialist laboratory and into the factory, where the practical applications are actually taking place. Analysis is therefore becoming more common.

A conventional thermometer has a sensor section, the bulb, which is filled with alcohol (Fig. 1). It connects with the capillary vessel which amplifies the sig-

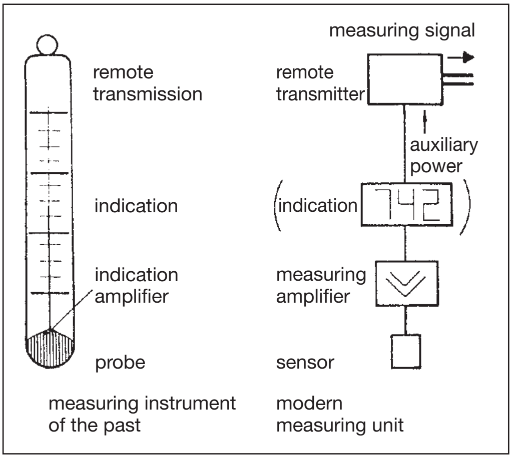


Fig. 1: Comparison: temperature measurement today and in the past.
The modern measuring unit has the same function as measuring instruments in the past but with remote output for the measuring signal in addition (according to Rüttiger).

nal for the temperature reading through the reduction in diameter and its lens effect. The liquid column in front of the scale indicates the reading. The modern measuring device has the same functional elements, only the form, which has been adapted to the new purpose, has changed. A significant difference is that the reading is no longer stored in the memory of the observer, but is converted into signals by means of amplifiers which are suitable for remote transmission. The sensor, or the sensing element, is the main focus. A physical value (temperature, in this case) or a physico-chemical quantity (such as the pH value) is converted into an electrical value either directly or indirectly. In most cases, the signal is a weak current or a voltage which is so low that amplification is required. A measuring amplifier is required for this. It must be matched to the sensor both in terms of amplification and input resistance, amongst other parameters. Often auxiliary power needs to be fed to the measuring amplifier of the sensor. It is important that the sensor and measuring amplifier are completely compatible, and they should therefore be procured as a set from the same manufacturer. The readings are transferred by various types of remote signals.

The transmission lines vary from simple bell wires to twisted wires (pairs of wires) through to coaxial cables if larger distances or higher transmission rates are required. Optical waveguides (glass fibre cables) and wireless transmissions (infrared transmitters and receivers, similar to television remote control) are modern forms of transmission elements. The "content" of the data supplied by the measuring signal is more important for the receiver. It may be a "raw" measuring signal, without range alignment or zero point adjustment, or it may be a "processed" signal where even the non-linear characteristic curve of the sensor is evened out and the standard temperature drift for sensors is compensated using an additional temperature sensor. Between these two extremes, all variations are possible, even sensors in which the range alignment takes place automatically (autoranging) or is switched remotely by a central exchange. On-off switches and phased signals are classed as digital signals in terms of the way in which the remote signal represents the reading.

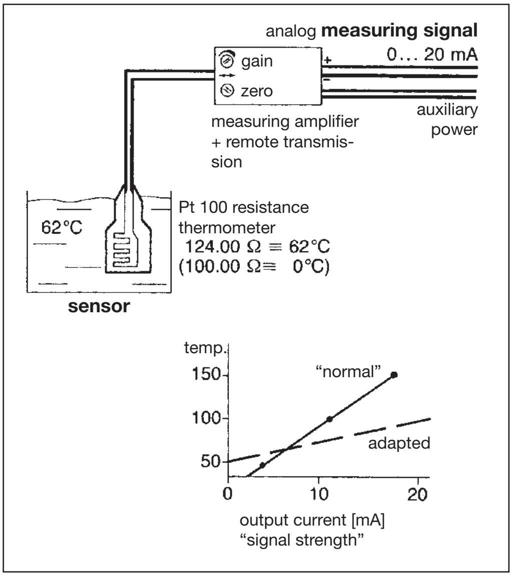

Fig. 2: Analogue measuring signals (according to Rüttiger).

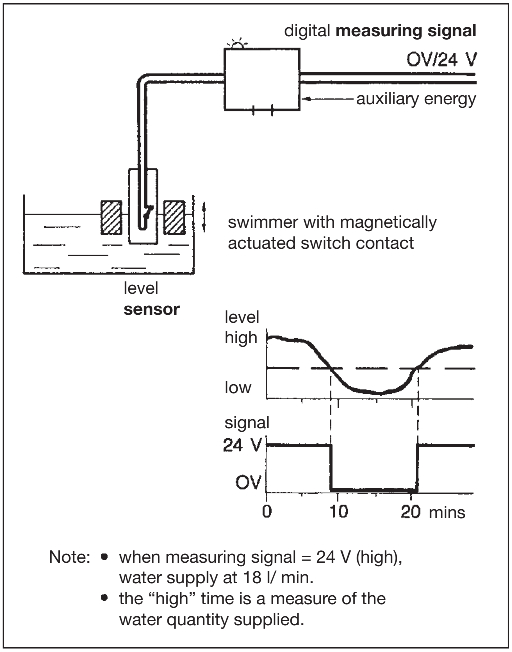
The analogue signal is still the most similar to previous "readings" (Fig. 2). The electrical resistance in a resistance thermometer (Pt 100) varies with the temperature. It is connected to an ohmmeter or a "resistance meter", which operates in conjunction with a tele-transmitter by superimposed current. The advantage of the so-called "superimposed current" is that it is forcibly maintained by the amplifier. Even if the contacts corrode slightly and long cables have high resistance, the signal current does not change. Fig. 2 shows the calibration curve in addition to the connection diagram. This calibration curve can be recorded even with a simple multimeter or service digital voltmeter. The sensor is moderated, the auxiliary power is connected to the amplifier and the current is measured using the remote signal output. The unbroken line, "normal", shows that the amplifier is obviously adjusted for HT devices. The calibration curve can be modified by means of regulating screws; in this example, the zero point (temperature value at 0 mA) and the gradient of the curve. The broken line indicates modification to an open device in which the liquor temperature does not exceed 100°C. What is significant in this example is that the signal current generated from the tele-transmitter increases, the higher the temperature. Current and temperature have an analogous relationship, hence the name "analogue signals". Adaptability is also significant. A sensor can be adapted favourably (broken line) or unfavourably (unbroken line) using analogue signals. Favourable adaptation is very time-intensive and is therefore rarely used.



Note:
- when measuring signal = 24 V (high), water supply at 18 l/ min.
- the "high" time is a measure of the water quantity supplied.

Fig. 3: Digital measuring signals (according to Rüttiger).

Digital measuring signals (Fig. 3) are remote signals which only have two states or two levels, e.g. for current/no current or high voltage/low voltage. Fig. 3 shows this type of measurement system. A simple level sensor is upgraded as a "measuring device". For processing in a computer, all signals which register a process state are in the first instance measuring signals. Using the levelling probe, it is possible to measure a level at a point. This is again shown in the calibration curve section. Physical connection of the sensor effect: the auxiliary energy (24 V d.c.) is in direct contact with the level sensor. If the float rises with the liquor, it closes the contact at a level of 80 cm. The + 24 V voltage is looped to the remote output. The remote signal leaps from 0 V to + 24 V. If the level drops, the float also falls and the contact is opened. 0 V appears in the transmission line again. An indicator lamp is often utilised which displays the switch status of the float. This is useful for maintenance and fault finding.

Typical sensors in textile finishing are as follows:

a) Thickness gauge for fabrics and knitwear. Sensor: distance sensor, micrometer. Measurable variable: thickness of textile in mm.
b) Residual moisture gauge for fibres. Sensor: conductivity (insulation) gauge with contact rollers. Measurable variable: relative moisture in %.
c) Surface temperature of textile fabrics. Sensor: series of thermometers with rotating apertures to measure the heat radiation of fabrics. Measurable variable: textile fabric residual moisture (indirectly using the wet bulb temperature).
d) High humidity measurement during application of product. Sensor: microwave transmitter (10 GHz) with horn antenna attached for multiple transmission with receivers for the microwave radiation transmitted by the fabric. Measurable variable: fabric moisture.
e) Residual moisture in textile fabrics. Sensor 1: intensity of an infrared water band reflected in front of the fabric. Sensor 2: intensity of generally reflected infra-red light. Measurable variable: for thick fabrics, the relative moisture, for thin, open fabrics, the absolute moisture.
f) Residual moisture in textile fabrics. Sensor: condenser; variation in capacity across water in the field. Measurable variable: absolute moisture per m^2 converted into %.
g) Oxygen content of a gaseous phase. Sensor: oxygen molecules are attracted into a homogenous magnetic field in the direction of higher field strength due to their paramagnetism. If two gases with different oxygen content (one of which has a high moisture content, for example, which "dilutes" the oxygen content) meet in a magnetic field, a difference in pressure forms between them. Measurable variable: moisture content of steam (in comparison to air).
h) Hydrometer. Sensor: buoyancy of a body in solutions (measuring range 0–1.6 g/ml). Measurable variable: liquor concentration.

Constant development has taken place in the field of chemical sensors. Mass spectrometry, associated with gas chromatography, dominated the field of advanced analytical instrumental methods for approx. 20 years. This was followed by liquid chromatography, associated with mass spectrometry, together with various other instrumental methods which have been simplified into detectors, such as Fourier transform infrared and mass-specific detectors which are suitable for gas chromatography. These are all now in use and have enhanced the range of resources available to analysts. Molecular beam technology is impressive due to its high separating capacity and sensitivity. Conventional element analysis and microanalysis have been replaced by higher performance instrumental techniques. These coupling systems cover everything from individual analytical devices to complete analysis systems to sensor technology.

Monitors designed on the basis of gas chromatography, which can be regarded as automated, modular instruments and as complete analysis systems, carry out all the stages of an analytical experiment coherently. They enable automatic chemical monitoring of parameters relating to hygiene at work and safety issues as well as ongoing monitoring of emissions relating to the environment. They can be used to control and monitor processes. If the analytical principles in fluid systems realised in these monitors are transferred from the gaseous phase into a mobile phase, the technology of Flow Injection Analysis (FIA) results. This not only enables an extraordinarily high analytical flexibility to be combined with a high sample sequence, but also enables solutions which are simple to achieve.

Although ion-selective electrodes are sensitive, they are only definitely able to measure certain ion concentrations continuously if their technical use is defined at the same time as potentiometric sensors are being developed. Biosensors are still in the process of being developed, while electrochemical “Field Effect Transistors” (FET) based on semi-conductor technology, probes or photoacoustic sensors, piezo oscillators, phonon sensors and thermistors represent another important area of development and application for sensors in textile finishing (according to Widmer and Rüttiger).

The number of ion-selective electrodes has increased considerably over recent years as it is now possible to produce selective complexing agents for some cations. In the meantime, commercial electrodes have become available which correspond selectively to surfactants. The electrical signal arising with a potentiometric measurement system can be used for control purposes. In recent years, a number of sensors have been developed which supply an optical signal. These are referred to as optic sensors or optrodes. Their operation is based on the fact that a dyestuff or other molecule is immobilised on a carrier material. This molecule forms a complex with the compound to be identified which has a different absorption spectrum to that of the initial compounds. The spectral range at a given wavelength can be measured using a spectrophotometer when optical waveguides are used.

Sensor technology Recording parameters which are spatially difficult to access without contact, and processing the values obtained in computers. → Sensor engineering.

Separating course A gap created in the knitting of tubular fabric caused by omitting one or more needles in the relevant knitting system. This can also be used as a guide for opening tubular knitwear (→ Tubular fabric slitting machines).

Separation of mixtures Mixtures can be divided into solid mixtures, solid/liquid mixtures, solutions, gas mixtures, impure gas and liquid mixtures, according to their state of aggregation. The decisive element when choosing the separation method to be used is the state of aggregation of the mixture and its physical and chemical properties. In the separation processes, the reaction partners involved are not in pure form, but are mixed with other substances such as solvents.

One of the most significant separation processes is thermal separation. It is used in distillation, evaporation and rectification to separate homogenous materials and is carried out by addition or absorption of heat, using thermal molecular movement for the separation process. This causes a change of state in the component of the mixture which is to be separated. In the case of liquids, thermal separation is used for the processes of crystallising out, salting out, precipitation and evaporation. The prerequisite for evaporation to be used as a separation process to reduce the effluent pollution is a large difference in boiling point between the water and the pollutants. In other cases, the more expensive method of rectification should be selected as the thermal preparation method (see Fig.).

Separators Clarifying centrifugal machines. Heavy dirt particles adhere to the drum wall through centrifugal force, whereas clarified fluids and solvents drain off. Use: e.g. to clarify mercerizing liquor and organic solvents. As separators have a better effect the lower the density of a solvent, separators tend to be recommended for lighter, combustible solvents rather than for heavy, non-combustible solvents.

Septic Rotten, fostering decay. Contrast: aseptic. → Antiseptics.

Sequestering agent This is the term used for chemical compounds which remove polyvalent metal anions from water and are able to combine to form an anionic complex (sequestering, → Complexing agent); e.g. polyphosphate, ethylenediaminetetraacetic acid (EDTA). Inorganic polyphosphates are used as sequestering agents and builders in industrial and domestic detergents. From an ecological point of view, the use of this group of substances must be reduced as the phosphate load is one of the most significant contributing factors for the eutrophication of ground water. The potential applications for sequestering agents in wet textile processes of all types are diverse and, for the most part, have not been adequately researched.

The use of sequestering agents in water treatment, for example, can be useful e.g. when pre-treating cotton even when softened process water is being used, as a considerable amount of water-hardening substances are introduced by the untreated fabric. Some types increase the soil carrying capacity of surfactant liquors

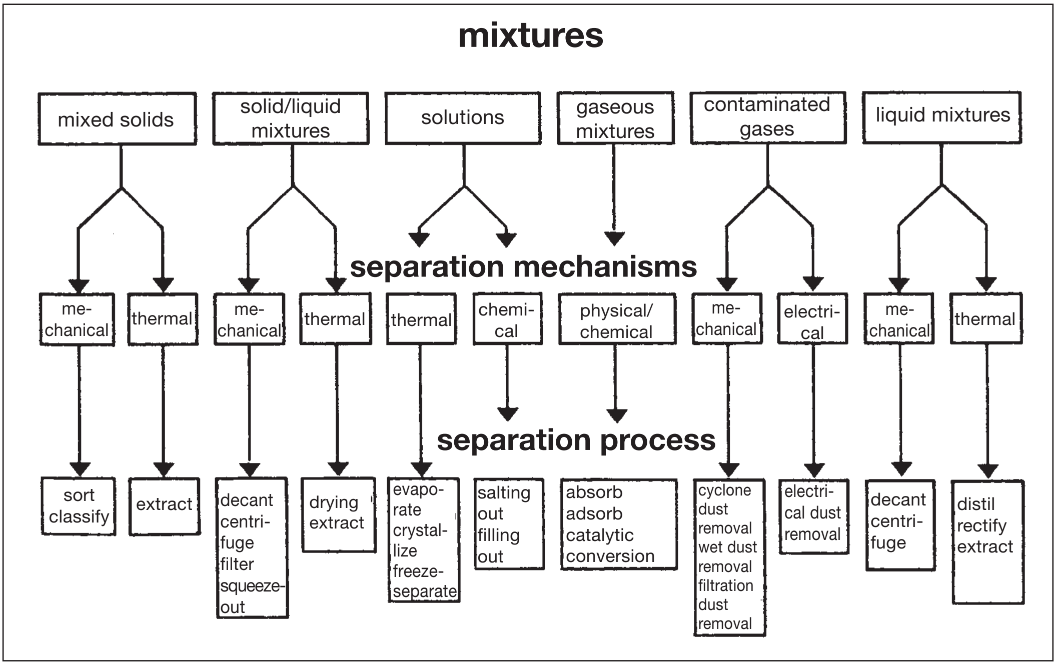


Fig.: Overview of processes for the separation of mixtures.

due to their dispersibility and therefore, may cause greying and hardening of the textile substrate for example, by redepositing the soil or sizing agent as loading substances from the wash liquor, even when only small quantities are used. The ability to dissolve solid deposits or to subject them to colloid-disperse distribution is utilised as an after-treatment to improve the fastness of dyes as dyestuff molecules and agglomerates which have not been fixed can be removed easily and thoroughly from the fibres. The delayed crystallization effect of some types not only delays the formation of inorganic deposits, it also has a positive effect on the separation of polyester oligomers.

Sequestering agents have three important properties:

1. Sequestering power: in the textile industry, "sequestering" is understood in the broader sense to mean the removal or the neutralizing of harmful metal ions (water hardening substances, heavy metal ions) from the water. The quality of water used in the textile finishing industry plays a significant part. In addition to undesired excess consumption of textile auxiliaries and dyestuffs, water hardness can cause disruption to processes, incrustations on the textile substrate, on the machines and pipes and inferior final fabric quality. Neutralizing the calcium and magnesium ions present in the water as water hardening substances can, in principle, take place either by removing them from the water before the actual process occurs (permutit process, ion exchangers) or adding materials which prevent their harmful effect. The alkali builders or sequestering agents used for this deactivate the water hardening substances and other harmful cations in the water such as iron, copper or manganese by precipitation, ion exchange, chelating or adsorption on the seed crystal surface. Even if the process water is softened before the liquor formulation, the addition of a sequestering agent brings certain clear advantages in respect to the reliability of the process.

The pretreatment of cotton, which is the most important example of this, should be described in more detail here. Over recent years, the content of non-cellulose contaminants in raw cotton has increased drastically. The main reasons for this are:

- the use of chemicals when cultivating cotton (insecticides and growth modifiers),
- harvesting machines, processing plants and packaging machines (pollutants from soil and husks)
- higher processing rates at all stages such as ginning, opening, carding, drawing, spinning, machine knitting, knitting and weaving (higher metal abrasion, poss. rust particles).

As the amount of additives can vary considerably depending on the origin of the cotton and its past history (in some cases up to 2 or 3 times the average values), it is becoming increasingly difficult for those carrying out the pretreatment to guarantee uniform, reproducible quality of the fabric which is ready for dyeing, printing or finishing. If in addition the standard 3-stage pretreatment sequence (scouring, degumming, bleaching) is shortened for economic reasons, a sequestering agent should always be added. Correct dosage ensures that the water hardening agents and heavy metal contaminants, which could result in catalytic damage, are thoroughly removed, and also offers other advantages, depending on the product group.

2. Dispersibility: the term “dispersing” (Lat.: diffuse, scatter) means that solid particles are distributed in a liquid. Due to the fact that the surface, which is large in comparison to the overall volume, is generally unfavourable in terms of its energy, particles in a dispersion tend to settle together to form agglomerates and aggregates. When added to the particle surface, certain types of sequestering agents (e.g. polyacrylate) cause an increase in the electrical charges of the same sense and thus increase the repulsive powers between the particles. In a similar way to when dissolving and emulsifying fatty or oily pollutants in liquors containing surfactants, it is beneficial as far as their energy is concerned for the surface of the solid particles to be increased. Consequently:

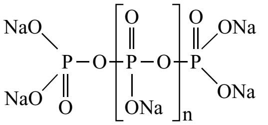
- Solid particles are prevented from settling.
- Agglomerates are split due to the repulsive powers and distributed more finely.
- The formation of flocculent and crystalline deposits and their coagulation is delayed.

3. Buffer capacity: buffering means that the pH of a solution can be maintained at a constant level in a narrow range when a moderate amount of acid or alkaline solutions is added. The preferred sequestering agents used in the textile finishing industry are weak acids, which are generally commercially available products in either completely or partially neutralized form (generally in the form of sodium salts). In solution or when strongly diluted, they decompose into ions; they dissociate. Hydrogen ions are added to the free acid ions, the sodium or alkaline earth hydroxides remain dissociated, however. When adding acids or alkalis which originate from, e.g. organic (fatty acids) or inorganic pollutants, or which could arise from (bleach) reactions, the buffer balance is shifted. Sequestering agent anions absorb excess protons or release them where there are insufficient quantities. The pH is kept relatively constant. Sequestering complexes with polyvalent metal ions do not dissociate as the sequestering effect is based on this. Accordingly, they are ineffective as buffers.

Properties of various groups of sequestering agents:

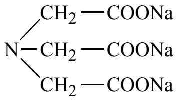
I. Inorganic condensed polyphosphates:

Advantages: ability to increase detergency efficiency and soil carrying capacity of surfactants; complexing power for calcium, magnesium and heavy metal ions.



Disadvantages: disadvantageous in hot, strong alkali liquors due to their low stability at temperatures of > 80°C and pH > 11 and in strong acid media. In these areas, it is possible that insoluble deposits will form. No selectivity for heavy metal ions when calcium and magnesium ions are present.

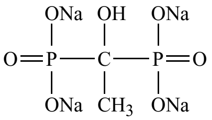
II. Amino-polycarbonates, e.g. ethylene diamine tetra-acetate (EDTA) or nitrilotriacetate (NTA; the following formula):



Advantages: high selectivity for heavy metal ions, therefore well-suited as a regulator for hydrogen peroxide bleach; good stability at increased temperatures; good alkali resistance.

Disadvantages: only resistant to oxidizing agents to a limited extent in hot and strong alkali media; practically no detergency efficiency and soil carrying capacity; at high alkali concentrations, diminishing complexing power; only effective in the stoichiometric region, therefore large quantities are required.

III. Phosphonates, e.g. hydroxyethylene diphosphonate:



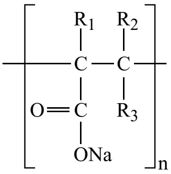
$$\begin{array}{ccccc} & \text{ONa} & \text{OH} & \text{ONa} & \\ & | & | & | & \\ \text{O}= & \text{P} & — \text{C} — & \text{P} & =\text{O} \\ & | & | & | & \\ & \text{ONa} & \text{CH}_3 & \text{ONa} & \end{array}$$

Advantages: high calcium, magnesium and iron binding capacity; high stability in cold and warm alkali baths and in strong alkali, oxidizing liquors; very selective effect on polyvalent heavy metal ions; effective in the lower stoichiometric region.

Disadvantages: only average detergent and dispersing action; may result in alterations in shade and dyestuff being dissolved out of the fabric due to the formation of hard complexes with the central atoms of dyestuffs containing metals.

IV. Polycarboxylates, e.g. polyacrylate:

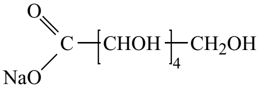
Advantages: excellent dispersing properties: solid soil, deposits, husks, etc. are removed from the fabric and stabilised in the liquor; high calcium, magnesium and heavy metal binding capacity; threshold effect: by adsorbing the polycarboxylate on the seed crystal sur-



face (e.g. of slightly soluble hard water salts), they are prevented from continuing to grow and being deposited on solid surfaces; due to the threshold effect, they are already in the lower stoichiometric region and therefore effective even when only small quantities are used; have the effect of delaying crystallization, thereby also avoiding or reducing silicate deposits in combination with sodium silicate; do not form hard complexes and therefore do not tend to corrode the central atoms of dyestuffs containing metals; by varying the monomer components used and the degree of polymerization, products with spec. property profiles can be synthesized.

Disadvantages: resistance and efficiency in strong alkali and strong electrolytic liquors are limited.

V. Polyhydroxycarbonates, e.g. gluconate:



$$NaO-C(=O)-\left[CHOH\right]_4-CH_2OH$$

Advantages: high sequestering power at limited acid/alkaline concentration.

Disadvantages: efficiency is very dependent on pH.

Sequestering agents and ion exchangers are shown in the Fig. (according to Plendl).

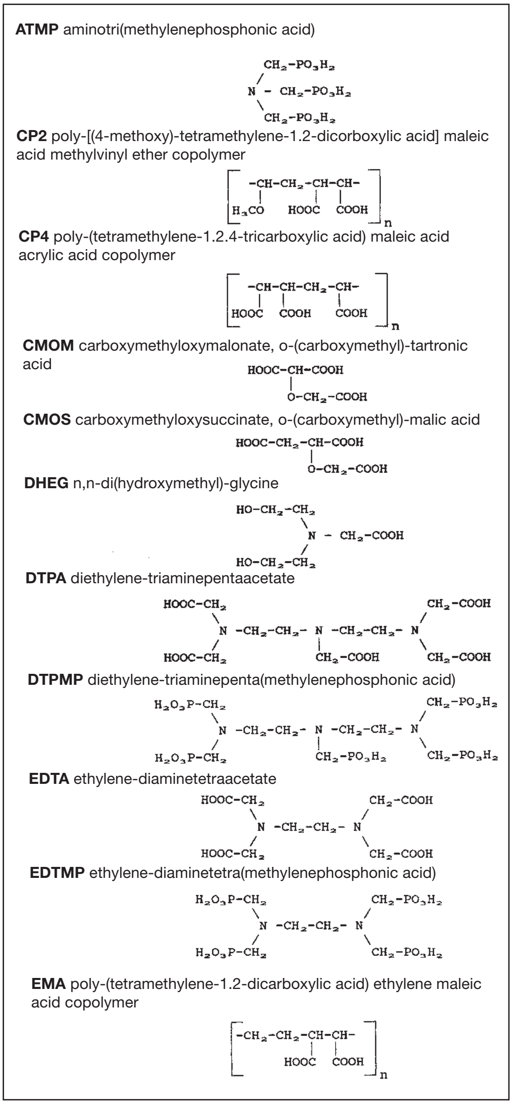


Fig.: Sequestering agents and ion exchangers (according to Plendl).

Sequestration According to DIN 53 900, the masking of dissolved metal ions which can form deposits with certain reagents, particularly surfactants. The effect is based on the formation of complexes which remain soluble in the medium in question. Sequestering agents are generally compounds which form chelates with the cation in question. Chelates (Gk. chélé = claw) are a special type of complex or co-ordination compound in which the cation is surrounded as if by a claw or a pair of tongs. Co-ordination compounds are higher order compounds. In the case of sequestration, a polyvalent cation is tightly surrounded as a “central atom” by other oppositely charged ions or by neutral molecules, known as ligands. Ligands must be able to supply at least one non-binding electron pair and the central cation must have a number of empty orbitals of a suitable energy level to accommodate these electron pairs. A ligand which is only able to supply one electron pair is referred to as a monodentate. The number of monodentate ligands which are able to be grouped around the central ion determines the co-ordination number of the relevant ion. For a chelate to form, it is necessary to have a ligand which can supply at least two pairs of electrons which are sufficiently far apart from each other in the ligand molecule to be able to form a bridge. This type of ligand is a bidentate or a ligand with two co-ordinate bonds. The majority of sequestering agents are polydentates with 4-8 co-ordinate bonds (Fig. 1)

Ion exchangers, which are either dissolved or suspended in water, are, in water insoluble suspended products for which the matrix consists of either an inorganic grid of Na-Al silicate (SASIL = Sodium Alumin-

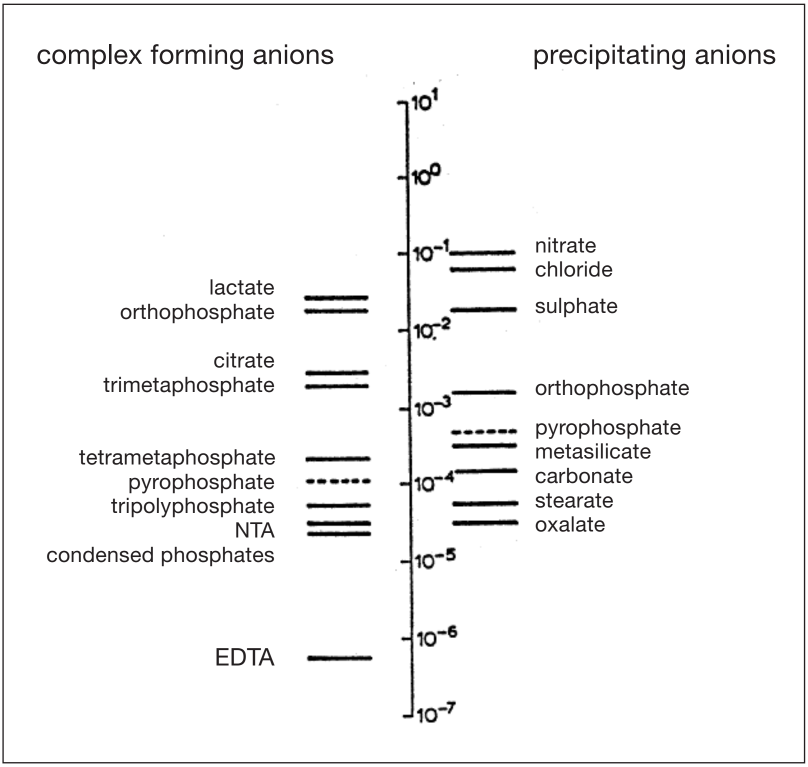

Fig. 1: The concentration of free Ca^{2+} ions following the formation of complexes with certain anions compared to the concentration following precipitation. The concentration of free Ca^{2+} ions is calculated for the dissociation of a 0.01 m solution of the 1:1 complex.

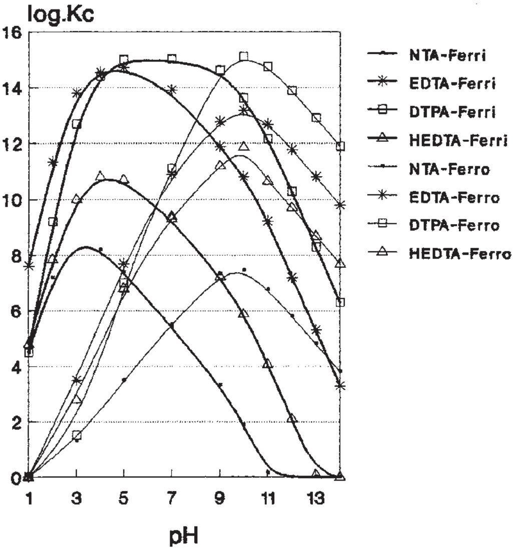
ium Silicate or HIB = Heterogeneous Inorganic Builder) or of a scaffold of partially crosslinked polycarboxylic acids. Products which are soluble in water, which are generally used in finishing processes, are polycarboxylic acids such as polyacrylic acid, polymaleic acid, copolymers of acrylic acid and maleic acid. When dissolved in water, these polymers form balls or helices, inside which the counterions can be exchanged.

The bonding capacity of the sequestering agents for metal ions is given by the stability constant K_S or the relationship between sequestered and free metal ions is represented by log K_S. The higher the value of log K_S, the more powerfully the cation in question is sequestered. The stability constant is not the only factor which determines the adhesive power of the cation in the chelate, however; the temperature, pH and electrolyte concentration are also significant. The effect of the pH value is determined by the calculation of the stability constants across the overall pH range. The stability constant corrected according to the pH is known as the conditional stability constant (log K_C). It is only possible to specify whether and to what extent a sequestering agent is suitable for a specific process with the aid of the conditional stability constant and an understanding of the effect of temperature and electrolyte concentration. Unfortunately the necessary reliable information



source: BASF.Trilon ES-8803.
T = 25 C . μ = 0.1

Fig. 2: The conditional stability constants ferrichelate and ferrochelate for polyaminocarboxylic acids.
Ferri = iron (II); ferro = iron (III).

is often not available and it is necessary to test at a later stage to ascertain which sequestering agent has the optimal effect and whether the use of a sequestering agent is actually economically justifiable.

Fig. 2 shows the extent of the effect of pH on the stability of the complex compound. Although the ferric EDTA complex has a much higher stability constant (log $K_S = 25$) than the ferrous EDTA complex (log $K_S = 14.3$), the latter is more stable at pH > 8. The influence of temperature on the Ca-EDTA complex can be seen e.g. as a decrease in the stability constant by approximately a factor of ten when the temperature is increased from 20°C to 60°C. Increasing the electrolyte concentration also results in a decrease in the stability constant. The rate of sequestration is generally relatively high; exceptions are those metal ions whose inner orbitals exchange electron pairs, e.g. Cr and Co. It takes several days for an equilibrium to be reached where the Cr-EDTA complex is used.

In addition to their complexing power, various sequestering agents also have the ability to stabilise dispersions, hinder the agglomeration of particles and prevent the accumulation of newly formed crystals. This last property is generally referred to as the threshold or swelling effect. It is not easy to determine and calculate the stability constant, and in some cases, it is not even possible. It is also difficult to make calculations in practice using these constants. Another option to determine the efficiency of a sequestering agent is therefore often detailed in fact sheets, namely by giving the binding capacity, generally for Ca^{2+} but also for other cations such as Mg^{2+} or Fe^{3+}. This binding capacity is based on the ability of the auxiliary in question to prevent the precipitation of a particular cation which is under the influence of an anion which causes precipitation (Hampshire test) or alternatively to prevent a freshly precipitated deposit from being dissolved once again (modified Hampshire test). In both test methods, other specific properties of the sequestering agents in addition to the stability constants also play a significant role, so care is required to ensure this data is not incorrectly interpreted in practice. (according to Engbers).

Serabend carpets (Mir carpets), Persian → Knotted carpets from the Sarawan region. Typical flame-effect patterning about the size of an egg on a red, blue or cream background. 120 000–250 000 Turkish knots/m^2. Mir from Mirabad has particularly fine patterning.

Serge (Fr.: serge = twill). Diagonally striped materials in twill weave. Name derived from the type of fibre (alpaca, woollen serge) and use (costume serge), also warp printed (serge vigoureux).

Serge de Nîmes Denim fabric for jeanswear; sail cloth trouser fabric, warp printed in indigo, originally white or brown. Specially sewn and riveted garments which are artificially aged (stonewash; sandblasted, biowash process). First jeans manufacturers to use serge de Nîmes: Lewis, Lee, Wrangler.

Serial washing machine → Continuous washing plant for laundry separated into batches consisting of 4–10 machine units (each with a capacity of 24 kg) in series which are separate from each other (modular construction principle) and have separate liquors. Counter current operation at timed intervals, with (in contrast to the conventional inner drum) horizontally partitioned “laundry agitators” which scoop the laundry from the lower trough (outer drum) and allow it to fall back freely into the bath after a half turn. Whenever the timing changes, the laundry agitators and transport valve ensure the laundry is passed into the next unit. Each unit serves as a treatment station for the programmed washing operation, each batch of laundry for the programmed washing operation remains alone until unloading. Hydroextraction using squeezers/calenders or a connected hydroextractor.

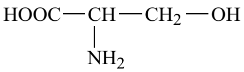
Sericin (silk gum). A silk gum substance which surrounds the fibroin filaments up to 19–28% and with them forms raw silk (→ Silk). A distinction is made between the white cocoon, which is known as “white bast” and that from yellow cocoons, “yellow bast”. Composition: 45% carbon, 32% oxygen, 17% nitrogen, 6.5% water. Sericin has a different amino acid structure to that of fibroin (→ Silk structure, see Tab.), i.e. basic and particularly acid groups in higher concentration (aspartic acid, glutamic acid, serine, threonine, tyrosine). Its isoelectric point is therefore pH 4.1, whereas that of fibroin is pH 4.9.

Sericin content of natural silk determination Accurately weigh out approx. 20 g of a sample, boil for 1 h in a 1% Marseille soap solution, squeeze out, hydroextract, rinse with water, squeeze out, dry for 4 h at 105°C and when calculating the sericin content use:

$$\text{sericin content in \%} = \frac{G_1 - G_2}{G_1} \cdot 100$$

G_1 = weight of the completely dry sample before degumming (original weight less the water content detected on the second sample);
G_2 = weight of the completely dry sample after degumming.

Serine Monoamino monooxycarboxylic acid. An → Amino acid which is present in wool (9.4%) and silk (16.24%).



$$\mathrm{HOOC{-}\underset{\displaystyle NH_2}{\underset{|}{CH}}{-}CH_2{-}OH}$$

Serviceability of carpets This is difficult to specify; in addition to fastness of colours/prints, the following need to be taken into consideration: abrasion resist-

Serviceability of carpets This is difficult to specify; in addition to fastness of colours/prints, the following need to be taken into consideration: abrasion resistance, tuft anchorage, soiling capacity, electrostatic charge, etc. Individual factors can be determined using test devices, provide a considerable amount of information on the actual serviceability and should be substantiated by treading tests.

Service life of textile plant and equipment As a valuation for depreciation, a distinction is made between a) the original cost (= cost value, book value, carrying value), b) present useable value (current value, i.e. value at the point the annual profit, profit or loss account or cost system is to be drawn up), c) replacement value (is always replaced by the present useable value in cost systems). The depreciation used for in-house cost system or annual profit or loss accounts cannot simply be based on the present useable value (replacement principle, sustaining productivity), as accounting principles alone would give a false basis for calculation. On the other hand, the commercial balance sheet or the tax balance sheet is used for the depreciation shown by the balance which is based on the original cost and guarantees the capital sum invested. For this depreciation, the service life is equated with the useful life and, as this cannot be accurately determined in advance due to the various associated factors of probable stress, activity and wear and ageing, this is estimated for specific years of operation. This assumes depreciation of the plant after expiry of the estimated service life, at which point the allowance for the reduction in useful value is deemed complete. In addition to the so-called annual linear depreciation, which is based on original costs, there is also degressive depreciation which is calculated from the relevant book value (remainder of investment as shown on the balance sheet). With the linear method, the depreciation quota remains the same until the final year; with the degressive method, it decreases annually. This corresponds to a large extent to the decrease in the useful value of the plant, and thereby, also to the practical trend in wet finishing companies for example, where higher depreciation in the early years make it possible for a replacement purchase to be made at an earlier stage.

Service life of textiles From experience in processing complaints, the term "service life" can be defined as the length of time for which the textile can be worn or used in terms of fashionable and aesthetic aspects. A highly fashionable item will therefore be suitable for use for considerably less time than a timeless article subjected to the same strains.

Servo component Element of the control system or regulating system. Operation to control a physical quantity in a mass or energy flow as required for the particular operation is known as "regulating". Regulating takes place at the regulating point. Servo components which are used to control an energy flow are known as "actuators".

Servo-hydraulic Machine components which are difficult to operate can be controlled more easily using oil pressure. The aid (servo) using oil (hydraulic) operates, e.g. with a gear chain, as follows (see Fig.): a pump which is part of the gear chain, supplies oil to the hydraulic control unit. The control valve controls the oil supply in the pressure cylinder of the disc assembly. Oil exerts a pressure to the conical disc in the chain, for axial transfer of the displacement disc and to forcibly move the driving gears. Servo-hydraulic makes it possible to preselect the speed of the driving motor while the gears are immobilized.

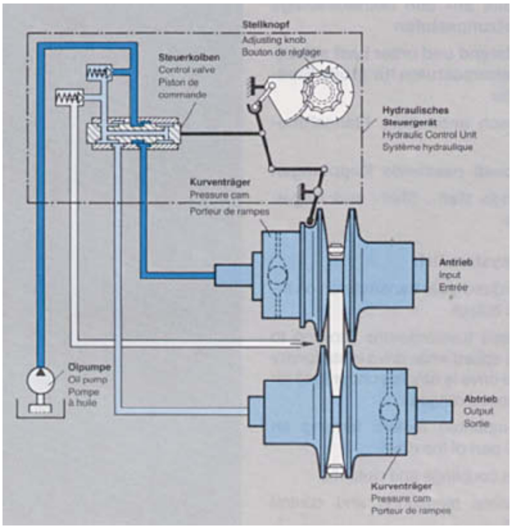

Fig.: Servo-hydraulic.

Sett The number of warp and weft yarns in fabrics (the number of stitches in knitwear) per unit of measurement, i.e. per 1 or 10 cm, often per cm^2. Magnifying glasses or yarn counters are used to determine the sett. The sett therefore corresponds to the distance from the centre of one yarn to another. Whether the yarns lie closely together or form open stitches is insignificant. Not to be confused with → Fabric density.

Setting,

I. Setting textiles in the sense of fixing dimensions or shape. →: Crabbing; Decatizing; Hosiery setting; Heat setting (→ Fixation), wet setting. The degree of setting, i.e. modification to the structure as a result of the influence of heat, can be defined in the case of polyester by determining the solubility in phenol/tetrachloroethane; this can also be achieved using differential thermal analysis (DTA) which can also be used for polyamide.

II. Setting colorations. This is achieved e.g. by fastness improvement agents and → Developer.

III. Setting prints: developing process to promote setting. This preferably takes place on a steamer.

IV. Setting dyestuffs generally using hot air (→: Thermosol single-bath processes; Thermosol two-bath processes), direct contact (hot roll fixation machines) or steamers.

Setting of carpet yarns This is necessary if yarns with high pile and low density are to be processed. Discontinuous steaming in rope form or as special packages in autoclaves is labour-intensive. A number of devices are available for continuous operation.

Setting-up time Proportional → Order processing time as work involved in preparing the fabric, which also includes the necessary transport. Subdivided into setting-up time and setting-up allowance. Example: in screen printing in the pressroom, manual stentering, gluing, etc. represents a setting-up time which places a considerable burden on order planning, which can be significantly reduced by the mechanisation of screen printing. The setting-up time is followed by the → Execution time.

Settlable solid pollutants in waste water According to the Abwasserabgabengesetz (waste water levy law), the solids measured in ml/l (soil components, fibre abrasion, etc.) in a water sample which settle to the bottom within a specific time.

Set yarns → Textured yarns which are pre-set, in contrast to highly elastic yarns. Fabrics manufactured using set yarns shrink considerably less in wet finishing.

Sewability Sewing threads can be described as having excellent sewability if they guarantee problem-free production, minimal downtime and optimise the efficiency of production plants. Other individual contributing factors include: the construction of the sewing thread, tensile strength, elongation at break, abrasion resistance, sliding properties and softness. Maximum stress is caused by modern high-speed seamers which convey the sewing thread through the eye of the needles up to 80 times, at speeds of up to 8000 stitches/min. at approx. 200 km/h until the loop formation is completed. This stress on the sewing thread (particularly when starting and stopping) is considerably higher than when used subsequently in the seam. Ensuring good sewability is a particular problem when developing suitable softeners and additives to improve the sliding properties of the thread in relation to the sewing needle (sewing thread lubricant). Suitable auxiliaries include polyethylene emulsions, paraffin emulsions and → Silicon elastomers. In extreme circumstances (depending on the speed, material to be sewn, needle gauge), needle temperatures of 280–300°C may occur. There are certain sewing sectors with high needle temperatures in which it is not possible to use synthetic spun yarns. The only solution is reduced sewing speed (lower temperature, longer sewing times, increased piece cost).

Sewability, improvement of → Sewing thread lubricant.

Sewerage filter (clarification filters). Precoated filters for dry cleaning are used to clarify the contaminated solvent circulating in the machine with a “separating barrier” of filter aid which is constantly replenished; these are so-called precoated clarification filters in which the filter residue (filter cake) is deposited on a supporting substrate. A clarification filter consists of a pressure-resistant housing with a tight fitting lid. The supporting substrate, which exists in a variety of types, arrangements and forms, is accommodated inside the housing. When compared with other older, clarification processes (especially those with separators), the fact that modern clarification filters not only offer a greater throughput but also have a greater clarifying capacity is decisive. Clarification filters should ensure a continuous, trouble-free and uninterrupted initial filtration performance and should be easy to clean in the shortest possible time without much servicing. An adequate filtration capacity is a further requirement; if the surface area of the filter is too small, the clarification performance per unit time is reduced.

Some terms specific to clarification filters include:

a) Filter cake discharge: removal of the contaminated filter cake accumulated at the base of the vessel from the filter; this is particularly important for single-batch filters. The removal of obstinately adhering sludge can be assisted by a built-in agitator in the base of the filter or by the application of pump pressure.

b) Filter cake sinking time (in single-batch filters): the time required for the filter cake detached from the support medium to collect on the bottom of the filter vessel and its subsequent discharge. This takes 5–30 min depending on height of filter, type of filter aid, solvent used, and the concentration of grease in the solvent.

c) Filtration surface area: the surface area of clarification filters available for precoating with the filter coating. In the case of multi-batch filters, its size in m^2 serves to determine throughput performance (e.g. 1200–1500 $l/m^2/h$) and therefore the pump capacity. For the same throughput performance, this can be considerably lower for single-charge filters.

d) → Filter auxiliaries.

e) Filter cake: a deposit consisting of filter aid and filtered-out suspended matter (soil) which builds up on the supporting substrate after precoating (ground coat, initial coat) and subsequent use in clarifying filtration.

f) Button trap and lint filter: this is a coarse filter installed between the machine and the pump to prevent the passage of pins, buttons, hooks, coins, etc. which could damage the pump. This filter should also be fine enough to retain lint since the latter can only be removed from the actual filter by opening the lid due to the fact that it floats to the surface and cannot be discharged with the filter cake.

g) Backrinsing: this involves pumping solvent through the filter in the opposite direction to that used in filtration. Backrinsing is carried out with filters that are not self-cleaning or when operational breakdowns occur with self-cleaning filters. It is only carried out when there is no danger of blocking the supporting substrate beyond repair from inside. For filter models with plate-shaped elements where the connecting sleeves have small cross-sections, backrinsing can only act on a small part of the filtration surface area.

h) Self-cleaning: a filter in which the filter cake is detached completely from the supporting substrate and sinks as soon as the pump pressure falls to zero under normal operating conditions (i.e.: average batch contamination, low concentration of grease and water in the solvent, and the use of a filterable dry cleaning detergent). Plastic filters are also self-cleaning even with high water concentrations.

i) Rinsing action: during cleaning processes with solvents, the cleaning effect increases with increasing quantities of (uncontaminated) solvent flowing through the material per unit time, i.e. by a rinsing action. Intensive rinsing through the material saves dry cleaning detergent. It is for this reason that efforts are made in dry cleaning to achieve optimum filter performance.

k) Precoat (ground coat, initial coat): the quantity of filter aid pumped into the filter with the uncontaminated solvent which precoats the supporting substrate before the actual filtering operation is carried out. The precoat forms a separating barrier between contaminated and filtered solvent. During subsequent clarifying filtration, a filter cake is gradually deposited on the precoat.

Sewerage filter aid → Filter auxiliaries.

Sewerage filtering → Solvent filtration in dry cleaning.

Sewerage-filter system (clarification filter systems),

I. Filter screens (mainly multi-batch filters).

a) Textile sieves: filter bags or screens usually made from synthetic fibres (formerly cotton), fluted cloth filters (saves space due to greater surface area) as well as candle or column filters. For cleaning purposes, filter bags must be removed from the filter housing. Filter disks, of circular shape and covered with synthetic material, are attached in series to a rotating hollow shaft mounted in bearings through which the filtered solvent can flow out. Rotation causes the filter coat, mixed with contaminants, to be detached from the filter elements through centrifugal force.

b) Metal sieves: woven metal mesh (openings approx. 0.01 cm) or perforated metal sheets. Plane metal sieves can be cleaned with mechanical squeegee systems. Circular metal sieves, candle or tube filters consist of filter tubes suspended above a plate floor inside a filter cylinder. Diameter approx. 2–4 cm. Cleaning is carried out by backrinsing. Flexible metal mesh filters in tubular form are kept under tension by means of springs which are released to discharge the filter cake.

II. Leaf filters (mainly single-batch filters): the filter elements consist of layers of relatively thin leaves (metal or plastic mesh). During filtration, solvent flows through the filter elements, precoated with filter powder, into drainage channels between the leaves.

a) Plastic leaf filters. These are composite self-cleaning coated filters built up by the superimposition of single rectangular leaves. Spacers and central perforations facilitate throughput and solvent drainage.

b) Metal leaf filters. Single filtration through rectilinear leaf elements made with wire of a specific thickness, the distance between which determines the size of the lamellar spacing. The latter is also achieved by stringing together a slightly coiled wire and a straight wire to form a composite structure. Metal leaves of this kind are built up from bent leaf elements. As filter elements, compressed spiral metal springs are used. Through appropriate construction of the spirals, e.g. a staggered hexagonal arrangement, adequate lamellar spacing between the compressed spiral rings is made available. Filters of this type are cleaned by simple expansion (“expanding filter”) which allows the filter cake to be discharged. The expanding filter is ideal both as a single-batch and a multi-charge filter.

III. Cartridge filters: these are multi-charge filters consisting of a fluted paper filter with a filter aid and activated carbon in granular form. They are firmly enclosed in perforated sheet metal to provide a suitable size of insert cartridge for the filter housing. When the filtration pressure becomes too high, the filter must be replaced and the old cartridge is either disposed of or discarded.

Sewing silk Tightly twisted strong silk yarn made from degummed reeled silk or schappe silk by twisting 2 to 3 silk strands together and then combining several of the resulting threads by applying twist in the opposite direction. Uses: hand and machine sewing.

Sewing technology The sewing together of individual pieces of textile fabric to make up a batch for processing is an important operation in a textile finishing plant (Fig. 1), as is the sewing of end-cloths to the beginning and end of the batch. The adjoining ends must not be sewn on top of one another, i.e. the seam must not be thicker than the fabric itself. For this reason, pieces are sewn end-to-end using butted seam sew-

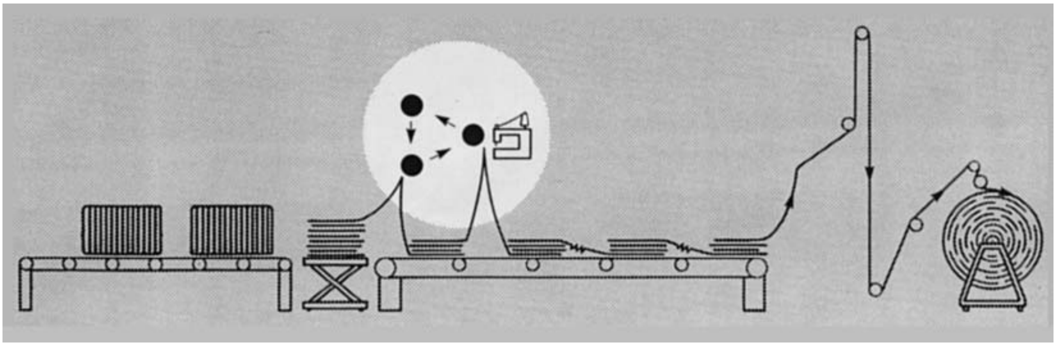

Fig. 1: Composing a batch by sewing the items piece to piece and rolling the batch together.

ing machines (Fig. 2). The seams need to be carefully sewn so that they do not tear during processing and cause break outs. Torn seams seriously reduce production. If, for example, a seam breaks during the passage of a fabric through a steamer, the machine has to be shut down completely and it may easily take more than 30 min before the machine is cool enough for an operative to enter the steamer and sew the broken out fabric ends together again. The steamer must then be heated up to the required temperature once more before production can be resumed which incurs even more downtime. Moreover, the guide rollers in processing machines can often be damaged by bending or warping due to piece ends from broken seams becoming wrapped around them.

Whilst seams must be strong in order to withstand the stresses and strains of processing, they must also be easy to separate. There are many sewing machines on the market capable of fulfilling this requirement. Special types of machines are also available for sewing wet goods. In order to produce individual seams in a textile finishing plant, portable machines are essential, and convenient transportable models are readily available for this purpose.

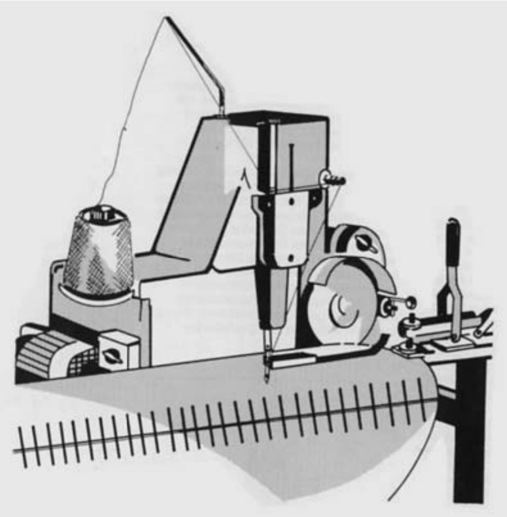

Fig. 2: Butt to butt sewing (Dohle).

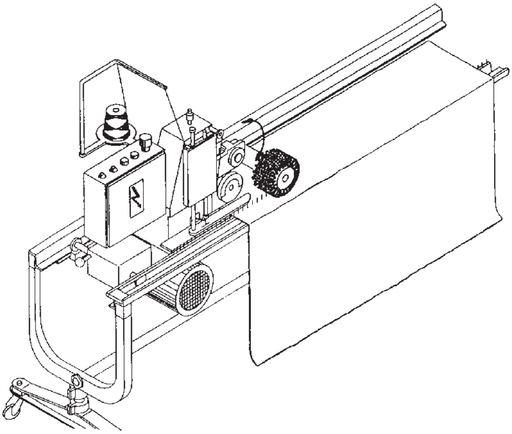

Fig. 3: Securing two piece ends in order to sew them together using a carriage-type sewing machine.

Apart from stationary, fixed head, high-speed sewing machines capable of 1500 stitches/min, so-called carriage type sewing machines are also used for sewing piece ends together. With this type of machine, both piece ends to be joined are held on parallel rows of pins (Fig. 3) and the sewing head travels along rails during the sewing operation. After the process is complete, the machine automatically sews back to the starting point. This type of sewing machine is particularly suitable for elastic materials since, in this case, it is not necessary to pull the material through a stationary sewing head by

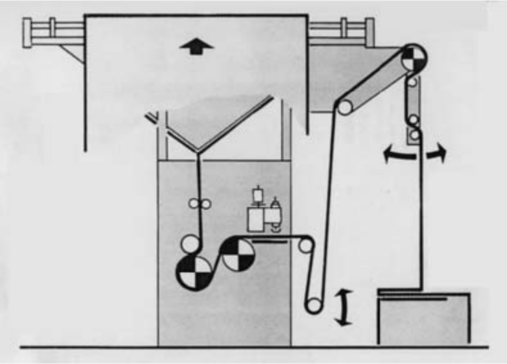

Fig. 4: Tubular sewing of both fabric selvedges.

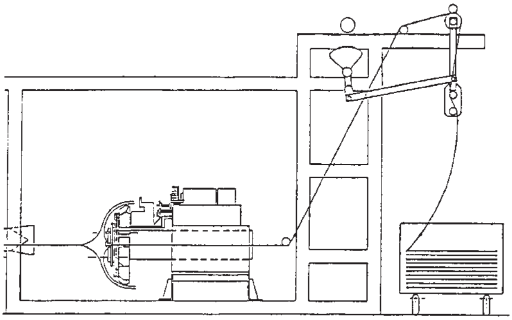

Fig. 5: Round stitching sewing machines for knitted tubular goods.

hand which could easily distort the fabric. By means of fabric scrays, the sewing operation can be integrated into a continuous finishing process. Various, particularly sensitive, woven and knitted fabrics have to be treated in so-called tubular form whereby the fabric is folded together (doubled) in the lengthwise direction and stitched edge-to-edge with special sewing machines, either continuously over the entire length (Fig. 4) or with individual stitches at periodic intervals. Circular sewing machines specifically designed for tubular knitgoods are also available (Fig. 5).

Sewing test in listing → Shade variation test for continuous dyeing.

Sewing thread A variety of textile yarn used for hand or machine sewing. The most important types of sewing thread include: mercerized cotton, silk-spun polyester, core-spun polyester (a core of polyester filament yarn with a cotton covering) and polyester staple. Sewing threads are numbered for size according to various systems (e.g. ticket number) where, generally speaking, the higher the number, the finer the sewing thread. → Sewability.

Sewing thread finishing An appropriate → Sewing thread lubricant is often applied to sewing threads as a finish in order to improve → Sewability performance.

Sewing thread lubricant Due to the increased demand for sewing threads made from synthetic fibres and the use of higher sewing speeds in industrial applications, sewing thread lubricants based on simple organic substances such as waxes or stearates are no longer sufficient to control the development of heat in the sewing needle, i.e. to provide a heat shield. For high sewing speeds, silicone-based products have been found to be particularly suitable.

Sew together In order to pass large batches made up of a number of pieces efficiently through the production process of textile finishing, the individual pieces are sewn together (→ Sewing technology, see Fig. 1). This is carried out on an industrial sewing machine.

S-Finish A term originally applied to the partial surface saponification of cellulose ester fibres (acetate and triacetate) by alkaline hydrolysis to reduce static charge and improve fabric handle.

→ Alkali treatment of polyester. Nowadays the term has also been adopted for an analogous treatment of polyester fibres in which a controlled partial saponification with alkali (NaOH) is carried out to achieve a silk-like lustre and handle, reduce the build up of static charges and improve anti-soil properties. Degradation of the fibre surface layer typically results in a weight loss of 12–14%. Precise control of the process is necessary in order to prevent excessive loss of tensile strength. Quaternary ammonium compounds are used as accelerators in the alkali treatment.

SFR Abbreviation for "Svenska Färgeritekniska Riksförbundet" = Swedish Association of Textile Engineers and Colourists; → Technical and professional organizations.

SFS Abbreviation for "Suomen Standardisoimisliitto" = Finnish Standards Organization; → Technical and professional organizations.

Shade build-up,

I. To achieve a uniform shade build-up in dyeing, combinations of dyes having similar rates of exhaustion should be used so that they will be taken up by the fibre as uniformly as possible in a specified period of time over a specified rise in temperature. With such combinations, the shade should initially appear lighter (after a short dyeing time and low dyeing temperature) but without any significant preferential exhaustion of one particular component in the combination nor, on the other hand, should there be incomplete exhaustion of one of the combination dyes over longer dyeing times or at higher dyeing temperatures.

II. Dyeing of polyamide or acrylic fibres with dyes or dye combinations at increasing concentrations. The purpose here is to establish the depth of shade which corressponds to the maximum build up of the particular dye or combination.

Shade number The number allocated to each of the 24 hues in the → Chromatic circle.

Shade of colour,

I. (position in colour space). In practice, this involves general sensations to → Colour of all kinds. So-called → Chromatic colour sensations are meant here, i.e. spectral colours defined by dominant wavelengths in contrast to → Achromatic colours. Shades can be specified by reference to visual colour standards, e.g. colour atlases. The → Chromatic circle provides a means of allocating a colour number to one particular shade in a retrogressive range of all shades and allows each shade to be defined with the appropriate letter of the → Grey series. Instead of dominant wavelength, the wavelength derived from its range is specified and the shade T corresponds at the same time to the colour number of the Ostwald chromatic circle. The ratio between the dominant wavelength and T follows from the chromaticity diagram in accordance with DIN draft 6 164. T allows the assertion to be made that the shade between any two colours T_1 and T_2, with the same saturation S and the same blackness value D, is proportional to the difference U and the difference between the respective values of T:

$$\frac{T_1 - T_2}{U} = \text{const.}$$

i.e. irrespective of T_1 as long as $D_1 = D_2$ and $S_1 = S_2$. The same considerations apply to → Lightness and → Saturation.

II. (dyeing) → Colour.

Shade reproducibility The possibility of achieving exact reproducibility of shade from the same dyeing recipe. In practice, two main problems influence shade reproducibility: on the one hand, poor reproducibility may be due to errors in weighing out the dyes specified in the recipe or inaccurate volume metering on the other. Moreover, variations in substrate pretreatment or the quality and/or source of the substrate itself can also influence shade reproducibility.

Shade, to The verb “to shade” is a term used in dyeing to bring about relatively small changes in the colour of a substrate by adding further small amounts of dye/s in order to match a given standard shade more accurately. → Shading corrections in dyeing.

Shade variation A coloristic term for a difference in colour (usually between a particular batch and a standard) which can also be expressed numerically by means of computer colour measurement. A colour difference expressed in ΔE units indicates whether a particular sample is the same shade as a standard pattern, i.e. whether it is a close enough match within specified colour tolerances. Variations in shade between a particular sample and a standard pattern are determined quantitatively.

Shade variation, colour change A change of colour following the completion of an order for a particular shade in dyeing on a continuous dyeing plant, or a colour way in textile printing, or a colour change in the mass coloration of man-made fibres.

Shade variation test for continuous dyeing The (visual or instrumental) assessment of fabric samples to check → Shade variation (side-to-centre shade variation or listing) should only be carried out after dried fabric has been allowed sufficient time to cool down completely. It is essential here to distinguish between genuine side-to-centre shade variation and shade variations caused by optical effects such as:

- colour differences due to lustre or roughness,
- a change in the angle of, e.g. two twill weave fabrics at a seam,
- variations in fabric density,
- optical colour differences due to a flatter or more plastic appearance of the material itself,
- differences in depth of colour in open-weave fabrics,
- differences in depth of colour due to variations in singeing.

A useful method to determine the source of side-to-centre shade variation is to sew various test samples (Fig.)

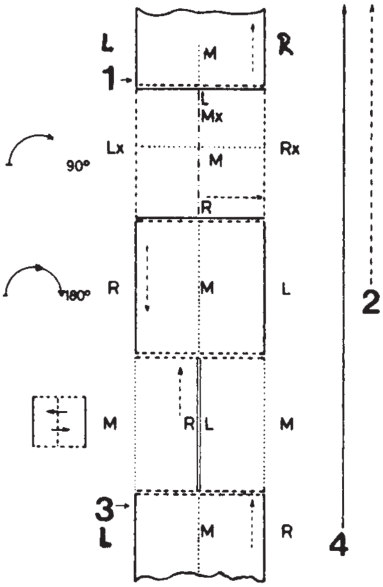

Fig.: Diagram showing the sewing-in of staggered fabric sections in a fabric web.
L = left; M = middle; R = right; Lx = left, rotated by 90°; Mx = middle, rotated by 90°; Rx = right, rotated by 90°; 1 = normal run of goods; 2 = original run of goods; 3 = normal run of goods; 4 = run of goods in test.

of the same fabric, which have been rotated through appropriate angles relative to the normal fabric direction, into the middle of a production dye batch, and then compare the results after dyeing.

Evaluation of the fabric test samples is carried out as follows:

1. Test samples M-R/M-L provide information on differences in shade and depth between the sides and the centre of the fabric.
2. Test samples R-L allow a comparison between the right and left hand sides of the fabric to be made.
3. Comparison of test samples Mx-Rx/Mx-Lx with M-R/M-L: if, for example, the edge Rx of the piece which has been rotated through 90° and R are lighter or darker than the centre Mx and M to the same extent, then the cause of side-to-centre shade variation is most probably due to a) unequal nip pressure of the padder rolls or b) uneven drying or thermosol treatment. If, on the other hand, it is established that the lighter or darker edges of test samples M-R/M-L do not correspond to test samples Mx-Rx/Mx-Lx, then it must be assumed that the fault lies a) in fabric construction or b) in fabric pretreatment.
4. By comparing the test samples M-R/M-L for normal running fabric with the test samples M-L/M-R for pieces rotated through 180°, information is obtained as to whether, for example, a particular defect in the form of a lighter or darker side of the fabric only needs to be sought in a) unequal pressure of the padder rolls or uneven drying resp. Thermosol treatment or b) in fabric construction or pretreatment.

Shading The appearance of colour variations in cut-pile carpets composed of synthetic fibres caused by changes in pile orientation (shadowing); crushing of the pile. The pile density (in the pile direction) of a pile carpet varies between the area of shading and its immediate surroundings due to the rotation of pile threads in different directions about their own axis.

In general, two different kinds of shading are encountered in practice:

a) In-service shading: in this case, the pile density resp. yarn twist is unbalanced over the entire surface of the carpet. Friction between the sides of adjacent pile threads delays the recovery of twist equilibrium; this friction is reduced by treading, brushing and vacuum cleaning. The elimination of friction and the untwisting process are promoted by a change in moisture content so that a reversible change in length results. A state of equilibrium for the individual pile threads is achieved over varying lengths of time dependent on differences in moisture content.

b) Shading in production: localized variations in pile density are produced and fixed, for example, by poor cutting of the pile; these variations are only overcome in final finishing (without any real levelling) by uniform pile processing and may become visible once again when the carpet is in use.

Testing: equipment for carrying out shading tests consists of a modified castor chair apparatus. In contrast to a standardized test apparatus, the castors do not roll over the material but execute milling actions in different directions. The carpet test specimen is moistened to different degrees and covered with film so that the special “shading-promoting” microclimate is maintained during the test. Shading is produced by the milling action of the chair castors within 90 min. If the material is largely resistant to shading, however, the pile will only exhibit a uniform flattening without any localized change in pile direction (Bendt and Huchzermeyer).

Shading corrections in dyeing, shading corrections in dyeing are carried out by “topping” the basic dyeing with suitable dyes as necessary in order to match a given shade more accurately.

Shadow effects → Dyeing of ombré or shaded effects.

Shag carpet A carpet with a long loose pile of manufactured fibres. Shag carpets are made with relatively coarse cut (or a combination of cut and uncut) twisted pile generally 2.5 to 5 cm in length. Because of its height, the pile tends to lie in a somewhat random fashion.

Shaker process → Powder-scatter coloration technique.

Shampoo cleaning of carpets and upholstery → Foam cleaning.

Shampooing → Foam cleaning.

Shantung Shantung derives its name from the Chinese province where it originated. A rough plain weave silk fabric made of uneven yarns which gives the material an irregular textured appearance due to the use of thicker yarns or long slubs in the weft. Originally made from wild (tussah) silk on hand looms in the Shandong (Shantung) province of China. Nowadays it may be produced from a) pure silk, in which case the yarns retain all knots, slubs and other imperfections, b) synthetic fibres or c) cotton. An imitation silk shantung has also been produced using lower quality bourette silk.

Shape memory The ability of a garment or other textile article to hold its manufactured shape as a result of durable-press finishing. These materials are able to recover their original set shape again after changes induced by e.g. laundering, since the resin finish is only cured after the fabric has been made up into the final shape of the garment.

Shape retention → Dimensional stability.

Shape stabilized cotton shirts

Non-iron shirts, or "Shape Stabilized Shirts", were put on the market in 1993 in Japan and soon enjoyed a boom period for about 3 years. After a short-term selling recession, sales have recovered and are now at a highly stabilized level, as shown in Tab.

SSP is a non-iron process, in which liquid ammonia pretreatment, post-cure resin and a high-level sewing system play important roles. From eight million pieces produced, five million are polyester-cotton 50–50 blend and three million are 100% cotton. The three million means that after a long history of development, 100% cotton non-iron shirts have become daily commodities for consumers. With VP, formaldehyde vapour and sulphur dioxide vapour are applied to make-up shirts in a closed system. Because the crosslinking reactions are performed after sewing, the VP process can be assumed to be a sort of post-cure process. The other non-iron processes are pre-cured types that do not show a high W&W performance compared to SSP or VP. The production procedure for SSP is the combination of liquid ammonia and post-cure resin finishing, shown as follows:

SSP (Post-cure)	Regular finish (Pre-cure)
Bleaching	Bleaching
↓	↓
Liquid ammonia treatment	Mercerisation
↓	↓
Resin application (special recipe)	Resin application
↓	↓
Sewing (with special care)	**Curing**
↓	↓
Pressing	Sewing
↓	↓
Curing	Pressing

Fig. 1 shows a typical liquid ammonia process of an ammonia-dry system. The fabric passes the main chamber, containing liquid ammonia for a few seconds, and then the liquid ammonia is immediately removed by a heat cylinder. Almost all the ammonia is recovered and recycled. No ammonia remains on the fabric at the end of processing.

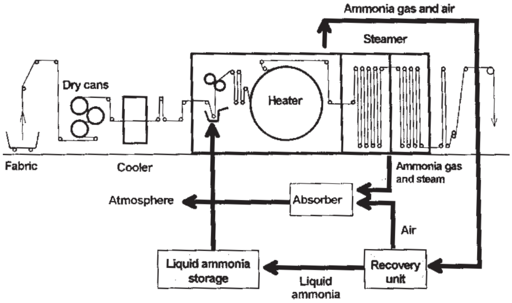

Fig. 1: A typical liquid ammonia processing unit of an ammonia-dry system.

Changes in the cotton fibre after liquid ammonia treatment:

- The fibre becomes deconvoluted and its surface is smoothed.
- The cross section of the fibre becomes round and the hollow space at the centre of the fibre (lumen) becomes smaller.
- The fibrils become ordered and average fibril distances appear.
- The degree of crystallinity decreases.
- The crystal structure changes to a rather expanded state.

Effects of liquid ammonia treatment on a cotton fabric:

- low shrinkage after washing.
- increase in shrink resistance.
- increase in the elasticity of each fibre.
- softer to the touch.
- increase in strength.

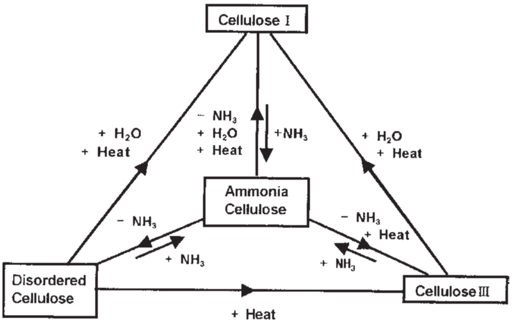

Fig. 2: The changes in the crystal structure.

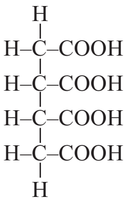
As can be seen in the model (Fig. 2), cellulose I (natural cellulose) becomes ammonia cellulose through liquid ammonia treatment. Then it changes to cellulose III on removal of the ammonia through heat treatment. Close observation of the model has shown that cellulose III re-converts into cellulose I under hot water and heat treatment.

Formaldehyde-free crosslinking: There is a need to replace formaldehyde-releasing agents now in widespread use for imparting flat drying properties to cotton fabrics. Recent efforts to replace these formaldehyde adducts of cyclic amides have focused on polycarboxylic acids. Butanetetracarboxylic acid (BTCA) and citric acid have been the most successful to date. Formation of ester linkages to cotton is believed to involve intermediate acid anhydride formation. The crosslinking agents must have one more carboxylic acid group per molecule than the number of required attachments to cellulose. Thus, the maximum number of attachments to cellulose for BTCA is three and for citric acid two. The properties of the modified cotton fabrics are good. BTCA, which gives a high level of resilience and more durability to laundering, is still too expensive to compete with the conventional formaldehyde-containing agents. Also the best catalyst, sodium hypophosphite, causes shade changes with sulphur dyes. Citric acid is less expensive but less durable and can have fabric yellowing problems.



$$\begin{array}{l} \;\;\;\;\;\;\;\;H \\ \;\;\;\;\;\;\;\;| \\ H-C-COOH \\ \;\;\;\;\;\;\;\;| \\ H-C-COOH \\ \;\;\;\;\;\;\;\;| \\ H-C-COOH \\ \;\;\;\;\;\;\;\;| \\ H-C-COOH \\ \;\;\;\;\;\;\;\;| \\ \;\;\;\;\;\;\;\;H \end{array}$$

BTCA

Recently improvements have been made to the polycarboxylic acid finishing system. A three component curing system containing triethanolamine, malic acid and sodium hypophosphite substantially increased the strength and abrasion resistance of BTCA treated cotton fabrics. The results suggested that BTCA can esterify hydroxyl groups of triethanolamine and malic acid as well as cellulose to produce a graft copolymer of cellulose with a more open structure and flexible three-dimensional molecular network than is obtainable with BTCA alone. Malic acid is comparable to citric acid in availability, cost and ecological acceptability. When activated by moderate amounts of BTCA it can serve as a non-yellowing formaldehyde-free durable press finishing agent for cotton. The activating effect of BTCA may be due to the esterification of the α-hydroxyl group of malic acid by BTCA, thus eliminating interference of that hydroxyl group with esterification and crosslinking of cotton. Tartaric acid was used as a coreactive additive with citric acid to improve both the textile performance and whiteness imparted by this durable press agent.

Shattering strength → Bursting strength.

Shaving An alternative term for → Emerizing, i.e. a mechanical treatment of loomstate woven cotton fabrics containing a high proportion of husks with fine-toothed blades or emerizing rollers.

Shear force In the case of textile fibres and fabrics, the effect of forces acting at right angles to their longitudinal axis.

With the Kawabata Evaluation System (KES-F-1) for assessing the handle of textile fabrics, a fabric specimen can be gripped by means of two clamping devices (spaced 5 cm apart) with the threads in parallel alignment (Fig. 1). During the test, the front clamping device is released by a coupling so that a pretensioning force is applied to the specimen. A shear deformation is produced by parallel displacement of the rear clamp through a shear angle of ± 8°. Three cycles are allowed to proceed in order to obtain a complete shear angle curve. During the measurement, the rear clamp is displaced relative to, and parallel to, the front clamping device at a rate of 0.417 mm/s. If a shear angle of + 8° is reached, the direction of movement of the rear metal block is automatically reversed and the test specimen relieved of stress up to 0° distortion. It is then subjected to distortion in the opposite direction up to a maximum angle of – 8° and relieved of stress once more.

Three parameters for the shear-elastic characteristics of the test fabric are read off the recorded curves (Fig. 2):

1. Shear stiffness (rise in shear stress/shear angle curve); G [N/m].
2. Spread of shear hysteresis at a shear angle of 0.5°; 2 HG [N/m].
3. Spread of shear hysteresis at a shear angle of 5°, or 3° for knitted fabrics; 2 HG5 [N/m] resp. 2 HG3 [N/m].

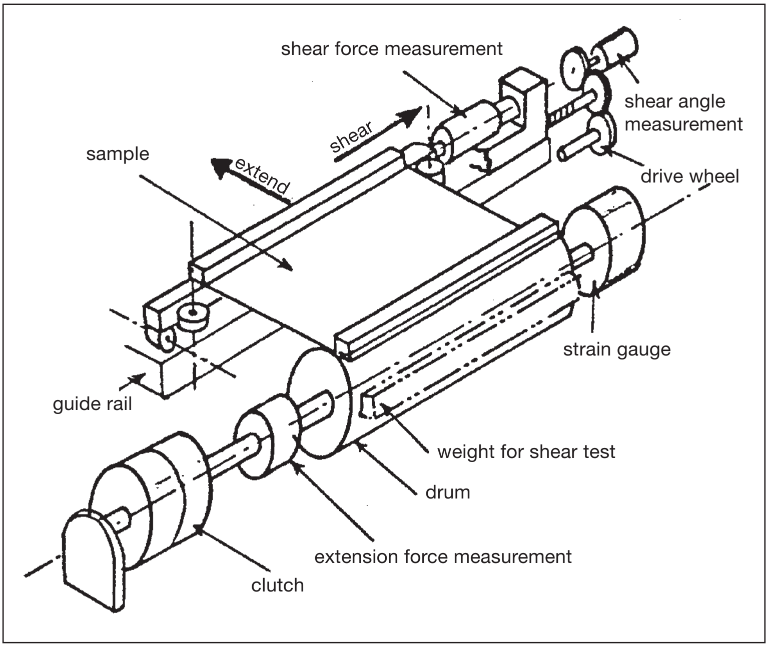


Fig. 1: A testing device for both tensile and shear elastic poperties (KES-F-1).

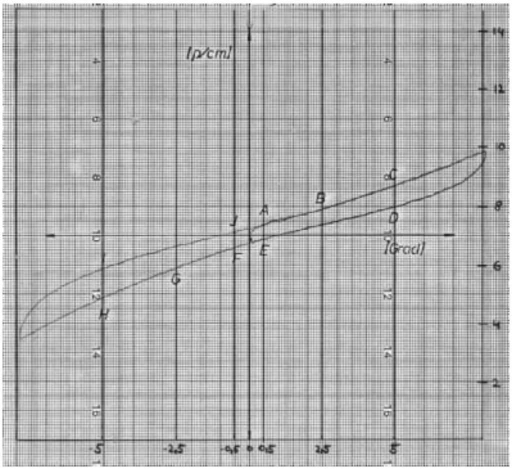

Fig. 2: Shearing stress curves.

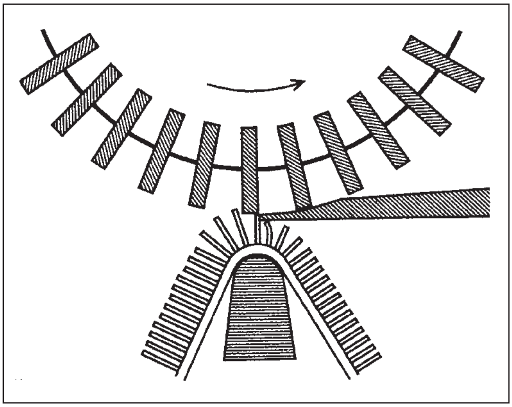

Fig. 1: A greatly simplified diagram showing the shearing process. The pile fabric is guided across the shearing table and is sheared between the shearing blades mounted on a cylinder (wrongly known as spiral blades) and a fixed blade.

The shear stiffness and the shear hysteresis at a shear angle of 5° are taken as a measure for the mobility of the yarns when sliding over one another.

Shearing (cropping). Unlike cutting (→ Cutting in textile finishing), shearing produces a characteristic finish on textile fabrics (Fig. 1). The extent to which a particular fabric is sheared varies according to requirements, e.g.:

- light shearing: e.g. pretreatment of grey cotton fabrics,
- normal shearing: close cropping of light fabrics,
- heavy shearing: e.g. shearing of velour pile or knitted loops.

Shearing usually involves a number of cuts (e.g. twice on the right and once on the left).

The fine projecting fibres present on the surface of flat fabrics may also be removed by cutting, i.e. by shearing, instead of singeing. In addition, the irregular fleecy layer formed during raising treatments has to be trimmed (sheared) to a uniform height. The shearing of

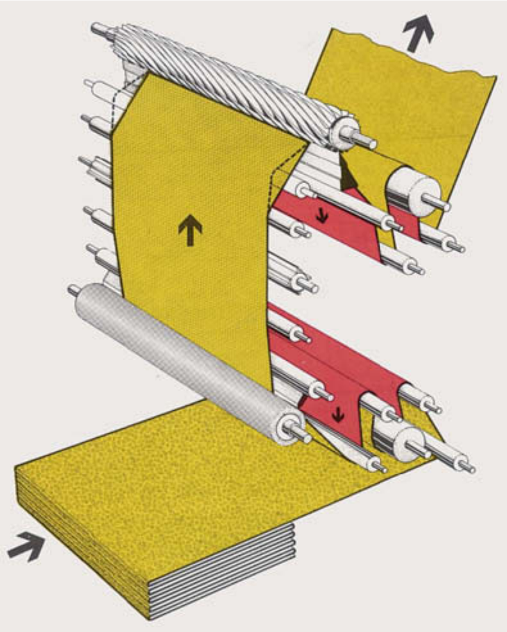

Fig. 2: A Lamperti shearing machine.

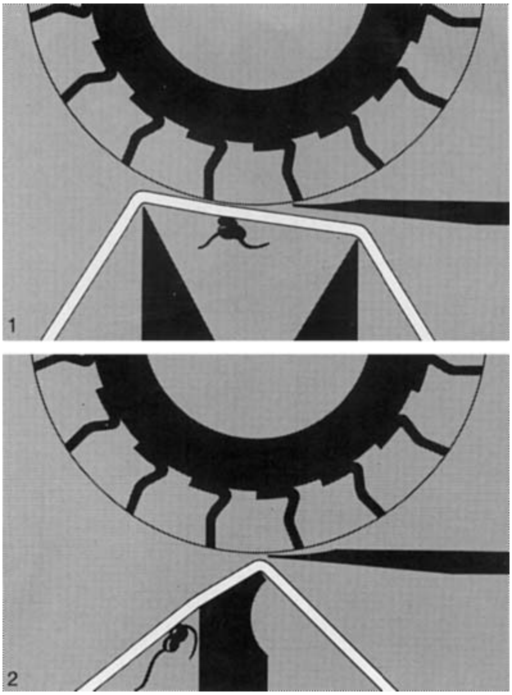

Fig. 3: Types of shearing table (according to Vollenweider): hollow table (1) and pointed table (2).

dry, or occasionally slightly dampened, fabric is carried out on machines with rapidly revolving cutting blades (shearing cylinder) which have a similar action to a lawn mower (Fig. 2). In this operation, the fabric to be sheared is drawn between a shearing bed and the shearing device which consists of a shearing cylinder and a ledger blade. The shearing table may be pointed or hollow (Fig. 3). In modern machines, it is possible to switch from one type to the other.

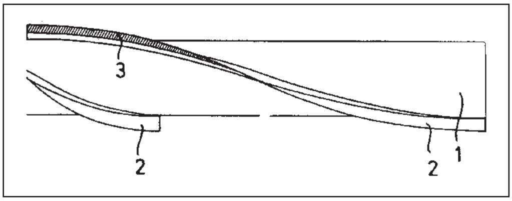

Fig. 4: A shearing roller with helical steel blades (2) and file profile (3) (according to Heusch).

The shearing roller has 24 helical steel blades around its circumference (Fig. 4). The distance between the shearing device and the shearing table is adjustable so that it can be adapted to the thickness of the fabric and the depth of cut required. One or several shearing devices may be provided depending on the particular type of shearing machine. They are arranged in such a way that both sides of the fabric can be sheared at the same time. Rotating brushes are installed both in front of, as well as behind, the shearing device to align the fibres correctly for shearing and remove cut ends after shearing. For velour qualities, a card wire brush roller (velour lifter) is used instead of a normal brush roller. In order to prevent the shearing device heating up during operation, a felt saturated with oil (lubricating felt) is placed against the shearing cylinder. Seams must not be allowed to pass under the shearing device otherwise they would be cut open. For this reason, either the shearing device is raised or the shearing bed lowered before the seam reaches the shearing point. This function is controlled automatically on modern machines by means of a seam detector. Where high productivity is required, several shearing machines are often run in tandem as a continuous production line. This procedure allows both sides of the fabric to be sheared. In some large plants, raising machines and shearing machines are combined in a single production line.

For the finishing of long-pile materials, combined polishing/shearing machines are used. The polishing effect is produced by means of a heated rotating cylinder (pile rotor). With certain structured materials, e.g. curtaining fabrics, the floating warp and weft threads have to be cropped. Suitable shearing machines for this purpose are equipped with a special system to align the threads by means of compressed air. Special models have also been designed for knitted fabrics. In order to cut longitudinal patterns in the pile, Vollenweider has substituted the fixed shearing bed by one composed of metal leaves. Depending on the position of the latter, the shearing knives will only come into contact with the pile in specific areas. In addition to these so-called longitudinal shearing machines, transverse shearing machines are also available. The axle of the shearing cylinder runs parallel to the warp and direction of the running fabric. These machines are regarded as somewhat antiquated. Specially constructed shearing machines are now available for shearing patterns in the material.

The shearing cylinder generally consists of a thick-walled hollow cylinder with a bearing journal firmly inserted at both ends. For small diameter cylinders, however, solid steel cylinders are usually employed. Depending on the particular design, the cylinder has 10–24 or, in the case of carpet shearing machines, up to 40 spiral blades mounted around its circumference. These are attached to the ends of the cylinder with screws in side recesses. The shearing cylinder must not be unbalanced in any way nor should there be any eccentricity in running, otherwise a uniform shearing action can no longer be ensured. The speed of the cylinder during shearing is between 500–2000 rpm depending on the particular article being sheared.

The cutting power of the shearing device is measured by the number of cuts per minute. This figure is obtained by multiplying the number of spiral cutting blades by the rpm of the cylinder. The “specific shear value” is given by the number of cuts per cm of material. It is obtained by dividing the cutting power by the fabric speed in cm/min. The specific shear value required depends in each case on the material to be sheared. In order to achieve the highest possible productivity for a given specific shear value, it is necessary to set both the cylinder speed as well as the fabric speed as high as possible. There is an upper limit to this, however. If the cylinder speed is set too high, a so-called “spoke-wheel effect” occurs: i.e. with a spoked wheel, it is impossible to thrust an object between the spokes when the speed is too high. The same situation applies to fibres during shearing which, at excessively high cylinder speeds, no longer have sufficient time to pass between the spiral blades. The shearing result therefore becomes poor again beyond a certain cutting power due to the fact that the fibres are only turned over, not cropped, by the rapidly rotating shearing cylinder.

Shearing spirals are supplied by machine makers in sizes of 1.1–2.0 mm. They are made in a variety of profiles which include:

- bayonet spirals,
- angle spirals,
- cleaning spirals; breaking spirals,
- mortice spirals,
- U or double spirals,
- knee spirals,
- concave spirals.

Both the knee and concave spirals, as well as the cleaning and breaking spirals are in common use in shearing machines for cleaning and shearing of textile fabrics. In special cases, e.g. for shearing carpets, mortice spirals are also employed in sizes up to 4 mm. Depending on their profile, the spirals have different cutting or wedge angles. Thus, shearing spirals, in which the cutting edges run perpendicular to the cylinder axle, have obtuse cutting angles (> 90°). Spirals, in which the cutting edges run in a straight line diagonally to the cylinder axle, have acute cutting edges (< 90°): e.g. knee or mortice spirals. The concave spiral has an even more acute angle. It is bent in accordance with a specific logarithmic spiral (hollow-ground form), so that the cutting angle does not change during the course of shearing. This fulfils the requirements for constantly uniform cutting characteristics. The shearing force on individual fibres can prove more effective with an acute, well-ground cutting angle. Due to the acute cutting angle, the force supplied by the shearing cylinder acts across a narrow line at right angles to the longitudinal axis of the fibre. With an obtuse cutting angle, on the other hand, the same force is distributed over a greater surface area.

Secure seating of the spirals is extremely important for trouble-free operation of the shearing cylinder. The commonly used angle, knee or concave spirals are provided with an angled foot or support limb which is bent in such a way that it matches the curvature of the cylinder and always points in the opposite direction to the rotation of the cylinder in order to absorb the pressure forces which develop during the shearing of fibres. Because they are wrapped around the cylinder several times, such spirals already have adequate purchase. It is therefore sufficient to secure the spirals simply by means of end screws in the side recesses. For spirals having a narrow gradient, additional screws are used, spaced at regular intervals, in order to attach the foot of the spiral to the cylinder body. In all cases, a more secure seating of the spirals is achieved the more often or more steeply inclined they are wound around the cylinder. At the same time, however, the pitch angle and consequently the cutting angle, is also increased. This can be precalculated from the length of the cylinder and the spirals. The number of windings increases for small diameter cylinders, higher pitch angles, or longer lengths of cylinder. A spiral with a single turn around the cylinder has only one cutting point whilst one with two turns already has two, and so on. Nevertheless, each spiral makes only a single cut during one revolution of the cylinder. For spirals with a single turn, the cut runs once along the length of the ledger blade during one revolution whereas, for a spiral with two turns, each of the two cutting points is only displaced by half the length of the ledger blade, i.e. only one cut per revolution occurs in this case also. A greater number of turns, which may be obtained by increasing the pitch angle, does not therefore bring any increase in performance. A greater pitch or cutting angle still has the disadvantage that the fibres could more easily evade the cutting action under these circumstances with consequent impairment of the shearing effect. With higher cutting angles, the effective cutting force perpendicular to the cutting edge of the ledger blade decreases in favour of the displacement force which acts parallel to the edge of the ledger blade (Fig. 5).

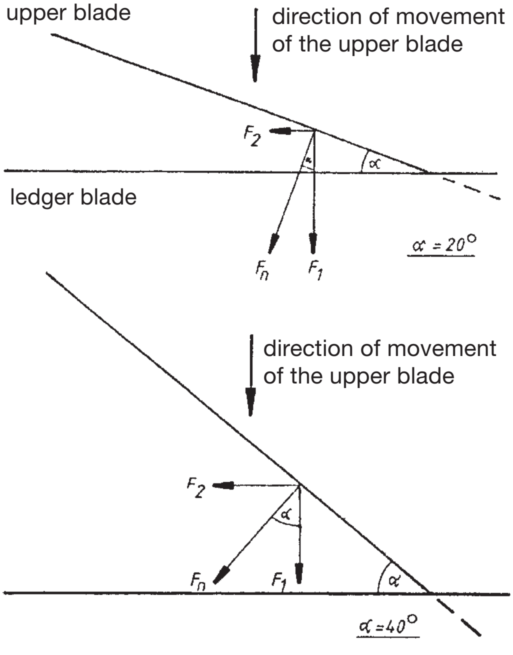

Fig. 5: Cutting and displacement forces during shearing.

During perpendicular movement of the shearing cylinder against the cutting edge of the ledger blade, the normal force F_n which runs perpendicular to the cutting edge of the upper cutting blade is effective. F_n is equally great at all points along the cutting edge of the upper blade. This force is made up of two components, i.e. the cutting force F_1 (perpendicular to the edge of the ledger blade) and the displacement force F_2 (perpendicular to the cutting force and therefore parallel to the cutting edge of the ledger blade). The application lines of F_n and F_1 include the angle again. If the pitch angles or cutting angles are known, the respective ratios of the sizes of F_1 and F_2 may be calculated as follows:

$$F_1 = F_n \cdot \cos \alpha$$
$$F_2 = F_n \cdot \sin \alpha$$

Since the value of F_n is equally great in both cases, it can be said that F_1 and F_2 behave like the cosine and sine of the pitch angle. The frictional forces between the cutting edges of the upper blade and ledger blade and the fibre, as well as the stiffness of the fibres act against the displacement force (Fig. 6).

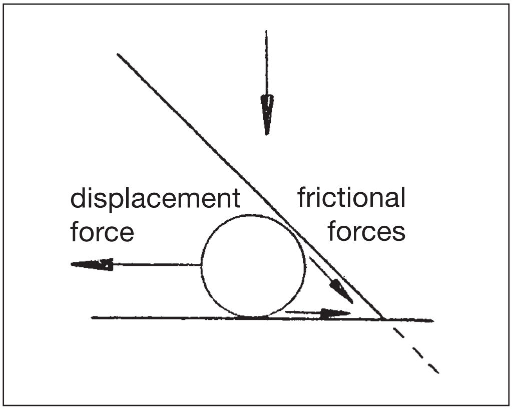

Fig. 6: Opposing forces during shearing which arise because of friction of the fibres and stiffness of the fibres.

Since the frictional forces are, among other things, also dependent on the pressure of the interfaces on one another, they become more effective the higher the cutting force perpendicular to the cutting edge of the ledger blade, i.e. the flatter the pitch angle. At the same time, the displacement force is smaller for a flatter pitch angle. Consequently, the pitch angle must be kept so small that the frictional forces reinforced by the cutting force are stronger than the displacement force. In the case of very soft and smooth fibres, such as cotton or fine synthetic fibres, the pitch would have to be so flat because of the low stiffness and low coefficients of friction, that firm seating of the spirals could no longer be guaranteed. In order to oppose the displacement force in such cases, the cutting edges are milled cut. Depending on the particular design of shearing cylinder, the spirals are secured to the cylinder body at pitch angles of 19–28°. Milled cut spirals with flat pitch angles are chiefly used for shearing low-pile fabrics such as velvet, knitted loop plush, etc. Smooth spirals are only used in shearing devices with a hollow shearing bed as well as for shearing lace and curtaining materials since, in this case, the teeth of a milled cut could scratch the surface of the material.

If the cutting edges have been produced with a milled cut, it is possible to mount spirals intended for shearing smooth and soft fibres at a higher pitch angle. Depending on how many milled cuts there are on the cutting edge of the spiral, a distinction is made between:

– extra coarse milled cut: i.e. approx. 7 milled cuts/cm,
– coarse milled cut: i.e. approx. 9 milled cuts/cm,
– semi-coarse milled cut: i.e. approx. 13 milled cuts/cm,
– semi-fine milled cut: approx. 15 milled cuts/cm,
– fine milled cut: i.e. approx. 18 milled cuts/cm,
– extra fine milled cut: i.e. approx. 22 milled cuts/cm.

The number of milled cuts is guided by the fineness of shearing and the thickness of the fibres to be sheared. Shearing spirals for shearing carpets usually have 9 milled cuts/cm; on the other hand, spirals with 18 or 22 milled cuts/cm are selected for worsted fabrics. As far as the shape of the milled cut is concerned, a distinction is made between milled cuts with a large milled cut spiral angle and those with a small milled cut angle. With the former type (conventional form), the fibres to be sheared slide first of all as far as the wedge-shaped serration where they are then cropped in tufts. In this process, it may happen that before reaching the wedge-shaped serration, the short fibres slip under the leading milled cut edge and are not sheared. Among those fibres that are actually sheared are some that may have had a longer slide path than those which reached the wedge-shaped serration at the outset. The quality of shearing is more uniform the shorter the slide path along the cutting edge of the ledger blade. Such a shortening of the slide path can be achieved with the aid of a finer milled cut or a higher pitch of the spirals.

With a milled cut profile having a small milled cut spiral angle (“patent milled cut” of Heusch in Aachen), the milled cut spiral angle is either 0° or it is kept so small that the frictional forces between the fibre and the cutting edges of the pair of blades are lower in every case than the forces of lateral displacement. The fibres are then cropped in their respective positions without sliding. A more uniform pile height is obtained in this way. Since it is generally only the wedge-shaped serrations that have a cutting function for milled cut profiles with a large cutting angle, and the surfaces of the serrations are hardly used for cutting, the extent of wear within the wedge-shaped serration may, under certain circumstances, be greater because the fibres gathered into tufts at this point require relatively higher cutting forces. With small milled cut spiral angles, the work of cutting is distributed over the entire milled cut wedge cutting area. Wear of the cutting surfaces is, therefore, more uniform and also less marked.

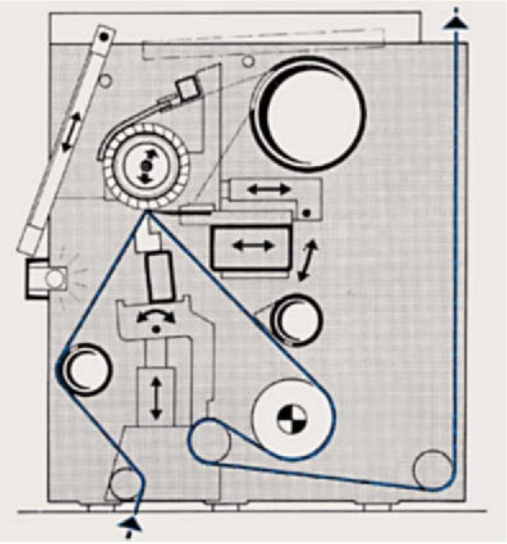

Fig. 7: A Menschner shearing machine.

The ledger blade is a 10–12 cm wide knife blade, 3–6 mm thick, corresponding in length to the width of the shearing machine (Fig. 7), which is ground on its underside for approx. 3 cm towards the cutting edge. In this way, an absolutely uniform contact surface between the cutting edge of the ledger blade and the fabric is achieved. On the side opposite the cutting edge, the ledger blade is attached by screws or clamps to the so-called blade carrier ledge on the ledger blade support beam. It is also important for the cutting angle of the ledger blade to be particularly small in order to obtain the cleanest possible shear. An acute cutting angle is obtained, on the one hand, by bevelling the leading edge by 15–45° depending on the type of machine and, on the other hand, by the hollow ground channel on the upper side of the blade. The greater the bevel of the leading edge, the more acute the cutting angle. An acute angle is more sensitive, however, and wears more quickly. In addition, such a cutting edge is more likely to overheat and burn out since it has a lower thermal capacity (less mass) than a blunt and thicker cutting edge. When the spirals of the shearing cylinder work against the ledger blade, the thinner cutting edge can absorb less heat of friction causing the temperature to rise more quickly. The size of the bevelling angle also depends on the design of the shearing bed. In all cases, the gap between the leading edge of the ledger blade and the shearing bed should increase in size towards the base. If this is not the case, fibre blockages can occur especially during the shearing of pile fabrics with a dense pile. In this case, the fibres already undergo bending prior to shearing and thus escape cutting. The hollow-ground upper channel is obtained by grinding with the shearing cylinder. For this purpose, the shearing cylinder is brought into such a position that the lowest point of the cylinder lies 2 mm behind the leading edge of the ledger blade. It is then allowed to rotate in the opposite direction to normal shearing at approx.

250 rpm and traverse to each side by 5 mm. By moderate pressure of the cylinder on the ledger blade with the addition of a suitable abrasive, it is allowed to work into the ledger blade until its leading edge has been ground to the required height (0.2–1.2 mm). The cylinder is then drawn forward again by 1 mm for shearing.

The hardness of the cutting edge must be uniform along the entire length of the ledger blade. Soft areas wear down more quickly during grinding and shearing so that thinner places develop in the ledger blade in these areas. This produces lengthwise stripes in the fabric during shearing. Since the cutting edge of the ledger blade generally exhibits a lower hardness than the spirals of the shearing cylinder, the wear is mainly at the expense of the former. This makes good sense, since it is less expensive to regrind a ledger blade than a shearing cylinder. During regrinding of the ledger blade, i.e. so-called whetting or sharpening, the shearing cylinder is lifted out of its bearings and, depending on the particular machine, the shearing bed is lowered. Alternatively, the shearing device is raised to allow free access to the ledger blade. A petroleum stone (i.e. a grinding stone moistened with petroleum) is then drawn along the leading edge of the ledger blade. In this process, the stone is applied in the same diagonal position as the original bevel of the ledger blade. This operation is continued until a fine burr has formed on its upper edge which may be detected by feeling with the thumb. After this, the shearing cylinder is lowered into its bearings again and the burr removed by rotating the cylinder in the shearing direction. If it no longer proves possible to produce a good shearing result by sharpening the ledger blade in this way, then the spirals themselves are blunt. In this case, it is necessary to regrind the entire shearing device.

Depending on the fabric, a pileless shearing as with milled cloth or a levelling of the cloth surface as with velvets might be necessary. The shearing task will mostly be conducted at the end of a finishing process. Only pile fabrics such as plushes, velvets, etc. are being sheared in greige state before dyeing. The shearing process influences the appearance of the cloth surface positively in such a way that hairiness of milled cloth such as flannels will be removed, thus avoiding the detrimental pilling effect, as well as providing an even pile appearance on pile articles like plushes, velvets or even milled cloth, blanket fabrics and so on, by levelling the cloth surface. Depending on the fabric to be sheared a shearing cylinder with 18, 20 to 24 spirals will be used. According to the fabric quality and the required shearing result, shearing lines enabling the shearing in several passages right and left are being used. For the finishing of pile fabrics such as plushes, fur imitations and blankets shearing aggregates combined with either a polishing cylinder or a table raising unit are in use. The table raising unit is used for raising and orientating the pile before shearing. The polishing cylinder with the electric heaters and four diagonal beater bars is needed for thermally stretching and arranging the fibres before the projecting fibre ends will be removed by shearing.

The Multicut MC-5 is a compact shearing machine which takes up little space and has short fabric passages, which does away with the familiar problem of edge curling in articles in which fabric tension is a critical factor. The newly designed, basic machine can handle both short- and long-pile articles. In order to avoid the notorious moiré effect especially appearing on low-pile fabrics as velvets, terry cloth, woven plushes, warp knitted velvets, Velveton, etc. the arrangement of the shearing spirals on the shearing cylinder has been changed (Fig. 8). This newly patented shearing cylinder gives the possibility to achieve production increases of up to 100% in comparison to the still usable fabric speeds. The conventional execution of a shearing cylinder shows shearing spirals being fitted onto the cylinder in equal distances regardless of the number of spirals used. This symmetrical arrangement limits the fabric speed especially on velvets, plushes and other low-pile fabrics. An increase of the fabric speed results in an increasing periodic variation of the pile length (moiré) and an obvious visibility of the peaks of this periodic variation. The sheared fabric surface looks uneven and of inferior quality. The new development of the shear-

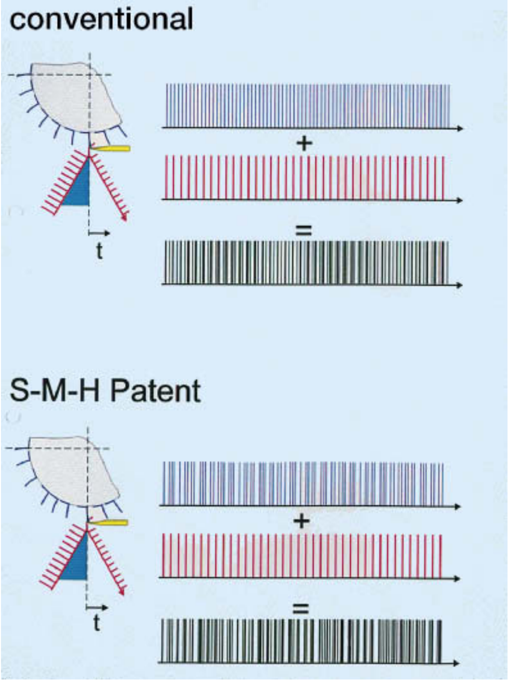

Fig. 8: Comparison of conventional and new shearing cylinders.

ing cylinder with asymmetrically arranged shearing spirals avoids the periodic changes by interrupting the uniform constant cut sequence of conventional shearing cylinders. The peaks of periodic variations are no longer visible, neither at considerably higher fabric speeds.

This new shearing machine is generally computer controlled. At the operating panel, just a fingertip is needed to start or stop production. Automatic adjustment of the shearing height, tension, fabric speed, felt lubrication, automatic fabric retraction at machine stops, e.g. the OP7 takes up all data and the MC-5 reacts automatically. Manual operation by single push buttons is, of course, also possible. The shear unit is within easy reach for regrinding. The felt lubrication is preselected via the OP7 and controls the oil supply and lubrication intervals even more reliably to protect the shearing tool and cut costs in terms of oil consumption. The speed or torque of the take-off roller including the folder can also be controlled to eliminate load alterations as a result of the folder movements, and thus an overstretching of the fabric or slipping of the roller. There are no separate switch cabinets but the electrical equipment is integrated into the side panelling. The fabric tension can be selected either via speed or torque control (for articles requiring different tensions or elongations). The dust extraction system has been revised in the shearing area in order to prevent soiling as much as possible. The drive of the cloth transport is effected by an AC drive. Steeples cloth tension regulation by potentiometer. Execution of the shearing cylinder according to requirements with 18, 20 or 24 spirals. Drive capacity of shearing cylinder 500–16 000 min-1 by AC drive. Rotational direction of shearing cylinder reversible for regrinding within the machine. Pneumatic lift-off of the dust extraction hood as well as shearing cylinder from working position for easy maintenance of the underknife. Shearing cloth rest as pointed, round, segment or roller type upon request. Steplessly adjustable shearing depth, legible from digital display. Mechanical oscillation of shearing cylinder. Safety cover at the shearing unit for accident prevention. Seam detecting unit for the automatic slowing of the shearing cloth rest, the pile lifting cloth rest as well as raising cloth rest. Pile lifting device with pointed cloth rest. AC drive for pile lifting roller. The rotational speed will proportionally be adjusted to a changing cloth speed. Further features are: Segmented cloth rest for the prevention of selvedge damages on worsted fabrics. Maintenance-free bearing of the shearing cylinder. Speedy exchange of shearing unit. Automatic device for quality control at initial cut. High cloth speed at optimum shearing effect by reinforced machine elements. At automatic processing the operation is effected only by means of on and off switch. High air flow at low energy consumption for the dust extraction. The storable programme control guarantees the precise control of all functions. Justomat for automatic adjustment of the shearing gap to the cloth thickness when shearing milled cloth.

Shearing blade A metal cylinder with 12–18 helical knife blades around its circumference is one of the key elements of a shearing machine (→ Shearing). The milled cut of the cutting blades produces an oblique shearing action so that any lateral yielding of pile fibres can no longer occur.

Shearing blades, grinding The ledger blade, which consists of a flat blade 10–12 cm wide, 2–3 mm thick, corresponding in length to the width of the machine, is ground on the underside approx. 3 cm towards the cutting edge. An absolutely uniform alignment of the edge of the ledger blade on the fabric is achieved by this means and the thin cutting edge of 0.2–0.4 mm is more easily obtained during grinding. The spiral blades of the shearing cylinder include straight, knee, and concave profiles. In the case of straight spirals, a right-angled cutting edge is formed by grinding to provide a contact surface for the edge of the ledger blade whilst a more or less acute-angled cutting edge is obtained with knee and concave spirals. The latter is more advantageous for shearing since their cutting performance lasts longer. Concave spirals are used almost exclusively in practice. Spiral blades are also produced with a so-called milled cut so that individual fibres are grasped and conducted more readily to the cutting zone of the shearing device. Milled cut spirals are more suitable than smooth cut spirals for the shearing of fabrics composed of 100% synthetic fibres as well as their blends. Synthetic fibres are harder and smoother than wool fibres and evade the cutting zone more easily if smooth cut spirals are used. → Shearing.

Shearing brush A brush roller to prepare the fabric pile for shearing. A brush with a fabric adjusting device in front of each shearing cylinder to achieve optimum alignment of the fibres for shearing, i.e. a pile laying brush. The drive to each brush roller is provided with reverse gears and settings for forward, off and reverse. These rollers are covered with bristles or card wire in a spiral arrangement. Any cut fibres loosely adhering to the back of the fabric after shearing are removed by beater rolls. In addition to a normal pile laying brush, a card wire brush may be installed before the 1st shearing cylinder for optional selection of either bristle or card wire brushing as demanded by the particular fabric. For velour fabrics, a special velour device is also installed before the 1st shearing cylinder with pile height adjustment as well as a pile laying brush. A brush roller, running in the pile direction, is also installed after the final shearing cylinder. All brushes and pile laying devices are connected to a suction extraction system for the effective removal of fibre dust and cut fibres.

Shearing height adjustment The shearing height on a → Shearing machine is the distance between the shearing device (shearing cylinder and ledger blade)

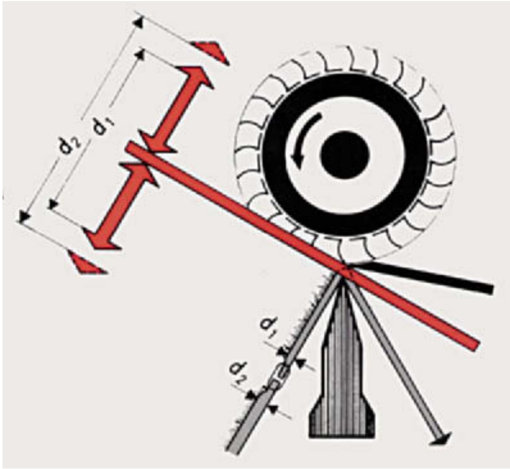

Fig.: Textiles of differing thicknesses (d_1 and d_2) require different shearing height settings in order to achieve the same shearing height.

and the shearing bed (see Fig.); this distance can be varied by adjusting the height of the shearing bed relative to the cutting blades in accordance with the thickness of the fabric. Some modern shearing machines have a thickness measuring device which accurately scans the thickness of the fabric which allows the extra thickness of a seam to be recognized and defined. The fabric speed is reduced to a constant value in order to lift the relevant treatment devices exactly at the seam point. After a seam has passed through the shearing zone, the production speed is automatically increased to the set value again. The thickness measuring device also provides an automatic shearing height adjustment at the same time. The given set value is readjusted and kept constant according to the fabric thickness. Manual adjustment of the shearing gap is therefore unnecessary when processing different articles and fabrics of different thickness.

Shearing machine (cropping machine) → Shearing is carried out with one or several shearing cylinders accommodated one behind the other in older shearing machines. In more modern machines, on the other hand, the cylinders are often mounted one above the other. The steel spirals of the shearing cylinder are usually in the form of concave spirals with either a smooth or a serrated (so-called milled cut) edge. In many cases, both smooth cut and milled cut spiral blades alternate with each other. Milled cut spiral blades have proved particularly suitable for blends with synthetic fibres since the smooth fibres are gripped more readily by the notches and cannot evade the cutting action in the shearing zone.

Two factors, above all, influence the quality of the shearing result in practice: the spread angle of the fabric in the region of the shearing bed and the cutting power of the shearing device during the shearing operation. A faultless shearing effect can only be achieved when these two factors have been optimized. The importance of these two factors becomes apparent whenever real cutting power is demanded, e.g. in the shearing of velour, velvet and similar pile fabrics. Experience has shown that the best results in close cropping are achieved when the specific cutting power is 18–24 cuts per cm. For velour and velvet fabrics, on the other hand, decisions relating to the number of shearing passages required have to be taken on a case to case basis. In general, the shearing of these materials is carried out at slower speeds and with more passages than is required for close cropping, with the depth of cut being adjusted progressively.

Shearing machines are generally quite sophisticated. Improvements to one model or another are perhaps still possible if a) the diameter, width and material quality of the shearing cylinder bearings are more favourably designed, b) if the bearing lubrication and heat dissipation are further improved and c) if the dimensions of the shearing cylinder itself are fully optimized.

Shearing machine circular-knit pile fabric A suitable single-cylinder shearing machine is necessary as a special machine for finishing circular-knit pile fabric. The shearing machine, model HPS, manufactured by Broma, was developed specifically to meet the requirements of elastic warp- and circular-knit pile fabric (Fig.). The final appearance of circular-knit pile fabrics after shearing is determined, first and foremost, by the quality of the shearing device. For this reason, the shearing cylinder in the HPS shearing machine has been designed as a particularly stable unit. This shearing cylinder is carefully balanced both statically and dynamically which guarantees vibration-free running both in the lower speed range for grinding as well as at high working speeds. Robust journals and bearings for the shearing cylinder provide increased reliability of concentric running during continuous operation as well as after frequent dismounting and re-installation. The spiral blades of the shearing cylinder have a milled cut. As a result, the fibres in circular-knit pile fabric are securely gripped and guided to the cutting zone. Sufficient clearance between the spirals ensures that the fibres of the elastic knit loop plush can be aligned with greater certainty. In this way, a maximum number of “sleeping” loops are gripped which reduces the shearing loss to a minimum.

The HPS shearing machine operates as a single shearing unit with a fixed shearing cylinder and a pointed shearing bed which can be lowered. A seam detector monitors seam passages so that the shearing bed is lowered at the appropriate time whilst the shearing cylinder remains in functional mode. This protects the shearing device. A high suction effect is achieved in

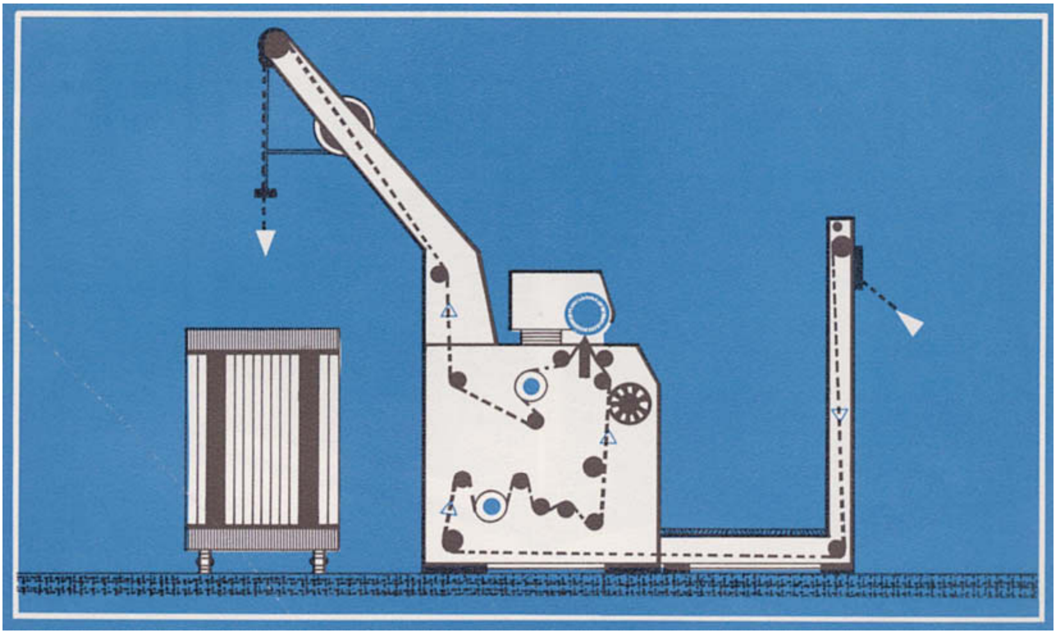

Fig.: Shearing machine circular-knit pile fabric HPS by Broma.

the HPS shearing machine which produces a better alignment of the fibres for shearing and reduces the deposition of shearing lint in the cylinder. In this machine, therefore, the application of suction not only serves the purpose of dust extraction but also assists in the shearing process at the same time. A direction reversing device makes it easier to check the shearing height at the beginning of a shearing run. Consequently, the shearing effect can be checked from the outset without any fabric loss. The fabric speed is adjustable over a wide range. The built-in hydraulic system ensures effortless raising of the shearing cylinder, e.g. for periodic grinding of the easily accessible ledger blade.

Shearing machine for knitted loop plush → Shearing machine for circular-knit pile fabric.

Shearing range A production line consisting of several shearing machines arranged one after the other for continuous → Shearing. This is a much more productive alternative than the batchwise shearing of fabrics which would otherwise require several passages on a single machine.

Shear properties of dispersions In contrast to simple (Newtonian) liquids, the rheological behaviour of dispersions containing solid particles is, in many cases, dependent on the nature of the shear stress to which they are subjected. During processing, dispersions are subjected to a wide range of shear gradients in flowing,

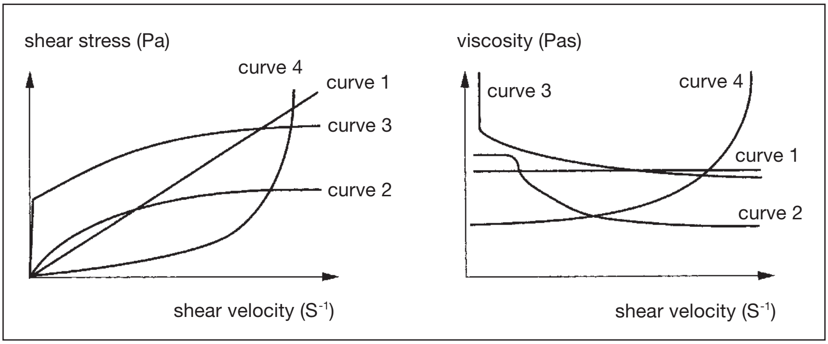

Fig.: The fluid properties and viscosity of different liquids exposed to shear stress (according to Burg and Jeschke).
Curve 1 = Newtonian liquid;
curve 2 = structurally viscous liquid;
curve 3 = plastic liquid;
curve 4 = dilatant liquid.

agitation, pumping and sieving, which is why rheological investigations have been carried out over rates of shear ranging from 10^{-1} to 10^4 m/s. High shear forces are encountered, above all, during the application of dispersions in spraying by rotor damping, so that a high resistance to shear is an essential property of dispersions suitable for this type of application (e.g. softeners).

The Fig. illustrates the theoretical progression of flow properties and viscosity for various liquids subjected to shear stress (→ Rheology). Dispersions often exhibit structural viscosity or pseudo-plastic flow properties. A decrease in the viscosity of such dispersions occurs with increasing rates of shear. Dispersions may also be subject to flow limits which become manifest by the need for a certain quantity of ultimate shear strain (force/friction surface) to be overcome first before the dispersion begins to flow. In this case, the dispersion is said to exhibit plastic flow properties. If, on the other hand, the viscosity rises with increasing rates of shear, the dispersion is said to exhibit dilatant flow properties. This property, which is undesirable in practice, occurs especially in dispersions with a high solid content. In addition to the viscosity behaviour which is dependent on shear-rate, an additional time-dependent flow property, e.g. as in thixotropy, has been established in some cases. The cause of this phenomenon is due to the application of too low a rate of shear in establishing a state of equilibrium as, e.g. in the formation of, or changes to, ordered structures during measurement (according to Burg and Jeschke).

Shear rate → Rheology.

Shear, to Trimming the pile loops of knitted plush fabrics by → Shearing.

Shear viscosity The → Viscosity of a liquid under a specific shear stress (→ Rheology).

Sheath core structure → Covering layer.

Sheathed thermocouples Thermocouple sensors encased in a protective outer steel housing suitable for installation in textile driers or thermofixation units (Fig.).

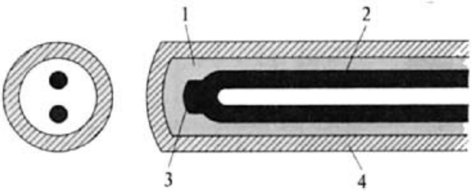

Fig.: Section through a sheathed thermocouple from Philips. 1 = insulating material; 2 = thermocouple wire; 3 = soldered joint; 4 = steel sheath.

Sheath layer fibres → Skin fibres.

Shed The path across the warp in a loom or weaving machine formed when some of the warp threads are lifted by their harnesses whilst others are left down or depressed during weaving to allow the insertion of weft (filling) threads by a shuttle or other picking mechanism.

Sheep's wool The fibrous covering of a sheep classified according to breed and origin (region of cultivation). According to the German TKG (Textilkennzeichnungsgesetz = Textile Labelling Act), only the → Wool from sheep may be described as wool. Wool that is shorn from sheep bred exclusively for wool production represents a more or less coherent → Fleece.

Sheet-dye process (slasher-dyeing process) A conventional continuous dyeing process for the dyeing of cotton warp yarns in open-width form, chiefly with indigo. The main disadvantage is that the process has to be interrupted if just a single end break occurs. For this reason, the → Long-chain dye process is often preferred in practice. In order to eliminate this particular disadvantage, an alternative double-sheet dyeing process, with at least two superimposed open-width warps, is often used. A more uniform liquor uptake is achieved due to the thicker double layers of warp threads.

Combined slasher sizing and dyeing has also been employed for the application of azoic coupling components (naphthols) to cotton warps for subsequent development with a diazo compound after weaving in order to produce warp-dyed effects.

Sheets Special sheets made of nonwoven material (cellulose, polyester) or polyurethane foam used as a support medium for impregnation with active substances, e.g. softeners. They are used as → Tumbler finishes.

Shellac A natural resin secreted by a scale insect Laccifer lacca (Coccus lacca) and deposited on the branches of trees in India. After collection, washing and purification by melting and filtering, it is formed into thin sheets which are later fragmented into flakes of orange shellac. This may be dewaxed and bleached to a transparent product. Commercial grades: (1) orange, TN (impure), fine, superfine, heart, superior and (2) bleached and dewaxed (colourless). Shellac is much tougher than other natural → Resins and has a melting point of approx. 100°C (115–120°C according to other sources). Molten shellac has a typical resinous or turpentine-like odour. It is sometimes adulterated with other resins or colophony. The development of a red-violet colour on addition of a few drops of acetic anhydride and conc. sulphuric acid to a sample of shellac indicates the presence of colophony. Solubility: shellac is soluble in 90% boiling ethanol (a wax-like separation occurs on cooling), the solution is turbid and possibly gelatinous; solubility in ether is 10–18% (a higher solubility = adulteration); if the shellac is of pure quality, an almost clear opalescent solution is obtained on boiling 10 parts of shellac with 5 parts of sodium tetraborate and 200 parts of water. Prolonged storage has an unfavourable influence on the solubility of shellac (especially bleached shellac). Storage under water is favourable. Shellac is soluble after partial saponification in alkalis and borax solution with a (red-violet) colour. Density of shellac = 1.035–1.14; saponification value = 185–225. Use: basis of some special finishes, leather finishing, wax and leathercloth, calico printing, oil sizes, (spray) paints, varnishes, Indian inks, etc.

Shell roller Besides solid copper rollers, on the surface of which a design is engraved by etching to facilitate transfer of print paste to textile fabrics in roller printing, so-called "shell" rollers are also used. Shell rollers are made by the electrodeposition of a 2–10 mm thick layer of copper on to a cast iron or steel cylinder. Shell rollers have also been made by pressing a 10–15 mm thick copper shell on to a steel cylinder. Two end pieces, 200–250 mm in length, are normally sweated into both ends of the cylinder to achieve the required taper and locating tab for the mandrel. Apart from their overriding cost advantage, shell rollers have a number of disadvantages compared to solid copper rollers, e.g. they are less durable, more prone to accidents and are less easily repaired when damaged. Moreover, unless the deposit of copper is fairly thick, they cannot be turned off and used again for another design.

Shepherd's check A small check effect which may be in black and white or in contrasting colours. The check effect generally consists of groups of 4, 6 or 8 yarns of the two colours in even-sided twill weaves, usually 2/2 twill. The term, shepherd's check, probably originates from the plaids worn in former times by shepherds in the hills of the Scottish borders ("pepita" is an alternative term used in Germany and Austria for shepherd's check). Shepherd's check is produced in cotton, wool, silk or man-made fibres. A dogstooth or → Houndstooth check is a particular variety of shepherd's check effect.

Shetland,

I. Originally, the term "Shetland" was a mark of origin for a yarn spun by hand exclusively from the wool of sheep bred and reared in the Shetland Islands. The wool from the Shetland sheep is particularly fine and imparts a soft handle to the textiles produced from it.

II. Currently, the term "Shetland" is applied loosely to all medium to coarse carded yarn fabrics produced from fairly coarse wool qualities (roughly equivalent to C quality), usually with a twill weave construction and a light to medium melton finish. The weave structure should still be recognizable after finishing; generally mottled, i.e. wool-coloured. The shades are principally mottled grey over blue and reddish brown. In general, Shetland fabrics are largely insensitive to creasing and have good resistance to rubbing and abrasion. Occasionally, worsted yarn Shetlands are encountered which are given a smooth finish. Uses: men's jackets, light to medium weight between-season coats as well as winter coats in the form of double cloth; lighter weight qualities are also used for women's jackets, costumes and coats.

III. Where the term "Shetland" is qualified by adjectives such as "genuine", "pure", "real", or any description with a similar meaning, this implies that the wool has actually originated in the Shetland Islands.

Shibori technique A Japanese tie dyeing technique similar to the old → Kasuri method. It differs from the latter, however, by stitching gathers into the woven fabric, either completely or with intermediate spaces before dyeing, often using repeated overdyes and/or resist dyes to achieve a multitude of elaborate patterning possibilities. The final designs include attractive white resist effects. Uses: dresses, kimonos, scarves, shawls, upholstery. The process is carried out in small Japanese factories specializing in this particular technique. Shibori is similar to the Malayan and Indonesian → Plangi.

Shiner picks → Shiners.

Shiners Alternative terms include: shiner picks, tight picks, tight weft (filling) threads, tight ends, fiddlestrings. A shiner is a warp or weft thread, usually consisting of a continuous man-made filament yarn with a higher lustre than its immediate neighbours in a woven fabric. It is a common defect in woven fabrics and is almost exclusively due to a particular thread being overstretched so that it lies more tightly in the fabric structure and exhibits an increased lustre. Causes: cross-sectional variations in individual filaments due to localized differences in drawing, damage by deformation, variations in yarn twist, variations in air humidity during processing, etc. Since the dye affinity of shiners usually differs from that of the normal adjacent yarns in a fabric, uneven dyeings are inevitable.

Shingosen fabrics A Japanese term for "new synthetic fibre" which specifically applies to polyester microfibres with silk-like characteristics used in womenswear. Finishing involves subjecting the polyester material to an alkaline weight loss of 3–5% by the pad-steam process in order to obtain super microfibre products, i.e. fibres with a linear density of approx. 0.1 dtex.

Shiraz carpets Contrary to expectations, Shiraz carpets are not produced in Shiraz itself but in the whole Fars area of which Shiraz is the capital. The various carpets known by this name are, in fact, woven by different nomadic tribes who have lived for centuries on the Fars tableland. The bazaar in the town of Shiraz is the trading centre for these carpets.

Ground looms are used even for those carpets woven by semi-nomadic people living in small Fars communities. The warp and weft are executed in wool except for some types woven by semi-nomadic people who use cotton. The weft can be either single or double, according to the particular tribe, but the pile is always produced with wool. Some tribes use the Persian knot whilst others use the Turkish. In both cases, the number of knots per unit area varies considerably, e.g. 100 000–250 000 knots/m^2. It is however, impossible to be precise about the average knot density of Shiraz carpets because the quality varies enormously from tribe to tribe. The best qualities are those woven by the Arab and Basiri tribes, which are also known as Shiraz Extra.

Shiraz decoration is typically nomad. The motifs are simple and geometric, executed in bold straight lines and bright colours. The most common motif, and one by which a Shiraz carpet may be identified, is a single diamond-shaped lozenge in the centre of the carpet or repeated along the length twice or three times according to the size. The diamond shape is usually light or dark blue and the field is almost always red and decorated with stylized plant motifs.

Shiraz gum → Asiatic gums.

Shirley Institute A well-known British textile research institute based in Didsbury, Manchester, formerly the headquarters of the British Cotton Industry Research Assocation (BCIRA). The Shirley Institute was amalgamated with the Wool Industry Research Assocation (WIRA) in 1988 to form the British Textile Technology Group (BTTG).

Shirting A German term for a type of → Chiffon in the form of a plain weave semi-matt cotton or viscose lining material which is mainly dyed black or grey. It is starched and given a glaze finish. Finer qualities are similar to jaconet. Uses: furnishing fabrics, cloth-backed maps and bookbinding.

Shirvan carpets Provenance: the village of Shirvan is situated near the south-west shore of the Caspian Sea and the district of the same name in the southern part of Azerbaijan.

Technical details: The warp and weft is in wool in antique specimens, in wool or cotton in those woven between 1850 and 1920, and completely in cotton in modern examples. The pile is always in closely-cropped wool. The Turkish knot is used to give a knot density of 150 000–250 000 knots/m^2. Modern examples usually have a higher knot density than the older or antique ones. Shirvan carpets are woven in various sizes but are most commonly produced in small or long narrow shapes. As with other Caucasian carpets, Shirvans have a widely varied decoration which is similar to, but smaller than that of → Kazakh carpets.

Small Shirvan rugs are woven either in prayer rug or normal form. In both cases, the decoration is, for the most part, made up of a design composed of minute stylized diamonds and tulips or boteh motifs. Shirvan rugs are varied in colour. Usually the ground is a sober colour such as dark blue whilst the motifs are quite vivid. White is predominant in the borders.

Shives Short pieces of woody waste in flax which are almost entirely removed during the breaking and scutching operations involved in → Flax processing.

Shock catalyst A strongly acidic catalyst used in the application of resin finishes by the → Shock-cure process, e.g. certain organic acids such as citric acid, mixtures of metal salts of strong acids with complex-forming hydroxycarboxylic acids.

Shock cooling Rapid cooling, e.g. of dyed goods, or a more or less exhausted dyebath, by partially running the dyeing machine and adding cold water. Purpose: to control the temperature, e.g. when making further additions of dye for shading.

Shock cooling is also carried out after the heat-setting of synthetic fibres by impingement with cold air in order to stabilize the heat-setting effect.

Shock-cure process A variant of the → Dry crosslinking process; in this case, crosslinking is achieved by shock curing within a few seconds (20–60 s) either at high temperatures (170–190°C) with conventional resin finishing catalysts, e.g. magnesium chloride or, alternatively, at 140–160°C with so-called → Shock catalyst. Both the drying and curing stages are usually combined in a single pass through a finishing stenter.

Shock drying The shock-like drying of textile fabrics in jet drying (→ Jet driers).

Shock dyeing Rapid transfer of dye liquors into a dyeing machine.

Shock dyeing test A test for the evaluation of dyes and levelling agents in package dyeing. A yarn package of polyester fibres or filaments is heated to 130°C in a dyeing machine. Afterwards, the disperse dye liquor is transferred rapidly into the dyeing vessel and the dyeing process interrupted after 15 min. Samples of dyed polyester material taken from the inside – centre – outside of the package are then knitted into fabric samples to assess the uniformity of dyeing.

Shock filter cleaning Cleaning of clarification filters by a reduction in pressure or the agitation of flexible filter elements.

Shock freezing A process originally operated in Lowell, Mass., (USA) in 1935 which involved a shock-like cooling of wool textiles to between – 30 and – 45°C by spraying with liquid air or nitrogen until freezing occurs. The wool was then dusted vigorously to remove impurities. This process was developed for wools heavily contaminated with vegetable matter but is no longer of any practical importance.

Shock oxidation → Vat dyeings, oxidation of.

Shock setting Dry heat-setting of polyamide and polyester piece goods with hot air. This treatment is usually carried out on heat-setting stenters at high temperatures, e.g. by heat-setting the goods at 190–220°C for 5–20 s depending on the substrate.

Shock treatment E.g. shock bleaching, shock dyeing, shock curing, etc. These terms are commonly used to paraphrase short-duration treatments in finishing such as the direct introduction of fabrics without preheating into a treatment system already heated to maximum temperature.

Shoddy Fibrous material made in the woollen trade by reducing new or old knitted or loosely woven fabrics in the form of → Rags and thread waste to a fibrous state (graded as class I). It is a form of → Reclaimed wool having a staple length which is generally longer than that of → Mungo.

Shore hardness A hardness scale which is in common use internationally for vulcanized materials such as rubber as well as plastic rollers. Measurements are made with a hand-held tester in which the resistance of the material under test to the pressure exerted by a needle is read directly off a scale. This test has the advantage of being simple to carry out and is also suitable for testing rollers already installed in machines. It is, however, not altogether accurate. Measurements range between 40–100 Shore which can, however, represent different degrees of roller hardness for various makes of rubber. There is no correlation between Shore hardness and → DVM softness values. → Roller hardness.

Short bast fibres Cottonized bast fibres; → Cottonized flax.

Short-Cure-Process A 2-stage permanent-press finish. Stage 1: mild curing of finished fabric for a short duration at low temperature. Stage 2: final curing under severe curing conditions after the fabric has been made up into garments.

Short liquor In the sense of liquor with a low amount of liquid, e.g. 1 : 5. Opposite: → Long liquor.

Short liquor jets Waste water quantities and energy use are substantially decreased in dyeing in an exhaustion process using a short liquor-to-goods-ratio (FV).

Winch beck	FV 1 : 30
Short liquor jet	FV 1 : 6
Airflow	FV 1 : 3

Construction features of short liquor jets: In the Roto Stream system (Fig. 1), the cloth is transported over a winch and through the subsequent nozzle. The liquor level is extremely low. The cloth is outside the liquor. It is possible to increase the liquor level and rinse in the overflow however. The transportation of the cloth (feed) is eased by the freely turning, internal drum. The design, with controlled placing (= plaiter), allows a more even and consequently increased loading of the (plaiter) drum.

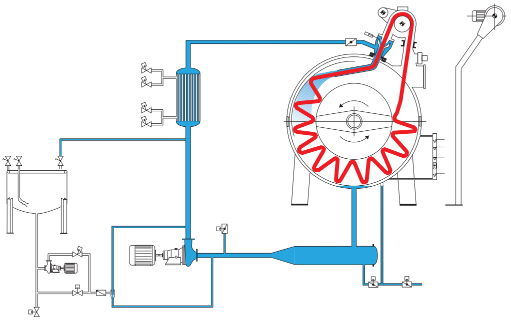

Fig. 1: Roto Stream (Thies).

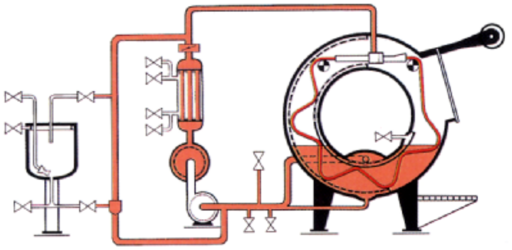

Fig. 2: Ring Soft (Thies).

In the Ring Soft system (Fig. 2) the material is transported via two winches and a wash section. This gentle fabric transportation is beneficial to critical items; the cloth is less roughened and not bobbly. The lowest liquor-to-goods-ratio is approx. 1 : 6. Increase to approx. 1 : 10 is possible. Rinsing can also be carried out in the overflow.

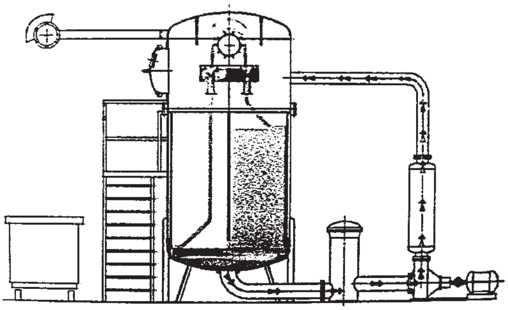

Fig. 3: Pandora (MCS).

Another method is pursued in the Pandora (Fig. 3). The jig technique is called to mind and work is carried out in the Pandora as follows: The cloth runs, driven by a large winch and an overflow nozzle, from one fabric storage tank to the other and back again. The liquor which flows in from the overflow nozzle runs through the cloth into the bath and is pumped to the overflow nozzle again. The cloth also dwells outside the liquor in this machine. The liquor-to-goods-ratio may be adjusted upwards from 1 : 4. It is possible to rinse in the overflow.

The cloth transportation is based on a new system in the Air Flow (Fig. 4). The drive is via a winch and across the strong air flow, in which liquor is injected. Winch speed and air flow are controlled. The cloth lies on a teflon grill outside the liquor and is sprayed with finely atomised liquor.

The liquor level can only be altered a little, as the

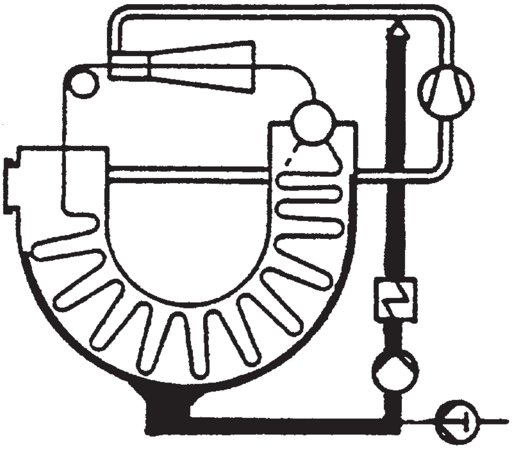

Fig. 4: Air Flow (Then).

cloth should not stand in the liquor or be covered with liquor. Running problems due to the higher weight and due to the resistance in the liquor would result otherwise. On the other hand a certain liquor level should be reached, as no injection circulation is possible if not. Rinsing in the overflow is not possible. Continuous rinsing with an open discharge valve (via extension vessel) is possible (according to Bacher).

Short liquor ratio dyeing Dyeing in accordance with the exhaustion processes in the short liquor-to-goods-ratio, in general 1 : 10 and below, brings the benefit of less water and energy consumption.

Short liquor ratio foam dyeing process Carried out in drum dyeing machines using suitable chemicals with addition of aqueous liquor in the form of foam for various use for all textiles (mild treatment, crease-free finishing) in the extremely short liquor-to-goods-ratio (1 : 1–2). Identical dyeings of good reproducibility result in all processes using conventional dyes. Lowering of water/energy costs, reduced dyebath additions, also reduced waste water quantities.

Short liquor ratio machine Generally have the following characteristics (Fig. 1):

I. Jet dyeing vats with
- winch or conveyor roller unit,
- winch with a nozzle connected downstream and transport stage or nozzle connected downstream, with compressed air feed and transport stage,
- accumulator with low liquor level or freely rotating rotor as a dwell zone or non flooded dwell chamber with stainless steel conveyor belt.

II. Overflow or jet machines with
- winch,
- winch with rinsing funnel or nozzle connected downstream and transport stage,

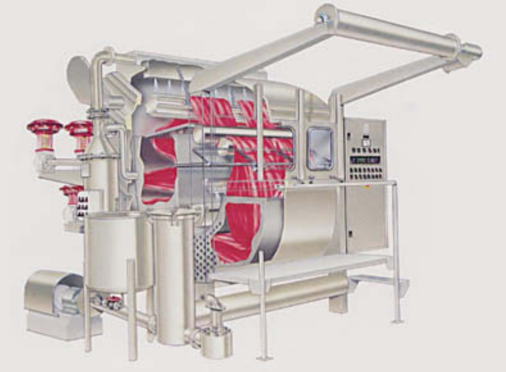

Fig. 1 : "Diplo" model short liquor ratio piece dyeing machine (Sclavos).

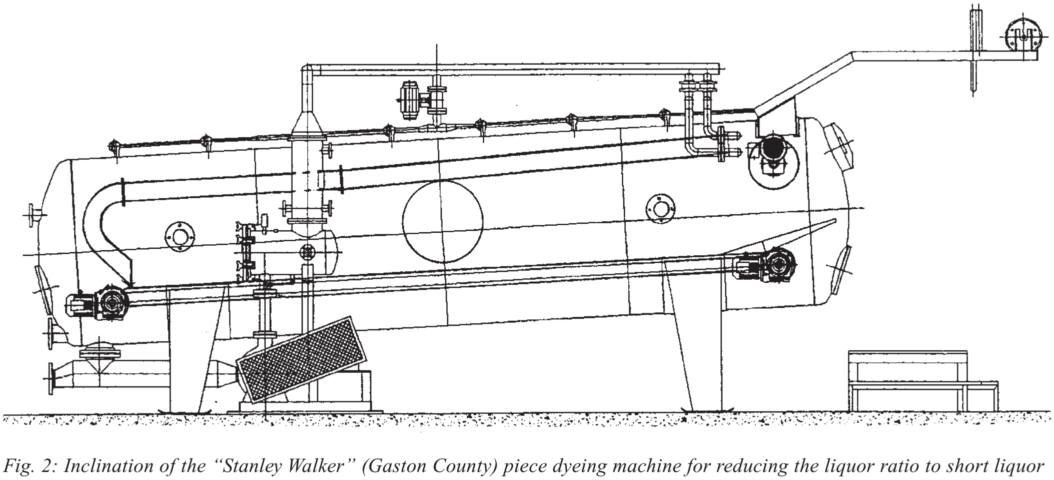

Fig. 2: Inclination of the "Stanley Walker" (Gaston County) piece dyeing machine for reducing the liquor ratio to short liquor level, with fabric transport on a conveyor system from the sump forwards.

- fully flooded storage tube, which guarantees even throughflow of the cloth in treatment liquor.

The smallest liquor-to-goods-ratio possible is approx. 1 : 8.

The horizontal construction (Figs. 2 + 3) accommodates the reduction of the liquor-to-goods-ratio. The dyeing in the bath is supported during rope dyeing by suitable plaiting down systems (Fig. 4).

The reduction in water consumption is to the fore in the short liquor technique; this not only applies to the reduction of the preparation liquors, but chiefly also to the decrease in rinse water quantities required. Solutions for short liquor technique offered by machine manufacturers have the following features:

- mechanical cloth transportation or combined nozzle/mechanical. Previously allocation of tasks varied between nozzle and roller (winch).
- fabric drum arrangement (dyeing vat) of the kind in which the cloth glides and is laid in folds in one place. In some designs, plaited cloth is moved forwards (Fig. 2). It is important to avoid fold formation for too long for most finished tubular knitgoods (removable by opening tube from time to time; mechanically, via liquor circulation or via blowing in air).

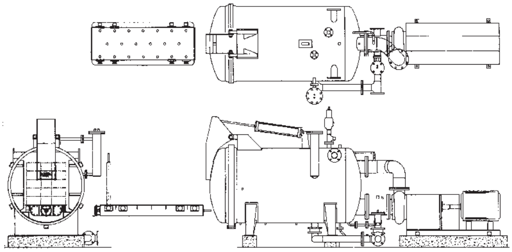

Fig. 3: Different perspectives of the HPD-2000 horizontal short liquor yarn dyeing machine system (Morton).

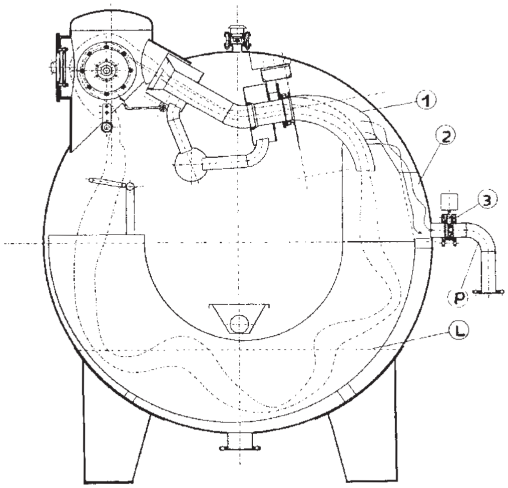

Fig. 4: "Microwash" system in an Apollon short liquor technique piece dyeing machine (Sclavos).
1 = fabric rope plaiting system with liquor bypass;
2 = Microwash drain; 3 = drainage pipe valve (P);
L = liquor level appropriate to short liquor ratio 5–7 : 1.

Advantages of short liquor technique:

- saving of water;
- saving of thermal energy;
- saving of chemicals (chiefly electrolytes, products for setting a particular pH, etc.);
- improvement in the dye yield (in some dye classifications; this means better reproducibility because the dyeing equilibrium is displaced in favour of the material);
- higher operational safety, particularly with regard to levelness.

This allows the process to be simplified or the heating-up speed and the pH-dependent process stages to be accelerated and also results in:

- reduction of dyeing time and/or
- decrease in the number of misdyeings because the number of corrections of faulty dyeings also goes down with increased operational safety and reproducibility.

Short-loop drier (festoon drier). Universal drying machine for delicate viscose fabric, for tubular jersey fabrics and for the gentle pre-drying of resin impregnated fabrics to avoid pre-curing and migration of the epoxy resin. Tension-free transport of the fabrics (see Fig.) in the form of short loops passing in continuous travel over vigorously vibrating rollers, producing constantly changing points of contact. The goods are subjected to air currents on face and back and the fabric is able to shrink without hindrance. If the loops of fabric are long, the term used is festoon drier.

Fig.: Short loop fabric transport of knitted fabric in a Tube-Tex festoon drier.

Short period dyeing technique Process for increasing productivity with the aim of reducing dyeing time to a minimum without jeopardising the levelling of the dyed goods.

Short period heat setting (shock setting), takes place on special stenters, on which synthetic fibres are thermofixed in seconds at very high temperature.

Short period steaming of vat dye → Flash ageing has great importance in the fixation in vat dyes in accordance with the two-phase process. Sodium dithionite and other suitable materials are used as reducing agents. Steam periods of 15–30 seconds. Most familiar machine designs are the flash-ager and the arch steamer (Benteler).

Short-ratio thickener Thickening agent with rheological properties, even at low concentrations, which cause it to run from a glass rod as individual drops, not smoothly in the form of a long strand (→ flow properties of printing thickeners).

Short steaming process → Reactive dyes in direct printing.

Shoulder padding Shaped inserts used as → Interlinings in men's and women's jackets and coats to confer a desired shape. Shoulder padding usually consists of wool or cotton wadding (often lined with muslin) and/or an expanded foam material resistant to dry cleaning.

The use of shoulder padding in garments is very much dependent on the dictates of fashion.

Shrinkage A negative change in the dimensions of textile products which involves a reduction in area (length and/or width) of a fibre, yarn, fabric or other textile due to the influence of various agencies, e.g. wetting, laundering, dry cleaning, etc. The total shrinkage potential of a textile material is a combination of several shrinkage mechanisms. →: Dimensional change of textiles; Compressive shrinkage.

Shrinkage effects A collective term for plastic effects on fabrics produced by localized → Shrinkage process.

The degree of shrinkage is influenced by the construction of the textile as well as the morphological characteristics of the participating fibres. Shrinkage takes place in relation to the external conditions involved in finishing (Fig. 1) or during subsequent use of the textile. Shrinkage is reversible and changes to extension on reversal (Fig. 2). Shrinkage is also a reaction to a previous extension of the material and represents a relaxation of the forces to which it was subjected in earlier stages of processing and which became fixed temporarily, either mechanically in the textile construction, or by physico-chemical mechanisms in the polymer structure. For relaxation to take place, enough energy has to be applied for these latent forces to be released. Machines designed to induce shrinkage must therefore apply mechanical as well as thermal energy in order to neutralize fibre/fibre adhesion by overcoming the frictional forces and other interactions between the polymer molecules such as hydrogen bonds, salt linkages and hydrophobic interactions. The relaxed, shrunken, state is then fixed in the material (albeit only temporarily) by re-formation of the linkages in the relaxed state. Some machines are better able to fulfil these conditions by the treatment of fabrics in rope form (Fig. 3) whilst others are specifically designed to achieve optimum

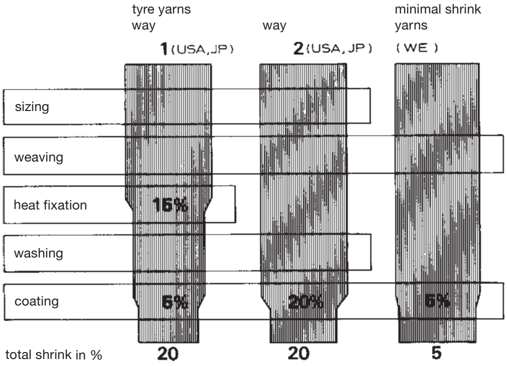

Fig. 1: The controlled shrinkage of different yarns in different finishing processes (by Akzo).

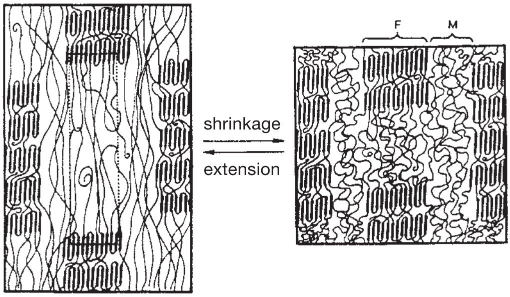

Fig. 2: Proposed model of the structure of synthetic fibres in a stretched and shrunk state by Berndt.
F = fibrils (molecules arranged in crystallized and non-crystallized layers); M = matrix (continuous molecule chains, only crystallized to a small amount).

Fig. 3: Henriksen shrink: a shrinkage drier for tubular knitted goods, which are transported into air jet shafts by drive rollers (2) and thrown against baffle plates (3) by hot air before residing for a period of time in the basket (7) during each cycle of the continuous process.

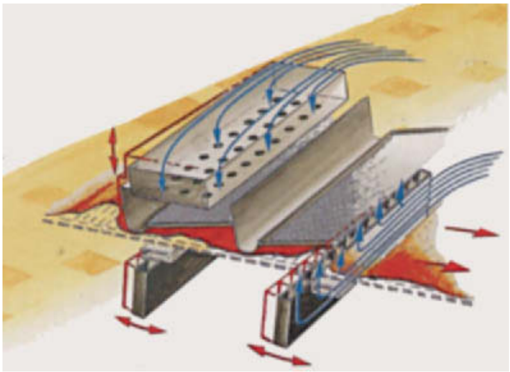

Fig. 4: Obermeier shrink: open-width goods lie on a carrier belt (broken line) and are lifted from below by backwards and forwards vibrating jet boxes while being pressed down from above by fixed jet boxes, resulting in the goods progressing in a sinus-like fashion.

Fig. 5: Controlled shrink between a hot cylinder (right) and thick rubber belt (black) (by Morrison).

shrinkage by treatment in open-width form (Fig. 4). In terms of machine concept, a distinction is also made between those machines where shrinkage of the fabric takes place in a fully relaxed state and those which involve a tight-strand passage (controlled shrinkage) through the shrinking zone (Figs. 5 + 6).

Shrinkage fibres Acrylic, polyamide, polyester or polyvinyl chloride fibres which have not been preshrunk are used for the production of high bulk type textured yarns (e.g. 18% shrinkage reserve) used in the manufacture of needled composites and (up to 40% shrinkage reserve) for artificial furs and similar products.

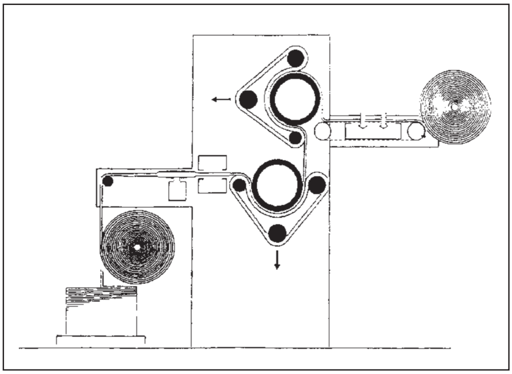

Fig. 6: Controlled shrink on a Sperotto-Rimar machine for cotton knitted goods.

Shrinkage measurement of knitgoods A variety of methods are used in practice, e.g.:

I. Wash test at 60°C as specified in DIN 53 892 and DIN 53 920 with subsequent drying: this procedure is used to simulate the dimensional changes which occur during laundering and subsequent treatment in a tumbler drier. Three representative test specimens are taken for measurement and allowed to condition under standard atmospheric conditions for testing textiles as specified in DIN 53 802 until equilibrium has been reached. The specimens are then removed and marked for measurement on a smooth flat surface in accordance with DIN 53 870. After the test procedure has been completed, the specimens are again allowed to condition before dimensional change is determined. In order to determine the sum of all shrinkage components, i.e. the overall shrinkage potential, it is necessary to carry out this test procedure repeatedly.

II. Wash test as specified by Marks & Spencer. This procedure deviates from the DIN standard test method with subsequent tumbler drying insofar as the underlying principle is based on imitating the shrinkage of a made-up garment and subjecting this test specimen to a laundering and tumbler treatment for the determination of shrinkage. The test specimen is allowed to condition again after the treatment before determining any dimensional changes in length and width between measuring marks drawn on the specimen before testing.

III. Weight/surface area method: this procedure is based on calculating the degree of shrinkage from the change in weight/surface area caused by washing. This method provides the finisher with a measure for the shrinkage stability requirements of a particular fabric in terms of shrinkage per unit area and average linear shrinkage. Test specimens of a specific surface area (A_0 = 100 cm^2) are taken from the fabric with a circular sample cutter. After washing, the weight G_1, without those parts of the test specimen removed by washing, is determined. This enables the weight per unit (FG) area of the test specimen before washing to be known, i.e. weight per unit area:

$$FG = \frac{G_1}{A_0}$$

In order to determine the weight per unit area after washing, a specific surface area ($A_2 = 50\ cm^2$) must be taken from the washed and shrunk test specimen and then weighed. Thus, weight per unit area after washing:

$$FG = \frac{G_2}{A_2}$$

The sampling procedure is explained in Figs. 1–2 as follows:

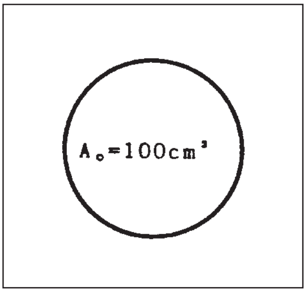

Fig. 1: Sample (A_0) of area 100 cm^2 to be measured before washing.

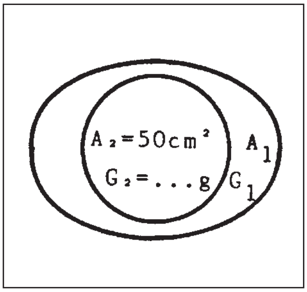

Fig. 2: Sample (A_1) after washing (approximately elliptically deformed) and the second sample (A_2) of area 50 cm^2.

The change in weight per unit area is given directly from the results of weighing the test specimens of specified size prescribed above:

$$FS\ [\%] = 100 - 50 \cdot \frac{G_1}{G_2}$$

The calculated shrinkage per unit area (FS) as well as the mean linear shrinkage (LS) appear as positive values. The mean linear shrinkage of a knitted fabric is defined as the linear change in length of a test specimen (contraction of elliptical axes). The mean linear shrinkage is the average of the elliptical contraction in all directions; it is a measure for the required stabilization of yarn in a knitted fabric:

$$LS\ [\%] = 100 - 10\sqrt{100 - FS}$$

IV. Determination of linear deformation: with this method, it is possible to determine the linear deformation after a test load quite independent from the fabric shrinkage. When circular-shaped knitted fabric specimens undergo a change in shape after application of a working stress, the circular form is transformed into an ellipse. This change in form provides evidence that a contraction or elongation has occurred which corresponds to linear deformation. The percentage elongation or contraction after a wash treatment is determined with the aid of a set of test stencils of 0–25% contraction, divided into 10 measurement ellipses. If the test specimen is smaller than the ellipses, then linear deformation is also accompanied by a degree of shrinkage. The change from a circular to an elliptical form, however, does not imply that the directions of courses and wales coincide with the axes of the ellipses. Deviations in the courses and wales are read off the ellipse axes in angular degrees.

V. In order to measure the geometrical changes in woven and knitted fabrics, markings are drawn on the fabric as described for conventional methods of shrinkage measurement and any change in their dimensions is determined after a treatment by hand. These measurements are, however,

- destructive,
- discontinuous,
- random,
- liable to subjective errors.

Evaluation of the applied markings provides, in each case, an average value of the number of loops per unit length. This raises the question as to how the shrinkage in individual loops can be determined with greater statistical reliability. Since no continuous measurement data is available for the measurement of shrinkage, the following sensors have had to be developed:

a) Measurement of shrinkage by image data processing systems: for this purpose, the light intensity profile of the individual loops is evaluated geometrically and, unlike conventional test methods, a local analysis is carried out. The loop structure of the optically detectable textile surface is described as a periodical process with highly superimposed coincidental variations. The measuring task of the system is based on freeing the fundamental period, i.e. the average loop width, from these variations. The Video Shrink Inspector VSI (Sick) represents a commercially available system based on this principle. This computer-controlled image data processing system analyses close-up images of the textile surface. The dyed knitted or woven fabric is guided loosely over a measuring head containing a miniature infra-red semi-conductor camera and a special stroboscopic source of infra-red illumination. An image section, measuring 2 x 2 cm is digitalized and stored in the computer with a resolution exceeding 250 000 pixels with 256 grey tones per image in each case. A correlation pattern recognition procedure determines a statistically assured mean loop length and width from the highly irregular fabric texture. This is converted into a dimensional change in length and width by comparison with a stored reference or with the results from an additional measuring head and is displayed within seconds to an accuracy of 0.5%. The actual image recorder is housed in a casing together with the illuminant source. A high resolution CCD matrix camera with 500 x 580 pixels is used as the image sensor. The CCD video camera has a high sensitivity in the near infra-red region. The material is illuminated with two infra-red radiators positioned at right angles to each other. These radiators emit 25 pulses/s which are of very short duration, so that sharp images can be captured even with a rapidly moving web of fabric. The times of measurement are sufficiently short to serve as a control parameter. The camera is adapted to the spectral characteristics of the illuminant source with the aid of a built-in infra-red filter. This largely excludes any influence of interfering stray light. A CCD camera provides images which can be resolved into numerous individual elements. Each of these elements can be detected, i.e. they can be digitalized for computer processing. The radiant intensity of the individual elements is recorded and represents the ratio of light intensity to the illuminated surface. Since the illuminated surface is constant at 2 x 2 cm, the radiant intensity is proportional to the light intensity. The measuring sequence is subdivided into four stages:

- Depending on the method of measurement, the cameras are calibrated before measurement begins.
- During the measuring phase, sufficient measurements are taken to obtain the mean values desired.
- Depending on the setting, the measurements are converted into output values.
- The converted and processed results are displayed on a monitor screen and, if desired, transmitted to a printer via a 0–20 mA interface.

These four phases are supplemented by the calculation of statistical results. Provided sufficient measurements have been run, a statistical series is produced. The application of this image processing system for shrinkage control is carried out:

- continuously,
- quickly,
- non-destructively and contact-free.
- measurements of changes in geometrical form are independent of the density and moisture content of the textile materials.
- production statistics can be produced with a statistical reliability which far exceeds that achieved by manual methods of shrinkage measurement.
- because of the rapid determination of measurement data, corrections to the production process can be made immediately and defective production avoided by the adjustment of machine settings.
- the system contributes to the automation of manufacturing stages and quality control.
- image data processing systems represent an additional expenditure for an industrial enterprise, although the purchase price is offset by the considerable advantages which they offer.

b) Shrinkage measurement by radiometric systems: the method of shrinkage determination which involves measurement of weight per unit area (III) shows that the weight per unit area of knitted fabrics is increased and the extent of shrinkage can be calculated exactly. The procedure described in III must, however, be regarded as an experimental detection method. If the control of dimensional change is to be carried out in a production department during processes such as drying or shrinking, then the experimental test proves to be

- time-consuming, and
- residual shrinkage values are not immediately available for the adjustment of machine settings,
- the test is destructive,
- only a relatively small number of random samples can be taken.

These disadvantages can be eliminated with radiometric measuring systems. When radioactive isotopes are beamed through absorbing materials their intensity is reduced in proportion to the material's mass. After passing through a layer of material, the original intensity I_0 falls to a value I, and the following exponential equation may be derived from this relationship:

$$I = I_0 \cdot e^{-KF}$$

I = radiation intensity after passing the absorbing layer,
I_0 = radiation intensity of the isotope,
F = material's mass in cross-section,
K = proportionality factor, linear weakness coefficient.

The weight per unit area, thickness and density of a test material can thus be determined from changes in the amount of energy emitted by a radiation source of known intensity. Isotopes are an atomic species of a chemical element with the same number of protons but different numbers of neutrons and nucleons. The latter exhibit spontaneous radioactive decay. Radioactive radiation therefore describes the property of unstable atomic nuclei in emitting constant energy in the form of α-rays (helium nuclei), β-rays (electrons) and γ-rays (energy-rich photons) without external influence. In β-decay, the emitted particle rays consist of fast electrons. The atomic number of the corresponding atoms changes but not the mass number. The newly created elements are mostly radioactive again and continue to decay in so-called decay chains. The speed at which the radioactive isotopes are converted into their decay products gives the half-life value.

Krypton 85, a β-ray isotope of the inert gas of the same name, is well suited for virtually all weights associated with textiles. This isotope has a half-life of 10.7 years and covers a weight range from 50–1000 g/m^2 with a high degree of accuracy. The β resp. electron-emitting isotope is encased in a solid radiation-proof cast-steel casing, and β-rays are released through a shuttered aperture only when the unit is switched on for measurement. An ionization chamber filled with inert gas serves as a radiation receiver. The incident electron radiation, the intensity of which is attenuated through absorption by the textile web, creates an ionization flow in the receiver. Incoming electrons are carried away by the electrodes. The ionization flow is proportional to the incident radiation, i.e. the heavier the fabric in the scanning gap, the smaller the flow in the ionization chamber. This flow thus represents a measure for the weight per unit area of a textile material.

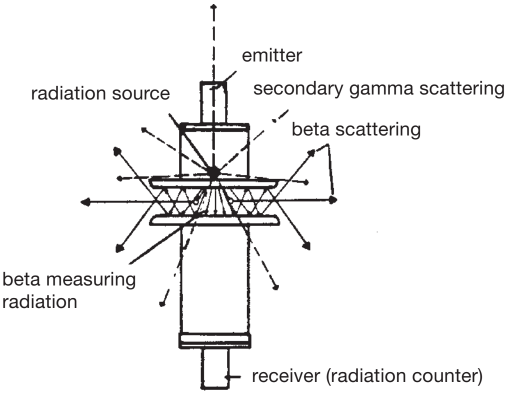

Fig. 3: The flow of radiation from a Gravimat (Mahlo) when the radiation emission window is open.

Gravimetric measurement can be carried out in a shrinkage machine. The radiometric measurement of weight per unit area is used for the continuous control of textile webs on stenters as well as for shrinkage control in compressive shrinking processes. A suitable system for this purpose is illustrated in Fig. 3. This unit consists of the following components:

- measuring head,
- electronic analysis,
- display unit,
- operating panel with set-point adjustment.

For gravimetric monitoring of shrinkage processes, a device for measuring the weight per unit area must be installed at fabric entry and another similar device at fabric exit from the machine. These measuring units determine the actual weight per unit area by differential measurement. If this measurement deviates from a given set value beyond the tolerance limit, then the control unit must obtain information in order to restore the given set condition. Regulation is carried out by means of a servomotor which is actuated by the pressure roll of the shrinkage machine. At the same time, the speed must also be controlled, since more fabric has to run into the machine per unit time to produce an increased amount of shrinkage.

Shrinkage of cellulose The shrinkage of textiles composed of cellulosic fibres and their blends has different causes which are not exactly distinguishable from one another. The low elastic extensibility and dimensional change of fibres during transition from the dry to the wet state by swelling are the main causes of shrinkage here. During swelling, the fibres undergo a change in cross-section which induces shrinkage. Swelling occurs through the penetration of water molecules into the cellulose structure and their attachment to the surfaces crystallites through hydrogen bonding. This process takes place mainly in the less ordered non-crystalline regions of the fibre. Since viscose has a higher proportion of non-crystalline regions, the degree of swelling is greater than native cellulose. During swelling, some existing intermolecular forces can be ruptured. The fibres become shorter due to an increase in volume. The swelling of native cellulose fibres occurs mainly in the width whilst the longitudinal swelling is only slight. Swelling subsides to a large extent on drying. The causes of this anisotropy are the crystalline regions, the orientation of which is parallel to the fibre axis. In the case of long molecular chains, more forces of cohesion are formed and swelling becomes more difficult. With increasing fibre crystallinity, the absolute degree of swelling is lower and, consequently, fibre stability is higher. Linear density, type of yarn and fabric construction have a secondary, but not insignificant influence on dimensional stability.

In each of the individual process stages from spinning, weaving, bleaching, dyeing through to final finishing, yarns as well as woven and knitted fabrics remain under tensile stress from the first to the last stage of processing. These latent stresses are stored in the fibre in the form of new hydrogen bonds and have a considerable influence on the degree of shrinkage. The built-in stresses participate in a gradual re-formation of a change of shape in the elastic region of the fibre when wet processing is carried out under largely tension-free conditions. It therefore follows that fabrics which have not undergone any relaxation during the final stages of finishing will shrink. The extent of dimensional change in the weftwise direction depends on the fabric construction and whether the preceding finishing stages were carried out under high or low tensile stress. Depending on the type of fabric, dimensional changes up to 20% can take place in the warpwise direction.

In → Resin finishing, the stresses stored in the easily ruptured network of hydrogen bonds become fixed through the superimposition of an additional network which may be permanent or temporary depending on the type of crosslinking agent used. Under these circumstances, the stresses can no longer be broken down. They represent stored energy and reduce the ability of the fibres to resist mechanical influences.

Much more important than the influences of weaving are the various parameters involved in the production of knitted fabrics. In this case, it is the knitter who determines the final dimensions of the fabric and not the finisher. He must decide whether the grey width, the inner tensions in the fabric and the finished width are sufficiently well matched to each other that the finisher can deliver the required finished width, the specified shrinkage values, and a uniform weight in the finished fabric. Whatever measures are taken in finishing to adjust the dimensional stability of a fabric so that it corresponds with specified weight and width requirements, their effect is always temporary. During the first laundering treatment after making up, the fabric will attempt to assume a fully relaxed structure. For this reason, the knitter, finisher and garment manufacturer must be aware of the effects of the various knitting parameters on dimensional stability since, in this case, textile finishing actually begins at the fabric manufacturing stage.

Factors in weaving and knitting which have an influence on wet processing include:

- fibre raw material: natural or synthetic fibres;
- fibre structure: orientation, crystalline or no-crystalline regions;
- fibre geometry: length, linear density, crimp, shape of cross-section;
- yarn construction: staple, continuous filament or textured yarn; blend ratio;
- conditions of weaving/knitting preparation;
- set-up of weaving and knitting machines;
- fabric structure.

All measures taken during previous processes must be coordinated in such a way that the fabric exhibits as little shrinkage as possible before final finishing. The shrinkage and propensity to creasing of woven and knitted cellulosic fabrics can be influenced chemically by the deposition of crosslinking resins and subsequent crosslinkage of cellulose molecules via their OH groups. In this process, covalently bound linkages are formed between the fibre and the chemical crosslinker. This limits the mobility and extensibility of the cellulose molecules which leads to brittleness and a loss in tensile strength. The main problem in resin finishing is the need to keep losses in fabric elasticity within acceptable limits whilst, at the same time, achieving optimum easy-care properties and dimensional stability.

Shrinkage testing (shrinkage resistance tests). The purpose of these tests is to control those dimensional changes (→ Shrinkage) of textile products which are of relevance to the consumer. A wide range of shrinkage tests for different fibres and applications are now in use, the procedures of which vary to a greater or lesser extent in different countries. Procedures to determine the dimensional change of textile fabrics are given in the following DIN standards: DIN 53 892, DIN 53 894 and DIN 53 898 (→ Shrinkage measurement of knitgoods). DIN 53 866 deals with the shrinkage behaviour of single and folded yarns.

Shrink fastness test → Shrinkage testing.

Shrink-finishing tunnel A machine for the compacting and → Shrinkage of piece goods in particular. Fabrics are processed continuously in open-width form. The machine consists of two preshrinking units, a vibration jet drier with three open-mesh conveyors and beater rolls, a steaming zone, transport conveyors, hot air nozzles for undulating movement of the plaited fabric, and a cooling zone at the delivery end. This type of machine is particularly recommended for raising the loops of knitted loop pile fabrics before shearing as well as the shrink resistant finishing of knitgoods in general. Residual shrinkage values capable of meeting the ideal standard of below 1% are achieved.

Shrinking machines Machines for the shrink-resistant finishing of textiles by mechanical compression in a moist hot state (→ Compressive shrinkage) or a tension-free treatment in a steam atmosphere (Fig. 1). The objective is to achieve residual shrinkage values up to 1% max. in subsequent use.

The shrinkage calender made by Heliot (Fig. 2) is described below as an example. Fabric first enters a J-box for compacting or automatic feed (A). This is followed by a device for the detection of holes, 2 motorized feed rolls with adjustable speed (B). A device for opening out knitted fabric by means of 2 pneumatic spreaders (C). Illumination of both sides of the fabric in the working area. Adjustable overfeed. Steam box for vertical steaming through 3 double steam rails (D). Extraction of excess steam and removal of condensate (E). 2 shrinkage units each consisting of a heated roller with controllable surface temperature and an endless felt blanket (with controlled contact pressure and automatic centering) (F). Regulating system between both shrinkage units for tension-free treatment. Connecting conveyor to the folding unit (G). Transport conveyor for tension-free feed (H). Suction extraction of accumulated moisture (I). Video monitoring of the folding opera-

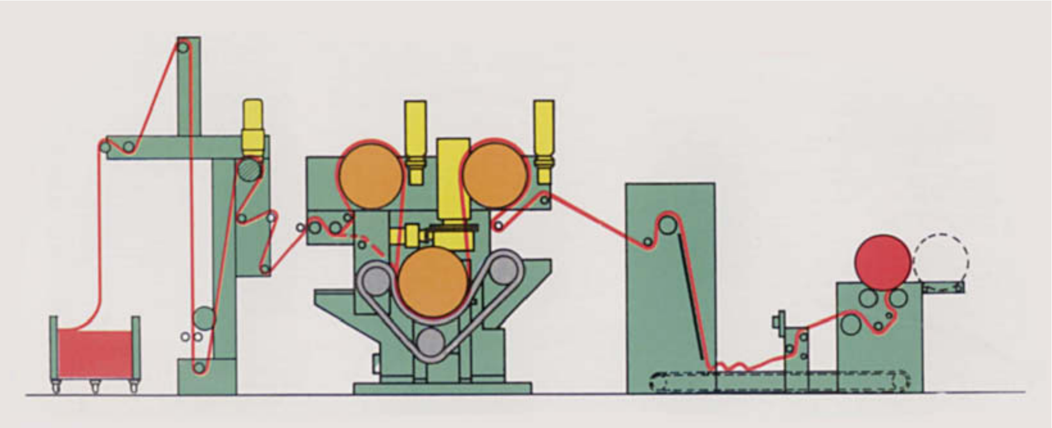

Fig. 1: Top-Tex shrinking machine (Monforts).

tion. Static eliminator. Feed rollers for the rear spreader (J). Folding device with rectilinear movement (K). Weight application to flatten the fabric for uniform folding (L). Batch-changing unit (M). Moveable folding table (N). Automatic cutting unit (O). Transfer of cut end on to completed batch of folded fabric. Conveyor belt (P).

Shrinking of knitwear One of the most important care and use properties of clothing textiles is shape retention during wearing and washing. A positive influence on the dimensional stability of knitwear made from cotton is possible by means of chemical treatment or also using mechanical processes such as controlled → Compressive shrinkage. Chemical stabilizing is avoided if possible for ecological reasons because knitwear worn close to the skin, which contains urea-formaldehyde derivatives as resin finishing agents, possibly contracts little known interactions with the skin. Terms such as "green cotton" (special tumbling in the Henriksen Tric-O-Dry) or "natural cotton" (treatment using liquid ammonia) make use of the market trend in textiles, which are loaded with as few chemicals as possible. Purely mechanical processes of compressive shrinking such as the Top-Tex-W system (Monforts) for example or compactor types on a shoe shrinkage basis (Hunt & Moscrop) have therefore gained strongly in importance.

The compressive shrinking of textile fabrics is influenced by mechanics, humidity, heat and time. If a parameter is missing or if its effect is inadequate, there is a negative influence on the result of the shrinking process. The unstable knitwear is often stretched longitudinally after wet treatment. These tensions are more or less strongly blocked depending on the magnitude of the frictional forces between the threads of adjacent stitches. The knitwear is compressed by the compressive shrinkage, i.e. the frictional forces within the strained stitches are raised; the stitch can be brought back into its most favourable energetic form. The contact pressure in the rubber cloth/steel cylinder sandwich, i.e. the normal force, should be selected so that on the one hand the fabric adheres on the rubber cloth and the linear change of the rubber cloth can increase; on the other hand the frictional force between shrinking cylinder and knitwear should be overcome. The frictional forces within the bonding points of the stitch and between the fibres should be overcome during the compression process.

The knitwear is carried more loosely across a steam cylinder before the shrinkage process. With an pressure of 6 bar the maximum temperature is 165°C. The steam pressure should be selected so high that a pressure of 0.5-0.8 bar is formed in the cylinder wrapping and the risk of condensate forming in the steam drum is avoided. If the relatively cold knitwear circulates in the steam cylinder, the steam condenses on the fabric surface. It should be assumed that one section of the residual fabric moisture also contributes to condensate formation. The condensate film prevents the coefficient of friction between shrinkage cylinder and knitwear in the subsequent shrinkage process. The rubber cloth is cooled with water when the machine is commissioned. The water is squeezed out until a certain residual moisture has been reached; this moisture content also positively accommodates the shrinkage process. The internal friction of the knits, which the rubber cloth transmits to the fabric, can clearly be overcome because of the moisture, and the knitgoods flow into each other better. The heat and moisture transfer of the steam represents an important task in the preparation of the fabric for the shrinkage process. The condensate splits polar bonds between polymer molecules and thereby causes a fibre swelling. The mobility of the polymer chains is in turn increased. The textile fabric together with the compressed rubber cloth circulates approx. half of the shrinkage cylinder circumference. This phase represents the dwell period of the compressive shrinkage process. Mechanically pushing together the fabric into the new dimension follows. At a machine speed of 20 m/min, the dwell period is approx. 3 seconds. In connection with the shrinking unit, the knitwear is fed to a heated solvent cylinder, which removes the condensate film from the fabric surface; the knitwear is fixed in comparison to the ironing process. Only after passing the solvent cylinder, after the de-swelling, can hydrogen bonds be re-formed and the fibre material stabilised, i.e. the fabric is temporarily fixed using secondary valences.

If a textile fabric is hydrothermically treated and mechanically pushed together longitudinally, a compressive shrinking takes place. The shrinking should be controllable by the clamping of the rubber cloth on the shrinkage cylinder. The compression is achieved via surface elongation and subsequent surface compression of the rubber cloth with a change of curvature at the same time. The soft, elastic material alters its shape due to the clamping of the rubber cloth on the cylinder. The rubber cloth becomes thinner in the area of the clamped point proportional to the contact pressure. The cloth should inevitably be stretched based on the volumetric constancy of the rubber, i.e. its surface is enlarged. The fabric only reaches the stretched rubber cloth surface shortly before the nip. The forced elongation reduces elastically on leaving the pressed area, i.e. the rubber cloth becomes thicker again and thereby shorter. The turning knitwear must recognise the movement of the rubber cloth, as it adheres; the flat, heated shrinkage cylinder, however, may slide by on the fabric. The knitwear is pushed together, which is expressed in an increase in the stitch density.

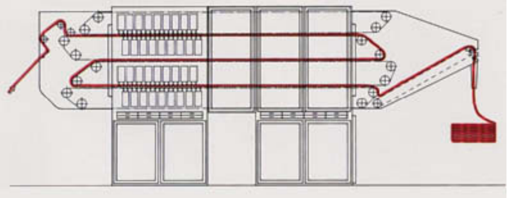

Fig. 1: Santex "Santashrink" shrink drier for the tension-free drying of knitted fabric.

It is also possible to shrink knitwear in special dryers (Fig. 1). Good shrinkage results can be achieved and the residual shrinkage values considerably improved using a special knitted fabric drier. Under the influence of intensive ventilation, the fibres return to their original natural form and a large part of the total tension potential is thereby depleted. The fully relaxed state of a stitch is characterised by an ideally formed stitch, which is then adjusted if the forces from the yarn bending to the stitch loop and the frictional forces in the bonding points, which must have reached a minimum value, are in equilibrium. In order to obtain residual shrinkage values in conformity with market conditions, more variables, which influence the shrinkage potential, should be considered (Fig. 2):

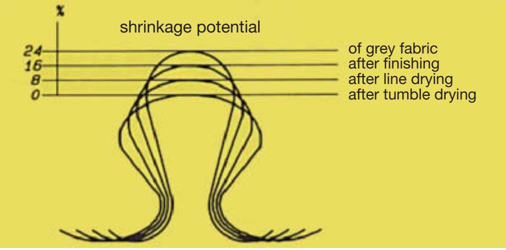

Fig. 2: Shrinkage potential of a stitch in various processing conditions with the absolute round stitch as a system with lowest shrinkage potential.

- stitch structure, bonding forces and yarn material;
- knitting machine setting, lead and material tension;
- separate pretreatment stages and the effects of time and temperature connected with them;
- extended dwelling and sine-shaped fabric movement in the shrinkage drier as well as changing how the fabric is laid;
- finish treatment after the shrinkage drier, storage and packing.

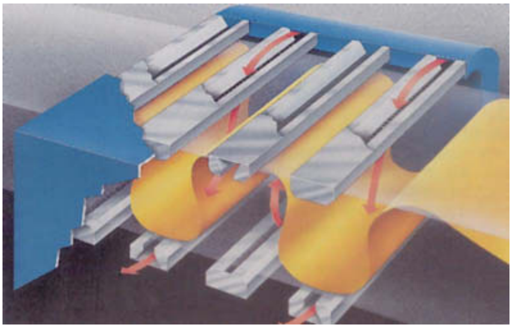

Fig. 3: Obermaier drier with no conveyor belt.

The brace in brace driers (Fig. 3) has offset vibration in the middle and bottom stage between the ventilation zones in order to additionally increase the relaxing process in the fabric. The fabric disengages in the rapid exchange from the brace, due to the vibrations, and drops back again. The fibre bonding is opened by the vibration, loosens up the stitches and encourages shrinkage behaviour until it is a reproducible, dimensionally stable finished good. The untensioned fabric guide and fabric movement are easy on the surface, but encourage shrinkage, and produce a good handle and give the fabric volume.

The knitwear is laid down in even creases, lying close behind one another, using an adjustable rotating brush roller, immediately after the fabric transfer onto the drier strip in the brace drier from Brückner (Figs. 4 and 5). Density and depth are given to the folds corresponding to the shrinkage potential of the knitwear across the possible lead of the fabric transportation device up to 120%. The knitwear is spread by using a brush roller with an arrow-shaped bristle arrangement and rolled up edges are opened at the same time.

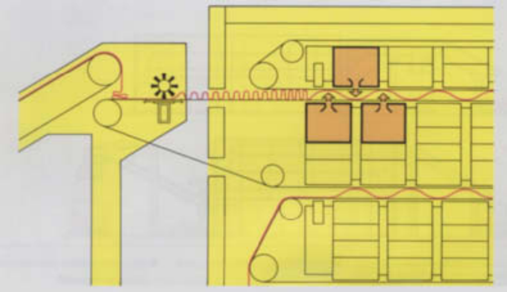

Fig. 4: Brückner conveyor belt drier (diagrammatic).

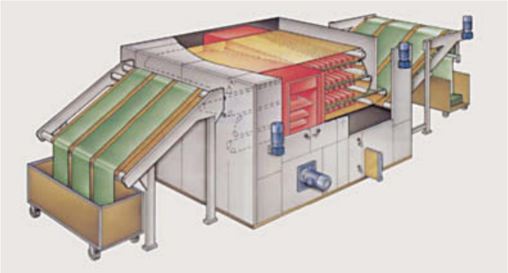

Fig. 5: Brückner conveyor belt drier.

Shrinking of power Concerns → Dimensional stability due to → Non-shrink finish.

Shrinking process Anticipation of → Shrinkage caused by mechanical and/or hydrothermal finishing processes of → Non-shrink finish.

Shrink-proof finish → Non-shrink finish.

Shrinkproof finishing Grammatically speaking, this is a term that should really be restricted only to finishes capable of producing a fabric with a residual shrinkage of zero (an absolutely shrinkproof fabric is not possible in practical finishing) but which is commonly used (erroneously) for finishes which reduce the residual shrinkage of textile fabrics to a level consistent with their fitness for purpose. The correct term for these finishes is → Non-shrink finish.

Shut-off devices Stop-cocks, sliding valves or other suitable valves for stopping or regulating the passage of flowing or stored liquids, gases, steam, etc.

Shuttle A boat-shaped yarn-package carrier, often made of hardwood with a metal tip at each end, used in → Shuttle looms to insert the weft (filling) yarns through a shed formed between the warp yarns during weaving. As the only → Weft insertion systems in a shuttle loom, the shuttle has an aperture to hold a pirn or cop on which a limited supply of weft yarn is wound during weaving preparation. The pirn or cop contains sufficient weft yarn to insert several picks before the empty yarn package is replaced with a full one in order to continue the weaving process.

Shuttle looms (shuttle weaving machines). In a shuttle loom, the weft is inserted by means of a → Shuttle which is propelled over a race plate through the shed of separated warp yarns. The shuttle is propelled from side to side by a wooden shaft called a “picking stick” so that the weft yarn is inserted alternately from left to right and vice versa thus producing a closed selvedge (in contrast to all of the more modern → Weft insertion systems introduced in the meantime). Weft insertion by means of a shuttle is the oldest insertion system on mechanical looms. For many weaving applications nowadays, shuttle looms have been replaced by more efficient shuttleless machines, e.g. air and water jet looms, etc. Shuttle looms are, nevertheless, still widely used for carpet weaving in which heavy, thick yarns are processed at low speeds. → Weaving.

SI,

I. Israel Standard.

II. → Sisal, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

III. → SI system of Units (Système International d'Unités).

IV. Styrene-isoprene (polymer).

Si,

I. → Sisal, → Textile fibre symbols, according to DIN 60 001 up to 1988; this abbreviation was changed in 1991 to → SI.

II. Symbol for the non-metallic element silicon (atomic number 14).

SIC Israeli standards organization. → Technical and professional organizations.

Siccatives, drying agents Desiccants as additives for drying oils, for the preparation of → Varnish and in linseed oils. Insoluble siccatives: compounds of inorganic or low molecular organic acids. Soluble siccatives: metal salts soluble in linseed oil, ether, etc. Molten siccatives are products manufactured by, for example, melting metal oxides and colophony.

Side-by-side fibres (S/S types) → Bicomponent fibres.

Side-to-side shading → Tailing.

Siebenbürgen rugs Small oriental → Knotted carpets, which arrived in Siebenbürgen during the Turkish occupation of South-Eastern Europe and were used to decorate the churches in the manner of the independent principality at that time.

Siemens Derived SI unit of → Electrical conductance, e.g. for electrometric measurements. 1 S is equal to the electrical conductance of a conductor of electrical resistance 1.

Sieve applicator in flock printing For flock coating of small parts, panels, pullovers for sample purposes in manually operated small flock coaters, which work using a spherical sieve for take-up of the flock as well as electrostate sieve applicators.

Sieve-drum drier Loose material, hank yarn, spinning cable, carded strip, woven and knitted fabrics are sucked through a current of hot air to a drum covered with screen fabric and in this way, dried. Sieve-drum driers (see Fig.) are characterised by their high performance over a small area. The principle is also used for thermofixing, steaming, washing, in the smoothing machine and with continuous dyeing. The sieve-drum drier differs from the circular stenter in that the needle tapes are fixed to the drum and have to be detached and reattached if the width of the fabric is changed. Advance devices may also be used. The machine is designed especially for drying nonwovens. The sieve-drum drier is therefore an airing drier with pure fresh air reverse flow and exhaust discharge in the first drying section, in which the initial drying stage takes place.

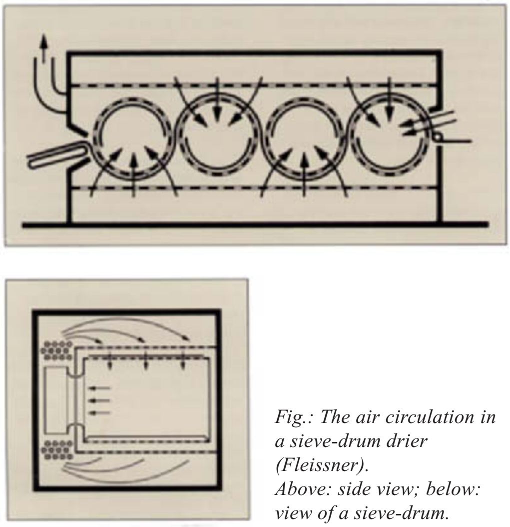

Fig.: The air circulation in a sieve-drum drier (Fleissner). Above: side view; below: view of a sieve-drum.

The single-drum speed is adjustable to the lengthwise fabric shrinkage. The fabric is freely transfered from drum to drum so that shrinkage is also possible crosswise. The drier is therefore well-suited for tension-sensitive fabrics, which is supported on top of the curved sieve-drum surface and so prevents any distortion or gathering. From energy consumption calculations it emerges that the sieve-drum drier performs well within the airing system (compared with the plate conveyor drying machine and the circular tension machine) and has a 30% lower energy consumption in comparison with the jet system with the stenter.

Sieve-drum drier, perforated drum type Revolving sieve drum used for accelerated, gentle drying (e.g. for knitted fabrics). The fabric, fed from the supplier conveyor belt, passes over the surface of the rotating drum to the lift-off device and the cuttler. Through the low air pressure (fan) generated inside the drum, constantly pre-heated air is sucked through the fabric, circulated repeatedly in the drier, reheated again and removed virtually saturated. An economical drying method especially for spinning cable, flock, hank yarn, woven and knitted fabrics. Perforated drum driers have proven their value because the airing component fundamentally affects the drying power. It has since been possible to make the perforated drum drier an equal rival among very economical driers through the arrangement of tension chain feeds or complete tension chains. Nor is there any doubting the fact that, besides the positive ventilation features, the perforated drums also ensure a perfectly safe conveyance of the fabric, both with and without overfeed, with two-way air supply provided by transfer to counter-rotating drums. It is useful if the drum bodies are fitted with coarse and fine mesh covers, in order to both eliminate contact heat and allow certain currents operating below the web to be effective. Perforated drum driers are therefore powerful because the supporting drum body allows them to operate with full air impact and good flow technology guarantees an even arrangement of air over the entire working range.

Sieve-drum drier, reverse flow type An English construction of the sieve-drum drier system, where warm air, unlike with the normal system, is blown from inside to outside.

Sieve-drum steamer Steamer based on the principle of the → Sieve-drum drier, where textile runs are held on rotating sieve (suction) drums by steam.

Sieve-drum washing machine Drum washing machine based on the flow through principle. The liquor flows due to gravity towards the laterally arranged axial pump, which ensures an equal level over the working width to be achieved inside the drum (Fig. 1).

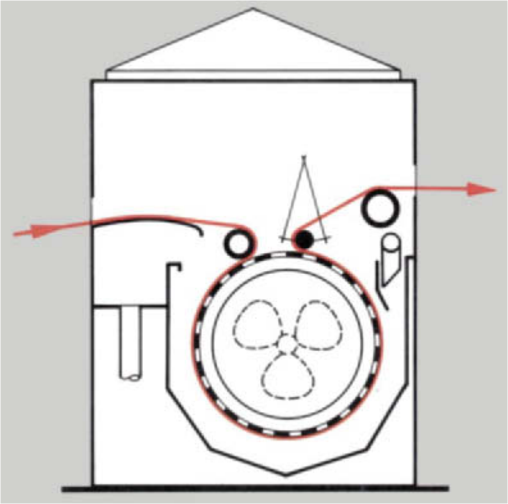

Fig. 1: A sieve-drum washing machine (Babcock).

The differential pressure operates over the entire drum circumference, being mainly the result of the fibre passage resistance and the section of the drum not covered with fabric. The drum shell is finely perforated on the outside with a large open area, and is smaller on the inside towards the liquor flow limit on the side of the web. The fabric entry in the drum section is relatively short compared with conventional roller vats. Sieve-drum washing machines are especially suitable for pure rinsing and impregnating purposes (Fig. 2), as well as for knitgoods (low-tension cloth guide).

Sight glass Built into pipelines, condensate returns, etc. for checking the flow, purity, absence of bubbles.

Sighting (marking, identification dyeing) is aimed at temporary dyeing to prevent confusion of dif-

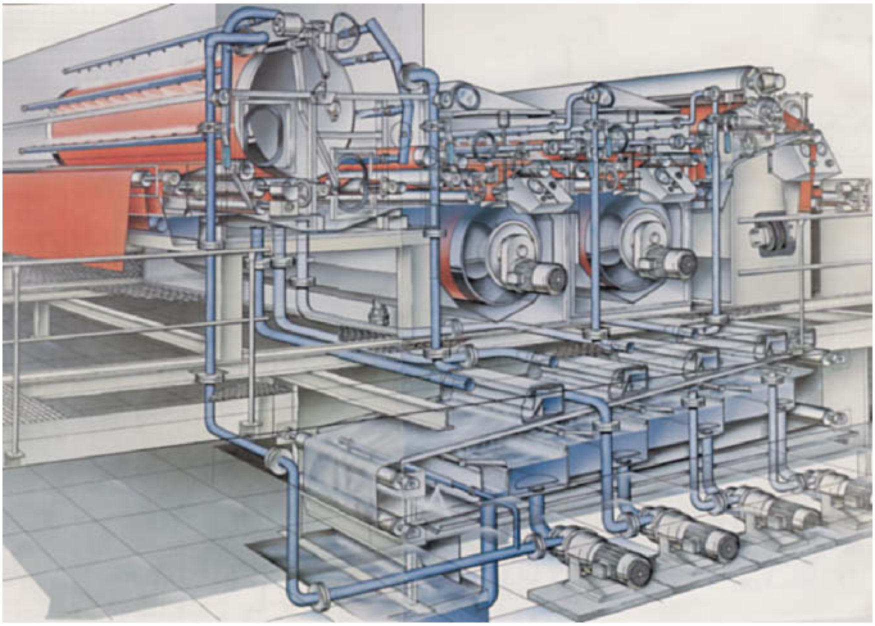

Fig. 2: A sieve-drum washing machine (Babcock) with collection of the washing liquor outside the goods compartments and its re-use through spraying onto the sieve-drums.

ferent yarn twists, yarn types, materials and the like. Sighting frequently also occurs with the manufacture of fancy-ply fabrics to control the distribution of different types of fibres in the design. Requirements: easy to wash off again (even after intermediate steaming, fixing or decatizing) without damage to the material. Application: sprinkle 0.1–0.5 g/l dry dye (mostly concentrated dyes without fibre substantivity) in spooling oil or sizing, distribute well with high-speed mixer, sieve. Impregnate the yarn cold, squeeze out the running thread and dry at a low temperature.

Sighting colours → Textile markers.

Sighting dyes Non-substantive dyes for the particular stubstrate, which can be added to colourless printing pastes to reveal repeat inaccuracies on blades and rollers and later washed off again (e.g. for white discharges, half-tone reserves, leuco vat ester dyes, stabilized azo dyes, phthalocyanine dyes). Frequently also colourless substances (e.g. fluorescent brightening agents) which fluoresce in UV light.

Sighting thread Sensor-exciting metal thread as a separating thread or sewing thread (→ Seam detector).

Sigokki machine There are various possibilities of applying a printing background in resist printing. The easiest is to print the background via the pre-printed resists on a rotation film-printing machine. At the same time, it is recommended to use two blotch printing templates, with one template covering any printing faults of the other template, such as lint markings. One possible way of applying ground dye pastes has been developed in Japan. The Sigokki machine is a mixture of a padding machine and a roller printing machine. The system is simple in construction and design and is in widespread use in East Asia (see Fig.).

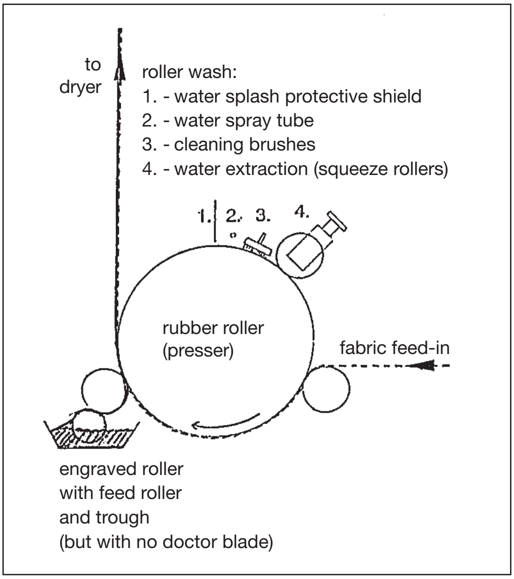

Fig.: Sigokki machine.

Silica gel (active silicic acid), SiO_2, manufactured from → Water glass (sodium/potassium silicates) by conversion by sulphuric acid under certain concentration and temperature conditions. Acidic manufacture: fine-pored A type (bulk density approx. 720 g/l), alkaline manufacture: coarse-pored B type (bulk density approx. 450 g/l), grain sized approx. 2–6 mm. Properties: ability to mechanically link with water and release it again by heating (regenerating above 450°C). Principle: sponge-like structure of numerous extremely fine capillaries (diameter some millionths mm). Use: in absorption systems, A type for drying and cleaning of industrial gases and space air drying with air-conditioning systems, B type for drying liquids, especially liquid hydrocarbons (benzine, benzole, etc.). Distinction: A gel transparent and clear, B gel milky.

Silicate boiler scale (SiO_2), most dreaded modification of → Boiler scale, caused by silicate in boiler feed water (even 5–10 mg/l SiO_2 is a risk to boilers operating at high pressure). Has a particularly low thermal conductivity. 0.2 mm layer thickness causes local overheating, buckling of the tubes, etc.

Silicate ion-exchanger → Zeolites.

Silicate of soda → Sodium silicate.

Silicates Salts of the meta, ortho and polysilicic acids. Not soluble, non decomposed in any solvent. The aqueous solution has a limited service life (tendency to gradual flocculation or drying up). Even a small addition of acid causes gelatinous separation (→: Sodium silicate; Water glass).

Silicic acid Numerous hydrogen-oxygen modifications of silicon (Si); e.g. orthosilicic acid H_4SiO_4, metasilicic acid H_2SiO_3 and polysilicic acids. The salts are called silicates.

Silicon (Si), atomic weight 28.4; melting point approx. 1450°C; density 2.3; non-metal; large, monochrome crystal or grey or brown powder (amorphous form). The former is somewhat chemically inert, the latter considerably reactive. Reducing agent, resistant to acids, boiling alkali forms alkali silicates. Produces with water, hydrogen acids or silicic acids, the latter being more or less hydrous (salts = silicates, e.g. water glass $Na_2Si_4O_9$). Silicates are mostly insoluble in water. Potassium, sodium and associated elements form high-viscosity solutions (water glass). Alkali silicates (fused with aluminium, iron, etc.) are familiar as → Zeolites. Forms with hydrogen silanes (e.g. monosilane H_4Si), with halogens e.g. silicon fluoride SiF_4, fluorosilicic H_2SiF_6 (salts = fluorosilicates). With metals and similar elements of silicides (e.g. + carbon; silicon carbide SiC). Numerous compounds are derived from organic or inorganic silanes, such as halogen silanes, which can alkylate. Alcohols form silanols (R_3SiOH)

or silicols (≡C–Si–OH), whose sodium salts, esters, amines produce silazanes (≡C–SiN=) and, by hydrolysis, oxygen compounds of the siloxane type (–SiR_2–O–). Thus, from organo-siloxanes (≡C–Si–O–), the major → Silicones of the type $[(CH_3)_2SiO]_n$, i.e. "silico-ketones" (Kipping), are produced by polymerization.

Silicon carbide (carborundum), SiC, variously coloured (reddish, greenish blue, black) crystals, very chemical and heat resistant, diamond-like hardness, density 3.2. Is obtained from coal and quartz at over 2000°C. Use: as grinding and polishing material; for fire-resistant bricks and electrical resistance bodies.

Silicone antifelting treatment allows knitwear manufacturers to produce machine-washable woollen articles by the application of → Silicone elastomers.

Silicone-based dyes serve to permanently dye glass fibres in dark shades, as well as to modify the properties of normal silicone oils and resins.

Silicone-based textile auxiliaries → Silicones represent important auxiliaries in the textile industry for processing and finishing. They have many advantages due to their universal application possibilities, problem-free handling, free choice of type of application, gentle cross-linking, great efficiency and slight environmental pollution.

Silicone catalysts Hydrogen methyl polysiloxanes (→ Silicones) require special catalysts for cross-linking, the choice of which creates the possibility of influencing the overall effects of the fabric.

Silicone coating The cross-linking of → Silicone elastomers to lattice-type structures occurs at the reactive points by means of special cross-linkers under the influence of metal organic special catalysts and heat. A cross-linker must have at least three reactive binding sites per molecule so that an elastic lattice structure is produced. Usual cross-linkers are:
- methyl hydrogen siloxanes
- tri or tetra-alcoxysilanes
- triaminosilanes.

The special catalysts are used to accelerate the cross-linking reaction.

The basic substance with silicone coating is in all cases polydimethyl siloxanes, i.e. long, linear polymer chains, which consist alternately of silicon and oxygen atoms. The residual valencies of the silicon are usually saturated with methyl groups. The polymer chains are equipped with a defined number of reactive groups such as vinyl groups. Vulcanization (see Fig.) occurs at these places.

Another essential component of silicone rubber is the active fillers. Active means that the surface of the fillers (gen. highly disperse silicon oxide) interacts with the polymer chains, which reinforces the mechanical properties. However, the viscosity or plasticity of the mass greatly increases with the filler content. With coating processes such as spread coating, dip coating or spraying, certain viscosity limits may not be exceeded, however. For this reason, silicone rubber has frequently been dispersed in organic solvents, the viscosity controlled via the quantity of solvent and the dispersion applied to the textile. At any point in the coating process, however, the solvent must evaporate again, be recovered by condensation, be burnt or, in the worst case, emitted into the environment.

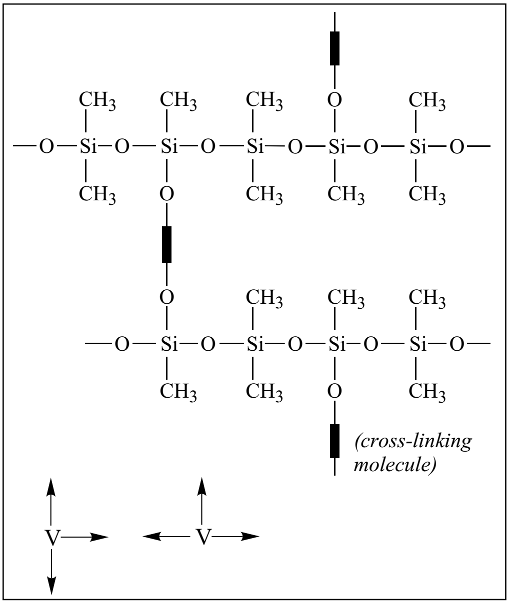

Fig.: Three-dimensinal cross-linking of silicone coatings as vulcanization.

In the automobile, tyre, food and printing industries, as well as in textile-processing systems, silicone-coated conveyor belts for sorting and production lines have been successfully used for decades. Virtually all manufacturers of silicone-coated conveyor belts have since gone over to solvent-free production. For this application, single-component silicone masses, cross-linking at room temperature, have been developed with a low viscosity, as has liquid silicone rubber. Conveyor belts must be flexible in a temperature range from – 50°C to + 250°C. Chemical resistance and abrasion resistance are taken for granted. Special types of conveyance systems with steep angles of inclination have anti-slip properties. For process belts in the food sector, solvent-free silicone rubbers are available. For special working processes, electrically conductive, antistatic coatings are necessary. There are also solvent-free alternatives available for this.

Increasingly, airbags are part of the standard equipment of motor cars. They protect the occupants in an accident against impact with the windscreen, steering wheel and fascia. The fabrics used need to be gastight and temperature-resistant due to the thermal development of the propellant.

The polychlorobutadiene-coated fabrics used exclusively in the years of development are still processed the most often today. Disadvantages such as slow elimination of hydrogen chloride at increased temperatures, distinct blocking behaviour and poor resistance to ageing have become apparent in the course of time. In addition, large amounts of solvents are required in the coating process. This has led to considerations as to how polychlorobutadienes can be avoided. Two main directions have been taken:

1. Yarn manufacturers, weavers and garment manufacturers are working on the possibility of managing with uncoated fabric.
2. Parallel to this, silicone rubber has been tested as coating material and considered suitable.

The development of special types makes for solvent-free coating of polyamide fabrics even using low coating amounts of 20 g/m^2. Both types of airbag, uncoated and silicone-coated, are already used in cars. There are advantages in favour of the silicone-coated airbag. These are, first and foremost, improved gasproofing, which prevents carbon monoxide (propellant gas) from escaping, and great flexibility, which facilitates manufacture and folding and makes for the smallest packing volumes. In addition, silicone coating prevents friction of yarn on yarn with vibration and provides the proper heat protection upon igniting the propellant. As a result of these advantages, silicone-coated airbag fabrics are increasingly accepted.

Silicone cross-linking For the silicone cross-linking of reactive-group → Polydimethylsiloxane at least trifunctional cross-linkers are required so that an elastic network structure is achieved, e.g. methyl hydrogen siloxanes, tri- or tetra- alcoxysilanes and triaminoalkylsilanes. Silicone cross-linking usually takes place in the presence of special catalysts and may drain off as condensation (OH terminal group), addition (vinyl terminal group) and as peroxide cross-linking (methyl terminal group).

Silicone elastomers High-molecular → Polydimethylsiloxane with terminal hydroxyl groups, which cross-link with hydrogen methylpolysiloxanes in the presence of catalysts, e.g. tin alcyl compounds or silicic acid esters. Used in solvents or aqueous emulsions (solvent technique enables better effects) as → Silicones in finishing, e.g. for elastic finishing of knitwear made of synthetic fibres, antifelting finish and the like. Further properties include: soft handle; positive effect of the resistance to chafing, sewability, pilling behaviour and bursting resistance with knitgoods.

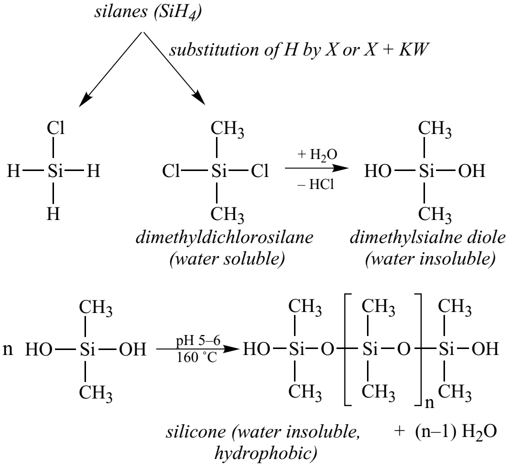
Silicone fibre African → Bast fibres, similar to ramie. Natural colour grey, also bleached. Produces no cold feeling on the skin with sweating. Spun according to the type of combed yarn, especially blended with wool for sportswear, stockings, gloves, etc.

Silicone finishes for textiles Give the textiles, if desired, hydrophobic properties (silicone additive of 1–1.2% of the dry weight of the fabric), protection against wet dirt, a soft handle and improvement to the sewability and abrasion resistance.

Silicone finishes, stripping May be required with defective silicone finishes. Is difficult, however, particularly if the fault is not detected until after hardening. By means of an acid treatment with 60 g/l hydrofluoric acid (alternatively oxyl acid and suitable polyphosphates and acid-resistant wash-active substance) in 60 min at 80–90°C, if necessary with a subsequent chemical cleaning.

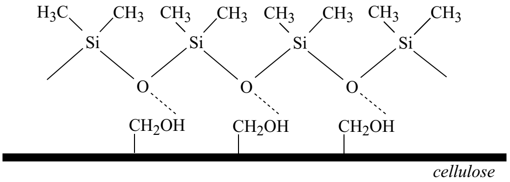
Silicone rubber Synonym for → Silicone elastomers. Poor resistance to abrasion. Resistance to acids is excellent to moderate, to solvents poor (aliphatic/aromatic hydrocarbons), to oxidation, ozone, sunlight ageing, excellent, to flammability moderate to good.

Silicones (polysiloxanes) are, as organic silicon compounds, among the synthetic polymers. They represent important auxiliaries in the textile industry for processing and finishing. They offer advantages due to their universal application possibilities, problem-free handling, free choice of type of application, gentle cross-linking, great efficiency and slight environmental pollution. Starting from dialkyl or diaryldichlorsilanes and water, polysiloxanes or rather silicones are produced by polycondensation.



The properties of the condensates can be affected by the addition of trialkyl or triarylchlorsilanes (chain termination) or alkyl or aryltrichlorsilanes (cross-linking). Application, for both synthetic and native fibres, occurs either according to the exhaustion process or by padding. Precondensated polysiloxanes (as solutions in organic solvents or as aqueous dispersions) are normally applied to the fabric together with catalysts. After drying on the stenter, the actual condensation takes place with temperature (150–160°C, 0.5–3 min). So far hot condensation has had the greatest significance of the various cross-linking options. Addition cross-linking is also usual, however, using siloxanes with vinylene groups and hydrogen siloxane cross-linkers. Zinc, tin, lead, magnesium and zirconium compounds are all suitable as catalysts for condensation. Cross-linking lasts some 30–60 s at 120°C, 15–30 s at 150°C. Usually H-siloxanes (methylhydrogenpolysiloxanes), dimethylpolysiloxanes or combinations of both are used. The H-siloxanes in particular are capable of cross-linking due to their movable hydrogen atoms (catalysts: tin, zinc, lead). The choice of catalysts allows the overall effects of the finishes to be consciously affected.

Silicones are in a position to cross-link with cellulose, whereby the ether groups align themselves according to the primary hydroxyl groups of the cellulose (epoxy resins which condense under temperature and with catalysts having the aligning effect).



The silicones settle advantageously on the fibres in a more or less formed film, so that no gaps which can destroy the properties of the silicone films arise. The fabrics being impregnated need to be thoroughly precleaned.

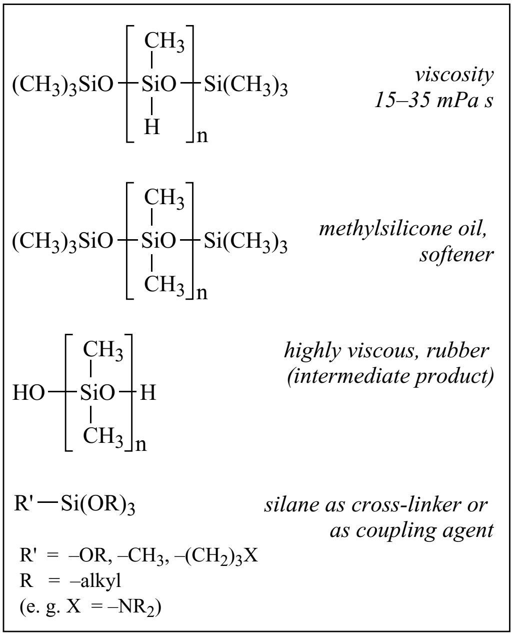
The consistency of the silicones can extend from oily via elastic to a resinous state:

I. Silicone fats and oils: polysiloxanes with a linear chain structure and relatively small average degree of polymerization.

a) Silicone oils are produced from difunctional silanes. They involve liquids with a chain or ring-shaped molecular structure and a silicon component of 36%. Properties: water-clear liquid of varied viscosity with low setting point and good heat resistance, water and adhesive repellent, low surface tension, strong compressibility, soluble in all non-polar solvents, higher homologues are odourless and tasteless, resistant to oxidation. Use: gloss and flow agent in polishes and paints, lubricant, etc.

b) Silicone fats are manufactured from silicone oils; non-drip, heat-proof lubricants e.g. for stenter.

II. Silicone resins: polysiloxanes with reticulated structure and relatively high average degree of polymerization. Manufactured from trifunctional silanes or mixtures of di- and trifunctional silanes.



$$(CH_3)_3SiO\left[\begin{matrix}CH_3\\ |\\ SiO\\ |\\ H\end{matrix}\right]_n Si(CH_3)_3$$

viscosity 15–35 mPa s

$$(CH_3)_3SiO\left[\begin{matrix}CH_3\\ |\\ SiO\\ |\\ CH_3\end{matrix}\right]_n Si(CH_3)_3$$

methylsilicone oil, softener

$$HO\left[\begin{matrix}CH_3\\ |\\ SiO\\ |\\ CH_3\end{matrix}\right]_n H$$

highly viscous, rubber (intermediate product)

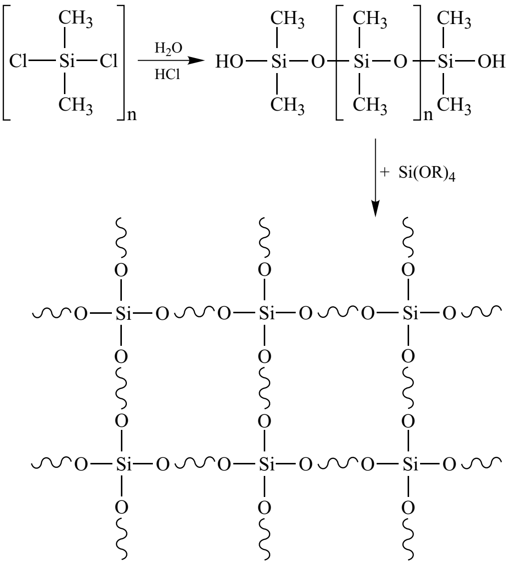
$R'—Si(OR)_3$

silane as cross-linker or as coupling agent

$R' = –OR, –CH_3, –(CH_2)_3X$
$R = –alkyl$
(e. g. $X = –NR_2$)

Properties: silicones are hydrophobic. A hydrophobic effect occurs through the spatial arrangement of the silicone compounds condensing on the fibre surface. Silicones are therefore used for hydrophobing (= water-repellent finishing). This waterproof film allows wash-fast effects to be achieved. Unfortunately, this is frequently accompanied by a deterioration in the fastness to light and rubbing. The effect can be easily verified using rain tests.

In addition, silicones also work as softeners. They allow fibres and threads to glide better in the overall structure. Besides a supple and soft handle, this finishing achieves improved wettability at the same time, which is particularly important for polyamide fabrics for tents or umbrellas. Together with carbamate or glycol resins, silicones are also used for crease-resistant and permanent-press finishes. Silicones are weatherproof since they have no unsaturated groups. They have good elasticity, which is attributable to the helix shape of the chains and can be reinforced still further by slight cross-linkings. The polar Si-O-Si bonds allow any contact to polar surfaces to be made, while the hydrocarbon residues point in the opposite direction. Normal silicones, therefore, have good surface activity and are, as a result of their low volume solubility and high surface solubility, antifoaming agents and separating agents in high concentrations, and foamers in small concentrations. Silicones react sensitively to residues of anion-active auxiliaries. They require careful stor-



age and clean preparation because they split off hydrogen.

III. Silicone elastomers (synonymous with silicone rubber): high molecular polysiloxanes with functional terminal hydroxyl groups which cross-link in the presence of catalysts with hydrogen methyl polysiloxanes.

They provide a soft, supple, surface-smooth handle, improved wrinkle recovery and crease resistance in combination with resin finishing (makes for a 50–60% reduction in the synthetic resin quantity as well as improved abrasion resistance, wettability, etc.).

Silicones in finishing While in the silicon crystal the atoms are arranged regularly in relation to each other, in the amorphous silicon this order is lacking. The transition from the crystalline to the amorphous state, therefore, has some disadvantageous consequences. On the one hand, the mobility of the charge carriers in the amorphous product is clearly smaller than in the crystal; on the otherhand, the amorphous structure produces a high concentration of non-saturated silicon bonds (Fig. 1). These express themselves as defective states in the band gap. One possibility of rendering the free bonds passive to a large extent consists of saturating them with hydrogen. With the manufacture of amorphous silicon layers, e.g. by plasma destruction of silane (SiH_4), the hydrogen passivation of the free bonds occurs almost automatically.

Owing to the large electro-negativity difference between silicon and oxygen, there results in silicon-oxygen compound, a negative partial charge on the oxygen (e.g. silicates, Fig. 2). With corresponding silicic acid esters, which are usual in resin finishing as sewability improvers in the form of dispersions as additives, this charge distribution is symmetrical and makes

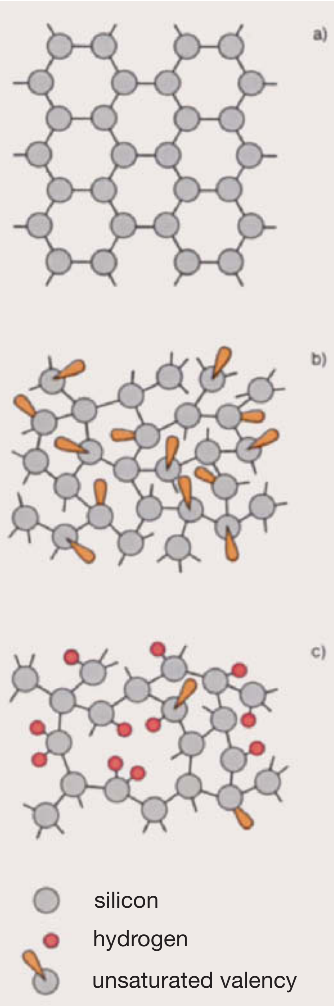


Fig. 1: The (diagrammatic) arrangement of atoms in: a) crystalline silicon; b) pure amorphous silicon; c) hydrated amorphous silicon (a–Si:H).

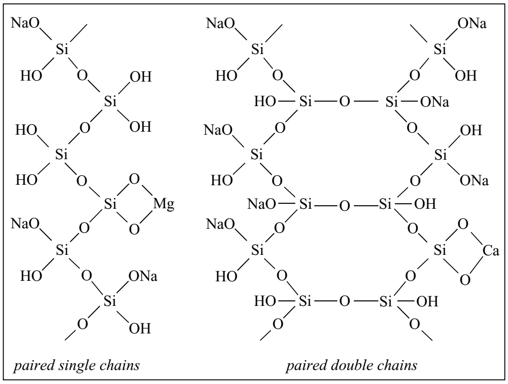

Fig. 2: The structures of single and double chains in silicates (water glass).

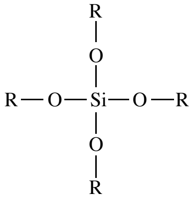
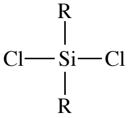
the silanes into stable compounds, e.g. tetra-alkyloxysilane (additive for resin finishing):



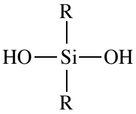
$$\mathrm{R-O-\underset{\underset{R}{|}}{\underset{O}{|}}{\overset{\overset{R}{|}}{\overset{O}{|}}{Si}}-O-R}$$

If dihalogensilane is hydrolyzed



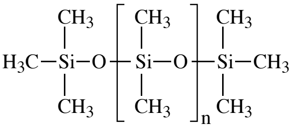
$$\mathrm{Cl-\underset{R}{\overset{R}{Si}}-Cl}$$

in the presence of monochlorsilane (chain stopper) or trichlorosilane (brancher), cross-linked siloxanes are formed by the autocatalysis of halogenhydrogen produced in the meantime via polycondensation of the metastable hydroxysilanes



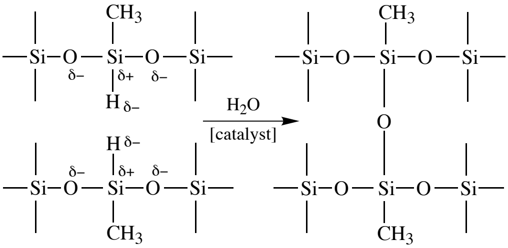
$$\mathrm{HO-\underset{R}{\overset{R}{Si}}-OH}$$

with the brancher and linear siloxanes, e.g. dimethylpolysiloxane (softener), are formed with the chain stopper:



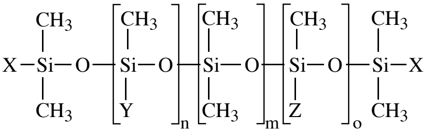
$$\mathrm{H_3C-\underset{CH_3}{\overset{CH_3}{Si}}-O-\left[\underset{CH_3}{\overset{CH_3}{Si}}-O\right]_n-\underset{CH_3}{\overset{CH_3}{Si}}-CH_3}$$

While the Si–O bond of the latter might be polarized, it is only firm enough to preserve the polymer material of the silicones. This basic framework is not only infinitely variable in its chain length; the equilibration ability is so rich in variants with suitable catalysts that any sequence in the main chain and specific terminal groups can be aimed at. In addition, the silicon atom has vacant 3d orbitals in its electron configuration, the result being that, through coordinative expansion, reactions with nucleophiles are possible, which among other things permit all side chain modifications such as condensations, additions and radical reactions as polymer-analogous reactions, especially when hybridic hydrogen (negatively polarized) is present:



methylhydrogenpolysiloxane *cross-linking (hydrophobing)*

In the general formula for silicones (polysiloxanes)

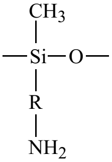


$$\mathrm{X-\underset{CH_3}{\overset{CH_3}{Si}}-O-\left[\underset{Y}{\overset{CH_3}{Si}}-O\right]_n-\left[\underset{CH_3}{\overset{CH_3}{Si}}-O\right]_m-\left[\underset{Z}{\overset{CH_3}{Si}}-O\right]_o-\underset{CH_3}{\overset{CH_3}{Si}}-X}$$

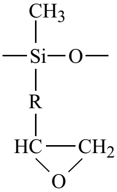
there are three main possibilities of modification with the organic substituents $-CH_3$, –X, –Y, –Z:

a) sequence in the copolymer,
b) terminal group modification,
c) side chain modification.

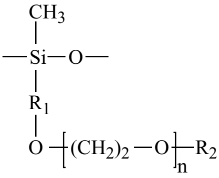
It is possible to build in as side chains:



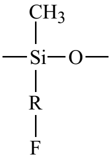
antistatic agent, antifelt finishing



cross-linking agent for fine finishing, antifelt finishing



defoaming agent, softener, hydrophilation, soil release, silicone surfactants



oleophobic finishing

The following requirements result for a defoamer:

- The defoamer must be insoluble in the foaming system. It must not, therefore, dissolve in the liquid lamella.
- The defoamer must spread as rapidly and evenly as possible over the lamella to suppress the surfactant

mineral oil defoamers		silicone oil defoamers	
70–80 %	oil	5–20 %	silicone oil

Tab.: The composition of defoaming agents.

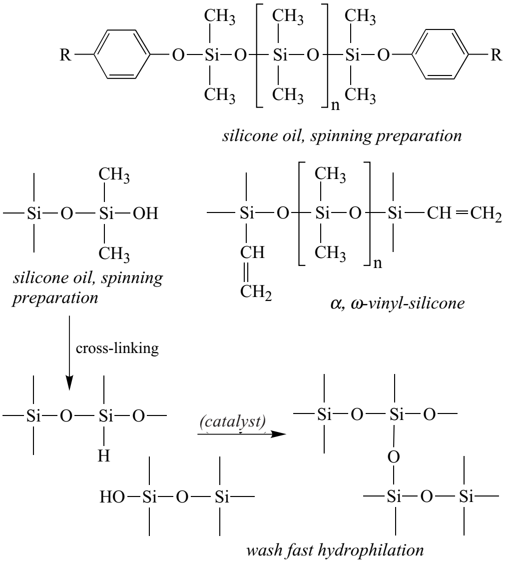
molecules, i.e. it must have a smaller surface tension than the latter.

- The defoamer should also produce lattice defects in the boundary surface, which is achieved by the insertion of hydrophobic fillers.

The Tab. shows the composition of two types of defoamers chiefly used in the textile industry, silicone defoamers being visibly superior to the mineral oil defoamers, in effect, on account of the low surface tension of the silicone oil.

Elementary halogenation produces silicofluorochemicals (Fig. 3).

The following can function as terminal groups:



In this way, a group of trivalent silicones is produced, which can be processed into silicone elastomers (Fig. 4). For the production of silicone elastomers on textiles, the minimum curing temperature is important (Fig. 5).

Silicones can also display a surfactant character (Fig. 6) by being stimulated differently; in this way cationic, anionic and amphoteric surfactants are formed.

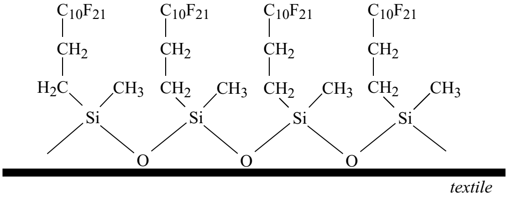


Fig. 3: Textile finishing using silicofluoro chemicals.

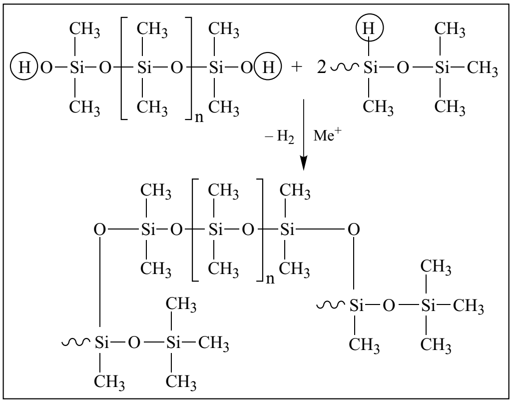

Fig. 4: Three dimensional cross-linking of silicone elastomer.

Siloxane polymers (Fig. 7) can be altered extensively in their characteristic profile, e.g. by modifying of the polyether component.

Emulsions of alkoxy-aminoalkyl terminally modified base oils are also used, which are present in water highly aggregated and sterically inhibited as “dormant prepolymers” since the hydrophobic silicone polymer prevents the access of water to the reaction centres. It is only through water vapour (Fig. 8) that these silicones become monomolecular and not aggregated, and reactivation occurs, e.g. subsequent to a “dry process”, since silicones have great penetration power for gases of any type. Via hydrolysis, release of alcohol and base-catalyzed silanol condensation (primary amino groups), elastomers are formed with outstanding handle properties (amino modified). “Pure” single-component products require neither separate cross-linkers nor external catalysts.

In the course of development, type and degree of the amino modification have been varied, with quaternary groupings also finding access. New types of emulsifying techniques allow for the production of extremely fine-particle “microemulsions”, where the constituents also penetrate the textile substrate via micropores. To the hitherto pure surface effect is added a quantum of “inner softness” so that supersoft properties result. The extreme fine particle nature of these types of emulsions

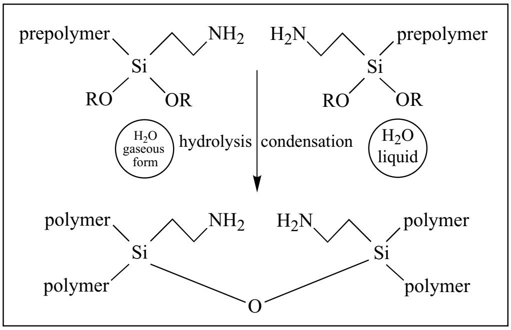

Fig. 8: The reaction mechanism for single-component silicone elastomer.

systems. Multistage syntheses, low production capacities and sophisticated emulsifying techniques mean, however, that the price of amino modified silicon microemulsions is high. Extenders therefore reduce the content of "super softeners" (according to Haug, and Seidel and Kiesling, as well as Hardt, and Gysin).

Silicone softeners Silicones provide textile substrates with a combination of soft handle, smoothness, gloss, fullness, elasticity and sewability with excellent permanence at the same time. A soft, flowing handle can be an influential criterion when purchasing textiles. At a time of more demanding consumer claims, silicones are increasingly common as textile softeners. A decisive share of these silicones in textile finishing is allocated to the amino-modified polydimethylsiloxanes. The softening effect of the silicone oils is based on their slide performance both on the fibre surface and in the fibre itself. Amino-functional groups linked to polydimethylsiloxanes enable an improved orientation and substantivity of the silicone on the substrate. This leads to an optimally soft handle and is often described by the term "supersoft".

The mainly used aminoethylaminopropyl-functional silicones ($–Si(CH_2)_3NHCH_2CH_2NH_2$) may contribute to the yellowing of the textile, especially white goods, at the drying temperatures customary in textile finishing. While the tendency to yellowing of this type of amino-functional silicone may be minimized through optimizing various parameters, such as amine content, viscosity and formulation, it cannot be avoided altogether, however. The soft handle of this type of silicone is accompanied by a certain hydrophobing of the fibres. Since the moisture content of clothing textiles etc. is determined by the transport of the moisture away from the skin, the hydrophilic property of the fibres is crucial to the wearing comfort. Although silicones in textile finishing have originally been valued due to their water-repelling properties, the trend in soft handle finishing is towards more hydrophilic silicones.

Dirt should be easy to remove from textiles. This presupposes a slight affinity of the fibres for oily dirt. The soil-release properties of textiles are affected by the finishing. Generally, with silicone softeners, a parallel can be observed between reduced hydrophoby and improved soil-release values. In the application, amino-functional silicones are generally applied to the textile substrate in the emulsified state. Then the drying and heat setting takes place. At the high drying temperatures found upon contact with atmospheric oxygen, a more or less strong thermal yellowing (dependent on the amino group content) is observed, which is more disturbing on white goods in particular. This thermal yellowing is attributed to an oxidative breakdown of the amino-functional pendant groups under the formation of chromophoric groups. The tendency to yellowing is particularly acute with the aminoethylaminopropyl group and has to do with the arrangement of the two amino groups (bridged primarily and secondarily via ethenes) preferred for oxidative chromophore formation. The sensitivity of amino groups to a thermooxidative breakdown can be affected by the number and type of alkyl substituents on the nitrogen as well as by the use of protective group techniques such as acylation reactions.

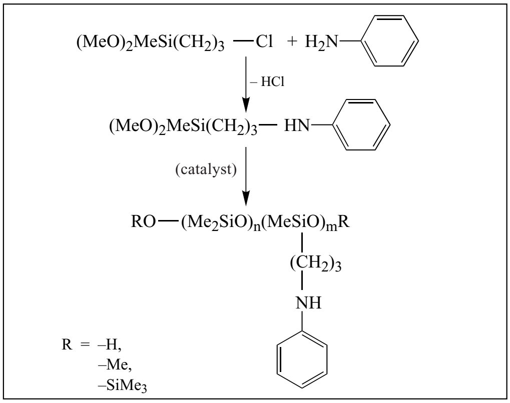

Fig. 1: The synthesis of cyclohexylaminopropyl functional silicone.

Assigned to amino-functional silicone softeners, the following approaches present themselves: synthesis of new, variously substituted amino-functional polysiloxanes. The product class of the cyclohexylaminopropyl-functional silicone oils demonstrates a combination of finishing effects relevant to textile softening. These involve a soft handle, combined with a degree of whiteness at low hydrophoby and good soil-release values. Cyclohexylaminopropyl-functional silicone oils can be manufactured as shown in Fig. 1.

Varying the parameters of polymerization (viscosity), amine content and terminal group reactivity

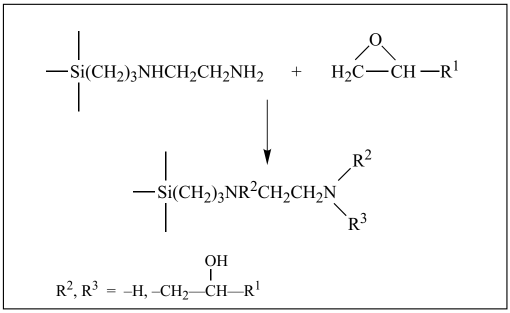

Fig. 2: *Alkalisation of the aminoethylaminopropyl function with epoxides.*

(Me$_3$Si-terminated or MeOHSi/HOSi-terminal) allows product types that meet special requirements to be accessible. Alkylation reactions represent one possibility of increasing the degree of substitution of the aminoethylaminopropyl function. In addition, the reaction with epoxides (alkyl oxides, glycidol, epoxy-functional silanes and siloxanes) is proposed among other things in order to reduce thermal yellowing (Fig. 2).

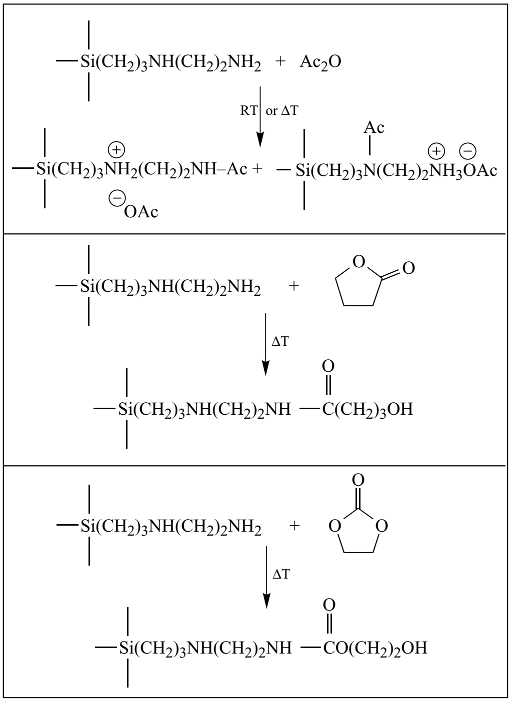

Fig. 3: Acylation in order to reduce thermal yellowing. From top to bottom: acylation with acetic acid anhydride; acylation with g-butyrolactone; acylation with ethylene carbonate.

Alkylation reactions of this type occur relatively unspecifically so that a reaction takes place with both the primary and the secondary amino group while multiple alkylations right down to quaternization may occur. To convert an essential part of the primary amino group into a higher degree of substitution, an overall high degree of conversion is needed. The unfavourable arrangement of the two amino groups with respect to thermal yellowing in the form of an ethane bridge remains intact, with the result that only moderate improvements in whiteness can be expected. It is also a disadvantage in processing terms that a strong viscosity increase occurs with the inevitable pre-reaction of the amine and epoxide components, which can negatively affect the ensuing emulsification. With the finishing, moreover, undesirable roller deposits may come about due to premature cross linking reactions. For the reasons specified, therefore, the direct synthesis of silicone oils containing only secondary amino groups is preferred to the subsequent alkylation of amino-functional silicone oils. The stability of amino groups towards thermooxidative breakdown can be significantly increased by acylation, i.e. conversion into amino groups. This principle is also transferable to amino-functional polysiloxanes. Essentially, this involves acylation with acetic acid hydride, γ-butyrolactone and ethylenecarbonate (Fig. 3) (according to Lauterschläger, Bindl and Huhn).

Silicone surfactants Organic molecules, which comprise the functional lyophilic groups, are bonded with an existing lyphobic silicone back. Silicones containing Si–Cl or Si–OR groups in the fundamental building blocks are assumed here. These might be converted with hydroxyfunctional reaction partners such as polyethers or fatty alcohols. These esterification or transesterification reactions occur invariably with good yields. This represents, besides the equilibration reaction, an important condition for the precise synthesis of customized silicone surfactants. The Si–O–C compound obtained in this way is not permanently hydrolytically stable especially in acidic or alkaline solutions, with the result that the use of silicone surfactants of this type is limited in aqueous media to neutral pH. Such silicone surfactants may be generally used without any problem in anhydrous organic systems. A hydrolytically stable Si-C compound is obtained with the aid of a hydrosilylation reaction. Hydrosilylation may be carried out with precision and good yields. In addition, Si–H functional siloxanes are converted in the presence of transitional metal catalysts (usually platinum complexes) with terminally unsaturated organic reaction partners. These are chiefly used with a certain surplus to guarantee a complete reaction of the Si–H groups.

Among the organo-polysiloxanes, the non-ionogenic polyether polysiloxanes form one of the most important substance groups; reference is also made to non-ionogenic silicone surfactants. The physical properties of these products can be varied to a great extent through changes in the length of the polysiloxane chain, through the polysiloxane/polyether ratio, through the number of polyether side chains and through the ethenoxide/propenoxide ratio in the polyethers, the result being that these copolymers have a large property spectrum (→ Silicones in finishing).

The basic building blocks for the manufacture of silicone surfactants are functional polydimethylsiloxanes, whose reactive centres are formed by Si–Cl, Si–OR or Si–H groups. The equilibration reaction allows the basic building blocks to be manufactured with great precision and reproducibility. Simple types are built up linearly. The functional group is terminally bonded in α-, ω-positions. Proceeding from this type, it is possible to obtain polymer surfactants in which each molecule is defined di-functionally, which therefore produce, in the strict sense, a surfactant with the general structure ABA, where the compatible remainder is designated as A and the polymethylsiloxane component as B. It is also possible, though, to synthesize higher molecular block copolymers with alternating lyophilic and lyophobic sections, if the siloxane building blocks are converted with similarly linear α-, ω- functional reaction partners. Such a surfactant type would therefore be built from repeating AB units. Here the reactive groups are laterally bonded to the linear polymer backs in a comb-shaped arrangement. The distribution of the lateral groups corresponds to the balance established by equilibration reaction. With other types, the siloxane ridge is branched. The surface activity of the copolymers richest in methyl groups is clearly the highest. Accordingly, these also display the best wetting action on polar and non-polar hydrophobic surfaces and are effective foaming agents in water.

Silicone test This simple qualitative test for → Silicones customary in water-impermeable finishes is based on the transferability of siloxanes from the textile material to glass by means of hot concentrated sulphuric acid. Method: pour 1–1.5 ml conc. sulphuric acid over approx. 50–100 mg test fabric in a new test tube, shake in a small Bunsen burner flame (without regard to the dissolution and any blackening of the liquid). Interrupt the shaking every 3–5 s and observe, away from the flame, how the shaken-up acid runs back along the test tube wall. If the acid is brought to the boil after 1–1.5 min at most, and the inside of the tube remains evenly wetted, the result is negative. Should, after approx. 20–40 s when still holding the test tube, a sudden downflow of the approx. 250–300°C, hot conc. sulphuric acid occur prior to reaching boiling point, it needs to cool down again. After pouring away the main quantity, wash out the remaining acid with distilled water, displace the water again with sulphuric acid and reheat. Should the sudden downflow reoccur after 20–30 s, the result is positive. The effect will disappear depending on the amount of silicone either at the start of boiling or only after lengthy heating. 0.5–1 mg polysiloxane can still be easily recognized. The result is negative with silicic acid. A further possible way of testing for silicones consists in reducing the fabric to ashes, with the silicones being converted to SiO_2, melting the ashes with a 6-fold quantity of sodium carbonate/potassium carbonate and dissolving in water. The solution is tested as follows:

a) Addition of some ammonium molybdate, acidification with nitric acid and heating. Yellow colouring indicates silicates or phosphates.
b) Replace solution with a surplus of freshly prepared 5% ammonium molybdate solution, adjust with hydrochloric acid to pH 3 and pour this solution in a surplus of freshly prepared sodium stannate (II) solution. Blue colouring indicates silicates and phosphates.

Silk The production of wild silk and the Bombyx mori type only comprise 0.2% of the world's fibre yield. Owing to fashionable demand, however, global production is growing. Bombyx mori, as the most important silk, is usually processed to grège fibres in the country of production. The seriplane test involves winding it visually on black panels and assessing the evenness of the threads in order to classify the quality of the yarn. Schappe silks are obtained in silk cultures after spinning off the cocoon of Bombyx mori. Wild silks, e.g. Tussah (China) or Eri (India) are obtained from wild caterpillars and processed into fabrics in the country of origin. Japan supplies just below 10% of world production; China is the major supplier of silk with 60%. India supplies approx. 14% of world produc-

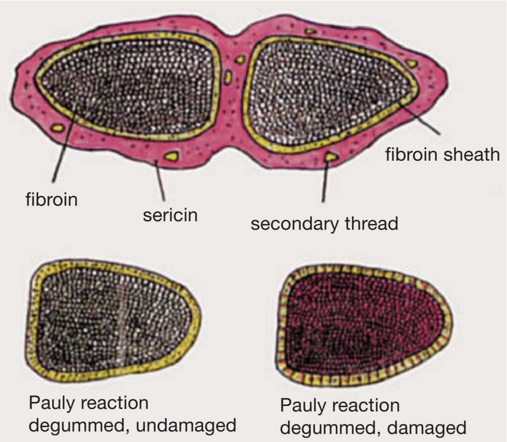

Fig. 1: Cross-section of a raw silk thread, and cross-sections of fibroin both damaged and undamaged following a Pauly reaction.

tion. Russia has a 6% and Brazil a 3% share in silk manufacture.

Silk consists of fibroin threads that are embedded in a sericin gum (Fig. 1).

With wild silks, the → Degumming, i.e. the detaching of the individual filaments from the gum, is difficult and laborious. Schappe silk is usually degummed in the yarn. Approx. 25% of silk gum has to be removed from Bombyx mori, and 5–15% from Tussah silk. Degumming occurs according to four processes (each at pH 9–11.5, 15 min to 5 h):

a) at 98°C with Marseille soap
b) at 98°C with surfactants
c) at 50–60°C with enzymes
d) at 128°C with water.

The average length of the section that can be reeled off varies, however, and is dependent on the genus, size, quality and type. As a rule, 600–800 m are reeled off in a test basin, though under operating conditions the length is only 400–600 m. The trimmings have a length of 250 mm. The length of a raw silk thread may reach 1500 m. The silk thread of a Tussah silk worm reaches a length of 1200–1400 m, of which approx. 600–700 m can be reeled off.

The fibre width and fineness of the raw silk thread differs depending on the origin, breed, sex and size of the cocoon. The fineness of the double thread, i.e. of silk that has not been degummed, is 15–25 µm or 1–3 dtex. The individual threads are 13–28 µm wide and have a fineness of approx. 1 dtex. This makes degummed silk the finest natural fibre. A filament of the Tussah silk worm (Fig. 3) is essentially coarser than that of the Bombyx mori (Fig. 2). It has a cross section of 40–80 µm and a fineness of 3.7–7 dtex. The fineness values can only be specified as an average since the strength within a cocoon shows great variations from beginning to end. The smallest number is found with the silk thread at the beginning. The thickness of the thread increases gradually, gains particularly rapidly in the final layers of the cocoon and is almost three times as large at the end. Such unevenness makes obtaining a uniform raw silk thread especially difficult. To compensate 5–6 cocoons are reeled together to form a multifilament that is subsequently twisted.

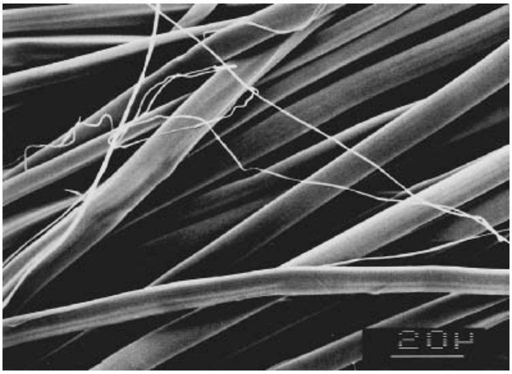

Fig. 2: Scanning electron microscope image of mulberry silk.

Fig. 3: Scanning electron microscope image of tussah silk.

I. Properties: non-degummed silk has a density of 1.37, degummed 1.25. With 2.5–5 cN/dtex, raw silk has a tensile strength which almost that of synthetic fibres. The wet strength is 75–95%. The tensile strength of the yarn is dependent on the length of the fibres, i.e. it becomes smaller with decreasing fibre length. That is why reeled silk has an essentially greater strength than Schappe silk and this in turn has a greater strength than Bourette silk. The abrasion resistance of silk is high. The adhesive silk gum has a negative effect, however, since the fibrous substance can chafe and is thus self regenerated. A loss of abrasion resistance can be seen with loaded silk since the adhesive metal salts make the threads brittle. That is why, with fabrics of this kind, rolling is preferable to folding. In a normal climate, silk will absorb 9–11% moisture, with 100% atmospheric humidity even up to 30%, without feeling damp. The water retention value is 40–45%. In its dry state, silk has a slight elongation of 10–20%. The elongation strength of raw silk is at 29%, that of degummed silk at 24%. Wet elongation 120–200%. Degree of elasticity 70%. The elongation and elasticity values of raw silk are higher than those of degummed or loaded silk. Silk has similar hygroscopic properties to wool. Degummed silk has swelling capacity and absorbency. Characteristic is an anisotropic fibre swelling which lies in the longitudinal direction at 1.65% and in the transverse direction at 18.7%. The sericin alone is the carrier of the natural yellow dyestuff. Depending on the origin, whitish, yellowish or greenish cocoons can be found. The silk fibroin of mulberry silk is either colourless or whitish and transparent, rarely yellowish. Since sericin is released upon boiling off or degumming, the white colour is characteristic of degummed silk. Wild silks are mostly light brown, though sometimes dirty-white or reddish. In contrast to mulberry silk, dyestuffs are also contained in the fibroin of Tussah silk, with the result that no white thread can be obtained with this even by boiling off and intensive bleaching conditions. Silk only obtains its shimmering lustre when the sericin is removed. The lustre depends strongly on the origin. Temperatures which are too high during soaking and insufficient tension when reeling off and drying affect the lustre adversely. Frequently the fibre loses some of its lustre by artificial loading. At the same time, silk gains in fullness as a result of degumming and obtains the characteristic silky handle or “scroop”. This handle should be neither soft nor hard, but rather allow a certain crackle to be felt (Fr. “craquant”). Tussah silk differs from mulberry silk in its harder handle and less exquisite lustre.

II. Chemical behaviour:

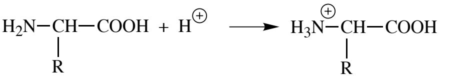
a) Heat: On heating silk to 120°C, no noticeable changes can be detected other than a gradual vaporization. If the temperature is raised to 130–150°C, the following reaction will occur: ammonia from amino acids begins to vaporize; the sericin becomes hard, its solubility in water deteriorates. The silk acquires a dark colouring, which gradually changes into a yellowish grey-brown shade. A change in the properties first occurs with temperatures of 160–170°C. The decomposition of the fibres can be seen from the increasingly darker shade and the smell typical of this reaction. The ash of the silk contains phosphates, sulphates, calcium salts, magnesium and iron. In air, the silk fibre will oxidize, which happens extremely slowly, however, under normal conditions. This process can be accelerated through increasing the temperature, though this is insignificant in a dry atmosphere. With increased atmospheric humidity, silk will oxidize more rapidly.

b) Light: the amino acids are in a position to absorb ultraviolet rays. Under their action, the intermolecular compounds become gradually weaker, thereby reducing the durability of the silk. After ten days of radiation by sunlight under glass, durability is reduced by 19%. With the same amount of radiation without protective glass, this value is 34% and rises in summer to 98%. Sericin has the task of protecting the fibroin from the effect of light.

c) Moisture: when silk is soaked in water, increasingly large quantities of salt and sericin dissolve with rising temperature. The composition of the water has a great effect on this. In boiling water, the fibre becomes rough, loses its lustre and durability, and swells up. Swelling can likewise be observed in a damp environment. Should a cocoon thread be placed in water at 18°C, the diameter increases by 16–18% and the length by 1.2%. When the cocoon cases are washed in warm water at 55°C with a liquor-to-goods ratio of 1 : 20, irregular weight losses of 0.37–3.51% will result. The values are different when boiling them in a 3%-soap solution (liquor-to-goods ratio 1 : 60): they vary according to the genus and type between 22–29%.

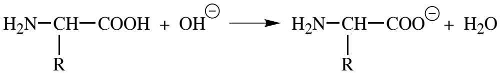
d) Acids and lyes: the silk fibroin is an amphoteric substance, which has binding power for both acids and lyes. It is hydrophilic in character corresponding to its amino acid composition.

acid bond:



$$H_2N{-}\underset{\substack{|\\ R}}{CH}{-}COOH + H^{\oplus} \longrightarrow H_3\overset{\oplus}{N}{-}\underset{\substack{|\\ R}}{CH}{-}COOH$$

base bond:



$$H_2N{-}\underset{\substack{|\\ R}}{CH}{-}COOH + OH^{\ominus} \longrightarrow H_2N{-}\underset{\substack{|\\ R}}{CH}{-}COO^{\ominus} + H_2O$$

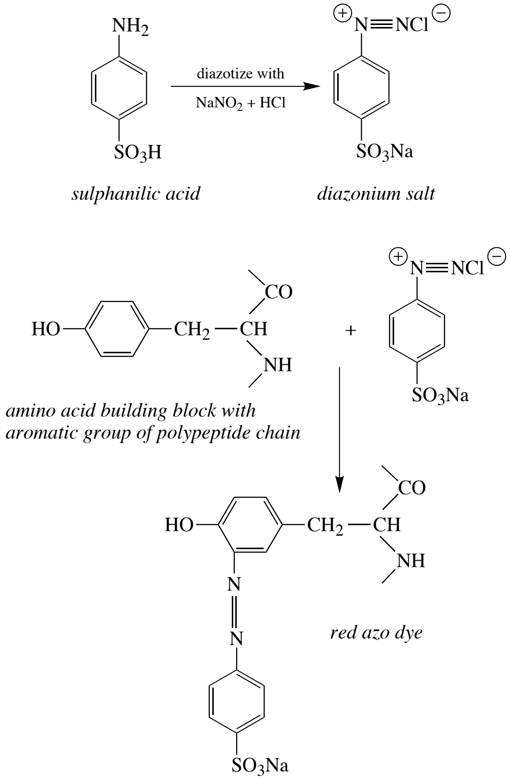
The diamine carbon acid content is smaller with silk fibroin than with wool keratin with the result that a max. approx. 0.024 gram equivalents of acid are capable of binding 100 g silk fibroin. The acid-binding power increases, as it does with wool, with increasing pH, whereby a saturation value is initially achieved between pH 1.3 and 0.8. It is only below pH 0.8 that the acid take-up increases rapidly, which is related to the charging and acid-binding power of the carbon amide group of the peptide bond conditioned by it. Warm, diluted mineral acids, such as salt and sulphuric acid, do not attack the fibroin, but dissolve the sericin. With moderately concentrated mineral acids, a shrinkage of the fibre can be seen, which is applicable in finishing (crêpe effect). Concentrated sulphuric acid destroys silk immediately. With cold or especially hot nitric acid, silk turns a yellowish colour. Organic acids have less effect on mulberry silk. Natural silk will dissolve through boiling with glacial acetic acid under pressure.

The max. base-binding power is hard to determine since the fibroin is attacked with increasing hydroxidion concentration. The base-binding power is roughly equivalent to that of wool. The binding mechanism of alkalis on fibroin is explained by the enolization of the amidized carboxyl group, whereby the alkali enters the hydroxyl group of the carbon atom adjacent to nitrogen. Lustre and handle are impaired by the action of diluted lyes while the sericin is dissolved. Through the action of alkalis on mulberry silk, the adjacent polypeptide chains are hydrolytically divided. This results in a shortening of the chains.

e) Pauly reaction as proof of degumming: with wool this reaction is based on the fact that the amino acid building blocks with aromatic groups form a red azo dye with diazotized sulphanilic acid. An amino acid building block of this type with an aromatic group is, for example, tyrosine, which is present in both wool

Next Page

and silk. The dyeing reaction proceeds according to the following:



The Pauly reaction has also been tested on silk. It was found that the gum turns an orange-red with the Pauly reagent (Fig. 1). It can be seen from this reagent whether the silk is degummed or not, i.e. where there is yellowing, the silk is clearly degummed and also undamaged. With orange-red coloration, it needs to be decided microscopically and by subsequent degumming of a test sample that the silk is degummed. If gum can no longer be shown to exist, the orange-red coloration signifies damage to the silk fibroin (white chate marks). Degummed Tussah silk turns a yellowish brown through the Pauly reagent and bleached Tussah silk is stained slightly orange (bleaching of Tussah silk is not possible without some minor damage). Mechanically damaged silk fabrics will also turn red, since the fibroin sheath is destroyed by a little tyrosine and thus the core of the fibre becomes accessible with a high tyrosine content.

Silk bolting cloth → Screen mesh, Screen gauze.

Silk damage Testing for damage to natural silk occurs by determining the viscosity of a solution of natural silk in concentrated aqueous lithium bromide solution.

Silk dusting Occurs due to the splitting up of silk under the effect of alkali or too great a mechanical stress in the working liquors and gives the fabric surface a whitish appearance, as if sprinkled with flour.

Silk dyeing The most important dye classes are acid, metal complex (predominantly 1 : 2), direct and reactive dyes. Cationic, afterchrome, vat (indigo) and vat leuco ester dyes are only used in special cases. In the high-fashion sector, classic brilliant shades in the red, blue and green range cannot as yet be replaced by more genuine products of equal value (Tab.). In contrast to wool and polyamide, the absorption curve for silk is different. Absorption already begins at 30°C and has virtually reached the optimum at 60–70°C. With the moving dye, e.g. on the overflow, this temperature range should be used since the risk of damage to the fabric increases at higher temperatures (dusting). A 60 min dyeing period at 60–70°C is gentler than 40 min at 90°C. To obtain equal dyeings, care should be taken to ensure that a rise in temperature in the dye bath of 1°C/min is adhered to.

I. Dyeing in the pH range of 4.5–7, depending on the dye depth, shade and type of fabric. pH control by means of acetic acid or buffer system of sodium acetate/acetic acid, no addition of salt necessary. Levelling agents are important; fibre preserving agents (lubricants) are advisable when dyeing in the hank.

II. Dyeing in a weakly alkaline soap bath at pH 8–8.5 (e.g. with Marseille soap), addition of sodium sulphate, no levelling agents necessary. Better fibre preservation, better evenness. Depending on the colouring, the shade will turn out slightly lighter. For larger batch-

es and lighter shades, the cold dwell process may be used (pad batch 24 h).

III. Process for reactive dyes: various reactive systems can be dyed on silk. Fixing mechanism and binding stability differ, as do the resistances. With weaving yarns, the demand for resistance to degumming may also be important; then dyes should be selected which are stable in the hot alkaline bath. Two processes are normally encountered:

a) Exhaust dyeing in the alkaline range (sodium carbonate or sodium hydrogen carbonate) at 50–70°C with the addition of large quantities of salt (up to 100 g/l for black).
b) Cold dwell process with alkali (sodium carbonate or sodium hydrogen carbonate), poss. urea, dwell time 24 h at room temperature.

To achieve good wet fastness properties, a subsequent washing treatment at approx. 80°C is important for both processes; care should be taken to ensure that the mechanics are protective (according to Hofstetter, Flensberg and Hammers).

Silk dyeing machines There are dyeing machines specially developed for silk, in which the silk fabric is treated as gently as possible. To this end, driven reel winders with a particularly large radius are used, especially in overflow machines, to prevent slippage of the fabric (see Fig.).

Silk fabric inspection packaging In silk finishing operations, description for areas in which pieces are checked and made ready for consignment.

Silk finish → Silk scroop.

Silk finish for cotton (Schreiner effect), discreetly shimmering “silk lustre” on fabrics (e.g. damasks, satin, linings, shirting fabrics, etc.), also combined with synthetic resin intercalations, as washproof or permanent silk finish (dress and blouse fabrics). In each case, there is a refraction of light effect on the fabric surface of the finest ribs, only visible under a magnifying glass, which has been produced on a silk finish calender. Silk finish is recommended with qualities of fabric which preclude mercerization for cost or technical reasons (linings or certain dress fabrics).

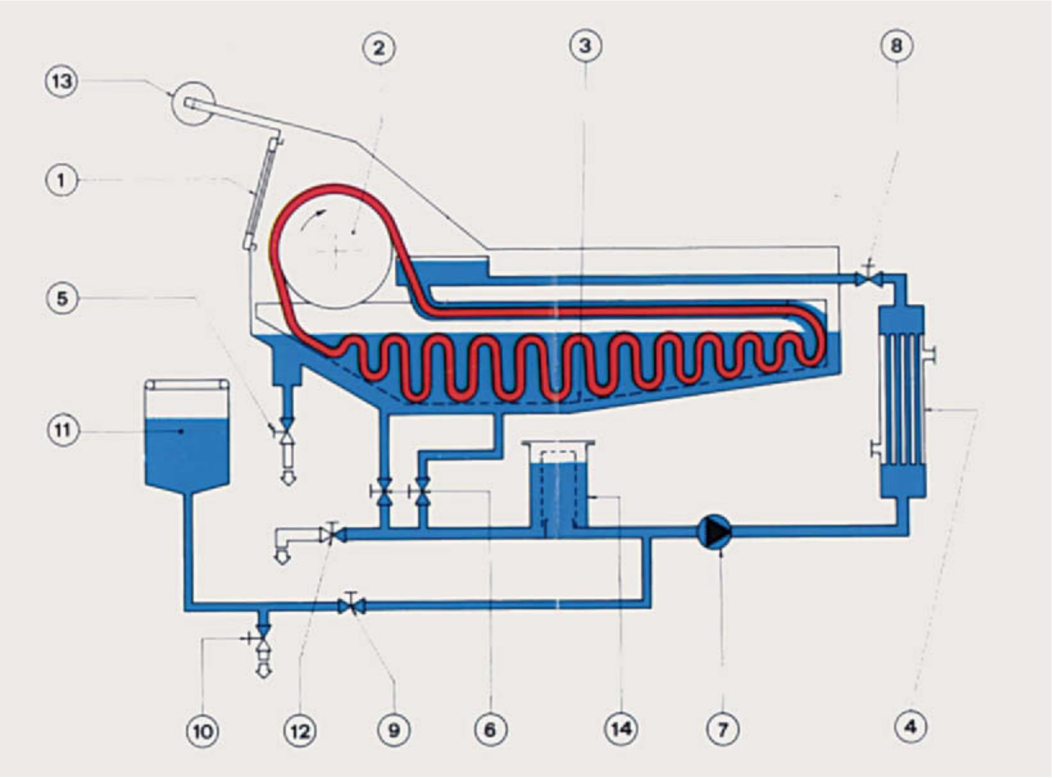

Fig.: A Mezzera overflow for silk.
1 = loading; 2 = guide winch; 3 = channels for fabric transfer; 4 = heat exchanger; 5 = overflow valve; 6 = suction control valve; 7 = main liquor circulation pump; 8 = demand control valve; 9 = product intake control valve; 10 = drain valve for additives; 11 = preparation tank for dyes and additive products; 12 = machine drain valve; 13 = unloading winch; 14 = filter.

Silk finishing The finishing of silk is usually limited to restoring the handle and lustre worsened by other finishing processes (bleaching, dyeing, drying). The finishing of the different silk qualities varies depending on the desired handle. Besides the handle of the fabric, the following finishing effects on silk are important:
- dimensional stability, thread straightness/shrinkage
- no formation of folds, white chate marks, dusting
- resistance to slipping
- resilience
- scroop (crackly feel)
- soft, flowing drape
- hydrophilic property
- non-marking of water drops
- dirt repellence
- oil and water repellence
- antistatic behaviour.

If so far the main focus of attention has been on traditional handle finishing, the question of greater fastness to care and wear of the silk is being raised with increased frequency. As with other fairly easy-care textiles, issues such as crease resistance, anti-electrostatic effect, elasticity, stain removal and the machine-washability of silk up to 60°C and 80°C are being discussed. Problems regarding the wet fastness level of dyed or printed silk have been able to be solved through the use of reactive dyes.

It should not be forgotten that "easy-care" finishing of the silk only represents a real improvement if the outstanding natural properties of this natural fibre are preserved and an improved resistance of the silk to mechanical strains of all kinds is achieved in addition (according to Flensberg and Hammers, Monney and Moreau).

Silk grass (Honduras silk grass) Longest type of bast fibres belonging to the → Bromelia fibres (Central and South America). Cream-coloured, silky bright, fine and soft (surpassing the Cantala and Mauritius fibre).

Silk gum → Sericin.

Silk hardening → Degumming.

Silk printing Besides direct printing, discharging is one the conventional modes of operation. Resist printing has only been able to gain limited acceptance. The printer uses several ranges of dyes, in order to do justice to the demands in discharge printing.

I. Direct printing: acid, acid milling, 1 : 2 metal complex and reactive dyes are taken into account. The first three groups, properly selected and cationically after-treated, facilitate good fastness to water and washing up to 40°C. For greater demands, reactive dyes should be used. There is increased use of continuous festoon steamers compared with the star, as well as the development of better open-width wash machines.

II. Discharge printing: a lot of experience and continuous monitoring form part of the implementation. The choice of dyes and the discharge chemicals under the existing operating conditions are crucial. Process:

a) white discharge;
b) coloured discharge with direct, acid, metal complex or cationic dyes as illumination dyes;
c) coloured discharge with vat dyes.

Direct, acid, metal complex or reactive dyes are considered as background dyes. The dischargeability of each dye delivery should be checked. The choice of the reducing agent is greatly dependent on local conditions as well as the process chosen. Some illumination dyes are not very fast to wet treatment, the upshot being that they cannot withstand one wash (even at low temperature); the fastness to light of some elements is also only moderate. The choice of discharge-resistant dyes increases considerably with tin dichloride. Some elements are at a wet fastness level that permits a wash up to 40°C. The yellow cast of the discharged portion that is added to the illumination shade has a coloristically negative effect, however. Last, but not least, the corrosive effect of tin dichloride on the steaming equipment should be considered (separation from hydrochloric acid). Only the coloured discharge with vat dyes on the reactive ground supplies washable silk prints with wash fastness properties up to 40°C and above. The process is not technically simple, however. In addition, many of the suitable indigoid vat dyes have disappeared from the market so that colorists are limited in their choice of shade.

III. Resist printing: resist printing processes represent an interesting alternative to discharge printing from a coloristic point of view and are particularly well-suited to table film prints on silk. The process is based on the property of special resist agents to resist certain acid and metal complex dyes, while not preventing others from fixing to the fibre. The colorist is thus given the opportunity to manufacture a large choice of ground and overprint shades. In this wet-on-wet process, only one operation is required. The resist printing processes are technically easier to control than discharge printing and offer greater operational safety (according to Hofstetter, Monney and Moreau).

Silk ribbon finish At one time a valued special type of finishing based on resins and ether-soluble gums in benzole and similar for (esp. thread-dyed) pure-silk (taffeta, Liberty) ribbons, to achieve a full, solid handle, without stiffness or hardness. Since then, synthetic resins have been increasingly used for silk ribbon finishing.

Silk scroop (scroopy handle, craquant, crackly finish, crunchy feel, silk finish, silky handle). Crackly handle due to subsequent treatment of textiles with soap or fat emulsion and organic acids (folic, lactic, acetic, tartaric, citric acid). The silk scroop is not usually stable in storage, leaves an unfavourable flabby handle and a slightly rancid odour due to the eliminated fatty acids. Is dependent on the climate (humidity).

Silk structure The microfibrils in the fibroin consist of stretched protein chain molecules that congregate in flat layers via hydrogen bridges. These layers are folded (pleated sheet structure). In the hierarchy of raw silk fabrics, it is recognized that this is a compound structure of fibrils (individual fibroin filaments) in a matrix (sericin) (Fig. 1). The individual fibroin filament is a compound of fibrils and interfibrillar material. The fibrils consist of crystalline domains embedded in non-crystalline material.

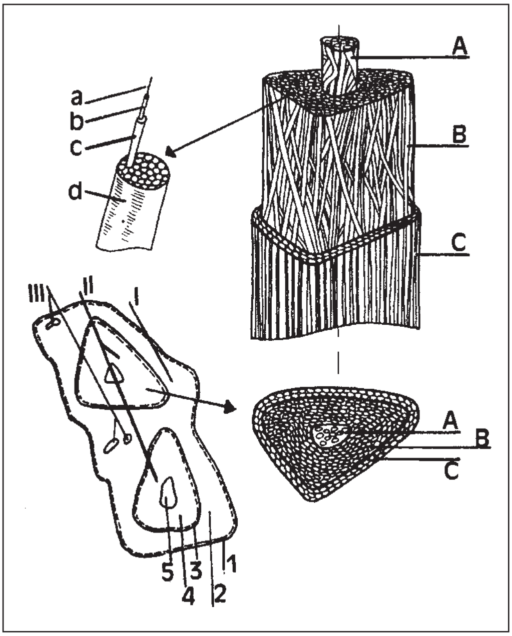

Fig. 1: The hierarchically organized structure of silk from sericin and fibroin.
I = sericin; II = fibroin fibres; III = secondary threads; A = core zone; B = fibre layer; C = skin or mantle zone; 1 = sericin skin; 2 = sericin layer; 3 = fibroin skin; 4 = fibroin layer; 5 = fibroin core; a = elementary fibril; b = microfibril; c = macrofibril; d = fibril rope.

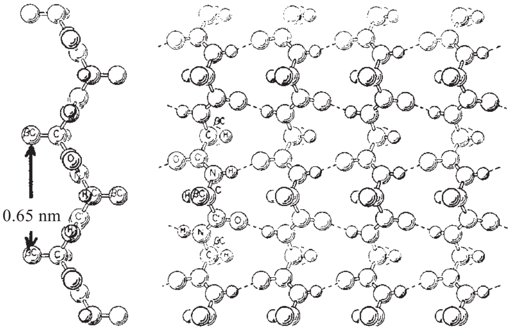

Fig. 2: Pleated sheet structure (according to Pauling) with parallel protein chains and a reflection from the fibre axis (b in the unitary cell) of 0.65 nm as demonstrated by X-ray radiography.

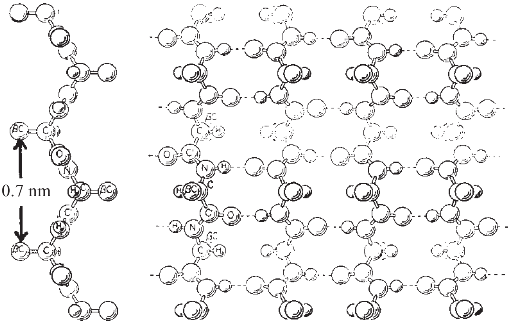

Fig. 3: Pleated sheet structure (according to Pauling) of silk fibroin with antiparallel protein chains with typical hydrogen bridges and characteristic X-ray reflection of 0.7 nm.

Pauling distinguishes between parallel and non parallel pleated sheet structures (Figs. 2 and 3). It is characteristic of the pleated sheet structure of the silk fibroin that the amino acid residue of the glycine is inserted in the polypeptide chains in a regularly alternating manner; hence the reason why all other side chains, e.g. the methyl group of the alanine protrude from one side of the layer; only the hydrogen atoms of the glycine residues protrude from the other side (Fig. 4). The pleated sheets are packed together face to face and back to back. This results in a sandwich structure with methyl groups between the pleated sheets, which in line with the greater space requirement of the methyl groups need to be remote from each other. The methyl group of the inserted alanine residues is the most frequent side chain in the pleated sheet structure. The peptide chains in the crystal lattice of the β pleated sheet structure are usually connected to each other by means of hydrogen bridges between the peptide bonds so that layers are produced.

In hydrolysates of silk fibroin, 18 different amino acids were identified and quantitatively determined (see Tab.). There are precise findings available concerning the amino acid sequence in the fibroin. Approx. 60% by weight of the fibroin can be separated out of a colloidal aqueous fibroin solution by enzymatic hydrolysis with chymotrypsin and be isolated as X-ray crystalline powder. This powder consists of a chemically homogeneous polypeptide in which the amino acids glycine, alanine and serine are present in the molar ratio 3 : 2 : 1. The predominant repeating unit is a hexapeptide that repeats either 8 times $[\text{Ser-Gly-Ala-Gly-Ala-Gly}]_8$ or 7 times $[\text{Gly-Ala-Ser-Gly-Ala-Gly}]_7$.

Silk fibroin is a mixture of two different fibroin

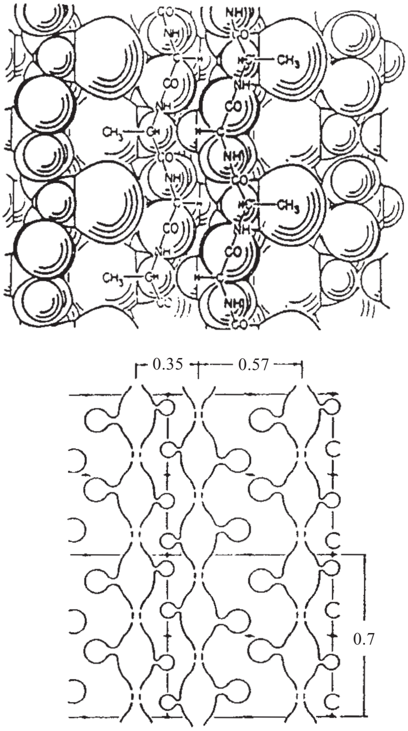

Fig. 4: The different separations (0.35 nm and 0.57 nm) between silk fibroin chains due to the grouping of all methyl groups in hydrophobic pools (0.57) and due to the orientation of the residual hydrogens in other pools (0.35).

amino acid	co-confibroin (according to Lukas)	fibroin from the posterior silk gland (according to Shimura)			sericin (according to Komatsu)

Tab.: The amino acid composition of silk protein in mol %. (lg. sub. = large subcomponent; sm. sub. = small subcomponent).

molecules, which differ slightly in their molecular weights. After the reduction of few disulphide bridges, a heavy (H) and light (L) polypeptide chain are formed in the molar ratio 1 : 1. The amino acid compositions of these chains are reproduced in the Tab. (H = large sub-component; L = small sub-component). The H chain occurs in three variants (F, M, S), the L chain likewise in three variants (A, B, C). The composition of the particular variants is genetically controlled. From the table, it can be seen from amino acid analyses of the total fibroin artefacts that a protein mixture is present. Only amino acid analyses of the two sub-units lead to correct results.

Silk union Generic term for fabrics that contain natural silk or filament yarns similar to silk in one thread system.

Silk waste →: Bourette; Schappe(silk).

Siloxanes Oxygen compounds of → Silicon. Polysiloxanes:→ Silicones. The siloxane bond is, on the one hand, solid enough to make silicones useable as materials and still reactive, and on the other, it can synthesize macromolecules of virtually any size and constitution by the aid of diverse chemical processes. A direct consequence of this property is the so-called equilibration capacity, i.e. the thermodynamic controlled reorientation of siloxane bonds in relation to molecular weight, type and effect of the individual building blocks by acid or alkaline catalysts. The greatest advantage of this behaviour consists in the exact reproducibility of all properties of a given silicone and the possibility of subsequent correction. By varying the chain length and the organic groups bonded to the silicon, especially by deliberate modification involving specific terminal and/or pendant groups, a variety of methylpolysiloxanes have been developed that are used in the textiles industry (→ Silicones in finishing).

Silver (Ag). Atomic weight 107.93. White precious metal, soft and tough, can be stretched, hammered and polished, resistant to air (hydrogen sulphide traces cause dark colouring). Good conductor of electricity and heat. Melting point 960.2°C; density 10.5. Soluble in dilute nitric acid, concentrated sulphuric acid and potassium cyanide solution. Compounds: silver is monovalent, as colourless silver nitrate it is soluble in water, as silver chloride (white) it is soluble in ammoniac, not in dilute nitric acid; silver bromide (yellow), silver iodide (yellow) is insoluble in ammoniac. There is a tendency to complex salt formation. All water-insoluble compounds are soluble in excess ammoniac (except for silver iodide). Use: metal for valuable apparatus parts and measuring instruments. Non-metallic compounds especially for volumetric analysis.

Silver-bronze → Bronze printing.

Silver nitrate stains Typically light to dark brown, normally blurred edge. To remove: a) potassium iodide solution 10% takes around 60 min, then sodium thiosulphate solution 10% if necessary; (old stains) pre-soften overnight with fatty alcohol sulphanate solution and potassium iodide solution 10–20%, wash out, continue as above; b) potassium cyanide solution 5%, with thorough subsequent rinsing.

Silver number, silver index Indicates how much silver is reduced and separated from 100 parts test material numerical expression of bleach damage on cellulose fibres.

Silver printing → Graphite prints. Carried out with appropriate → Metal powders.

Silver test with ammoniacal silver solution Solution A: 1 g silver nitrate and 10 ml water. Solution B: 4 g sodium thiosulphate and 100 ml water. Mix solutions A and B, and add sufficient thiosulphate until the precipitate is dissolved. Then add solution C (4 g ammoniac and 100 ml water). Bring everything to the boil, filter and preserve the light-sensitive solution in brown bottles. Application: to test for hydrocellulose, especially with subsequent treatment with dilute ammoniac. Yellow-brown colouring according to the degree of damage. Also to test for wool damaged by sunlight (black colouring).

SIM Malaysian standards organization. → Technical and professional organizations.

Simili → Metallized yarns made from artificial gold.

Simili mercerizing Mechanical glaze finishing of fabrics (white goods, shirting fabrics, damasks, coloureds in fast dyeing) without chemical application, by calenders in the wet state at high thrust and high temperature (up to approx. 300°C, thrust approx. 80–120 t, speed approx. 10–25 m/min) for surface deformation effects. As a cheaper process for manufacturing glazes similar to → Mercerizing, which is very fast to water and, to a certain extent, also washfast.

Simon-Goodwin charts → Colour difference formulae.

Simple cleaning In the context of dry cleaning, cleaning and drying only without a specific stain removal stage (spot removal).

Simple perforation → Drum perforation.

Simple round perforation → Drum perforations.

Simplex fabrics Velour-type surface processing of knitwear made of cotton or synthetic fibres such as polyester, polyamide, acetate and triacetate. Originally limited primarily to glove qualities, for clothing fabrics including sport and leisure articles.

Simulated grass matting Rot resistant, coarse artificial grass matting made from coloured synthetic fibres, usually polypropylene.

Simulated leather foil As per DIN 16 992/1980: Plastics film with simulated leather surface finish.

Simulation tests Degradation test procedure to assess the biological level of waste water treatment plants (see Fig.). The degradation process is simulated in laboratory models under practical operating conditions, as in the aeration tank of a waste water treatment plant. Unlike → Screening test OECD 301 E, simulation tests involve systems with a high bacterial cell density (activated sludge) and continuous dosing, whereby the test substance is tested using high quantities of readily degradable compounds ("synthetic waste water"), i.e. under practical operating conditions. The average residence time of the test substance in the aeration tank of the treatment plant is normally 3 h, being a value that is significantly greater in modern waste water treatment plants and thus conforms to somewhat stricter test conditions. If over a period of several weeks the reduction in the test substance is determined

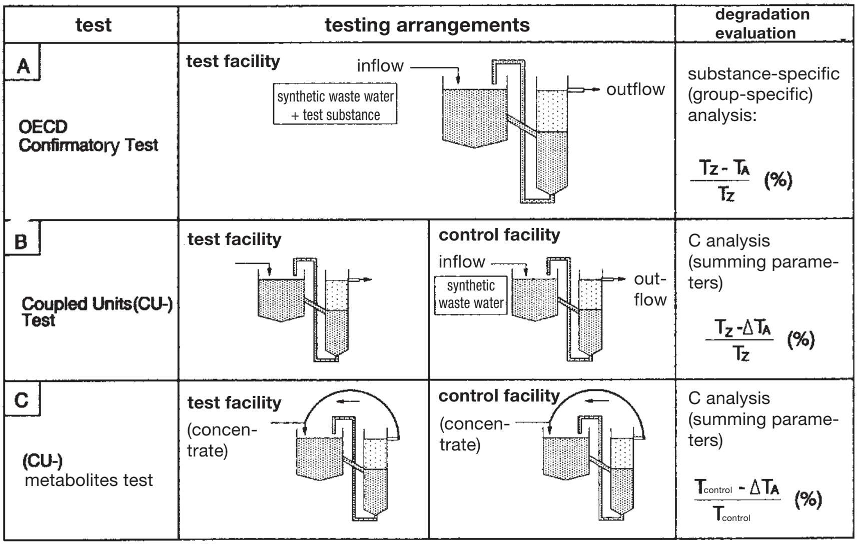

Fig.: Degradation testing system based on sewage treatment simulation tests.

in the inflow and effluent of the test treatment plant from a substance (group)-specific analytical procedure, such as MBAS or BiAS measurement, this will yield the scale of the primary degradation that can be expected under waste water treatment plant conditions. Within the framework of surfactant legislation, the so-called OECD Confirmatory Test constitutes the reference test as to whether the statutory required primary degradation is satisfied at least 80 % by a surfactant, insofar as this has not already been verified by the results of the OECD screening test (according to I. Steber).

Simultaneity factor Term used in electrical engineering for economically comparing the sum of all connected loads of the built-in power users in a (machine) unit with the so-called working load, the maximum sum of all connected loads of power users that are simultaneously operative in the work sequence of such a unit.

$$\text{simultaneity factor} = \frac{\text{connected load}}{\text{max. working load}}$$

Singeing Scorching, gassing of fibre ends protruding from surfaces on yarns, fabrics, etc. if a fluffy fabric is not required. Singeing is predominantly carried out on textile fabrics manufactured from yarns in the form of knitgoods or wovens. The aim is to achieve a smooth and fibre-free surface, which is essential both for subsequent processing in textile finishing and for desired serviceability properties. Knitgoods or wovens made from all types of fibrous materials or their blends can be singed, with singeing having special significance in cotton finishing. The smooth surface obtained exhibits the following improved properties in the textile fabric:

- clearer visualization of the particular textile fabric,
- reduced soiling with subsequent processing,
- more stable fabric appearance in the dyeing with plain colours due to reduced diffuse light reflection,
- sharp contours to the printed pattern with print fabrics,
- antipilling finish obtained, especially with fabrics made of polyester or cotton/polyester.

A distinction is made between direct and indirect processes:

I. Direct: The dry fabric passes a red hot metal radiator (500°C) or a non-luminous gas flame (all types of gas are possible). With contact singeing, the textile fabric is guided over heated plates or rotating cylinders (approx. 750°C). Contact singeing is primarily used to singe velvet. When the machine is idle, the textile fabric is automatically removed from the cylinder. The fabric speed is 70–80 m/min. The singeing effect depends on the contact surface between the textile and the heated element. Risk of fire can be prevented by installing a so-called spark suppressor.

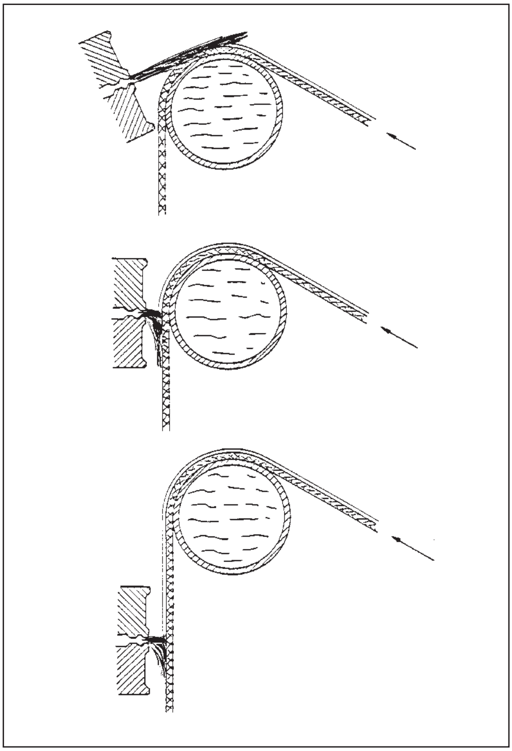

Fig. 1: Singeing positions using an open flame (by Osthoff). Top: tangential singeing; centre: singeing on a water-cooled roller; below: singeing free-moving goods.

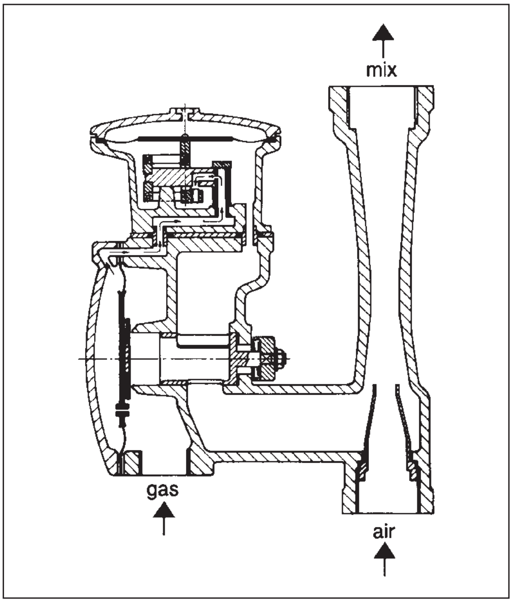

Fig. 2: Producing the gas/air mixture (Parex).

II. Indirect: The fabric passes heated ceramic bodies arranged at intervals and emitting IR rays.

The temperature of the singed fabric is a measure of the singeing effect. The high speed of the fabric protects it from charring (50–200 m/min). Plate singeing is rarely used as a direct process; it has been supplanted by cylinder singeing. The indirect processes have become more significant due to the need to protect the textiles. The textiles are normally singed in the raw state, less often between the stages of scouring and bleaching or dyeing. In practice, wovens are chiefly treated in this way since this pretreatment is too uneconomic for yarns.

The singeing of synthetic fibres assists in reducing the tendency to pilling. Three positions are distinguished between when singeing with a naked flame (Fig. 1).

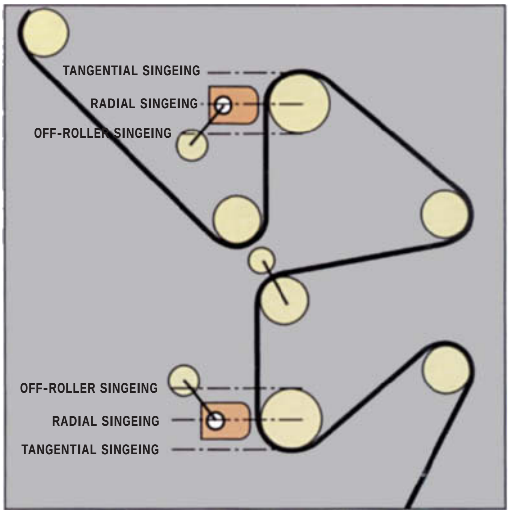

Fig. 3: Fabric flow in a singeing machine (Julien).

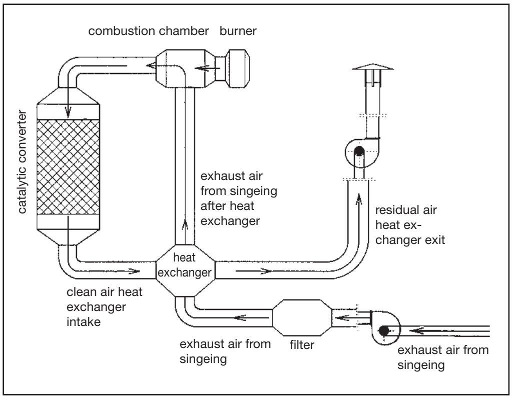

Fig. 5: The thermal afterburning of exhaust air from singeing (Osthoff).

What is important when singeing with a naked flame is the constant mix of air and gas (Fig. 2). At the start of the pretreatment, the cotton fabric passes through the singeing machine (Fig. 3), prior to any sparks being extinguished in a roller beck (Fig. 4).

The exhaust air from singeing can be disposed by after combustion in the existing steam boiler by means of a system depicted in Fig. 5. Other special post-combustion systems are also well known.

Singeing machine Especially used for wovens and knitgoods with low-tension controlled throughput involving several singeing positions: tangential, counter-roll and counter-fabric. Especially used for the technical pretreatment of knitgoods in tubular form prior to mercerization (Fig. 1).

The singeing machine is preferably used for cord,

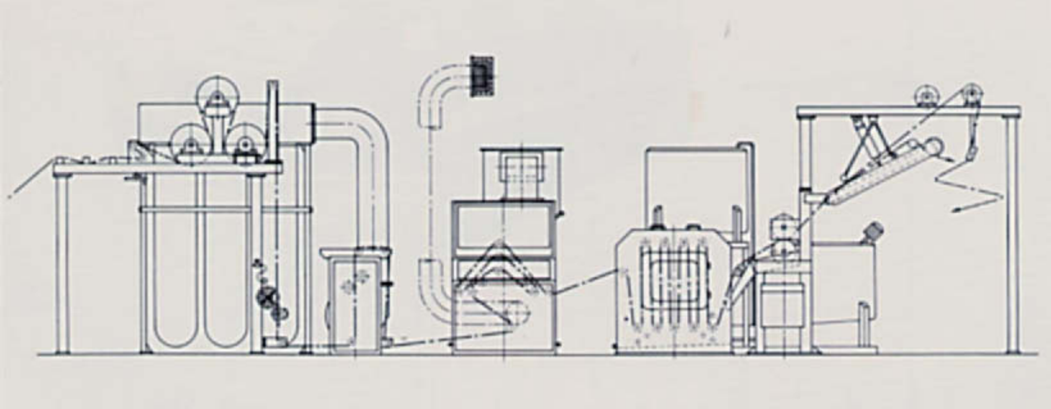

Fig. 4: The beginning of cotton pre-treatment, with singeing and spark suppression.

Singeing machine for tubular knitgoods

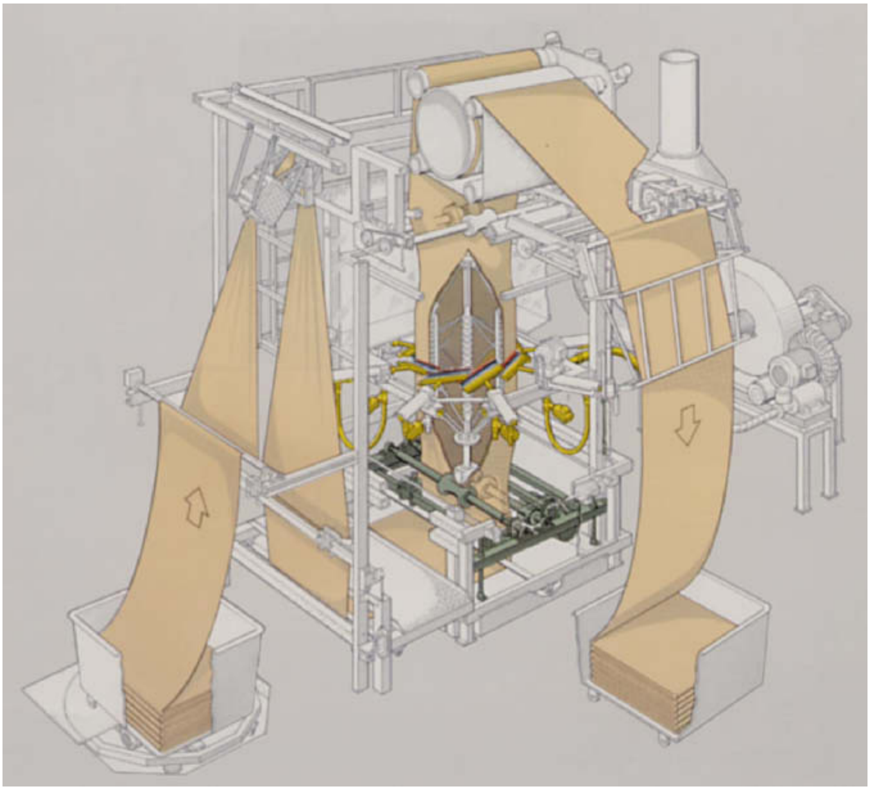

Fig. 1: *Tube singeing for knitted goods (Dornier).*

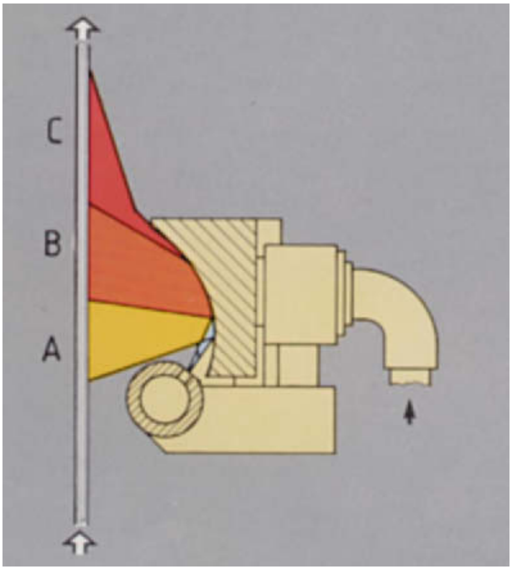

Fig. 2: The way in which a singeing machine works (Julien): zone A = pre-drying by infrared radiation; zone B = the effective working area of the flame across a wide fabric web; zone C = the afterburning zone.

with the avoidance of singeing stripes. To separate fibres on and between the ribs, high burning potential is required. The cord back that is not being singed runs against water-cooled rollers.

Singeing speed: 50–100 m/min (cord), 50–180 m/min (flat woven fabric [Fig. 3]). Predrying, flame singeing and after combustion will occur at these speeds in front of the burner flame (Fig. 2).

Singeing machine for tubular knitgoods A singeing machine with an annular burner designed for knitgoods in tubular form. The singeing of tubular knitgoods is one of the problems for which satisfactory solutions have recently been offered. All previously available systems are fraught with disadvantages, which have prevented the singeing of tubular goods from really gaining acceptance, even though there is no denying the general recognition there has been of the need for this system with many fabrics.

The singeing machine for tubular knitgoods is equipped with one or two rotating burners, i.e. it can be used for two sizes of tubular fabric. The tubular fabric is opened and guided via a conically shaped basket. The basket is carried in rollers similar to the familiar tubular fabric stretcher. The elasticity of the knitgoods allows the diameters of the goods to lie between 10–15% be-

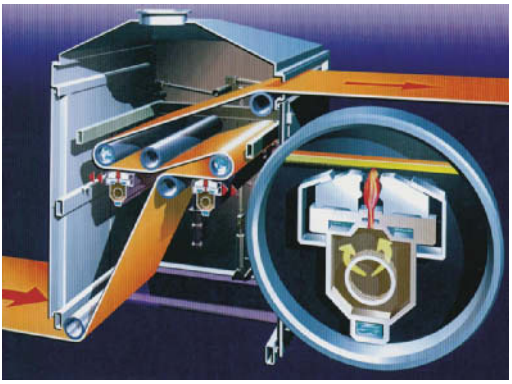

Fig. 3: Singeing unit (Küsters).

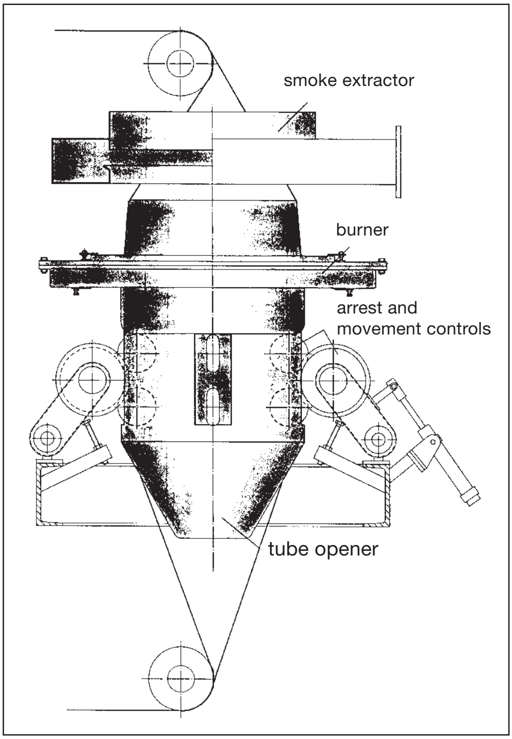

Fig. 1: A singeing machine for tubular knitgoods (Osthoff).

low or above the diameter of the guide basket. At the delivery end, the guide basket is conically shaped. In this area the singeing flame impinges on the tubular fabric, which is completely open at this point. Singe markings are therefore out of the question.

As a burner, the singeing machine for tubular knitgoods in Fig. 1 uses a device which is similar in structure to a double-jet burner. Adjustable drive units allow the singeing speed to be regulated to meet requirements. The operating speed is adjustable between 30–80 m/min. The singeing machine for tubular knitgoods is equipped at the outlet with a plaiter, which is fitted with a spark arresting roller. Converting the singeing machine from one dimension of tubular fabric to another is easy since both the burner and the guide basket can be changed quickly and without much effort by appropriate auxiliary devices. The disposal of the waste gas (Fig. 2) is via a suction channel, which is located above the burner and connected to a fan designed to meet the requirements. The singeing machine for tubular knitgoods depicted in Fig. 3 uses diagonally positioned burners.

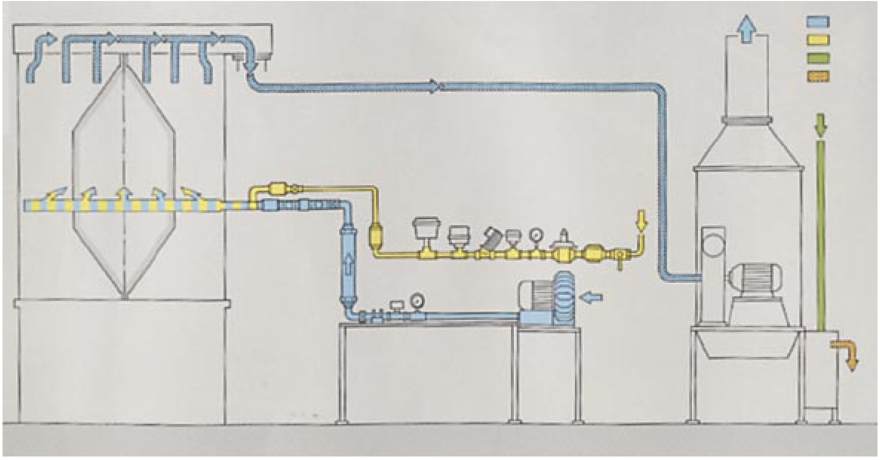

Fig. 2: Flue gas treatment for an Osthoff singeing machine for tubular knitgoods.

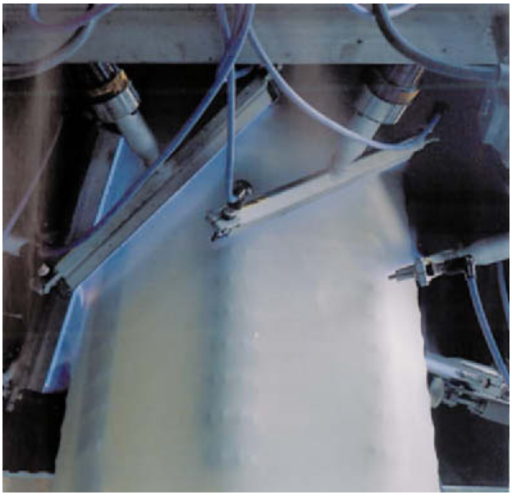

Fig. 3: Machine for singeing tubular knitted goods (Dornier).

Dornier (Fig. 4) has developed a new singeing concept on the basis of the thoroughly proven circular expander from its mercerising machine. It enables tubular knit fabrics of cotton and its blends in all the usual diameters to be singed evenly and free of selvedge marks. The fabric is guided over the circular expander under controlled tension so that

- the stitches are opened and intensive singeing can be performed on the fabric in its circular form,
- with the fabric being singed in its tubular form, selvedge marks are avoided,
- optimum singeing is applied to each tube diameter,
- process reproducibility is guaranteed.

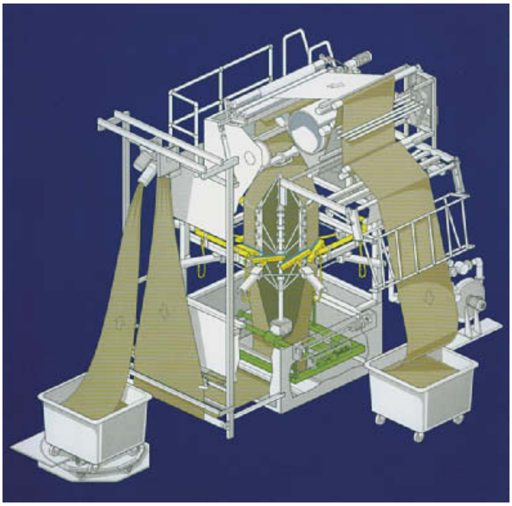

Fig. 4: Circular singeing; technical drawing of Dornier singeing machine, type EcoSinge.

The fabric is guided onto the circular expander via a turntable and untwister. Located around the circular expander are eight swivelling burners. These are mounted on a ring such that the full flame width of each segment can be applied to the fabric irrespective of the diameter setting. The diameter of the circular expander is power-adjusted and coupled to the burner adjustment system. Thus the gap between the burner and fabric remains the same.

Single-bath chrome dyeing process → Chromate dyeing process; Chroming of dyes.

Single-bath chrome mordant → Metal mordants, for mordant and chrome dyes.

Single-bath exhaustion process Dyeing process in which several components are applied to the fibre in a dye bath, e.g. dispersion dyes and cotton, wool or cationic dyes.

Single-bath extended steaming process Continuous dyeing process for various types of fibre and groups of dyes. The padded dye is fixed by prolonged steaming (up to 15 min). With pad-steam systems, the economical steaming period is only 60 s. Single-bath extended steaming processes have only been possible since suitable steamers have been available.

Single-bath/pad/dwell process Reactive dyes are padded together with lye or water glass/lye.

Single-bath process Treatment, especially for dyeing blended fibres, in a bath, i.e. with dyes for each component. Contrasting process → Two-bath process, i.e. treatment in two consecutive baths. Variants: Single-bath single-stage process corresponds to single-bath process. Single-bath two-stage process, whereby, at the end of the first treatment stage, the second stage is carried out in the same bath.

Single-bath single-stage process → Single-bath process.

Single-bath 2-stage process → Single-bath process.

Single-bath steam process for reactive dyes Principle: padding with dye and alkali and steaming with/without intermediate drying.

Single charge sewerage filter Serves as a → Sewerage filter, where in each working charge a fresh filter layer is deposited on the filter elements, the soiled filter cake is cleaned. The filter cake is either maintained under pump pressure (self-cleaning) or has to be stripped off (usually automatically) by backwashing, or by compressed air or mechanical devices. Single charge sewerage filters have, with the smallest dimensions, max. flow, greatest rinsing action, smallest greying risk.

Single coarse raw silk Simple, coarse raw silk thread (8–10 cocoon threads) made from inferior cocoons, e.g. as inlay threads for spun metallic yarns.

Single-component coating system Polyurethane coatings whose mass contains linear polymers with a high molecular weight. They do not require any subsequent hardening after coating and drying.

Single end sizing Process involving guiding threads through nozzles which separate several chambers from each other. Residual drying in heated pipes (< 12 m long), subsequent batching on crosswound yarn packages. Owing to the fast speeds, not suitable for sizing warp ends in industrial standards. Applied to special yarns (e.g. asbestos threads, novelty yarns, sighting thread). Basic disadvantage: nozzle change for each size range. – Manuf.: OPI.

Single face fabrics (plain jersey fabrics) → Knitted fabrics with only right-side loops on one side of the fabric and only reverse-side loops on the other side of the fabric.

Single filaments Monofilament chemical fibres.

Single-layer stenter → Horizontal stenter.

Single-metal machines E.g. double drum machines with inner and outer drum consisting of the same material; almost exclusively stainless steel.

Single package centrifuge Especially for large textured yarn packages. – Manuf.: Frauchiger.

Single-phase printing process The printing paste contains, besides dyestuffs, the chemicals required for the application, e.g. reducing agents with vat dyes or alkalis with reactive dyes.

Single-pole system Hank dyeing equipment where the yarn hanks are treated suspended from only one pole.

Single squeegee Screen printing squeegee with one blade.

Singlet oxygen Referred to as an active molecule in bleaching processes. The oxygen molecule is paramagnetic and has two unpaired electrons. It is therefore a diradical although under normal conditions it is relatively non reactive for homolytic substitutions and additions. For the oxygen molecule in the normal state, the structure

A

$$:\ddot{O}=\underset{\cdot\cdot}{O}:$$

would initially be expected with a double bond. However, the normal state of the molecule has the term symbol $^3\Sigma$, and from this it emerges that two electrons are not paired. Consequently the molecule is very paramagnetic. The structure with double bonds represents the first excited state $^1\Delta$. The atoms in the normal state, stable at 93.8 kJ/mol are held together by a single bond and two three-electron bonds. The number of electrons and orbitals exactly matches the structure

B

$$:O\overset{\cdot\cdot\cdot}{\underset{\cdot\cdot\cdot}{-}}O:$$

where each oxygen atom has occupied one of the four valency orbitals with a free pair of electrons. Another orbital is then available for the single bond, and the remaining two are available for the two three-electron bonds. Since the bonding energy of one three-electron bond is approx. half as large as that of a single bond, roughly the same stability can be expected for structure B as for structure A. Another interaction needs to be taken into account, however, namely the coupling of the two three-electron bonds. Each of these has an unpaired electron. Its spins can consist of either a singlet state or a triplet state. In the first case they are opposed, in the second rectified. These states have different stability. The triplet state is more stable. If the movement of the two electrons is not completely synchronized, they can dwell for a time on the same oxygen atom. Then the interaction between them is greater than when they are found on different atoms. These ideas are further underpinned by the existence of a $^1\Sigma$-state, which is approx. 158.3 kJ/mol, less stable than the normal state. This state also has the structure B, although the two odd electrons here have an opposed spin. Thus the unfavourable energy interaction between the two three-electron bonds is involved. The mean value of the energy of this state and the normal state is not very different from the energy of the state with a double bond.

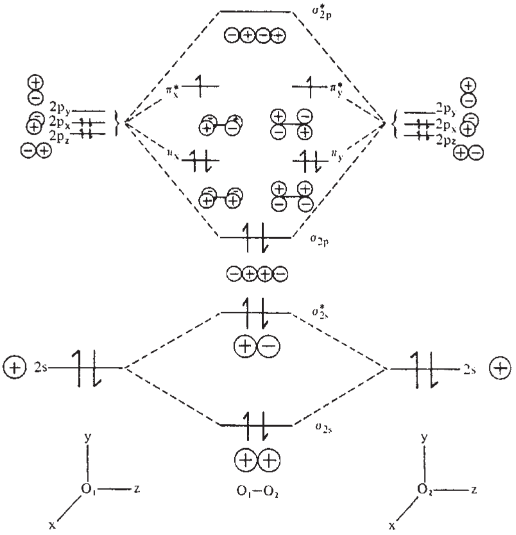

Fig. 1: The molecular orbitals and energy levels of oxygen.

Fig. 1 depicts the states of the electrons involved in the oxygen molecule. It is clear from this that the triplet state has the lowest energy and thus the most stable. The three lowest energy configurations of the oxygen molecule are shown in the Table. The structure of the oxygen atom in the various shells can be seen in Fig. 2.

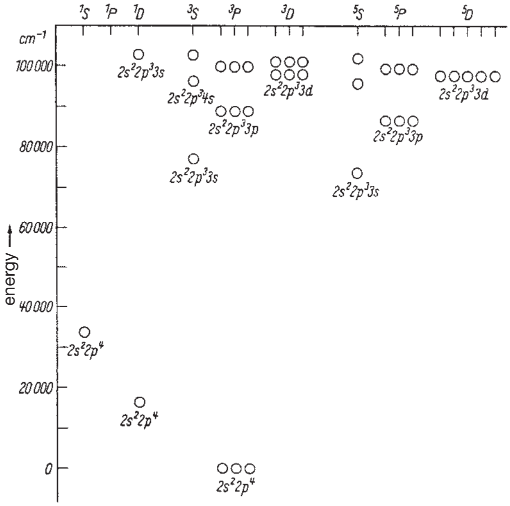

Fig. 2: Energy level diagram of the oxygen atom.

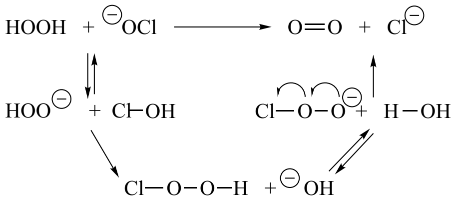
Because the $^1\Sigma$-state is approx. twice as energy-rich as the $^1\Delta$-state, the state $^1\Delta$, with 45 min life in the gas phase, is 500 times as viable as the state $^1\Sigma$ (Tab.).

electron state	$^3\Sigma$	$^1\Delta$	$^1\Sigma$
name	triplet	singlet	singlet
highest occupied molecular orbital	↑ ↑	↑↓ —	↑ ↓
rel. energy content [kJ]	0	92	155
life-time [secs]			
in the gas phase	∞	3 000	7–12
in solution	∞	10^{-3}	10^{-9}
valency linkage electron structure	↑|Ö–Ö|↑	Ö=Ö	↑|Ö–Ö|↓

Tab.: Oxygen molecule energy configuration.

As early as 1927 it was discovered that when mixing a sodium hypochlorite solution with H_2O_2 the reaction showed briefly red. The spectroscopic analysis of this reaction revealed that excited oxygen (singlet oxygen) is the emitting species. A general theory was ultimately postulated, according to which, at least in the majority of reactions involving H_2O_2 or peroxides, primarily excited species of molecular oxygen could be formed which transfer their excitation energy to appropriate acceptors. This is because the energy levels of excited molecular oxygen are in the 250–300 kJ range, which is also required for many organic chemiluminescences. With regard to the mechanism of the H_2O_2 hypochlorite reaction, both radical and heterolytic processes are discussed approximately according to



Essentially, with the singlet oxygen process for stabilizing wool, treatment with formaldehyde is carried out in the presence of hydrogen peroxide. With the reaction between the two compounds, the formaldehyde molecule is activated, as singlet oxygen is formed and therefore becomes extremely reactive. A formaldehyde of this type prefers to react with lysine segments of wool protein and forms cross-bonds. The reactions occurring between peroxide and formaldehyde can be described as follows: in the alkaline medium, formaldehyde is quantitatively oxidized by hydrogen peroxide by developing hydrogen gas and forming sodium formiate. If the medium were not alkaline, methyl peroxide would be isolated. A recorded chemiluminescence spectrum contains the bands characteristic of molecular singlet oxygen.

Single weft carpet Woven carpet, in which each row of knops is fixed in with only one weft.

Sinnerscher Circle Approximate classification of the significance of four washing parameters (chemistry of the surfactants, washing time, temperature and washing mechanics) to define the cleaning efficiency of a drum washing machine (see Fig.).

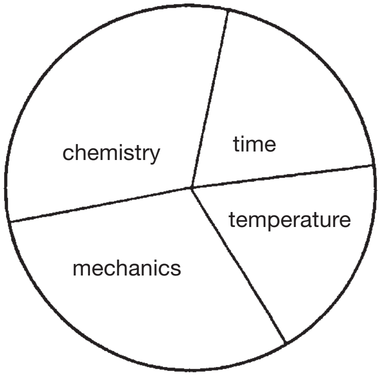


Fig.: The Sinnerscher Circle for representing washing performance.

Sintering Surface method of → Melting, i.e. melting at increased temperature; e.g., with the → Heat sealing of polyethene, the thermoplastic material forms a more or less continuous film, depending on the distribution density, which is capable of being heat sealed with other fabrics. The melting temperature of the material allows conclusions to be drawn as to sintering temperature. The sintering capacity is a function of degree of polymerization, degree of crystallinity and melting point.

Sinter, to → Adhesive-bonded textile.

SIRO "Scientific Industrial Research Organisation", Australian textile research organization; → CSIRO.

Si-Ro-Set colour fastness Method of dyeing with Si-Ro-Set treatment, i.e. possible effect on the shade and possible staining of white wool and cotton as a result of the treatment. The dye should be selected according to the application of the finished goods, i.e., only reduction-insensitive dyes may be used in dyeing.

Si-Ro-Set process Australian process for surface fixing and manufacturing of permanent creases and pleats on woollen articles such as trousers, skirts, etc. by treating with a solution of thioglycollic acid derivatives and subsequent shape fixing by steaming.

SiroSpun process Process developed by CSIRO and IWS, by which a 2-ply yarn is produced at one spinning position, making twining redundant (see Fig.). This process allows a special spun-twisted yarn to be manufactured directly on the ring spinning machine. At the same time, two slubbings are fed parallel through the drafting zone. The technological operation corresponds to the production process for normal single yarn, with the distinction that two slubbings are spun simultaneously per spinning position. With parallel spinning, the permanent control of the Siro yarns with the aid of a mechanical thread monitor prevents unwanted single yarns from being produced. The use of the special SiroSpun thread monitor is the basis for a perfect Siro twist being wound onto the cops.

Spinning process: inside the drafting zone, two specially developed condensers separate the two roves of yarn in the pre- and main drafting zone. Both roves are drawn separately, and the twist is obtained as usual by means of ring and traveller. The parallel-drawn slubbings are joined after the pair of rollers at the drafting-zone delivery end. A thread guide is located in the spinning zone for joining the two bands of fibres drawn in the drafting zone. Between this thread guide and the pigtail thread guide, there is a pair of blocking rollers, which produces a twist back up in this section of yarn. A ring groove is milled in the surface of the pair of rollers on one section of the circumference. It causes the twist arising from the spindle to be blocked on the full diameter and only allows it to reach the upper drafting zone as far as the union junction once it has passed through this groove, with the result that the two bands of fibres are twisted together. The twist travels to the individual components as far as the nip. Both threads combine after the delivery cylinder of the drafting zone with the pre-determined twist to the desired yarn count. Expressed in another way: the resulting yarns are twisted around each other in one operation. Hence a two-ply yarn is produced with the same direction of twist as the individual components. The ever-present uneven qualities balance each other out over the length of the yarn between nip of the front cylinder and winding onto the empty bobbin. The twist of a ply yarn is, therefore, as even as the twist with a single yarn.

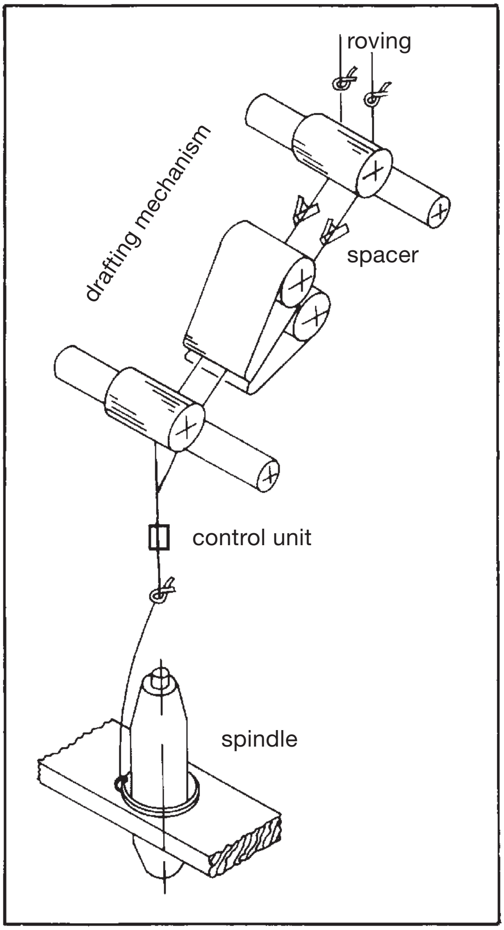

Fig.: SiroSpun spinning position for worsted yarn (Zinser) (spin twist process).

This process produces a false twist or spun-twisted yarn, which conforms to a genuine ply yarn in terms of character and properties. The economic advantages of the SiroSpun process are:

- elimination of the usual twisting process, hence elimination of costs,
- small space requirement,

- greater capacity with the same spindle speed,
- smaller staffing costs.

SIS Swedish standards organization; → Technical and professional organizations.

Sisal → Hard fibres of subtropical agave types (Mexico, Brazil, Africa, Indonesia). Named after the oldest port of exportation of Sisal in Mexico. Snow white to yellowish. Fibre bundle 60–150 cm long. Strength 35–55 cN/dtex. Not very resistant to seawater. Chemical composition: 65.8% cellulose, 10% water, 1.2% lignin, 0.3% fat and wax, 1–4% ash. Dyeable similar to → Manila fibre. Application: binding yarn, cord, string, ropes, sacks, sail cloth, carpet industry, decoration materials, also for finer fabric. Sisal tow for upholstered materials.

Sisal-Manila fibre test → Billinghame's test.

SISIR Singapore standards organization; → Technical and professional organizations.

SI System, conversion factors The conversion factors for the non-metric or Imperial units into the SI system are shown in Tables 1–15. These tables are intended to assist in converting the old units encountered in the USA and Far East.

unit name	unit symbol, abbreviation	relationship	SI equivalent
inch	″		$25.\underline{4} \cdot 10^{-3}$ m
my, micron	µ	$1\ \mu = 1\ \mu m$	10^{-6} m
millimicron	mµ	$1\ m\mu = 10^{-3}\ \mu m$	10^{-9} m
ångström	Å		10^{-10} m

SI System of Units

SI System of Units A system of agreed coherent metric units (Système International d'Unités) proposed for international acceptance in 1960 and which is now in use for all scientific and most technological purposes in many countries throughout the world. SI units are based on the MKS (metre-kilogram-second) system and have now replaced units formerly used in the CGS (centimetre-gram-second) system and the f.p.s system (Imperial units). There are numerous derived units (Newton, joule, etc) and scales of decimal multiples and submultiples, all with agreed symbols. The SI system was accepted as an ISO Recommendation in 1969, incorporated into German Federal Law in 1970 and covered by a DIN Standard under DIN 1301 as well as an EC Directive in 1971. Since 01.01.1978, the SI system with its established base quantities, base units and derived units, has assumed unlimited legal validity throughout the Federal Republic of Germany.

The base units of the SI system are summarized in Tab. 1 and the decimal multiples and submultiples in Tab. 2. For some important derived units of base quantities, or derived quantities in frequent use, special names are used. The derived SI units with independent names are listed (alphabetically) in Tab. 3 and the most important quantities and their corresponding units are given in Tab. 4.

dimension	SI basic unit	
	name	unit symbol
length	Metre	m
mass	Kilogramme	kg
time	Seconds	s
electric current strength	Amperes	A
thermodynamic temperature	Kelvin	K
substance quantity	Mol	mol
intensity of light	Candela	cd

Tab. 4: The most important dimensions and their SI Units (according to Böge).
1) All quotients of a statutory unit of force and a statutory surface unit, e.g. N/cm^2, are also admissible.
2) All products of statutory force and length units or of statutory power and time units, e.g. kWh, are also admissible.

SI Units → SI System of Units.

Sivas carpets Are fine, medium-size → Knotted carpets from the north Anatolian city of Sivas. Warp and weft in cotton, pile in low lustre wool; the Turkish knot is used with approx. 280 000 knots/m^2. Although Sivas carpets come from the heart of Anatolia, they bear no resemblance to the primitive nomad-type carpets woven in large numbers in this region. The Sivas motifs are clearly of Persian inspiration and the customary decoration is similar to that of Persian → Tabriz carpets, both in the medallion and corner design.

The colours used for the ground are usually white and ivory. The designs are always in pastel shades such as pink and pistachio green. Sivas carpets can easily be distinguished from Tabriz carpets because of their less solid feel, lack of compactness in the pile despite close cropping, the lack-lustre quality of the wool, and the use of pastel shades.

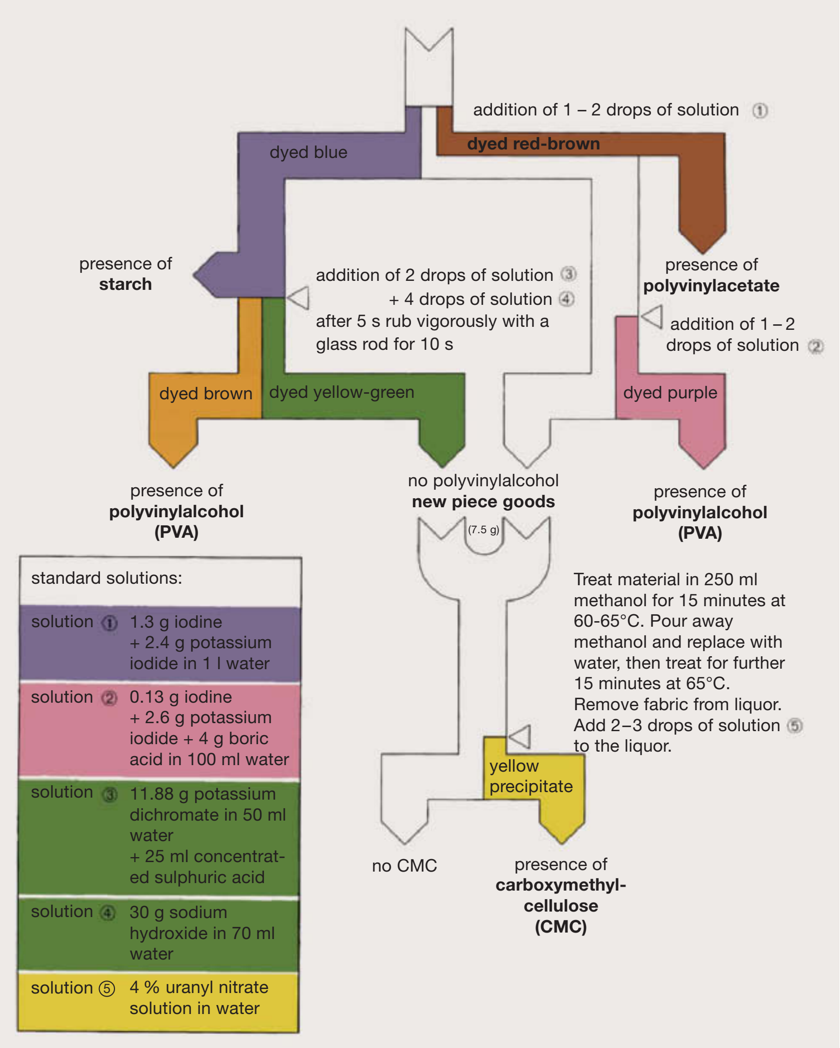
Size bridging The size present between warp yarns applied in machine sizing causes adjacent yarns to adhere together during drying due to the formation of an unbroken size film, i.e. size bridging. In the warp splitting section, after drying, these size bridges are torn apart, i.e. a large part of the size film is broken up at this stage (= increased dust build-up and yarn hairiness). The problem may be remedied by predrying or preheating.

Size content, starch based An air-dried sample of weight M_1 is boiled in dichloromethane, filtered, treated with cold methanol and then with water. Finally, the sample is tested for the presence of a starch based size with iodine solution in potassium iodide. If no more starch is present, the sample is boiled in water with Marseilles soap, filtered, and the weight M_2 determined. This procedure is also suitable for the determination of starch based finishes. The percentage size content is given by:

$$= \frac{M_1 - M_2}{M_1} \cdot 100$$

Size determination, qualitative The analytical scheme illustrated in the Fig. can be followed in order to determine the type of size present on a woven fabric.

Size liquor pick-up This variable is dependent on



Treat material in 250 ml methanol for 15 minutes at 60-65°C. Pour away methanol and replace with water, then treat for further 15 minutes at 65°C. Remove fabric from liquor. Add 2–3 drops of solution ⑤ to the liquor.

standard solutions:	
solution ①	1.3 g iodine + 2.4 g potassium iodide in 1 l water
solution ②	0.13 g iodine + 2.6 g potassium iodide + 4 g boric acid in 100 ml water
solution ③	11.88 g potassium dichromate in 50 ml water + 25 ml concentrated sulphuric acid
solution ④	30 g sodium hydroxide in 70 ml water
solution ⑤	4 % uranyl nitrate solution in water

Fig.: Diagram showing the process for the determination of size (by Sandoz).

most of the parameters involved in → Sizing. It offers a useful means of determining the approximate degree of sizing (usually calculated by multiplication with the size liquor concentration). Because of the diverse influences in individual cases, however, size liquor pick-up values determined under specific circumstances are not transferable to different sizing conditions (see → Sizing, degree of).

Size recycling Since the polymers used for sizing textile yarns lead to high levels of waste water pollution during desizing, the importance of size recycling is clearly demonstrated by means of a materials balance of the sizing process (Figs. 1 and 2). As environmental pollution regulations become ever more stringent, textile companies are confronted by legislation with the choice either to recover sizing agents from the waste water or to pay for disposal costs.

Synthetic sizing agents are now available which can be recycled. The recovery of these products is also economically viable for small textile plants who are able to take advantage of this technology collectively.

For size recovery, suitable sizing agents must, among other things, exhibit the following properties to facilitate recovery by ultrafiltration:

- water-solubility,
- thermal and mechanical stability,
- biological resistance,
- easy removal by washing,
- low to medium viscosity.

Experience in various production units has shown that a range of PVA sizes, certain acrylate sizes, CMC sizes, and mixtures of these components, meet these requirements.

The advantages of size recycling may be summarized as follows:

- reduced environmental pollution,
- reduced waste water and fresh water costs,
- cost savings due to repeated use of the sizing agent,
- more economical use of high-quality sizing agents,
- improved weaving efficiency,
- high economy due to the short pay-back time for the required plant.

Sizes are selected according to the following criteria:

- dusting propensity,
- film characteristics,
- clinging tendency,
- moisture absorption,
- increase in yarn strength,
- ecological aspects (waste water pollution, capable of recycling),

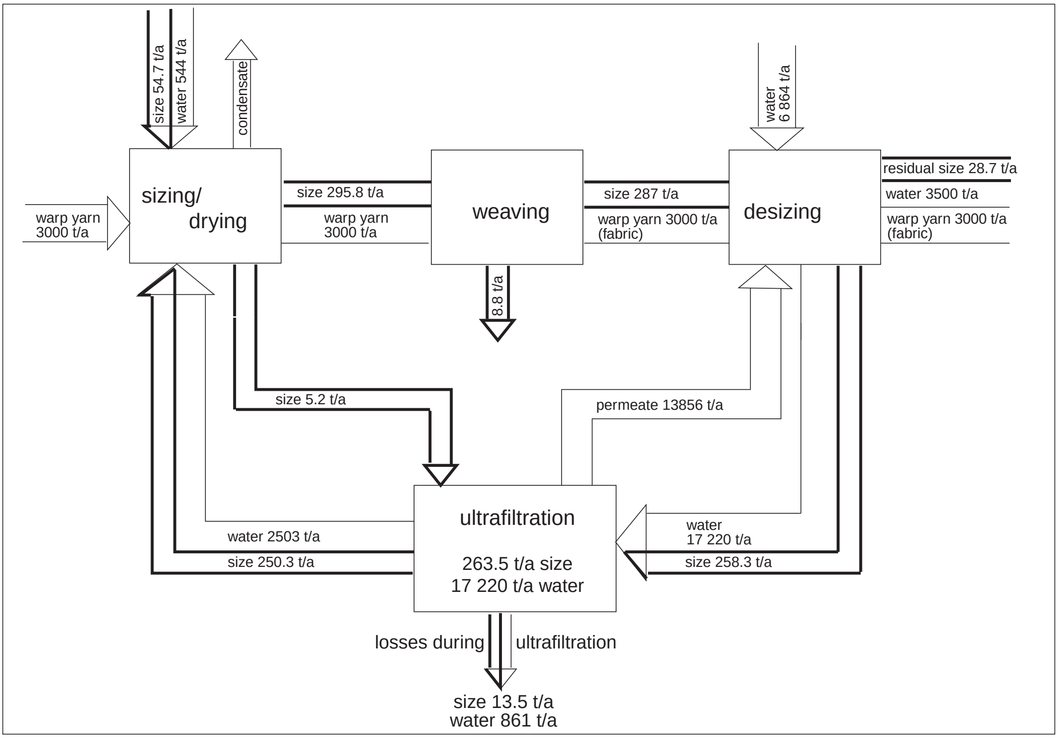


Fig. 1: Balance of resources with recovery.

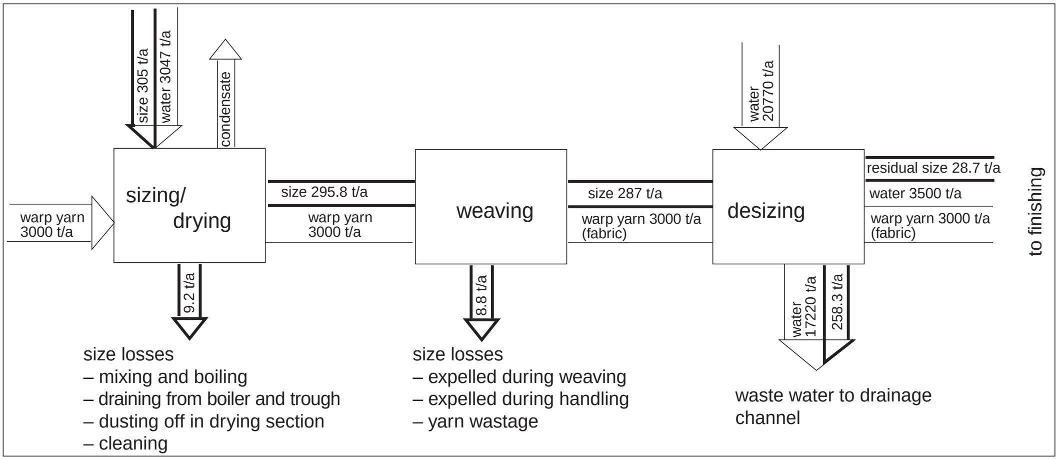

Fig. 2: Balance of resources without recovery.

- ease of removal in desizing,
- price,
- sizing conditions (process technology).

The synthesis of a size in the form of copolymers, e.g. from acrylic acid derivatives and ethylene, which can be eliminated in waste water treatment plants, could be based on the principle illustrated in Fig. 3.

As an example, three characteristic monomers, as possible segments in an acrylate polymer size, will now be referred to:

a) Polyacrylic acid: characteristic component carboxyl group; high affinity for water, the polymers have very good dissolving properties in water;
b) Polyacrylonitrile: characteristic component cyano group film hardener, good size adhesion to the fibre;
c) Polyvinylether: characteristic component ether group; low affinity for water; hydrophobic component and softening element depending on the chain length of R_2.

Since the properties of the polymers combine additively with the properties of the monomers used, it is e.g. possible to produce a polymer specifically from the three monomers alone with the desired hydrophilic-hydrophobic balance, a predetermined degree of hardness and appropriate adhesive properties.

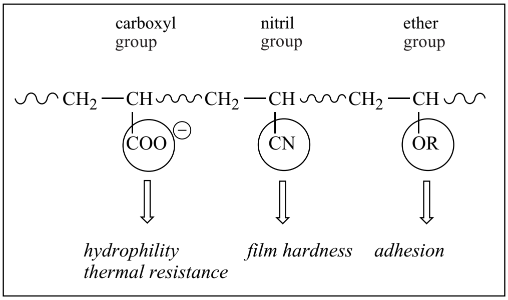

Fig. 3: The structural principle of eliminable sizes in the form of copolymers.

The substances used as sizing agents originate from the macromolecular region; they are either natural materials or entirely synthetic polymers. A decision to use a particular sizing agent should, in principle, be based on the intended application, and should not only influence the sizing process itself as favourably as possible, but also the subsequent finishing stages as well. It is highly probable that, with today’s state-of-the-art technology, both these objectives can be realized at the same time, especially with regard to the ecological aspects of size recycling (Tab. 1).

However, for all those operations which follow sizing and weaving, another property of these polymers is of decisive importance; i.e. their complete removal from the fabric during suitable washing processes and, as a prerequisite for this, the highest possible tendency for solvation (Figs. 4 and 5).

A consideration of the chemical structure of the most important compounds used as sizes leads to an appreciation of their different physical behaviour towards the “agent of removal”, i.e. water. The interrelation of their functional chemical groups to water molecules is decisive for the swelling capacity and ease of removal of the polymers under washing off conditions as well as their suitability for recycling. Due to their own dipole characteristics, OH groups react towards the dipole water with the formation of relatively labile hydrogen bonds whilst substances containing carboxyl groups enter into ionic bonds with polymer salt characteristics under the inclusion of water molecules. This is the reason for the high tendency of polyelectrolytes for solvation, e.g. of polyacrylates. This results, for exam-

Tab. 1: The relative importance of recoverability compared with other properties of selected sizes.

ple, in the ease of removal of size or mixed size films by washing. In association with less soluble sizing agents, the solvating properties of polyacrylates are responsible for triggering extremely welcome water transport phenomena.

In the case of a starch/polyacrylate mixture, the acrylic component swells much faster than the starch, and finally breaks open the entire structure of the size film due to its highly swollen state, thereby promoting the transport of water into the size film. This has important consequences in pretreatment, i.e. in the presence of polyacrylates, the enzymatic degradation of starch can be accelerated and, in many cases, an enzyme treatment can even be replaced by a considerably shorter and much simpler oxidative desizing. In this case, however, the possibility for size recycling is lost.

The wet processing stages of woven fabric pretreatment carried out prior to dyeing, such as scouring, boiling off, bleaching, mercerising, etc. are carried out in alkaline media. The cellulose is swollen by alkali and thereby made accessible for chemical reactions. The presence of sizing agents on the fabric has a very variable influence on the accessibility of cellulose to alkalis and therefore their swelling capacity.

Polyvinyl alcohol and polyacrylates are typical water-soluble sizing agents. Polyvinyl alcohol sizes can be easily recycled (Tab. 2).

Polyester can also be made dispersible in water by the introduction of sulpho groups. Water-dispersible polyester-based sizes are produced by the polycondensation of several products such as dicarboxylic acids, diols, polyethylene glycol, sulphonated aromatic dicarboxylic acids. The following polyethylene terephthalate with sulpho-isophthalate groups can be mentioned as an example:

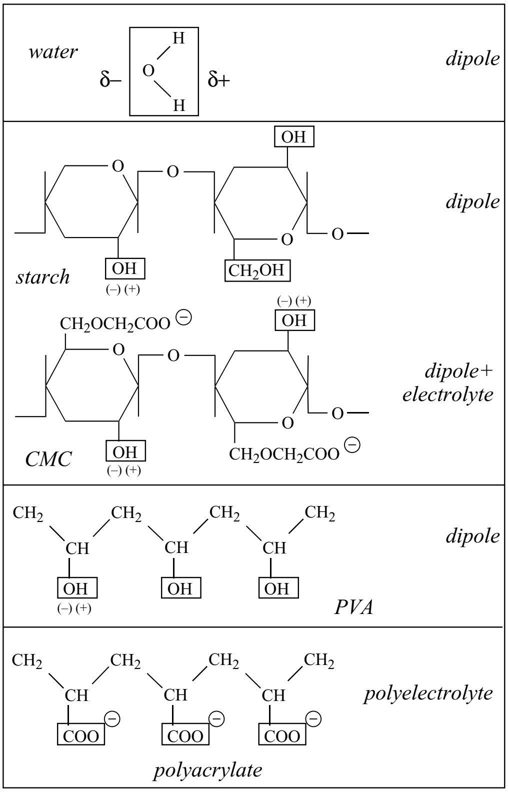

Fig. 4: Chemical structure of the most important partners during desizing.

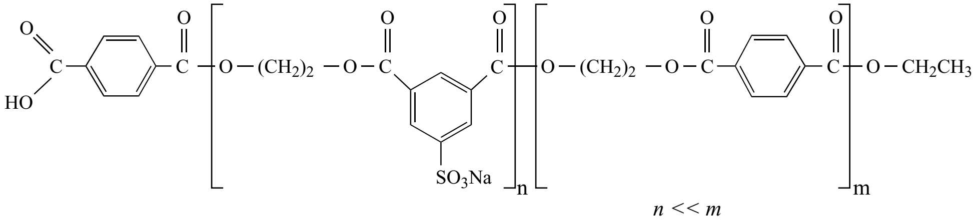
polyvinylalcohol	polyacrylates
test	
iodine reaction with boric acid iodine spot test	spot test on PES fabric spot test with Merck mixture indicator
elimination	
breakdown: possible only with adapted bacteria	breakdown: very poor elimination of between 30 % and 80 % by agglomeration or precipitation
precipitation: not good due to dispersants, e.g.: – borax + sodium sulphate – ferric salt	precipitation: good, e.g.: – H_2SO_4 or other strong acids – Na^+, Cu^{2+}, Al^{3+} precipitated with sodium borates
recycling: possible and effective	recycling: possible and effective
advantages	
– very high mechanical properties – mixes with almost all sizes – strongly elastic film – little impact by ambient humidity	– readily soluble – resistant to alkalis – no boiling – does not form skin – low dusting – easy to handle
disadvantages	
– forms skin – forms foam – sensitive to alkalis – sensitive to peroxide – dissolves slowly	– hygroscopic – not thermally resistant to ammonium salt polyacrylates (NH_4) – odour (NH_3) – sensitive to changes in climate



Starch is the most important sizing agent worldwide, and derivatives of starch are also used as sizing agents. As natural products for sizing, the galactomannanes are also employed. Such natural sizing agents, however, cannot be recycled since they lack the necessary water solubility (Tab. 3) and must therefore be removed by enzymatic degradation (according to Lamprecht, Schönberger, Langer, Dachs and Schlüter).

Size residues The presence of size residues on textile fabrics always gives rise to faulty dyeings and prints. Effective control after → Desizing is therefore indispensable. Size residues may be determined analytically.

Sizing,

I. The sizing of warp yarns involves 3 stages (Fig. 1):

1. Selection and preparation of a suitable sizing liquor (size cooking).
2. Saturation of the yarn sheet with sizing liquor in the padder.
3. Temporary fixation of the size on the yarn (the application of size is temporary since it is removed

starch and starch derivatives	galactomannanes	carboxymethylcellulose
test		
iodine/starch spot test TEGEWA colour scale	iodine test not possible ninhydrin colour reaction	precipitation with uranylnitrate or cationically active substances
elimination		
biological breakdown > 90 %, even for starch derivatives (poorer breakdown only for starch ether) precipitation: possible but not effective	biological breakdown > 80 % precipitation: possible but not effective	biological breakdown insignificant; higher breakdown rate may be obtained by mixing with starch precipitation: not good, better for example at pH 2–3 or using multivalent cations
recycling: not good	recycling: not good	recycling: possible
advantages		
– favourable price – withstands high humidity – withstands alkali – breaks down biologically starch derivatives – water soluble – reduced retrogradation – altered viscosity	– washes out well – smooth film – not sensitive to electrolytes and alkali – adheres strongly – free from salt	– washes out well – does not form skin – can also be used at low humidity – strong, clear films – adheres well
disadvantages		
– recycling only with conserving agent – high use of product for starch or modified starch: – highly viscous – forms skin – builds up on rollers – adhesion reduces with ageing	– recycling only with conserving agent – high price (product use lies between that of starch and synthetic size) – no iodine test – has own colour – deposits on rollers – may form lumps – variable viscosity	– possible corrosion damage if salt content too high – deposition/build-up – sticky soiling if humidity too high – precipitates at too high temperature

Tab. 3: Non-reusable natural sizes.

again during desizing) by drying (e.g. on a cylinder drier).

The objective of sizing is to improve the running properties of the warp during weft insertion. In the weaving process, the frictional behaviour of the yarns against each other (and consequently their surface properties) is decisive for increased weaving performance (reduction in broken ends and picks). If the yarns are regarded as porous solids with a loose structure, the capillary system of small cavities associated with each other can be described as pores into which the size liquor diffuses by displacement of air. The hairiness of the yarns, which is a feature of yarns produced from staple fibres, represents a characteristic irregularity of the yarn surface which is influenced by sizing (Fig. 2). The sliding surfaces of the yarns being sized are therefore reduced by the deposition of size between the surfaces (this also applies to filament yarns).

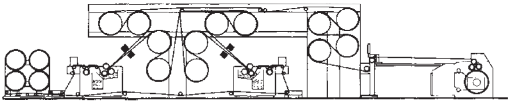


Fig. 1: Sizing line with 2 sizing troughs, 12 cylinders for drying the assembled warps, and beaming unit (SMH)).

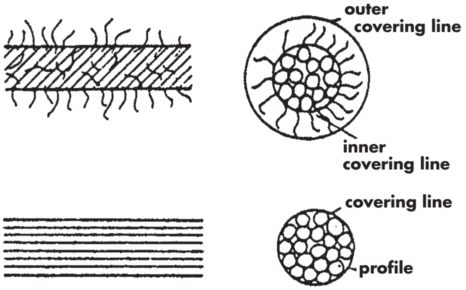

Fig. 2: Difference in the sizing of staple fibre yarn (top) and continuous filament yarn (bottom).

Besides this sheath effect, the yarn cross-section is so strongly bonded in the form of a core effect by loading with the sizing agent that the strength of the yarn is increased for the duration weaving until the subsequent desizing process. In spite of this, tensile forces also arise during shed formation, in addition to the "clinging" effect (through hairiness), caused by tension on the warp which the warp yarn must be able to withstand. Size add-on in the size box depends to a considerable extent on the viscosity of the sizing liquor. The viscosity of the size depends greatly on the temperature and is, of course, also influenced by the type of polymer. The degree of sizing can be determined and controlled by the continuous measurement of water uptake by the warp and the liquor concentration (Fig. 3). Variations from the target add-on are compensated by controlling the nip pressure, i.e. if the size pick-up is too high it is increased and if the size pick-up is too low it is reduced.

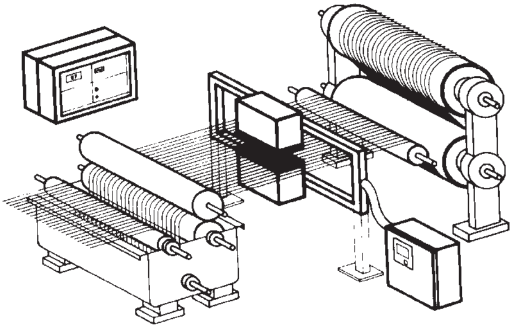

Fig. 3: AS 120 material moisture content meter (Pleva).

II. Wet sizing (Fig. 4 and 5) is a pretreatment for yarns to be processed as warps for weaving into textile fabrics. Sizing protects the yarns against mechanical stresses in the weaving process by the application of a film of → Sizing agent which envelops the yarn and which subsequently must be mainly removed again in finishing (see Tab.). The composition and quantity of application of the size must be adapted to the type of yarn. Weaving efficiency is highly dependent on sizing. The type of sizing agent (see Fig. 6) is also important in finishing which is why close cooperation between the weaver and the finisher is desirable. Sizing is carried out in hank form (hank sizing) but mainly in the warp from beam to beam (warp sizing) or from a warper's creel or a section warper (tape sizing).

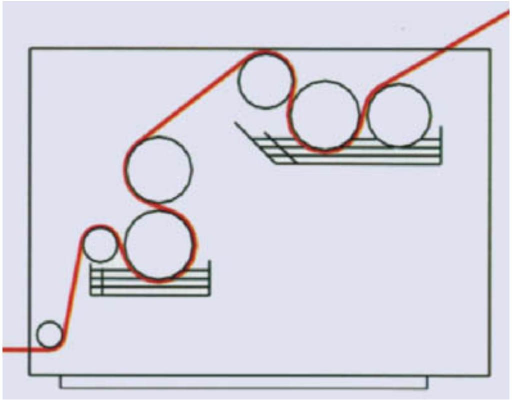

Fig. 4: Wet sizing with prewetting and subsequent sizing of the outer part of yarn.

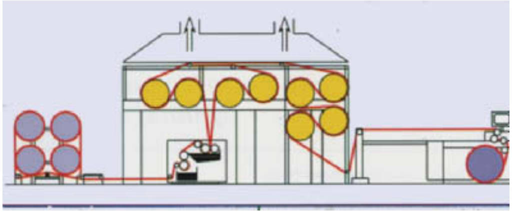

Fig. 5: Wet sizing plant (SMH).

For the classic warp sizing process, the size has to be cooked in a kettle after which the size liquor is trans-

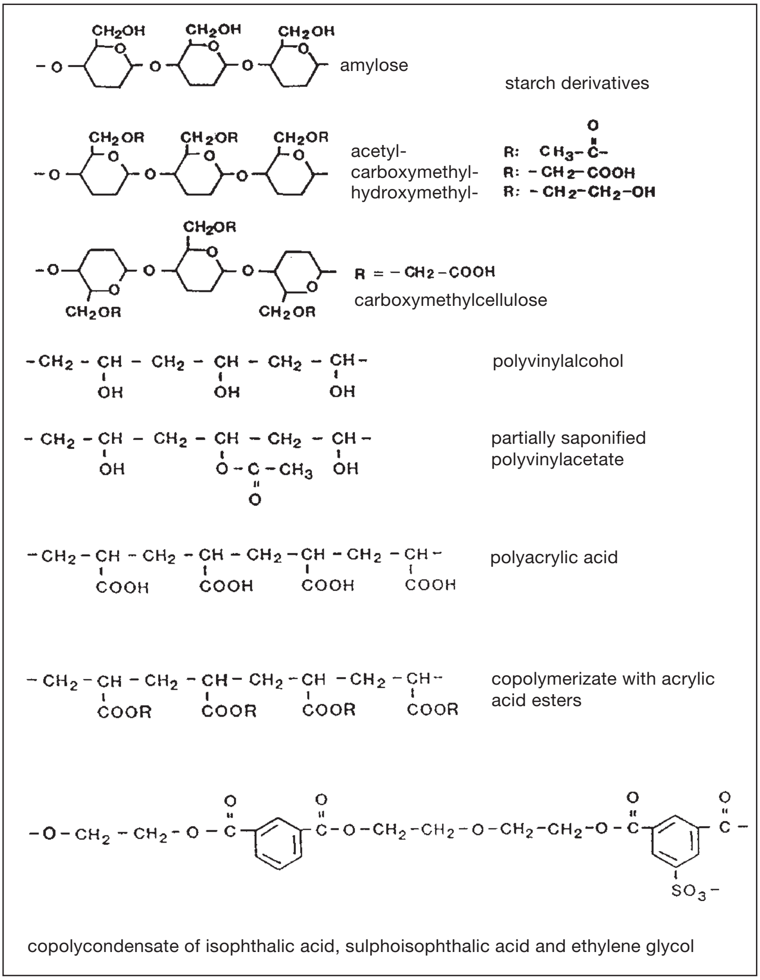

Fig. 6: The chemical structures of sizes.

ferred to a heated storage vessel from where it is finally delivered to one or several size boxes for application to the warp sheet. The wet yarn is subjected to “wet extension” whereby the individual yarn fibres slip against one another and the yarns are stretched. This wet extension in the process is often necessary in order to be able to control the behaviour of the yarns; it is, however, not desirable since the strength of the yarn is generally reduced as a result. Excessive extension of the yarns during sizing is a common cause of broken ends in weaving.

The warp is squeezed between one or several pairs of rollers at pressures of 300 kg to (in high pressure size boxes) 10 000 kg. The impregnated warp then passes over drying cylinders supplied with superheated steam. During this stage, water evaporates from the still wet yarns into the surrounding air which is normally collected under a hood and discharged by means of an extractor fan into the atmosphere through the roof. In order to expel the water quickly enough to achieve high processing speeds of, e.g. 100–125 m/min, the yarn is “cooked” on the drying cylinders. This rapid drying often leads to size bridging between individual yarns. The layer of warp yarns is peeled off the cylinders as a result of which individual fibres or hairs protrude from the fibre bundles. If the working speed changes, drying is either excessive or insufficient since the system inertia cannot be overcome quickly enough to compensate for changes in temperature/speed. After leaving the drier, the yarns are separated with the aid of lease rods.

In some cases, waxes are recommended instead of sizing. Moreover, efforts have been focussed on developing methods for the recovery of sizes and heat from sizing machines. The type of sizing agents and additives, application quantities, and the drying method have also been thoroughly investigated. Difficulties have been encountered in measuring the concentration of the size liquor. Measurements made with refractometers are regarded as problematic. Furthermore, the possibility of size recovery and biodegradability are receiving increased consideration in the selection of suitable sizing agents. In addition, efforts are being devoted to the control of size add-on by means of appropriate measurement and control systems. →: Sizing agents selection criteria; Size recycling.

Sizing agents The role of a sizing agent is to provide yarns for weaving with the necessary smoothness, compactness, pliability and strength in order to make them more suitable for further processing in the loom or weaving machine and more resistant to mechanical stresses. Basis of sizing agents: mainly degraded starches, animal glues, water-soluble cellulose and starch derivatives, mucilages from plants, water-soluble polymers and plastic dispersions as well as drying oils (see Tab.).

I. Water-soluble sizing agents: these are chiefly used for warp sizing on sizing machines: a) Natural products: mostly based on starch or proteins and, less frequently, on sodium alginate. These sizing agents are preferred for hydrophilic fibres. b) Modified natural products, such as cellulose or starch derivatives of the starch and cellulose ether resp. starch ester type, which are likewise preferred for hydrophilic fibres. c) Synthetic products specifically for hydrophobic fibres which can be classified into the following types: vinyl derivatives mostly in the form of polyvinyl alcohols in different viscosity ranges and varying degrees of saponification, as well as polyacrylate derivatives with an acidic character or neutral polymers resp. copolymers with outstanding suitability for practically all man-made fibres. Modified polyesters with water-solubilizing sulpho groups

II. Aqueous sizing agents based on plastic dispersions: specifically designed for application together with water-soluble sizing agents for hank sizing. These products contain water-insoluble plastics finely dispersed in water, e.g. mainly vinyl derivatives, chiefly polyvinyl acetate dispersions and polyacrylate resin dispersions.

III. Oil sizes and organic glues.

IV. Water and glue-free sizing agents.

Sizing auxiliaries These include products based on fat components used as additives to → Sizing agents in order to improve the softness and smoothness of warp yarns for subsequent weaving, e.g. animal and vegetable fats and oils as well as sulphated or emulsified fat and oil compounds, water-soluble synthetic waxes as well as paraffin and wax emulsions.

Sizing control systems In order to ensure reproducible sizing even, e.g. when running at extra slow speeds, attempts are made to measure and control as many parameters as possible in the size box (see Fig.).

The concentration of the size liquor may be controlled by refractometry. Temperature influences the refractometer measurements (refractive index) as well as the viscosity of the size liquor, consequently the liquor pick-up changes according to the speed of running, which is why attempts are made to regulate the nip

pressure. The liquor level in the size box is also controlled.

Sizing, degree of The running properties of warp yarns in weaving is highly dependent on the quality of warp sizing. Thus, the incidence of broken ends only remains low within a limited range of "optimum sizing" conditions. When warps have been over-sized or under-sized, the number of broken ends increases (see Fig.).

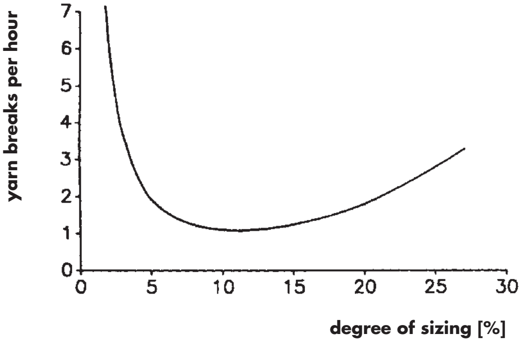

Fig.: Effect of degree of sizing on yarn breakage rate.

Because of its large contribution to weaving efficiency and fabric quality, considerable efforts have been made for a long time to adjust the degree of sizing to a value known to be optimal and maintain this value at a constant level. However, this can only be achieved with difficulty for the following reasons:

- the degree of sizing can only be measured directly with considerable outlay (e.g. by radiometric methods);
- the degree of sizing is dependent on many parameters which can change, depending on the article, from batch to batch and/or change within a batch depending on time.

Moreover, the degree of sizing is dependent on several factors, e.g.:

- parameters of the warp, i.e. warp yarn density;
- parameters of the warp yarn, i.e. spinning technology, type of fibre, fat and wax content, linear density, twist, hairiness;
- parameters of the sizing agent, i.e. affinity of the sizing agent for the yarn;
- parameters of the size liquor, i.e. concentration, viscosity and temperature (here the viscosity is not only a function of the sizing agent and the prescribed liquor concentration, but also the processing involved in size cooking);
- parameters of the sizing machine, i.e. number of sizing troughs, constructional features, warp passage and speed, pressure and adjustment of the squeeze rolls, warp tension in the wet zone (according to Trauter).

Sizing machines Are used for machine → Sizing of rapidly running individual yarns (between yarn packages), of hank yarns (hank sizing is of secondary importance only because of inadequate capacity; the process is carried out on hank dyeing machines), the sizing of already warped tape warps and, for large scale production reasons, of warp beams. This latter involves the open-width passage of warp yarns from back beams resp. a multiple beam frame (usually in a step-by-step arrangement), through the size box and the drier for beaming. Sizing machines are equipped with high performance control and regulating systems for almost all working parameters up to automated monitoring, the

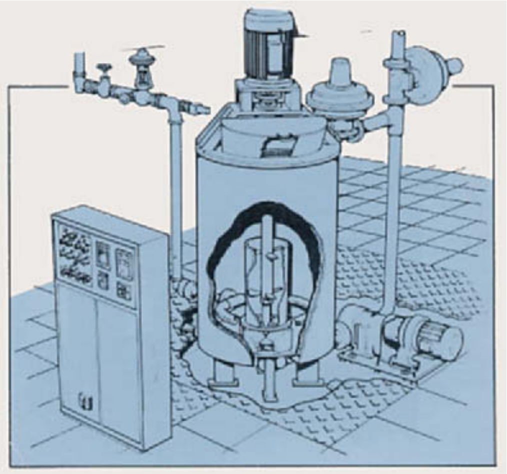

Fig. 1: Size boiler (SMH).

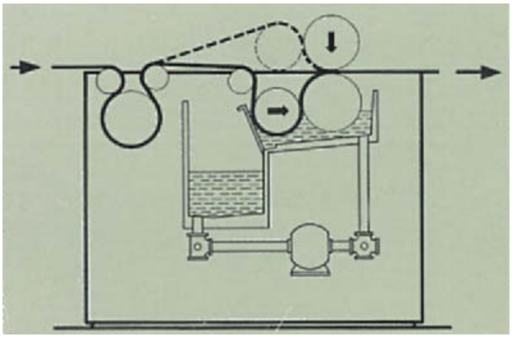

Fig. 2: Size trough (SMH).

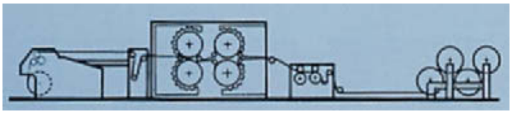

Fig. 3: Cylinder drier.

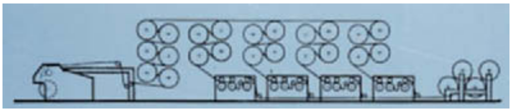

Fig. 4: Warp division machine.

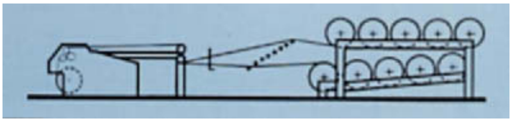

Fig. 5: Assembler machine.

size box (trough) with one or two rollers or with double immersion and squeeze rolls. Useful control and regulating systems to achieve a constant level, viscosity and temperature of the size liquor are technically important features of modern sizing machines.

The following equipment is necessary for sizing:

- a size boiler to swell the polymers (Fig. 1),
- a size trough with high-performance squeeze rolls (Fig. 2),
- a cylinder drier with optimum heat utilization (Fig. 3),
- in certain circumstances, a section warp division machine (Fig. 4),
- in certain circumstances, an assembler machine (Fig. 5).

Sizing selection criteria During shedding on the loom, the strength of the warp yarns is subjected to severe tensile forces on the one hand and the clinging together of hairy yarns on the other. This clinging of the yarns occurs to a greater extent in the temple and selvedge area since the tensile forces acting on the warp yarns are lower here. High tensile forces on the warp yarns are more likely to open up yarns which have clung together. It is therefore difficult to set the optimum tensile force on the warp yarns particularly since the level of warp tension is not constant across the width of the warp. On the one hand, the yarns must not be subjected to excessive tension and, on the other hand, if the tensile load is too low the yarns will cling together. A compromise must therefore be found which will appear somewhat different for each type of yarn and each type of article (Fig. 1). For a certain tensile load on the warp yarns, which lies between clinging and overloading of the warp yarns, the number of end breaks are at a minimum.

In order to produce a textile fabric on a high-performance weaving machine, the warp yarns have to meet the following requirements:

- the yarns must have adequate abrasion resistance and yarn strength,
- the yarns should have a high and uniform residual elongation as well as uniform warp yarn tension,
- the yarns should have a low degree of hairiness and a low snarling tendency,
- the yarns should run without any crossing of the yarns.

With shuttleless weaving machines, good shedding performance of the warp yarn sheet is decisive for high weaving efficiency. Sizing sticks down the projecting hairs on the yarns and increases the strength of the yarns by bonding the core of the yarns.

To achieve this, sizing concentrations of approx. 100 g/l size are applied in the size box. Because of the viscosity of the size liquor, warp separation is necessary under certain circumstances in order to obtain better penetration. For this reason, the sized warps must be assembled (united again) afterwards. The warp con-

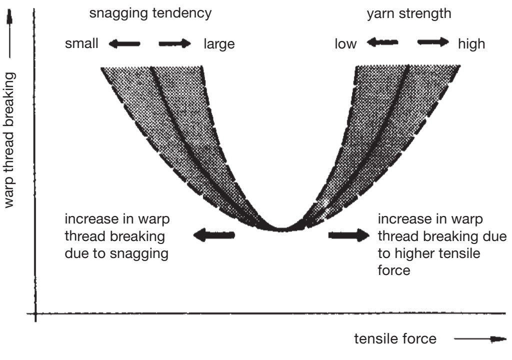

Fig. 1: The optimum for warp thread tensile force between tensile stress and snagging stress.

Sizing selection criteria

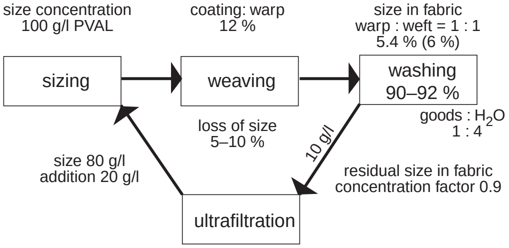

Fig. 2: Schematic showing work required for size recovery.

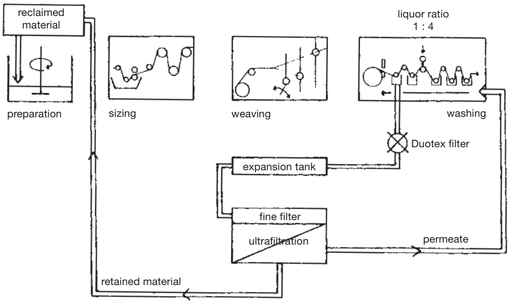

Fig. 3: A real example of size recycling.

tains an add-on of approx. 12% size after sizing or, in other words, the woven fabric contains approx. 6% of size. In recent years, efforts have been directed towards size recycling from desizing baths (Figs. 2–3).

Sizing has assumed considerable importance for a variety of reasons:

1. Fabric quality and the unit capacity of weaving machines are dependent to a large extent on the type of size used. Weaving plants are under pressure to increase the unit capacity of their weaving machines, e.g. by optimization of the sizing process through the application of synthetic sizing agents.
2. In order to partially offset higher wages, productivity has been increased by the introduction of high-performance weaving machines. These high-speed weaving machines subject the warp yarns to a considerably higher strain than the former conventional weaving machines which, again, demands improved sizing agents.

The type of sizing agent used, and the quantities of sizing agent necessary to ensure satisfactory weaving performance, are a function of several parameters (e.g. fabric construction, type of weaving machine, type of fibre and yarn quality); consequently, these parameters

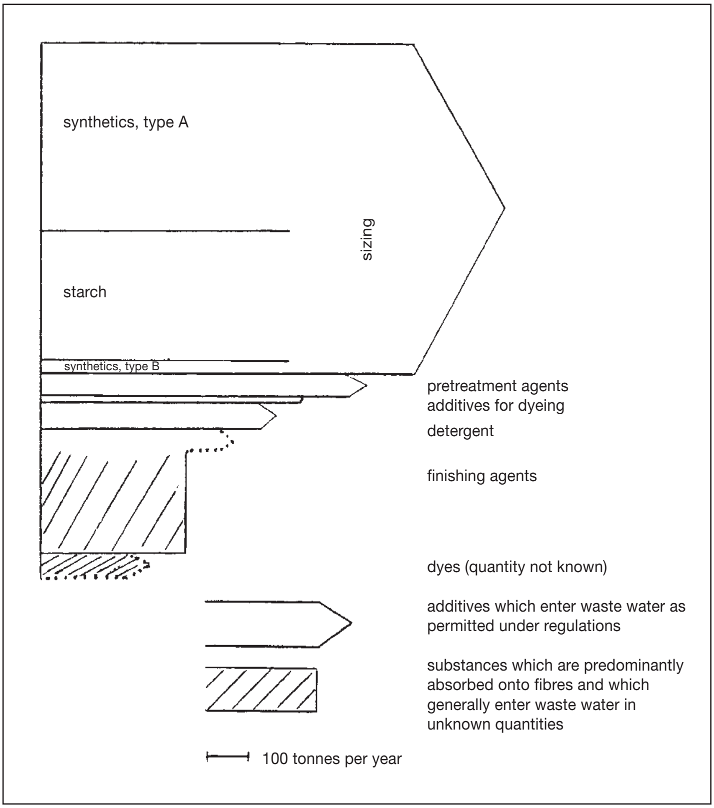

Fig. 4: An extremely simplified list of materials used by a textile finisher with a waste water output of approx. 1000 m³ per day and a COD of 1800 g/m³; TOC utilization is approx. 25%.

must be individually established for each weaving plant. In Germany, about 150 products for sizing (sizing agents and additives) are currently available in the market. Annual consumption is approx. 20 000 t of sizing agents.

Sizing agents for textile sizing are produced from 5 different basic raw materials:

- starch (chiefly potato starch),
- carboxymethylcellulose (CMC),
- polyvinyl alcohols (PVA),
- acrylates (A),
- polyester (PES).

Unfortunately, the environmentally-friendly starch sizes exhibit the lowest sizing efficiency so that weaving plants are often compelled, for the reasons given above, to use synthetic products in order to ensure the required quality standards. As a consequence, the proportion of synthetic sizes has risen to 45%.

For a textile finisher, sizing agents account for approx. 50% and more of the total organic pollutant load (determined as COD) in the waste water (Fig. 4). In view of this quantitative importance of sizing agents in waste waters, it seems reasonable, from an economic aspect, to question:

1. What level of pollutant load does desizing contribute to the waste water?
2. To what extent can the sizing components be degraded/eliminated in a biological waste water treatment plant?
3. What measures can be taken to effectively reduce waste water pollution from this process in the textile finishing industry?

The above questions can be answered as follows:

1. Random sample analysis of desizing liquors from 5 different finishing plants gave the following results:

- pH: 6–7 resp. 11–13 depending on the process,
- COD: 500–20 000 mg/l,
- hydrocarbons: < 0.1–5 mg/l,
- AOX: < 0.02–1.3 mg/l,
- arsenic: 0.01–9* mg/l

(* source unknown, but probably due to biocide/pesticide residues).

2. Apart from potato starch and its derivatives with a low level of substitution, none of the common synthetic sizes for staple fibres currently available in the market are biodegradable to a satisfactory degree. Non-biodegradable means that the sizing agent is neither biodegradable nor can it be adsorbed or stripped by sewage sludge.

Synthetic sizing agents therefore remain to a large extent in the water courses. Sizing agents are officially not (yet) included as hazardous substances in the corresponding lists (e.g. 129th EC List etc.). Whether synthetic sizing agents will be included in such lists is not foreseeable at present. In any case, not all sizes are biodegradable (Fig. 5).

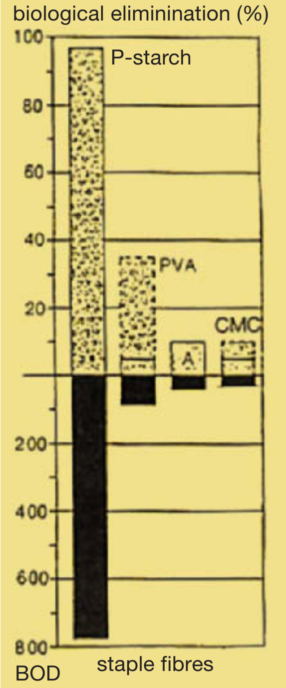

Fig. 5: The BOD values and ease of biological elimination of sizes. P-starch = potato starch; PVA = polyvinylalcohol; A = polyacrylate sizes; CMC = carboxymethylcellulose.

The Chemicals Law (ChemG – Chemikaliengesetz) is concerned with the control of new products as a first priority. It contains, however, an authorization for the limitation/banning of so-called “old substances”. Nevertheless, it cannot be assumed that the legislator will make use of this as far as synthetic sizing agents are concerned.

The Detergent and Cleaning Agent Law (WRMG – Wasch- und Reinigungsmittelgesetz): under the heading “Definitions”, it is stated in the WRMG under § 2, paragraph 1, clause 3: “detergents and cleaning agents are given equal consideration and, according to definition, are applied to surfaces and, with a single cleaning using products for the purpose of clause 1 (surfactants) are largely removed and, according to experience, can enter water courses”. Sizing agents fall within the scope of the WRMG for which a fundamental requirement of biodegradability resp. at least a high degree of biological elimination applies. This fundamental requirement, however, requires a concrete preparation by a statutory order in accordance with § 3, paragraph 2. Serious considerations with regard to making use of this regulatory authorization do not exist at present.

Waste: sizing agent residues from preparation vessels and size boxes are industrial wastes and must be disposed of as such. The “disposal” of such residual concentrates by the waste water route is forbidden by Appendix 38 of the German Water Resources Law (WHG – Wasserhaushaltsgesetz).

Waste water: a fundamental distinction has to be made here between the federal and regional water laws and municipal regulations.

With regard to sizing agents in particular, it is stated accordingly in the German Water Resources Law (WHG) under its § 7a, among other things that the sources of origin of waste water containing hazardous substances are subject to statutory regulations. This is enforced by the Waste Water Origins Regulation. The requirements placed on waste waters from such sources are intended to be defined in the amendment to the administrative regulations in accordance with § 7a of the WHG. The corresponding administrative regulation for textile manufacture/textile finishing is therefore expected. A draft is, however, already available (Appendix 38). These administrative regulations are in one part:

– minimum requirements in accordance with generally recognized state of technology which only apply to direct polluters and, in one part:
– minimum requirements in accordance with the current state-of-the-art (for hazardous substances) which are applicable both to the direct polluter as well as the indirect polluter. For the indirect polluter, however, a further regulations by the German states is necessary.

As far as sizing agents are concerned, the amended draft contains

– the fundamental requirement for synthetic sizing agents to be retained with recycling resp. disposal by state-of-the-art measures;
– concrete threshold limits for the obligation to treat segregated streams of waste water by state-of-the-art technology; one of these parameters is the degree of biological elimination (determined by the so-called → Zahn Wellens Test).

Waste water from desizing must be treated by present state-of-the-art technology in order to meet these threshold limits if the COD exceeds 5000 mg O_2/l and the COD elimination lies below 75% in the aforementioned test. If the COD concentration lies above 30 000 mg O_2/l, a COD elimination of 90% is stipulated. These values imply that the usage of water corresponds to the state of production technology and a falling short of the COD concentration by "dilution" is not involved. As far as COD elimination in the Zahn Wellens Test is concerned, no experience is yet available for segregated waste water streams from desizing. The execution of this ordinance, i.e. the waste water analytical tests, shows how many and which industrial plants are affected. The first-mentioned fundamental requirement for the recovery of synthetic sizes is first of all intended to be carried out, above all, by so-called vertical plants since, in this case, the size recovery can be associated with economically advantageous recycling.

3. Wherever possible, readily biodegradable products should be used as sizing agents. The problem here, however, is that such products often do not satisfy technical application requirements. Attempts are currently being made to develop biodegradable and, at the same time, high-performance sizing agents (new starch and galactomannan derivatives); however these products have either not yet been perfected or they do not allow a complete substitution of synthetic sizes which are difficult to eliminate biologically.

For the use of sizing agents which are readily biodegradable, investigations should be carried out with the effect of treating the desizing liquors by anaerobic means since, for energy reasons, it is senseless to degrade the energy in the sizing agents with aerobic energy again; it is much more sensible to recover anaerobic energy in the form of biogas. Attempts to introduce biologically eliminable sizes (new acrylate sizes) with adsorption as the predominant elimination mechanism have not proved satisfactory since a problematic displacement in the sewage sludge takes place.

So long as the use of readily biodegradable sizing agents is not possible for technical application reasons, increased efforts must be devoted to the development of recyclable sizes. A 100% recycling is not possible. The technology for the recovery of synthetic sizes based on PVA, CMC and PAC is ultrafiltration. With this membrane technology, reusable concentrates are produced from desizing liquors of relatively low concentration by the selective extraction of water. For pure PVA sizes, this method of recovery and reuse is already an established technology. Efforts must be made to push the larger weaving plants to desize their woven fabrics themselves so that desized goods can be offered to the market in order to exploit the economic advantages of recycling. The commission finisher should also be encouraged to go over to receiving desized goods or to stipulate the type of sizing agent to be used (even for fabrics from the Far East and overseas) even though this measure does not appear feasible at present.

SKE A German abbrev. for "Steinkohleneinheit", i.e. coal equivalent. It is the quantity of heat produced by 1 kg of coal with an average → Thermal value of 29 400 kJ (7000 kcal). The use of this unit is no longer permissible.

Skeins A form of yarn package consisting of an unsupported coil of yarn. Each → Hank is twisted several times, folded in half, and the end tucked through a free opening.

Skew straightener A device for straightening skew distortion in textile fabrics, e.g. with the aid of rollers.

Skin burns,

I. Burns caused by acids: the affected area should be treated immediately with water and sodium bicarbonate.

II. Burns caused by alkalis: the affected area should be treated immediately with water and boric acid.

Skin compatibility of antimicrobial finishes The question concerning the purpose of an antimicrobial or hygienic finish is based on the physical condition of human beings. On the one hand, consideration has to be given as to how an active substance to be used in such finishes should be classified with regard to its toxic properties towards the animal and plant world whilst, on the other hand, there is the question of its skin compatibility. In this regard, it is clear that only those substances with a low degree of toxicity are suitable for antimicrobial finishes. Completely non-toxic substances for this application are unknown. On this basis, suitable products are selected if a test for skin compatibility carried out beforehand has revealed no negative aspects.

The largest organ of the human body with approx. 18% of the body's weight is the skin, the boundary layer (1.6–2 m^2) with a defensive and protective function. The horn layer of the skin protects the body against the penetration of chemical substances and microorganisms. The surface of the skin is covered with a film of skin fat which is composed of free fatty acids, bound fatty acids, triglycerides and components such as squalene, cholesterol, wax alcohols and other substances. The surface pH of healthy skin lies between 4–7. This "acidic covering" provides a defence against disease-causing microorganisms. These pH conditions must therefore be taken into account in the selection of an active substance for antimicrobial finishes. The pH of human perspiration in the sweat glands lies between 5.5–6.75. Salts, lactic acid, pyroracemic acid, uric acid, amino acids and ammonia are the main components of human perspiration. Perspiration is decomposed by microorganisms and the volatile decomposition products are responsible for the typical odour. Perspiration and the fat film are nutrients for bacteria and fungi on the one hand whilst, on the other hand, substances are also present on the skin which inhibit the growth of microorganisms. Healthy skin is therefore in a state of equilibrium with the microorganisms present on it and their action. The frequency with which this equilibrium is disturbed, however, is revealed by the fact that approx. every 5th patient seeking the services of a medical practitioner appears to be suffering from a skin disease. In some parts of Germany, more than a third of the inhabitants suffer from athlete's foot, a type of fungal infection which, in turn, can be a source of subsequent bacterial infections. Every skin has its own microflora. Due to the influence of an active substance on the fibre of a textile which is contact with the skin, there is a danger that the body's own microflora will change since the equilibrium is disturbed. As a result germs, including those causing disease, would achieve predominance and lead to interference of the skin's function. Moreover, as a consequence of a long-lasting action of the active substance, germs could develop resistance and resist a subsequently desired growth inhibition. With long-lasting action of a substance, sensitization reactions can also occur. Finally, the phenomena of allergies must be considered. Not every human being is able to tolerate certain substances. Because of these expected negative influences of antimicrobial active substances, an antimicrobial finish for textiles worn for long periods in direct contact with the skin e.g. underwear is, for hygienic and microbiological reasons, generally avoided.

Skin diseases (dermatitis) can be caused by certain finishing chemicals, organic solvents, disinfectants and preservatives, dyeing carriers, textile auxiliaries, dyestuffs, etc. by handling the products on the one hand, and by wearing textiles containing residues of these substances on the other. In most cases, a certain hypersensitivity (→ Allergy) of the skin towards a particular substance mentioned above exists which is, however, tolerated without any reaction by the majority of subjects who come into contact with it. An individual hypersensitivity can either be an inherited predisposition or may be acquired by constant contact with a particular agent. Specific measures for skin protection have a preventative effect (e.g. the wearing of rubber gloves and the use of skin protection ointments or barrier creams). The factor/s responsible for triggering a skin reaction is difficult to determine in individual cases. With → Textile eczema, a distinction is made between non-specific non-allergic and allergic contact eczemas. A causative connection can exist for persons with sensitive skins, e.g. towards particular items of clothing produced mainly from coarse materials. Textiles made from synthetic fibres can also cause skin irritations since the hydrophobic surfaces are not able to soak up perspiration. Skin irritations due to purely mechanical effects may also be caused by tight-fitting garments. On the other hand, allergic contact eczemas originate, in the majority of cases, not from textiles themselves but from the residues of finishing chemicals applied to textile fibres. The following eczema-inducing agents have been discussed in the literature: urea-formaldehyde derivatives, some azo and disperse dyes, chromates and rubber components. The detection of agencies which trigger eczemas is carried out by skin patch tests with textile constituents and types of materials, exposure tests and chemical analysis. For atopic subjects, it is recommended to give newly-purchased textiles a domestic wash before they are worn on the body.

Skin effect → Covering layer.

Skin fibres,

I. Fibres with a → Covering layer.

II. → All-skin fibres.

III. → Core-spun yarns.

Skin incompatibility Possible causes of skin incompatibility reactions with regard to clothing include the following from a dermatitis point of view:

I. Irritative reactions (wool sensitivity): textile incompatibility which manifests itself by itching and scratching, occasionally accompanied by reddening, to eczema symptoms in more severe cases, are understood to be caused by irritations of the skin by specific types of textile fibres. It is an expression of so-called wool sensitivity as encountered much more frequently in atopic patients with neurodermatitis than with control subjects and patients with eczema of a different origin. Wool intolerance occurs more frequently on moist skin and with younger rather than older patients. The irritations are triggered via peripheral nerves, especially pain receptors.

II. Allergic reaction (hypersensitivity reactions): for the demonstration of allergic reactions to textiles, two types are important:

1. Type I reaction: with this type of immediate allergic reaction, the triggering allergen contact takes only seconds or minutes. A skin reaction in the form of nettle rash (urticaria), in the mucous membranes as hay fever, conjunctivitis or bronchial asthma can then occur. The disease symptoms are caused by the meeting of the allergen (antigen) with specific antibodies present in the body of sensitized patients which are attached to the surface of mast cells. If antigens and antibodies in the skin or mucous membranes come into conflict with each other, signal or messenger substances (preformed mediators) are released which results in the formation of the above-mentioned inflammatory reaction.

2. Type IV reaction (late reaction): in this case, the skin reactions reach their peak after 24–72 h and, from time to time, even after 4–6 days. The changes in the skin correspond clinically to allergic contact dermatitis with reddening, formation of lumps and blisters, discharges and scaling, accompanied by itching. The type IV reaction is promoted by specific sensitized T-lymphocytes which are formed after contact with the allergen in association with the Langerhans cells of the epidermis in lymph nodes and other immune cell-forming organs, and enter the skin via the bloodstream where they are present for sufficient time for a reaction to occur.

Allergic reactions to textiles are mainly contact resp. type IV reactions and, less frequently, type I reactions (according to Klaschka).

Skin rug A hand-woven → Flat carpet in the form of a weft-figured carpet produced from a single weft consisting of narrow cut strips of skin at a predetermined width (also includes those rugs where the strips of skin are used in the warp with a yarn weft). The edges and ends of the rug are bonded.

Skins The untanned outer skins of particularly large agricultural animals (e.g. cattle, horses, pigs) as well as smaller land animals and large aquatic animals (e.g. fish, lizards, snakes, whales, crocodiles). →: Pelts; Tanning; Leather.

Skin wool (fellmongered wool, lime wool, pelt wool). Produced from the skins of slaughtered sheep (as well as other domestic animals). Production: as enzyme wool, as sweated wool (Mazamet wool, lime wool, slipe wool) by a) shearing, or b) by extraction with the hair roots, or c) as b) but after a prior treatment with milk of lime to dissolve the hair roots to give so-called lime wool which must consequently always be regarded as chemically damaged wool. → Recovered wool.

Skittery dyeings An irregular speckled appearance in dyed goods produced by colour differences between adjacent fibres or parts of the same fibre due to a variety of causes (→ Skittery dyeing wool).

Skittery dyeing wool The uneven dyeing in the region of individual fibres which can be more pronounced in blended wools is described by the terms skitteriness, tippy dyeing, → Dichroism, etc (→ Tippy dyeing). Beyond a certain threshold value of dichroism (this term is used in respect of polychromatic effects as in a series of standard dyeings), the eye detects such dyeings as weaker in shade and uneven in appearance even with the best blending of the individual fibres. The skittery sensation thus depends on several factors, not least from the observer himself and from the form of the textile material.

Skitteriness is due to the fact that individual wool hairs exhibit differently dyed areas and is caused by uneven damage, especially during the growth phase. The most severely damaged parts are on the outside and are described as tips; the entire remaining part of the fibre is often described as the root. That part of the wool hair which can be unambiguously recognized coloristically, e.g. with cationic dyes, as the tip usually amounts to 5–35%. Wool from different sources differ markedly in this respect. As far as the fact that it is often difficult to decide where the tip (i.e. the most severely damaged part of the hair) stops, this will only be referred to in passing. Even though one generally only speaks of the tips and roots, all possible gradations exist between them. In the case of dyeings with more strongly dyed tips the term “positive dichroism” is used whilst the reverse situation is described as “negative dichroism”. The eye reacts more acutely to the positive variant, which is not only due to the fact that the strength differences may be more pronounced in this case, but also because the proportion of tips is less percentagewise than the proportion of roots.

A test for the quantitative determination of skitteriness is shown in the Fig. This is achieved by the mixing of different dyed slivers of known dye concentration and assessment of the resultant felts by experienced colourists. In this experimental procedure, negative dichroism was produced by keeping the root/tip ratio constant at 70 : 30. The total dye content of the blend, consisting of roots and tips, was likewise kept constant so that, theoretically, no differences in colour strength

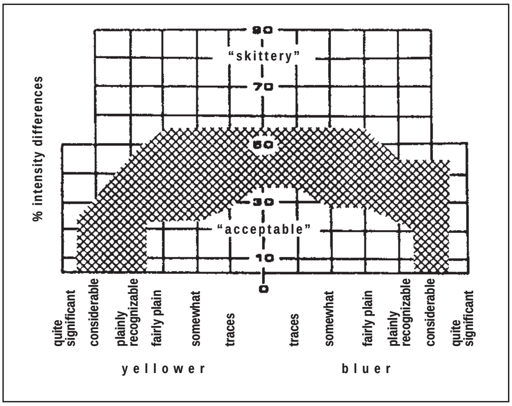

Fig.: Visual assessment of the skitterines of wool felts relative to intensity and shade differences in the admixtures (Ciba-Geigy).

should occur. This was achieved by the fact that in the case of pre-existing negative strength difference of the tips, the roots must have been dyed correspondingly darker. In strength terms, the same measures were adopted for the shade variations "yellower" or "bluer". The hatched area in the Fig. represents the skitteriness sensation threshold which was established from the different assessments of the colourists. Within and without the hatched zone, the assessments were uniformly acceptable or skittery. With negative dichroism, differences in colour strength greater than 40–50% occur relatively seldom. Pronounced skitteriness is therefore to be feared when the elements relating to dichroism vary in dye combinations, so that shifts in shade between roots and tips occur (according to Hertig and Scheidegger).

Skittery roller printing May be caused by, for example, poor engraving, excessive viscosity of the printing medium, excessive wiping of the medium out of the engraving or through clogging of the engraving. It can be alleviated by improving the engraving, or thinning the printing medium, by use of a stiffer doctor blade or reducing the pressure on the blade, or else by using rotary brushes for applying the printing medium.

SKT An abbrev. for "Schweizerische Klassifikation Textil", i.e. Swiss Textile Classification. A committee for textile documentation in Switzerland. The association for documentation is responsible for preparing a classification system for the textile finishing sector. The structure of the SKT is based on the decimal system.

SL → Slag wool, → Textile fibre symbols, according to DIN 60 001 up to 1988.

Slack mercerization → Mercerizing of cotton textiles on chainless mercerizing machines without tension. Fundamental requirements: suitable construction of the textile material (floating weaves), no tension during the mercerization process, the stretch effect is set by subsequent resin finishing.

The process is mainly employed to produce weft stretch cotton fabrics and is sometimes referred to as "chemical stretch" or it is applied as part of the process for crease-resistant linen. Dye affinity is increased but there is no increase in lustre.

Slag wool Synthetic → Mineral fibres (also crimped) produced from liquid blast furnace slag, used mainly for sound and heat insulation. Despite its good fire resistance, it has not been taken up by the textile industry, even in fibre blends, because it is very brittle and breaks easily; an irritant to the skin. Moreover, the oxidizable sulphur content (2–5%) readily leads to the formation of highly corrosive sulphuric acid in the presence of moisture.

Slaked lime → Calcium hydroxide.

Slasher dyeing → Warp sizing and dyeing.

Slasher dyeing machine A continuous plant for combined dyeing and sizing of warps for weaving (with diazo dyes or indigo) in the open-width state by means of a two-bath single-stage process for dyeing, development and sizing. From the warp beam frame the plant consists of: a dye trough (low liquor content), intermediate drier (15–30% residual moisture content), sizing unit for dye development and sizing (2 pairs of squeeze rolls and 2 immersion squeeze rolls), main drier, storage compensator, drier splitting section to separate the warp yarns for weaving. Yarn tension is measured at the entry to and exit from each unit with infinitely variable control.

Slasher-dye process A synonym for the → Sheet-dye process.

Slatted expander Expander combinations consisting of wood laths to maintain a fabric web in the fully open-width state. Depending on requirements, the wood laths are available with or without a rubber covering.

Slat-type black out For this application, special fabrics are given a light-impenetrable blackout coating. After finishing has been completed, the fabric is cut into strips and can, in this form, be assembled in predetermined constructions for windows so that they can rotate about their longitudinal axis as so-called roller blinds. The required stiffness of the individual slats is also achieved by means of the blackout coating which consists of several coats (e.g. white latex, latex with carbon black, white latex.).

Sleeved roller → Shell roller.

Sliding-oscillating centrifuge A type of centrifuge which, instead of pendulum feet, has a so-called sliding-oscillating bearing mounting (see Fig.). Its particular advantages include a low space requirement, better accessibility, only horizontal vibrations, and therefore less stress on the foundations, and considera-

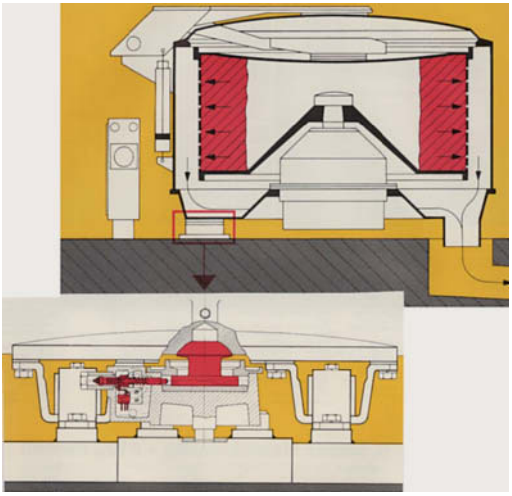

Fig.: Sliding-oscillating centrifuge with pneumatic lid- and frame opening (Krantz).

bly less loading sensitivity. The rimless model is fitted with a failsafe locking device and compressed air lid safety device; electronic speed control > 200 rpm, which can be used to set the desired end speed according to fabric type in a step-less rate (via inductive sensor in centrifuge's outer casing). Pneumatic lid opening after drum stop. Basket diameter 1200 mm, basket height 600 mm (according to Krantz).

Sliding valve A stop device used in wide diameter pipelines for steam, heating, liquids, etc. Similar to → Valves, but designed for horizontal flow, with hand wheel (operated hydraulically or electrically by means of auxiliary current push-button control), screw-threaded spindle and sliding gate. The contact faces are somewhat inclined to each other, sealing is by means of a stuffing box. The material used is generally similar to valves. Depending on the particular application, numerous designs are available, e.g. as stop valves, channel valves, membrane and quick-acting sliding valves, etc.

Slip resistance,

I. An important serviceability property of carpets, rugs, mats, etc. is that they do not slip on floors. This property calls for considerable attention with regard to the different types of floorings and the cleaning products used. In terms of finishing, slip resistance is primarily a function of the binder used (→ Backcoating of carpets). Slip resistance is most pronounced with non-filled coatings. The addition of pigment significantly reduces the slip resistance and is all the greater, the more the pigment particles are concentrated on the surface of the coating film.

II. The resistance to slippage of warp over weft threads, or vice versa, in a woven fabric. Slippage resistance mainly involves a comparative assessment. One test method provides approximate numerical values by comparison of the stress-strain curves (breaking load/breaking elongation) of two strips of textile material torn in a tensile strength tester, as well as a further strip which has been cut through at right angles and then sewn together again to form a simple seam. In this connection, the elongation of the sewn strip is greater than that of a normal strip without a seam due to slippage of the threads. For the same load, the difference in elongation values is a measure of the slippage resistance. Standard test methods include BS3320 : 1988 and Marks & Spencer test method P12.

Slipe wool Recovered wool obtained by treating pelts with lime and sodium sulphide or some other depilatory. This treatment loosens the wool which can then be pulled away without damaging the hide.

Slippage The slippage of e.g. drive belts on a pulley, or ropes of fabric in dyeing and processing machines, etc. are typical of this kind of slippage. If, for example, the reel of an overflow resp. jet dyeing machine runs faster than the rope of fabric being transported, the resultant slippage puts a lot of strain on the material. Synchronization of the fabric speed with the reel is therefore a necessary requirement. Particular attention must be paid to continuous control of fabric running in such machines and the effective circulation speed of the material should be indicated. In addition, a small free and lightly running control reel can be installed between the main reel and the acceleration tube of the machine (see Fig.) which is only driven by the fabric rope, so that its peripheral speed always corresponds to the effective fabric speed. The rotation speed of the control reel can be evaluated electronically and transmitted to a display

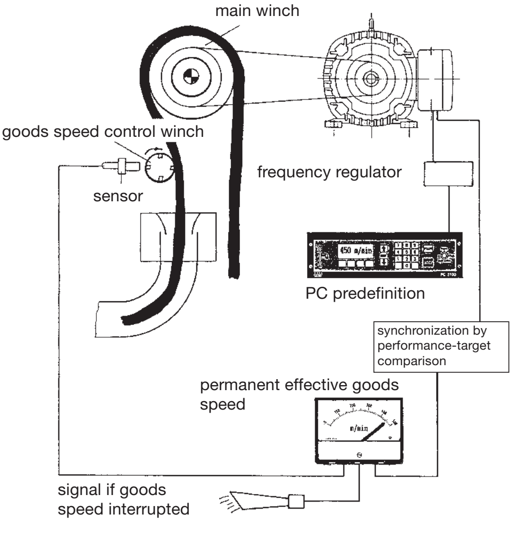

Fig.: The automatic synchronization of both winch speed and goods speed (Scholl).

unit which then provides an analogue or digital display of the effective fabric running speed. This not only allows the effective fabric running speed to be read directly at all times during the treatment, but also enables the fabric running to be optimally adjusted manually or automatically at all times so that the speed of the material and the main reel, as well as the jet pressure, are precisely matched and synchronized with one another. By this means, good running properties and minimum strain on the material is achieved.

A second, no less important, task of this system is the continuous monitoring of material transport. In contrast to other systems that monitor the fabric run with the aid of the magnet in the seam detector, which can only detect running malfunctions after each fabric circulation (which can take several minutes), the described system reacts immediately, i.e. without delay. If the circulation speed of the fabric falls below a freely adjustable limit value adapted to this speed, the machine stops immediately and a warning light or acoustic signal draws the operator's attention to the malfunction. The seam detector installed below the service port between the storage compartment and the main reel serves only its intended function, i.e. to stop the fabric run for sampling or unloading when the seam containing the magnet reaches the area of the service port.

Slit dye tube A flexible → Dye tube made of perforated stainless steel which is cut longitudinally in order to provide radial flexibility.

Slot clearer A special squeegee developed for rotary screen printing in the form of a narrow rectangular colour box (with print paste feed from outside) which is placed inside the rotary screen. The floor consists of two plastic lips which seal the slot on the inside of the screen by pressure on the squeegee.

Slow centrifuging A short centrifuging only, which is not carried out at full revolutions, i.e. the machine is switched on for a short period and immediately switched off again and the brake applied (centrifuge wet); 10–12 centrifuge revolutions are given whereupon, e.g. net curtains must be immediately suspended since each intermediate storage in the wet state leads to the formation of creases.

Slow motion, inching (extra slow speed, inching). Slow running of high production machines to allow time to make necessary adjustments, e.g. fabric tension, seam passage, etc.

Slub fabrics are produced (entirely or partly) from → Slub yarn.

Slub or knot density (knotted carpets) → Knot density.

Slub yarn A fancy yarn containing → Knops.

Sludge disposal With many aerobic and anaerobic biological waste processing methods, the question as to how best to dispose of the accumulated biosludge arises again and again. The growing microorganisms in biological processes die off at some time and must, just like an excess of microorganisms, be removed from the system. Usually, the microorganisms themselves build large voluminous flock-like structures which settle out relatively easily. However, the large voluminous structure results in an enormous water-binding capacity, i.e. in addition to the cell water, a typical biosludge contains between 98–99% water. Such a mixture is not easily disposed of. By adding 10–20 g/m^3 of a cationic flocculant, biosludges can be concentrated by pure sedimentation or sieving to levels of up to 6% dry substance content. Since such a biosludge with 94% water has a paste-like structure, any further separation of water is technically difficult. To achieve further water extraction in screen presses, centrifuges or chamber filter presses, therefore, a further addition of 50–100 g/m^3 of

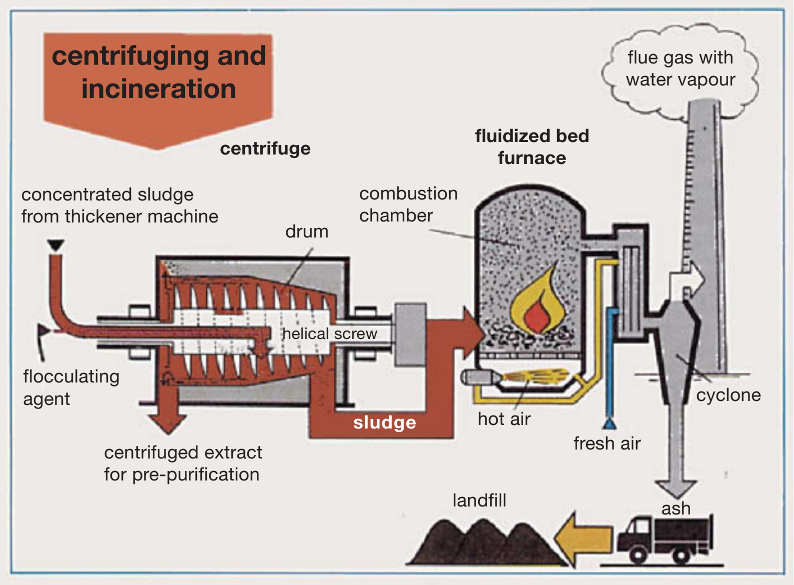

Fig.: Sludge treatment by incineration.

flocculant is necessary in order to obtain a sludge with a 15–20% dry substance content. A biosludge with a 20% dry substance content feels like wet cardboard and has a corresponding firmness. A further water extraction by machine is not possible. Consequently, this biosludge containing 80% water must be incinerated (see Fig.). Disposal by land-fill is forbidden because of the biological activity still present in the sludge, which can lead to unpleasant smells and other possible damage.

Sludge distillation An auxiliary or second still for dry-cleaning machines specially designed for the cleaning of workwear, hides and leather. Its purpose is to distil off the (chlorinated hydrocarbon) solvent as extensively as possible which, due to heavy contamination with oils and grease, therefore has a higher boiling point.

Sludge drier The principle of a sludge drier is based on the function of a thin-layer evaporator. A rotor distributes the material to be dried as a thin layer on a tube-shaped, indirectly heated, exchange surface at an appropriately high speed. Between the exchange surface and the material being dried, a layer of steam forms in ideal conditions which prevents caking and allows the material being dried to rotate without frictional losses. The thinner and more uniform the layer, the quicker the steam can diffuse through the material and the higher the drying capacity. If the material to be dried has a tendency to cake (this is dependent on the type of sludge and therefore cannot be excluded), appropriate constructive devices can be built-in to prevent such incrustations (see Fig.).

Sm Symbol for the element samarium (62).

Smeared prints Are formed by inadequately ground doctor blades in roller printing so that the print paste is insufficiently removed locally next to the engraved areas of the roller. The problem can be remedied by regrinding the doctor blade and/or by adjusting the position of the doctor blade against the printing roller.

Smog Consists of a mixture of smoke and fog and represents a visible pollution of the atmosphere (usually in the presence of considerable haze) over large cities and highly industrialized areas. It is largely the result of reactions between organic compounds and lies predominantly close to the ground during unchangeable weather conditions. Above a critical concentration, smog causes respiratory problems, eye irritations and the gradual destruction of dyes and colouring matters on textiles, which may also be accompanied by damage to the fibres. Olefin-based hydrocarbon pollutants from motor vehicle exhausts and their photochemical reaction products, together with the participation of nitro-

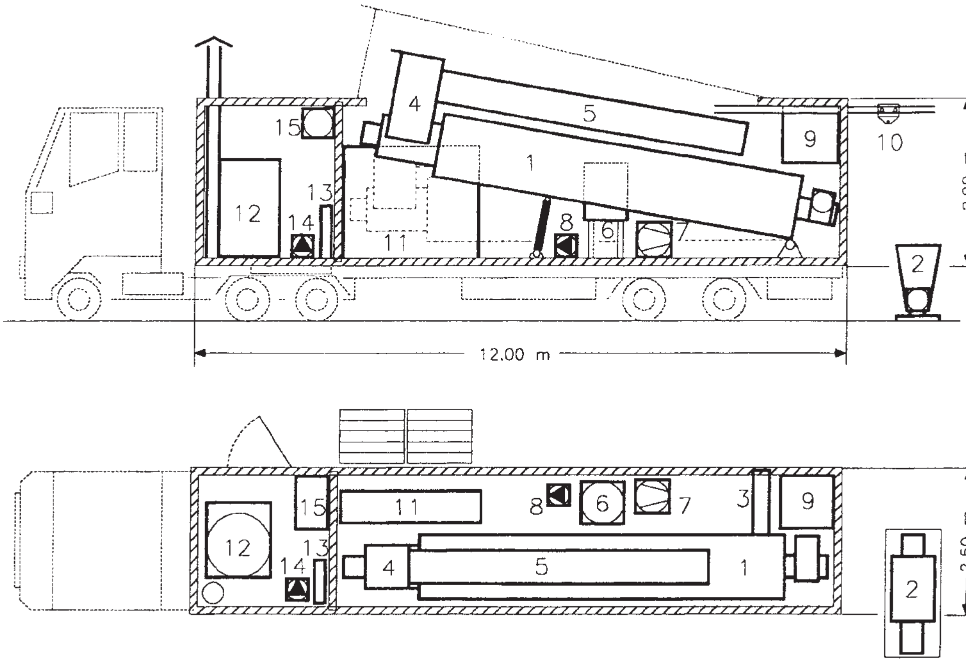

Fig.: A mobile sludge drier.
1 = thin layer drier; 2 = sludge metering pump; 3 = dried sludge output compacting screw; 4 = water lock; 5 = evaporator condenser; 6 = phase separator; 7 = vacuum pump; 8 = evaporator condensate pump; 9 = adsorption filter; 10 = extensible assembly device; 11 = central switch cabinet; 12 = steam generator; 13 = feed water preparation / process water injection; 14 = boiler feed pump; 15 = feed water barrel.

gen oxides in the air, make a particular contribution to smog formation as well as local concentrations of sulphur dioxide, nitrogen oxides and soot-laden fog. The principle of smog formation is based on the following reactions:

$$NO_2 \xrightleftharpoons{\text{sunlight}} NO + O \xrightarrow{O_2} \text{oxidant}$$

$$\text{oxidant} + \text{hydrocarbon} \longrightarrow \text{peroxides, aldehydes, acids}$$

$$+ \; SO_2 \longrightarrow \text{sulphur trioxide}$$

These reactions proceed quite quickly in most cases, and involve new free radicals with possibilities for polymerization and chain reactions.

The primary ingredients of photochemical smog are often non-toxic and include certain hydrocarbons and oxides of nitrogen. The phytotoxic products of photochemical reactions are peroxyacetyl nitrates, ozone and nitrogen. They are initiated by the energy of sunlight and are injurious to vegetation and some animals, even when present only in minute quantities (0.1 parts per million) and for a short duration (e.g. 8 hours exposure).

The clear links between many health problems and smog has led to several governments in the developed world introducing legislation to promote the use of smokeless fuels and reduce the emission of noxious and toxic gases into the atmosphere, e.g. → TI-air (TA Luft, Germany), British Clean Air Act (U.K.) and the Federal Clean Air Act (USA).

Smoke is a visible cloud of airborne solid/liquid particles resulting from incomplete → Combustion, or chemical reaction; the smoke particles are generally smaller than 1 µm. Smoke is an important constituent of → Smog.

Smoke development Different quantities of smoke are generated by textile fibres during combustion and is measured by the density of the smoke (see Tab.). Fibres such as wool or acrylic generate less smoke than, e.g. polyester or cotton so that the risk of being overcome by toxic smoke is less. The application of flame-retardant finishes should reduce the generation of smoke from textile fibres.

fibre material	smoke production (cm^3/g)
polyester	410
cotton	121
polyacrylnitrile	84
wool	57
aramide	2

Tab.: The smoke production of various fibres.

Smooth backing (smooth coat). A smooth, less structured, backcoating with a lower degree of foaming applied to textile floorcoverings for the purpose of achieving good resistance to slippage and cutting.

Smoothen, to A term used in laundering for → Mangling and → Pressing. In wool finishing, the term is used for steeping (wet setting, crabbing).

Smooth foam backing (flat foam). A smooth, non-structured, foam carpet backcoating.

Smoothing agent is a special type of textile softener in which the smoothing effect is based on reducing friction between individual fibres or particles of finishing agents. Cationic products are more effective as smoothing agents than anionic or non-ionic products.

Smoothing and calibrating calender A special calender for the thickness calibration and surface smoothing of needlefelt nonwoven filters for liquid media (see Fig.).

Smoothing index → Smoothness number.

Smoothing machine Consists of an oil-heated steel cylinder with 4 transverse grooves (temperature

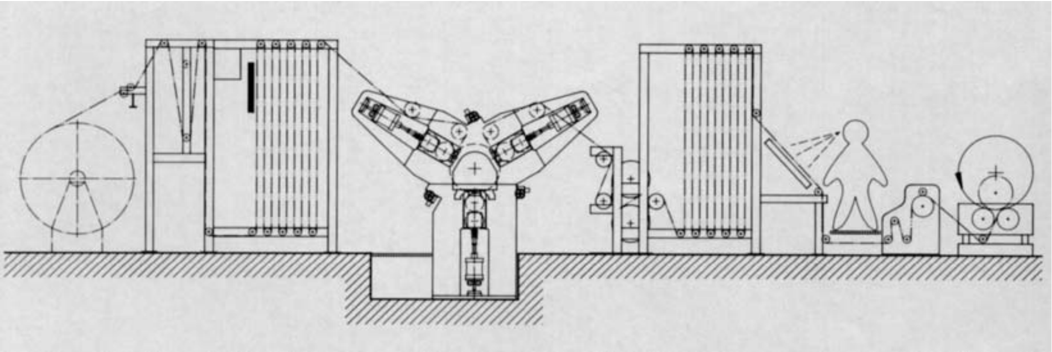

Fig.: Calibrating calender (WUMAG) for nonwoven textiles.

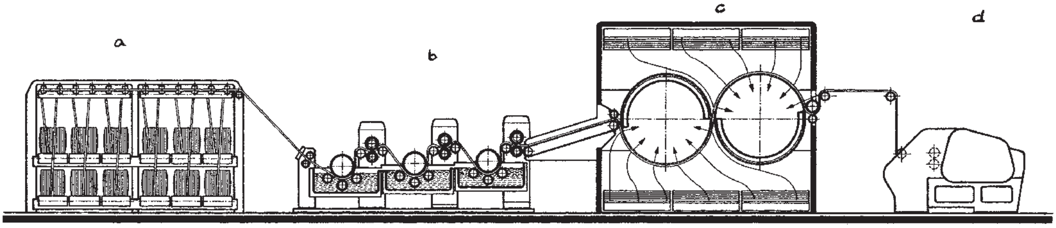

Fig. 1: Wool top treatment on a smoothing machine (Fleissner).
a = entry; b = washing/smoothing machine; c = air-smoothing; d = pin drafter.

up to 250°C) which runs against the fabric at 150–1500 rpm, with various fabric positions (effected by means of a felt blanket to control the wrap angle of the fabric) and flattens protruding fibres (by splicing). This flattening can, in certain circumstances, be permanently set with the aid of a previously applied fixing agent (applied by brush) in a subsequent thermal treatment.

Smoothing machine, backwashing machine (ironing machine, pressing machine). Washing machine for combed tops. Consists of unwinding frame for combed sliver packages, 2–3 washing and 1–2 rinsing vats (each with squeeze rollers), drying rollers, pressing rollers and a combing device at the outlet. Scouring baths are generally neutral or alkaline with ammonia with synthetic detergents (Fig. 1).

A backwasher with agitating scouring drum and associated support and working rollers (Fig. 2). In the form of individual or twin steeping baths with a side propeller pump situated by each of the slowly rotating drums (scouring liquor taken from inside the drum replaced by fresh liquor flowing from out to in). Drying is normally carried out in a perforated drum drier (air polishing).

Fig. 2: Fabric entry and exit top sheets in a suction drum back washing machine (Fleissner).

Smooth leather → Leather, with a smooth surface, e.g. morocco and nappa leather.

Smooth loops In tufted (pile) carpets where the loops have been produced from bulked filament yarns with little or no twist in contrast to twisted loops.

Smoothness appearance A subjective assessment criterion for the appearance of textile surfaces, especially for durable-press (DP) articles after household washing. The smoothness appearance is assessed by comparison with 3-dimensional standards (Wash-and-Wear Standard, DP-Rating and the Monsanto Crease Formation Standards as photographs). The smoothness appearance depends on a range of influence factors and the quantity of resin finishing agent as well as the degree of crosslinking exercise a decisive influence here.

Smoothness effect → Smoothness appearance.

Smoothness number This may be defined as the relative fibre-to-fibre resistance to friction where a low smoothness number corresponds to a smoother effect achieved by the application of → Smoothing agent. Examples: smoothness numbers of various products (2 g/l) related to the untreated fabric (smoothness number = 100):

glycerol	128
castor oil fatty acid sulphate, highly sulphonated	134
sulphated castor oil, medium degree of sulphonation	113
paraffin, emulsified	88
oleyl alcohol sulphate	54
sulphated olive oil, low degree of sulphonation	48
wax alcohol sulphate	42
triethanolamine-stearic acid ester, neutral	39
acidic	35–27

Smoulder To burn slowly without flame but with visible light.

Smoulder, to → Smoulder.

Smyrna carpets (→ Oriental carpets),

I. A general trade name for → Turkish carpets exported to Europe via the Turkish port of Smyrna (today's Izmir). For more than a century, Smyrna (Izmir) was the centre of the oriental carpet trade. European buyers, each with their own particular requirements, went to Smyrna where those requirements were met by local merchants who would accept orders for any type of design at very reasonable prices. These were usually copies of other well-known types of Turkish carpets produced in designs to satisfy European and American preferences and were often woven with inferior materials with a relatively low knot density. They were made principally in Ushak, Isparta, Sivas and Smyrna itself.

II. Coarse, soft, not very durable, deep-pile → Medallion carpets of Greek origin.

SN Sunn → Standard abbrev. for textile fibres according to DIN 60 001 T4/08.91.

Sn,

I. Sunn → Standard abbrev. for textile fibres according to DIN 60 001, in use until 1988. After 1991, changed to → SN.

II. Symbol for the element tin (50).

Snag,

I. A loop which has been pulled out of fine-knit hosiery due to the smoothness of the fibres (ladder). Drop stitches in smooth weft-knit fabrics are wales which, as a result of a broken thread or needle damage, are present as unformed threads. Drop stitches can be eliminated by "taking up" the loops in their old form with opposing interlacing. The prevention of drop stitches by a change of the loop formation in smooth weft-knit fabrics, generally by loop transfer or by pressing-off loops (i.e. transfer of half the loops from one needle bed to the other with crosslinking of adjacent loops) provides an assurance against laddering. Anti-snag finishes also provide some degree of protection against snagging. An anti-snag finish is a collective term for any finishing treatment which is intended to reduce the risk of laddering in fine hosiery by bonding the threads. This type of finish has nothing to do with so-called "ladder-free stockings" since the special characteristics of the latter are created by the type of thread interlacing in the knitted fabric as shown in the Fig. (according to Hofer).

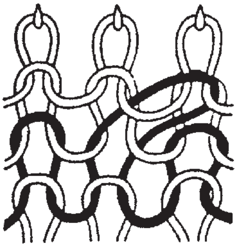

Fig.: Diagram showing ladder prevention by snagging.

II. (pulled thread), a slub-like structure consisting of individual capillary fibres, 2–8 mm in length, which has been pulled out of the whole thread. It occurs mainly with polyamide yarns and knitted fabrics (hosiery).

Snagging Box (ICI). A laboratory instrument for testing the sensitivity of knitted fabrics, e.g. women's outerwear, to snagging (formation of → Snags). Each of two rectangular fabric samples, cut out of the material in the lengthwise and widthwise direction, are shaped into tubes and pulled on to a rubber roller. The edges of the samples are stuck to the rubber roller with adhesive tape and the test specimens are treated for 5 h in a rotating (60 rpm) cube-shaped box with a steel spike in each wall. Assessment is by comparison against a photographic standard with 4 progressive stages of snagging.

Snapper in roller printing This is a printing defect consisting of a double stripe of colour with a white centre running vertically up the piece. It is caused by a small, relatively soft, foreign body becoming trapped between the edge of the doctor blade and the printing roller during printing thereby lifting the doctor edge at this point. As a consequence, the foreign body itself prevents any print paste from penetrating at the centre of the "lift" but allows excess print paste to pass on either side of it (i.e. on the non-engraved surface of the printing roller) from where it is transferred to the fabric. The foreign body is generally a loose thread from the fabric being printed, or particles of dried thickener from the print paste. The problem is remedied by washing off the doctor blade, printing roller and colour box and straining the print paste.

Snarl (twist). The twisting of e.g. a rope of fabric as an undesired effect in, e.g. winch dyeing. The term also applies to single and ply yarns (see Fig.).

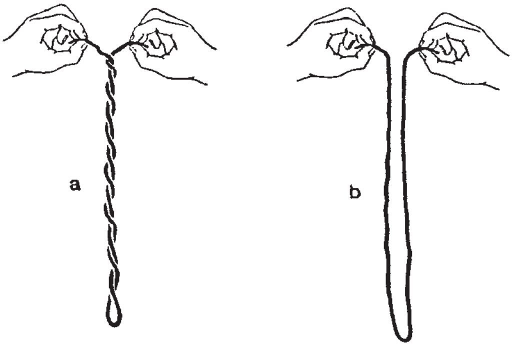

Fig.: Snarling in a snarling FZ yarn (a), twist-free yarn (b).

Sniffing method An olfactory test for determining the odour threshold in the microbiological decomposition of organic substances on textiles (→ Antimicrobial finishes). It is of limited application, however, since individual sensitivity to the smell of ammonia varies greatly. The blow-through test, in which the presence of ammonia is determined with the aid of → Nessler's reagent, is more precise.

Soap Alkali salts of fatty acids with a minimum of 12, and a maximum of 18, carbon atoms. The first signs of surfactant properties are already apparent from 8 carbon atoms upwards. The hydrophilic part of an anionic surfactant is due to the presence of COO– groups, and the hydrophobic part is due to the presence of an alkyl residue, e.g. sodium stearate $C_{17}H_{35}COONa$. All sodium, potassium and ammonium salts of fatty acids exhibit good solubility in water; all magnesium, calcium and aluminium salts are insoluble in water. The latter accounts for the fact that, in the presence of water hardness salts (e.g. magnesium, calcium), soaps form insoluble precipitates. Saponification of fatty acids with caustic soda or sodium carbonate yields soda soaps (curd soaps, hard soaps), whilst saponification with caustic potash or potassium carbonate yields potash soaps (semi-solid or soft soaps).

Properties: the anionic and surface-active substance is subject to a reversible hydrolytic breakdown in water which results in an alkaline reaction. Advantage: excellent washing effect which can be attributed to the action of soap as a protective colloid. Disadvantage: soap is not resistant to water hardness which means a loss of washing agent in hard water due to precipitation of the insoluble soap. This precipitated soap is deposited on textile materials which results in unlevel dyeings and an unpleasant handle on the goods. Soap is not resistant to acids and is therefore not very suitable for processes carried out in an acidic medium (e.g. wool finishing). Soap is not stable to electrolytes and salting out can occur in the presence of salts. For this reason, it is not stable to sea water. Some of the drawbacks of soap can be eliminated by condensation with condensed phosphates. The unsatisfactory properties of soap have led to the development of synthetic → Surfactants.

Importance in textile processing: originally, soap was only used for washing. Later on it was also used for cleaning oily textiles, milling, scouring, bleaching, as a wetting and levelling agent, emulsifier, degumming, desizing, water repellency, and as a spotting agent, etc. Because of their negative properties, soaps have been displaced by synthetic surfactants in commercial and household detergents. In general, it can be assumed that soap is precipitated out by calcium and magnesium ions in waste water treatment. In the case of biological waste water treatment, however, soap breakdown is more difficult.

Soap flakes are produced from dried, cut, hard soap.

Soap handle The preferred handle for worsted yarn wool fabrics which, in former times, was achieved by using soap in scouring and milling.

Soaping aftertreatment of dyeings and prints Improves the quality of the fabric when given as a final process before the goods are sent for finishing.

I. (Fast) dyeings: not only genuine fast dyeings but also, e.g. acid wool dyeings and blended wool yarn dyeings are soaped to achieve better rub fastness. Contrast dyeings, or white and coloured effects on different fibres, are also frequently soaped; in the latter case, it is preferable to use slightly acidic surfactants. Diazo dyeings are also soaped (at approx. 50°C) to improve the colour fastness to washing. In this case, and especially with vat, reactive, vat leuco ester, sulphur and naphthol dyeings, the loosely-adhering dye particles are removed from the fibre by an aftersoaping treatment thereby giving cleaner fabrics with improved colour fastness to rubbing and fully-developed brilliant shades.

II. Prints: an aftersoaping treatment serves to produce prints with higher colour fastness by removing dye particles adhering to the surface of the fibres (e.g. naphthol and vat dyes) or unfixed dye (e.g reactive dyes). The shades are more brilliant as a result. The optimum temperature depends on the class of dye. Synthetic detergents are mainly used for aftersoaping.

Soaping machine This type of machine consists of a vat with squeeze rolls for wetting out wool piece goods that only require a short milling treatment. When the addition of milling agent is made by pouring it into the machine, this does not result in satisfactory distribution of the product.

Soaping of vat dyeings and prints This treatment is essential for the achievement of correct shades and optimum colour fastness to light and rubbing. After oxidation, the vat pigments are present in a finely divided form on the substrate. During the soaping treatment, however, aggregation occurs to form large crystallites which are more resistant to physical and chemical influences. The soaping treatment is carried out at the boil in each case with soap, soap and sodium carbonate, synthetic detergents or synthetic detergents and sodium carbonate. Where only hard water is available, the addition of water softeners is necessary.

Soap paste (soap glue) → Pasting.

Soap powder Dried, pulverized → Soap (produced from soap paste and sodium carbonate) with a total fatty acid and resin acid content of 5–40%.

Soap regeneration in processing baths The effectiveness of soaping baths is easily reduced during use. The main causes (apart from the obvious consumption of soap in binding soils of various kinds) include, e.g. water hardness, turbidity, and a drop in pH. Although often overlooked, the carry over of undesired chemicals from previous treatment baths also plays a part here. In many cases, a renewed, increased, efficacy of the soap bath is assured by refreshing the liquor or raising the pH again. Variations in pH may be compensated by the careful addition of caustic soda liquor.

However, the use of sodium carbonate for this purpose is undesirable in order not to load the state of equilibrium unnecessarily.

Soap residues (fatty residues). Coarse agglomerated residues of soap, fat, lime salts, and dark pigment soils, often appearing as numerous spots which are deposited on garments during washing. They are caused by using a soap with an excessively high fat content or (usually) by carrying out the first rinse with cold water. They can be eliminated by using → Syndets or a slightly acidic rinse water.

Soap steamer A processing unit for the treatment of piece goods at the boil after dyeing or printing. The running fabric is immersed in the soaping bath and then steamed. With this system, several wash compartments in an open-width washing range can be saved.

Soaps with modified fatty acid residues Besides the carboxyl group –COOH, the hydrophobic hydrocarbon residue is modified (modified alkyl chain) in these soaps, which inhibits hydrolysis and increases the resistance to acids and water hardness salts. Such soaps are of interest in milling.

Soda → Sodium carbonate.

Soda ash → Sodium carbonate.

Soda bleach lye → Sodium hypochlorite.

Soda cellulose (alkali cellulose). Represents the first stage in viscose rayon manufacture. Cellulose pulp is steeped in warm caustic soda liquor (17–18%) for 1–2 h, and then pressed to remove excess solution. The treated cellulose is broken up in a shredder to form powdery crumbs. The crumbs are then aged for several hours during which time the caustic soda reacts with the cellulose to form soda cellulose.

Sodalite, cage zeolite A blue, grey, yellow or colourless mineral consisting essentially of sodium and aluminium silicates with sodium chloride in a cubic crystalline form of the type Na[Cl(AlSiO)], which occurs in certain basic igneous rocks. The hollow structure of sodalite is important as a lattice unit in → Zeolites.

Soda vat → Fermentation vats.

Sodium → Alkali metals. Sodium, symbol Na, is a soft, silver-white metal which oxidizes rapidly in air. It is wax-like at room temperatures and brittle at low temperatures. Atomic weight 23.05, m.p. 97.6°C. Sodium is lighter than water (density 0.97) and has the typical properties of an alkali metal; the positive sodium ion forms water-soluble colourless salts with colourless acid ions.

Severe fire risk in contact with water in any form (stored in air-tight containers or under naphtha or similar liquid that does not contain water or free oxygen), ignites spontaneously in dry air when heated.

Sodium acetate (acetate of soda, sodium ethanoate). CH_3COONa; molecular weight 136. Colourless odourless crystals or anhydrous salt. Solutions in water are weakly alkaline. Uses: neutralization of mineral salt esters on cellulosic textiles; reduction of acetic acid acidity (buffering); neutralization of naphthol diazo solutions; aftertreatment of sulphur black (prevents tendering); additive for diazo solutions in dyeing and printing with naphthols, etc.

Sodium alginate Sodium salt of → Alginic acid, $C_{10}H_{18}O_{10}(COONa)_2$; soluble in cold resp. warm water under rapid stirring (it is advisable to allow freshly prepared solutions to stand overnight). Boiling in water reduces the viscosity. Solutions are non-foaming. Stable to alkalis but sensitive to acids (especially below pH 3). The addition of a complexing agent (5–25% of the weight of alginate) is recommended in hard water. Solutions are sensitive to bacterial decomposition (the addition of 0.2% salicylic acid, formaldehyde, etc. can be used as a preservative). Uses: sizing agents, finishing agents, water-repellent impregnations. The main use of sodium alginate is as a thickener for textile printing (discharge pastes, roller and screen printing, easy to wash off, uniform viscosity, excellent penetration in printing, non-foaming, flows readily, good colour yields, sharp outlines). Suitability as a thickener for textile printing: especially important for reactive dyes, azoic diazo dyes, vat leuco ester and vat dyes; not suitable for cationic dyes, chrome dyes and naphthols. The viscosity of sodium alginate thickeners is determined by the degree of water hardness and the alginic acid content.

Sodium aluminate (aluminate of soda). Na_3AlO_3 or $Al(ONa)_3$, molecular weight 144.25. Colourless small lumps or fine powder with 35% Al_2O_3 (stable to air) or 50% Al_2O_3 (somewhat hygroscopic, store in air-tight containers); both forms are readily soluble in water. Uses: waste water treatment, water softening, oil removal from feed water and desilification; mordant for dyeing alizarin red (on cotton), etc.

Sodium aluminosilicate (sodium silicoaluminate). A series of hydrated sodium aluminium silicates with the approx. formula $Na_2O–Al_2O_3–3\,SiO_2 \cdot 5\,H_2O$. Available either as a natural or synthetic product; crystalline, insoluble in water. The use of sodium aluminosilicate as an inorganic ion-exchange compound (→ Zeolites) is well-known. By exploiting this property, it is also used as a builder in classic detergent compositions in addition to pentasodium triphosphate. During the transport phase from the user through the sewer system to the waste water treatment plant, the concentration of harmful heavy metal ions is reduced.

Sodium bicarbonate (bicarbonate of soda) → Sodium hydrogen carbonate.

Sodium bisulphate $NaHSO_4$; molecular weight 120. White fused lumps, colourless crystalline mass or coarse-grain powder, readily soluble in water with an acidic reaction. Uses: finds considerable use in wool dyeing instead of sodium sulphate/sulphuric acid.

Sodium bisulphite $NaHSO_3$; molecular weight 104. Colourless crystals, powder (both readily soluble) or as a commercial solution with a density of 1.33–1.38. Odour of sulphur dioxide. Alkaline reaction. Uses: as a reductive bleach (for protein fibres); as a spotting agent (especially for permanganate resp. manganese dioxide stains); as a substitute for sulphurous acid; as an afterbleach with potassium permanganate; as an antichlor; often substituted with → Sodium dithionite; as a discharging agent in discharge printing (with zinc dust), etc.

Sodium borate (borax, sodium tetraborate, sodium pyroborate). $Na_2B_4O_7 \cdot 10\,H_2O$; molecular weight 382; density 1.7. White crystals or anhydrous powder. Soluble in water; the solution is fairly strongly alkaline. Uses: mild alkali, textile printing, application of alkali blue (wool dyeing); manufacture of hat proofs; addition to finishing liquors (as a preservative); solvent for alizarin dyes and casein; flame-retardant impregnations; component in soaps and gloss starches; flux.

Sodium carbonate (soda ash, soda, soda crystals, Leblanc soda, Solvay soda, carbonate of soda),

I. Anhydrous sodium carbonate (soda ash), Na_2CO_3; molecular weight 106.01; density 2.5. White powder soluble in water.

II. Crystalline sodium carbonate, $Na_2CO_3 \cdot 10\,H_2O$; molecular weight 286, density 1.45. Colourless crystals, effloresces readily, forms hard lumps when stored under damp conditions; water-soluble. Solutions are strongly alkaline.

Uses: water softening; alkali scouring, bleaching, degreasing, washing, etc.; additive to dyebaths; component in detergents and washing powders; soap filler; cleaning agent for metals, etc.

Sodium chlorate (chlorate of soda). $NaClO_3$, molecular weight 106.5; density 2.5. Colourless crystals, hygroscopic, toxic; water-soluble. Powerful oxidizing agent; textiles moistened with sodium chlorate are readily ignitable. Uses: powerful oxidizing agent especially in textile printing and aniline black dyeing.

Sodium chloride (common salt, cooking salt, table salt, sea salt, rock salt). NaCl; molecular weight 58.5; density 2.164. White crystals readily soluble in water; saturated solutions boil at 107.7°C. Uses: chiefly as an addition in dyeing, especially with substantive dyes to increase the rate of dye exhaustion on the fibre; spotting agent on coloured silk (prevents bleeding); regeneration of base-exchange filters (water treatment); salting out soaps; tanning; electrolyte addition in developing baths for 2-phase printing (prevents bleeding); addition to water baths in the dyehouse laboratory to achieve a higher boiling point, etc.

Sodium chlorite $NaClO_2$; molecular weight 90.5; white crystals or crystalline powder, odourless, very stable product. Dilute neutral and basic solutions can be heated to 100°C without decomposing. Acidic solutions decompose very rapidly:

$$\begin{array}{llcl}
(1) & NaClO_2 + H_2O & \rightleftharpoons & HClO_2 + NaOH \\
(2) & HClO_2 & \longrightarrow & HCl + O_2 \\
(3) & NaClO_2 + HCl & \longrightarrow & HClO_2 + NaCl \\
\text{or} & 5\,NaClO_2 + 4\,HCl & \longrightarrow & 4\,ClO_2 + 5\,NaCl + 2\,H_2O
\end{array}$$

The associated bleaching action is therefore pH-dependent. Uses: bleaching agent for cellulose (chiefly linen and cotton), cellulose pulp, paper, cupro, acetate and viscose fibres, as well as polyamide, acrylic, polyester and polyvinyl chloride fibres, waxes and straw products, edible and inedible oils, etc.; oxidation of vat and sulphur dyeings.

Sodium chlorite bleach,

I. Cellulosic fibres: sodium chlorite produces excellent bleaching effects with a high degree of fibre protection. It can be applied by full bath treatments or by discontinuous and continuous padding methods. Also suitable for acetate and triacetate (→ Bleaching agent, sodium chlorite). Sodium chlorite itself has no bleaching action but only that of the chlorine dioxide formed during its decomposition which further decomposes into chlorine and oxygen. This reaction only proceeds quickly enough in acidic media below pH 5. Damage to the fibre can occur at pH < 3. For full bath bleaching, organic acids (acetic or formic acid) are preferred to adjust the pH. In addition, diammonium or sodium phosphate are added as stabilizers. In pad-steam processes, organic acids are substituted by products which split off acids by the action of heat, i.e. so-called activators (e.g. ethyl acetate, chloral hydrate). Commercial liquid forms of sodium chlorite can also contain an activator addition already.

II. Synthetic fibres: with the exception of polyurethane and some individual acrylic fibre types, the sodium chlorite bleach is the most suitable bleach for synthetic fibres in which the material is treated exclusively in a long liquor. Applications on the padder are not suitable in this case. The bleaching effect is not equally good on all fibre types and staple fibres are more easily bleached than continuous filament yarns. Traces of metal salts (iron, manganese) in the fibre can lead to discoloration of the bleached material. After bleaching, complete removal of the often obstinately persistent chlorine is essential; if rinsing proves insufficient, an antichlor bath with sodium dithionite or sodium bisulphite must be used. A chlorite-resistant optical brightener may be added to the bleaching bath if a maximum white effect is desired.

Disadvantage of the sodium chlorite bleach: environmentally problematic process because of the toxicity of the gases liberated during bleaching as well as chlorine pollution of the waste water (AOX).

Sodium citrate (trisodium citrate). $Na_3C_6H_5O_7$; molecular weight 258.15; white crystals or granular powder, odourless, stable in air, pleasant acid taste, soluble in water. Combustible. Uses: inactivating addition for complexing water hardness salts (the action of sodium meta and polyphosphates is inferior in this regard).

Sodium dichloroisocyanurate → Chloroisocyanuric acids.

Sodium dithionite (sodium hydrosulphite, "hydros"). $Na_2S_2O_4$; molecular weight 174. Sodium dithionite is a white, water-free, powder which is readily soluble in water and should only be stored in a completely dry state in a cool place. Solutions decompose readily into sodium thiosulphate; it is a powerful reducing agent; alkaline solutions eagerly absorb oxygen. Uses: the most important reducing agent for stripping dyeings; reducing agent for the dyeing of vat, indigo and sulphur dyes; reducing agent for the printing of vat dyes by the 2-phase process; bleaching agent (especially for wool); antichlor; spotting agent (for dye, fruit, perfume, rust and ink stains, perspiration, etc.). Sodium dithionite-formaldehyde compounds (so-called sulphoxylates) are used for stripping dyes, and as more stable reducing agents for the dyeing and printing of vat dyes, and discharge printing.

Sodium dithionite dissolving station In many dyehouses, large quantities of sodium dithionite ($Na_2S_2O_4$) are used. This chemical compound is difficult to handle manually because it is harmful to health and also gives rise to unpleasant fumes and irritating dusts. Above all, it is dangerous because of its property of spontaneous ignition if it comes into contact with moisture. For these reasons, the van Wyk company (Holland) has developed a sodium dithionite dissolving station (see Fig.) in which this chemical can be dissolved automatically at the required concentration. Moreover, caustic soda liquor and 2 auxiliary products can also be added automatically at the desired dosage. The process is continuous keeping the small mixing tank at a pre-determined level. From this tank, the dyeing machine(s) are fed automatically. Since the mixing tank has a small capacity and is completely enclosed, the sodium dithionite is handled very efficiently with minimum loss by oxidation. A completely self-controlled system can be realized with the aid of new sensors for measuring the redox potential. The dissolving station can be installed with automatic loading systems to suit customer requirements, e.g. a sack emptying and conveyor system as well as an automatic emptying system for large containers.

Fig.: Sodium dithionite dissolving station (van Wyk).

The dissolving station consists of: (a) measuring hopper, (b) dosing screw transporter, (c) weighing system with 2 load cells and weight transmitter, (d) 4 dosing pumps with adjustable stroke volume and frequency, (e) 1 water dosing system with volume meter and pulse transmitter, electromagnetic water valve and flow control valve, (f) 1 mixing tank, and (g) stainless steel mixer. The control system is based on an "Intel Bitbus Microcontroller System" and is operated by means of a Burr Brown TM 2700 microterminal installed near the dyeing machines. The operator selects a recipe and the unit automatically produces this recipe for the period required. A warning lamp indicates when the measuring hopper needs refilling; at the minimum level an alarm sounds at the operating terminal. Preparation is continuous during the refilling stage. The standard system has a storage capacity for 30 recipes.

Sodium exchanger → Ion exchanger.

Sodium formaldehyde sulphoxylate → Sulphoxylates.

Sodium hexametaphosphate (→ Graham's salt, metaphosphate). $NaPO_3$ also as $(NaPO_3)_6$ or $Na_2[Na_4(PO_3)_6]$. Density 2.4; mol. wt. 612. White powder, hygroscopic, soluble in all proportions (visco-colloid). Reacts as a weak acid, 1% solution ca. pH 6.5. In solution with an excess of Sodium hexametaphosphate and in the presence of hard water salts and heavy metals forms soluble complexes (also at higher temperatures; optimum effect at approx. 70°C). Dissolves Calcium soaps and similar compounds. On standing in hard water: turns turbid and forms flocks without salt precipitation. Reaction: → Complex phosphates. Application: water softening to 0° German hardness; scouring, degreasing, milling, after-soaping, desizing, bleaching, dyestuff dissolving and rub fastness improvement of dyebath additions; builder for laundering detergents, etc.

Sodium hydrogen carbonate $NaHCO_3$; mol. wt. 84; density 2.2. White powder, soluble in water; solution is weakly alkaline (phenolphthalein is an indicator); over 65°C breaks down to form CO_2, Na_2CO_3 and H_2O. Usage: Neutralization of naphthol-diazo solutions; buffer; in printing, etc.

Next Page

Sodium hydrogen sulphite → Sodium bisulphite.

Sodium hydroxide (caustic soda, caustic lye). $NaOH$; molecular weight 40.01; density 2.13. White crystalline mass (flakes, lumps, pearls, sticks) hygroscopic, absorbs CO_2 from the air (to form sodium carbonate). Water soluble, also soluble in alcohol: heat strongly evolved on solution; solution strongly alkaline. Viscous lye: density 1.357 = 32.5 wt.% = 44.1 vol.% (1 litre = 441 g). Concentration in aqueous solution determined by aerometer or titration. Below 100 g/l NaOH sodium hydroxide solution is in the form of hydrated ion hydrates. These ions have a hydrodynamic diameter of 1.5–2.0 nm. With increasing concentration of sodium hydroxide and a reduction in the amount of available water molecules, and from 150 g/l, an increasing presence of hydrated ion pairs is found, with a diameter of 1.0–1.5 nm. Finally from 200 g/l there begins an increase in the solution of hydrated dipole hydrates and eventually dipole hydrates. These ions have a diameter of 0.5–1.0 nm. Applications: Caustic boiling, mercerizing (Fig.), degumming, crabbing, causticizing, vat dyeing, naphthol dyeing (base application), boiler water softening, etc.

Sodium hydroxide process Used to determine microscopic evidence of light damage to wool fibres. Chopped fibres are placed on a slide between the object carrier and the cover slip and flushed with 0.1N sodium hydroxide. Under the microscope, damaged fibres show as swelling strongly with twisted fibres and deep surface fissures.

Sodium hypochlorite (bleach lye, chlor soda, bleaching soda, Eau de Labarraque, sodium bleach liquor, sodium salt of hypochlorous acid). $NaOCl$; mol. wt. 74.5. white powder (anhydrous condition), Crystalline (hydrated, $NaOCl \cdot 6\,H_2O$). Normally used as the hypochlorite lye: clear, yellow-green, free from calcium salts, stabilised (stable for cool storage during months); density 1.21–1.23 with 140–160 g/l active chlorine, equivalent to 147–168 g/l NaOCl. Storage conditions: a) if possible at lower temperatures : 10–20°C; b) store (according to storage temperature) for maximum of 1–2 weeks. Applications: bleaching of cellulose; scouring agents → Bleaching agent, sodium hypochlorite.

Sodium hypochlorite bleach In comparison to → Calcium hypochlorite has an advantage in the absence of calcium, hard water salts. Therefore easier rinsing, weaker acidification (cost), softer fabric handle, also retains white effects better and helps to avoid local fibre damage by calcium chlorite particles. Clear disadvantage: AOX loading in effluent.

Sodium hypochlorite liquor (hypochlorite lye) → Sodium hypochlorite.

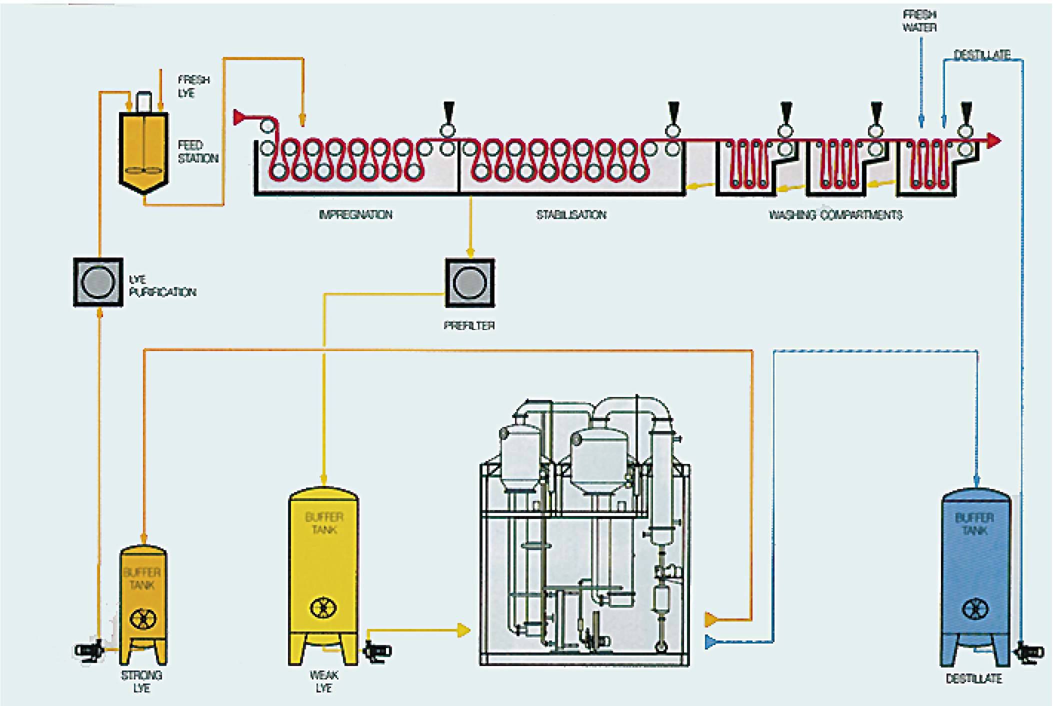

Fig.: Caustic soda recovery system from GTV based on an evaporation process.

Previous Page

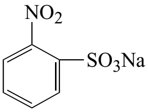
Sodium hyposulphite → Sodium dithionite.

Sodium metabisulphite Common name for sodium pyrosulphite $Na_2S_2O_5$. Results from splitting off water from sodium hydrogen sulphite $NaHSO_3$ or saturating a solution of sodium hydrogen sulphite with sulphur dioxide SO_2.

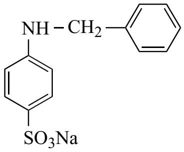
Sodium metaphosphate → Sodium hexametaphosphate.

Sodium metasilicate Na_2SiO_3, $Na_3[HOSiO_3] \cdot 5\,H_2O$; Alkaline silicate; anionic. Protective colloid, dispersing and scouring auxiliary; alkaline; temperature stable; somewhat hard water stable; alkali stable.

Sodium m-nitrobenzene sulphonate Used to inhibit the reductive effects of caustic and soda boiling, (bleaching dyed goods), as reserving agent for vat dyestuffs in discharge printing and similar methods.



Sodium N-benzylsulphanilate Fine white to yellowish powder, easily soluble in water with neutral reaction. Extensively used in dissolving hydrotropic dyestuffs and as a dispersing agent, especially for vat and leuco-vat dyestuffs in printing: effective as a levelling agent, increases the yield and improves fixation.



Sodium nitrite (nitrite, saltpetre). $NaNO_2$; molecular weight 69; density 2.17, white to pale yellow crystals, weakly hygroscopic, easily soluble in water, slightly soluble in alcohol. Applications: Diazotising azo dyestuffs (1 part sodium nitrite and 3 parts nitric or sulphuric acid; ratio is important to produce the required nitrous acid); dyeing with leuco-vat dyestuffs; in printing, etc.

Sodium nitroprusside (nitroferricyanide). For the identification of wool. 2 crystals of sodium nitroprusside ($Na_2[Fe\{CN\}_5\{NO\}] \cdot 2\,H_2O$) are dissolved in a little water. Some fibres are dissolved, with boiling if necessary, in 5% sodium hydroxide solution; a few drops of sodium nitroprusside solution are added. In the presence of sulphur (wool) an intensive red-violet colour forms. Natural silk and regenerated protein fibres do not give a colouring.

Sodium number (SN). Expression for the required minimum alkalinity (to avoid hard water deposits) of feedwater in mg/l of NaOH. For very low salt-content water 200–500; for phosphate containing water 400–2000; for phosphate-purified water 100–400. Application of the SN limiting value also covers the presence of 4000 mg/l chlorine, 8000 mg/l SO_3, 1500 mg/l P_2O_5 and higher values. Calculation:

$SN = \text{mg NaOH} + 0.222 \text{ mg } Na_2CO_3 + 0.667 \text{ mg } Na_3PO_4 \cdot 12\,H_2O + 0.222 \text{ mg } Na_2SO_3$.

Sodium perborate (peroxyborate, perborate, peroxy sodium). $NaBO_3 \cdot 4\,H_2O$; molecular weight 154, colourless crystals or fine powder, stored as a dry powder, water soluble; in pure form contains 10% active oxygen that is slowly released on warming (→ Sodium percarbonate). Application: Laundering detergent formulation component (10–20%); bleaching (oxygen bleach methods); oxidation of high fastness dyeings; de-sizing; purification of starch, solubilising of algae, seaweeds, etc.

Sodium percarbonate (sodium percarbonic acid). $NaCO_3 \cdot {}^1/_2\ H_2O$; molecular weight 149.13. Contains 21% peroxide = 10% active oxygen. White powder, water soluble. Breaks down to evolve oxygen and form sodium carbonate. Application: Oxidation and bleaching agent (normally with a stabiliser), additive to washing detergent formulations especially as a replacement for → Sodium perborate.

Sodium peroxide (sodium superoxide). Na_2O_2; molecular weight 78; density 2.81. Pale yellow, fine particulate powder (or compact granules of 0.3–1.5 mm ∅) 19–20% active oxygen, very hygroscopic, odourless; 97% purity; ignites in damp conditions in concentrated form and also in the presence of flammable material (paper, wood, etc.) water soluble with emission of heat (decomposes to hydrogen peroxide and sodium hydroxide. Application: Oxidizing agent for vat and sulphur dyestuffs; bleaching agent for silk, wool, cotton, linen, viscose, etc.) In soluble form after the addition of sulphuric acid (to neutralize) and addition of phosphate to make weakly alkaline, stabilizer etc. to produce a non-yellowing full white product (softer fabric handle and less fibre damage).

Sodium phosphate, dibasic Better named disodium hydrogen phosphate. → Sodium phosphates.

Sodium phosphates (→ Monophosphates),

I. Primary sodium phosphate (monosodium phosphate, sodium dihydrogen phosphate) NaH_2PO_4. White salt, easily soluble; slightly hygroscopic when fully dry. Reacts acidic, 1% solution pH 4.2, Anhydrous form exists (with 15% bound water) as monohydrate ($\cdot 1\,H_2O$, density 2.04) and dihydrate ($\cdot 2\,H_2O$, 34.5% H_2O, molecular weight 138). Application: Water preparation especially for boiler feed as corrective method after base exchange. Dosing ca. 20 g. sodium phosphate crystals/m^3/l° hardness whereby there is a minimum 1° carbonate hardness from sodium hydrogen carbonate.

II. Secondary sodium phosphate (disodium hydrogen phosphate). $Na_2HPO_4 \cdot 12\,H_2O$; density 1.53; molecular weight 358. Colourless crystals; readily efflorescent; water soluble; solution is weakly alkaline, 1% solution ca. pH 8.5 – 9.2. Crystallises with 2 molecules of H_2O; resistant to weathering. Application: Water preparation especially for boiler feed (60 g/m^3 and residual hardness) especially after the softening stage; weighting of silk, dyebath additive as a mild alkali (substantive sulphur dyestuffs), fixing agent for aluminium mordant (alizarin red), flame retardant impregnation, builder for laundering detergents.

III. Tertiary sodium phosphates → Trisodium phosphate.

Sodium polyacrylate → Polyacrylate sizes.

Sodium pyrophosphate, acid → Disodium hydrogen phosphate.

Sodium pyrosulphite $Na_2S_2O_5$; mol. wt. 190. White powder, water soluble. Has similar properties and application (although higher SO_2 content of 67.37%) to sodium hydrogen sulphite.

Sodium sesquiphosphate $Na_3H_3(PO_4)_2$. Known as a polyphosphate; changes on heating to a neutral mixture of alkaline mono-phosphates at 300–500°C. Application: as detergent and boiler de-scaling agent.

Sodium silicate (sodium salt of silicic acid, water glass). $Na_2SiO_3 \cdot Na_2Si_2O_5$; molecular weight 304. Solid mass, powder or clear, highly viscous solution (strongly alkaline) with 35–40°Bé (contains 27% SiO_2 together with 8% NaOH); store in air tight conditions. Application: Degumming of silk; caustic and keir boiling; stabiliser for peroxide bleaching; silk weighting; dyeing of alkali blue (wool); flame retardant impregnation; in printing; matting of viscose; soaping assistant; component in washing powder and liquid soaps; adhesives, etc.

Sodium stannate (preserving salt, tin soda). $Na_2SnO_3 \cdot 3\,H_2O$; molecular weight 267. Easily water soluble crystals, solution (hydrolysed) strongly alkaline. Used as a swelling agent e.g. for viscose filament yarn (by diffusion of salt solution into the fibre) and, by thermal decomposition for the stabilising and storage of stannic acid gels (similar effect and improved by a treatment with barium chloride solution with the formation of barium stannate), as matting pigments. Application: weighting of silk; flame retardant impregnation (textile finish); matting of viscose.

Sodium stearate (sodium salt of stearic acid). $C_{17}H_{35}COOH$ molecular weight 306.46. Saponified stearic acid. White flakes; soluble in water and alcohol. Application: manufacture of household soaps and tallow soaps, finish component, etc.

Sodium sulphate (Glaubers salt, sodium salt of sulphuric acid, sulphate). $Na_2S_2O_4$ molecular weight 142; density 1.46.

I. Anhydrous, known as “Duisburger sodium sulphate”, white powder, iron free and 99.5–99.8% pure, water soluble with gentle heating.

II. Crystalline, colourless crystals of high purity, easily efflorescent, water soluble with temperature lowering. Application: Salt in the dyehouse (neutral baths: like sodium chloride for salting out dyestuffs, increases dyestuff rate of exhaustion; acid baths: reducing acidity, slows the rate of exhaustion of dyestuffs); in standing baths for increasing the salt content and raising the boiling point; component in many powder-form dyestuffs (diluent); additive in weighting formulations, etc.

Sodium sulphide (sulphuretted sodium). $Na_2S \cdot 9\,H_2O$; molecular weight 240. Fused mass or crystals (ratio 1 : 2), colourless (also weakly yellow), smell of hydrogen sulphide, hygroscopic, water soluble with alkaline reaction; gradually decomposes in the presence of air; reducing agent. Application: dissolving and dyeing with sulphur and vat-sulphur dyestuffs; de-hairing agent (tanning), etc.

Sodium sulphite (sodium salt of sulphurous acid). $Na_2SO_3 \cdot 7\,H_2O$; molecular weight 252. White crystalline powder, ca 25% SO_2, easily efflorescent (with oxidation to sodium sulphate), water soluble, weakly alkaline solution. Application: antichlor; reducing agent (printing); preservative; corrosion inhibitor in process water (binds acids), etc.

Sodium tetraphosphate $Na_6P_4O_{13}$. Anhydrous sodium tetraphosphate contains ca. 60.4% P_2O_5 and 36% Na_2O, is hygroscopic and reacts weakly alkaline. In contrast tripolyphosphate will bind more calcium ions. Used as builder for paste/highly viscous synthetic detergents.

Sodium tripolyphosphate (TPP, triphosphate, tripolyphosphate, sodium polyphosphate). $Na_5P_3O_{10}$; washing powder additive. Application: chelating agent for water softening; feed-water preparation; hot water supply systems; laundering; milling; after-rinsing, etc.

Sodium tungstate (sodium salt of wolframic acid), $Na_2WO_4 \cdot 2\,H_2O$); molecular weight 330; density 3.25. Colourless crystals, water soluble. Application: flame retardant and water repellent finishes.

Sodium Xylenesulphonate $C_6H_3(CH_3)_2SO_3Na$. Highly effective hydrotropic agent for fat free soaps, scouring agents, washing powders and similar.

Soft dyeing technique Term used for gentle handling of fabrics in the dyeing process with overflow or jet dyeing machines having controlled liquor flow.

Softener formulations Textile softeners are used to vary the handle of fabrics (similar to filling, stiffening and weighting finishes). They should demonstrate a positive effect on the handle of treated textiles; many textiles require softer, smoother, supple handle for the best sales potential. They may also serve to improve the processability and wear characteristics of the textiles.

Most textile processes, according to their intensity, *the influence of handle modifiers*

- textile characteristics:
  handle, volume, softness, fall, odour
- mechanical properties:
  stretch, elasticity, abrasion resistance, tensile strength, tear strength, smoothness, pilling tendency, sewability
- functional properties:
  moisture management (hydrophilic / hydrophobic), antistatic, flame retardant, dirt resistant, sewability, rope crease prevention, antimicrobial
- aesthetic properties:
  colour nuance, fastness, permanence, whiteness, thermal migration

influencing factors specific to production

- environmental acceptability (manufacture and use):
  biological breakdown, toxicity, irritant potential, corrosiveness, bath exhaustion, transport
- resistant to:
  storage restrictions electrolytes, water hardners, acids, alkalis, jet suitability (foam, shear forces), storage stability (heat, frost), drying and fixation processes
- handling:
  viscosity (suitable for metering), concentrate, stock emulsion, solubility
- compatibility:
  bleach liquor, dye liquor, reductive post-cleaning, optical brighteners, synthetic resins, catalysts, chemical finishes

Tab.: Requirements profile for textile softeners.

will more or less lead to the removal of oils and the enbrittlement of textiles. The softeners must replace this natural softness and suppleness. Often, a softener must also reduce the tendency of textiles to build electrostatic charges. A wide variety of chemical compounds of differing constitutions are used for formulating textile softeners. They often contain a hydrophobic molecular component. The hydrophobic part is usually an alkyl chain of 16–18 carbon atoms length if it is to contribute a softening effect. The varied application possibilities for softeners is further complicated by the variety of subjective assessments possible with so many different chemical types. The requirements profile for softeners establishes another set of criteria (see Tab.).

Handle modification may be considered according to the following usage criteria:

- functional softeners where the use above all is based on the correction of unwanted side effects of formaldehyde based cross linking finishes;
- process aids to improve the ease of make-up of knitted goods (especially for avoiding needle damage in high speed industrial sewing);
- handle modification to correct harsh handle effects, establishing a handle effect in the sense of a full, smooth and voluminous handle goods.

The following generalisations apply without regard to fibre types:

- the hydrophobic group should be as linear as possible, not branched.
- the number of C atoms in the hydrophobic chain component should ideally lie between 16 and 18.

Each substance has specific properties that are dependent on the ionic group. Substances with the same ionic character have varied properties entirely dependent on the type of hydrophobic group they are attached to. There are substances that give the best smoothing effects and substances that give the best softening effects. It is possible to differentiate between these products by determining their corresponding static and dynamic friction characteristics.

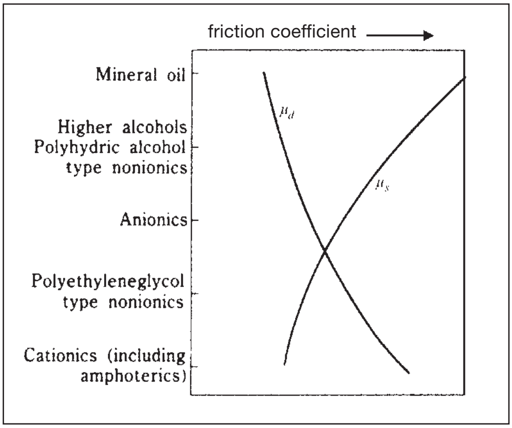


Fig.: The influence of the hydrophilic group on the reduction of the coefficients of friction.
μ_d =dynamic coefficient of friction, μ_s = static coefficient of friction.

It can be seen in the Fig. that mineral oil and a higher alcohol are good lubricating agents on account of their specific friction values but are poor softeners. In contrast, cationic softeners have low static and high dynamic friction values.

I. Non-ionic products have been widely used as textile softeners over many years. They form products that are typical for the ionic character but cannot however form salts. In the case of non-ionic bodies, a fatty chain of high molecular weight provides the softening effect, solubility is provided by condensation with a ethylene oxide chain. In comparison to anionic and cationic softeners, as a group they show the best resistance to heavy metal- and alkaline earth-salts.

The length of the ethylene oxide chain is variable; it determines the solubility as well as playing a part in the softening effects. A higher ethylene oxide content gives a lower softener effect. To produce non-ionic softeners a saturated compound is used with a carbon chain length between 16 and 18.

To produce softeners on this basis:

a) Condensation of a fatty acid with ethylene oxide. This produces a fatty acid polyglycol ester with the following formula (R = hydrophobic tail):

$$R–COO–(CH_2–CH_2–O)_n–CH_2–CH_2–OH$$

They give textiles a soft silk-like, scroopy handle.

b) Compounds that are made from fatty acid amines and amides that give, in comparison to the previous fatty acid polyglycol esters a distinctively softer handle. They have the general formula of:

$$R–NH–(CH_2–CH_2–O)_n–CH_2–CH_2–OH$$

alkylamine polyglycol ether

or

$$R–CONH–(CH_2–CH_2–O)_n–CH_2–CH_2–OH$$

fatty acid polyglycol ether

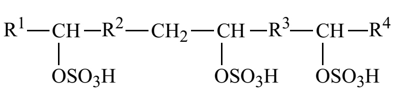
c) Between these 2 types are found, in softening effect, the condensation products of fatty alcohols with ethylene oxide. They have the general formula:

$$R–CH_2O–(CH_2–CH_2–O)_n–CH_2–CH_2–OH$$

Non-ionic softeners find application on all fibre types (both natural and synthetic). They may be combined with anionic and cationic products and can, with pale shades that do not require after-soaping or rinsing, be added directly into dyebaths. Without substantivity, they are principally used for working in short liquors, for padding or standing baths. Softeners on a non-ionic basis have an advantage in their universal applicability but have the disadvantage in their lesser softener effects in comparison to anionic and cationic products.

II. Anionic softeners are composed of a high molecular weight fatty chain with their notable solubility conferred by $–COONa$, $–OSO_3Na$ and $–SO_3Na$ groups. The basis for many anionic softeners are soaps. Their general chemical constitution is $R–COONa$, whereby R is an alkyl chain with 16 to 18 carbon atoms.

One possibility for the manufacture of such softeners is in the treatment of oils, fats or fatty acids with strong sulphuric acid or chlor-sulphonic acid. Important for the quality of such products is the degree of sulphonation. Higher levels of sulphonation lead to improved chemical stability although the softening effect may be somewhat reduced. They have the following general formula:



$$R^1-\underset{\substack{|\\ OSO_3H}}{CH}-R^2-CH_2-\underset{\substack{|\\ OSO_3H}}{CH}-R^3-\underset{\substack{|\\ OSO_3H}}{CH}-R^4$$

By suitable blocking of the carboxyl group of fatty acids it is possible to produce the so-called → Fatty acid condensation products, which find common usage in textile finishing as effective softeners. The masking of these groups is made by condensation with amino- group containing and also by condensation with oxygen group containing alkyl sulphonic acids. These are known by the general formula (where R^1 = higher molecular weight fatty acid residues; R^2 = alkyl sulphuric acid):

$$R^1–COO–R^2 \qquad R^1–CONH–R^2$$

Fatty alcohol sulphonates are further used by blocking the carboxyl group or completely replacing it. In this way, carboxyl-free softeners are produced as higher sulphated fatty alcohols.

These are represented by the general formula (R = high molecular weight fatty residues):

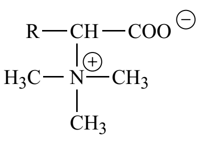
$$R–CH_2O–OSO_3Na$$

Whilst these substances are not substantive, they must be exhausted onto the fibres.

III. Cationic softeners form the major part of the total market for textile softeners. They rely on the typical high molecular weight fatty chain for their softening effects but their solubilising group is not based on sulpho- or sulphate groups, instead a quarternary group is used to form a soluble salt. They obtain their capillary activity from the cation and the positively charged cation is attracted to the fibre surface, so that they are aligned with the fibre to give the best effects. Due to this additional electrostatic attraction cationic softeners have clear advantages over anionic softeners and can give wash durable effects. Similar to all softeners, the chain length of the hydrophobic tail plays an important role. The special character of the → Quarternary ammonium compounds give them a dominant position in the range of textile softeners based upon good water solubility, high adsorption on the fibre surface, anti-microbial effect, good smoothing effects.

Cationic softeners are mainly produced by replacing the long chain fatty acid with → Polyamines or ethanol amines (→ Fatty acid ethanolamides).

IV. Amphoteric softeners: Quarternary ammonium salts, based on derivatives of betaines are, under certain conditions, good softeners. If they have a suitable fatty chain next to a basic or acidic group then they may be used as textile softeners. Products with amphoteric character have the following general structure:



$$\begin{array}{ccccc} & R- & CH & -COO^{\ominus} & \\ & & | & & \\ H_3C- & & \overset{\oplus}{N} & -CH_3 & \\ & & | & & \\ & & CH_3 & & \end{array}$$

V. Softener dispersions are differentiated from the foregoing surface treatment products in not containing hydrophilic groups to provide water solubility, instead they are combined with a suitable → Emulsifying agent to bring them to a form that allows their use in finishing liquors. The starting point for softener emulsions a usually →: Waxes; Paraffins; Fatty acids or other fatty chain groups and also silicones. Similarly polyethylene waxes can be used in emulsion form.

A special product group in the softener dispersions are silicone emulsions, usually high molecular weight α, ϖ-dimethyl-polysiloxane (→: Silicone in finishing; Silicone softeners). Both primary and secondary silicone emulsions are identified. With these emulsions are very soft, smooth, silk-like handle is achieved, also known sometimes as the silicone handle.

Softeners Used to increase the suppleness and to achieve a certain character in fabric handle by an end finish applied to yarn, wovens, knit-goods, etc. also as additives in sizing and finishing liquors, etc. Products used are normally surface active substances, mostly cationic, or preparations based on oils and fats.

Softening of textiles (avivage, softening, lubricating), sales directed, working practice of softening bleached and dyed goods to confer an advantageous handle and possible lustre. Hank yarns have an improved value in the ease of unwinding. In silk dyeing it is the term used for treating dyed goods by a warm bath containing organic acid (acetic, formic or lactic). It is used during bleaching or as an after- or end-treatment, in finishing during dipping, impregnating or nipping between rollers or through spraying on a spraying machine.

1. softening = softness of handle stressed
2. firm or hard handle = lubrication without softening of handle
3. handle finish = → Silk scroop

Softening in this context is most important for fibres and yarns that will be used in needling processes, e.g. non-wovens, tufted carpets and sewing threads. For the spinning of synthetic continuous filament yarns, the control of the applied amount of lubricant is a prime process criteria.

Softening of water → Water softening processes.

Softening range The temperature range for synthetic fibres (according to each fibre type) that lies between becoming thermoplastic and the true melting point. It is not identical to the → Transformation temperature but lies somewhat above.

Soft fibres Term for → Bast fibres in contrast to → Hard fibres.

Softflow rope dyeing machines Fabrics with a sensitive surface character that may be subject to creasing or surface roughening during the dyeing process are dyed on machines using the oveflow principle in soft flow dyeing machines (see Fig. 1). Here the goods are not moved through a jet pipe but fall onto a smooth plate or are twice overflow-treated (Fig. 2).

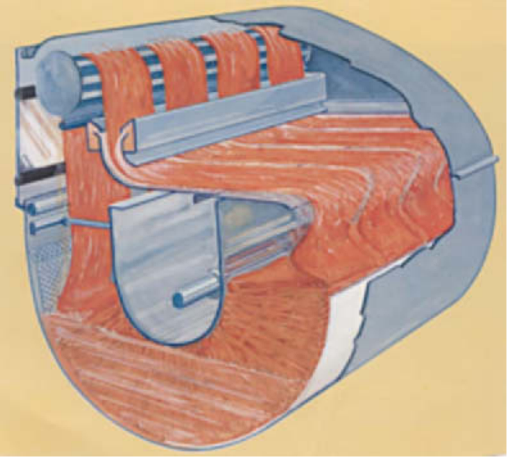


Fig. 1: The principle of a softflow rope dyeing machine.

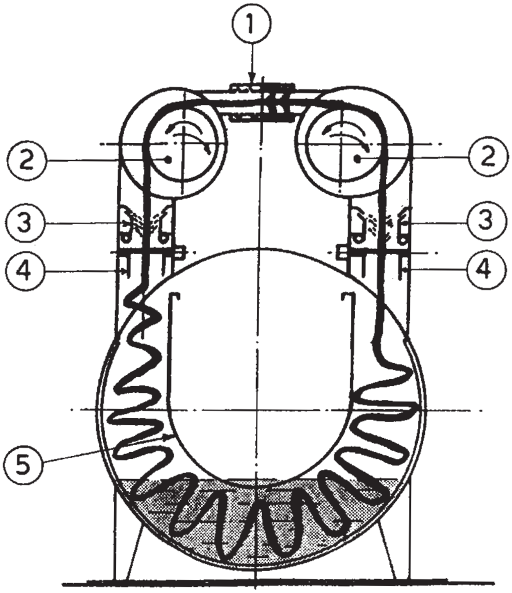

Fig. 2: Counter-flow piece rope dyeing (Caber Toboga). 1 = jet; 2 = dragging reel; 3 = flow and counter-flow; 4 = plaiter; 5 = container.

Soft handle treatment The final required handle for textiles is also linked to ease of processing and enhanced ease of use. A soft, smooth and supple fabric handle is a market demand for many textiles. Fibres of all types go through many different process stages and will lose the greater part of any contained fats, oils and preparations on the way. Fabric handle modification is

physical/chemical properties
- – solubility in water
- – vapour pressure curve
- – distribution coefficient (oil/water)
- – hydrolysis
- – viscosity
- – density
- – metabolites formation

effects on biological systems
- – algal growth
- – fish toxicity
- – reproduction
- – fertiliser effects

breakdown and accumulation
- – screening tests for biological breakdown
- – extended tests for biological breakdown
- – sewage sludge
- – soil
- – fish tests

effects on health

a) short term toxicology
- – acute toxicity
- – aquatic toxicity
- – skin irritation, eye irritation
- – skin sensitization
- – sub-chronic toxicity
- – teratogenic properties

b) long term toxicology
- – carcinogenic properties
- – chronic toxicity among many others

Tab. 1: Environmental perspective on the relevant factors in the evaluation of soft handle agents.

usually from an additional process and should also contribute to avoiding any tendency to build electrostatic charges.

An environmental requirements profile for → Softeners can be seen in Tab. 1. Starting materials for classical fabric softeners include natural oils and fats that can be chemically modified. Selected silicones used as softeners in microemulsion form are considered to be “supersofteners”. The following technical application factors are used to differentiate between the effects of different softeners (Tab. 2);

a) Ionic charge: increasing effect from non-ionic to anionic to cationic.

b) Nitrogen content: Fatty amine, fatty acid amine and quarternary ammonium compounds show that increasing softener effects come with increasing nitrogen content. Quaternary ammonium compounds, however, show problems linked to alkyl group substitution. There are risks from factors such as carcinogenicity, toxicity, mutagenicity, allergenic potential, irritant effects and explosion risk (see Tab. 1)

c) Chain length of the hydrophobic residues: Softeners often show a pronounced similarity to hydrophobic agents, especially cross linkable softeners. Hydrophilic softeners have no straight chain backbone and are not as critical.

d) Softeners in dispersion form: The nature of dispersions from fats, oils, waxes, paraffins, or polyethylenes are varied.

e) The application method: Softeners are applied by various methods and these have a large effect on the end results:
   - – add-on method (padding),
   - – spraying,
   - – exhaust methods.

	softness	smoothness	yellowing	low foaming	substantivity	hydrophilic
anionic sulphurated fats, oils, fatty acid condensates, containing sulphonated groups	–	+	+	–	–	+
non-ionogenic oxethylated products of fatty acids, fatty alcohols, fatty amines, fatty amides	–	–	(+)	–	(+)	+
cationic salts or quaternized compounds of tertiary amines, aminoesters, aminoamides	+	–	–	(+)	+	–
amphoteric betaines, amino oxide	+	–	–	–	+	+
dispersions of fats, oils, waxes, paraffins, polyethylenes, ailicones, polyurethanes	–	+	(–)	+	(+)	–

Tab. 2: Implementation concept for hydrophilic soft handle agents.

The assessment of softening effects can only be made according to subjective criteria by questioning experienced (in handle assessment) persons. A standard fabric (100% cotton – rotor spun yarn) is padded with a series of softening finishes. The test patterns are identified only by codes and assessed by a large sample of assessors. Each candidate uses a numbered pattern that meets the handle criterion. The samples are then sorted in comparison to this sample.

Softness index Calculated from the factors of surface smoothness or friction, yarn thickness and compressibility. Fabrics are tested as 1 cm. wide strips. Evaluation is based upon a 10 batch. The softness index indicates e.g. treatment with dist. water 1; with 0.5 gpl soap 1.10; after acidic bleach on cotton 1.36.

Softness number → Softness index.

Soft velours carpet Velvet like tufted floor covering based on fine denier yarns. Finishing is based on the use of combined shearing and polishing machinery.

Software System data and also application based service for electronic data processing. It includes the operating system, compiler, service programmes produced by computer manufacturers or specialist firms who control and service the → Hardware.

Soil Everything that must be removed from the goods e.g. pigment soiling, chalk deposits, fat and oil flecks from the loom, excess dyestuff from the dyeing process, over dyeing, diazotisation, from naphthol dyeing, from print thickeners and similar.

It may be differentiated:

I. water soluble organic and inorganic soiling:

a) sugar, syrup, starch, flour, urea;
b) organic acids, fruit acids;
c) proteins (blood and egg white);
d) inorganic salts.

II. water insoluble inorganic soiling:

a) cement, plaster dust, soot;
b) earth pigments such as clay and silicate.

III. water insoluble, non polar, organic soiling:

a) hydrocarbons (grease, asphalt, tar);
b) colour pigments and lacquers;
c) plant and animal fat.

IV. water insoluble, polar organic soiling:

a) fatty acids (perspiration);
b) polymers.

Soil adhesion Most fibres, under normal atmospheric conditions, have an electrochemical double layer built as a surface skin around the fibre that, because of its polarity, influences the soil adhesion potential of the fibre. There is thus a correlation between the → Zeta potential and the soiling behaviour of the fibres. Fibres without this surface zone have their → Soiling behaviour influenced by their polar molecular groups.

Soil burial enzyme test For the testing of substances e.g. textiles, and their biological degradation under rotting conditions (→ Soil burial test). The test is performed (according to Giesen-Wiese) as follows:

1. Pre-dried earth is prepared at 37°C to pH 8.0 with a phosphate buffer and 30% moisture content.
2. 0.5% by weight of an enzyme preparation cellulase activity is mixed in.
3. Non-woven samples are damped-off in buffer and laid sheet-wise in the earth-enzyme medium.
4. The samples are stored in a closed container at 28°C.
5. After removal, the samples are rinsed in cold water and then dried.
6. The effect of biological degradation on the samples by weight loss is assessed.
7. E.g. “Bio-inlay” (100% viscose fibres) shows a loss of weight of ca. 40% after 8 weeks burial.
8. A viscose content of 50% shows a loss of more than 50%.
9. A fully synthetic, binder-free inlay fleece in the same period of time will show a loss of less than 5%.

Soil burial method → Soil burial enzyme test.

Soil burial test (burial strength test, earth rotting test, → Soil burial enzyme test), testing of textiles for resistance by rotting by bacteria and fungi. Made by burying test samples in moist active earth mixtures (30% moisture; e.g. garden soil with 1/3 humus, rotted leaves and sand or earth, horse manure and sand), with pH and temperature suitable adjusted; after days or weeks the tensile strength is assessed. Comparison is made with a blind sample that has undergone similar treatment. A normal cotton fabric would be completely degraded after 5 days, whereas a cyanoethylated cotton (3.8% residual nitrogen content) would after 22 weeks show no signs of degradation. More exact methods, under laboratory conditions, involve using sterilised earth , inoculation with selected moulds and the burial of samples in closed containers under constant temperature and moisture. In the USA the estimation of fabric strength is made on a sample four times wider. In comparison to strip testing the comparable loading to break point gives higher strength values.

Soil hiding The soil hiding effect is based on fibre cross-section and decitex. Trilobal profile yarns with lower decitex show greater soil hiding effects than round cross-section fibres with higher decitex. Trilobal soil-hiding, hollow fibre types show weaker dyestuff yields, require more dyestuff for the same depth of shade than normal types. Reduced soiling effects are also possible through matting effects; e.g. the result of matting polyamide and polyacrylonitrile fibre is double the soil uptake in comparison to non-matted fibres with the same apparent degree of soiling. A high level of soiling is frequently due to incorrect choice of dyestuff.

Soiling → Soil adhering to textiles, most frequently caused by mechanical effects (fibre attraction) or electrostatic effects. →: Soiling behaviour; Anti-soiling finishes.

Soiling behaviour Soiling behaviour of textiles is extremely dependent on the type of fibre; → Soil release. No standardized tests exist for the soiling behaviour of carpets, because there are so many different types of soiling (dust, mud, lint of all types), and different colours and patterns. However, institutes use internal testing methods that permit absolute conclusions under specified conditions, and there is a method of testing stain soiling in Switzerland.

Soiling, staining,

I. Accumulation of → Soil, usually localized.

II. In mixed fibre dyeing, tainting of surrounding fibres by dye that is only intended for a specific area of fibre. The problem can frequently be alleviated by an intermediate reduction clear.

III. Unintentional dyeing of adjacent fibres (white or coloured) during wet finishing processes.

IV. Unintentional dyeing of white adjacent fibres during fastness tests. → Staining.

A polyester-wool mix can be used as an example of wool soiling in mixed fibre dyeing: Dispersion dyes colour the wool in the fibre mix by means of direct adsorption from the dye bath, or as a result of the dispersion dyes migrating from the polyester fibre onto the wool. This type of soiling can be restricted by using appropriate agents (resist agents). Alternatively it can be removed with an intermediate reduction clear, using reduction agents and/or surfactants. The following definitions apply:

1. For polyester fibre:
    a) Dispersion with non-ionogenic products: the quantity of dye adhering to the surface depends on the type of dye used, and is usually greater in the first dyeing phase. As the dye temperature increases, the quantity decreases and generally disappears after a boil period of 30 min, so that the polyester fibre has virtually no dye left adhering to its surface.
    b) Dissolving with acetone: the proportion of dye adhering to the surface is relatively smaller than the quantity of dispersible dye, and with this method it reaches almost zero during the course of the dyeing process.
2. For wool:
    a) Dispersion with non-ionogenic products: The observation of superficial dye presence is carried out in the same way as 1a), although the quantity will always be larger than on the polyester fibres. Depending on the dye used, this quantity will be at its highest when the temperature is between 60 and 80°C.
    b) Dissolving with acetone: although the influence of the dyeing sequence on the quantity of dye bonded to the surface is similar to 1b), the quantity of dye that is soluble in acetone is proportionally larger in comparison with the dispersible dye. This is an indication that the non-ionogenic products are not absolutely efficient.

Soiling test Wash or dry clean a test sample of a textile that has been artificially soiled, so that the level of optical brightening (→ Whiteness, degree of) achieved after washing or dry cleaning can be comparatively assessed. In principle, the soil test incorporates a combination of three soil types, such as carbon pigment, saponifiable fat, mineral oil (standard soil types).

Tab.: Limiting values of the Dutch soil pollution list.

Soil pollution (ground pollution). In 1983 the Netherlands passed an interim Contaminated Land Clean-Up Law threatening or requiring the necessity to clean up soil or ground pollution. This Law contained a requirement to identify the risks to health from contaminated land. The Law contained a "Contaminated Land Clean-up Instructions Manual" that set out the limiting concentrations, as well as administrative and practical requirements for cleaning up of contaminated land and water resources. Three aspects were addressed in the definition of the hazard assessment:

– type and concentration of hazardous material.
– the local contamination situation.
– the land use.

The points were not used singly but also considered was the scale of the hazardous material pollution and the possible impact of a clean-up operation defined, and if the clean up were possible and would not extend the scale of the problem or if a land use accepting the risks were possible.

Assessments were not to be made on the basis of any individual aspect but in consideration of all aspects. The working manual contained details of a large range of organic and inorganic hazardous substances with well-known effects on land and ground water. To give only the land values as an example, they were grouped in 3 concentration areas, A, B and C (see Tab.). Group A contains values that are typical for background land concentrations in the Netherlands. They are dependent on the land conditions and must be individually determined. Exceeding the limiting values of

Group A indicates a clean-up. Group B contains test values that, if exceeded, require an on-going investigation. A criterion applied here is the possibility of continuing risk to public health or the environment. If the limits of Group C are exceeded it is necessary to determine if a clean up can be carried out in the short term or should be evaluated with a view to being started. If a clean up is to be carried out it will not base solely on the limiting values but also on an evaluation of the use of the land in the context of the surrounding area. In Germany there are no regulations defining such limiting values for land. At the time of writing the Environment Ministry has not decided if it will apply a Regulatory or Land Protection Law approach. (according to Schollmeyer).

Soil redeposition Redepositing of removed dirt onto the goods during washing or dry-cleaning processes. Anti-soil redeposition: Counteracts the re-deposition of dirt during washing.

Soil release The property of dirt, especially oil-based, being more easily released from textiles during cleansing processes. Synthetics and resin finished synthetic/cellulosic mixtures are poor in this respect in comparison to natural fibres.

Soil release finish Application of finishing processes that are specifically designed to ensure more efficient laundering of soil and stains. Soil release products currently in use can be based on the following chemicals, for example: Silicium compounds, carboxymethylcellulose, ethoxylated compounds, polyglycol ester of terephthalic acid, acrylic acid polymers, and fluorochemicals. Frequently utilized in combination with resin finishing agents under the conditions specified for crosslinkers. Generally speaking there are no conditions of application specific to soil release finishing. The level of permanence of the soil release effects achieved is dependent on the product used. Good soil release effects are achieved through application of the → Dual action principle, using fluorochemicals that are oleophobic and hydrophilic. → Antisoiling finish.

Soil repellency Resistance to soiling as a finishing effect, which prevents soil penetration, or makes it difficult. Examples of soiling include dry soil (dust), wet soil (fruit juice, ink), oils and fats (engine oil and skin grease). → Anti-soiling finishes.

Soil repellent finish Alternative term for → Antisoiling finish. Prevents dry soil deposits on synthetic fibre textiles. Should not be confused with → Soil release finish.

Soil Resistance Merit Rating (SMR). Factor of soil resistance for carpets, taking into account the influence of colour. SMR indicates how high the soil concentration should be in a white test sample, so that the same apparent level of soiling as a specific colour can be achieved. The higher this value is, the greater the soil resistance of that colour. These values are defined on the basis of reflection measurements using a green filter (y value).

SMR examples:

white	1.0	mid-blue	33.0
light yellow	2.1	red	18.0
light grey	1.9	violet	17.0
mid-grey	9.5	olive green	21.0
beige	4.7	dark green	63.0
lemon yellow	3.6	dark brown	97.0
light green	4.4	coffee brown	190.0

Evaluation:

1.0–3.9	very bad
4.0–7.9	bad
8.0–15.9	fairly good
16.0–30.9	good
> 31.0	very good.

Soil-resistant Resistance against water-bound soil, fatty substances and pigment soiling.

Soil suspending property The extent to which a product is able to hold insoluble particles in → Suspension and/or prevent them from redepositing on the clean surface of the textile. Most synthetic washing agents have poorer soil suspending properties than soap; however non-ionogenic surfactants in particular (such as alkylphenolglycolether) can be far superior. The soil suspending properties can be improved by the addition of → Builders (soil suspenders).

Calculation of soil suspending property:

$$\%STV = \frac{\%WG_b - \%WG_w}{\%WG_0 - \%WG_w} \cdot 100$$

STV = soil suspending property,
WG = white content,
WG_0 = white content of white (unwashed) test textile,
WG_w = white content after washing in soil liquor without wash-active substance (water value),
WG_b = with wash-active substance.

Sol Colloidal substance in solution, such as glue in water. In this instance, it can be termed a hydrosol, because it is a water-based “solution”.

Solar cell Semi-conductor photoelement for converting radiated energy into electrical energy.

Solar collector Device for converting radiation from the sun into heat and conveying it to a heat transfer medium.

Solar radiation and materials Outside the Earth’s atmosphere, solar radiation shows a continuous spectrum in a wavelength range of approx. 0.5–3500 nm. A range of 280–3000 nm eventually reaches the Earth’s surface because of absorption processes in the atmosphere (oxygen, ozone, carbon dioxide, water vapour, etc.). The radiation strength of global radiation (= direct and dispersed radiation) and its spectral distribution are determined by the geographical extent and the daily/seasonal position of the sun. The radiation strength and wavelength limit of UV radiation are determined by ozone levels in the stratosphere, which are also subject to seasonal and geographical variations. A certain amount (quantum) of the energy present in sunlight can be absorbed by molecules. The energy level of absorbed radiation is dependent on the wavelength. Absorption in the short wave UV range is higher than for longer wavelengths or in the visible spectrum, but even at 500 nm it is 239 kJ/mol. Both the corpuscular theory (light is described as particles) and the quantum theory (light is described as energy in the form of waves) can be applied to sunlight.

Energy absorption from light alters the electron structure of the affected molecule, which in turn affects its readiness to participate in chemical reactions. This means that conditions are very different in comparison with the molecules in their basic state. The fact that chemical conversions are usually only on a small scale can be explained by the fact that the high energy level of individual molecules is only concentrated for a very short period. In other words, the energy absorbed is discharged again rapidly, and the molecule returns to its basic state (see Fig.).

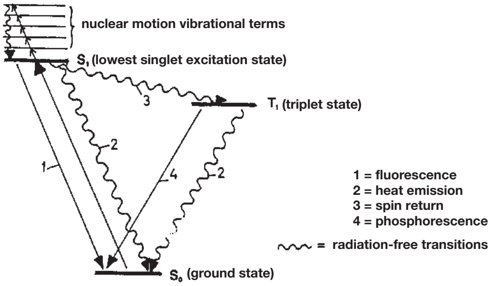

Fig.: Molecular excitation and intramolecular deactivation (BASF).

When a molecule absorbs energy, it transforms from a singlet ground state S_0 to a vibrational term of the agitated singlet state S_1. Even higher energy states cannot be achieved by the wavelengths discussed here, or they undergo "inner conversion" within an incredibly short time (10^{-12} s) and revert to the lowest level of the S_1 state without radiation. Deactivation of the S_1 state can occur in various different ways: it can occur intramolecularly, as a result of energy transfer to adjacent molecules, or by means of chemical conversion with other substances. There are three different possibilities for intramolecular deactivation:

1. Light emission, fluorescence (transition 1): this effect can be utilized beneficially, for instance with optical brighteners. When this happens, the basic state S_0 is reached in the nanosecond range (10^{-8}–10^{-9}), which means that the lifespan of an agitated S_1 state is approx. 1000 times longer than that of the high-energy S_1 level.
2. Deactivation by means of radiation-free transition to the basic state with heat emission (transition 2): the lifespan of the lowest singlet agitated state in this case is significantly shorter than one nanosecond.
3. Radiation-free deactivation by means of spin reversal, i.e. by means of conversion to the triplet state T_1 (transition 3): the energy level of this condition is lower than that of the S_1 state; however its lifespan, in the millisecond range up to approx. 100 s, is many thousand times longer than that of the S_1 state. For this reason it is particularly important for further chemical conversions, even when concentration of the partners is low.

The T_1 state can transform back to the basic state S_0 in the presence of radiation (transition 4). This type of radiation is known as phosphorescence. Subsequent deactivation can also occur without radiation (transition 2). However, intramolecular deactivation is not the only possibility for S_1 and T_1 states, they can also be deactivated by means of processes involving other molecules. The most significant of these processes is energy transfer to other molecules in the same environment (acceptors). This energy transfer can occur without radiation, or with light emission from the first molecule, with subsequent absorption by the second. This can occur as singlet-singlet transition and triplet-triplet transition. This type of energy transfer is the basis of all photosensitized processes. Example of energy transfer (D = dye; A = molecule in the environment [acceptor])

singlet-singlet transition:
$D^* (S_1) + A (S_0) \rightarrow D (S_0) + A^* (S_1)$

triplet-triplet transition:
$D^* (T_1) + A (S_0) \rightarrow D (S_0) + A^* (T_1)$

Measurement of the radiation of the sun at outdoor exposure stations is usually carried out using a pyranometer. The measured values are stated in Langley units (1 ly = 4.19 J/cm^2). Pyranometers record all the radiation from the sun that reaches the Earth, consisting of direct solar radiation and diffused radiation from the sky (wave range approx. 300–3000 nm). In test reports it is the recorded dose of radiation that is stated instead of (or as well as) the duration of exposure, when establishing the cause of a particular property change in a fabric. Examples of these altered properties are colour change (visual or colorimetric definition), or percentage loss in breaking strength of a non-illuminated fabric. The relationship of the Langley units to the property changes of exposed materials is problematic with results from different test stations, or materials that have been illuminated at the same place but at different times of the year. Comparison of Langley data can lead to incorrect interpretations due to solar radiation conditions that vary seasonally and locally (according to Baumgarte and Wegerle).

Solid fats In particular they contain → Stearic acid and palmitic acid (palm nut oil, pig lard, beef tallow, etc.). Beef tallow in particular produces very hard, solid (tallow) soaps with good cleaning properties but less foaming. These soap products are particularly effective at temperatures of 80–90°C. Tallow soaps can also be used for proofing.

Solidify → Freezing point.

Solids content Dry substance content (in g) per kg of thickener, e.g. locust bean flour 20–25, locust bean flour derivatives 20–250, guar derivatives 40–250, starch ether 100–400, carboxymethyl cellulose 40–200, hydroxymethyl cellulose 15–40, crystal gum 250–330, carragheenates 50–100, polysaccharides 40–200, alginates 30–120, tragacanth 65–80, starch 80–100, polyvinyl products 100–200, polyacrylic products 200–250, British gum 500. For less noticeable stiffening (thickening of pad liquors for pad dyeing), a low solids content is preferable – the most suitable for this purpose are alginate, locust bean flour and tragacanth. Thickeners can have a high or low solids content.

Solubilising power Ability of dissolved → Surface-active compounds and compounds that are heavier than water or insoluble to behave organotropically, i.e. to appear soluble. → Solubilization.

Solubility Can be achieved in a water-based medium with hydrophilic groups; in a non-polarized solvent it is the hydrophobic part of the molecule or ion that is responsible for solubility. The solubility depends on the size of the groups in question. As a basic principle it can be said that similar substances will form a solution (Liebig).

Solubility of size films The solubility of sizing agents in water is a flexible term. A product that takes 20 hours or a week to dissolve must still be classified as water-soluble. Because of the water solubility, the dresser assumes that the size will wash out easily. The person responsible for pretreatment has to prove that the opposite is true under certain circumstances. In sizing, there could be anything from starch that will wash out easily, to starches that are decomposed by enzymes or by means of oxidation. In addition to this, some of the modified starches, of which the chemical compositions are rarely known, can for instance become as soluble as pure potato starch if overdried. For this reason it is usually recommended for a commission textile finisher to desize using enzymes or by means of oxidation in cases of uncertainty.

Fully synthetic sizes include polyacrylate and polyvinyl alcohol sizes, which can be used on cellulose fibres as well as warps made totally of synthetic fibre, and “polyester sizes”, which are usually used on polyester filament warps. There is also CMC size (carboxymethyl cellulose), which is semi-synthetic and is usually used in conjunction with a fully synthetic size. Synthetic sizes have considerable advantages for the weaver, and similarly there are advantages in pretreatment. Although the sizes are based on water-soluble polyvinyl alcohols and acrylates, in practice one wash is not sufficient to remove the sizes. There are three major reasons for this:

1. As well as any sizes that are easily soluble in water, there can be additional sizing fats and waxes (in the size recipe formulation and/or developing subsequently on the warp). This slows the solubility because water penetration is reduced.
2. The sized warp can sometimes be overdried, which is also linked with water penetration worsening.
3. Synthetic sizes may have been combined with modified starches with poor solubility or no solubility at all.

In addition to these reasons, water-soluble sizes behave like thickeners with a low solids content; in other words their solutions still have a considerable level of viscosity even in low concentrations. If size is mixed with water, it does not become a solution immediately but goes through a gel phase first. Sizes will only dissolve if enough water is available, and enough time is allowed for diffusion. If the allocated time within the wash period is too short, it is recommended that the fabric is desized after the impregnation-dwell process. Double impregnation is also advantageous. This ensures that enough liquor is always available for the diffusion and swelling processes of fibre/size. Apart from the level of water solubility, synthetic sizing agents have the following distinguishing characteristics:

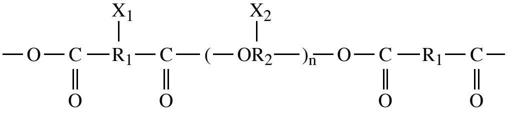
a) Acrylate sizes for staple fibre warps have ionic characteristics, and as salts they form true solutions of low viscosity. For this reason they are easily and rapidly soluble, i.e. washable.
b) Carboxymethyl cellulose sizes act in the same way as thickeners, and because of this they can also be used as wallpaper paste. A large amount of water is required for them to form a solution, and a specific thickening time. They are not acid/alkali sensitive.
c) Polyvinyl alcohol sizes form solutions that disperse colloids and have a higher viscosity than acrylate sizes. In contrast to acrylates they are precipitated with alkali instead of acid.

Polyvinyl alcohol sizes can be decomposed and removed in an alkaline medium, by means of oxidizing agents such as persulphate or peroxide. The oxidizing agent causes the macromolecules of the size to split into smaller units so that they can be washed off.

To summarize, for the successful desizing of synthetic sizing agents the following rules apply:

- fast wetting, liquor absorption > 80%;
- sufficient thickening time;
- sufficient water availability during the washing process;
- no alkali presence with polyvinyl alcohol, or if so, only in combination with oxidation agents;
- for acrylate sizes no acid must be present (pH not below 5.5).

Sizes based on polyester condensation products: polyester condensation products are usually present in the form of sodium salt. For this reason they are less suitable for warp sizing on water jet weaving machines (see Fig.).

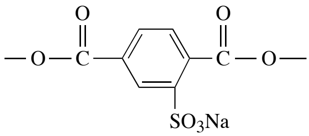


$$-\mathrm{O}-\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}-\overset{\substack{\mathrm{X}_1\\ |}}{\mathrm{R}_1}-\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}-(-\overset{\substack{\mathrm{X}_2\\ |}}{\mathrm{OR}_2}-)_n-\mathrm{O}-\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}-\mathrm{R}_1-\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}-$$

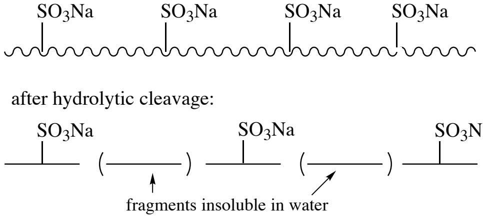
R_1 = aromatic, cycloalipathic and aliphatic hydrocarbon residuum with 2–6 C atoms
R_2 = C_2H_4 (n = 2–10), C_3H_6 (n = 1 or 2), CH_2–cycloalkyl–CH_2
X_1 = SO_3, $OC_3H_6SO_3$, $CO_2CH_2CH_2SO_3$ of aromatic R_1
X_2 = $CH_2O–(CH_2)_3SO_3$– of alipathic R_2, X_1 = H

Fig.: Polyester condensate.

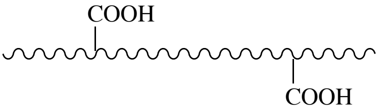
The structure of polyester condensate can be shown in a simplified form:



When these sizes are washed off, a pH of 9 must not be exceeded. If the concentration of alkali is too high, it will result in hydrolytic cleavage of the polyester condensation product, with the result that fragments without sulpho groups to trigger solubility will remain on the warp as insoluble residue.



Ammonium acrylates and ammonium methacrylate copolymers are present on the warp after drying as insoluble polyacids.



This type of size is well suited to water jet weaving machines. However, more alkali is required for washing off than with polyester condensates (according to Angstmann and Bassing).

Solubilization Ability of a water-based liquor containing surfactants to completely dissolve water-insoluble substances and organic solvents/water. This process can be explained by micelle formation of the surfactants (see Fig.) and their orientation towards the interface between the substance to be dissolved and the solvent. This is of practical significance in textile finishing and dry cleaning.

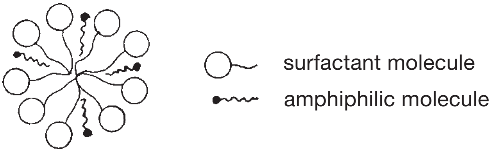


Fig.: Model illustrating the solubilization of amphiphilic substances through placement in the micelle, similar to surfactant molecules (according to Lange).

Solution (true solution), even distribution of one substance in another (by means of diffusion), or a → Phase consisting of several different particle types (components), that cannot immediately be converted into each other (from Pauling). The principal component of a solution is the solvent, and the other components are classified as the solute. Some of the best-known types of solution are the following:

I. Gas in gas (gaseous solution).

II. Gases or liquids in a liquid (liquid solution). Unlimited (e.g. water/alcohol) or limited (e.g. 7% ether).

III. Solid substances (salts) in liquids, with temperature dependency: at max. solubility (saturation) = saturated solution. The opposite is a non-saturated, dilute solution, with a low level of the dissolved substance.

IV. Solid substances in solid substances (e.g. metal alloys as a solid solution, or if crystal mixes occur as a crystalline solution; this category also includes polyester dyeing with dispersion dyes, or inter-penetrating polymer networks, for example).

Solution pressure (solution tension), the tendency of solid soluble substances to deliver ions or molecules into a liquid. Similar to so-called electrolytic solution tension, where every metal exhibits a greater or lesser tendency to discharge ions into water.

Solution process Substances such as surfactants, salts or dyes dissolve in liquids, without a chemical process, to form solutions. The solute particles impart specific properties to the solution, such as lowering vapour pressure or raising the boiling point in comparison with the solvent in its pure state.

1. Lowering of vapour pressure: Raoult's Law is the principle behind the lowering of vapour pressure, which is directly proportional to the mole fraction of the solute:

$$\Delta p = x_2 \cdot p_0$$

p_0 = vapour pressure of pure solvent,
x_2 = mole fraction of solute.

This equation is a limit rule applicable to dilute solutions, and it describes the process of vapour pressure lowering when substances are dissolved at a constant temperature. Since the vapour pressure curve of a solution will always run below the vapour pressure curve of the solvent, the boiling point should rise if the pressure is constant (see Fig.).

2. Raising of the boiling point: a substance dissolves under constant pressure, which causes the boiling point to be raised. Both of these physical properties are directly proportional to each other. The following equation applies for raising of the boiling point at constant pressure:

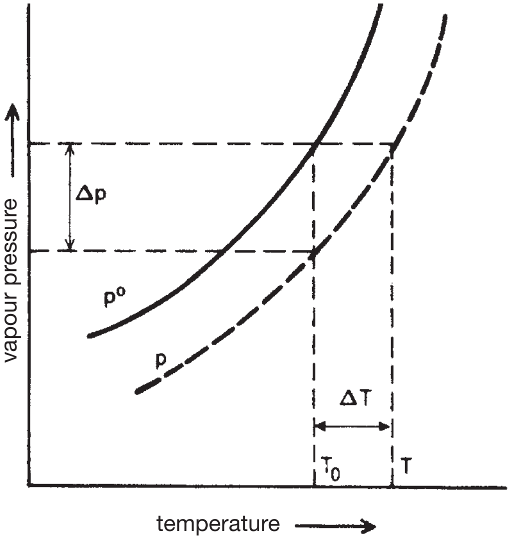

Fig.: The reduction of vapour pressure Δp and the elevation of the boiling point ΔT of a solution as shown in a diagram of pressure against temperature.
—— pure solvent, – – – solution.

$$\Delta T_s = E_s \cdot n$$

n = number of solute moles,
E_s = molar raising of boiling point.

Raoult's Law is equally applicable to the raising of the boiling point as it is to the lowering of steam pressure.

Solution wash processes Consisting of two phases:

Phase 1 (reaction-monitored): dissolving of the water-soluble substance.

Phase 2 (diffusion-monitored): removal of solution (liquor exchange).

On this basis, the solution wash processes are labelled by the following criteria:

- At the beginning of the wash process, the substance to be washed off is in a solute state in the textile.
- There are no chemical bonds or affinities between the substance to be washed off, the textile, and the wash liquor.
- The wash process is a diffusion process that tends towards a concentration equilibrium.

However, in practice these criteria are never fulfilled completely. One reason for this is that not all of the substances to be washed off are present in a solute state at the start of the wash process (example: when washing off after cold-dwell bleaching). The second reason is that chemical bonds exist between the textile and the chemicals, for instance in the case of caustic soda liquor, the most widely used chemical in textile finishing.

The basic equation for substance migration during the washing process is as follows:

$$G \approx \gamma \cdot (c_1 - c_2)$$

G = chemical exchange quantity per time unit,
γ = substance exchange value,
c_1 = alkali concentration in fabric,
c_2 = alkali concentration in wash liquor outside fabric.

The substance exchange value γ is defined as D/h, where D is the diffusion constant of the electrolyte to be washed off, and h is the diffusion path. From the above equation, conclusions can be drawn for washing machine design. The diffusion coefficient D is dependent on the chemical. The following proportionality applies:

$$D \approx \frac{T}{\eta_w}$$

T = absolute temperature of wash liquor
η_w = dynamic viscosity of wash water, which becomes significantly lower as the temperature increases.

Both influence factors result in an increase in the diffusion coefficients of approx. 400% in a temperature range of 20–100°C. It is therefore important to keep the temperature of the wash liquor in all wash compartments as high as possible, i.e. close to boiling point, as far as the substrate and/or the process permit. Since the diffusion path h is the denominator in the definition equation for the substance exchange value γ, the objective is to keep this path as small as possible, to ensure that a high substance exchange value is achieved. The diffusion path extends from the position in the chemical in individual cellulose fibres to the turbulent flow of the wash water surrounding or flowing through the fabric. External deposits on the fibres, close to the continuous flow channels, are easier to wash off than the substance inside the fibres, because the diffusion path is shorter. Therefore it is clear that the diffusion path does not remain constant throughout the wash process. Short diffusion paths can be achieved if the wash water flows through the fabric as perpendicular as possible to its surface. This consideration can be confirmed by the well-known, high-performance specific effects achieved by suction drum washing machines in which the water is sucked through the fabric. In washing machines where the roller fabric feed is over alternating rollers, there is a throughflow at each looped roller, if the wash water on the side of the fabric facing the roller is at least partially forced through the fabric by the wedge pressure between the fabric and the roller. On the rollers beneath the liquor, the water has to be forced through the fabric against the pressure of the water surrounding it. If the liquor trough in which the lower rollers are dipped, which is always the case in roller vat washing machines, is missing, there will be no back pressure, and fabric throughflow will be more efficient.

In order to achieve the best possible washing effect, the strongest concentration rate possible must be maintained between fabric and wash water, according to the equation stated previously. Since wash water economy is one of the most important requirements of a washing machine, maintaining a high concentration rate must not be at the expense of an increased water throughput. Instead the solubility and soil suspending properties of the wash water must be utilized more effectively, by bringing the same wash water into deliberate direct contact with the fabric many times. As the concentration difference at the end of a washing machine is nearly 0, it is only possible to wash off the water-soluble chemical fully after an infinite period of time (see Fig.)

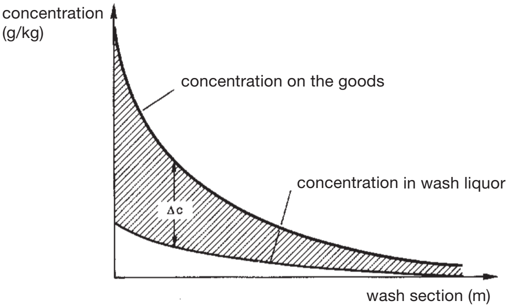

Fig.: The concentration profile within the wash section of a roller vat.

Concentration curves from a wash session can be drawn for the chemicals being washed off the fabric and the chemicals in the wash water for the duration of the wash in a roller vat washing machine. This shows that there is a considerable gap between the two curves at the point where the water enters the fabric (due to the counter-flow principle = discharge side of the wash water). This simply means that the dissolving and soil suspending properties of the wash water are not being utilized efficiently enough. The wash water clearly does not come into contact with the fabric being washed frequently enough or intensively enough. If the relatively large flow cross-section of the wash water in a roller vat washing machine is analysed, it becomes clear that at least some of the wash water flows straight through the machine without coming into close contact with the textile (according to Tischbein).

Solvation Term for the formation of dissolute additive compounds (solvates) between solute particles and any solvent (water, ammoniac, alcohol). Where water is present → Hydration.

Solvay soda Term relating to the extraction process used for manufacturing soda (sodium carbonate).

Solvent application of softeners → Softening of textiles in organic solvents during → Dry-cleaning or → Solvent milling.

Solvent bleaching Oxidation bleach with sodium chlorite in organic solvents. Peroxide bleaching of wool using tetrachloroethylene liquors was an example of an exhaustion process in → Solvent technology in textile finishing. Aqueous emulsions of H_2O_2 in tetrachloroethylene have 100% attraction to hydrophobic wool, which they bleach during the drying phase, continuing for 24 hours until bleaching is complete.

Solvent carbonizing In a process developed by Sperotto-Rimar for carbonizing fabric (Fig.), the woollen cloth is first treated with tetrachloroethylene, so that the water on the surface of the hydrophobic wool fibre is exchanged for tetrachloroethylene. Immediately after the solvent treatment, an aqueous sulphuric acid bath flows through the fabric. According to Sperotto-Rimar, the sulphuric acid/water mix should primarily be attracted to the hydrophilic burrs (it should be remembered that the burrs consist of approx. 60% cellulose and 40% lignin). After the burn phase in a heat recovery oven, there is often no neutralizing process, since woollen textiles only retain a low amount of residual acid in this system.

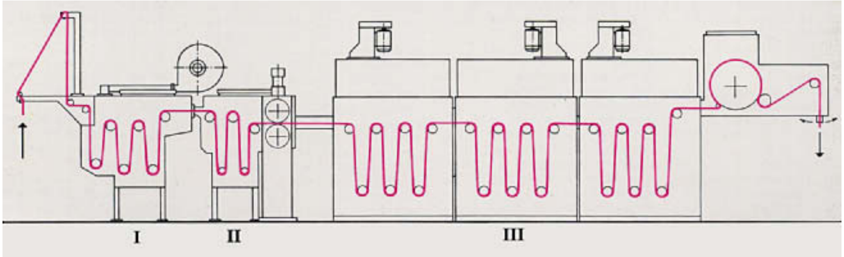

Fig.: A Sperotto-Rimar solvent carbonizer. I = loading with tetrachloroethylene; II = impregnation with dilute sulphuric acid; III = drying and burning of the wool fabric.

Solvent distillation can be carried out in large-scale plants (see Fig.). The solvent containing impurities is routed to the first distillation still. The rectifying power of the column above separates the solvent into low-liquor and distillate, which is condensed. The remaining exhaust vapours that do not condense have to be adsorbed. → Solvent recycling.

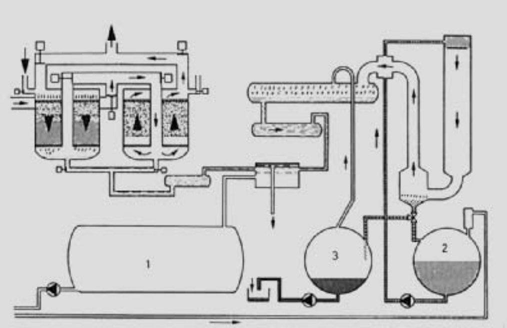

Fig.: A Brückner solvent recovery system (scaled for a distillation throughput of 2800 litres per hour).

Solvent dyeing This means dyeing without water, i.e. using solvents. This is only possible for light shades with no fastness, and is therefore of little significance.

Solvent dyeing (organic solvents) A process developed in the 1970s, which was designed to replace water as a dyeing medium with suitable solvents, because water was becoming more and more expensive and scarce. Solvent dyeing is only used in specialist dyeing areas as a complementary process for existing aqueous dyeing processes. Areas of application are:

I. Fully fashioned dyeing, where the process operates according to the principle of dry-cleaning.

II. Polyester dyeing, particularly the dyeing of high-tension polyester sewing thread.

Both of these process types are exclusively discontinuous processes, in which tetrachloroethylene (perchloroethylene) is used as the solvent. Process advantages: No fabric pre-cleaning is required; several finishing phases can be combined; the drying process is simplified. There are two different types of dyeing process:

1. Ionic dyeing process for polyamide and wool: water-soluble acidic dyes and special tetrachloroethylene-soluble acidic dyes are used for both fibre types. Since hardly any dyeing occurs without the addition of a "solvent aid", it is essential to add water, because otherwise no ionic bond will be able to form between the dye and the fibre.
2. Non-ionic dyeing process for polyester: in this process, the coloristic advantages and the process advantages stand out particularly in comparison with the aqueous process. Tetrachloroethylene, ethylene glycol, diethylene glycol and glycerine are all examples of a possible solvent medium.

Overall it can be concluded that this type of solvent dyeing has not become well established, because the appropriate dyes have not been developed, and the primary solvent, tetrachloroethylene, is associated with environmental problems.

Solvent dyeing processes → Solvent dyeing (organic solvents).

Solvent evaporation rates from wool Wool retains traces of water as well as tetrachloroethylene during the drying process. A woollen fabric was soaked with 20.8% water, and a parallel sample was soaked with 20.8% tetrachloroethylene. The samples were dried at 60°C in a slow air current. Tetrachloroethylene was expelled from the wool considerably more rapidly than water. The table depicts the rate of evaporation and the residual quantities of water/tetrachloroethylene in relation to wool:

	start	after 5 min	after 10 min
water	20.8%	9.3%	2.8%
tetrachloroethylene	20.8%	2.3%	0.9%

Solvent filtration in dry cleaning During dry cleaning operations, filtration is necessary for the continuous removal of suspended, insoluble and, where possible, even dissolved impurities from the contaminated solvent. Solvent clarification is mainly achieved through the use of filters with the addition of special filter aids, e.g. filter powder. This technology is far superior to former methods based on, e.g. separators, as far as the supply of clean solvent and rate of throughput is concerned.

Solvent flammability Flammable liquids that are used as solvents and have a boiling point of up to 150°C generally have a flash point below 55°C. According to German classification of flammable liquids, liquids that are not water-soluble and have a flash point between 21°C and 55°C belong to the hazard classification AII. Light heating oil, for example, falls into the hazard classification AIII. Where flammable liquids are used, it is assumed that the application temperature is not higher than the flash point for that liquid. For AII liquids, the application temperature must be well below the flash point. Because of this, these liquids are subject to much more stringent safety measures than liquids in hazard class AIII. The latter usually have a boiling point higher than 150°C, meaning that they are less volatile. This can be disadvantageous with regard to the drying temperature and distillation. However, they tend to be used in preference to the more volatile, flammable solvents. When assessing the explosion hazard, it was assumed in the past that it was sufficient to avoid an explosive atmosphere if the application temperature of a flammable liquid was at least 5 K below its flash point. That was based on the assumption that the flash point was identical to the lower explosion point. However, if the flammable liquid is distributed in a fine mist of droplets, for instance if the solvent is evaporated and condensed during recovery, this safety interval is no longer adequate. The reason is that the explosion point can only apply to the flammable substance in vapour form. For solvent mixes with no halogenized components, including benzine hydrocarbons, the explosion point is about 15 K below the flash point. The application temperature should not exceed the lower explosion point. On that basis, the maximum application temperature of a flammable solvent mix with a flash point of 55°C would be 40°C. This temperature would be too low for drying cleaned textiles. To raise the drying temperature, the fabric being cleaned would have to be dried in a protective atmosphere of inert gas, such as nitrogen or carbon. If distillation is carried out under atmospheric pressure, the flash point will certainly be exceeded. This will result in areas where there is an explosion hazard, in which more stringent safety regulations will be applicable. It is possible to reduce the boiling temperature of the flammable solvent by means of a vacuum. However the installation of a vacuum pump introduces mechanical moveable parts into the system, which should be avoided in an area where there is an explosion hazard.

Solvent health hazards The directive for use of dangerous substances (→ Legislation on environmental protection) is applicable for classifying solvents according to their level of influence as a health hazard. The following liquids are considered to be an extreme health hazard: benzene and its homologens where the boiling point is below 150°C (toluene, xylene), methanol, dioxan, organic halogen compounds (→ Chlorinated hydrocarbons) where the boiling point is below 200°C (e.g. carbon tetrachloride, symmetrical dichloroethane, di-, tri and tetrachloroethylene, chlorobenzene and chlorofluorocarbons) and carbon disulphide. The directive also provides information concerning limitations of use, and states that any solvents to which the directive applies must be clearly labelled in black writing with a black warning border on an orange background, with the following text:

CAUTION!
Hazardous vapours – do not inhale!
Observe safety regulations!

Solvent impregnation agents For → Solvent impregnation of certain specialist products that are soluble in hydrocarbons or chlorinated hydrocarbons. Base materials are particularly solid hydrocarbons, such as paraffin (oil), ceresin, synthetic wax, chlorinated rubber, organic metal compounds in the form of solute metallic soaps of higher fatty acids or metallic polyoxides, with solid hydrocarbons, waxes etc; synergetic copolymer-hydrocarbon compounds; silicon polymers; aluminium alcoholates.

Solvent impregnation (solvent waterproofing). Specialist technique for waterproofing in organic solvents (benzine, heavy benzine, tetrachloroethylene, etc.) with → Solvent impregnation agents. Important in dry-cleaning for re-impregnating garments after cleaning.

Solvent milling → Milling in solvents.

Solvent naphtha Specific purposes of these products are as solvents for lacquer manufacture, to dissolve resins, rubber, fat, dyes, etc. Boiling point ranges from approx. 140°C–200°C. Together with an emulsifier and an active substance, they are also a component of carriers.

Solvent recycling Requirement for working with tetrachloroethylene economically. In comparison with soft water, tetrachloroethylene is currently 700–2000 times more expensive. In addition to this, there are unintentional waste water costs, whereas the cost of solvent recovery for re-use is nowhere near as high as the cost of the tetrachloroethylene itself. For this reason, solvent technology can be economically efficient if recycling is used to its full potential, taking into account the following points:

a) Solvent distillation: principal method in continuous circulation, made easier by 2 significant facts: the low evaporation heat of tetrachloroethylene (at 220kJ/kg less than 10% of the heat of vaporisation of water) and a higher boiling point. Solute impurities in tetrachloroethylene remain in the still sump, and need to be separated easily as a concentrate.

b) Solvent volatilization: recycling method for fabric that has been wetted with tetrachloroethylene after cleaning, or application of tetrachloroethylene-based finishing chemicals. The fabric is dried in warm air, and the vaporized solvent is condensed at the same time in water-cooled heat exchangers. The low specific heat of the tetrachloroethylene (= 0.85 kJ/kg) in relation to water, and a low heat of vaporisation of the tetrachloroethylene provide favourable conditions for volatilization. In most plants, the clean, hot cooling water (40–65°C) generated during the distillation and drying processes is also recycled by utilizing it for specific purposes.

c) Solvent adsorption method: method of diverting the used tetrachloroethylene back into the circuit for reuse, which is also a necessary measure for environmental reasons. When the fabric is cooled and ventilated, ambient air is used to flush solvent gas residues out of the fabric (final phase). The air is then passed through an activated carbon filter, where the residual gases are transferred to the carbon. When the carbon becomes saturated, the solvent is driven out by water vapour and re- condensed.

Solvent retention Characteristic of solute substances, where they bond physically with components of the solvent when the boiling point is raised. As the solvent is extracted from the solution by vaporization, the remaining solution will gradually become more concentrated. The more concentrated the solution becomes, the more effective the solvent.

Solvents Main component of this type of → Solution. According to this definition, water acting as a solvent in an aqueous salt solution is considered to be a solvent, for example. However the popular definition of solvents is organic solvents. There are specific requirements for solvents used in textile finishing:

The principal chemical requirement is that a solvent is a relatively inert, stable liquid, which does not react with any of the (textile) substances with which it comes into contact. The physical requirements are much more differentiated. The solvent should have good solubilizing properties concerning fats and oils. Common commercial surfactants should be soluble in it. These surfactants should have sufficient dispersion stability for pigment soiling, so that there is no subsequent uptake of detached soil by the textile (known as soil suspending properties). In addition to this it should be possible to solubilize water as a solvent with these surfactants, so that the removal of water-soluble soil can be improved in this way. On the other hand, the solvent should not have such extreme solubilizing properties that fibres and synthetic substances swell or even dissolve in it. In order to ensure that the solvent can be recovered economically, it should be slightly volatile, and also colourless and as odourless as possible. The level of purity should be as high as possible, and the boiling range as narrow as possible. If solvents are flammable, a compromise must be reached with respect to the boiling temperature. The ideal physical properties are related to viscosity and density. The solvent should be fluid, and its density should be significantly above or below 1. The density is necessary so that the solvent can be easily separated from water after recovery because of the difference in mass.

From a physiological point of view, the important requirements are that the solvent is neither carcinogenic nor does it cause mutation, and if possible it should not resorb through the skin. The maximum concentration permitted in a workplace (TLV value), where there will be long-term effects on humans, should be 50 ppm – in other words 50 ml of solvent vapours in 1 m^3 of inhalable air.

Ecological requirements have now become so manifold that this list can only include a few of the main points. In Germany, any liquids that constitute a hazard to water are allocated to classes 0–3, where the class number denotes the level of hazard to water. The highest class number is the most hazardous. Solvents are classified according to acute toxicity for mammals, bacteria and fish. Since tetrachloroethylene falls into water hazard category 3, it would not fulfil the requirement. It is not only the atmospheric lifespan of the solvent that is crucial regarding degradability in the troposphere (the lowest layer of the atmosphere), it is also important to assess the breakdown products as to whether or not they constitute an environmental hazard. The only solvents with potential to decompose the ozone layer are compounds that contain chlorine and have a high level of atmospheric stability. Their chlorine atoms react with the ozone layer in the stratosphere. The greenhouse effect occurs due to the fact that the atmospheric layers nearest the Earth are gradually heating up and the higher layers are cooling down slowly because the reflection of radiated heat is obstructed. This effect has not been measured yet for most substances, apart from the anthropogenous substances carbon dioxide, methane, dinitrous oxide and fluorochlorocarbons. The breakdown products of these substances must also be considered. One ecological requirement that has become very relevant at the moment is the recycling potential of the used solvents from distillation residues. In general it is more economical to recycle solvents than to dispose of them by incineration.

Solvents and fibre swelling As an example, loose wool fibres, yarn or woven fabric can be immersed in distilled water, with parallel samples in tetrachloroethylene. After a short length of time, a swelling or adsorption equilibrium is reached. The standard centrifuge method is used at a speed of 3500 rpm. After 5 minutes the centrifugal weight (centrifugal swelling) is record-

	increase in cross-section in %	increase in length in %
viscose fibre	6–7	8–12
cotton	0	8.7
wool	3.5	6.1

Tab.: The dimensional changes to different fibre materials in tetrachloroethylene.

ed, which is then used to calculate the quantity of liquid in the fibres as a result of swelling or adsorption. The result for wool is that it adsorbs approx. 40% water, but only approx. 19% tetrachloroethylene. If the molecular weight of water and tetrachloroethylene is taken into account, it can be concluded that the adsorbed quantity of tetrachloroethylene, which has significantly larger molecules, is equivalent to only about 10% of the quantity for water. This small quantity of tetrachloroethylene has a slight swelling effect on wool, and the fibres only adsorb it superficially. The Tab. shows how certain fibres exhibit dimensional changes in tetrachloroethylene. Dimensional changes in tetrachloroethylene are significantly less than for water.

Solvent scour Washing off scrooping or solvent preparations (solvent finishing). In the treatment of polyester, it should be remembered that this type of fibre is capable of solvent sorption, which accelerates dye diffusion.

Solvent scour process for wool → Raw wool scouring using organic solvents, usually only to extract lanolin. Australian method: spray with benzine (white spirit), squeeze off, and then rinse with water jets. Swedish method: (Laval oil or petroleum scour) with petroleum fraction boiling at 170–270°C. The solvent is filtered after use, cleaned and recovered by means of distillation.

Solvent sizing Sizing of warp ends (widthwise) using organic solvents. It is carried out in a completely sealed pressure system in a suitably constructed solvent sizing machine. Polystyrene, for instance, is applied cold, can subsequently be removed from the fabric by means of tetrachloroethylene (desizing; extraction possible using ultrafiltration), and long-term experiments in the weaving industry have shown that this method is well suited to sizing.

The solvent sizing machine shown in the Fig. is a sealed-system machine with a partial vacuum (to prevent solvent vapours from escaping). Path of warp yarn, starting at the warping beam: a) air lock; b) sizing unit with an observation window running across the width of the machine, height-adjustable immersion roller, pneumatic squeezing units, liquor level control, low pressure/vacuum monitoring, solvent spray device for roller cleaning; c) drying chamber for hot-air drying at approx. 120°, 132–138° contact drying on 2 Teflon-coated drying cylinders, automatic pressure/temperature (atmosphere) in a deodorizing zone; d) drying zone and preparation unit for final scouring with wax or paraffin (2 heated troughs with water-cooled application rollers, freely-adjustable immersion depth and circumference speed), beaming machine, pre-selectable yarn tension control (yarn run-off, sizing, drying, dry dividing zone, winding). Solvent-saturated drying air circulates around water-cooled condensers, any other air is removed by suction using solvent recovery equipment (activated carbon filter), where it is blown out into the atmosphere after the solvent has been adsorbed (the proportion of solvent must be below the permitted TLV level of 30 ppm). This causes a partial vacuum, which prevents solvent vapours from escaping. Solvent regeneration is carried out using separate distillation equipment.

Solvent soaps → Fat-solubilising detergents. Incorrect expression for → Dry-cleaning detergent.

Solvent-soluble dyes Analogous to → Oil-and-fat soluble dyes.

Solvents – thermal decomposition At the following temperatures, solvents are liable to thermal decomposition:

tetrachloroethylene	150°C
trichloroethylene	120°C
1,1,1 trichloroethylene	160°C
CFC 113, CFC 11	150°C

Solvent technology in textile finishing,

I. Addition processes: finish with solvent-soluble organic products, usually for final finishing of dyed or printed fabric, e.g. discontinuous solvent methods:

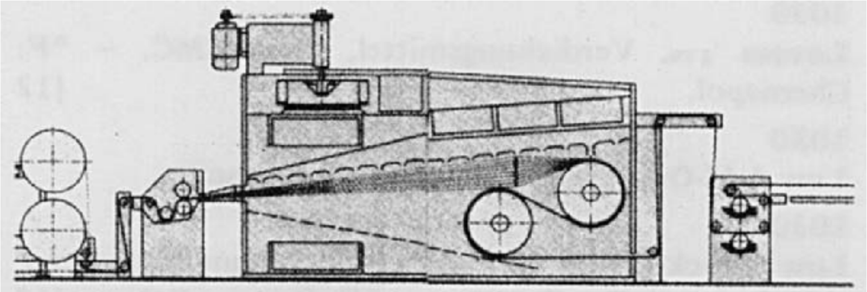

Fig.: Solvent sizing machine

- improved handle resulting from the use of softeners in machine-knitted goods;
- antifelt finishing of woollen knitted fabric with silicon elastomers.

Examples of continuous solvent methods with full-width treatment:

- anti-static finishing of synthetic knit and weave fabrics;
- finishing of pretreated synthetic print fabrics with wetting agents;
- application of optical brighteners;
- finishing with filling agents;
- hydrophobization both with silicon and oil-repellent products, and with metal salt/ wax formulations;
- finishing with silicon elastomers;
- solvent carbonizing.

II. Exhaust processes: adsorption of dispersed liquid phase on hydrophilic fabrics (wool, cotton), usually emulsified aqueous product solution in tetrachloroethylene, which has a quantitative fabric uptake if fabric movement is discontinuous, e.g. in solvent bleaching and solvent milling (= 5–30% water to dry wool weight).

III. Pigmenting processes: breakdown of insoluble product additives into pigments, using mechanical pressure, they are then removed mechanically, for instance by after-print cleaning (polyester, polyamide, triacetate weaves and knits). For fixed prints a high-pressure tetrachloroethylene liquor jet is applied, causing insoluble (acrylate) films (print thickeners and synthetic sizes) to be broken down into pigments, which, in an insoluble state, are washed off and flushed away as unfixed print dye residues. Operating speeds in solvent continuous technology are > 50m/min. The print thickeners or sizes accumulate with dye in the form of a thick solvent-free sludge, which is disposed of as hazardous waste.

IV. Subtractive processes: dissolving of solvent-soluble substances (oils, fats, waxes, preparations) and associated insoluble impurities (pigments). The residues subtracted from the fabric (texturizing, spinning and winding oils, preparations/non fixed dispersion dyes, etc.) that occur through distillation and are easy to dispose of, account for 8–10% of the fabric weight, which means large plants running at least several shifts per week.

V. Displacement processes: subtractive purification using mechanical displacement and emulsification of the liquid phase. First, swelling and dissolving of water-soluble products is triggered using minimal quantities of water on the fabric, then the aqueous solution is driven or emulsified off the fabric surface by means of intensive high-pressure tetrachloroethylene jets and the fact that tetrachloroethylene is not water-soluble. The solvent emulsion or mix is subsequently distilled, and the resulting concentrated residue is free of waste water.

Solvent usage in dry-cleaning A historical parallel can be drawn between the status of environmental legislation and the state of solvent technology in dry-cleaning (Fig. 1).

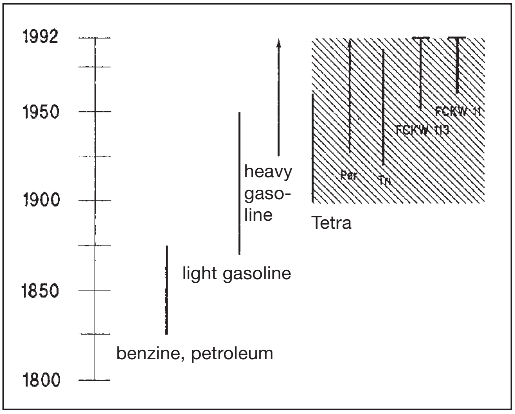

Fig. 1: The history of the usage of solvents in dry-cleaning. Tetra = carbon tetrachloride; Per = tetrachloroethylene; Tri = trichloroethylene; FCKW 113 = trifluorotrichloroethylene; FCKW 11 =trichlorofluoromethane.

During the exhaust and door-opening phases (Fig. 2) in dry-cleaning machinery, the exhaust, which contains tetrachloroethylene, used to be passed through a filter and out of the machine. The filter bound the tetrachloroethylene vapours by adsorption. If the filter capacity was exhausted, the solvent had to be recovered by means of activated carbon evaporation. After the filter had been air-dried, it was ready for use again. In addition to the positive aspect of exhaust cleaning and solvent recovery, daily use of activated carbon filters caused many different types of problems in the plant. Regeneration of activated carbon systems required input from employees in the evening, since the equipment was usually set up to cope with a daily capacity. There was also extra consumption of energy during the

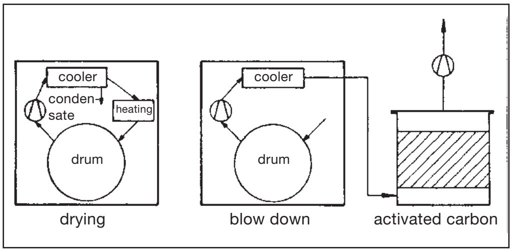

Fig. 2: The classical system with blow-down on dry-cleaning machines.

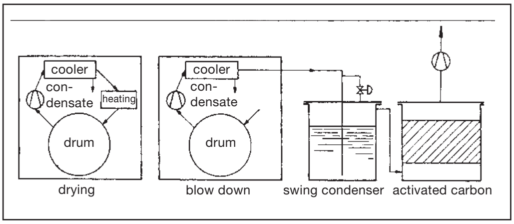

Fig. 3: The classical system with a swing condenser.

evaporation process, as well as censure by the industrial inspector if the equipment was overloaded or badly maintained.

In order to improve this situation, the back pressure condensation system was developed in the mid-1970s (Fig 3.). During the exhaust phase, the exhaust flowed against a standard hydraulic seal, which caused the solvent vapours to condense in the cooling machine rather than reach the filter. If the access door was opened, the seal was bypassed by means of a butterfly valve, and the exhaust was allowed to freely pass through until it reached the activated carbon. The advantage of this combination was that the adsorption capacity of the activated carbon was multiplied by a factor of 2 or 3, so that it only needed to be regenerated every second or third day, thereby saving energy, solvent and man hours. This was basically the first step towards sealed cleaning machines, which were launched on the market in the early 1980s (Fig. 4).

This type of machine did not discharge exhaust into the atmosphere. During the drying and exhaust phases, the air was routed through a closed circuit across a cooler with coolant throughflow, where the tetrachloroethylene vapours were condensed as far as possible. Even when the access door was opened, the exhaust-free characteristics of the machine were retained. It was during this phase that the weak point of the process became apparent. The tetrachloroethylene concentration in the drum was approx. 4000 ppm. At the edge of the drum, concentrations of up to 2000 ppm were measured. Since there was no removal of the solvent by suction to atmosphere, the escape of tetrachloroethylene vapours into the room could not be ruled out.

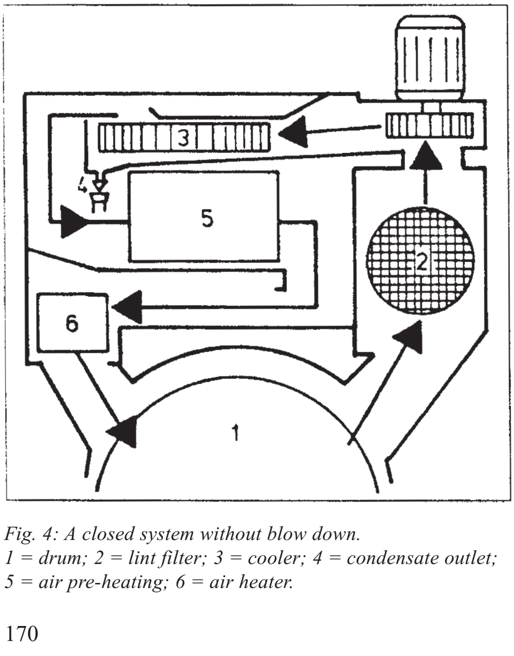

Fig. 4: A closed system without blow down.
1 = drum; 2 = lint filter; 3 = cooler; 4 = condensate outlet; 5 = air pre-heating; 6 = air heater.

For this reason it is not surprising that traces of tetrachloroethylene were found in foodstuffs stored in rooms adjacent to dry-cleaning machines. In Germany, foodstuffs containing a level of tetrachloroethylene higher than 0.1 mg/kg must be withdrawn. The legislation covering this can be found in the directive on maximum solvent values (Lösemittel-Höchstmengenverordnung) dated 01.01.1990. The usage of tetrachloroethylene also has to be regulated legally, because it is a potential toxic and ecological hazard. At an international level there is not such precise legislation for chlorinated hydrocarbons, including tetrachloroethylene, as there is for chlorofluorocarbons. There is one legislative declaration, albeit a specific one, the Declaration of the 2nd International North Sea Protection Conference in 1987. This regulates the burning of solvent waste at sea, as well as any depositing of hazardous substances in the form of waste water into the North Sea, which includes CFC solvents. Further directives are contained in various different parts of the EC guidelines, relating to the protection of water and the disposal of rubbish. In 1991 in Germany, the use of tetrachloroethylene was about to be banned. It was not until the professional unions protested emphatically, explaining that there was no alternative at that time, that the directive banning the substance was rescinded. However, this retraction was only on the condition that new directives were followed, which stated that tetrachloroethylene emissions had to be drastically reduced. For instance, the tetrachloroethylene concentration in adjacent premises where food is manufactured or sold was allowed to be a max. 0.1 mg/m^3, and from 01.01.1996 this applied generally to all adjacent premises [second directive for execution of the German pollution law (March 1991)]. This is an immense requirement, considering that the TLV value is 345 mg/m^3. The limits for waste water are also similarly stringent. Although they are set at a national level in Germany, there are also parameters at a super-regional level – CFC solvents as an independent substance must not exceed the threshold value of 0.2mg/l.

The new directives also state that in a dry-cleaning plant using tetrachloroethylene as a solvent, the concentration in the drum where the fabric is cleaned must not exceed 2g of tetrachloroethylene per m^3 of air. Previously the permissible limit was approx. 15g/m^3 of air. Understandably, a cleaning machine requires more time to achieve a target of 2 g/m^3 as opposed to 15g/m^3. However, longer drying periods with the machine drum rotating mean that mechanical effects exerted on the textiles are automatically more pronounced, which can lead to surface raising in sensitive fabrics, such as parts of micro-filament fabrics that are particularly liable to wear, or stiff parts. In addition to this, there is also a problem which has gone unnoticed in the past, caused by stiffening, linings and padding. For example an anorak with proofed outer material and thick non-woven fleece padding requires twice as much, if not three times as much drying time as normal garments. Furthermore if the anorak only dries when the drum is rotating it means that the anorak's outer material and padding are subjected to mechanical effects for twice or three times as long. In situations such as this, it is often a better idea to wash the garment in water (if the fabric care label and garment properties will tolerate this).

A further problem affecting textile manufacture in the broadest sense that has arisen as a result of the new legislation in the second BImSchV (Bundes-Immissionsschutzverordnung – German Federal Immission Protection Regulation) is the fact that pre-trials are no longer possible in the textile cleaning industry, because the open use of tetrachloroethylene is no longer permitted. Neither is it possible to carry out a pre-trial to establish whether textiles, dyes, finishes and accessories are resistant to tetrachloroethylene. This means that the fabric care label becomes more significant when it comes to a clear definition of the fabric care instructions. Sealed machines certainly make matters easier for the textile industry when it comes to dealing with environmental legislation:

- Solvent usage is significantly reduced,
- Working hours for regeneration are not necessary,
- There are energy savings.

However, sealed machines relocate the emissions from the atmosphere to the work room. This happens:

- During the loading and unloading phases,
- When high pressure in the machinery is released via the water separator,
- Through broken seals.

In order to comply with TLV values in ppm for tetrachloroethylene in the future, the exhaust fumes from the machinery released during loading and unloading must be discharged through a filter into the atmosphere. However, if that is the case, there is a requirement for a new process for exhaust purification and recovery, that combines the advantages of the old process and avoids the disadvantages caused by the main emissions (Fig. 5).

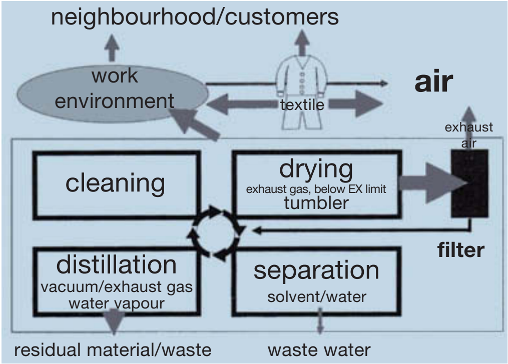

Fig. 5: The main sources of emission from dry-cleaning.

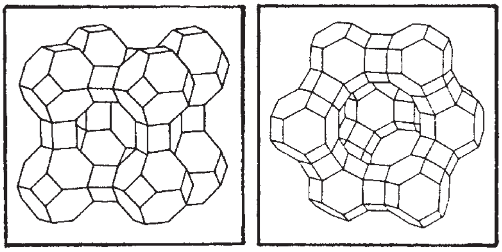
It is possible to filter solvents out selectively using molecular filters (Fig 6.), because of their crystalline structure and precisely defined pore diameters. A tailor-made type of molecular filter is selected for each solvent. As regards adsorption capacity, molecular filters provide an internal surface area of more than 1000 m^2/g. During the exhaust phase of the cleaning machinery, the exhaust fumes flow against a hydraulic seal. The back pressure condensation principle ensures that most of the solvent vapours present in the exhaust are recovered in the cooler.

A low-level partial airflow that is necessary for fabric ventilation is passed over the filter insert into the atmosphere. If the access door is opened, the exhaust bypasses through a butterfly valve via the filter and then straight into the atmosphere. Whilst the machine is almost sealed during the exhaust process, the system is open during loading and unloading. The number of loading and unloading operations is counted electronically, and constitutes a critical measurement for achieving the capacity limit of the filter. If this limit is reached, the machine operator is alerted by means of a visual signal that desorption is now necessary. Regeneration is carried out in a sealed circuit with hot air. To do this, circulated air is routed from the fan to the molecular filter insert via the heating unit, which can either be electrically or steam heated according to pref-



type 0.3–0.5 nm $Na_{12}[(AlO_2)_{12}(SiO_2)]\cdot xH_2O$

type 1 nm $Na_{86}[(AlO_2)_{86}(SiO_2)_{106}]\cdot xH_2O$

Fig. 6: Molecular sieve = sodium aluminium silicate.

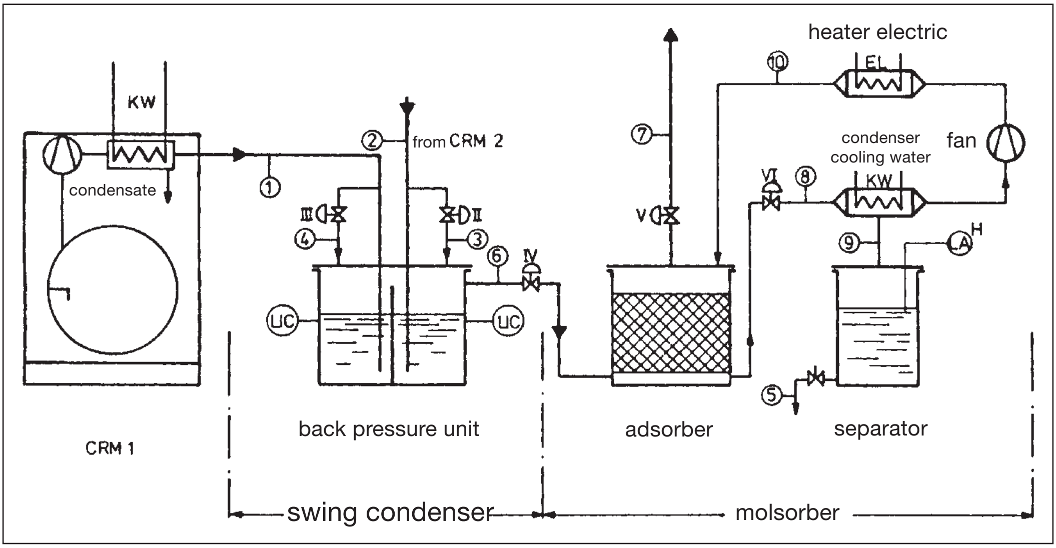


Fig. 7: Diagram showing the principle of the HKN process of the molsorber type.

erence. This air circulation forces the solvents out of the pores of the molecular filter and picks them up. After they have left the filter, they are cooled down in a heat exchanger, and the solvent vapours are condensed. The solvents flow into the separator, where they accumulate. The air circulation is sealed again, and the process is repeated. If solvents are recovered the heater switches itself off, and the plant is run cold as a sealed circuit (Fig. 7).

There are three aspects that are important for future cleaning techniques and associated textile requirements from a global point of view:

1. Effect of withdrawal of availability of CFC 113 (trichlorotrifluoroethane, which has been banned in Germany since 1991) as a solvent: so far the only solvent available as a replacement that can be accommodated in fabric care labelling is non-aromatic heavy benzine. As opposed to CFC 113, treatment with this type of hydrocarbon must be clarified on two points:

- drying must be carried out at 60°C, instead of 40°C, as was the case previously,
- the duration of dyeing is extended.

The resistance to temperature of sensitive textiles becomes a more important factor, as does the resistance to increased mechanical action.

2. Extension of the mechanical period where tetrachloroethylene is used as the solvent: taking into account the extent to which emission-reducing measures become established on a global basis, it should be assumed that the drying period could be extended by as much as 100%. Resistance to mechanical action takes on more importance.

3. Increasingly more wet treatment in commercial textile cleaning plants: “Wet treatment” should be strictly differentiated from household washing conditions. Specialist textile cleaning plants have washing machines and washing auxiliaries at their disposal that are designed to cope with the requirements of particular textiles. The number of revolutions, the direction of revolution, and the effective temperature can be adjusted appropriately depending on the sensitivity of a particular textile, and the optimum drum size can be used. Drying occurs at a temperature ranging from warm to hot, either with the article hanging up, or if appropriate, in a tumble-dryer, which is certainly a possibility for synthetic fibre textiles.

To establish whether cleaning in the future should be done using water or solvent, the following parameters should be taken into account:

- degree of soiling,
- tetrachloroethylene retention properties during drying,
- availability of tetrachloroethylene at commercial dry-cleaning plants.

Overall, wet treatments in textile cleaning will increase proportionally over the next few years. Dimensional stability and colour-fastness are gaining in importance. The current level of knowledge and constantly changing parameters mean that it is no longer a straightforward matter to decide whether to wash or dry-clean. Because of the current legal situation, both cleaning methods require cost-intensive extras, which applies in general to dry-cleaning with tetrachloroethylene or heavy benzine. For washing this applies in a more specific sense (particularly in the case of heavily soiled workwear).

Solvent volatility → Evaporation number.

Solvent/water interface In dry-cleaning and solvent finishing: where there is a solvent/water mix (e.g. tetrachloroethylene), the water proportion in the separation system, where the tetrachloroethylene, having a greater specific weight, separates from the lighter water. If the water separator is not functioning properly, there will be an odour of tetrachloroethylene, for instance. In dry-cleaning, the solvent/water interface accounts for approx. 10% of the fabric weight; however the tetrachloroethylene content can vary.

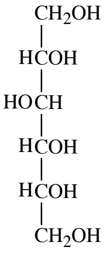
Sonator Sonic generator for rational generation of sonic waves (rhythmically generated surges 6000 per min) for intensive subsequent impregnation, wet aftertreatment, rinsing, and for more thorough dyeing of dense fabrics, seams, etc. If the working liquor is subjected to ultra-sonic pressure surges, the fabric is kneaded, which should achieve significantly better penetration within a short time, and is also gentle on the fabric.

Sonic velocity as a measure for exhaust air moisture →: Exhaust air moisture measuring systems; Fluidic oscillator.

Sorbate, Sorbent → Sorption.

Sorbitan fatty acid esters These are generated as a result of → Sorbitol (glucose alcohol) dehydration. The resulting anhydrous sorbitols are esterized with fatty acids. Depending on the fatty acid used, sorbitanes are water-soluble (palmitic acid and stearic acid) or dispersive (lauric acid and oleic acid), and they have excellent emulsifying properties.

Sorbitol Hexahydric alcohol. Manufactured by reducing d-glucose or dextrose derived from starch or maize. There are different forms: a) white powder or colourless needle-shaped crystals, melting point 100–120°C, easily soluble in water, pyridine, methanol, acetic acid, phenol, not so easily in cold alcohol; b) syrupy solution with 70–80% sorbitol content, density greater than 1.26, neutral, non-reducing, odourless, non-toxic, sweet taste.



$$\begin{array}{c} CH_2OH \\ | \\ HCOH \\ | \\ HOCH \\ | \\ HCOH \\ | \\ HCOH \\ | \\ CH_2OH \end{array}$$

Application: alternative to glycerine for sizing, finishing, dyeing, printing; for plasticizing rubber and glue; for softening the gelatinous layers on print rollers.

Sorption Addition, uptake. The substance carrying out the sorption is known as the sorbent, and the substance undergoing sorption is known as the sorbate.

I. Adsorption: enrichment of a substance in the interfacial layer of two adjacent phases. The components being adsorbed are known as adsorptives, and the solid interacting with the adsorptive is known as the adsorbent. In the adsorbed state, the adsorptive phase that is held onto the surface of the adsorbent by adhesion becomes the adsorbate. The opposite process, the release of the adsorbate, is called desorption.

II. Absorption: inclusion of a substance into the chemical structure of another substance, during which the interface between the phases is lost. As well as physical absorption, there is also chemical absorption, in which a chemical bond is formed at the interface.

The word sorption is used for processes in which it is difficult to distinguish between absorption, adsorption, chemical sorption and physical sorption, or if absorption and desorption are indistinguishable as separate processes.

Sorption isotherms Graphical representation (→ Isolines) of a fibre sorption situation, e.g. for water (vapour) from the surrounding air, for non-ionic dyes as a constant distribution between the liquor and fibre/ dispersion dye (→ Nernst's distribution law), for ionic dyes on fibres with ionic groups as isothermic dependency on concentration and pH (Langmuir isotherms), for ionic dyes on fibres with non-ionic groups using the empirically-identified adsorption isotherm (direct dye on cellulose: Freundlich isotherm).

Sorrel salt → Potassium tetroxalate.

SOTP "Second Order Transition Point", temperature limit for synthetic fabrics, which is below the melting point, above which there are no further significant changes to loss of breaking strength, degree of shrinkage and fibre elasticity at treatment temperatures. Strongly crystalline fibres have a low melting point, and less crystalline ones have a high melting point, such as:

polyester fibre	79°C
polyamide fibre	79°C
wool	> 120°C

Sound From a physical point of view, sound consists of mechanical oscillations in an elastic medium. The occurrence of sound is linked with the existence of material. Sound can occur in solid bodies as well as in a liquid or gas medium. Sound that uses air as its medium is the most common form of sound in everyday life. It can be triggered as a direct result of activating a solid body, as long as the oscillating bodies are in contact with the air, and an effective contact with the air is possible. Air particles that have been triggered to oscillate, in turn activate further adjacent particles, and so on. This results in a periodic sequence of the air becoming denser and thinner, and spreading out in waves. At certain intervals, the same activation status repeats itself in

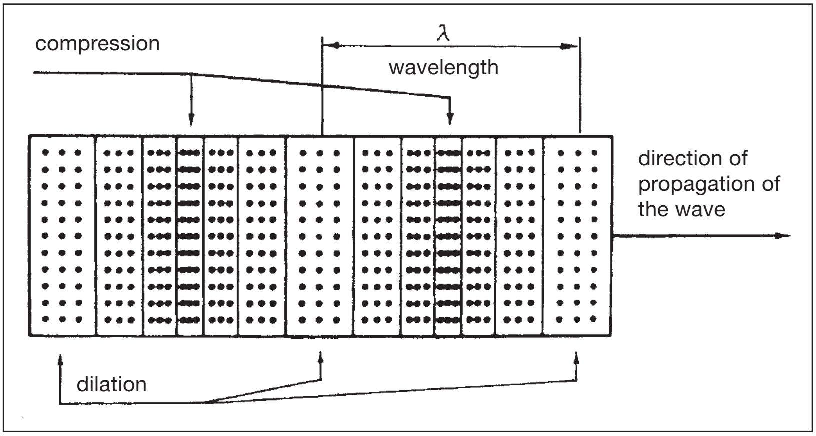


Fig.: Diagram showing the propagation of sound in the form of a longitudinal wave.

the direction of propagation of the wave movement. Since particle excursion follows the wave dissipation direction, it means that the resulting waves are longitudinal in direction.

The activity originating from a point source of sound spreads out in all directions in space. All particles that are the same distance from the sound source are on the same point of a spherical shell and have the same phase length (spherical waves). This type of wave is always found in close proximity to the sound source. Further away from the source, small parts of the spherical shell converge in planes (plane sound wave). If the oscillating air particles are replaced by highly elastic mass points for experimental purposes, the situation shown in the Fig. arises.

If the chronological sequence (frequency f) of activation is constant, it means that the interval between two states of activation of the same type that follow on from one another is of an equal size. These intervals are the wavelength λ. The product of the frequency and the wavelength gives the speed of dissipation.

The speed of dissipation is a characteristic value for each substance, and in the case of gases it is dependent on pressure, density and other factors. Where the air pressure is normal and the temperature is 0°C, this speed is 332 m/s. At the upper limit of human hearing at approx. 18 kHz, the corresponding wavelength is then approx. 1.6 cm. It is possible to generate ultra-sound waves at frequencies of up to 10^9 Hz (hypersound). The length of the path in air is approx. 0.6 µm (path length of visible light, average free wavelength of molecules in the dissipation medium). When sound dissipates, the particles only oscillate about their equilibrium positions, there is no further directional movement. During wave movement, the particles are only responsible for spreading the sound energy, no transmission of material takes place.

The space filled with material in which the sound dissipates, is known as the sound field. The sound field can be described quantitatively by means of sound field dimensions, based on which the speed of the sound is the speed at which the wave dissipates in that area. In contrast to sound speed, sound velocity expresses the speed at which individual particles in the sound field move about their positions of equilibrium. Both these measurements describe different physical situations. In air, the oscillating air particles manifest themselves as a chronological change in air pressure. The changes in pressure represent the changes in acoustic pressure, which by definition is the deviation of the overall pressure from the state of equilibrium. The acoustic pressure, a measurement that is subject to change, overrides normal atmospheric pressure, and has a chronological value of zero. The sound of normal speech at a distance of 1 m from the speaker causes an acoustic pressure of approx. 10^{-2} to 10^{-1} N/m^2 (according to Schollmeyer).

Sound-absorbing panels Usually made of cork or composites, designed to absorb noise, in other words, to lower the noise level.

Sound insulation Acoustic protection and heat insulation in modern buildings, achieved by means of floor coverings (carpets).

Sound level (sound pressure level), expressed on a scale in dB = decibels ($^1/_{10}$ bel). Human hearing ability forms the basis for measurement, which has a sound pressure range starting at the minimum audible level of $2 \cdot 10^{-5}$ Pa (Pa = Pascal) up to the pain threshold at $2 \cdot 10^2$ Pa (at 1000 Hz). → Industrial noise pollution.

Sound level measurement The German industrial standard for noise measurement applying to machinery and driving units is DIN 45 635. Fig. 1 shows an example of how points are arranged for the measurement of noise emission for a textile machine in line with DIN 45 635 T32, where the measured distance from the machine represented here with the letter d is usually 1 m.

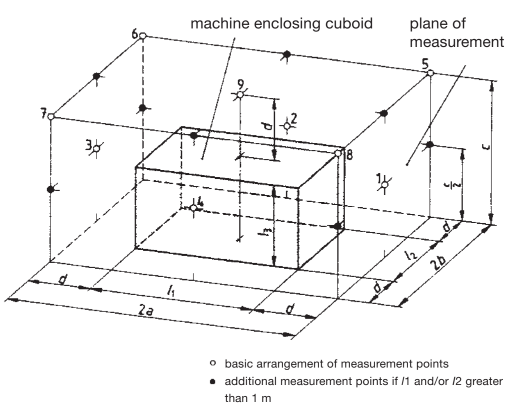

Fig. 1: Sound level measurement: the plane of measurement, the locations and the total of measurement points meet the requirements of DIN 45 635 T 32 for textile machinery up to 2 metres in height.

The sound pressure level is usually measured according to evaluation A. This sound pressure level L_A is defined as the time/space-related sound pressure level evaluated according to A, recorded on the enveloping surface of an imaginary cuboid at a distance of one metre from the surface of the drives. If necessary, this measurement must be corrected to compensate for external noises and influence factors caused by the room itself. The acoustic capacity level L_{WA} [dB(A)] can be calculated by the addition of the dimension L_S to L_{PA} using the following equation:

$$L_{WA} = L_{PA}\ 1\ m + L_S$$

The following applies for the average value of L_S: approx. 10–12 for smaller drives up to 3 kW, and for larger drives up to 100 kW approx. 12–15. This can be used as a basis upon which to predict noise development (Fig. 2). It is becoming increasingly easy to obtain definite information from the manufacturers of the machinery. The VDI directive 2159, which was developed to cover toothed gearing and also includes quality classification, provides guidelines on the state of the technology (VDI is an abbrev. for the Society of German Engineers = Verein Deutscher Ingenieure). There is also the VDE standard 0530, containing specifications for electric motors. An overview is available for some types of helical gearing, taking this standard into account. The overview shows that the gears conform to the VDE standard, and that it is possible to implement categories B and C of the VDI directive (high and very high rate of production).

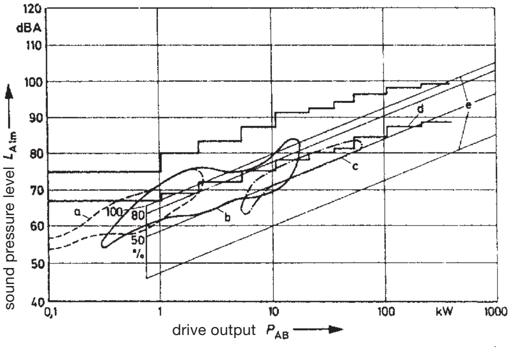

Fig. 2: The sound pressure levels of different drive systems. a = spherical washer drive; b = laminated chain drive; c = all-metal contact drive; d = permitted level according to VDE 0530 for surface cooled motors; e = quality classification according to VDI 2159.

The following steps must be followed to establish the acoustic capacity level:

- recording of the machinery noise level at each point of measurement L'_{pi}
- calculation of the mean value L'_p
- recording of the external noise at each point of measurement L''_{pi}
- calculation of external noise correction K_1
- definition of environmental correction K_2 (e.g. using a comparative sound source or measuring the echo interval)
- calculation of the sound pressure level for the area being measured
  $L_p = L'_p - K_1 - K_2$
- calculation of the area being measured L_s
  $L_s = 10 \cdot \lg S/S_0$
- calculation of the acoustic capacity level
  $L_w = L_p + L_s$

Furthermore the standard usually requires definition of the emission value in relation to working areas, for one or more workstations allocated to the machine. For most textile machinery, a measurement at a distance of 0.5 m from the machine profile, and 1.6 m in height is defined in the appendices to Part 32. The value obtained must be corrected to compensate for external noise (K_1) and environmental influences (K_2), in the same way as the sound pressure level for the measured area.

For some other types of machine, an "indirect" process is described for defining the emission level with respect to the working area, which enables the acoustic capacity level to be used for calculation. This process is basically the same as the calculation of the sound pressure level for the measured area L_p for a specific distance, e.g. 0.5 m, by subtracting the appropriate dimensions from the acoustic capacity level. This method is particularly advantageous for measuring compact hand tools, because the dimensions of the measurement area can always be given as a constant value (the measurement area is the same for all types of machinery). The emission value relating to the working

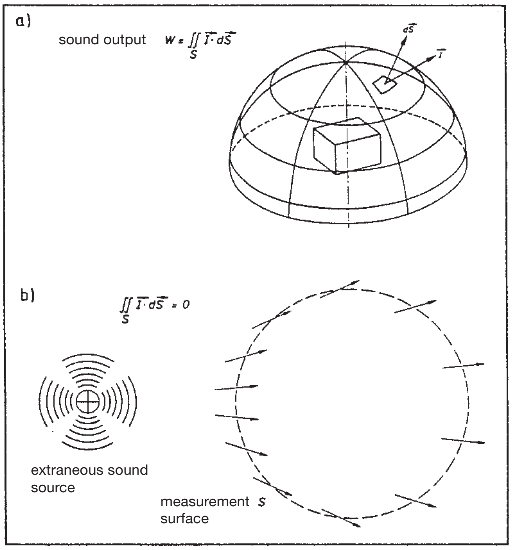

Fig. 3: Determining the noise emission from a machine by the measurement of sound intensity.
a) on the measurement surface S; b) suppression of an extraneous source of noise lying outside the measurement surface.

area can therefore be calculated by subtracting one of the constant values published in the measurement regulations from the acoustic capacity level.

Since noise measurement can often not be carried out until the machine has been installed at its permanent location, and under comparatively unfavourable environmental conditions, the conditions of measurement stated in DIN 45 635 T 1 and the corresponding ISO standard can not always be adhered to. It is only possible to correct environmental influence factors and the effect of external noises up to a certain point. To tackle this problem, there are ways of using measuring devices based on sound intensity measurement technology, which allow the recording of noise emission from machinery independently of environmental influences, even where the external noise level is relatively high. Specialist measuring devices are necessary for sound level intensity measurement. They usually consist of a measurement probe with two sound pressure microphones that can measure the energy flow of the sound using vectors, i.e. taking both quantity and direction into account. This means that the non-directional diffused proportion of the sound (environmental influence) is not included in the measurement. External noise influence is eliminated by measuring in the usual sealed area (Fig. 3), as long as the external noise level remains constant during measurement.

Sound pressure (acoustic pressure, sound pressure change), refers to the periodical changes in pressure that occur in a sound wave. The unit of measurement is Pascal.

Soundproofing Achieving reduction of noise emission is a significant aspect of textile machinery construction. In order to achieve this successfully, the construction engineer has to assess the noise level generated by individual components of the machine during the design phase, and when the machine is under construction he has to implement specific measures to combat noise. To design low-noise machinery, it is essential to have knowledge of the principles of machine noise emission, the physical context, and the rules governing low-noise construction.

Noise can be defined as any type of sound that constitutes a disturbance or a nuisance to people, or is detrimental to health. Machine noise falls into two categories, depending on how it is distributed – airborne sound and solid-borne sound. If the airborne sound is generated directly by sound oscillations caused by a flowing medium, a combustion and explosion process, or the sound of an explosion, it means that it is purely airborne sound transfer.

Examples of airborne sound generation:
- air flow,
- flow around edges and rods,
- suction and exhaust openings,
- flow in pipes,
- rotating parts,
- belt drives or blowers and ventilators.

If the sound is transferred indirectly, i.e. oscillation is first triggered in a solid body, which then transmits the oscillation onwards causing airborne sound to radiate from its external surfaces, it is called solid-borne sound. Solid-borne sound in machinery is generated when solid bodies collide, e.g.
- stopping,
- meshing,
- cam/tappet.

As a result of interactive forces on machinery components, e.g.
- bearings,
- cam gears,
- chains,
- couplings,
- brakes,
- friction wheel gears.
- mass forces caused by an out-of-balance situation.

As a result of interactive forces involving a sealed medium, e.g.
- hydraulic equipment,
- pneumatic equipment.

Noise development in machines is primarily influenced by changing the applied forces and their ranges, and secondly by preventing sound from dissipating. For solid-borne sound, the solution is to insulate and dead-en the machine parts, for instance by encapsulating them. With textile machinery in particular, the noise is caused by a large number of moveable parts and comes from various different sources. The total volume of two equally loud sources of sound is only 3 phon higher than a single one. For this reason, anti-noise measures must always be applied to the loudest noise source of a machine. Any measures applied to the lesser sound sources will make no difference to the overall level as long as the loudest source remains unchanged, because the loudest source determines the overall level. → Noise protection.

Sour off Adjustment of pH after alkaline processes, using acids, usually to pH 7 (neutral).

Southern Regional Research Center (SRRC). American organization for textile research; part of the Agricultural Research Organization, and therefore also representing cotton cultivation and Research into Textile Use for Cotton. → Technical and professional organizations.

Soybean oil Semi-drying oil obtained by pressing or extraction from soya beans; brown to greenish-yellow, odour/taste similar to olive oil. Easily soluble in ether. Saponification number 189.5–212.6; no non-detergent fatty matter. Use: oil sizes.

Space dyeing Sectional printing or dyeing of yarn and cable in varying stages of processing, various colour shades, as well as in different intervals and lengths. In space dyeing it is scarcely possible to differentiate between dyeing and printing. The space dyeing process provides an opportunity to create interesting types of pattern. Multi-coloured, irregular motifs and imaginative effects on the fabric can be achieved by using yarn with partially bordered patches of colour. The washed-out looking, asymmetrical patterns on upholstery covers and domestic textiles (floor coverings) are particularly dominant. Also, this type of printing also occurs in knitwear and ladies'/gentlemen's wear made from multi-coloured yarn. Outerwear made out of multi-coloured yarn is always dependent on current fashion, and for this reason they only appear on the market at irregular intervals. Depending on the process, the patterns produced are either reproducible or random, which can not be reproduced identically. Space dyeing is the collective term for several different types of process (continuous or discontinuous), which usually carry an imaginative brand name.

There are 6 different groups for yarns, each with different working methods:

I. Printing on knitwear: The knit-deknit process is the most economical space dyeing process, and it has gained much importance at an international level. The process was patented by the F. Whitaker company, Philadelphia (USA). The following manufacturers have produced machines under this patent: Fleissner (Germany), Murphy (USA), Ilma (Italy), Radici (Italy). The principle of this process is based on applying the dye liquor onto tubular knitted fabric. First a tubular knit is manufactured, which is then sent to the printing machine as a batch for ground dyeing, where the first stage is passing it through the padder for ground dyeing. It is always the palest colour in the required colour scheme that is applied during the padding process. The next stage is to print the required patterns and colours onto the tubular fabric with print rollers, using the wet-on-wet printing process. The print rollers have a specific pattern (engraved or relief), to avoid patterning faults after tufting. The most common type of machine used for this purpose is the duplex printing machine, which prints both the upper and lower sides of the tubular fabric at the same time, because with normal print rollers it is not possible to achieve good print penetration. After the printing process there is a continuous fixing process in saturated steam, after which the printed fabric is washed and dried. Finally the printed tubular knit is rewound, and it has crinkle arcs in the knit layers that are not set fast. The type of crinkling is dependent on the stitch size of the fabric knit. If the crinkle arcs of the thread are not required they can be removed. The wound yarn is then batched onto cones and routed to the tufting machine. The knit-deknit process (Fig. 1) is primarily used for coloration of floor coverings.

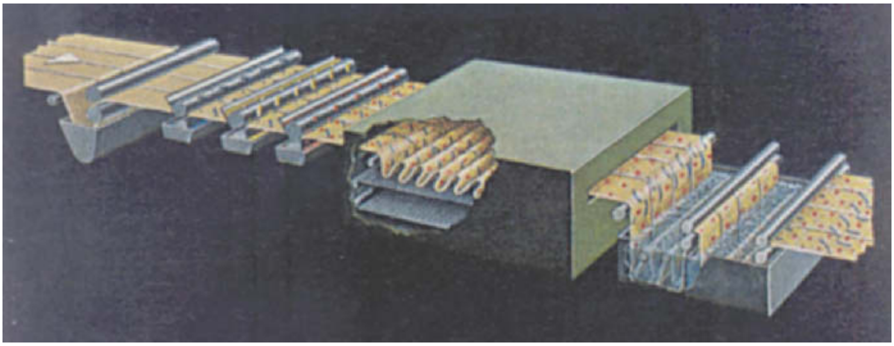

Fig. 1: The knit-deknit process (by Bayer).

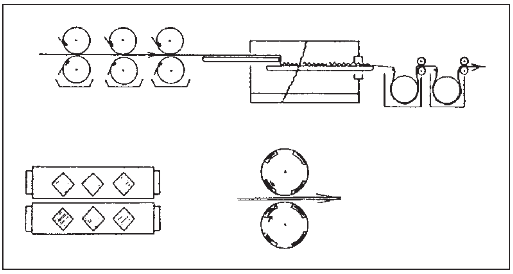

Fig. 2: A Fleissner space dyeing machine.

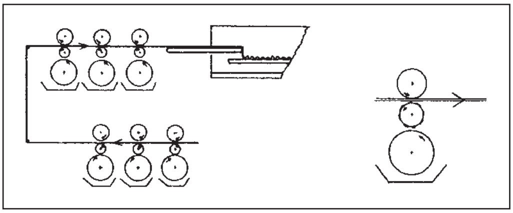

Fig. 3: A Murphy space dyeing machine.

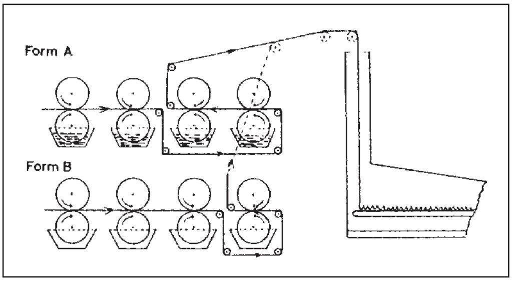

Fig. 4: An Ilma space dyeing machine.

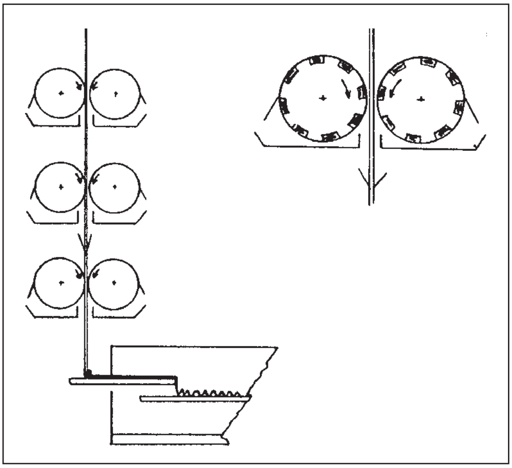

Fig. 5: A Radici space dyeing machine.

The main factor that differentiates between the types of process is the different printing systems used, i.e. the print rollers and their arrangement. The rollers can be manufactured from steel, rubber or wood. If steel print rollers are used, the patterns are engraved, if they are made of rubber, the patterns are embossed in the form of a full rubber relief facing of the rollers, or with wooden rollers, foam rubber patterns are stuck to the rollers. Depending on the type of machine, either both sides of the fabric are printed simultaneously, or first one side is printed and then the other. The arrangement of the print rollers is dependent on the machine, and can either be horizontal (Figs. 2–4) or vertical (Fig. 5), and this is a significant factor for print precision.

II. Warp printing: This is another space dyeing method that is used globally, and its characteristic feature is that warp yarns can be both padded and printed. In the Laing process (Fig. 6), warp yarns (up to 500 threads running concurrently) are first padded (in the same way as the knit-deknit process) and subsequently printed. There are two rollers of different sizes for printing, and the lower of the two, which is the smaller, is positioned so that it dips into the dye trough. The dye paste is only transferred to the yarn when the relief patterns on the upper and lower roller meet together, so that a perfect pattern profile is guaranteed, without any patterning faults, during the subsequent tufting process. If the print roller pairs are arranged in series, multicoloured effects can be achieved. The warp yarn is continuously steamed after printing, and it is then washed, dried and wound onto section beams.

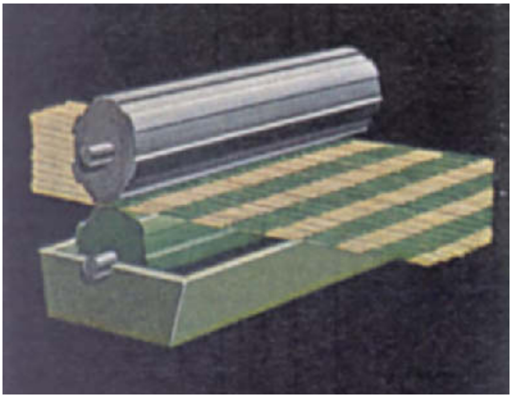

Fig. 6: The Laing process (by Bayer).

The Stalwart system (Fig. 7) is similar to the Laing process, the main difference being that smooth rollers are used instead of relief rollers. With this system, the lower roller is also positioned to dip into the dye trough. The dye paste is only transferred to the required point on the yarn when the upper and lower rollers are

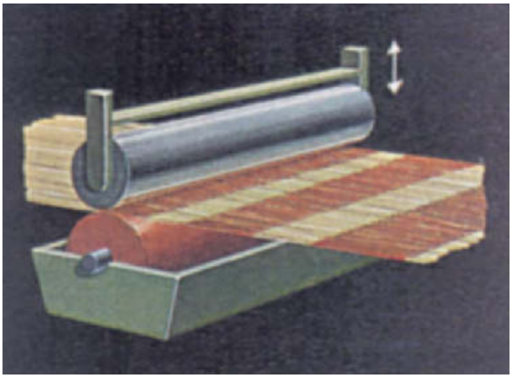

Fig. 7: The Stalwart system (by Bayer).

pressed together, until the upper roller lifts again. The print contact time governs the length of the colour stripes – a shorter contact time produces a shorter stripe, and vice versa. It is possible to set up a series of several printing machines. This equipment can be used to manufacture long space patterns on a large scale, or self-shades.

The Martin process is also comparable with the Stalwart system. However, this process does not just use a single smooth roller per colour for printing the entire width of the warp yarn; instead it uses several rollers that can be operated independently of each other. This provides scope for greater variation.

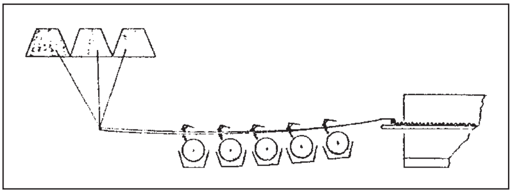

Fig. 8: A Fleissner space dyeing machine for threads.

The Fleissner space dyeing process (Fig. 8) has a certain level of similarity to the Martin process. Warp yarns are printed with the space effect in this process as well. The yarn, depending on pattern, is pressed onto the dyeing rollers by means of impulse controlled irons, where it is wetted with the dyeing liquor (printed). Depending on the yarn speed, the impulse control can determine the length of printed colour stripes. The maximum possible number of colour print rollers that can be used at any one time is six. After the printing process, the yarn is set in a perforated steamer using saturated steam.

The equipment used for Zaza printing (Fig. 9) works on the principle of a Vigoureux printing machine. The warp yarn is passed between an upper relief roller and a lower felt roller, which is supplied with dye paste from the dye trough via a rubber roller. The relief rollers can produce geometrical repeated patterns as well as horizontal and diagonal stripes. In sections where the raised areas of the relief press the warp yarn onto the felt rollers, the dye passes through the yarn from below through to its upper side. In this situation, the relief roller only has patterning properties. The machine operates with four pairs of rollers, in other words five colour shades can be produced including the ground colour and the four shades that can be printed onto the yarn. The Zaza system is mainly used for space dyeing fine titre yarn for outerwear and knitwear.

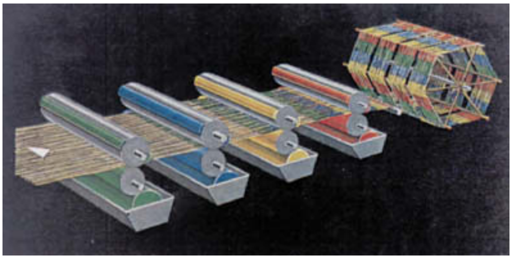

Fig. 9: Zaza printing (by Bayer).

Using the SWA space dyeing process (Fig. 10), it is possible to print warp yarns with up to 40 threads at an operation speed of 110–115 m/min. The dye liquor is applied by means of a metal roller that transfers the dye liquor in the trough onto a felt roller. Above the felt roller there is a smooth roller, the upper roller (which can also be substituted by a relief roller with a regular pattern sequence). The yarn passes between the felt roller and the upper roller; if any dye paste needs to be transferred, the upper roller is pressed onto the felt roll-

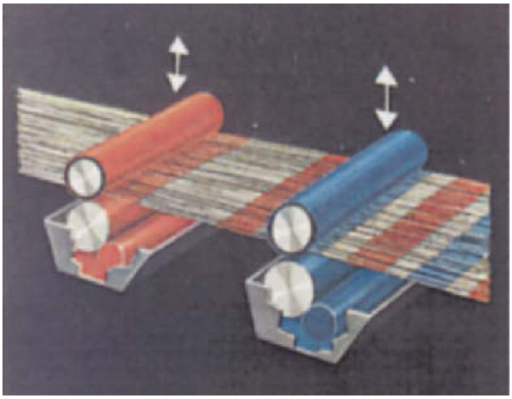

Fig. 10: An SWA space dyeing machine (by Bayer).

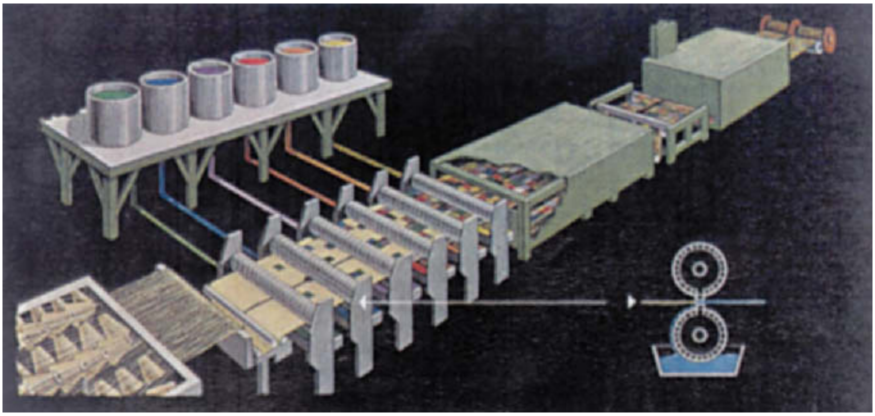

Fig. 11: The Crawford-Pickering multicolour process (by Bayer).

er. The print process is controlled via a monitor, which communicates the required impulses to the print rollers. A separate print unit is required for each dye paste applied. After printing, the yarn is partially dried in a hot air duct and then wound. The dyes are set in saturated steam.

With the Crawford-Pickering multicolour process (Fig. 11), patterns can be applied to warp yarn with a high level of precision, for the production of tufted carpets. It operates according to the principle of a continuous programmed print. In the printing system, each colour paste (usually 6 shades) has an allocated print unit, consisting of two rollers positioned vertically over each another. Both rollers are equipped with a large number of mechanically controlled stamps. The lower roller is for the purpose of applying the paste, and the upper one provides resistance. Each stamp on the dye roller prints 4–5 threads at a time. After the continuous steaming, washing, vacuum extraction and drying processes, the yarn is divided up into threads printed by the same stamp onto 4–5 identical beams, each with a total of 126 threads. If a tufting machine with 5/32 inch partitioning is used, 126 threads will result in a pattern repeat of 50 cm. If the process is combined with a patterning system, it is possible to apply the design to the carpet with the same level of precision.

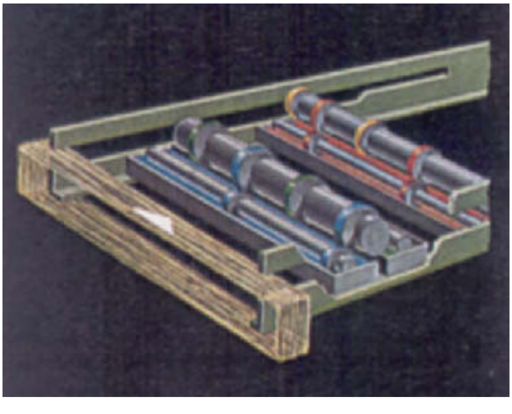

Fig. 12: A Timmer hank yarn printing machine (by Bayer).

The entire process, from carpet design to pattern printing can be exemplified as follows: A geometric pattern is tufted so that a 4 cm length of thread results in a 1 cm pattern length in the finished carpet. The printed pattern has pulled together after tufting with a ratio of 4 : 1.

III. Hank yarn printing: The Timmer hank yarn printing machine (Fig. 12) can be used to print woollen, polyamide, cotton, viscose and silk yarns in hank form. The printing process is divided into four phases, and $^1/_4$ of each hank is printed in each phase. The hanks are automatically moved lengthways, so that the next quarter of that phase can be printed. Moving along in a crosswise direction and pausing are also controlled automatically. In this way, the hanks are guided 4 times through four pairs of rollers. Patterns can be created by means of colour combination, and by printing patterns onto the hank yarn using the rollers. Care should be taken that only the specified hank size (1371 mm) is used. Any differences can be bridged up to 50 mm.

The VH-Syn-O-Flow process (Fig. 13) enables multi-colour dyeing of yarn in hank form in a single process, in contrast to the previous system. The hanks are arranged moderately densely around a stainless steel drum provided with a slit. In this way, 60 separate colour stripes in any combination can be applied to the hank. The dye is applied automatically, by applying the dye liquor to the hank yarn through the slit in the stainless steel drum. All the dye liquors being used in the process are applied at the same time. The dyeing process lasts approx. 30–90 s, depending on the fineness of the yarn. After dyeing, the yarn is removed by hand and set, depending on the dye used. The total machine charging process takes about 5–6 min. The machine capacity is approx. 50–75 kg/h.

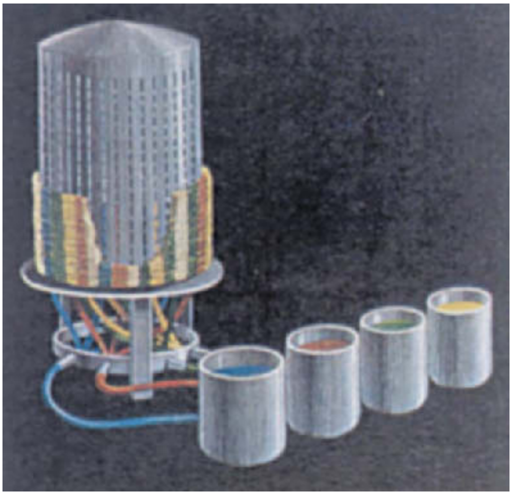

Fig. 13: The VH-Syn-O-Flow process (Hendricksen) (by Bayer).

A multispace dyer (Fig. 14) is a plant for continuous dyeing and steaming of yarn and hank yarn. The essential machine components are:

- jet beam with 40 jet nozzles (the distance from the yarn is variable),
- steel perforated conveyor belt,
- steamer,
- exit table,
- four dye containers to supply the jets with dye liquor.

For the dyeing process, the yarn hanks are arranged on the conveyor belt one after another, at right angles to the direction of transport. They are then passed beneath the jet bar, which sprays 40 jets of dye liquor at the yarn. Stripes are produced on the hanks, which are perpendicular to the hank length. Space dyeing effects using four or five colour shades can be created, including the ground colour of the yarn. If two or more adjacent jets are charged with dye liquor in the same colour, broader stripes in that colour will result. Full penetration dyeing of the hanks can be controlled by the amount of liquor, viscosity and auxiliaries used. After dyeing, the hank yarn is carried through the steamer on the perforated belt, where it is steamed for 6–8 min. Immediately after steaming, a continuous or discontinuous scour and scrooping are carried out. The performance capacity is 200–280 kg/h. This type of plant is an alternative for smaller carpet manufacturers, both from a qualitative and a quantitative point of view, because of the relatively low space dyeing costs.

IV. Multi-colour effect on individual threads: it is inexpensive to set up the equipment to achieve this effect, however the production capacity is not sufficient for it to be able to compete against knit-deknit space dyeing and warp yarn processes. For this reason it is used for outerwear and hosiery.

The Eastern Colour Yarn Dyeing process (Fig. 15) provides a method of partially dyeing yarns using a centrifuge supplied with dye liquor. For dyeing, the yarn is rapidly unwound from a reel, routed past 1–3 dyeing centrifuges, sprayed and rewound (yarn winding machine principle). In the next stage, the yarn is shock-heated and rewound again. Setting is carried out by steaming. Up to three colour shades are possible, because there are three centrifuges arranged one above the other. This process is used exclusively for the outerwear and hosiery sectors.

The Superba process (Fig. 16) is similar to the previous process, but the dye liquor is applied vertically as the yarn is routed past on rapidly turning centrifuges. The drops of dye liquor that are spun out hit the yarn and produce small spots (speckled effect). 8 threads can be processed at a time. If longer spaces occur, perforated discs can be used. The decisive factors in this technique are the length of the perforations, the number of revolutions of the centrifuge, and the dyeing speed. The

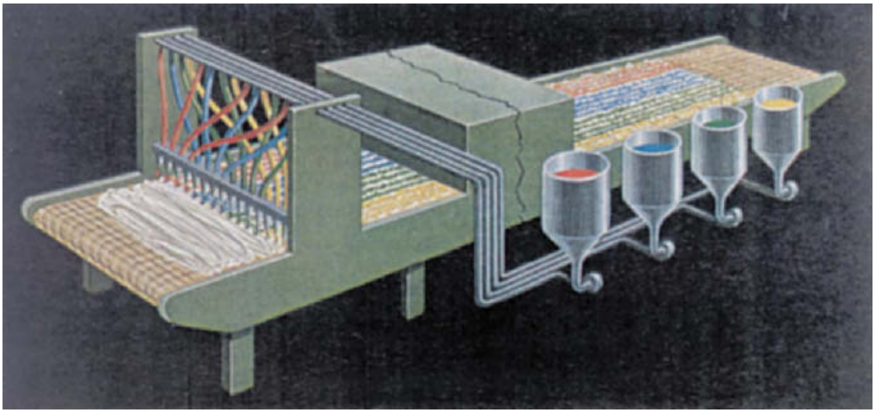

Fig. 14: A multispace dyer (Callebaut de Bliquy) (by Bayer).

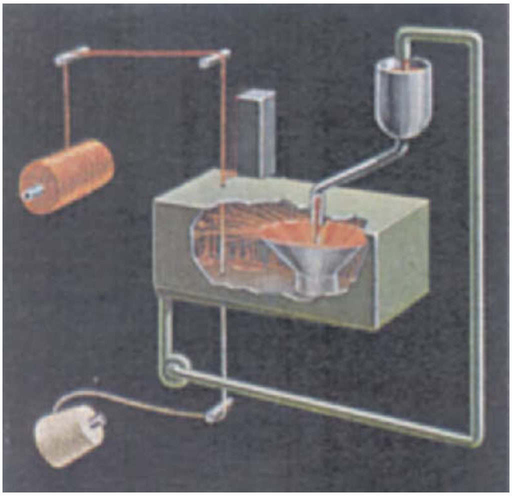

Fig. 15: The Eastern Colour Yarn Dyeing process (by Bayer).

Fig. 16: The Superba process (by Bayer).

maximum yarn speed possible is 800 m/min, at which speed it is possible to apply three colour shades using three centrifuges. After the dyeing process the yarn is plaited up in spirals on 4–8 perforated belts, and it passes through the setting chamber and drying box in this arrangement. The important aspect of this technique is that in most cases no aftertreatment is required since thickeners are not usually necessary. Depending on the planned subsequent processing, the yarn is wound straight onto large cones or put into cans (one can per thread). Yarns dyed using this method are made into outer garments and used for the microspace in tufted carpets.

The OPI process (Fig. 17) is used to create reproducible space dyeing effects on yarn. The length and spaces of the spray effects are variable using this method. There are three different functions in the process that produce the effects:

1. Spraying the dyeing liquor onto the yarn, which runs at speeds of up to 1000 m/min.
2. Removal of water from the soaked yarn using specially designed compressed air jets.
3. Dye setting using steam.

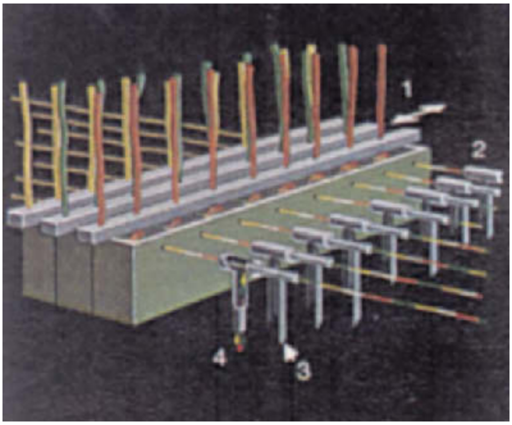

Fig. 17: The OPI process (by Bayer).
1 = nozzle bars; 2 = squeezer device; 3 = compressed air; 4 = excess dye.

The space dyeing effect is created by moving a jet beam back and forth. Each jet beam is equipped with 8 jets, and is positioned at a perpendicular to the direction of thread run. Depending on the required colour arrangement, up to three jet beams can be used in series, to enable rapid changeover between three colours, or so that 2–3 colours can be applied simultaneously. The equipment can be adjusted to create long and short space dyeing effects, which are dependent firstly on the running speed of the thread, and secondly on the speed of the alternating movements of the jet beams. These two factors can be adjusted independently of each other, providing the option of unlimited variation depending on how they are adjusted. The machine operates at speeds of 1000 m/min. Moisture is continuously removed from the thread by means of compressed air, which is done by passing the thread through a tube sealed by special jets. The pressure of 24 Pa ensures that superfluous dye liquor, when the thread enters the jet, is forced out. The advantage of this principle is that the outline of the sprayed colour area remains clear-cut because the water is removed suddenly. For this reason the dye liquor can be applied without using thickening agents, rendering scouring unnecessary. The water has been removed from the yarn to such an extent that it can be wound without the need for an interim drying process. After winding there is a continuous steaming process, followed by drying and rewinding. The OPI system does not occupy much space, and it operates at a high production rate. Because of this, there are several possible points in yarn processing where it could be incorporated, such as before a rinsing machine or before setting equipment, in other words continuous operation is possible.

Parallels can be drawn between the operation techniques used in the Unitika-Mixy process (Fig. 18) and Eastern Colour Yarn Dyeing, as well as with the Superba and OPI systems. Before the yarn is sprayed with dye liquor, it is stripped at high speed (up to 550 m/min) and heated. Then it is dried and rewound. The setting process is carried out discontinuously in saturated steam. Multi-colour effects as well as self shades can be created on the same equipment.

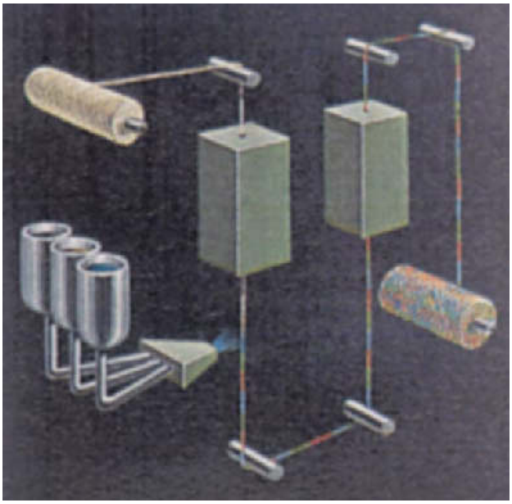

Fig. 18: The Unitika-Mixy process (by Bayer).

The Hörauf process (Fig. 19) can be used to create the space dye effect by means of a liquor application system that is relatively easy and safe. A pump for each dye liquor is used to spray a jet of liquor onto the yarn, which is running past at a high speed. The jets are interrupted by rotating punch tapes. Depending on the length of the spaces, perforated discs are used. The determining factors for creating the space area are the length of the perforation and the interactive control of the three spray stations. The process (which in this respect is similar to the OPI process) helps to reduce the level of applied dye liquor after spraying to meet the required liquor uptake percentage. As 2–3 dye liquors are applied consecutively, all the surplus liquor is simply removed. It is not possible to re-use it in the system. After the application of liquor, the yarn arrives at the winding device (and setting device), which is a Buddecke system. There are two or four continuous rubber belts that transport the yarn in a tension-free state along a cloth beam at right angles to the direction of transport through the steamer. The dwell time in the setting chamber is variable, depending on the winding density and yarn type. Finally the yarn is stripped off the carrier and wound onto reels. Any aftertreatment, such as washing and scrooping, can either be carried out continuously or separately depending on the type of machine.

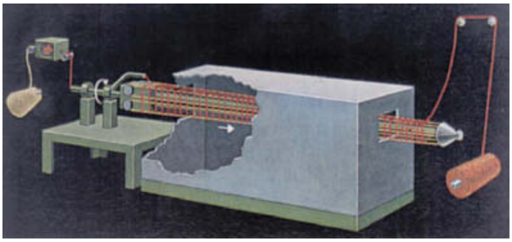

Fig. 19: The Hörauf process (by Bayer).

The Hirschburger process (Fig. 20) operates on the same principle as the Hörauf process, but in this process two threads can be wound simultaneously with one winding head. In the Hörauf process the beam is rigid, but in the Hirschburger system the beam rotates about its own axis. This method of construction means that no squeezing, vacuum extraction or jetting off of surplus liquor is necessary after liquor application. The winding head has three speeds of operation, adjustable between 600–1000 m/min. In this process the dwell time of the yarn in the steamer is also dependent on winding density, as well as the type and strength of the yarn.

The essential feature of the Spirovap space dyeing system (Fig. 21) is the perfect path of the plaited yarn along the conveyor belts. Up to 8 threads are plaited up in spirals on a perforated belt. A second belt covers the yarn from beneath at the turning point, so that the yarn

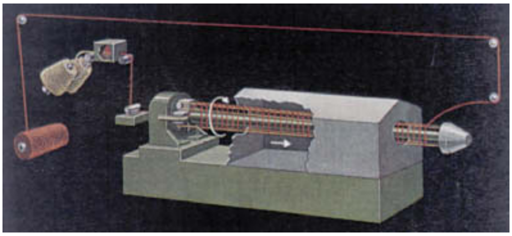

Fig. 20: The Hirschburger process (by Bayer).

is transported between two belts and any changes in direction will not affect the yarn. While the yarn is being transported in this way, it is printed from underneath with four print roller units. Next it is passed through the steamer, and the upper perforated belt is changed. There is a separate perforated belt for printing, and a belt for steaming. When the yarn has passed through the steamer it is rewound. The system has a maximum operating speed of 550 m/min.

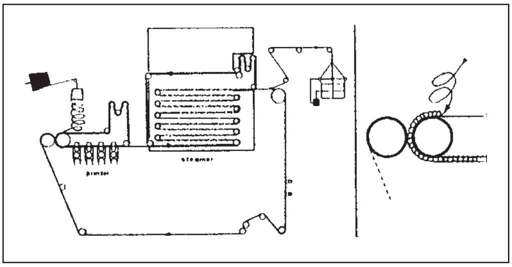

Fig. 21: A Spirovap space dyeing machine.

The Unispace process (Fig. 22) is used for treating manufactured garments as well as yarns in hank form or from a yarn package. 12 threads from the bobbin creel are fed simultaneously through the humidifying system, over the yarn plaiting device and piled up in layers to a certain height on a small printer's blanket. Once the yarn hanks have been treated they are spread out on the printer's blanket. For printing, the layer of yarn or fabric is fed slowly through the printing system (print saturator). The print saturator consists of print rollers that are equipped with several horizontally moveable jets, which are electronically programmed to charge the rollers with dye liquor. After spraying, the yarn is transferred from the print blanket to the conveyor belt, where it is plaited up and passed through the steamer. After the steaming process, the yarn is rinsed and squeezed off by a compressed air process. 12 threads at a time are plaited with a yarn plaiting device and then passed through the dryer. Finally the threads are rewound individually.

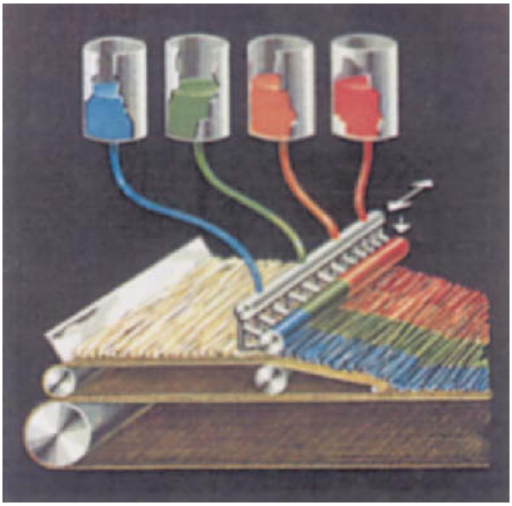

Fig. 22: The Unispace process (by Bayer).

V. Multi-colour effect on hank yarn: this can be achieved by using ombré dyeing techniques, for example. With this method, the first stage is to dye yarn hanks completely with the lightest colour shade, and then dip-dye them in a second dye liquor. The process can be repeated using a further liquor. Dye setting is done in the dye bath, since dyeing is done at boiling temperature. Usually two different colour shades are applied using this technique. Care should be taken that the boundaries between the individual colour shades are as sharp as possible, so that one shade does not blur into another. Ombré or shaded effects are highly dependent on current fashions and for this reason they only appear on the market from time to time, particularly in hand-knitted goods.

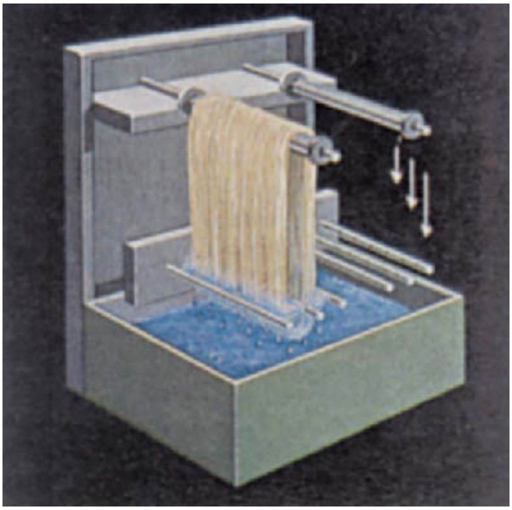

Fig. 23: The Hussong-Walker-Davis process (by Bayer).

The Hussong-Walker-Davis process (Fig. 23) is basically a mechanized version of ombré dyeing. This piece of equipment has several arms that can rotate about their longitudinal axis, upon which the yarn can be hung in hank form. Parallel with these arms, to the right and left of the hank, there are spray tubes that spray the almost boiling dye liquor through openings

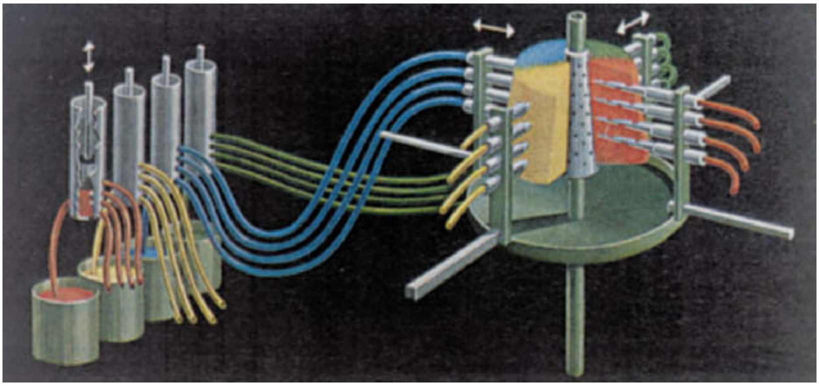

Fig. 24: The Astro-Dye process (by Bayer).

onto the yarn. The excess liquor drains off the yarn hanks and is caught in a liquor reservoir so that it can be routed round to the spray tubes. This sequence is repeated until all the dye has been taken up. The arms that hold the yarn hanks are adjustable in height, which means that the spray tubes reach a greater or lesser part of the lower section of hank. The dye is set in a way that is similar to the dye bath. Various different shades can be applied; however, the dye liquor must be changed each time. The yarn hanks on the arms are turned further by the interval defined previously, so that the second dye liquor can be sprayed on. This process is repeated until the hanks are completely covered. Self shades can also be created in this way, if the yarn is continually rotated past the spray tubes.

VI. Multi-colour effect on wound yarn packages: a specialist space dyeing technique has been developed by Astro Dye Works (Calhoun, USA). Using the Astro dyeing technique of injecting liquor into yarn reels (Fig. 24) it is possible to create variegated dyeing effects with a maximum of four different shades. The injection device consists of four star-shaped spars arranged at equal intervals around the winding, each having four vertically arranged perforated injection needles. In the dyeing process the injection needles, which are linked to the liquor containers via flexible tubes, are embedded in the reel and inject the dye liquor by means of compressed air. Depending on requirements, each of these 16 injection needles can be charged with one of the four dye liquors being used, which means that there is a wide spectrum of possible patterns. However there are certain tried and tested methods to achieve particular effects. The following requirements must be fulfilled if similar results are to be achieved:

- The yarn should be free of soiling.
- The cone should be tightly wound, in order to achieve the required capillary effect.
- The cones should be even in firmness and weight.
- Suitable dyes should be used, the important factors being good solubility and cold liquor stability.
- Exact metering of liquor.
- Suitable setting method, depending on fibre type and process.

Yarns dyed using the space dyeing method are characterized in particular by the fact that dyeing is truly random, i.e. the yarn is dyed at different points with varying intervals, without any regularity. There is no overall rigid design for the dye pattern. Textiles made out of this type of yarn also have an arbitrary effect (appearance), or there are colour zones at irregular intervals (colour image) of varying sizes (source: Bayer Colour Review).

Space printing As an analogy to the knit-deknit process (→ Space dyeing), this is a weave-deweave process or a lease-delease system (also used for yarn setting and bulking). A continuous warp yarn is woven on a loom without a shuttle, and on one side of the fabric a loop system is created. This method has advantages over the knit-deknit process: High production speed (approx. 1500 m of carpet yarn per min) and the fact that there is no yarn tangling.

Spacer Spacers are for supporting and sealing the yarn layers in yarn package dyeing.

Spark detection systems These are devices to protect against fire. They detect short visual impulses, caused by flying sparks, for example, and immediately implement appropriate action to combat the fire. Because of the risk level in a situation like this, they are combined with automatic fire extinguishing systems. Dry extinguishing substances such as halon or CO_2 are stored in accumulators in the middle or at the end of a textile processing chain. There are built-in radiation detectors in the feeder circuit, which provide constant monitoring of the duct and report passing sparks to the signal switchboard. In the event of an alarm, it shuts down the feeder ventilation system and triggers the dry extinguishers via a delay device.

Spark generation in electrical equipment Possible reasons for spark generation include: the insulation between two lamellae being worn (solution: short-circuit both lamellae and solder the problem area), the collector being out of true (solution: switch off or sand down), excessive revolution count, poorly centred anchor, damage to magnetic coils, using the wrong material for brushes, and a bad choice of lubrication for the collector. Solution: appropriate action must be taken on a large scale.

Spark quencher Spark quenchers extinguish sparks generated during singeing, which occur in pressure rollers, steam boxes or water immersion.

Sparta carpets → Isparta carpets.

Spatial formula → Configurational formula for spatial representation of chemical substances, using the → cis-trans- isomerism method.

Spau press Cold → Flat press.

SPC → Stored program control.

Special finishes on textiles Numerous special finishes have been developed in addition to the normal → Finishing process, due to the variability of fashion influences and higher quality requirements. Examples: anti-static finishes, anti-soiling finishes, burn-out printing articles, crush finishes, flame-retardant impregnation, embossing, anti-odour finishes, rubberizing (laminating), water-repellent finishes, non-crease finishes, crimped crêpe finishes, crepon printed effects, shrink-proof finishes, crêpe prepared by steeping in caustic soda, matt finishes, metallic finishes, moiring, moth-proof finishes, permanent finishing, pleating, friezing, sanforizing, slip-resistant finishing, anti-mould/rot/termite proofing, Si-Ro-Set process, brushed finishes, transparent and opal finishes, water-proofing, etc.

Specialist organizations → Technical and professional organizations.

Special soaps → Soap manufactured by saponificating alkalis, alkaline earths, ammoniac or amines, or by converting alkaline soaps with heavy metals. This type of soap is used for personal hygiene or for technical purposes.

Special washing agents These are for specialist washing processes and/or for certain textiles, such as detergents for coloureds, fine fabrics or wool, biological detergents, workwear detergents, detergents for institutional laundry and highly soiled laundry. They are also used in the commercial sector, where they are known as → System detergents. Special washing agents for fine and coloured fabrics do not contain any bleaching agents, and in many cases there are also no optical brighteners. Sometimes they contain cationic substances as well as non-ionogenic surfactants, which draw on the fibre during washing and result in an anti-static preparation as well as a scrooping effect in synthetic filaments. Cellulose ether, in particular, prevents dispersed soil particles from being reabsorbed by cellulose and synthetic fibres.

Special waste classification In line with a directive covering waste definition, there are specific requirements for waste of industrial origin that contain substances such as chlorinated hydrocarbons, because it is not possible to dispose of this type of waste with domestic waste. A company disposing of material containing solvent residues that have not been reprocessed has a basic obligation to identify them. It is particularly important to label any waste or residues with exact information. Hazardous waste is becoming very significant because disposal is so difficult, and because of the associated environmental dangers. Disposal takes place in incineration plants for hazardous waste or at hazardous waste disposal sites. → Waste management.

Special water consumption in open-width wet process plants can be calculated using the following equation:

$$\frac{\text{water consumption l/h}}{\text{fabric run kg/h}} = \text{l/kg}$$

Specific, essentially characteristic.

Specific action Suitable for a specific purpose, (usually) without any side effects; e.g. diastase action, where “specific” carbohydrates or proteins undergo water-soluble decomposition, with no side effects that damage the fibre.

Specific conductance Electrical → Conductivity of a cube with 1 cm edges made from the substance for which conductivity is being measured. Unit: S/m.

Specific gravity → Density.

Specific heat Heat energy in J (Joules) required to heat 1 kg of a substance to raise its temperature by 1°C.

Specific moisture content → Air humidity.

Specific pressure Linear pressure in relation to → Nip (during squeezing). The determining calculation with respect to liquor uptake is:

$$\text{specific pressure} = \frac{\text{squeeze pressure [bar]}}{\text{squeeze area [cm}^2\text{]}}$$

In order to calculate the specific pressure, the relationships between the roller cross section, the hardness and thickness of the roller covering, linear pressure and fabric speed must be known. If the roller has a smaller cross section, the specific pressure will be higher, and water removal will be more efficient to a certain extent. Hard, thin roller coverings made from soft rubber with a uniform thickness of 3–60 mm on low-diameter rollers, where specific pressure is low, are efficient at extracting water. The higher the fabric speed, the less efficiently water can be removed.

Specific strength → Tensile strength.

Specific water retention Quantity of solute water in relation to 1 g of → Dry-cleaning detergent. Specific water retention usually becomes lower as the concentration of dry-cleaning detergent increases (this tendency can reverse at a very high concentration).

Speckled → Mottled.

Speck printing The → Specks that are usually not required in printing are produced artificially by using encapsulated dyes, so that the resulting print profile consists of dots of equal sizes in a mono or multi colour way. This print effect can be carried out on various different types of fibre if suitable dyes are used, for example in transfer printing on polyester.

Specks,

I. Pitch tips or skin particles in wool.

II. In textile printing: dotted sprinklings in one or several colours of a colour way, usually caused by poorly dissolved or insufficiently dispersed dye, or print paste precipitation due to incompatibility of print paste ingredients, dye or thickeners. Specks can be produced deliberately in → Speck printing.

Specky print pastes Pre-mixed print pastes that instead of having even colour distribution are interspersed with little specks of dye known as colour specks.

Spectral Relating to the → Spectrum.

Spectral analysis Spectral analysis is based on the fact that each element has its own characteristic → Spectrum. This means that the presence of a particular element can be detected if its characteristic emission or absorption spectrum occurs. For this purpose equipment containing prisms is used, such as spectroscopes and spectrographs (with which the resulting spectrum can be photographed). Simplified spectral equipment can be used to carry out spectral analysis in the space of a few minutes, for instance to detect metal traces. Emission spectroanalysis provides accuracy levels of nearly 0.001%, and sometimes even greater accuracy can be achieved. This means that spectroanalysis is certainly a suitable method for identifying heavy metal traces in textiles, where this information is important and needed quickly. However, spectral analysis is rarely used in dye laboratories for dye testing. →: NMR Spectroscopy; Spectrophotometer.

Spectral colorimetry → Colorimetry.

Spectral colour density Physical measurement of → Saturation or → Depth of shade.

Spectral energy factor Corresponds to the level of → Reflectance.

Spectral lamps Small gas discharge tubes with oxide electrodes, in which metal vapours are caused to emit light. When the power is first switched on, only the inert gas glows. After sufficient heat has built up, when enough metal is present in vapour form, the inert gas ceases glowing, and a → Spectrum of metal appears that is easily activated. Sodium spectral lamps are supplied that run on alternating and direct current for colorimetric measurement. They produce almost monochromatic light, and any additional lines can be filtered out if required. Cadmium spectral lamps are constructed in a similar way, and are usually used for standard optical measurements because of their sharpness and intensity. The green and blue cadmium lines in conjunction with the red ones in → Spectrophotometer measurement form an ideal complement to mercury lines produced by frequently used mercury lamps (→ Ultraviolet lamp).

Spectral line The wavelength range resulting from the absorption or emission of light, for example for mercury there is the so-called mercury line 2536, which corresponds with the light emitted by a mercury atom on the same wavelength. The spectral colour is the (monochromatic) light of uniform wavelength defined by single spectral lines, on the basis of which the true colour valency of additive colour compounds should be identified.

Spectrofluorimeter → Blocking filters.

Spectrophotometer Instrument used for → Colour measurement according to the spectrophotometric principle (Fig. 1). The wavelength used to measure the reflectance or transmission can be continually changed. Either the whole reflectance curve is recorded or point measurements are taken at selected wavelengths depending on the automation. Prisms or diffraction gratings are used as monochromatic filters.

I. Non-fluorescent samples: the reflectance is measured as a ratio of the energies reflected from the sample and a white standard at the same wavelength. This ratio is independent of the light source. The standard colour

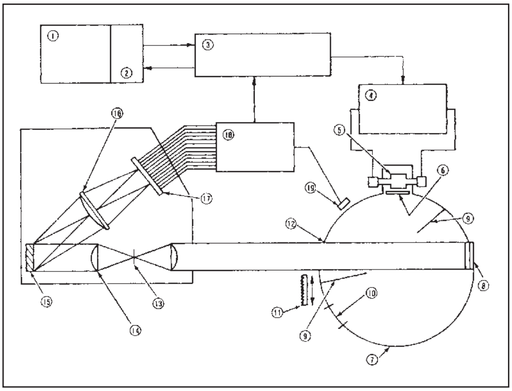

Fig. 3: The light path in a spectrophotomer with xenon flash and diffraction grating with no moving parts.
Diagram of measuring head d/8° MS 2020: 1 = keyboard and display; 2 + 3 = microprocessor; 4 = flash activation circuit; 5 = xenon flash; 6 = D 65 conversion filter; 7 = sphere; 8 = sample; 9 = deflector; 10 = mirror point; 11 = beam switch; 12 = observation point; 13 = entry slit; 14 = collimator lens; 15 = diffraction grating; 16 = condenser; 17 = silicon detector; 18 = electronics; 19 = reference detector.

values X, Y and Z are calculated from the reflectance curve for a chosen light source and observer. Application: for all purposes for which either the reflectance curve without standard colour values X, Y and Z (such as colour formulation calculations using dye selection, the evaluation of colour in artificial light and colour intensity comparisons, etc.) is sufficient or a high level of accuracy is required (necessary standard colour values X, Y and Z in depth of shade comparisons or colour differences on metameric pairs of samples are better calculated by using the reflectance curve rather than by measuring directly in a three-filter photometer). The path of the light ray in spectrophotometers is shown in Figs. 2 and 3.

II. Fluorescent (optical brightener) samples: measurement conditions:

1. The reflectance value is dependent on the spectral distribution of the light source. For this reason, the distribution must include the long-wave part of the UV range.
2. Polychromatic measurement set-up: the sample must be placed between the light source and the monochromatic filter as the fluorescence can only be properly excited by exposing the sample to the whole spectrum. Non-fluorescent samples can also be measured using a monochromatic arrangement (i.e. with the sample placed between the monochromatic filter and the detector).

Spectrophotometer, filter type Instrument used for → Colour measurement according to the spectrophotometric principle. Instead of one continuously operating monochromatic filter, a → Spectrophotometer has a large number of filters for particular wavelengths. The reflectance curve can therefore only be measured at the number of points corresponding the number of filters in the instrument. Narrow-band interference filters are used as monochromators and, in rarer cases, interference overlap filters. The number of filters ranges from 16–31 distributed at regular intervals over a range a 400–700 nm. Knowing the reflectance for a minimum of 16 wavelengths is sufficient for many applications.

Spectroscopy,

I. Nuclear Magnetic Resonance Spectroscopy (→ NMR spectroscopy) is used for routine monitoring of the chemical structure, configuration and purity of compounds. A prerequisite for this technique is that the sample must be soluble in deuterated solvents at room temperature.

II. Electron-Spin Resonance Spectroscopy (ESR spectroscopy) is a high frequency spectroscopic method used for examining paramagnetic compounds. This analytical method supplies information about the structural characteristics of radicals such as those which may be formed as a result of external effects, for example radiation and temperature. Using ESR spectroscopy, it is possible to investigate the chemical changes which occur during radiation or thermal treatment of polymers or textiles.

III. Infrared and raman spectroscopy supply information about molecular oscillations and can be used to elucidate the structure of compounds as well as supplying qualitative and quantitative evidence of chemical changes. The range of application has significantly widened particularly because of the development of the FT technique (Fourier-Transform Infrared and Raman Spectroscopy). In recent years, the application of FTIR spectroscopy has been especially successful in the following areas:

– elucidation of the chemical modification of fibres and other materials caused by finishing, radiation and weathering processes;
– examination of the uniformity of radiation treatments, softener applications and coatings, etc. on various substrates (such as natural and synthetic organic polymers and inorganic minerals and rocks).

In addition, various recording techniques are used depending on the sample material and approach to the problem:

– The recording depth during surface analyses can be varied between the limits approx. 10 and 0.1 µm by measurements using attenuated total reflection (ATR).
– Transmission measurements can also be performed on viscous materials with good reproducibility using the optical anvil diamond cell in the measurement.
– The crystallinity and orientation of polymer materials can be determined by using polarised light.

In addition to these, photoacoustic spectroscopy, FT raman spectroscopy and measurements for micro and emission infrared spectroscopy are also available.

IV. Fluorescence spectroscopy: computer-controlled recording luminescence spectrometers can be used to measure fluorescence, phosphorescence, chemiluminescence and bioluminescence. Apart from this, the fluorescence polarization option also allows examination of the rotational movement of molecules in solution.

V. Scanning photometric microscopy is a measurement technique which can be used in carrying out spectral analyses on microscopically small objects (such as textile fibres or fibre cross sections). Using → Photomicroscopy, it is possible to detect dyes, UV absorbent or fluorescent substances among other substrates, and the absorption and distribution of dyes among other substances can be determined in fibrous materials. Knowledge of the dye absorption and the distribution on, or in textile fibres provides a glimpse into textile dyeing processes and systematic analyses make it possible to optimise the dyeing formulations.

VI. X-Ray photoelectron microscopy (XPS) is a method used to determine the elements and their bonding states in the surface of solids (the recording depth is a few nanometers). The advantages of this analytical method, (almost free of interference, reliable bond data and the possibility of quantitative measurement) particularly apply to natural fibres and synthetic fibres. The following are examples of applications of the method:

– verification and identification of surface coatings,
– examination of changes resulting from surface treatment or ageing,
– recording of depth profiles (in combination with a method involving the removal of material; ion-sputtering or mechanical erosion in UHV).

VII. → Atomic absorption spectroscopy (AAS): the atomic absorption spectrometer is used for heavy-metal analysis. The instrument is equipped with various atomising devices which are used for example, in flame and flameless atomisation in a graphite resistance furnace.

Spectrum The spectral lines or → Light wavelengths resulting from the splitting of light. This concept communicates itself to other physical phenomena. There are optical spectra (in the visible wavelength range), infrared, ultraviolet and x-ray spectra depending on the range of wavelengths covered by the spectral lines. In each case, they are distinguished by:

1. Lines or discontinuous spectra (composed of many individual coloured lines which, when photographed, appear as dark stripes).
2. Band spectra (composed of groups of many individual line bands crowded within the range of black or almost black = band head).
3. Continuous spectra (e.g. the continuous rainbow spectrum of sunlight).
4. Emission spectra (of luminescent substances or substances which emit light when excited, consisting of coloured lines, bands or a continuous coloured spectrum appearing on photographic plates as pale and dark areas).
5. Absorption spectra (are incomplete, i.e. thin bands or lines are missing in the spectrum to give a characteristic pattern - the absorption spectrum is like a negative form of an emission spectrum (for example, when white light passes through a cupra ammonium hydroxide solution, the yellow and orange parts of the absorption spectrum are missing).

Spectrum locus → Chromaticity diagram.

Speed In physical terms, speed is the distance covered divided by the time taken for it to be covered ($v = s/t$) measured in m/s or km/h. Textile finishing machines are differentiated from each other by:

I. the production speed, where the fabric speed is measured at the exit (in m/min.)

II. the nominal speed or max. production speed (according to DIN draft 64).

III. the differential speed or the difference between the local fabric speed and the production speed as a percentage of the production speed, e.g. forward slip on a shrinkage line.

Speed indicator → Tachometer.

Speed measurement of yarns and fabrics In many processes, the speed of textile materials has a significant effect on product quality. Speed measurement is also suitable for the open-loop or closed-loop control of processes. Examples of measurement applications are:

- movement of fibres in an air stream,
- processing of fibre slivers,
- speed of filament and fibre yarns,
- speed of nonwovens, knitwears and fabrics.

The speed signal can also be used for measuring length, for example, the length of yarn from the package and the length of textile webs. The classical mechanical length and speed measurement methods operate using measurement pickups, the accuracy and reliability of which, in many cases, is insufficient. The measurements are mainly affected by two types of error:

1. Surface errors result from the penetration of the measurement wheel into the often soft surface which is being measured because the contact pressure is too high. In this case, the measurement wheel is picking up the length of the bow in the surface resulting from the contact pressure so the length of the test material corresponds to the chord of this arc. The measurement errors which result are positive. Especially in the case of sensitive surfaces, damage may result or at least undesirable effects which reduce the value of the goods.
2. Slippage errors result from insufficient friction between the measurement wheel and the goods being measured which gives rise to slipping between the surfaces. The wheel slippage has a series of effects, the errors from which, are in many ways, not reproducible.

With the development of micro- and optoelectronics as well as laser technology which took place at the end of the sixties, an extensive amount of research work was devoted to this area. These methods are contactless and do not give rise to the sources of error found using the mechanical speed and length measurement techniques. Suitable marks can be applied at regular intervals to the test surface for measurement of speed and length using contactless sensors. The number of marks passing the measurement site gives the length of material and this, in relation to the period of measurement, can then be used to determine the speed. It is also possible to measure the length and speed of moving objects using a contactless method without adding the marks. There are four different methods available for this approach.

The Doppler method makes use of the effect produced by a moving object of reflecting an electromagnetic or sound wave at a different frequency to that of the wave, before meeting the object. The amplitude of the frequency is directly proportional to the speed of the object. In the case of the laser-reference beam Doppler method (Fig. 1) the light emitted by the laser is split into a reference beam and measurement beam by a beam splitter. The measurement beam meets the moving surface at a velocity v and is reflected as diffused light. The scattered light at the new frequency is collected via a lens and superimposed on the reference beam reflected from a mirror (→ Laser Doppler Effect). The resulting pulse signal gives rise to fluctuations in intensity which are then recorded. The speed is obtained by counting the Doppler oscillations. With a differential laser Doppler method, the light emitted by the laser is split into two beams which are intersected again at the surface of the moving test material. Superimposing the two signals with displaced frequencies produces a pulse which a photodetector records as intensity fluctuations. The pulse frequency is directly proportional to the surface speed.

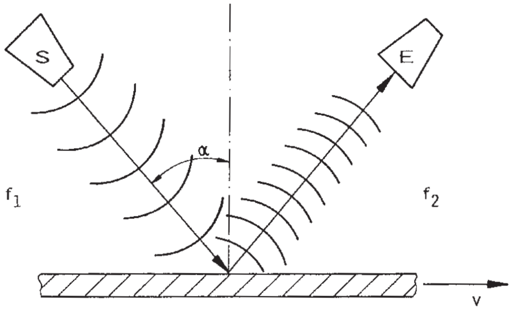

Fig. 1: Principle of the Doppler method for speed measurement.

With the interference (Speckles) method (Fig. 2), a laser beam reflected from a rough surface shows intensity inhomogeneities which are caused by interference phenomena (so-called "granularity"). If the object is moved, the light pattern also. When the moving light pattern is observed using a diffraction grid, an alternating frequency appears which is proportional to the speed of the object.

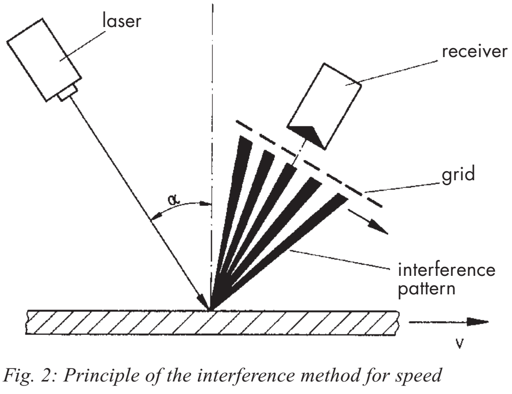

Fig. 2: Principle of the interference method for speed measurement.

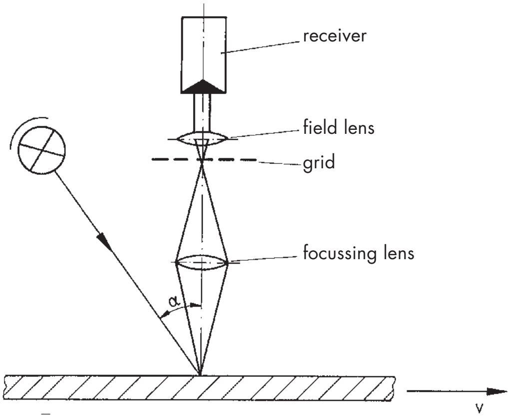

Fig. 3: Principle of the local-filter method for speed measurement.

In the case of the local-filter method (Fig. 3), the light (coherent or incoherent) reflected from a stochastically rough surface is allowed to fall through an optical grid, with the slits aligned vertically to the direction of motion, and the beam is summated accordingly. As the surface moves, a signal is produced yielding a spectrum which has a frequency proportional to the speed.

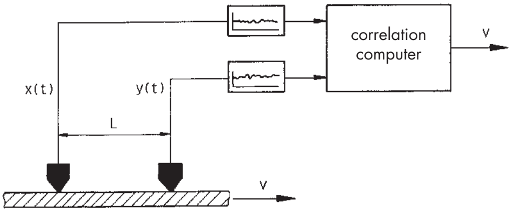

Fig. 4: Principle of the correlation method for speed measurement.

The correlation methods (Fig. 4) use the stochastic fluctuating characteristics of the test object (such as the surface structure, degree of reflection and diameter of electrostatic charge), which are otherwise perceived as disadvantageous, as marks for the speed and length measurement. The correlative speed measurement is based on the measurement of the time required for a certain test material to pass between two sensors arranged one after the other at a distance L in the direction of motion. The two sensors produce the signals x(t) and y(t). Ideally, both signals are of identical shape and are only displaced towards each other by an amount equal to the running time Δt.

$$y(t) = x(t-\Delta t)$$

If a cross-correlation of the two signals is now used to determine the time shift $\tau = \Delta t$, then the speed of the test object can be found from the relationship $V = L/\tau$. (according to Wulfhorst).

Spent fish or train oil → Tanning.

Spermaceti The fat of species of whale, scaly, crystalline, purified white, greenish white transparent, fracture appears like mother of pearl, glossy. So-called synthetic spermaceti (in most cases hardened sperm oil): friable; weak smell (unlike train oil) greasy; poor quality: harder, resembles stearin. Adulterated: frequently by stearin (harder, fine crystalline structure). Melting point: 42–54°C. Solubility: soluble in 7 parts hot or 35 parts cold alcohol; freely soluble in ether and chloroform, etc.; slightly soluble in petroleum spirit; turns pale yellow and rancid after prolonged boiling (calcium carbonate addition). Unsaponifiable matter 49–54%. Use: sizes and finishes, etc.

Spher- (Gk.: spaira = sphere; circle), ball-shaped.

Spherical float Controller for → Steam trap.

Spherical molecules → Colloid.

Spherocolloids → Colloid.

Spherulites Spherical or toroidal shape crystalline structure in high polymers composed of groups radiating from a point. Usually small but easily recognizable under a polarization microscope, where the illumination of each cell is restricted by a dark interference cross. They are caused by “inhomogineities” and arise e.g., while the liquid phase cools down. They are in most cases undesirable in synthetic fibres. They are not always a problem in coarse fibres but slightly impair the strength of fine fibres (fibre fracture) and impart a light coloration.

S-phrases (safety phrases). Safety instructions for the handling of hazardous substances (in Germany, in accordance with the ArbStoffV – Arbeitsstoff Verordnung – Working Materials Ordinance) in accordance with EC directives. In each case, the phrase is assigned a number or number combination for the substance in question, for example, S 36 = Wear suitable protective clothing (standard phrase). → R-clauses.

Spider silk Product of silk spider (Madagascar). Without silk glue. Extremely light. Strength, glaze and elasticity similar to genuine silk but finer.

Spin dyeing → Mass coloration.

Spin finishes “Oiling agents” consisting of oils or fats and surfactants the behaviour of which, depending on the task in hand and composition, comes somewhere between textile lubricants and textile softening agents. The finish should give the fibre a glaze which is adjusted to the preparation process. It also suppresses the build-up of electrostatic charges on the fibres and produces a certain degree of thermal protection at the same time. Finishes which are suitable for these requirements should be simple to handle and easy to dissolve or emulsify. They should wet as spontaneously as possible and spread well on the fibre surface. They must be physiologically and ecologically harmless and not corrode metals, plastics or other operating materials.

During the manufacture of synthetic fibres, auxiliary agents are applied to the filament yarn during spinning, imparting to it the properties needed for processing. These fibre spin finishes, the composition of which is known only to the supplier of the auxiliary agent or the filament-yarn manufacturer, are usually water-based systems and are applied to the synthetic fibres at a rate of 0.1–1.0%, by weight. Spin finishes used in industry in fibre manufacture are, as a rule, multi-component systems which may contain the following constituents depending on the type of fibre and the task in hand: adhesives or lubricants, emulsifiers, wetting agents, fibre finishing agents, antistatic agents, moistening agents, bactericides and anticorrosive agents among others. At 40–70%, lubricants make up the main part in the mixture. Taken together, the emulsifiers, fibre finishing agents and the antistatic agents almost make up a complete spin finish up to a few percent. Here, mineral and ester oils act as lubricants although other components such as emulsifiers and surfactants may also have friction-reducing properties. The function of the fibre finishing agents, i.e. of holding the individual filaments together in the yarn, is specifically fulfilled by castor oil ethoxylates or sarkosides. The emulsifiers perform the necessary dispersal of hydrophobic components in the water-based system for the application, with alkylphenyl and alkyl alcohol ethoxylates being regarded as the most important surface-active substances. All ionic or polar substances, such as the alkali and ammonia salts of organic and inorganic acids or amine oxides, act as antistatic agents.

Knowledge of the effectiveness of the individual classes of substances named, i.e. the association of their chemical structures with certain functions and the application of a spin finish makes it possible to target the developing new spin-finish systems to their application. However so far, no results are known to have been acquired of the relationship between application behaviour and the effectiveness of a finishing preparation, which point to a relationship between the structure and the physical properties of a practical preparation, on the one hand, and the preparative effectiveness of this "aqueous auxiliary agent preparation" on the other. Especially in the light of filament-yarn manufacture using increasing spinning speed, particularly good take-up, distribution and adhesive properties on the filaments are required. The physical state and the physical properties of the water-based spin-finish preparations are decisive in satisfying these requirements. Small amounts of side products which cannot be considered safe in terms of their toxicity, at least in the case of not-particularly refined grades of mineral oil, and the restriction on the loading of effluent with these relatively slowly broken down mineral oil fractions, lead to a limitation in their use, especially in Germany, if not indeed to a total ban in future on the resulting hydrocarbons in effluent.

Thermostable, easily biodegradable emulsified ester oils represent a compromise. However, in the case of heating processes such as drawing or fixing, problems arise due to uncontrollable cracking reactions leading to the formation of residues in, for example, the texturizing heater. Further development has led to the use of special polyalkeneglycolethers. These products which are generally described under the collective term EO/PO products, represent a large proportion of modern texturizing spin finishes. A range of viscosities which have a favourable level of friction for the texturizing process, is obtained by selecting a series of base products with graded molecular weights. These types of spin finishes are characterized by a high lubricant-film stability, high thermal stability and the formation of the least amount of cracking residues. A serious disadvantage of these products is their low susceptibility to biological decomposition. The statutory requirements being prepared in Germany with regard to the biodegradability of textile effluents (biodegradability > 80% in the OECD simulation test) has forced the development of product alternatives which are more favourable in terms of their toxicological effects on the ecology. Starting from the idea that an appropriately high molecular weight is necessary to achieve both good lubrication properties and sufficiently high thermal stability and that the resulting viscosity of the spin finish systems largely determines the level of friction, certain sizes of molecule have to be obtained. On the other hand, it must also be taken into consideration that for cracking behaviour to be favourable over the whole molecule, potential cleavage sites must be incorporated evenly and, in order to achieve a high level of biodegradability and physiological safety (skin tolerance, etc.), functional groups which are relatively easily attacked biologically (e.g. by hydrolysis) must be introduced while enlarging the molecule. Here, carbonyl groups are available for use as links. Compounds are formed in this way to give the following polyether/ester structure:

$$R_1(-O-\underset{\underset{R_2}{|}}{C}-C)_n[-O-\underset{\underset{O}{\|}}{C}(-O-\underset{\underset{R_2}{|}}{C}-C)_m]_z-O-\underset{\underset{O}{\|}}{C}(-O-\underset{\underset{R_2}{|}}{C}-C)_n-O-R_1$$

R_1 = linear or branched, saturated or singly unsaturated alkyl residue with 3–22 C atoms
R_2 = hydrogen or low alkyl residue with 1–2 C atoms
n = total number from 0–10
m = total number from 4–16
z = total number from 0–3

Freely water soluble, self-crosslinking thermostable products are obtained with lubricating properties and good cracking behaviour. These base products biodegrade well and skin-tolerance tests have shown that due to the ester structures formed, skin irritation is no longer observed in the case of the starting products (EO alkyl alcohols). With a result of 95% from the OECD simulation test, the biodegradability of the classes of substance described must be considered high and therefore comply with the strictest requirements in contrast to EO/PO-based lubrication components of similar molecular weight. The sum of aquatoxic test parameters such as fish, bacteria and daphnia toxicity leads to the conclusion that these are less aquatoxic than comparable groups of surfactants with similar surface actions or wetting properties, such as certain alkyl alcohols x EO, sulphosuccinic acid esters or alkyl sulphonates with LC_{50} of 1–10 mg/l. With an ascertained toxicity of $LD_{50} > 5000$ mg/kg, these products are categorised as non toxic. The high skin tolerance may be regarded as another advantage as a large number of other surfactants used as spin finish components are evaluated as “skin intolerant”.

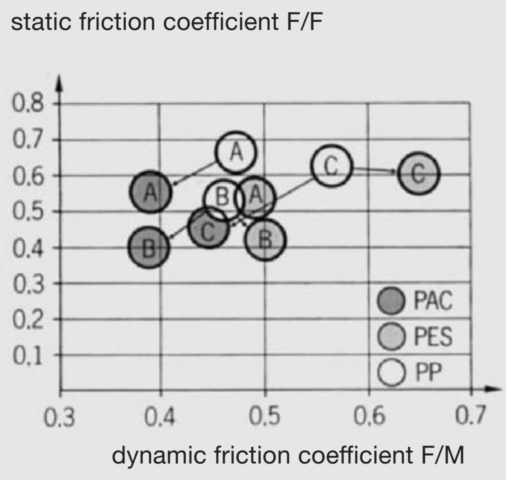

Fig.: Diagram showing the adhesion /slippage behaviour of various finishes (A–C) by the arrangement of frictional locations within the smoothness nomograph.
A = fatty acid polyglycol ester; B = phosphoric acid ester; C = fatty acid amidoamine; PAC = polyacrylonitrile; PES = polyester; PP = polypropylene.

A not altogether problem free representation of the adhesion/lubrication behaviour of spin finishes is offered by the assignment of friction sites in the so-called smoothing monogram (Fig.). In this, the fibre-fibre friction measured within the speed range of a few mm/min is delivered via a dynamic fibre-solid coefficient of friction (usually thread-metal at around 100 m/min). As a rule, the measurements are carried out on filament yarns using, for example, the Rothchild F meter under standard atmospheric conditions. Although the diagram offers no information on the effects of fibre crimping, spin-finish additives or climate, it can be used for comparative assessments.

The diagram shows the friction sites of different spin finishes as circles. The friction effects produced by the same spin finishes vary from fibre to fibre. A no less important criterion for the workability of, for example, polypropylene spun fibres is the potency of the antistatic effect of the spin finish. Dynamic testing methods are frequently used for the measurement of a charge on the fibre substrate immediately after a process involving friction, e.g. on the running card. The charge can be reliably recorded after spinning using an electrostatic induction voltmeter. Defined climatic conditions are a prerequisite for reliable results.

Spin finishes have a large influence on the processing of synthetic fibres for needle-punched felt. These type of nonwovens are encountered in a large number of different applications, for example, in floor coverings and wall coverings, car furnishing fabric (boot and parcel shelf), lining materials, geo-non-wovens (road building and landscape gardening) as well as blankets. The problem, which cannot be solved by mechanical means or choice of fibre alone, presents fibre spin-finishing with important tasks: reducing needle resistance forces, increasing non-woven density, reducing fibre damage and facilitating neater structure formation during pol needling in loop and velour production (according to Veitenhansl, Winck and Herlinger).

Spindle,

I. Device on spinning and twisting machines for holding packages and the like for imparting a twist to or roll-batching yarn.

II. → Hydrometer.

III. Threaded shaft for the transmission of turning motion.

Spindle cells Inner cell layer accounting for the largest proportion of matter in → Wool structure.

Spindle crown → Spinning cake.

Spinnability of wool Spinnability is improved when wool is dyed at the isoelectric point, i.e.

- lower losses at the setting, less attack at the combing noils on recombing, less suction waste on the ring-spinning frame, i.e. a total of around 0.5–4% (worsted yarn: 2%; carded yarn: 3.5%) higher yield,
- improved run properties of the slub yarns and fewer yarn breaks during ring spinning.

Spinning Formation of yarns or threads from fibres.

I. Natural fibres: three stages depending on the type of fibre and properties:

1. Aligning the (loosened and mechanically pre-

cleaned) fibres in parallel to form a sliver (combed top; card sliver) or slub-yarn threads, pulling out and drawing.
2. Twisting to form the threads or yarn.
3. Winding up to form the hank or package or something similar.

→ Spinning processes for staple fibres.

II. Man-made fibres: fibre formed by passing the spin solution or dope through spinnerets (with numerous fine holes) into a regenerating bath which causes the fibre to harden (wet spinning) possibly stretching the fibre at the same time (stretch spinning) or the fibre may be hardened by evaporating the solvent (dry spinning). Different synthetic fibres (such as polyamide) are spun from a melt and then stretched (→ Melt-spinning process). → Spinning processes for man-made fibres.

Spinning bath additives Used during the spinning of man-made fibres:

1. To improve the spinnability and, if necessary, to modify the properties of the spun product (→ Modifier). Spinning bath additives for the spinning solution are surfactants or preparations made from surfactants, e.g. sulphonated oils, alkyl sulphates, aliphatic acid condensation products of alkyl amines and onium compounds. Spinning bath additives for spinning melts are chiefly pigments (dye pigments and delustring agents), optical brighteners, antioxidants and light-stability agents.
2. To clarify spinning baths and prevent build-up at the spinnerets and spinning-bath pipework. These are surfactants or preparations made from surfactants, e.g. sulphonated oils, alkyl sulphonates, aliphatic acid condensation products, oxalkylation products of alkyl amines and onium compounds.

Spinning cake (spindle crown), a yarn package which has been spun according to the centrifugal or so-called can or pot spinning method (rotating pot resulting in the shape of a ring-shaped cake with the characteristic hole in the centre. These slightly conical spinning cakes occur in different sizes but they are always in the form of compact blocks of yarn tightly wound in almost parallel layers.

Spinning lubricants (spinning oils),

I. Combinations of mineraloil based chemicals with the addition of lubricants, antistatic agents and emulsifiers, etc. used for the fault free running of spinning and stretching processes for synthetic fibres. Spinning oils must be removed before dyeing as they, or their residues, will have an effect on the levelness of dyeing. Not to be confused with → Coning oils.

II. Suitable additives are added to the spinning solution instead of applying the spinning oil to the filament afterwards.

III. Lubricating agents applied to natural or man-made fibres depending on the type of → Textile lubricants which ensure stretching and spinning in all spinning-mill operations. The preferred raw materials are surface-active polar compounds derived from aliphatic alcohols and aliphatic acids. Their chemical nature allows them to be easily removed during the wet processes which follow and makes them ecologically compatible. A modified spinning oil has been successfully used in dust control during cotton spinning. → Spin finishes.

Spinning preparations → Spin finishes.

Spinning preparations for friction texturizing Preparation problems mostly arise in association with changes to yarn titre or speed. With high machine speeds, the usual mineraloil- and esteroil-based spinning preparations, problems have not increased. Particularly in regard to thermal stability, the more recent spinning preparations are differentiated according to two principles:

I. Substances which change under the influence of heat by decomposing rather than melting and are then extracted in the form of gaseous products (such as carbon dioxide, carbon monoxide, aldehydes and water vapour).

II. Thermally stable products additional to the fibre surface with high adhesion, and which may be in the compound itself or can be applied by so-called bonding agents.

Spinning preparation for high polyester and polyamide delivery speeds are:

a) Spinning preparations for the magnetic spinning process:

– mixtures of mineral oils and ester oils such as butyl stearate as the lubricant

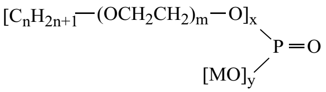
$C_{17}H_{35}–COO–C_4H_9$ *butyl stearate*

– emulsifiers and antistatic agents

$C_nH_{2n+1}–CO(OCH_2CH_2)_m–OH$ *aliphatic acid ethoxylate*
n = 9–17, m = 4–12

$C_nH_{2n+1}–(OCH_2CH_2)_m–OH$ *aliphatic alcohol ethoxylate*
n = 8–16, m = 4–12

$C_nH_{2n+1}–SO_3M$ *alkylsulphonate*
n = 14–17; M = Na, K, amine



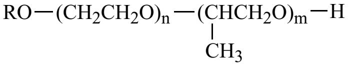
$$\begin{array}{l}[C_nH_{2n+1}{-}(OCH_2CH_2)_m{-}O]_x \\ \qquad\qquad\qquad\qquad \searrow \\ \qquad\qquad\qquad\qquad\quad P{=}O \\ \qquad\qquad\qquad\qquad \nearrow \\ \qquad\qquad\qquad [MO]_y\end{array}$$

phosphoric acid ester
n = 6–18, m = 0–10
x = 1–3, y = 3–x
M = Na, K, amine

b) Spinning preparations for friction texturizing:

– mixtures of co-polyethylene oxide polypropylene oxide alkanols with random distribution and as block copolymers

$RO–(CH_2CH_2O)_n–(CH_2CH_2CH_2O)_m–H$



$$RO-(CH_2CH_2O)_n-(\underset{CH_3}{\underset{|}{C}}HCH_2O)_m-H$$

- mixtures of aliphatic acid and aliphatic alcohol ethoxylates

$C_nH_{2n+1}-CO(OCH_2CH_2)_m-OH$ *n = 9–17, m = 4–12*

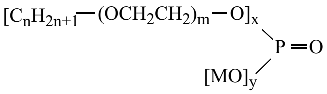
$C_nH_{2n+1}-(OCH_2CH_2)_m-OH$ *n = 8–16, m = 4–12*

- endbonded aliphatic alcohol ethoxylate

$C_nH_{2n+1}-(OCH_2CH_2)_m-OR$ *n = 4–12, m = 4–15; R = alkyl group*

c) Spinning preparations for magnetic and friction texturizing:

- specifically phosphoric acid esters



$$\begin{array}{l}[C_nH_{2n+1}-(OCH_2CH_2)_m-O]_x \\ \qquad\qquad\qquad\qquad\qquad\quad \searrow P=O \\ \qquad\qquad\qquad\qquad [MO]_y \nearrow \end{array}$$

n = 6–18, m = 0–10; x = 1–3, y = 3–x; M = Na, K, amine

- mixtures of aliphatic acid and aliphatic alcohol ethoxylates

$C_nH_{2n+1}-CO(OCH_2CH_2)_m-OH$ *aliphatic acid ethoxylate n = 9–17, m = 4–12*

$C_nH_{2n+1}-(OCH_2CH_2)_m-OH$ *aliphatic alcohol ethoxylate n = 8–16, m = 4–12*

In the spinning mill, these concentrates are applied as emulsions or solutions (above or underneath the discharge duct near to the winding machine), either using conventional rotary preparation rollers (usually sintered ceramic) or by means of jets.

Spinning processes for man-made fibres differ according to whether they are melt-spinning, wet spinning, dry spinning, gel spinning or dispersion spinning. Wet-spinning processes are expensive to use and dry spinning processes are expensive in terms of investment. Melt spinning is the most economic method:

I. Melt-spinning: the polymer chips are placed in a spinning pump. The melt is forced out through spinnerets and the threads cooled in the air. The threads are drawn at a rate of 1000–6000 m/min. Melt spinning can only be carried out on thermostable and fusible polymers (thermoplastics). Polyamide, polyester, polyolefins and glass fibres can be spun depending on the process. →: High-speed spinning; Microfibres.

II. Wet spinning: this method is used for polymers which decompose on melting. 5–25% solutions are forced through spinnerets by means of a spinning pump. The threads are coagulated in a regenerating bath and stretched in a stretch bath. The method operates with drawing speeds from 50 to 100 m/min. The cost of recovering the solvent makes this method expensive. Viscose, cupro- and polyvinylalcohol fibres are drawn using this method.

III. Dry spinning: In this case, 20–45% solutions are used. After leaving the spinnerets, the threads enter a 5–8 metre channel in which they are blasted with a counter current of hot air so that the solvent evaporates. This method allows drawing speeds up to 300–500 m/ min. Only polymers which dissolve in volatile solvents can be used. The method is used with polyacrylonitrile (25% in dimethylformamide), chlorinated polyvinylchloride (45% in acetone) and cellulosetriacetate fibres (approx. 20% in dichloromethane).

IV. Gel spinning: 35–55% solutions are used with this method. Because of the low solvent content, the shape of fibres produced is very stable. The drawing speed is around 500 m/ min. Polyacrylonitrile and polyvinylalcohol fibres are spun using this method.

V. Dispersion spinning: this is a special process for insoluble and non-fusible polymers. Inorganic polymers are added to the dispersions of the polymer to be spun in order to raise the viscosity and stabilise the fibre. After the thread has been formed, this polymer is burnt off while the polymer particles forming the fibre fuse together. This process is used to spin polytetrafluoroethylene fibres.

All spinning processes run in four stages, according to the same scheme. The first stage involves extruding the spinning solution or fluid through a spinneret, the lengths of the threads produced being controlled by their spinnability. During the second stage, the threads begin to harden while internal stresses are equalized. The still semi-fluid threads pre-stretch under their own weight in the third stage while the chains are already becoming weakly aligned. During the fourth stage, the threads are finally stretched and achieve their final characteristic properties (strength, etc.).

The ability to form long continuous threads varies with the material. For any given material, the achievable fibre length depends on the viscosity η of the fluid and speed v of the spinning process. The length L of the fluid fibre goes through a maximum as the product $v \cdot \eta$ increases. The maximum achievable fibre length is called the spinnability. It can be seen from the curve $L = f(v \cdot \eta)$ that the spinnability is controlled by two processes: cohesive failure and capillary failure. A certain amount of elastic energy can be stored in every viscoelastic fluid. Among other things, this phenomenon leads to the Barus effect. When a certain value has been exceeded, the fibre breaks due to cohesive failure. This fracture process has derived its name from the fact that it depends on the cohesive energy of the material as well as the viscosity of the fluid, the speed of the process and the modulus of elasticity. The capillary fracture is the fusion fracture and is dependent on the surface tension as well as viscosity and speed. The mechanism which sets in earlier, leads to fracture. For this reason, the optimum value is sought for L for any particular value for $v \cdot \eta$.

The function $L = f(v \cdot \eta)$ has the following consequences: if the speed and/or viscosity during spinning is too low then a capillary fracture will result. The fibre disintegrates into individual droplets. Viscosities which are too low occur, for example, when the solution is dilute or if the spinning temperature is too high. A cohesive fracture on the other hand occurs when the relaxation times are too long, which happens, for example, when molecular weights are high or when gel formation during wet spinning is too rapid. Cohesion fracture is brittle fracture (according to Elias).

Spinning processes for staple fibres Unlike the conventional ring-spinning frame, which has 6 or 3 process stages in its optimized form, the non-conventional spinning processes for producing rotor-spun yarns, air-jet-spun yarn, friction yarn or covered yarn manage with fewer process stages (Tab. 1).

Tab. 1: Ring and rotor spinning processing sequences.

Each one of the five processes mentioned is characterized by a special principle in fibre bundling and the respective method of applying the twist which results in the different yarn structures producing the characteristic properties of the spun yarn.

I. Ring spinning frame: due to the good fibre guidance system, this method is capable of processing practically all fibres within a wide range of titres. The ring-spinning frame is therefore very flexible. The high yarn tension and control of fibre orientation during spinning means that ring-spun yarns are firm and even (Fig. 1). Only when the proportion of short fibres is high is the uniformity of the yarn not at its optimum.

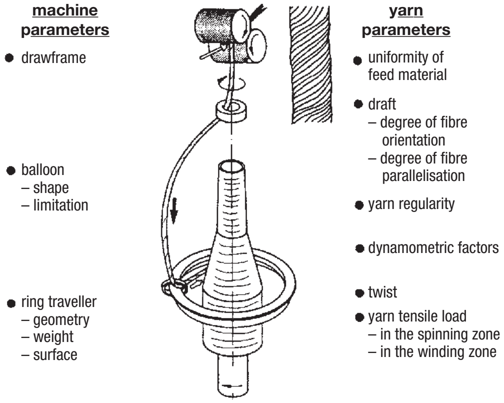

Fig. 1: Parameters affecting quality and ascertainable yarn features for ring spinning.

Because the card sliver is uniformly successively stretched and twisted as the ring-spun yarn is made, all the fibres are arranged in a spiral of uniform pitch parallel to the yarn axis. At the same time, all fibres are constantly kept under tension and have little or no opportunity to become randomized.

The fibres which are partially anchored in the core of the yarn and partially project out of the yarn account for the high level of hairiness of ring-spun yarn. The difference between this yarn and other yarns is that practically all fibres contribute to bearing the tensile load of the yarn. For this reason, a high proportion of the fibre strength is transferred to the strength of the yarn (substance utilisation). Because the fibres are well aligned, the ring-spun yarn can be fully untwisted and the twist factor can be measured precisely. The individual steps in the ring spinning process can be brought together in an integrated process (Fig. 2).

II. Rotor spinning: this process is fairly flexible in regard to the fibre length but is most suitable for processing short to medium staple lengths and is restricted to coarse to medium fine yarn (Fig. 3). The

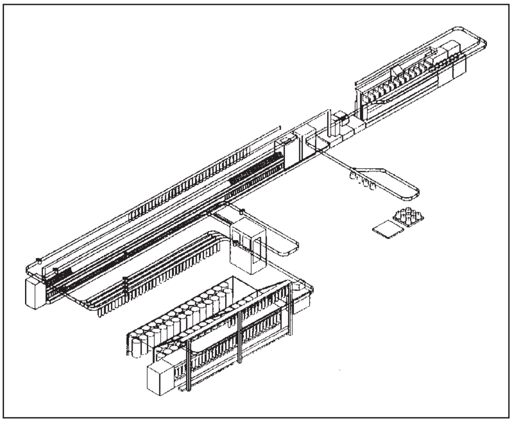

Fig. 2: Fully automated ring spinning machine.

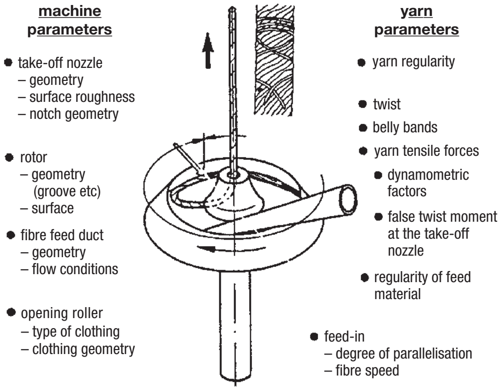

Fig. 3: Parameters affecting quality and ascertainable yarn features in rotor spinning.

yarn has less strength than ring-spun yarn depending on the process. Formulae for yarn torque and tension:

– required yarn torque:

$$M_{Btorque} = f\,(\text{fibre strength, etc.})$$

– actual yarn torque:

$$M_B \cong P_B \cdot r \cdot \alpha$$

P_B = yarn tension at point B
r = yarn radius
α = torque coefficient

– yarn tension:

$$P_B < \mu \cdot \text{tex} \cdot \frac{l_f}{2} \cdot R \cdot \omega_R^2$$

μ = coefficient of friction fibre/rotor wall
l_f = average fibre length
R = radius of rotor
ω_R = angular velocity of rotor.

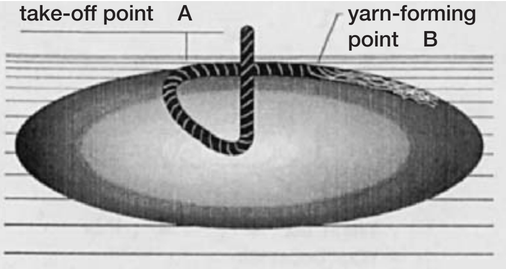

Fig. 4 Take-off point and yarn-forming point in rotor spinning.

As the run of fibre fed into the rotor grooves (Fig. 4) periodically crosses the yarn-discharge area, randomised fibres or fibres wrapped around the yarn as a covering cannot be avoided. The core of rotor-spun yarn has a constant twist which is comparable to that of ring-spun yarn. However, it is in the nature of this spinning method, that fibres wrapped around the yarn are twisted in both directions which prevents the sliver from opening up completely when the yarn is untwisted. The deviation of the measured twist value from the actual twist value is labelled T%. The value may be anywhere between 0 and 50% depending on the choice of fibre and the machine specifications. When rotor-spun yarn is under tension, the load is not or is only partially borne by the randomized fibres and fibres wrapped around the yarn. It is therefore clear why a rotor-spun yarn is not as strong as a ring-spun yarn using the same fibres (→ Ring-spun/rotor-spun yarns, properties of). Fig. 5 shows the functional parts of a rotor spinning machine.

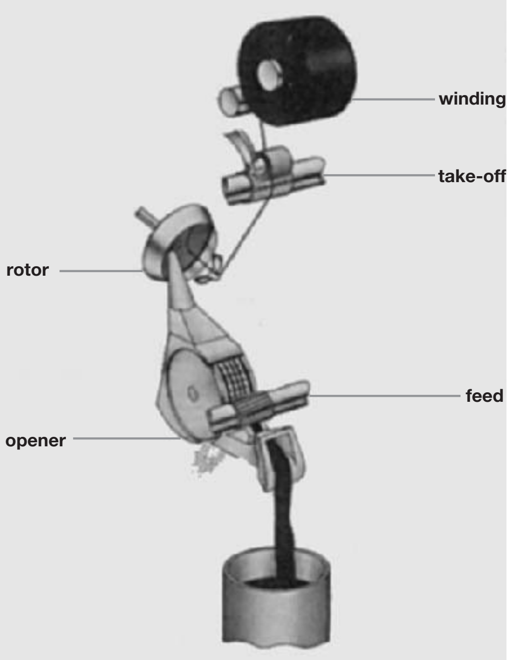

Fig. 5: Rotor spinning (SKF).

III. Air jet spinning: because the fibre control is good, this method is suitable for processing medium sized to long fibres, i.e. combed cotton and man-made fibres of medium to fine titres (Fig. 6). However, it is not possible to spin carded cotton of relatively high short fibre content or use it to manufacture fine yarn.

Spinning processes for staple fibres

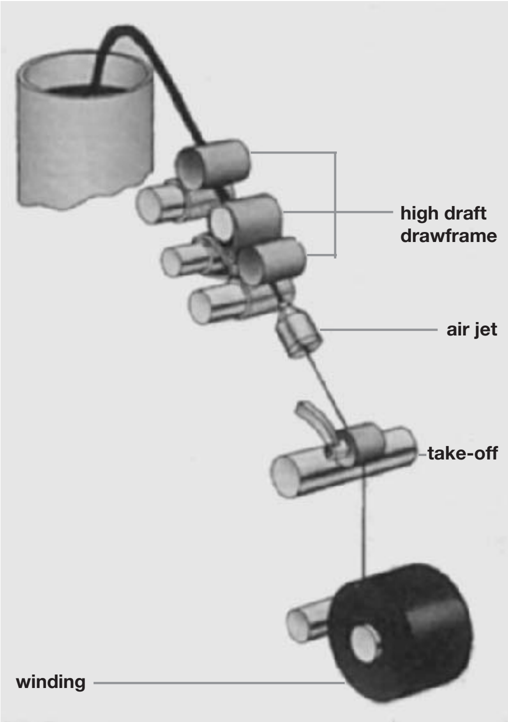

Fig. 6: Air jet spinning (SKF).

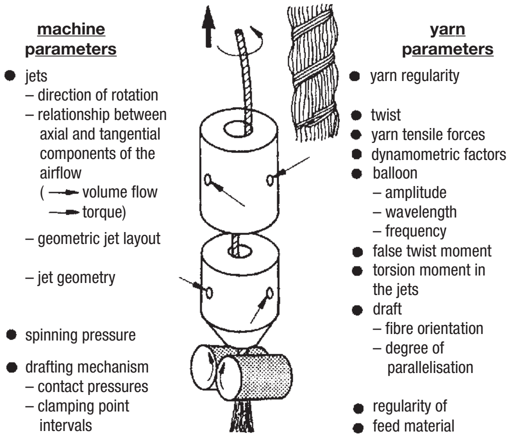

Fig. 7: Yarn parameters affecting quality and ascertainable yarn features in air false-twist spinning.

Air jet spun yarns are covered or wrapped yarns with a specified proportion of external bonding fibres which are wrapped around a core of parallel fibres. If only a single jet is used, the covering fibres are mechanically separated from the core fibres at the exit of the stretching roller. If two air jets are used, one after the other, the first jet winds the loose surface fibres around the rotating core of the yarn. The second air jet produces a false draught. As soon as the yarn passes the second jet, the core twist returns to zero while the covering fibres wind tightly around the core, strengthening the yarn by cohesion friction.

The optimum yarn strength is achieved (Fig. 7) when the proportion of covering fibres is around 10–25%. This means that the presence of a smaller percentage of the covering fibres or loosely wound fibres leads to soft yarns of lower strength, and conversely, a correctly measured percentage of tightly wound covering fibres yields stronger and harder yarns. This principle of yarn formation also explains why polyester fibres with higher friction values and standard staple lengths can be processed using this method while cotton fibres with lower friction values and shorter fibre lengths present problems.

IV. Friction spinning: from the technical details it follows that this method is fairly flexible with regard to fibre length but is more suitable for fibres with short and medium staples. As with rotor spinning, friction spinning is restricted to coarse to medium titres (Fig. 8). Yarn strength may be even less than it is for rotor-spun yarn, and may be problematic, depending on the system.

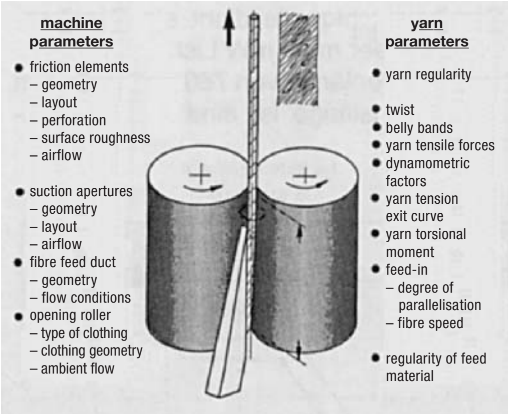

Fig. 8: Yarn parameters affecting quality and ascertainable yarn features in friction spinning.

Feeding the individual fibres to the nip of the friction drums (Figs. 9 and 10) produces a type of random-fibre zone but no covering fibres. The combining up of the fibres and introduction of the twist occurs simultaneously (a process which takes place once and is the cause of a few structural problems). The yarn take-off at right angles to the friction surfaces gives rise to a corkscrew arrangement of the fibres in the yarn. Under tension, the fibres on the circumference of the yarn

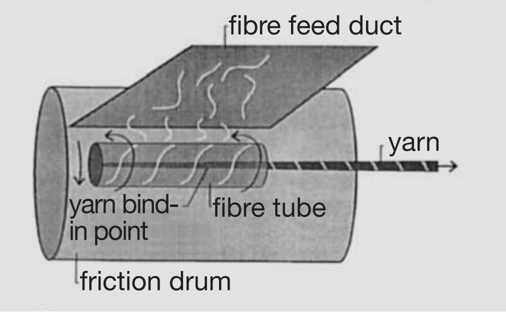

Fig. 9: Fibre transition from feed duct to yarn in friction spinning.

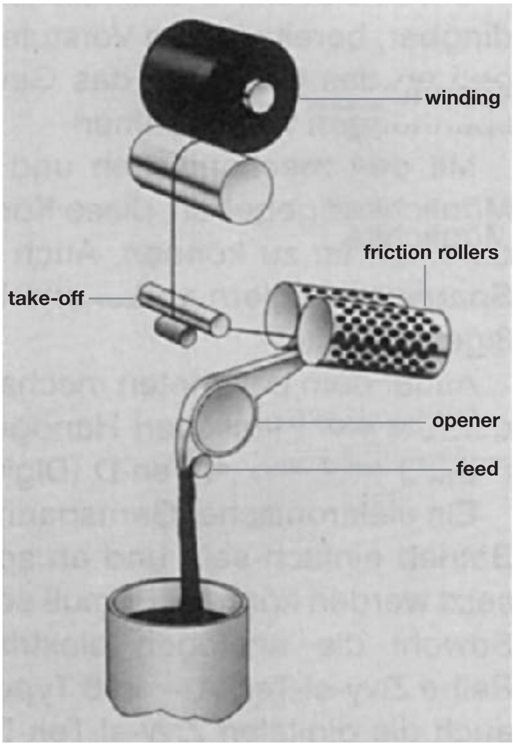

Fig. 10: Friction spinning (SKF).

must first orient themselves to the essentially coreless axis of the yarn. Protruding fibres which give the yarn a high level of hairiness and good covering properties can be more easily drawn out of the sliver. A twist can be established in friction yarns but the uniform twist produced by this method in the core of the yarn does not allow an objective comparison of twist values.

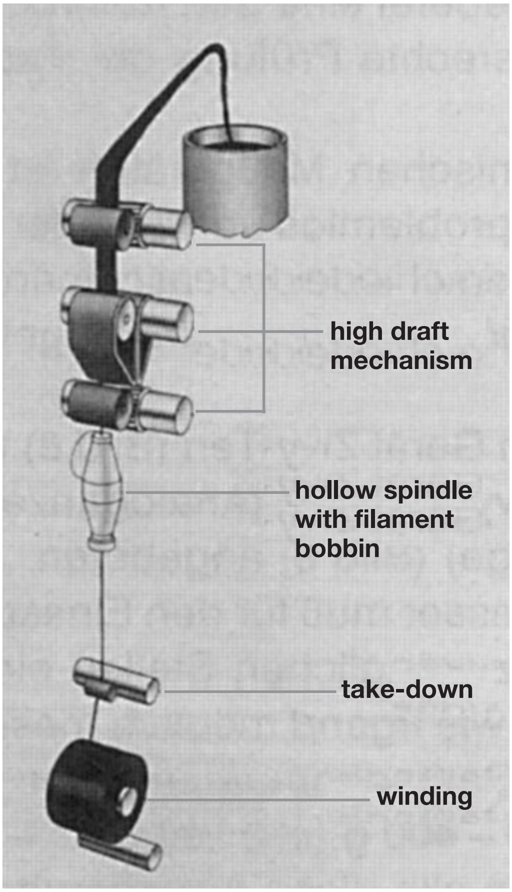

Fig. 11: Wrap spinning (SKF).

V. Wrap spinning: unlike the false-twist yarns, wrap-spun yarns are reproduced from a continuous sliver with a different composition to the yarn core (Fig. 11). Filament yarns are usually used which are spun around a yarn core composed of parallel staple fibres all running in the same direction in spiral twist. By making an appropriate choice of size and type of both components and different wrap densities, yarn structures can be produced with properties which can be varied within a wide range. However, in the interest of giving the yarn a pleasing appearance, the wrap components should not represent more than 5–10% of the total weight of the yarn. In the case of wrapped yarns, it is the core which takes up most of the tension. The larger this is, the tighter the strangle hold the wrap has on the parallel fibres in the core. This produces the cohesive forces which resist the load. It therefore follows that the tension used to apply the filament wrap to the core is more important than the number of loops in the wrap themselves.

In a productivity comparison (Figs. 12 and 13), the difference between the ring spinning method and the other high-performance methods becomes clear. Ring

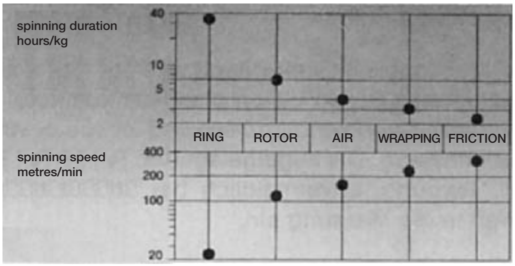

Fig. 12: Productivity comparison between various spinning methods.

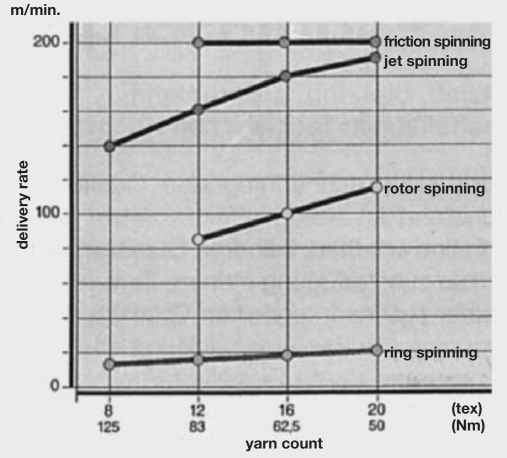

Fig. 13: Possible delivery rates of individual spinning methods relative to yarn count.

spinning is the slowest method but, by optimization, it becomes the fastest spinning method by a considerable degree. Particularly when processing polyester for example, attention must be paid to the danger of damaging the yarn. Jet spinning is faster than rotor spinning but, depending on the yarn count, friction spinning achieves the highest values with a constant delivery of 200 m/min.

A technological analysis of the different spinning systems with regard to quality of yarn and flexibility leads to the following conclusions: a critical aspect of yarn quality for new spinning systems is the yarn strength (Fig. 14). Strength comparisons of the different systems show that ring-spun yarn always produces the highest values. Rotor- and friction-spun yarns achieve relatively good values with short fibres, whereas air-jet-spun yarns achieve relatively good strength with man-made fibres. On comparing the yarn count ranges of the different spinning methods, ring spinning again proves to be the superior method. With regard to

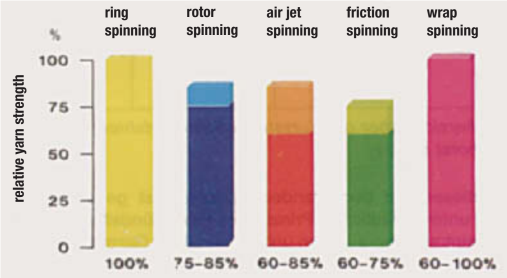

Fig. 14: Comparison of achievable yarn strength in various spinning methods.

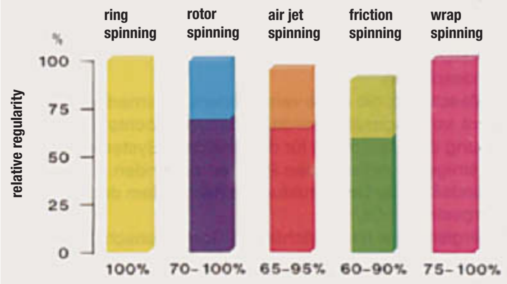

Fig. 15: Comparison of achievable yarn uniformity in various spinning methods.

yarn uniformity, friction-spun yarn is somewhat less uniform than the others (Fig. 15). The possible ranges of application can be derived from these quality and flexibility comparisons. It is clear that non-conventional spinning systems are not as universally applicable as the ring spinning system. In spite of this, these yarns

can be produced economically and with sufficient quality to manufacture a number of end products. In future therefore, several spinning systems will compete with each other on the market (Fig. 16) as the property profiles of the yarns are so different (Tab. 2):

- ring spinning: indispensable for high-strength yarn and structurally durable yarns.
- rotor spinning: of interest particularly for the processing of coarse and medium fine fibres for a wide range of end products. The application range can be increased by combing the cotton.
- air jet spinning: most suitable for long fibres, i.e. combed cotton and mixtures in medium to fine titres (area of application chiefly shirts and bedding).
- friction spinning: the softness of friction yarns means that they can be used in knitted fabrics in spite of their reduced strengths.

(according to Wulfhorst, Stalder, Hartmannsgruber, Schönung and Denssen).

Spin texturizing Targeted effect on structure during the spinning of filaments leading to, for example, higher elasticity and bulk.

Spiraldo system Device on → Winch beck. The winch is in the form of a spiral which enables the perfect control of a batch sewn together to form a continuos rope. Different piece lengths do not matter. However, the individual loops have the same lengths, which can be selected. Loading and discharging is much faster than if each piece is sewn together in a loop.

Spiral steamer (Krostewitz steamer or Gerber system). Universal steamer for printed goods (dry fabric fixing): spiral-shaped fabric feed-through (guide-roller contact on one side only), centrally located Teflon guide blade and fabric exit to the side. Fabric content 43–200 m.

Spirit → Ethanol.

Spirit-soluble dyes Used as so-called “brightening dyestuffs” in leather dyeing for dyeing greases, plastic, many types of lacquers and metal foils, etc. Also used for retouching. The light fastness of spirit-soluble dyes is dependent on fastness of the dye and lacquer composition.

I. Cationic dyes (selection): spirit solubility and strength good; light fastness moderate.

II. Acid dyes: spirit solubility and strength somewhat less but light fastness better. Selection rather restricted.

Splicer Controllable ancillary device on automatic bobbin winders which carry out the splicing operation at the winding head when there is a thread break.

I. Cationic dyes (selection): spirit solubility and strength good; light fastness moderate.

II. Acid dyes: spirit solubility and strength somewhat less but light fastness better. Selection rather restricted.

Splicer Controllable ancillary device on automatic bobbin winders which carry out the splicing operation at the winding head when there is a thread break.

Automatic bobbin winders with knotting devices can be fitted with splicers as an upgrade.

Splicing Intense intermingling/interlooping of the thread ends of two overlapping slivers (yarn) by means of a targeted stream of compressed air. Splicing technology is regarded as a genuine alternative to knot-free joining technology.

The knot-free spliced joining of yarn ends is carried out by an automatic splicer. Particularly in the case of the worsted yarn sector, knot-free thread joins have proved themselves particularly valuable in knitting and weaving in comparison to knots which, due to their tendency to catch, cause the threads to break or overstretch at the thread guides. Apart from this, knots have an unpleasing appearance due to their differing dye affinities during piece dyeing. Spliced joins can be used universally and practically never fail. At the join, the thread ends are compacted so that diameter of the join is only 1.2 times that of the thread. The strength of the join is about 80% of that of the yarn. In the fabric, spliced joins in the yarn are invisible or almost invisible in comparison to knots.

Split fibres (splice fibres). Manufactured from polyethylene-based polymer films (melting point 130°C) (depending on longitudinal cut, mono-axial heat-stretched and thermoset) or polypropylene-based polymer (melting point 165°C) (mono-axial or bi-axial heat-stretched, thermoset and longitudinal cut), subsequent splicing or splitting as well as crimping and staple cutting. In principle, mechanical separation into elements while stretching, whereupon the disintegrated film is subjected to a powerful stream of air or high-frequency sound. This produces a fine parallel gossamer layer of very fine fibres of high breaking strength and abrasion resistance. Narrow fibre strips are separated from the initial fibre veil and twisted into small slivers or fibrous yarn. Split fibre yarn has the appearance of a continuous, voluminous, multi-filament yarn of synthetic fibre with short protruding fibre ends. Coarse split fibres are suitable for the manufacture of chenille-type yarns for the carpet industry.

Splitting Two-component fibre systems which are spun as such and should be thermally or chemically treated during the finishing stage so that the two components separate from each other and the fibre titre becomes significantly finer. A flock coated warp velvet made from two-component fibres must be thermoset before splitting in order to avoid creasing during chemical splitting. Splitting is carried out from long liquor with 10% caustic soda at boiling point for 30 min. A second thermosetting process must then be carried out to sinter the split fibres (210–220°C for 30–40 s).

Sponge rubber → Foam rubber.

Spontaneous combustion → Combustion without the application of heat from external sources.

Spontaneous ignition temperature (SIT, ignition point), lowest temperature at which spontaneous ignition occurs due to gas formation (→ Flammable liquids).

Spores Reproductive and permanent form of → Bacilli and (→ Moulds) which are produced by the same fungus. No other → Bacteria produce spores. Spores such as those found in the soil are not harmful to the human body. Anthrax spores on the other hand are harmful. After the spores are formed, the rod-like body decomposes, releasing the spores. Properties: extreme resistance to heat, cold, drying out (over periods of years) and high pressure.

Sporicide → Spores annihilation. → Sterility.

Sports clothing → Functional clothing for special requirements (→ Active wear); not to be confused with → Sportswear.

Sports jacket Fashionable men's jacket with sack-shape cut; without shape, used as a summer jacket; shaped, used as a sports jacket (also high-quality, elegant designs, 250–500 g fabric weight) with shape-retaining interlining also used as a holiday jacket (→ Topper).

Sportswear Leisure sports and town and weekend clothing in the form of → Casual wear in a functional but smart genre, with sports-like attractive details; includes knitted wear and imitation leather.

Spot-bonded nonwovens Spot-shaped welded nonwovens made from a mixture of thermoplastic and non-thermoplastic fibres reinforced by passing through a calender. The rollers have helical engraves lines, the raised parts of which are distanced from each other so that the welded area accounts for no more than 13% of the whole area. → TCF process.

Spotting,

I. Pouring several portions of treatment liquors manually on to goods during dry cleaning.

II. Behaviour of short thickeners (usually structurally viscose thickeners). The portions of printing paste transferred from the valleys of a printing roller in Rouleaux printing, or through the perforations of a rotary screen, or through the interstices of a flat-screen gauze onto the textile substrate, which do not spread into each other, to give a level film of printing ink. Instead, the small spots left behind result in a cloudy printing image after fixing.

Spotting agent Used for removing local contamination (spots, etc.) on textile goods. They differ as follows (Fig.):

1. Dry spotting agents: all organic solvents (mixture); used with the total exclusion of water.
2. Wet spotting agents: used with water. Essentially a solvent-containing surfactant combination including emulsifiers with washing or cleaning properties such as amine soaps, alkyl sulphates, alkyl sulphonates, fatty-acid condensation products, alkyl-aryl sulphonates or oxalkylation products.

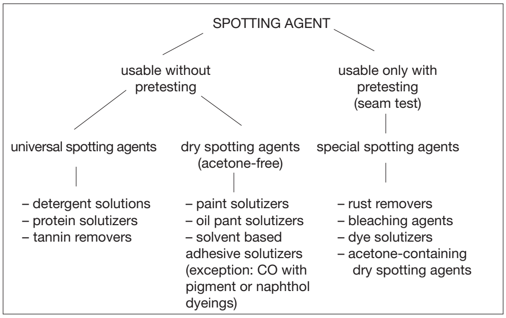

Fig.: Spotting agent differences.

Spotting powder Used to absorb moisture during spotting in order to prevent the appearance of the feared stain borders. Active components: talcum, kaolin, fullers earth and gypsum.

Spray additive Method of softening textiles in the dyed-fibre flocks.

Spray application Handle-modifying finishing or moistening of textiles carried out by spraying finishing liquor on to the textile web (Fig. 1). In contrast to other application methods, the goods are not immersed. Finishing liquors are mainly applied in concentrated form < 40% and preferably 10–20%. Special spraying machines are available for finishing fabrics according to the → Low wet pick-up method, especially for wash-and-wear finishing (Fig. 2). With this unit it is possible to apply a uniformly distributed thin layer of liquid over the whole width of the goods on the right side which then soaks thoroughly into the fibres.

Spray applicators → Spray finishing machine. Also used for applying plastics to fabric or nonwoven webs by spraying the plastic onto the substrate without contact instead of applying it with a doctor blade, for example, in the case of floor coverings.

Spray bonding spraying plant used for bonding polyester- or siliconized-fibre based nonwovens. Web transport using circulating conveyor belt. Spraying performed using traversing spray guns across the textile

web, switching off automatically at the edge of the web. Water cascades in the spraying booth for washing down spray droplets and recombines in an separator/collector located at the side.

Spray coating,

I. Method of polyurethane coating by chemical foaming as graded coating on, for example, (tufted) carpet backs, in which all agents are mixed in a mixing head and then sprayed immediately on to the back of the carpet through special nozzles. The spray coating is controlled by the precise maintenance of mixing ratios and temperature so that during coating, a part of the mixture penetrates into the back of the carpet before foaming and anchors the knops. Not until after this does the chemical foaming take place by the isocyanate reacting with the small amounts of water residing there to form urea derivatives and carbon dioxide, which serves as the gas component for turning the sprayed coating into a foam. Pre-coating and fillers are not ab-

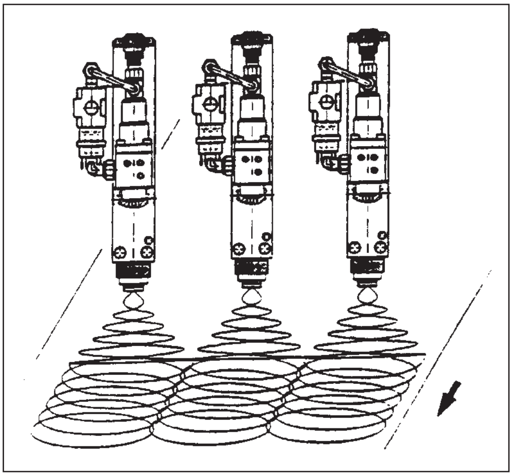

Fig.: Spray coating extruders in action (Nordson).

solutely necessary. After applying the chemicals: heating by infrared heating line (compensated heat losses) and hot embossing calendering. → Polyurethane preparation plants.

II. Meltable polymers (hot-melt adhesives) can be extruded from nozzles arranged next to each other across the width of the textile (see Fig.). Two threads of the polymer are laid in accordance with a specified principle before hardening thus forming a coating of initial substrate which receives a second substrate later and which is laminated on.

Spray-dampening Finishing character work; particular usual for washing cloths and wool cloths and the like in order to impart the desired moisture content and heavy, soft handle to the fabric. In most cases with non-supersaturated moist air after the drying frame (stenter drying) on the spraying machine by spray jets or rotating brush rollers according to the so-called "natural moisture" principle.

Spray dyeing machine A form of → Hank dyeing machine for dyeing hank yarn on perforated yarn-carrier tubes with firmly connected rotating hanks. The machine gently turns suspended hanks. The liquor is sprayed on the hanks through the perforations. Units are available with up to 30 carrier tubes. The hanks of yarn are suspended next to each other and behind each other on the perforated tubes (Fig. 1) which turn cyclically in order to move the hank in a repeat fashion (according to a register). The pumped dye liquor sprays out of the perforated tube (Fig. 2) through the yarn and flows down the hank into the heated sump from which it is pumped round and used again.

Another type of hank dyeing machine, dyes, centrifuges and dries hanks of wool and wool blends in a single process. The triangular shaped carrier arms which carry the hanks of yarn are attached to a rotor (Fig. 3). During dyeing, the liquor circulates through the arms into the yarn, is captured in the liquor tank and delivered to the dyeing process via filters, circulation pump and heat exchanger. After dyeing, the yarn is centrifuged on the carrier arms and then dried by the introduction of hot air via a secondary circuit. A blower circulates the air which has been heated in the heat exchanger.

Spray finishing Finishing with → Spray dyeing machine, used particularly for pressure-sensitive silk, viscose filaments and blended fabric articles such as crêpe de chine, marocain crêpe, flamisol crêpe, georgette crêpe, bark crêpe, moss crêpe, blister crêpe, matelassé, hammer blow and even for taft and similar smooth articles as well as for dress fabrics and linen fabrics for correcting the final handle. The advantage over padder finishing is that only a small amount of finishing liquor is applied. The aqueous film which is squirted or sprayed on in most cases also offers advantages during subsequent manufacture. Appropriately low viscosity finishing solutions are used as the spray liquor, if necessary, in combination with glycerine or something similar or with softeners, organic acids (for scroopy silk finish), matting agents and fragrant finishes, etc. Quickly and easily applied solutions are then mostly applied directly on the stenter dryer otherwise the goods are left rolled up beforehand. → Jet impingement.

Spray finishing machine Special machines derived from older spray dampening machines which apply finishing liquors in the form of powders or low viscosity mists through nozzles either on one or both sides as a form of → Spray finishing. There are different designs such as those with an open arrangement (additional extraction equipment or improved supply of fresh air reduces exposure to personnel), those in separated chambers (the goods passing in and out through wall slots) up to high-performance machines with integrated, enclosed atomising chambers through which the goods pass vertically up past batteries of air nozzles arranged on both sides across the web at a speed 6–36 m/min. Continuous closed loop speed control, crease and tension-free passage with all the necessary monitoring equipment; can also be used for moistening or dampening purposes.

Spray guns Used for moistening (spraying) textiles, during stain removal, dry-cleaning or re-touching (wardrobe) and used for leather dyeing, spray finishing, spray printing with printing ink solutions and lacquering, etc. Various different designs, in most cases using a push button valve (instantaneous shut-off), for example, at mains water pressure as a water-spray gun and used with compressed air for dye solutions and lacquers, etc. particularly in the case of leather spray dyeing, and used without compressed air, with electric drive, automatic boost pump, finger-control and nozzle regulation, etc.

Spray impregnation Application with device for → Low wet pick-up of synthetic-resin pre-condensate solution, by spraying. Advantage: energy saving and improved utilization of the condensation equipment.

Spray printing The pattern is produced by → Stencils for spray printing. The thin and finely matched printing ink solutions are sprayed through the fine stencil voids on to the goods using nozzle atomizers (Fig.) or compressed-air spray guns (air extraction and safety spectacles required). In principle, all classes of dye are suitable; fixing and washing as in the usual applications. → Chromojet printing of carpets. Nozzles are controlled by a computer program for applying an uneven, non-systematic pattern to fabrics.

Spray systems Spray the treatment liquor on to the goods over a broad front via nozzles in order to intensify the liquor exchange. Fig. 1 shows how the

goods are moved by the two carrier rollers (1) in the Diplo system from Sclavos. The spray nozzles apply the liquor (2) before the folder (3) takes off (plaits) the goods into the J-box (5). As the swollen rope leaves the goods storage chamber, the front cascade (6) sprays the goods with liquor again while the air nozzles (8) blow on to the goods.

In the Spray-Tex spray washing unit (Babcock, Fig. 2), contamination adhering to the surface, non-fixed dyes, chemicals and textile auxiliaries are loosened by spray jets with adjustable pressure and washed away. The wash water which is re-circulated via filters (temperature regulation adjustable up to 98°C) is sprayed on to the goods through flat jets with a high degree of evenness over the entire width of the goods (Fig. 3).

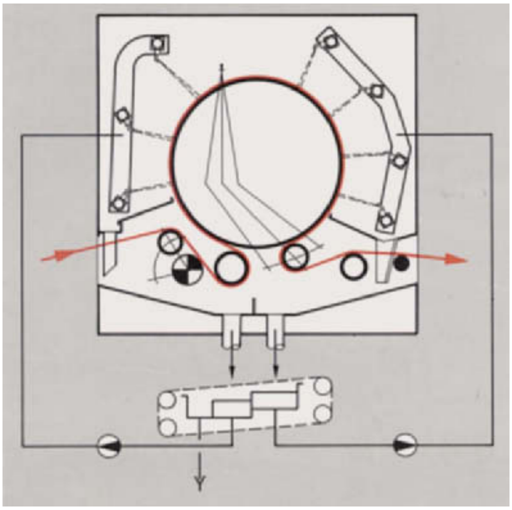

Fig. 2: Spraying during washing (Babcock) through both the perforated drum and through the goods.

Fig. 3: A suction drum wash compartment with a spraying system (Babcock) covering the full width of the goods.

Steam/water mixtures are also suitable for spraying. Thus, in 1987, the technical world was made aware of this method through the "Shock steam" pretreatment of cotton fabrics (Fig. 4).

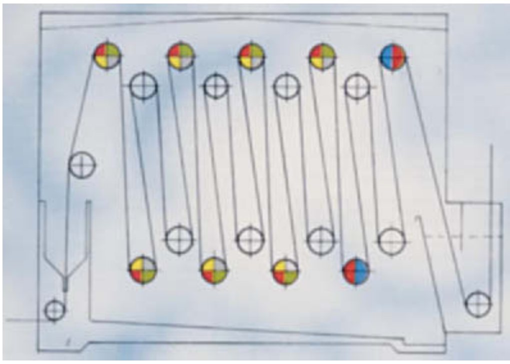

Fig. 4: Shock steam (Asisa).

The goods were intensively sprayed through with the treatment medium through perforated deflection rollers. At ITMA 1991, Kleinewefers KTM introduced the Raco-Yet spray system (Figs. 5 and 6) which operates according to this principle. Finally, there is also the wash system which uses the Injecta principle from Benninger which is a spray unit (Fig. 7).

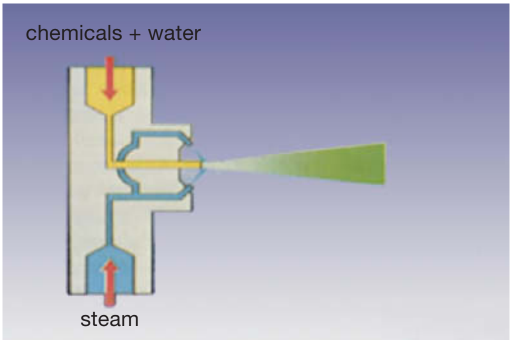

Fig. 5: A two-component mixing nozzle with external mixing (Kleinewefers KTM).

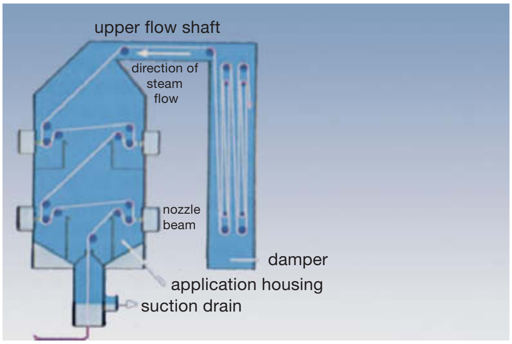

Fig. 6: Application housing with nozzle beam and connection to the damper (Kleinewefers KTM).

Spray test American test method for waterproof impregnation, by sprinkling artificial rain using a funnel-shaped sprinkling nozzle on to a stretched test sample. Excess water is removed by rolling a metal cylinder over the surface once, and weighing and drying to a constant weight (precisely controlled conditions). The Swiss Standards Specification and the → Pfersee-testing instrument are based on this test.

Spray washing machines Preferably used for the first phase of after-print washing of printed goods for the gentle acceleration of prints when removing thickeners and excess dye at low temperatures (Fig. 1). The machines significantly reduce the danger of ground contamination or shade modification due to staining in the treatment baths which follow, in which temperatures and times must be adhered to. The power and water consumption is justified because experience has shown that stains which appear during the first stage can only be removed during the following stages at considerable extra expense (residue problem). High-pressure spraying and low-pressure spraying have different and specific effects. Because the effect of high-pressure systems is almost purely associated with the surface, they are used at the start of the wash line during the after treatment of printed goods. Low pressure systems should not be applied until later.

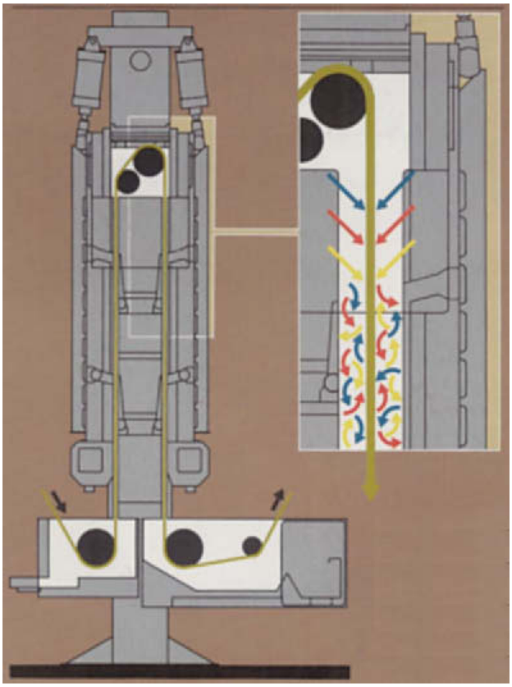

Fig. 7: Section through an Injecta wash system with funtional diagram (Benninger).

I. High-pressure spraying: the washing effect is good between 10 and 30 bar, but below 10 bar good performance can only occasionally be achieved (depending on the thickener). Above 30 bar, the increase in effect is no longer justifiably related to the water and power demand for pumping. As high pressures and large volumes of water require pumping powers which are no longer justifiable on economic grounds, interest is focused on small volumes of water through small diameter high pressure jets. However, the jets are susceptible to contamination and tend to block. The best processing method is to have the printed side facing down while spraying it from underneath at a slight tangent with the goods almost lying on top; liquor which has sprayed can fall freely from the goods, so there are no blocking effects, and filter effects and redeposition practically never occurs. Changing the angle of the jets has a pronounced effect. Because they act as a “surface plane”, thickeners and excess dye are removed from the surface of the goods but the effect is less pronounced between the threads (depending on the weave and thickness of the goods) and is almost non-existent be-

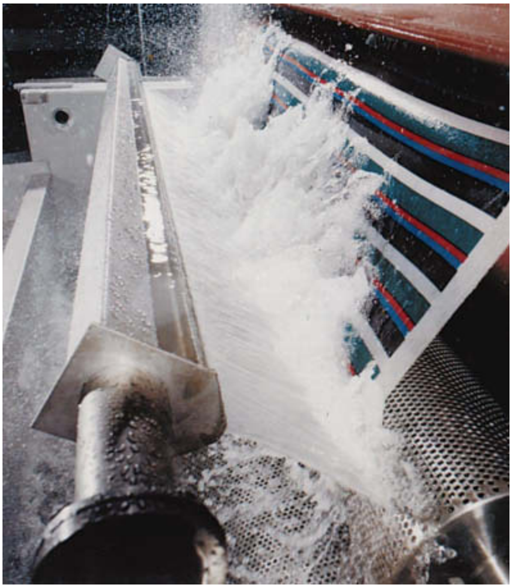

Fig. 1: An Arioli spray system in the first washing bath of an after-print washing of printed goods.

tween the fibres. Depending on the power, the effect is much greater for intense/saturated surface print than it is for intense penetrating print. Under the same working conditions, blank print thickeners are better removed in all cases, using high pressure sprays, than the same thickeners when fully immersed in a bath followed by padding. The spray effect is dependent on the preceding softening or dwell time due to the effect of the print-fixing conditions: over about a minute, there is no improvement, in fact, some thickeners get worse. Hot wetting followed by cold spraying is better than cold wetting alone.

II. Low-pressure spraying (e.g. as in a ribbed-drum washing machine, Fig. 2, with cycle rate at 120 m^3/h (2000 1/min) at 0.6 bar): surface effect for thickener which has not yet been loosened is significantly less than it is for high-pressure spraying. The cleaning effect (where surface cleaning is anticipated) is greater on thickener and excess dye lying between threads and in some cases between fibres. Blank surface printed thickeners are better removed using the full bath padding method. Taking also the risk of redeposition into account, low-pressure spraying with circulation during the after treatment of printed goods should not come first in the washing line. Unsuitable temperatures or chemicals will shift the equilibrium, contaminate the goods and may reverse the washing effect. In extreme cases, the machine becomes an applicator. High circulation powers result in fast and good distribution of fresh water and, possibly, chemicals; low-foaming products must be used otherwise circulation will be impaired.

Even for this machine, assembling several units one after another means less of an improvement in the cleaning effect from machine to machine because the effect achieved is more strongly dependent on speed than it is on the high-pressure spraying process. After successful cleaning of the surface, a slow time dependent transfer begins.

Jet spraying of goods plays a very important role in the unit in Fig. 3 showing a modified roller vat. All wash liquor is fed by separate pumps from the base vats which has not come into contact with the goods, by horizontal pipes provided with spray jets. The wash liquor is sprayed across the width of the goods as they pass. Otherwise it is only in the sump at the lower deflection roller that the goods come into contact with the liquor. Ballast liquor, which does not act as wash liquor in the liquor exchange, therefore does not come into contact with the goods.

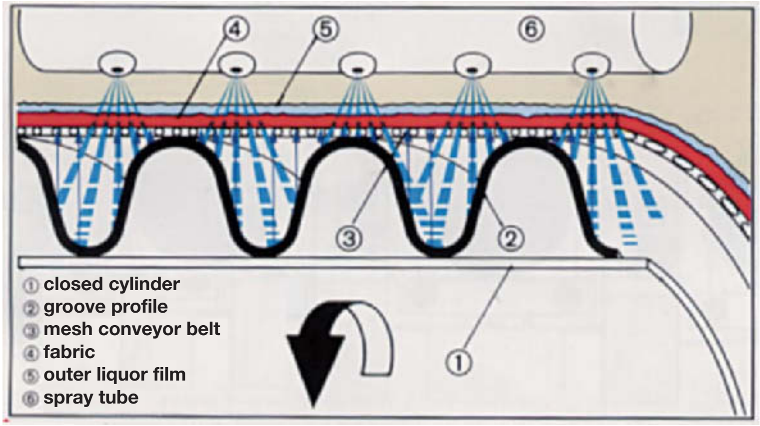

Fig. 2: Kleinewefers KTM ribbed-drum washing principle diagram.

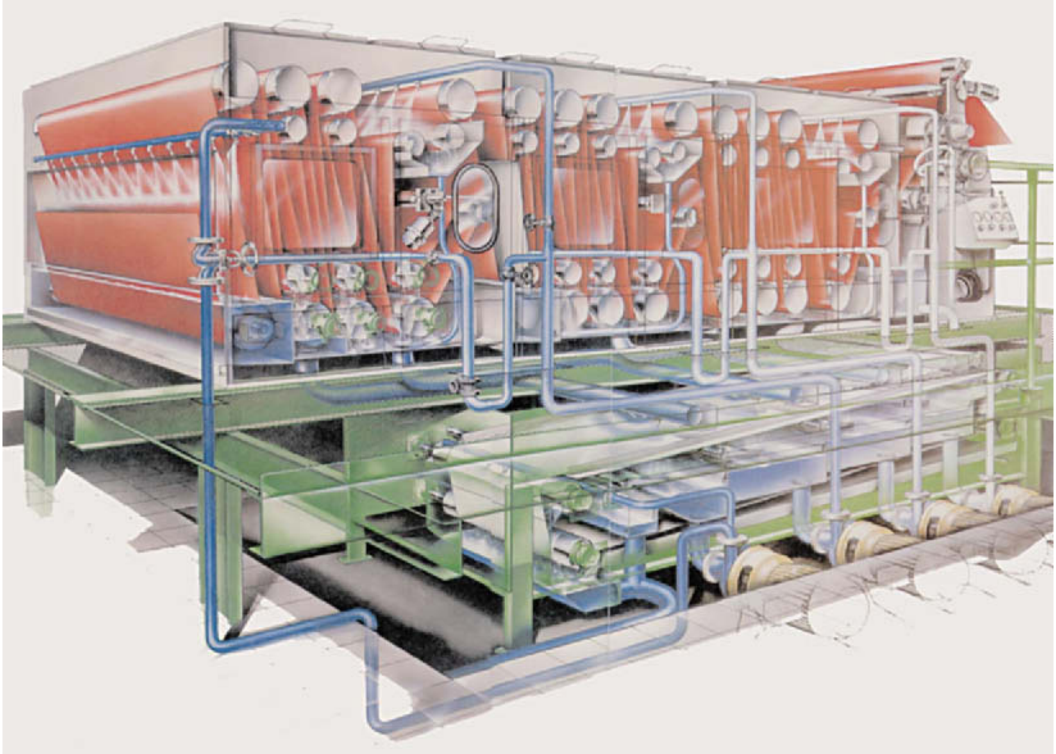

Fig. 3: The spray system in the Econ-Tex open width washing machine from Babcock.

Spread-coating (finishing). Application of thickened finishes using a → Doctor blade.

Spreader reel Special winch with slanting stainless-steel hoops for improved spreading of piece goods on the winch beck.

Spreading capacity Property of a fluid, particularly of a → Surface active compound which enables a drop of this fluid to cover the surface of another fluid or solid body spontaneously (→ Wetting).

Spreading coefficient In the case of surfactants, used for the determination of → HLB values. Within the HLB range of 7–15, the relationship between spreading coefficients and HLB values is linear. The spreading coefficient S_1 is determined from the surface tension σ_{WL} of a 1% surfactant solution in water, the surface tension of the organic phase alone σ_{OL} (preferably castor oil) and the surface tension σ_G of this solution against the organic phase:

$$S_1 = \sigma_{WL} - (\sigma_{OL} + \sigma_G)$$

The HLB value is found from a calibration curve which has been constructed from the spreading coefficients of a number of emulsifiers with known HLB values.

Spreading tension (→ Spreading coefficient), the tendency of a fluid to spread out over a solid surface is determined by the difference between its → Wetting tension and its → Surface tension. This parameter is called the spreading tension and is expressed in N/m. A positive value signifies that the fluid spreads on the surface spontaneously.

Spring sleeves consist of elastic, compressible metal springs used to facilitate the shrinkage of man-made yarn during the finishing process.

Sprinkler systems Automatic fire-extinguisher systems. In the event of a fire, the caps, made of solder which cover the sprinkler heads of the extinguisher system, melt (e.g. at 70°C) releasing the water, carbon dioxide or tetrachloromethane through the heads. Use: in stenters, raw material storage areas or throughout the whole factory.

Sprinkling process Dye powder is added directly to the stock thickener without first dissolving or making it into a paste. Dispersion, reactive and a few acid or metal-complex dyes are most suitable for this purpose.

Spunbond → Random webs.

Spunbonded fabric Compacted → Spunlaid fleeces.

Spun-dyed fibres Man-made fibres dyed in the spinning paste (spun-dyed).

Spunlaid fleeces → Nonwovens manufactured by spinning fibres in a melt, solution or wet spinning process and then laying on a conveyor belt (Fig.).

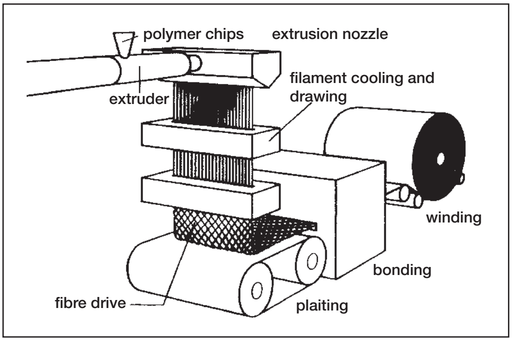

Fig.: Spunlaid fleece production principle (Freudenberg).

Spun yarn → Yarn spun from fibres.

Spun yarns According to DIN 60 000 strand-shaped structure made from → Staple fibre which is held together by twisting (spinning) as opposed to → Continuous filament yarn.

Sputter coating Using this technique, it is possible to apply defined coatings with the desired properties to the surfaces of flexible, sheet materials. Reflecting, conductive, insulating and magnetic properties are some which can be achieved. The main application at the present time is foils and films but some possibilities have emerged in regard to the application of sputter coating textiles.

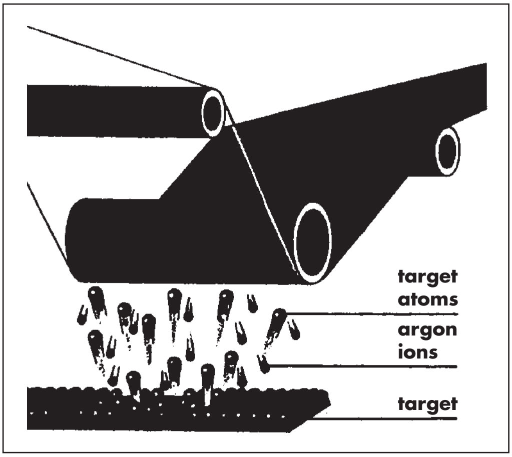

Fig. 1: Sputtering process (Heraeus).

Sputtering (cathodic atomization) is a vacuum coating method used for the production of thin coats. During the sputtering process, a corona discharge is created by an electrical field between the material source (target) and the substrate in an inert-gas atmosphere (Fig. 1). A plasma is produced which is an electrically conductive gas consisting of neutral particles, free electrons and positively ionized inert-gas atoms. Positive inert gas ions are accelerated from the plasma on to the target. When the ions collide with the target surface, atoms are released from the target material which hit the substrate at great speed to form a coating. The large number of target materials used (metals, alloys, ceramics and glasses) makes it possible to apply coatings with the required properties.

Sputter coating differs from alternative thin-layer technologies such as galvanizing, thermal or electron-beam vaporization and has the following advantages:

- a large number of materials can be precipitated,
- different materials can be precipitated simultaneously,
- the adhesion is better due to the kinetic energy of the atoms hitting the substrate and this produces a genuine bond between the substrate and coating,
- the coating properties are highly reproducible between tight tolerances,
- the process is environmentally friendly.

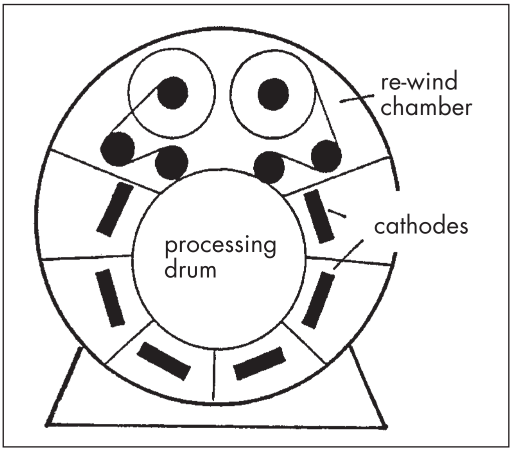

Fig. 2: Sputter coating machine (Heraeus).

The reeling mechanism is located in the upper part of the vacuum vessel (Fig. 2). The substrate is guided past 6 coating chambers by means of deflection rollers in the upper part of the vessel and then reeled up again. All 6 coating chambers can be pumped separately. The maximum possible width of the web is 1.68 m. The web on a single roll may be as long as 10 000 m depending on the substrate thickness. Before coating, the individual chambers are pumped out to a pressure below 10^{-5} mbar in order to leave as little residual gas as possible. After the working gas, typically argon, is allowed into the vessel, the working pressure is adjusted to 10^{-3} mbar. To precipitate a metallic coating of 10 nm thickness, it is possible to run the process at a web speed of around 10–20 m/min with a single cathode. When oxygen is added to the inert argon, the metal atoms react in a reactive sputtering process to produce an oxide which is then precipitated. Reactive sputtering requires time for the chemical reaction to take place and is therefore significantly slower. Typical web speeds range from 0.1–1 m/min for a single cathode (according to Siefert).

Squeegee contact angle Angle formed between the squeegee blade and the flat screen or the tangent to the rotary screen. In the case of the rod squeegee, it depends on the diameter (the smaller the diameter the greater the squeegee contact angle) but in the case of the blade squeegee, it is dependent on the angle at which the blade has been set. Together with the → Squeegee pressure, the squeegee contact angle affects the amount of print paste applied (→ Squeegee systems in printing).

Squeegee lifting mechanism in flat-bed screen printing If one-man operation is used in screen printing, the squeegee, providing it is not a tilting or double squeegee, has to be lifted above the printing paste on the side adjacent to the printer so that it can take the paste with it again on its return. Lifting devices are used for this purpose which come in various designs.

Squeegee pass The movement of the doctor blade from one side of the screen to the other. This movement can be carried out once or several times depending on the substrate, print style and printing press.

Squeegee pressure Together with the → Squeegee contact angle, this controls the amount of printing paste which is applied during flat and rotary screen printing. In the case of the magnetic-rod squeegee system, it is established by differences in the strength of the magnetic field, but in the case of the blade squeegee, it is determined by appropriately adjusted spring pressure (→ Squeegee systems in printing).

Squeegee profile The squeegee profile is characterized by the cross-section of the squeegee rubber. Depending on requirements, synthetic rubbers of different thicknesses are used which lead out on the side turned towards the screen gauze with the edge rounded off or cut flat or steep. → Squeegee systems in printing.

Squeegee setting Characterized by the → Squeegee contact angle.

Squeegee stroke → Squeegee pass.

Squeegee stroke length Distance travelled by the squeegee in screen printing in a single → Squeegee pass.

Squeegee systems in printing,

I. Rouleaux printing: the squeegee is used to scrape excess printing paste off the surface of the printing roller. It is mounted between the printing ink transfer roller and the printing surface and is attached via steel pins in bronze or brass bearings. These can be adjusted in a horizontal direction via threaded spindles screwed into the bearing head. Adjustments can be made in the vertical direction after these have been released. Thus, the angle of contact to the printing roller can be adjusted at will. The squeegee consists of a squeegee holder, a doctor blade and, if necessary, a support blade.

II. Screen printing: the squeegee is in the form of a sliding bar made of wood or metal with a straight scraping edge usually consisting of a rubber profile. Depending on the pattern, printing paste, gauze density and type of fabric, one, two or more → Squeegee passes will be necessary to apply sufficient ink paste to the surface of the goods. Improved designs of this blade squeegee are in the form of a double squeegee, double tilting squeegee and multi-colour double squeegee. The (magnetic) rod squeegee is gaining in importance.

III. Rotary-screen printing and rotary-screen printing of carpets: blade squeegees, rod squeegees and combined blade and rod squeegees are used in rotary screen printing and blade squeegees, rod squeegees and double rod squeegees are used in the flat-screen printing of carpets. The rod squeegee (with or without friction) is used in the rotary screen printing of carpets. The fan, box and split squeegees are special rod-squeegee designs.

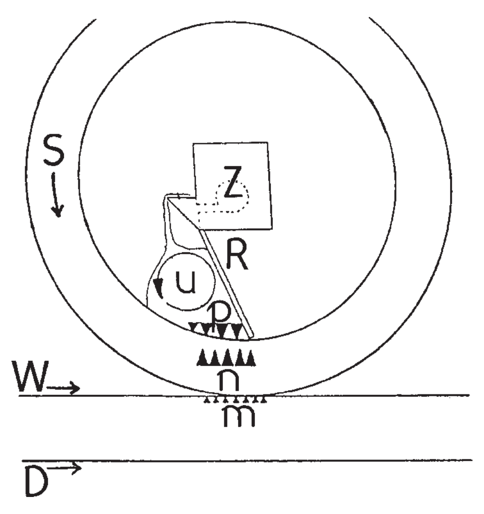

Fig. 1: Sketch showing the principle of print paste application with a blade squeegee in rotary screen printing.
m = penetration resistance; n = flow resistance; p = back pressure; u = circulation flow; D = direction of movement of printing blanket; R = blade squeegee; S = direction of screen rotation; W = direction of movement of goods; Z = paste feed pipe in the distribution duct.

Along with the traditional blade squeegee, the magnetic rod method is also becoming increasingly important in its use in textile screen printing. The discussion about the properties of both squeegee techniques is not only fired by arguments associated with patents but, more astonishingly, there is also a huge variety of opinions and views about where each system should be used. The user who is forced to decide on one of the two squeegee techniques has so far been basing his decisions on cost factors.

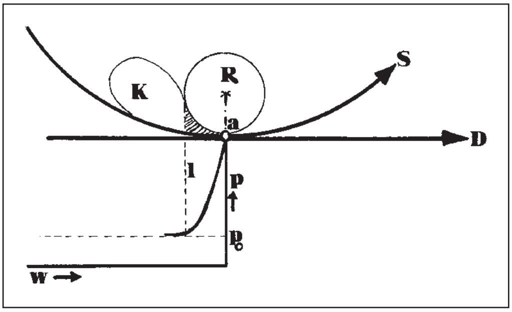

Fig. 2: The contact zone and back pressure diagram for a magnetic-rod squeegee in rotary screen printing.
a = contact point; l = border line; w = direction.
D = direction of movement of printing blanket; K = print paste wedge with hatched contact zone; R = rod squeegee; S = direction of screen rotation.

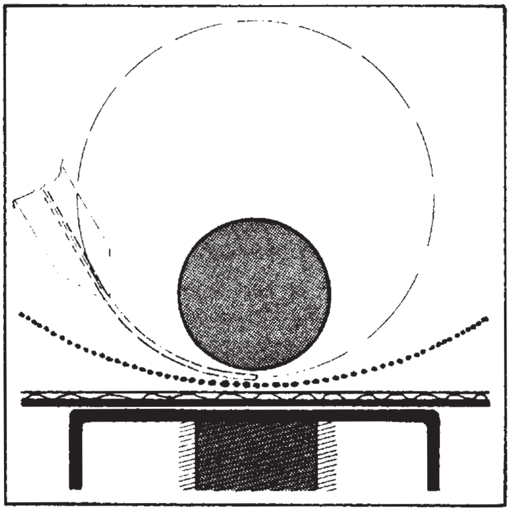

Fig. 3: Magnetic-rod squeegee of 25 mm diameter with a flat accumulation zone analogous to a flat-angled blade squeegee.

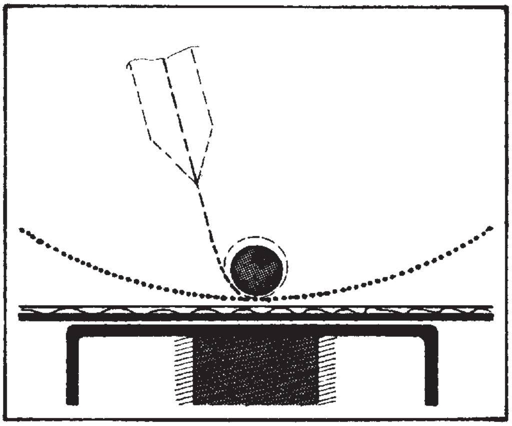

Fig. 4: Magnetic-rod squeegee of 8 mm diameter analogous to a steeply-angled blade squeegee.

The coating which is applied using the blade squeegee (Fig. 1) is more superficial; rod squeegees (Fig. 2) generally press the coating into the substrate more. Blade squeegees require a relatively coarse screen and printing pastes with relatively low viscosity for deep penetration. The rod squeegee is characterized by the type of coating (the rod behaves in a similar way to a roller and the contact pressure is relatively high) which resembles roller printing. Fine pattern details can be printed more clearly using the magnetic rod squeegee because its rod squeegee characteristics make it possible to use finer screens and printing pastes of higher viscosity. Large- or full-area patterns or ground prints can be printed more evenly by using a rod squeegee than by using a blade squeegee. It is preferable to install two rod-squeegee stations in existing blade-squeegee machines – one for the fine details (contours) and one for the large areas (blotches) (see Figs. 3 and 4).

Left/middle/right – when using the blade-squeegee technique, achieving a uniform coat on the left, middle and right becomes more difficult as the working width increases. On the other hand, evenness across the width is easy to obtain using the rod-squeegee technique because the magnetic field attracts the rod uniformly across the width – the greater the coating width, the greater the advantage of the magnetic-rod squeegee.

Blade-squeegee contact pressure: low to medium contact pressure; contact pressure produced mechanically (pneumatic, hydraulic or spring pressure and lever effects); risk of distortion – the force required for producing the contact pressure is introduced, or the squeegee is supported, via the ends of the squeegee unit. The capacity for adjustment and the reproducibility of the contact pressure depend on several factors. Adjustment can be corrected, or correction must be applied, on both sides of the machine.

Rod-squeegee contact pressure: medium to high contact pressure; contact pressure produced electromagnetically; distortion-free coating; contact pressure is produced by a magnetic field parallel to the rod without applying any load to the squeegee-unit mountings or the ink-paste feed pipe. The contact pressure is very easy to adjust and reproduce – adjustment is carried out by means of a printing pressure step switch at each printing station or continuously by using a rotary potentiometer.

The active wedge area is crucial for the determination of the contact time. In the print diagram, this area corresponds to the zone stretching from the initial rise in impact pressure, through the penetration resistance zone, to the squeegee contact point. The pressure behaviour in this area, which is known as the contact zone, has a significant effect on the amount of printing paste applied. A prerequisite for a uniform coating is a constant and defined level of ink paste over the entire printing width in order to keep the length and ratio of the two wedge areas constant. The discharge speed is dependent on the size of the impact pressure and the flow resistance of the screen. The size of the impact pressure is determined by the geometry of the squeegee, the squeegee force, the print speed and the flow properties of the printing paste. The flow resistance is determined by the percentage of the gauze area which is open.

The parameters which affect the process are divided into those which are variable and those which are constant as follows:

a) Variable parameters:
- squeegee geometry,
- squeegee force,
- print speed,
- level of printing paste,
- printing paste;

b) Constant parameters:
- screen,
- substrate,
- print cover.

Either the constant parameters can be adjusted at considerable expense in terms of time and money or they cannot be adjusted at all. They are used as the basis for selecting the variable parameters which can or must be adjusted at little cost during the printing process in order to achieve the desired result.

Squeegee geometry: the wedge area is characterized by the angle between the squeegee and the screen (squeegee angle) and the amount by which it extends in length and height (Fig. 5). The squeegee geometry describes the shape of the wedge area bound by the squeegee.

When observing the back pressure over the entire length of the printing paste wedge, it will be seen that it is not constant but increases in the direction of the point of contact of the squeegee and falls to zero at the squeegee edge (Fig. 6).

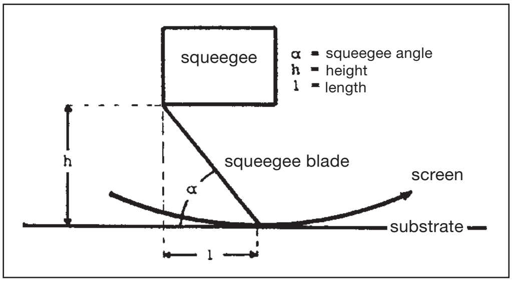

Fig. 5: Diagram of the squeegee angle.

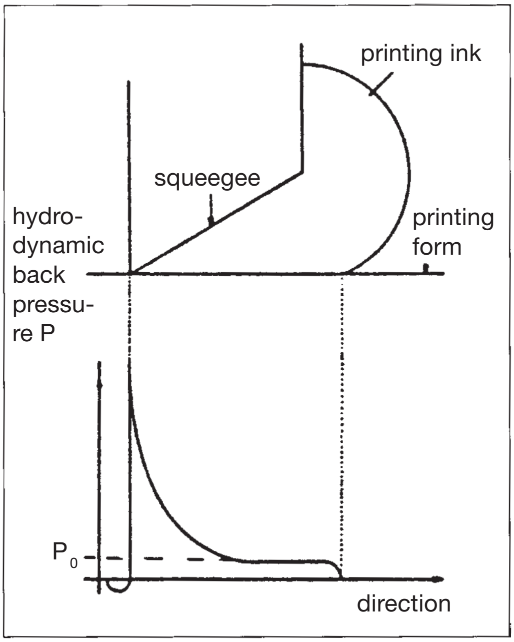

Fig. 6: The distribution of back pressure in the print paste wedge, P_0 = penetration resistance.

Theoretically, due to the suction effect of the substrates, it has to be assumed that transient negative pressures arise behind the edge of the squeegee. A variation in squeegee geometry alters the height of the back pressure and the width of the contact zone. In the case of large squeegee angles, relatively short term increases in pressure appear with steep flanks and low peak values. With small squeegee angles, the increases in pressure which arise are relatively long term with more gradual inclined flanks and relatively high peak values (Fig. 7).

The area under the curve can be taken to represent the amount of printing paste applied. According to this, the amount of printing paste applied increases as the squeegee angle decreases. These curves also show

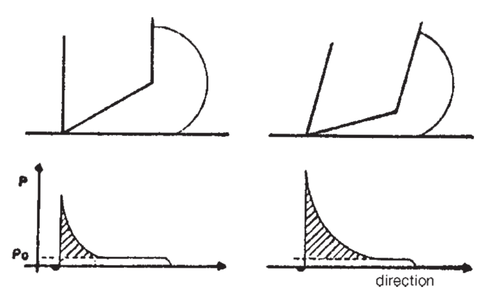

Fig. 7: The distribution of back pressure in the print paste wedge for large and small squeegee angles.

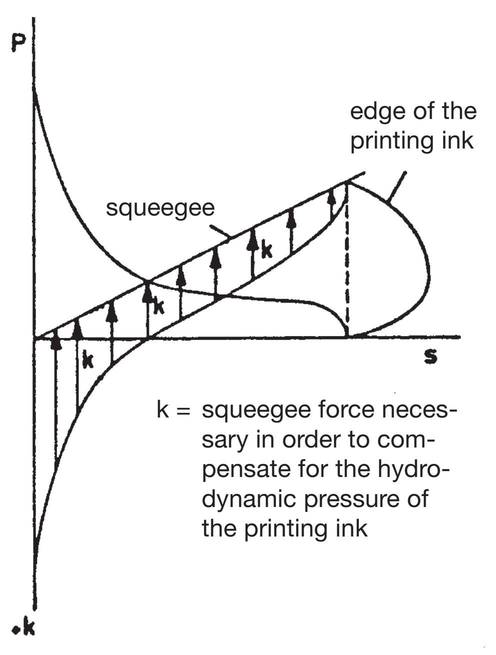

Fig. 8: Load on the squeegee resulting from the back pressure.

clearly the change in the width of the contact zone: in the case of a large squeegee angle, the contact zone is narrower but, with a smaller squeegee angle, the contact zone is wider provided the printing paste is kept at a constant level. This shows that clearly defined geometric proportions in the squeegee/screen/substrate region must exist in order to optimize the printing paste application and that this geometry is constant over the width of the printed area. The back pressure is not only felt by the screen and the substrate, but also by the squeegee. The squeegee force which presses the squeegee against the inside of the screen acts against this pressure loading (Fig. 8).

The different squeegee forces explain the better edge-middle-edge uniformity of the magnetic bar squeegee. In the case of the blade squeegee, the mechanical force exerted on the squeegee comes from above. The squeegee forces required in the blade-squeegee method, ranging from 100–400 g/cm, produce a squeegee loading of up to 74 kg for a print width of 185 cm. Under the stress of this loading, the squeegee housing distorts to produce variations in the squeegee angle. This problem does not arise in the case of magnetic rod squeegees. A corresponding design and arrangement of the magnetic bar produces a higher squeegee force which acts uniformly over the entire width of the print. In spite of this greater squeegee force, the screen loading caused by bar friction, which is produced by the squeegee bar, is less.

Under certain limiting conditions (such as high penetration resistance and low absorption capacity of the substrate) the blade squeegee exhibits vibration phenomena due to the residual elasticity of the squeegee lamella. The printing paste is not able to migrate into the substrate and the squeegee blade presses away towards the back so that application of the printing-paste becomes uncontrollable. Providing the squeegee bar is not bent, this situation cannot arise in the case of the magnetic bar squeegee. Here, the bar is seen to “float” under the limiting conditions mentioned above. The insufficient contact between the bar and the screen which results leads to a reduction in impact pressure and an increase in the residual film on the inside of the screen.

In the case of the blade squeegee, a contact zone of 30 mm and more is produced by the squeegee lamella. The squeegee geometry is varied by the angle adjustment and this produces both a broadening of the contact zone and an increase in the impact pressure. Squeegee kinematics: the movement of the screen alone has an effect. With the magnetic bar squeegee, vibration in the

Tab.: Comparison of the most important parameters of roll and blade squeegees (according to Ferber and Hilden).

squeegee geometry is produced by changing the bar diameter. For the diameters usually used in practice (10–30 mm), this leads to a contact zone ranging from 5–15 mm and the squeegee angle remains constant, depending on the design of the magnetic-bar. Squeegee kinematics: two sources of movement act on the printing paste – the squeegee bar and the screen. The different types of squeegee geometry and kinematics lead to the different back pressure diagrams shown in Fig. 9.

To summarise: qualitatively, neither of the two squeegee methods can be judged to be better (Tab.). Both the magnetic-bar and blade squeegees have their specific advantages and disadvantages. As long as no squeegee systems are built which show neither of the disadvantages mentioned but show all the advantages, the printer, who wishes to produce a sophisticated pattern at the appropriate quality, must be able to master and apply both techniques (according to Ferber and Hilden).

Squeegee washing machine After use, i.e. when changing the colour way or the design, both screens and squeegees must be washed down. Special washing

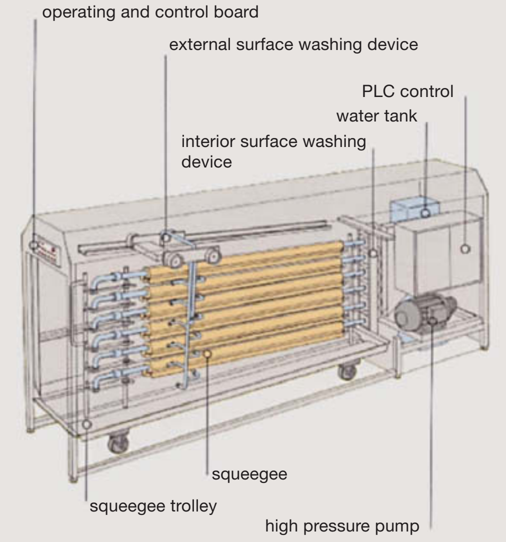

Fig.: A Stork squeegee washing machine.

machines are available for this purpose such as the Stork washing machine (Fig.).

Squeeze off Removal of water or other liquids adhering to the surface of the running webs by pressing between rollers, padder, water calender, aero-flex roller or Roberto roller. → Water extraction.

Different methods are available for uniform squeeze off (Fig. 1).

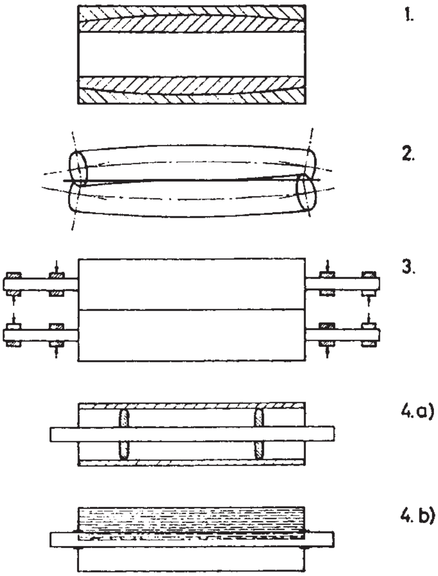

Fig. 1: Possibilities of homogeneous extraction. 1 = cambered core rollers; 2 = skew-positioned rollers; 3 = counter-moment loaded rollers; 4 = internally supported rollers, a) mechanical, and b) hydraulic (swimming roller).

II. → Mineral silicate fibres, → Textile fibre symbols, according to DIN 60 001 until 1988.

St → Stokes.

Stability test Used for the preliminary determination of the expected amount of damage from a temperature at 195°C for three hours (particularly in the case of linseed-oil sized viscose filaments) followed by tensile strength test. A drop of 15–20% in tensile strength indicates damage. The stability test allows the speeding up of lengthy processes on the fibre, it being possible to get a early glimpse of the workability of the affected material later.

Stabilization time (yarn mercerizing), time during which cotton ropes are rinsed after → Mercerizing under tension in order to prevent loss in glaze due to shrinkage.

Stabilized naphthol combination dyes Mixtures of naphthols and fast salts usually used in printing.

Stabilizers Bleaching auxiliaries for → Oxidative bleaching processes. These substances are used to regulate the release of oxygen, help prevent oxygen decomposition by catalysts such as copper, manganese and iron, etc. and prevent the loss of oxygen and prevent local fibre damage. Stabilizers are usually not needed in hard water.

A good stabilizer should be sufficiently effective in small amounts at low and high temperatures in alkaline, neutral and acid liquors. Waterglass is frequently used but does not work in soft water. → Magnesium silicate is the most effective stabilizer and even has a significant stabilizing effect in hot baths. Examples of commercially available stabilizers are fatty-alcohol sulphates, fatty-alcohol phosphates, fatty-acid condensation products or even ethylenediaminetetraacetic acid.

The following model should serve to explain how stabilizers work. The symmetrical peroxide molecule, H–O–O–H, is activated by the addition of caustic soda and forms the perhydroxy anion $^{-}O_2H$ by heterolysis. Homolytic decomposition of the peroxide is also possible (·OH). Both reactions compete and this steers the stabilizer towards the bleaching superoxide anionic radical [$\cdot O_2^-$].

The peroxide can be regarded as a weak acid which dissociates according to the following reaction (acid constant $K_a = 2.5 \cdot 10^{-12}$):

$$H{-}O{-}O{-}H \rightleftharpoons H^{\oplus} + H{-}O{-}O^{\ominus}$$

Hydrogen peroxide acts both as an oxidizing and a reducing agent depending on the medium:

oxidative:

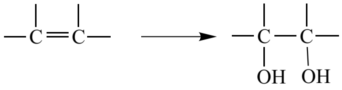
$$H_2O_2 + {}^{\ominus}OH \rightleftharpoons {}^{\bullet}O_2^{\ominus} + H^{\oplus} + H_2O + e^{\ominus}\ (E = -0{,}08\ V)$$

reductive:

$$H_2O_2 \rightleftharpoons O_2 + 2\,H^{\oplus} + 2\,e^{\ominus}\ (E = +0{,}7\ V)$$

The bleaching process gives rise to three effects:

1. Oxidation of the natural pigments in the cotton. These colour pigments, molecules with chromophor groups, can be oxidized by the peroxides and lose their original colour as a result.



$$-\overset{|}{C}=\overset{|}{C}- \longrightarrow -\underset{OH}{\overset{|}{C}}-\underset{OH}{\overset{|}{C}}-$$

(original colour) *(colourless)*

The stabilizer controls the peroxide reaction during the bleaching process by limiting the rate of oxidation while blocking the reactions which damage the substrate. Thus, the peroxide is aimed at bleaching alone. The result which is achieved, therefore, is the max. degree of whiteness without a significant decrease in the degree of polymerisation in the cellulose.

2. Formation of molecular oxygen. This side reaction causes a loss in oxidizing agent and results in a drop in the degree of whiteness as too little peroxide remains available for the bleaching process. The reaction is irreversible.

The stabilizer blocks this process in favour of the required bleaching effect, so that it can be ignored.

3. Oxidation of cellulose. The formation of atomic oxygen is dangerous to cellulose if it is not protected by an organic stabilizer. The stabilizer is effective in blocking this reaction and, as a catalyst inhibitor, protects the cellulose from catalytic damage.

Stabilizing section (stabilizing zone). Section of the piece mercerizing machine in which the caustic liquor is diluted by hot rinsing (to a density of less than 6°Bé) so that shrinkage of the goods (= loss of gloss) is effectively prevented. While the goods are in the stabilizing section, they must remain under tension.

Stabilizing stage Part of the → Mercerizing process. The most important factor during this part of the process is that the impregnated cotton is kept under tension while it is rinsed. X-Ray analysis is used to monitor the transition from cellulose I into Cellulose III. Once the caustic concentration in the goods has dropped below a certain level, rinsing can be continued without the item being kept under tension.

Stain blocking Finishing effect. Active stain blocking prevents penetration of stains and dirt into the substrate (oil-repellent finish). Passive stain blocking eases the removal of dirt which has got on to, or stains which have penetrated into the substrate (→ Soil-release finishing). Basic requirements: from a chemical point of view, it must be ensured that the perfluoroalkyl residue contains at least 4 carbon atoms and one CF_3 end group. The optimum effect is achieved when the perflouro chain contains 8 carbon atoms. The effect of the physical limiting conditions must not be underestimated – uniform distribution of the agent and optimum orientation of the perfluoroalkyl chain will have a beneficial effect, even in the case of small additions. Adhesion to the fibre is imperative for the effects to remain permanent.

Stain breakdown in clothing for dry-cleaning After critical examination, these contain on average:

60%	food and protein stains,
10%	fruit, coffee, inks, water colour and rust, etc.
15%	oil stains,
10%	old fat
5%	other stains.

Staining (colour bleeding) → Soiling:

I. The staining of adjacent undyed textile fabric (or multifibre strip) in colour fastness tests to water, washing, perspiration, etc., caused by the transfer of colorant from a test sample to the adjacent material. The degree of staining is assessed by comparison with the → Grey scales for fastness testing.

II. Staining (bleeding) on to white or coloured accompanying textile fibres during wet processes in finishing which is often caused by the presence of unfixed or inadequately fixed dyes on dyed or printed goods.

III. In textile printing the soiling of white grounds in the print afterwash.

Stainless steel,

I. Steel with special, chemical, physical and mechanical properties manufactured by special steel production techniques (usually in electric arc furnaces) with or without additions of alloying elements (alloy steels). In addition to numerous non-alloyed or slightly alloyed construction steels and tool-grade steels, stainless steels also include corrosion-resistant steels with high resistance to a wide variety of chemical agencies achieved by the addition of chromium, nickel, molybdenum and other metals. A remarkable property of stainless steels with a high nickel content which deserves mention here is the fact that their heat conductivity is only about 1/3 that of usual steels. Stainless steels are very important in textile dyeing and finishing as construction materials for the manufacture of processing machinery and equipment. All non-rusting steels are traded under various names (e.g. Remanite steels, VA steels, etc.) together with a commonly used numbering system to indicate the carbon content and/or type of alloy steel. V4A steel is mainly used in the textile dyeing and finishing industry. The resistance of V4A steel, which contains molybdenum, is particularly good to organic acids and bleaching liquors containing chlorite, etc. For resistance to salts, however, the machine maker's instructions must be observed.

II. (non-rusting steel). Alloy steels which do not corrode in water or in air with a high moisture content, even after long exposure, are described as non-rusting types. Alloy steels of this kind contain more than 12% chromium (chrome steel), e.g. typical formulation: 70–90% iron, 12–20% chromium and 0.1–0.8% carbon.

Stainless steel fibres (non-rusting metal fibres). Stainless steel metal filaments, e.g. metal filaments produced from stainless steel 18/8 or other stainless variants.

Stainless steel pickling The resistance of stainless steels to corrosion always demands clean metal surfaces. Consequently, after each welding operation, all oxide scale or blooming must be removed without fail. For large surfaces, this is achieved by treatment with steel brushes, emery abrasives, sand or glass blasting followed by a subsequent chemical treatment (so-called pickling process) until the oxide scale is completely removed (without roughening the surface). For the manufacture of textile dyeing and finishing machinery, it is sufficient to treat the stainless steel parts with an acid mixture of hydrochloric acid, nitric acid and water.

Stain removal → Stain removal dry-cleaning.

Stain removal dry-cleaning Stains are removed from garments after dry cleaning by means of an aftertreatment with suitable spotting agents. This differs from so-called stain removal processes carried out on materials which are not dry cleaned. The use of spotting agents involves a localized dry cleaning treatment, a wet afterclean, or a bleaching treatment etc., i.e. the art of applying all kinds of physico-chemical reactions to the smallest areas of a textile material in order to remove stains successfully in the shortest possible time whilst, at the same time, protecting the material, the dyeing and the finish as far as possible.

Stain removing, spot cleaning → Stain removal dry-cleaning.

Stain removing table A work table provided with a steam gun for wet and dry steam and air for drying the treated area as well as spray guns, vacuum extraction, etc. Work tops are of various designs but a stainless steel construction with perforations is generally preferred; stainless steel mesh work tops are also used. The table is usually operated with the aid of foot pedals. Virtually all stain removing tables are equipped with a swivelling sleeve board which also has a vacuum connection to an automatic vacuum vibrating valve which switches on when in use and is automatically switched off again when swivelled away from the working area. Most of the work on stain removing tables is carried out with the steam gun. Spotting brushes are reserved for special purposes only.

Stain-repellent finishing → Antisoiling finish.

Stains A collective term for the local discoloration of a textile which is usually undesirable. Stains are caused by chemical bonding between a particular → Soil and the fibre which, in the strictest sense, is not representative of a typical average soil removed by detergents in laundering. In contrast to such easily removed soils, stains must either be decolorized or destroyed with the aid of chemically-active compounds. According to this definition, typical stains produced on textiles are caused by fruit, wine, inks, coagulated blood, heavy metal salts, catalytically-oxidized and hardened lubricating oils, rust, etc. According to other definitions, however, stains are also regarded as a form of localized soiling on textile materials.

Stalagmometer An apparatus consisting of a glass capillary with a specified orifice which is used to measure the → Surface tension of a liquid by the drop method: suitable for dilute aqueous solutions (1–3 g/l). Measurements are based on a comparison, usually against the drop count of pure water: the results can also be converted into absolute values. Principle: low surface tension = smaller drops = a higher drop count. The apparatus is particularly suitable for determining the efficacy of surface-active textile auxiliaries in terms of the drop count and dependence on concentration (at the same temperature).

Stalk fibres A synonym for → Bast fibres.

Stamping inks → Marking inks suitable for marking textile fabrics with identification/reference numbers, etc. capable of withstanding the various treatments involved in finishing. Especially useful for duty-free textile imports to be finished and re-exported, etc. Rapid drying is very important.

Stamping machine,

I. Used for loose-stock dyeing. Loose fibres are press-packed into a dyeing cage by wet stamping, i.e. with the addition of water to wet out the fibres (see Fig.). These machines are available with a single, double or triple ram depending on the cylinder diameter, in order to press-pack the fibres for processing in a bleaching or dyeing cylinder. A homogeneous and densely packed block of fibres is necessary for optimum and uniform dyeing results. A special model is also available for the simultaneous and automatic loading/stamping of synthetic tow material, gauze bandaging and bast fibre tow.

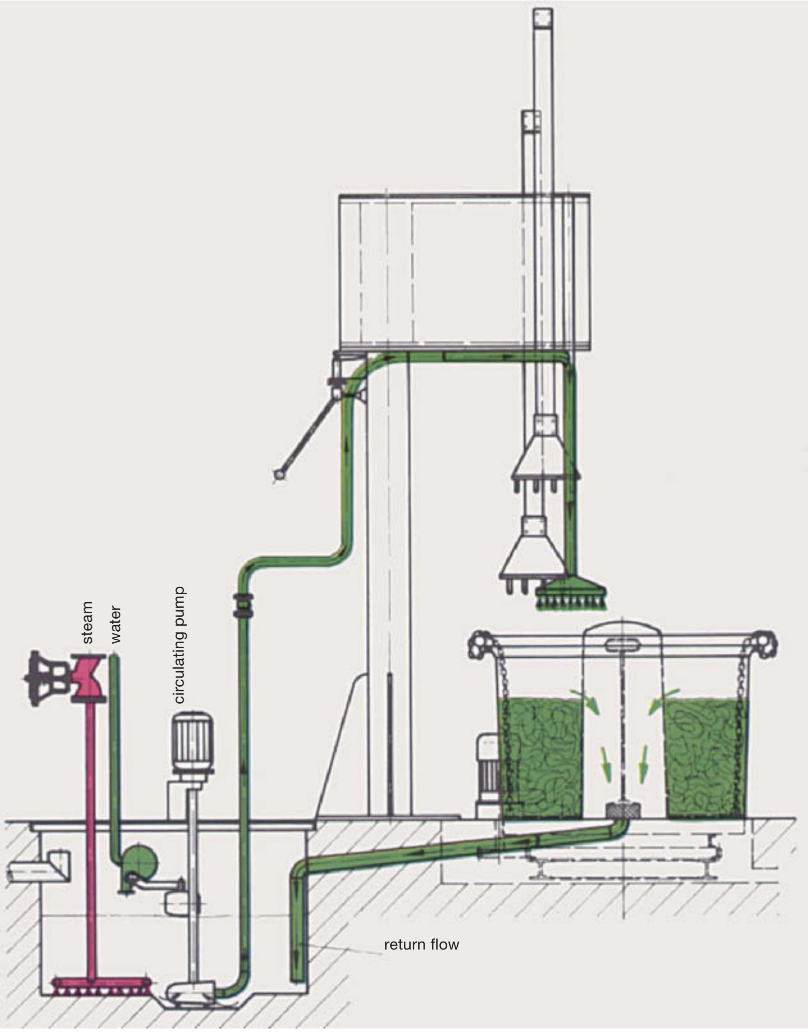


Fig.: Jasper stamping machine.

II. Used in mill engraving for textile roller printing. The first stage is to case-harden and temper the engraved die in order to make it tougher than the cylinder against which it has to be pressed. The hardened die is then placed in the clamming machine against a soft steel cylinder known as a "mill" which will subsequently be used to transfer the design on to a copper printing roller. The mill is either the same size as the die or larger. A specially prepared acid-resistant black paste is applied between the die and the mill in the machine. On rotation, this paste is then left in the engraved lines (hatching) and the roughened edges of the die grip into the soft metal of the mill. With gradually increasing pressures, the pattern lines are gradually transferred on to the mill as raised images coated with black paste. This frictional contact in the machine alternates with several passages through baths of acetic acid, and the acid-resistant coating protects the raised pattern lines which are gradually formed on the mill during immersion in the acid. When the correct depth has been reached by this etching treatment, the raised edges of the mill are turned by hand or on a lathe so that they are smooth and well below the patterned surface.

Standard abbrev. for textile fibres → Textile fibre symbols.

Standard atmosphere →: Air humidity; Air conditioning.

Standard cell A galvanic cell capable of delivering a fixed and constant electromotive force (emf) over a long period of time (when manufactured to exacting standards and used with due care). Uses: calibration of potentiometers and all other voltage measuring devices.

Standard depth dyeing A dyeing produced on a textile substrate from a series of graduated concentrations for the purpose of illustrating an individual dye in a dye maker's → Pattern cards.

Standard depths A series of arbitrarily chosen depths of colour, each of which is judged to be equal for all hues. Standard depths allow dyeing, colour fastness or other properties to be compared on a uniform basis. Also referred to as International Standard Depths as defined in DIN 53 235 and BS 1006: A01: 1978. Since pale dyeings fade sooner than deep dyeings, the colour fastness to light of a dyeing is expressed at different strengths (from 1/25 to 2/1) corresponding to light, medium and deep dyeings of a particular dye. The strength of a dyeing which has been exposed to a light fastness test can be ascertained by comparison with these standard depths. Standard depths are also used in all tests where the same depth of shade is a requirement (e.g. comparative colour fastness tests). The DEK standard depth scale contains about 20 shades produced in the following standard depths (on bright and matt fabrics for viewing under standard illuminant C): 2/1, 1/1, 1/3, 1/6, 1/12, 1/25 (DEK – Deutsche Echtheitskommission – German Fastness Committee). In addition to the foregoing, data for the blue and achromatic shades mainly involved in the production of navy blue and black colours is often given at depths greater than 2/1 SD; these are designated as navy blue/light (N/L), navy blue/dark (N/Dk), black/light (B/L) and black/dark (B/Dk).

Standard depths, colorimetric standardization Dye makers and textile dyers need to measure the dyeing properties and colour fastness of new dyes against available products. For this purpose, a generally accepted basis of comparison must be available. At the end of the 1920's, the first standard depths came into being through collaboration between the major German and Swiss dye manufacturers, who by 1930 had agreed on 10 physical colours of approximately equal depth, together with higher depth navies and blacks. These standard depths, which had been visually adjusted to the same depth of shade, were produced on different materials in order to make visual assessments easier to carry out. In 1935, the German IG Farben and the Swiss dye makers made a commitment to carry out light fastness tests at these depths and assess the results with the → Blue scale on wool which had just been introduced at that time.

By 1960, the 1/25, 1/12, 1/6, 1/3, 1/1 and 2/1 series of standard depths commonly used for textile dyes had already been established very much in their present form. Data on colour fastness and other properties on textiles is published by dye manufacturers at an arbitrarily fixed depth, known as 1/1/ standard depth (SD), which most colourists regard as being of approximately equal depth. Unfortunately, although it had long been taken for granted that this depth of colour had really been determined with some precision it had, in fact, only been vaguely defined. Thus, according to DIN 54 000, 18 dyeings in various colours are prepared which "appear to be of equal depth to the eye of a person with normal colour vision". This depth of colour is described as 1/1 standard depth. Obviously, considerable leeway exists as to what constitutes a standard depth dyeing for the production of these 1/1 standard depth dyeings. This is particularly so when a particular colour does not correspond to one of the 18 colours in the colour sample collection of "1/1 Standard Depths" (Fig. 1) as specified in DIN 54 000 (traditionally referred to as the "barrel organ"). Even here, however, colourists also have different opinions as to the "real" colour depth of these dyeings. For this reason, a colorimetric and unambiguous definition of the 1/1 standard depth for all colours has become an urgent necessity.

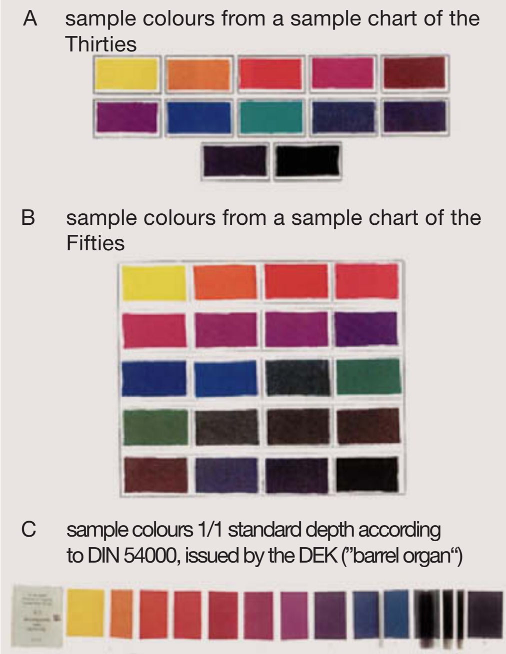

Fig. 1: Sample dyeings on colour charts compared with the DIN "barrel organ" of 1972.

A colorimetric definition for various colour depths in which the 1/3, 1/9 and 1/25 standard depths form the basis of the German Standard 53 235 was drawn up by L. Gall. The Gall formula for a 1/1 standard depth is indeed often used although it has not been widely accepted because it deviates too much from the average perception of experienced colourists (Fig. 2). In view of this situation, colourists of Sandoz AG likewise developed a formula which, in addition to the "barrel or-

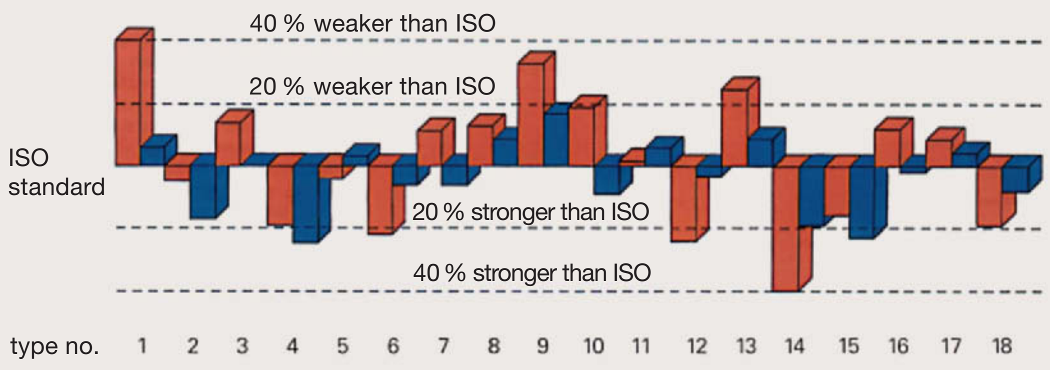

Fig. 2: Deviations of the Gall and the Sandoz standard depth formulations from the ISO standard. Orange = Gall formulations (mean deviation 21%); blue = Sandoz formulations (mean deviation 12%).

gan", was based on more than 100 dyeings spread over all colours and which, according to the consensus of several colourists, had been carefully adjusted to 1/1 standard depth.

The formula defines the space in which the colour loci of all dyeings at 1/1 standard depth lie in CIELAB colour space. This space takes the form of a shell over the C/H plane, i.e. for each purity C and each hue H, the standard depth lightness L_{RT} is given. The function $L_{RT} = f(C,H)$ meets all sensible mathematical conditions:

- it is unambiguous,
- it is continuous overall and continuously discriminating,
- the lowest value lies at C = 0, i.e. on the lightness axis. At this point, the space runs horizontally (parallel to the C/H plane).

With increasing purity, there is a monotone rise in all directions although this is not equally pronounced for all colour angles. The extent of this rise is given by the polynomial P as a function of the colour angle H. P is a cyclic spline function which at H = 0 is also constantly differentiable. The dependence of function P on hue supports the well-known Tatsache Rechnung which also exhibits poor equality of spacing in CIELAB colour space in terms of colour perception.

For a direct comparison with DIN standard depths, the 18 shades were dyed on a similar wool quality to that which had been used for the DIN standard, both according to the DIN model as well as according to the Sandoz formula. This provided a very good approximation to the still obligatory DIN standard depths. Uniformity within the colorimetric series was, however, judged to be better by comparison with the ISO standard depths. The absolute deviations of the new formula nevertheless lie below those which could, for example, have a negative effect on colour fastness tests (according to Christ, Griesser, Meyer and van Diest).

Standard deviation (s). A measure of the dispersion of a distribution or the scatter of a series of numbers or measurements about their mean value which is used in → Statistics. Standard deviation is defined as the square root of the average of the squared deviations of the observations from the group average. Squaring the deviations eliminates negative signs and concentrates attention on the magnitude of the deviations and not their sign.

Standard dyeing time [t_{70}-value, t_{70} (0.5)]. A parameter characterizing the dyeing process which is roughly inversely proportional to the dye diffusion constant. It gives the time in min at 100°C (at a liquor ratio of 40 : 1) required to achieve a bath exhaustion of 70% when dyeing is carried out at half the saturation depth (according to Hoffmann).

Standard electrode potential (E°). Standard electrode potentials are defined by measuring the potential in volts relative to a standard hydrogen half cell using a 1.0 molar solution at 25°C:

$$H_2 \rightleftharpoons 2\,H^+ + 2\,e^- = 0.00 \text{ volt}$$

Electrode potentials cannot be measured absolutely and are usually specified by comparison against a hydrogen electrode which is assumed to have an electrode potential of zero. In practice, a number of more convenient electrodes of known standard electrode potential are used. These are calibrated against the standard hydrogen electrode.

A so-called electrochemical series is established when metals are arranged in decreasing magnitude of their standard electrode potentials. The use of the series allows some qualitative generalities to be drawn. Thus, for example, the higher the metal is in the series the greater the tendency for it to be oxidized. The greater the negative value of the potential, the greater is the tendency of the metal to pass into the ionic state. A metal will normally displace any other metal below it in the series from solutions of its salts. Metals with a negative standard potential release their outer electrons more readily; are converted into the ionic state; easily remove oxygen from other metal oxides (therefore acting as powerful reducing agents); oxidize very rapidly and become very hot in the process. They convert the hydrogen ions of acids into electrically-neutral hydrogen gas and combine with the acid residue, etc. The reverse situation applies to metals at the other end of the series with a positive standard potential where powerful oxidizing agents are to be found; these metals are no longer attacked by non-oxidizing acids (hydrochloric acid, dilute sulphuric acid) and are insoluble in them (at room temperature with exclusion of air); they oxidize reluctantly and with a slight development of heat; the oxides are readily decomposed again, i.e. with the evolution of oxygen. These properties decrease more and more towards the higher end of the electrochemical series and vice versa. In each case, baser metals higher in the series precipitate more noble metals that are lower in the series from solutions of their ions and are themselves converted into the ionic state. From the standard potential, the corresponding values for any two metals may be calculated, e.g. in the electroplating of an iron nail with copper (in $CuSO_4$ solution) some of the iron goes into the solution and the nail is covered with a reddish brown layer of deposited copper since the copper gives up its electrical charge through a shift of electrons to the iron:

$$CuSO_4 + Fe \longrightarrow FeSO_4 + Cu$$

$$Cu^{++} + Fe \longrightarrow Fe^{++} + Cu \downarrow$$

$$Cu^{++} \rightleftharpoons Fe + 0.78 \text{ volt}$$

Standard illuminants (standard light sources). The reliability and reproducibility of any → Colour measurement is highly dependent on the spectral energy distribution of the particular illuminant employed, i.e. on its “colour”. In order to minimize the increasing difficulties of colour matching and colour measurement, so-called standard illuminants (DIN 5033) have been introduced in order to provide standard conditions of illumination which are unambiguously characterized by their standard chromaticity coordinates x, y and z (see Tab.). Thus, when the international system of colour measurement and specification was set up by the Commission Internationale de l’Éclairage (CIE) in 1931 it was recognized that standardized sources of illumination would have to be defined, and three such sources (CIE Standard sources A, B and C) were adopted at that time as approximations to three common conditions of illumination.

illuminant	x	y	z
standard illuminant E	(0.3334	0.3334	0.3332)
standard illuminant A	0.4476	0.4075	0.1449
standard illuminant B	0.3485	0.3518	0.2997
standard illuminant C	0.3101	0.3165	0.3736

Tab.: Standard illuminants and their standard colour value components x, y, z.

In terms of its spectral energy distribution, standard illuminant A was designed in 1931 to be representative of indoor artificial illumination and corresponds to a gas-filled coiled tungsten filament lamp. Standard illuminant B was supposed to represent daylight plus sunlight (lamp with filter) and standard illuminant C was intended to represent average daylight, resp. from a clear northern sky (artificial daylight produced by a lamp with filter) (see Fig.). Standard illuminant C is also specified for use with the → DIN colour chart. Both standard illuminants B and C are now largely redundant in favour of the standard D illuminants which have been introduced subsequently. Indicator colours on various chromaticity diagrams are used to check the spectral composition of a light source. The former standard illuminant E represented a → Standard white in the form of magnesium oxide, i.e. “pure white” light based on the equal energy spectrum.

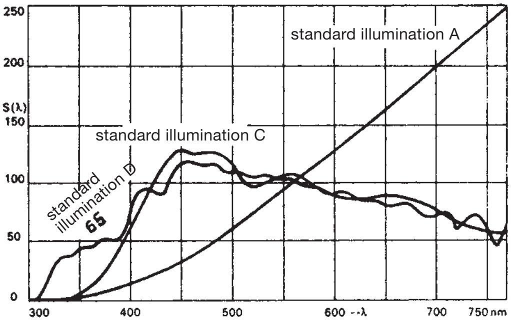

Fig.: Comparison of standard illuminant spectra.

The most important standard illuminants for textiles are:

1. A = tungsten filament light with a colour temperature of approx. 2800 K. An actual source corresponding to this illuminant is readily achieved, and calibrated standard tungsten lamps are available from standardizing bodies in most countries.
2. C = average daylight with a correlated colour temperature of 6774 K.
3. D_{65} = daylight with a UV component (daylight illumination). Studies have shown that standard illuminant C, which was formerly commonly used alone

to represent average daylight had too little energy in the invisible UV region of the spectrum to be of value in assessing fluorescent brightening agents (optical brighteners). Standard illuminant D_{65} was therefore introduced to overcome this problem and, with an approx. colour temperature of 6500 K and standard chromaticity coordinates of $x = 0.3127$, $y = 0.3290$ and $z = 0.3583$, it was accepted by the CIE as a standard illuminant in 1986. Its spectral energy distribution provides a good approximation of average daylight, taking into account the following types of variation:

- from early morning to late evening,
- from a blue sky to completely overcast conditions,
- different latitudes.

Standard light source → Standard illuminants.

Standard observer The standard observer may be defined as the perceptive functions representative of an observer with normal colour vision in → Colour measurement. In the CIE system of colour measurement, the relative amounts of three defined stimuli, mixed additively, required by the average observer to match spectral light at each wavelength under defined viewing conditions. The original 1931 CIE standard observer was based on experiments using a 2° field of view. This is a much narrower field of view than that normally used for critical colour assessments. Subsequent colour matching experiments therefore led to the development of the supplementary 10° standard observer in 1964. The 10° standard observer is recommended whenever a more accurate correlation with visual colour matching of fields greater than 4° is required and, since it is based on conditions of observation which more closely approximate those encountered in practice, it has gained increasing acceptance in recent years (see Fig.). It is used for the calculation of CIE coordinates.

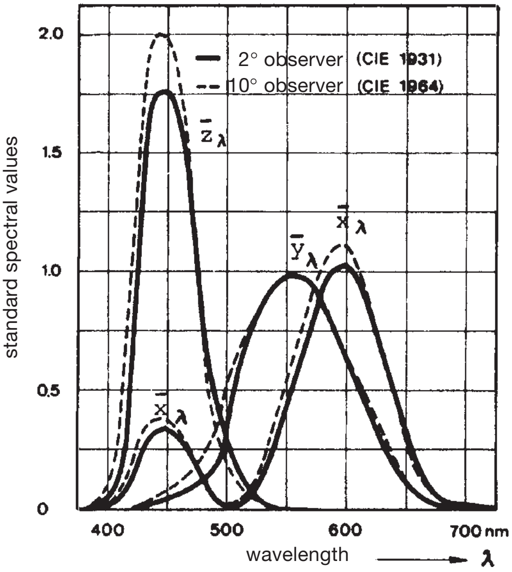

Fig.: Differently defined standard observers for colorimetry.

Standard reactions of man-made fibres Combinations of reactions for each class of fibre which allow a particular fibre to be clearly identified. For conclusive identification, however, all the reactions given for a specific class of fibre must be carried out in each case. The necessity to check these standard reactions constantly against new fibres coming on to market is a disadvantage.

Standard shades In textile dyeing and printing, these are shades in frequent demand, especially black, navy blue, brown, etc.

Standard soil → Soiling test.

Standard soiled fabric → Soiling test.

Standard solutions → Normal solutions.

Standard spectrum values and colour distribution curves characterize the sensitivity of the human eye to the red, green and blue components of visible light. The retina contains three stimulation centres with varying spectral sensitivity, each of which is particularly sensitive to one of the above-mentioned components of visible light. The sensitivity distribution of each of the three stimulation centres, arranged according to the wavelength of light, gives the standard spectral distribution curves (standardized by the → CIE in 1931): $\bar{x}$ (for red light), $\bar{y}$ (for green light) and $\bar{z}$ (for blue light). The light energy of all visible wavelengths falling on the stimulation centre in the retina is integrated according to the sensitivity for each wavelength and transmitted to the brain. The size of this signal, the standard tristimulus value (→ Colorimetric measures) X, Y, Z, is therefore the sum of the products of the light energy falling on the eye and the sensitivity for all wavelengths. → Colour measurement).

Standard strength dyes Dyes which have been adjusted in strength to customary commercial concentrations by the addition of appropriate diluents or extenders. Standard strength dyes are the standard products of a particular dye maker as illustrated in their pattern cards. →: Dyestuff commercial forms; Dye formulations.

Standard times A standard time is the time required for a motivated operative with an appropriate skill level to complete a work task including allowances for relaxation, machine breakdown and interruptions. If technological modifications to machines and production processes are introduced which have a positive or negative effect on already established standard times, the standard times must be checked again and/or recalculated.

The techniques of work study are applied in order to obtain a precise understanding of work flow, work loads and capacity utilization. Central to these timings is the observation of actual work flow undertaken by a work study engineer in order to record observed times for each work element measured in $^1/_{100}$ min units. A sufficient number of these timings allows reliable individual values to be obtained for each work element which is absolutely essential for the fixing of standard times. The results of the observations must be carefully recorded and the record of various timings, i.e. the figures on the time sheet, must be reproducible.

The particular circumstances under which the timings have been measured must also be recorded just as carefully as the times themselves. Since the work performance of the operatives integrated into the production process is subject to continual variation, the time and work studies must be carried out at various times of the day and over an extended period of time.

Starting from the combined time and work study results, individual values for each task to be undertaken are fixed and summarized in a manual. The individual entries are to be understood as net values only and include no allowances. These individual values allow the work study engineer to make cross comparisons against the same tasks carried out in other production departments or they can be used to make individual time comparisons with similar companies elsewhere.

The standard time determination (tA) serves to fix the times which the employee needs for the proper execution of an order assigned to him with normal performance. The standard time (tM), on the other hand, identifies the machine utilization time for a particular order without any contingency for possible waiting times.

For a machine operated by a single person, a standard time and work load calculation is required for optimum machine allocation. The frequencies are multiplied by the appropriate time values from the manual and entered in the corresponding columns tA and tM. For dyeing processes, the frequency values, e.g. for additions and sampling, are already fixed on the basis that a batch is dyed under normal operating conditions with one addition and three sampling operations (according to Hauser).

Standard time t70 A parameter in heat transfer printing. It denotes the time after which 70% of the quantity of dye initially present on a carrier substrate (paper) is transferred on to the textile material and therefore represents a measure of the dye's propensity for sublimation.

Standard white (→ Ideal white). For comparative reflectance measurements, only those pigments capable of giving a full matt white of 100% white content with as near complete reflection of the incident light rays are used. Relatively few substances are able to satisfy these requirements in practice however. For colour measurement applications, the following two pigments are used as standard whites: (1) barium sulphate, where the theoretically almost 100% white content applies exclusively to the chemically pure compound produced from a dried slurry, or (2) freshly prepared magnesium oxide where the degree of whiteness has been set at exactly 100 (%) for all wavelengths although it is, in fact, somewhat lower and decreases still further at increasing wavelengths.

Standards Organizations → Technical and professional organizations.

Standfast molten metal dyeing process (molten metal dyeing). A process developed in England mainly for the continuous vat dyeing of piece goods. It is based on the shock-like development of steam at the interface between an aqueous dyebath and a hot liquid metal bath. The fabric passes through a cast iron U tube (approx. 1.5 m high; walls approx. 3 cm apart) with both legs of the tube being connected at the base via a guide roller (distance approx. 16 cm). The extremely small dyebath (e.g. 4.5 l of vatted dye; temperature approx. 75°C; controlled liquor level 18–20 cm) is located at the fabric entry side and is open at the bottom so that fabric passing through the dyebath runs immediately into the steam-heated molten metal bath contained in both legs (normally maintained at 95–105°C by thermostat control; passage approx. 3 m) after which it leaves the other opening of the tube (fabric exit side) through a bath containing 10% sodium sulphate solution (approx. 18 l). Working principle: a) cylinder pre-drying; b) saturation with dye liquor in a hot dyebath; c) shock-like fixation and simultaneous application of pressure (120–200% pick-up, i.e. lower for a large surface area of fabric) in the hot molten metal bath with exclusion of air; d) removal of unfixed dye in the hot sodium sulphate bath together with any metal particles still adhering to the fabric (achieved by means of a rotating angular roller). The usual oxidation and soaping stages complete the process. At fabric speeds of 25–110 m/min (experimental recommendations for light to medium depth shades are 55–27 m/min) the immersion times in the dyebath are 0.5–0.1 s and in the molten metal bath 7–2 s. The normal working speed is 50–60 m/min. The average production capacity of the process is 27 m/min (including washing-off, colour changes, etc.). Working widths are usually 150 cm up to approx. 240 cm. Colour changes are easily and quickly executed in circulation without stopping the machine (5–10 min). It is also possible to establish dyeing recipes on a laboratory pilot machine. Metal charge: Lipowitz' alloy or Wood's metal usually with a melting point of approx. 70°C (in principle, the temperature of the molten metal bath is kept 20°C above its melting point; less adherence of metal to the surface of the textile). The quantity of metal required is approx. 2 t, and metal losses of the order of 0.11% or more per m of fabric are usual. Advantages: ideal for both small and large batches, suitable for many types of fabric (including those with uneven surfaces), quick colour changes, small volume of dye liquor (favourable for minimum dye consumption), accurate pre-matching of shades is possible in the laboratory, no differences in shade between the beginning and end of a batch, side to centre uniformity, good tone-in-tone dyeings on blend fabrics, no nip creases. Disadvantages: the problem of achieving well-penetrated dyeings on tightly woven fabrics has not been solved (it is advisable to apply the dye first by pigment padding), certain limitations exist with regard to maximum dye yields in deep shades, the process is only recommended for absolutely sulphur-free vat dyes to ensure reliable results, the liquor pick-up cannot be controlled, high investment cost plus licensing fee and metal losses. The process has, unfortunately, not lived up to its early expectations.

Standing bath dyeing In this method of dyeing, where batches are dyed in sequence, the dyebath is not changed during exhaust dyeing and only the exhausted dye is replaced after each batch has been dyed in order to restore the dyebath to its original state and ensure reproducible results. Despite its still secondary importance, the technique has attracted some interest on environmental protection grounds since economic exploitation of the fresh dyebaths is, in any case, largely assured. For all practical purposes, shades are matched in conformity to sample by laboratory matchings or computer colour matching. Dyeing from standing baths is still an important method in → Garment dyeing for the production of standard shades.

Standing dyebaths Dyeing from a standing bath makes use of exhausted dye liquors to produce further dyeings and therefore represents a worthwhile recycling technique. → Standing bath dyeing.

Stannic chloride (pink salt, tin tetrachloride, tin perchloride, tin (IV) chloride), $SnCl_4$, molecular weight 260, density 2.229–2.26. Colourless, water-free, corrosive, fuming liquid, almost chemically pure with a 45.4% tin content. Evolves heat on contact with water. Uses: mordant for alizarin dyeing, weighting of silk, clearing and softening of silk, manufacture of fuchsin, colour lakes.

Stannous acetate (tin (II) acetate, acetate of tin), $Sn(C_2H_3O_2)_2$, molecular weight 236. Aqueous solution. Used as a reducing agent in discharges on substantive dyes (especially black).

Stannous chloride (tin crystals, tin salt, tin dichloride, tin (II) chloride), $SnCl_2 \cdot 2\,H_2O$, MW 225, density 2.71. White salt, hygroscopic, soluble in water, powerful reducing agent. Uses: discharge printing, tin mordant (for shading alizarin red and pink on the yellower side to give fiery shades); aftertreatment (with soap) of alizarin red; resists (wool resists); spotting agent.

Stannous oxalate (tin (II) oxalate), SnC_2O_4, molecular weight 206.5. Uses: dyeing and printing of textiles; mordant for alizarin print pastes and dyeing (more vivid pink and red shades).

Staple fibre Unlike a continuous → Filament, a man-made staple fibre is produced in predetermined short lengths (cut into short lengths) for spinning into → Spun yarns (see Fig.).

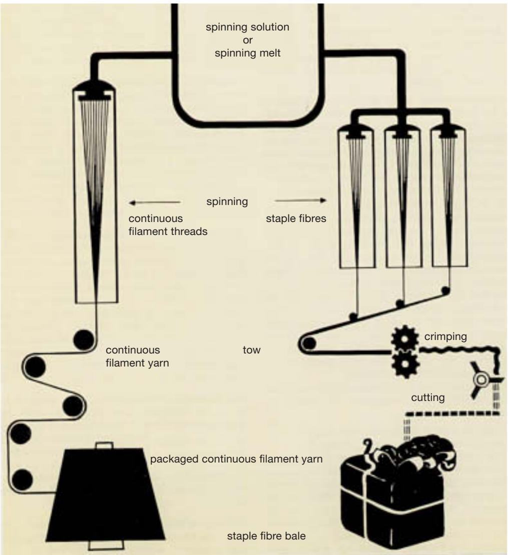

Fig.: Production of man-made continuous filament yarns and man-made staple fibres (simplified diagram).

Staple gun Used in screen making with → Staples.

Staple length is the average length of → Staple fibre which, in the case of man-made fibres, can be any predetermined cut length. The staple lengths (in mm) of some natural and regenerated cellulose fibres are as follows:

1–5 = jute
5–50 = recovered wool
10–25 = hemp
0–50 = cotton
15–50 = bourette silk
25–45 = flax
30–150 = viscose staple fibre
60–150 = schappe silk
70–200 = ramie
50–300 = wool
approx. 1000 = raw silk

Staples Used to attach screen gauze to the wooden frames of flat printing screens.

Starch occurs as microscopic granules in the roots, tubers and seeds of plants. The structure of starch is based on α-glucose residues resp. maltose groups, unlike cellulose (which is built up from β-glucose residues). The chief components of starch and some of their characteristics are given in the Tab. This clearly

Starch

characteristics	AMYLOSE	AMYLOPECTIN
in the starch granule	inner constituent	sheath constituent
potato starch	approx. 20 %	approx. 80 %
maize starch	approx. 30 %	approx. 70 %
chemical	mixture of linear polysaccharides in maltose bonding of 60–400 glucose residues, different chain lengths	mixture of intensively branched polysaccharides in isomaltose bonding of 600–6000 glucose residues, containing approx. 0.075 % P (as phosphate group, ester- like)
electrochemical	non-ionogenic	anionic (elec.conductive, reacts with lyes etc)
in hot water	colloidal soluble	insoluble, slowly swells to a paste, congeals on cooling
with iodine solution	blue colouration	violet to brown colouration

Tab.: Starch constituents.

reveals why potato starch in particular is used in Europe for sizing purposes whilst maize (corn) starch, on the other hand, is used for textile printing.

Arrowroot, potato, maize (corn), rice and wheat starch are important commercial sources. Starch products based on degraded starches for sizing and finishing are usually produced as more or less soluble starches. In the broadest sense, starch products may also include those based on fruit seed grains (carob seed grain), mucilages from algae, mosses, etc. which are also used as sizes, finishes and thickeners for textile printing.

Starch belongs to that group of polysaccharides characterized by the linking together of a more or less large number of sugar building blocks through glycosidic bonds to form macromolecules. The build up of starch from glucose molecules may be described by the following empirical formula:

$$n\,(C_6H_{12}O_6) \rightarrow (C_6H_{10}O_5)_n + (n{-}1)\,H_2O$$

In addition to the polysaccharide substance which is present as the chief component, starch grains also contain small proportions of lipoid-like compounds (0.04–0.63%) depending on the type of starch, as well as ash-forming constituents, especially phosphate. This is bound to the polysaccharide substance by ester-like linkages in potato and root starches. Native starch also contains 12–20% water. Starch consists of two structurally different polysaccharides, i.e. amylose and amylopectin. Because of their structure and average molecular weight, these components are responsible for the properties of starch. The amylose fraction which, depending on the type of starch, accounts for 14–27% of the starch, is built up in the form of a linear chain. The glucose units in amylose are connected by α-1,4-glyco-

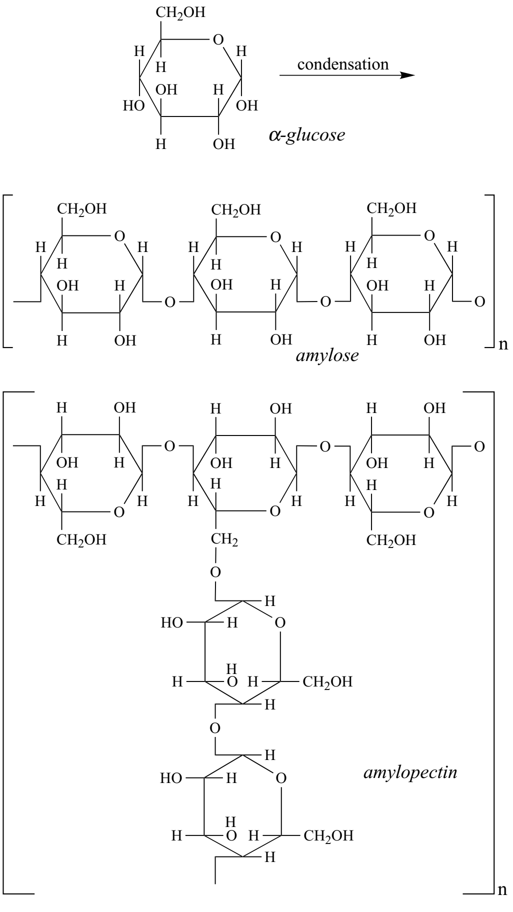

Fig. 1: The structure of amylose and of amylopectin.

sidic linkages so that each amylose molecule contains a reducing (aldehyde) and a non-reducing group. Amylopectin, on the other hand, has a branched structure resulting from the presence of additional α-1,6-glycosidic linkages (Fig. 1).

Chains of D-glucose units with α-glycosidic linkages such as those of amylose tend to assume a helical arrangement in which the glucose units are fixed in a chair configuration. This arrangement results in a compact shape for the amylose molecule even though its molecular weight is quite large (150 000–600 000). Amylose forms a blue inclusion compound with iodine in which a complete helix is formed from 6 glucose units, each with one iodine atom included in the hollow space (Fig. 2).

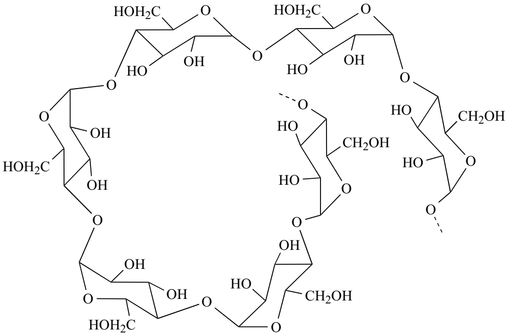

Fig. 2: Helical amylose structure.

Amylopectin has a structure similar to that of amylose (i.e., α-1,4 linkages) with the exception that in amylopectin the chains are branched. Branching takes place between C–6 of one glucose unit and C–1 of another and occurs at intervals of 20–25 glucose units. Physical measurements indicate that amylopectin has a molecular weight of one to six million. The branched amylopectin exhibits a largely globular spatial arrangement which becomes manifest in the high hydration capacity of the molecule. The complex structure of amylopectin may be explained by association between the free ends of the molecule branches by hydrogen bonding. In native starches, amylose and amylopectin are present alongside each other in the layers of starch grains. These are associated in a radial direction through hydrogen bonding and produce microcrystalline micelles. Even when starch is boiled in water, the cohesion within the micelles is so strong that they do not completely dissolve but form a loose network of associated molecules. During swelling in water, the free polysaccharide branches are solvated first, and then the ordered regions of the micelles (Fig. 3).

The term "modified starches" includes all those starch products whose properties have been modified by physical, chemical or biochemical means, whether this has been achieved by a change in the physical state, process of degradation, the introduction of functional groups into the starch molecule or a combination of various means.

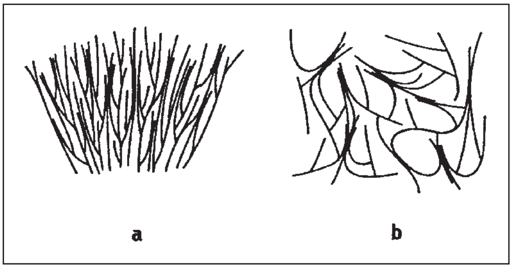

Fig. 3: a = the radial layered structure in a native grain of starch; b = the disintegration of the layered structure during swelling.

The aim of the sizer is to degrade starch on boiling to an extent where it develops a sufficiently stable viscosity. In this regard, care must be taken to ensure that the viscosity of the starch size does not decrease further under the action of shear stresses in the nip of the squeeze rolls in the size box and in the circulation pump. With a stable size viscosity the degree of sizing (→ Sizing, degree of) on the warps is constant.

Native starch is insoluble in cold water. This is due, to inter and intramolecular hydrogen bonding between the hydroxyl groups of the starch molecule on the one hand, and between the hydroxyl groups of bound water on the other. With a bonding energy having an order of magnitude of 10 kJ/mol, hydrogen bonds are weaker than valency bonds (approx. 100 kJ/mol). However, because of the great number of hydrogen bonds in this case, the bonding energy of a valency bond is reached in the starch so that the hydrogen bonds are not broken down in cold water and only a reversible swelling of the starch grains occurs. With an increase in the temperature to approx. 60°C, the amorphous regions of the starch micelles begin to swell first and, with a further increase in temperature, the crystalline regions also swell until the maximum viscosity is reached. Under increasing swelling pressure the amylose goes into solution whilst the amylopectin remains in a gel form. The conversion of swollen starch from the microgel state into a sol state is only achieved at temperatures above 100°C (pressure cooking). Solubility can also be achieved at temperatures below 100°C with the simultaneous application of mechanical energy by stirring or shaking. Under intensive stirring and the simultaneous introduction of atmospheric oxygen, oxidation of starch takes place and the swollen starch grains begin to collapse with a consequent reduction in molecular weight. The result is a colloidal solution consisting of swollen starch fragments, hydrated starch agglomerates and dissolved starch molecules. During storage at reduced temperatures, the starch paste sets again to a porridge-like consistency. This so called retrogradation is due to a recrystallization of the amylose fraction and presents several disadvantages to the sizer such as limited shelf life, reduced adhesive power, etc.

A number of different compounds have a hydrotropic effect on potato starch. This effect manifests itself by an increase in solubility, a reduced viscosity of the starch solutions, and a marked suppression of their thixotropic properties. The viscosity-dependence of potato starch on electrolytes is due to the phosphate groups of the amylopectin. Whilst native potato starch first begins to swell in aqueous solution at temperatures above 60°C, swelling already occurs at lower temperatures in the presence of hydrotropic substances and, with a further increase in temperature, a colloidal solution is obtained. A reduction in viscosity has been observed in the presence of water-soluble ionic substances (salts) such as potassium bromide, potassium iodide, calcium chloride and ammonium thiocyanate as well as water-soluble non-ionic compounds such as urea and thiourea. With ionic compounds, the action is induced by the anion. The effect of hydrotropic agents may be explained in a similar way to the influence of increased temperatures on the swelling of starch grains. At increased temperatures, the association of water molecules (cluster formation) is reduced so that the molecules can penetrate the starch grains more easily and cause swelling. When hydrotropic substances are added to the solvent, a hydrate formation of the ions resp. molecules of the hydrotropic agent occurs. Free hydroxyl groups are formed which cause the water molecules to become more hydrophilic so that they can penetrate the starch grains and bring about swelling followed ultimately by their solution. Some of the hydrogen bonds between the starch molecules are broken down so that the hydrated ions are now bound to the hydroxyl groups of the amylose by hydrogen bonds. Rupture of the hydrogen bonds between the starch molecules causes a considerable reduction in the viscosity of the solutions.

Starch/acids → Starch degradation with acids should normally be avoided (→ Starch decomposition, loss of starch substance); the formation of dextrin is more rapid and the rate of saccharification varies depending on the particular acid. Oxalic acid is an exception (0.1% of the weight of the starch) where hydrolysis proceeds as far as soluble starch and no dilution of the starch solution occurs even without neutralization.

Starch decomposition The degradation of starch proceeds through starch hydrolysis to complete breakdown of the starch molecule firstly to dextrin and then to starch sugar. In → Desizing processes, enzymes, e.g. → Diastases, are used for this purpose. However, in the preparation of starch solutions for sizing and finishing applications, other conditions are present so that in this case the greater quantities of starch exercise a protective colloid effect with the result that the optimum temperature lies somewhat higher; at lower temperatures any further degradation is inhibited. In the desizing process, the situation is different insofar as practically starch-free solutions are involved here and degradation of the starch can therefore proceed unhindered.

Starch degradation When aqueous suspensions of starch are heated, the following processes take place: firstly, the starch grains begin to swell and enlarge, then absorb water after which starch separates from the layers forming the grain, and the outer skin bursts. The soluble internal components of the grain swell out and are distributed in the water in colloidal form. The resultant → Starch paste consisting of coarsely dispersed starch particles is of no value for sizing or finishing in this form. A further diminution of the particles takes place without any significant degradation (molecular weight from approx. 150 000–15 000) by: a) increasing the temperature (110–120°C) with superheated steam under pressure; b) by stirring, forcing through fine nozzles, homogenization, and treatment in a colloid mill; c) through chemico-colloidal additions, i.e. inorganic or organic salts (urea, sodium salicylate, wetting and dispersing agents; d) oxidation products → Starch oxidation products. The end products of starch hydrolysis are valuable soluble starches. → Starch decompsition.

Starch degrading agent These products are used in → Starch degradation, especially for the production of textile sizes and finishes. Product basis: substances capable of liberating oxygen or preparations containing such substances, as well as → Enzymes. → Desizing agent.

Starch degrading enzymes → Diastases.

Starch esters These are starch products esterified with acetic anhydride, phosphoric acid or other acids which can be used as textile sizing and finishing agents. Starch esters produce more or less free-flowing pastes.

Starch ethers Mainly oxypropyl or carboxymethyl starches formed by the action of propylene oxide or monochloroacetate on starch. Monochloracetic acid gives the much used carboxymethyl ether which is anionic in character. Starch ethers are soluble in water to give more or less viscous solutions which exhibit good resistance to acids and metal salts. They are used as sizing and finishing agents, thickening agents for textile printing and, in combination with synthetic resins, also for resin finishing. As thickeners for textile printing, they have been recommended for use in mixtures with galactomannans or alginates to increase colour yields.

Starch film → Starch (sizing, finishing) films.

Starching machine,

I. Finishing mangle usually with a large trough (pad box).

II. → Yarn liquoring machine.

Starch modifications → Modified starches.

Starch oxidation products → Starch degradation resulting from the use of these products leads to the formation of soluble starches. Further → Starch decompsition is excluded. For textile sizes and finishes, an addition of approx. 10–20 g of a product capable of liberating oxygen (sodium perborate, percarbonate, persulphate, sodium or hydrogen peroxide, or products containing chlorine) is made per 1 kg of starch followed by boiling for about 10–20 min. Any weakening of the solution through dilution is excluded with this procedure. The addition of such catalysts accelerates the hydrolysis of starches (perborate gives a higher viscosity index; white content 89%) Under certain circumstances perborate causes yellowing. For starch hydrolysis, oxidation products (previously with additions of fats, waxes and glue if required) are superior to the → Diastases. For the → Desizing of starch-based sizes, on the other hand, the reverse is (usually) the case.

Starch paste External characteristics: opaque, sticky; iodine reaction: dark blue; solubility: insoluble in water; technical qualities: fibre adhering, pore blocking (suitable for use as a printing thickener), good covering properties, subject to chalking, readily forms dust. The starch films are non-transparent, of average strength and low elasticity.

Starch size Starch is still the most commonly used sizing agent for the weaving of cotton and viscose fabrics and has the advantage of being biodegradable. The question of → Size recycling, as in the case of synthetic sizing agents, does not arise with starch sizes. → Sizing selection criteria.

Starch (sizing, finishing) films The addition of wetting agents, softeners, etc. to starch solutions reduces the strength and extensibility of starch films. The addition of glue increases the strength but reduces the extensibility: the latter can be increased, however, by the addition of oil or glycerine at the expense of strength. The addition of vegetable gums (→ Locust bean flour) results in a firmer handle and greater stiffness, but with reduced tensile strength and increased resistance to abrasion.

Starch, soluble (soluble starches). This is not a starch product with a definite composition but represent a series of similar starch modifications which are completely soluble in hot water to give solutions of different viscosities which can be used for various applications in sizing and finishing. Solution characteristics: a) external appearance: transparent, thick, creamy, with coherent flow properties; b) iodine reaction: blue; c) solubility is only possible in hot water; d) technical qualities: good fibre penetration, good filling, stiffening properties, does not affect dyed or printed shades. Starch films produced from soluble starches are quite transparent and exhibit high strength and elasticity.

Starch sugars (starch syrup). As the end product of starch degradation, starch sugar is identical to → Maltose (malt sugar) and → Glucose (grape sugar). External characteristics: aqueous, without body; iodine reaction: colourless; solubility: readily soluble in cold water. Technical qualities: starch sugar has neither a stiffening nor a hardening effect and is hygroscopic.

Star dyed A term used to describe dyeings produced on the → Star frame.

Star dyeing A process for dyeing (usually delicate) textile fabrics in → Star dyeing machines, especially velour upholstery fabrics and other pile fabrics made of cotton, natural silk, acrylic, polyester, acetate, etc.

Star dyeing machines These machines are particularly suitable for dyeing delicate textiles (e.g. chiffon, cotton velvet, velour upholstery fabrics, chenille furnishing fabrics, and natural silk). In conventional star dyeing (vertical machine), the → Star frame to which the fabric is attached is lowered into the dyebath contained in a kier and moved continuously up and down with a gentle reciprocating motion (see Fig.). In the vertical type of star dyeing machine, the dyeing vessel is fully flooded with liquor. Consequently, this method of dyeing requires a relatively high consumption of energy as well as a considerable volume of dye liquor, and can therefore lead to relatively high environmental pollution.

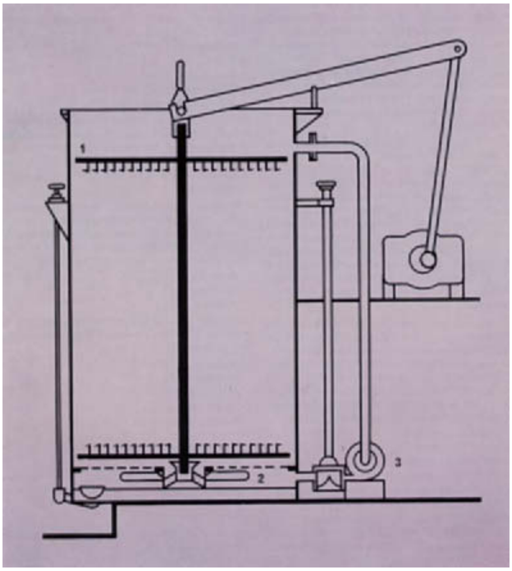

Fig.: Diagram of a suspension star (by Bayer).
1 = material carrier; 2 = heating coil; 3 = liquor circulation pump.

In the horizontal star dyeing machine, on the other hand, the fabric is supported on both edges between two parallel star frames fixed on a central axis to form a spiral batch. After the dual star frame, loaded with fabric, has been introduced into the dyeing machine, it is reciprocated mechanically in a half-flooded dyebath.

Star frame A frame having radial arms resembling the points of a star with hooks placed fairly close together on each arm. It is used to suspend delicate fabrics in the open width state in → Star dyeing machines, either from one edge (vertical star dyeing machine) or both edges (horizontal star dyeing machine). Starting from the centre of the frame, the fabric is suspended from the hooks to form a spiral batch. For fabrics with sensitive edges, a narrow cotton or linen strip is first sewn along the edge/s to be suspended. Star frames loaded in this manner are either moved up and down vertically (vertical machine) or horizontally about their axis (horizontal machine) in the dyebath so that, in the latter case, only half of the star frame is immersed in the dye liquor at any one time (advantage of shorter liquor ratio).

Star steamer → Batch steamers.

Start up (e.g. machine). The action of starting up a machine in order to set it in motion.

Star washing machine (X machine). A drum type washing machine with a → Compartmented drum.

Statex thread An elastic rubber (sheath) thread with the initially wrapped textile core thread dissolved out.

Static charge Whenever two different materials are separated an → Electrostatic charge builds up between them. A triboelectric effect is involved here and materials can be arranged in order according to their interactions. The more dissimilar the materials, e.g. carpet materials, the greater the charge produced. The intensity of the charge is influenced by several factors, e.g. type of carpet, shoe sole material, relative humidity and the person. An electrostatic charge which has built up remains on the shoe sole and the carpet, and a means of discharging it has to be found. This build up of an electrostatic charge on the shoes is distributed over the entire person and finally discharged to earth via a door handle, heating element or other metallic elements. This discharge can be unpleasant and, in some cases, can damage sensitive electronic equipment. The simplest solution to the problem is to increase the conductivity of the carpet so that when the surfaces are separated the charge is conducted away rapidly and cannot build up further.

Test methods for measuring the static charge:

1. Walk test (AATCC Test Method 134 – 1979): in this test a person walks backwards and forwards in a specified manner with specified soles and heels over a carpet which has been conditioned for at least 3 days in dry air (23°C and 25% relative humidity). The test person carries a sensor connected to a static voltmeter which registers the voltage absorbed by the body. The test is carried out with three standardized shoe soles: a) BAM = natural rubber; b) Neolite = synthetic rubber, and c) polyvinyl chloride = a typical synthetic shoe sole material. If the voltage exceeds the sensitivity threshold, the carpet has not withstood the Walk Test. The sensitivity threshold is the voltage at which only few people are aware of any static shock or discomfort. In general, 2000–3000 V has been agreed upon and, for this test, the limit has been fixed at 2000 V.

2. Electrical resistance test (volume resistivity): this test involves measuring the electrical resistance of a carpet – a property which is indirectly connected with its antistatic behaviour. A direct current voltage is applied via two electrodes in contact with the carpet which allows a direct measurement to be made of the volume resistivity. When the electrodes are placed on the back and face sides of the carpet, the mass or volume resisting force is measured; however, if they are placed on the surface only, a measurement of the surface resistance is involved. Several test methods are available and each method is based on its own electrode system. The two most well-known methods are the IBM/ICL Test and the test according to DIN 54 345 Part 1. The IBM/ICL method contains guidelines which state that the resistance of carpets in rooms where computers are used should be at least $5 \cdot 10^5$ and a maximum of $2 \cdot 10^{10}$ ohms. It is assumed that no static charge would arise between these values which could be conducted away through sensitive instruments.

In reality, no direct relationship exists between the volume resistivity of a carpet and its propensity to develop an electrostatic charge (according to Smith).

Static discharge A static discharge prevents the build up of an → Electrostatic charge. → Ionizers.

Static loading resistance The test according to DIN 54 316 is designed to simulate indentations on textile floorcoverings caused by furniture. The thickness of the specimen is determined before the application of a heavy load (2200 cN/cm^2; a_{2200}) = normal thickness a_{20}, as well as after a specified recovery time (60 min; $a_{20,E}$). The compressibility Z ($Z = a_{20}–a_{2200}$) and the depth of the indentation after the load is released e ($e = a_{20}–a_{20,E}$) provide a measure of the indentation propensity of the carpet. The appearance of the indentation is also assessed visually under specified illumination and viewing conditions after a specified recovery time. The test apparatus measures the thickness of the carpet and applies the required load by means of a pressure piston (circular support surface 10 cm^2).

Static pressure The equilibrium pressure which, in the dyeing of loose stock, wound yarn packages and hanks in HT dyeing machines, ensures safe treatment at temperatures above 100°C (high temperature conditions) as well as well-penetrated and level dyeings in a short period of time.

Statistical analysis All measurements or tests involve the accumulation of measurements in the form of individual values (or a series of measurements). We are concerned with measurable variables here (e.g. length, pressure, temperature, moisture content, etc.) which, in the main, obey a normal distribution. In contrast to these, however, some numerical results (e.g. for defects, rejects) obey a Poisson distribution. The most frequently used statistical measures applied to a series of measurements include calculation of the arithmetic mean $\bar{x}$, the standard deviation s, as well as the mean range R if necessary. Undoubtedly, the most generally useful statistical measure is that known as the mean, or average, obtained by adding together the individual values of the variable, and dividing the sum by the number of individuals. It is often referred to as the arithmetic mean and the word "mean" by itself always signifies the arithmetic mean. In order to compare a series of measurements where the mean values differ greatly from one another with regard to their mean variation, it is necessary to determine the variation coefficient v since the standard deviations are smaller for a series of measurements with small mean values and greater for a series of measurements with large mean values. The variation coefficient gives the standard deviation in % of the mean value.

Further information on a series of measurements gives the confidence limits resp. the relative confidence interval of the mean value at a selected confidence level. In technical statistics, a confidence level of 95% has become widely accepted in practice. The relative confidence interval of the mean value is given as a % of the mean value and, together with the selected confidence level, gives the range within which the true mean value lies. The distribution of individual values is also of particular interest and, in this case, it is not only the test for normal distribution but also the concrete form of the distribution (histogram) which provides important information relating to a series of measurements. The histogram (bar chart) is a graphical representation of a frequency distribution which in some respects is very similar to the frequency polygon. The x-axis is marked in the same way with the values of the variable being measured. The frequencies in the groups, however, are not represented by a point at a height proportional to their frequency, but by a rectangle with an area proportional to the frequency, having as base the x-axis between the group limits.

1. Arithmetic mean $\bar{x}$: as the most important parameter for a normal distribution the arithmetic mean gives the centre of the frequency distribution. Although it is the most familiar statistical measure, it should be emphasized that it only provides a partial description of the frequency distribution from which it is calculated. Distributions of very varied shape and spread may yet have the same mean. Nevertheless, it is an exceedingly useful measure, and provides enough information for many purposes:

$$\bar{x} = \frac{1}{n} \sum x_i$$

2. Variance s^2: a measure of the dispersion of a distribution of a random variable:

$$s^2 = \frac{1}{n-1} \sum_{i=1}^{n} (x_i - \bar{x})^2$$

The variance of a random variable is usually written s^2 and is the square of its standard deviation.

3. Standard deviation s: a measure of the dispersion of a distribution given by the positive square root of the variance:

$$s = \sqrt{s^2}$$

4. Variation coefficient v: a relative measure of dispersion:

$$v = \frac{s}{\bar{x}} \cdot 100\,\%$$

5. Absolute confidence interval of the mean value q: this parameter gives the range in which the mean value of the populations lies:

$$q = \pm t \cdot \frac{s}{\sqrt{n}}$$

6. Correlation coefficient r_{xy}: a measure for the linear relationship between x and y. The value always lies between the two limits –1 and +1.

$$r_{xy} = \frac{\sum_{i=1}^{n} (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^{n} (x_i - \bar{x})^2 \sum_{i=1}^{n} (y_i - \bar{y})^2}$$

7. Coefficient of determination B: this parameter identifies the percentage of dispersions of a characteristic which correlate with those of others:

$$B = (r_{xy})^2$$

8. Existence test t: this test is carried out in order to establish whether the correlation coefficient of the population can be zero or not:

$$t = \frac{r_{xy}}{\sqrt{1 - r_{xy}^2}} \cdot \sqrt{n-2}$$

The t-test is a test used on the means of small samples of one of these null hypotheses:

– that the sample has been drawn from a population of given mean and unknown standard deviation (which has therefore to be estimated from the sample)
– that two samples have both been drawn from the same parent population.

F-test: (1) A test applied to the variances of two samples, of the null hypothesis that they have both been drawn from the same parent population. (2) A test applied to the variance of a single sample, of the null hypothesis that it is drawn from a known normal parent population.

The t test involves the investigation of the variability of two mean values whilst the F test is defined as a dispersion test. For the practicing engineer it is important to know that the following procedures can be carried out with the F and/or t test:

– difference between target and mean values in a series of measurements,
– difference between two mean values/distributions,
– difference between two numerical values,
– poisson distribution.

In principle, all variants of the comparison between two variables with a freely selected confidence level have a common relationship (as a rule, a figure of 95% is adopted for technical applications). In this way, a tabulated value of a distribution (F or t) is always compared at a selected confidence level with the respective degrees of freedom and a calculated value. The following cases can arise: a) calculated value ≤ tabulated value (e.g. $F_e < F$), i.e. the difference between the observed variables (e.g. mean value and target value) is coincidental; b) calculated value > tabulated value, i.e. the difference between the observed variables is significant (according to Hörl).

Statistical certainty →: Confidence factor; Statistical analysis.

Statistical process control (SPC). In most organizations it is necessary to measure and establish the so-called “capability of a process”. In many industries this requires the use of certain procedures which are grouped under the general heading of statistical process control (SPC). In addition to measuring capability, controlling and improving processes through the use of statistical techniques, it might also be necessary to identify and classify lots of batches of material by their characteristics, select samples, determine any rules for acceptance or rejection of material or for adjusting the severity of inspection and the segregation and screening of rejected materials. The system should refer to the statistical procedures used and give the areas of their application. SPC is not only a tool kit, it is a strategy for reducing variability, the cause of most quality problems: variation in products, in times of deliveries, in ways of doing things, in materials, in people’s attitudes, in equipment and its use, in maintenance practices, in fact, in everything involved in the production process. With its aid, the statistical variability of processes and work flows is predictable. This contributes to better planning as well as the objective and rapid evaluation of data. On the one hand, undesired variations can be recognized in the form of a trend and promptly corrected and, on the other hand, positive aspects can be specifically reinforced. The SPC method (see Fig.) is supported by the control chart which provides a graphical representation of measurements dependent on time.

Statistical quality control An aspect of → Quality control which involves inspecting and testing a sample of a raw material, component or product in order to reach conclusions concerning the quality of all the output of that material, component or product. Where inspection or testing involves destruction of the product, statistical quality control based on sampling is the only means of monitoring quality. It is achieved by the application of mathematical statistical procedures, e.g. with the aid of → Control charts for acceptance tests on manufactured products by → Random sampling.

Statistics The mathematical manipulation and analysis of numerical data in order to quantify and interpret trends and frequencies in industry, manufacturing and technology. Statistics involves the objective evaluation of empirically determined measurements and analytical data. The results of statistical analysis provide reference points for a production department or measuring procedure with regard to its inherent limits of accuracy and inaccuracy. The science of statistics is used in industry to optimize production, e.g. in statistical → Quality control.

Status nascendi (Lat.). A nascent state (e.g. → Active oxygen).

Statutory units (in metrology) → SI system of units.

Steam (water vapour). Steam is normally generated at constant pressure in boilers. The heat content per kg, or specific enthalpy, of steam depends on pressure and temperature. Steam may be either saturated or superheated. Saturated steam is a vapour and, at a particular pressure, has a definite temperature, the saturation temperature. Superheated steam is a gas and, at a particular pressure, may have any temperature in excess of

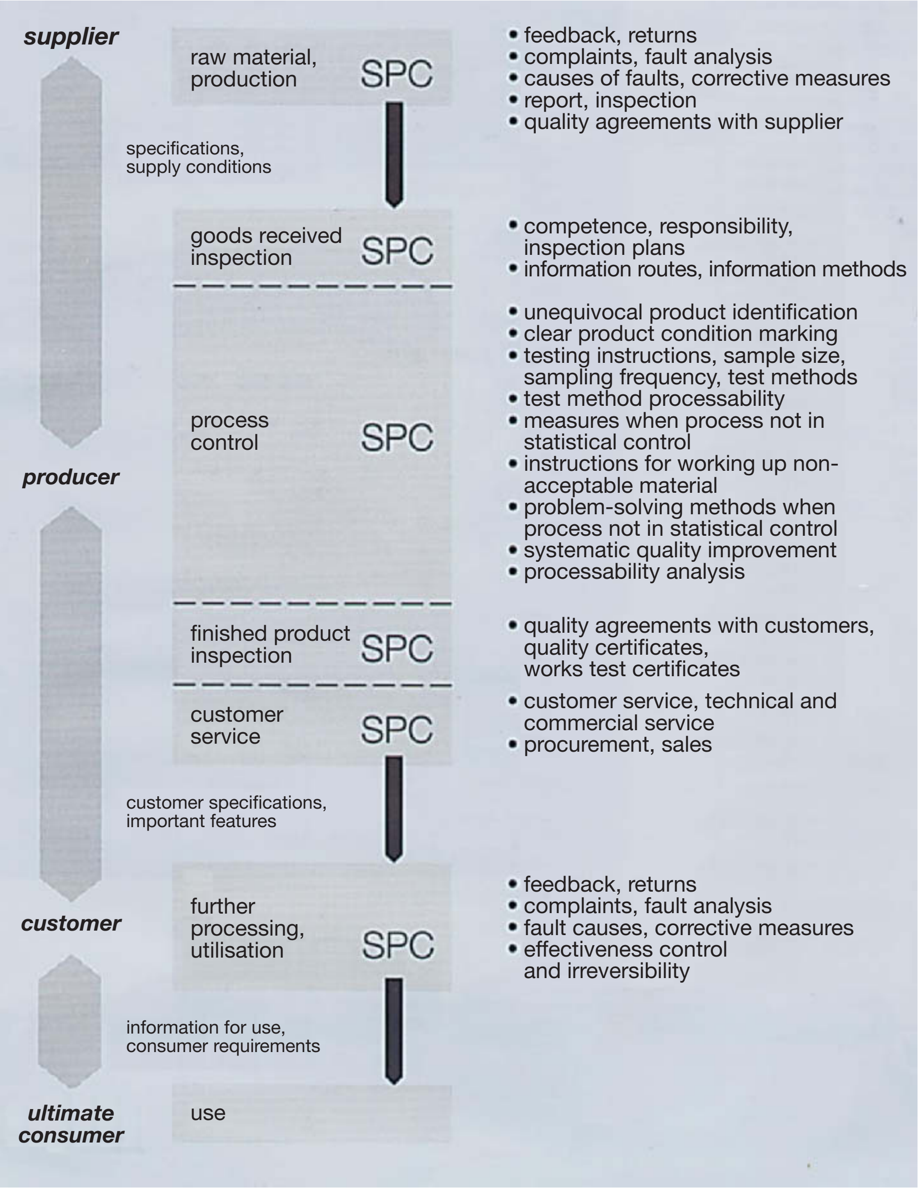

Fig.: Statistical process control system (SPC).

the saturation temperature. At normal air pressure (1.0133 bar) the temperature of water increases gradually to its boiling point at 100°C through an exchange of heat between a burning fuel and the water. With rising temperature there is also an increased development of steam, i.e. the rate of evaporation of water increases. When a further 2250 J (so-called heat of evaporation) is supplied to 1 kg water at 100°C in an open space (steam boiler), steam at 100°C is produced with an absolute pressure of 0.981 bar which represents a useful source of energy because of the high amount of bound (latent) heat energy it possesses,. If further heat is supplied, the steam pressure obviously rises above 0.981 bar. At the same time, the volume of 1 kg steam increases and the weight per m^3 in kg decreases (saturated steam). When steam is extracted rapidly from the boiler there is a sudden decrease in the steam pressure, i.e. the water temperature is higher than its pressure-related boiling point. A rapid development of steam therefore occurs, the water and steam are in a state of reciprocal equilib-

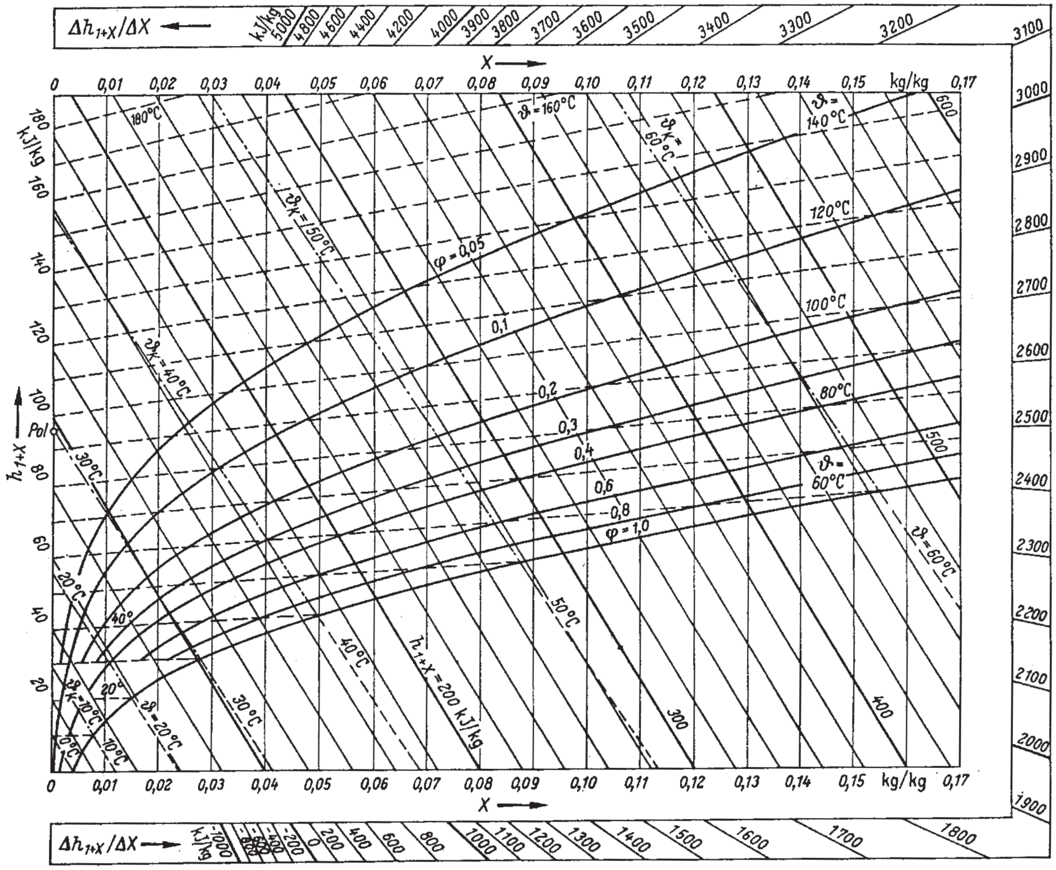

Fig.: Mollier – h, X – diagram for steam with a total pressure of p = 1 bar.

rium and the steam is said to be saturated (saturated steam). Since, the equilibrium shifts in favour of water at low pressure, unsaturated steam, i.e. wet steam, is formed under these conditions. On heating saturated steam without water its temperature increases, as well as the pressure in a closed boiler, whilst the weight of the steam remains unchanged. As a result, superheated steam is formed which can also be created in the distribution network (steam superheater).

Changes of the condition of this kind can be visualized for moist air, i.e. for the evaporation of water in the surrounding air in the Mollier-h, X-diagram (see Fig.). The absolute water vapour content X is plotted on the abscissa and the enthalpy on the ordinate. Both values are related to 1kg of dry air each time. The quantity of moist air per kg of dry air is 1 + X kg and its enthalpy is described as follows:

$$h_{1+X} = 1 \cdot h_L + X \cdot h_{WD}$$

h_L = enthalpy of dry air (kJ/kg),
h_{WD} = enthalpy of water vapour (kJ/kg).

For any temperature ϑ [°C], the enthalpy is:

$$H_{1+X} = c_{p,L} \cdot \vartheta + X\,(r = c_{p,WD} \cdot \vartheta)$$

$c_{p,L}$ = specific heat of air [kJ/kg/K],
r = evaporation enthalpy of water at 0°C [kJ/kg].

If the relationship h = f (X, ϑ) is represented as in the Mollier diagram, the region of unsaturated wet air (steam) would be crowded into a narrow wedge in the right-angled coordinates. For this reason, Mollier chose an oblique-angled coordinate system in which the X axis is so inclined that the isotherms of the wet unsaturated air for ϑ = 0°C lie horizontally.

As parameters, the temperature ϑ and the relative humidity of air φ are entered in the Mollier diagram. The saturation line φ = 1, represents the state of air saturated with water vapour (saturated steam). Next to it, the lines of constant dew point temperature ϑ_K are found. The points for conditions corresponding to pure water vapour lie at infinity in this diagram.

Steam as a liquor heating medium The heat transfer relationship between saturated steam and water is much more favourable than that from superheated steam. Superheated steam, being a gas, is a poor heat transfer medium and has a low film heat transfer coefficient. When direct heating is carried out with superheated steam, the steam outlet holes must be kept very small and at a sufficient depth below the surface of the liquor. When direct heating is carried out with saturated steam, the steam should not be too wet (dilution and overflowing of becks; considerable reduction in the transfer of heat) (see Tab.).

Heating method	Advantages	Disadvantages
Direct steam (under high pressure)	Small heating coils, small pipe diameters, small valves, dry steam	Poor heat utilisation frequently leaking flanges and valves
Direct steam (under low pressure)	Good heat utilisation	Large diameter piping, with poor steam traps (wet steam!) liquor dilution
Indirect steam (under high pressure)	Cheap piping system	Poor heat utilisation. Frequently leaking flanges and defective steam traps
Indirect steam (under low pressure)	Good heat utilisation	Large diameter pipes, large valves
(Hot water)	Best heat utilisation, permanently cleaner pipelines	No direct heating possible. High plant costs

Tab.: Advantages and disadvantages of steam heating methods.

Steam black → Aniline black produced on the fibre with sodium chlorate as oxidizing agent and yellow prussiate of potash (potassium hexacyanoferrate II) as aniline black catalyst. Steam black is also referred to as prussiate black.

Steam boiler Various types of steam boiler can be classified a) according to the steam pressure (low-pressure boilers up to 1.5 bar, high-pressure boilers above 1.5 bar); or b) according to the construction (natural circulation; controlled circulation boiler; forced flow-through boiler).

Steam boiler can be a packaged type, 3-pass fire-tubes steam boiler suitable for pressurized combustion of liquid or gaseous fuels (Fig. 1). The high efficiency, the steam quality, the high reliability are basically due to the following features:

- 3 smoke pass with the second and third pass inside the tubes,
- lagre furnace with low thermal load,
- wetback smoke reversing chamber,

Fig. 1: Steam boiler.

- large heat exchanging surfaces,
- large evaporating surface and steam chamber.

For small to medium-size generating plants, e.g. from 0.13–12.60 kg/s, the most frequently used construction is the treble-pass packaged boiler (natural circulation boiler): a free standing unit with minimum floor space requirements compared to the earlier walled-in corrugated fire tube boiler. These boilers have an adequate water capacity resp. steam space and therefore a good steam reserve. In spite of the adequately large water capacity, this type of boiler offers short heat-up times, e.g. within approx. 20–25 min at 11 bar in the case of oil-fired boilers, with a good steam quality. They are mainly constructed for operation with an overpressure as oil-fired boilers, i.e. a forced draught fan is no longer required. As a result, good CO_2 levels are achieved, there is a good utilization of flue gases due to the treble-pass construction and, therefore, favourable exhaust gas temperatures between 180 and 260°C depending on the pressure, load and clean heating surfaces; operating efficiencies up to 92% can be achieved with oil-firing; good water-side and flue gas-side cleaning access. Treble-pass boilers, together with a superheater, are also particularly suitable for the in-house generation of electricity. Treble-pass boilers are preferably heated by oil or gas or a combination of both. Theoretically, any treble-pass boiler can be heated by solid fuels with a grate installed in the fire tube. Because of the small fire tube, however, only a relatively small grate area can be accommodated. For this reason, a conversion from oil to solid fuel only gives approx. 60% of the steam capacity of an oil-fired boiler. If the boiler is to be fired specifically with solid fuels, treble-pass boilers with larger diameter fire tubes must be selected. Travelling grates with automatic belt charging are generally used as firing systems for high boiler capacities, or internally-fired plane grates with automatic belt charging or hand-firing for low to medium boiler

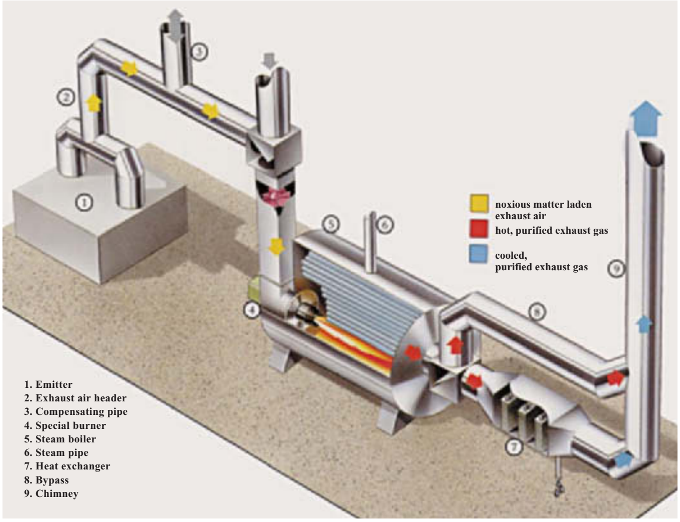

Fig 2.: Exhaust air combustion in a König "Sparal" system steam boiler.

capacities. Alternatively, sloped grate firing should be chosen specifically for wood waste supplemented by a blower unit for wood, dust and shavings. Treble-pass boilers are always pre-assembled in the factory as complete units before delivery, at least as far as low and medium capacity models are concerned. Advantage: no time-consuming on-site erection; installation is simply a case of mounting the unit on a level hard standing, connecting it to fuel, power and water supplies and to the steam system, and the boiler is ready to operate. Provision must also be made for disposal of the "blow down". Small treble-pass boilers are also available in the market as so-called product boilers, i.e. due to the water content, these boilers fall under the product number 10 (water content up to nominal diameter in m^3 x working pressure in bar; the number 10 must not be exceeded). These boilers can be erected in working areas and under residential areas. For small-sized plants, quick-acting boilers (forced through-flow boilers) are mainly used.

The main element is the tube coil which can be installed either vertically or horizontally. A vertical or horizontal construction is chosen depending on the height of the boiler room. Advantage: minimum floor space requirements, quicker readiness for service (approx. 2–4 min). Great attention must be paid to water treatment. Type of firing: oil or gas. Water-tube boilers are increasingly being used for lower capacities (natural circulation boilers); these are mainly constructed as vertical multiple-pass boilers (3 or 4 passes). Advantage: minimum floor space requirements, water content, short heat-up times (approx. 6–10 min). Type of firing: oil or gas. These boilers have frequently replaced the former vertical cross-tube boilers which are only occasionally found nowadays (high flue gas temperature, low efficiency). Traditionally, burners with the lowest possible excess of fresh air are used. Large quantities of hot exhaust air laden with pollutants can be satisfactorily processed in the burner of a steam boiler with a consequent saving of energy at the same time (Fig. 2).

Steam calender A machine used after the drying of finished knitgoods for steaming, compacting and stretching the fabric to the desired tubular width (see Fig.).

These machines are available in two versions:

I. Vertical steaming and compacting calender (European design) for vertical running fabrics: minimum floor space requirements, blind fabric passage, high running speeds not possible up to now.

II. Horizontal steaming and compacting calender (US design) for horizontal running fabrics: requires considerably more floor space, high running speeds possible (due to more intensive fabric steaming) and continuous working. Control and inspection of the fabric is easier than in I.

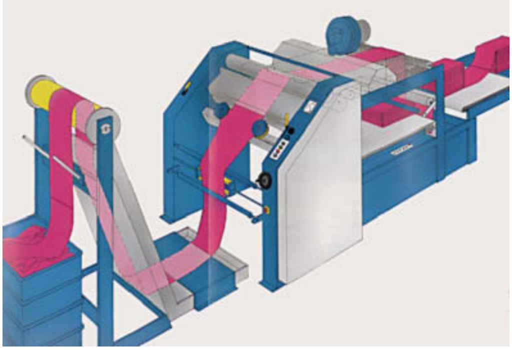

Fig.: Typical steam calender for tubular knitted fabric.

Steam colours An obsolete term formerly used in textile printing for all dyes requiring a steaming treatment after printing in order to fix the colours. Insoluble colorants, such as those used in metal powder and pigment printing were a typical exception.

Steam conditioning In order to ensure reproducible effects in pretreatment and dyeing at all times, the

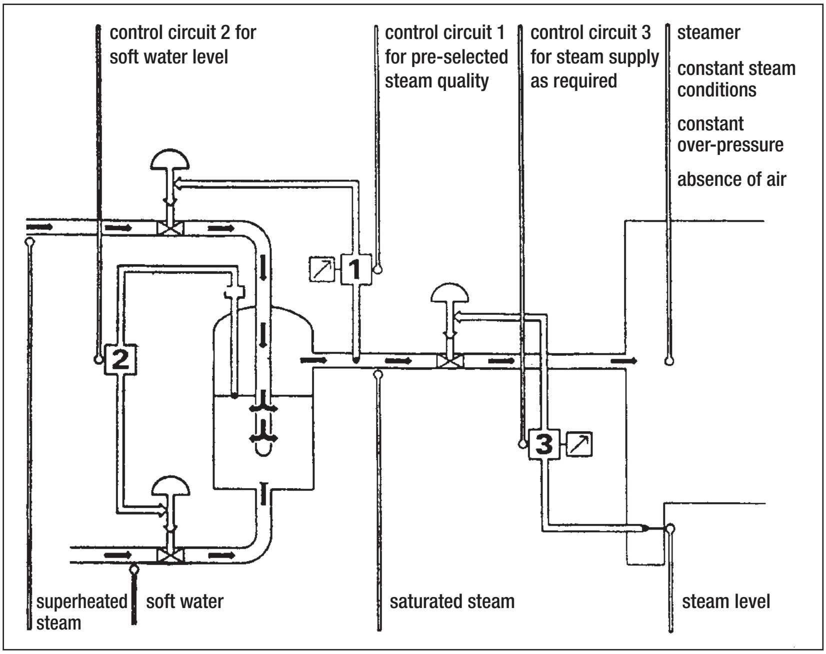

Fig.: Steam conditioning station with three automatic control circuits.

steam conditions inside the steamer must be absolutely constant. This means that a steam conditioning station must fulfil the following requirements:

It must be able to ensure a constant light overpressure and consequent absence of air in the steamer

- with a constant quality of saturated steam,
- for any length of time,
- irrespective of variations in the steam distribution network,
- irrespective of the surrounding temperature,
- irrespective of variations in operating conditions with varying steam consumption (fabric speed, nature of material, etc.).

Constancy of the steam conditions is, in the main, ensured by three different control circuits (see Fig.): both control circuit 1 (superheated steam supply from the distribution network) and control circuit 2 (soft water level in the mixing vessel) together ensure a constant quality of saturated steam. Control circuit 3 is responsible for the consumption of the corresponding steam feed to the steamer. An important point here is that the steam level passes in a special measuring tube underneath the steamer. Because of the easily measurable change in the steam level, the control unit can react immediately and exactly. The plant operates without an excess of cooling water.

Steam conditions In textile finishing plants, steam is generated in different types of boiler at high or low pressure. The steam is often further superheated in a turbine before leaving the boiler house for the generation of electrical energy, then reduced to a lower pressure and stored in the distribution network. The steam gives up its superheat to a greater or lesser extent in the steam main depending on the length of the main to the point of consumption and the quality of insulation. If the steam stored in the distribution network has a low degree of superheat, the steam soon reaches a state of saturation. Further release of heat leads to the formation of condensate and the steam becomes wet.

Depending on the technical execution and length of the steam main, as well as the steam throughput, losses of pressure occur which can be calculated with the following formula:

$$\Delta p = \xi \cdot \frac{\rho}{2} \; w^2 \; [\mathrm{N/m^2}]$$

ξ = loss correction value,
ρ = density [kg/m^3],
w = flow rate [m/s].

The condition of the steam at various points of consumption can therefore differ from the condition of the steam stored in the distribution network. The above-mentioned changes in the condition of steam may be represented in the so-called Mollier diagram (h, X diagram). → Steam. The enthalpy is defined as:

$$h = u + p \cdot V$$

where u is the internal energy, i.e. the sum of all the energy supplied to a stationary body in any form, and p · V is the work done by e.g. expansion against the surrounding pressure during heating. Entropy is a measure of the reversibility of a thermodynamic process. On release of the steam pressure (throttling), the enthalpy remains constant and corresponds to a horizontal line in the Mollier diagram. The entropy increases during throttling since a non-reversible process is involved.

If the steam was allowed to flow in the opposite direction, then no pressure increase would be obtained but the same pressure drop would have to be overcome in the other direction only. The following examples serve to demonstrate changes in steam conditions:

1. A release of the pressure of saturated steam at 6 bar to 1 bar gives superheating to approx. 139°C.
2. Cooling of superheated steam at 3 bar, 200°C to saturated steam condition. Approx. 147 kJ/kg (0.04 kWh/kg) has to be dissipated. Further release of pressure to approx. 1 bar and cooling to saturated condition. Approx. 50 kJ/kg (0.014 kWh/kg) has to be dissipated.
3. Wet steam at 4 bar with approx. 3% water content, which corresponds to 97% steam content, is already dry on releasing the pressure to 1 bar.

The development of superheating, the quantities of water necessary for cooling superheated steam, or the moisture content produced in the steam, can all be taken from the Mollier diagram.

The development and maintenance of constant steam conditions is very important for the trouble-free operation of each process where steam is required as a treatment medium. Pressure fluctuations, such as those which occur in all distribution networks, should first be controlled with a pressure regulator or pressure reducing valve. Wet steam should be passed through a separator which can also filter out coarse contaminants such as rust from pipelines as a rule. If the steam is superheated, then cooling to virtually saturated steam conditions is necessary in many cases (according to Tischbein).

Steam content tester A device for determining and controlling the steam content in a steam/air mixture. With this device the wet bulb temperature (= temperature of the wet bulb thermometer in a psychrometer) can be measured continuously thereby enabling the steam content to be determined. Other devices are based on determining the oxygen content in steam/air mixtures. (→ Zirconium sensor).

Steam-cure process A process for the continuous moist crosslinking of cotton with a nitrogen-methylol compound in the presence of a highly active catalyst mixture (magnesium chloride and citric acid) in a steamer supplied with superheated steam for drying and crosslinking (6–10 min at 130–140°C). Reaction takes place in the 15–5% moisture content range. Subsequent neutralization is not necessary.

Steam decatizing A process in which decatizing is carried out with steam (also known as blowing) in contrast to → Wet decatizing.

Steamer,

I. A program-controlled yarn steamer with radial through flow to ensure uniformity of the steaming effect.

II. An apparatus for steaming (Fig.) printed or padded piece goods, yarns, tops, hosiery, garments, etc. These steamers are of two types, a) batchwise or discontinuous steamers and b) continuous steamers.

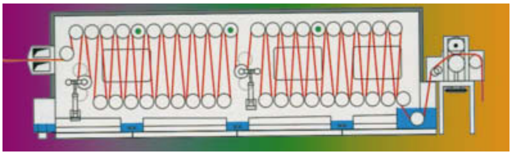

Fig.: Brugman steamer for dyeing.

Steamer for two-phase printing A special type of continuous steamer with a built-in padder, preferably with a small fabric capacity and a high steaming performance, e.g. rainbow or arch steamer, loop steamer, spiral steamer or → Flash ager.

Steamer grey A light woven fabric which is run into a steamer together with printed goods to prevent the dried print pastes on a printed fabric from marking off on to adjacent layers of the same fabric during the steaming process.

Steam finisher A steaming cabinet or steaming tunnel for batchwise or continuous steaming of outerwear garments in laundries and dry cleaning establishments. A notable finish effect is produced by movement of the garments in the steam/air flow especially in the case of blended fabrics.

Steam generator → Steam boiler.

Steaming Finishing process causing general increase in moisture levels, increased swelling, and therefore, further effects, such as improved washing. There are further specific effects on wool-based fibres, including partial alleviation of tension (tension-free steaming), fluffing and raising the pile, removal of creases caused by laying, storage, pressing and decatizing, stripping of shine caused by pressing, etc. The best method to use is to steam for approx. 3 min with saturated steam, but complete saturation of the fibre should be avoided (detrimental effects to the handle).

Steaming at atm. pressure, fastness to Capacity of the colour shade to resist being affected by steam (e.g. during steaming). The sample is placed between undyed cotton and the adjacent fabric for colour fastness testing. After rolling, the test sample is placed in the neck of a glass cylindrical flask, which is filled with boiling water. It is boiled for 30 min and then dried in warm air (< 60°C) without being touched. Any staining of the undyed adjacent fabric is evaluated using grey scales for fastness testing.

Steaming dummies → Steam ironing dummy.

Steaming of fibrous materials The purpose of steam treatments in textile finishing is to achieve rapid heating, if, at the same time, the fabric is required to have a high moisture content, and/or it must not be allowed to dry out. If the temperature of the fibre and its moisture content is raised, chemical reactions that occur during pretreatment and finishing can be accelerated, as can physical processes such as dye diffusion and molecular transpositions in the fibre that occur during setting.

Condensation takes place when the cold fibre first enters a steam atmosphere, and latent heat of 2250 J/g is released by the condensed steam. In de-aerated steam at atmospheric pressure, the fibre temperature quickly rises to 100°C. It can increase even further if there is a subsequent exothermic reaction. The quantity of condensate depends on the original temperature, specific heat and moisture content of the fibre. Saturated steam at a temperature of 100°C condensing on cotton at a temperature of 20°C with 7% moisture increases the moisture content of the fibre by 5.5 g/100 g. This increase will be of approximately the same proportions for other fibres. An acceptable solution and diffusion speed can often be guaranteed under these conditions. In the case of polyester however, diffusion into the fibre at 100°C occurs only very slowly. In order to achieve better mobility of the polymer chains and higher diffusion rates, saturated steam should be used at higher temperatures and higher pressure, or the steam should be superheated. Cellulose and wool fibres adsorb more water out of the steam once the temperature has reached 100°C, until the adsorption equilibrium is reached.

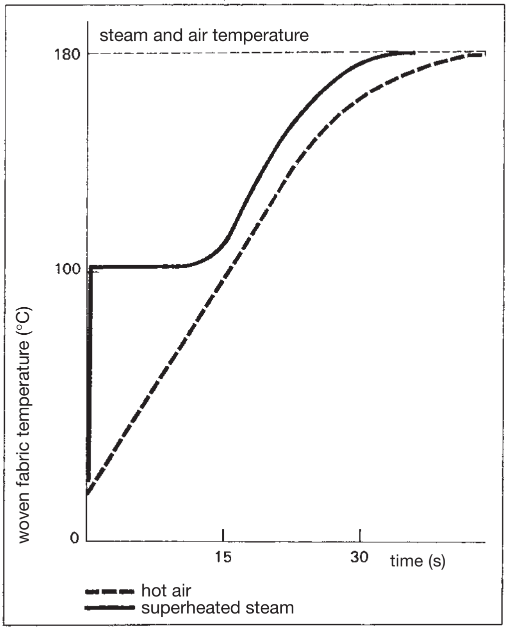

Fig. 1: Substrate heating rate in hot air and in superheated steam.

Steam condenses on cold dry fabric, causing its temperature to rise rapidly to 100°C (Fig. 1). The moisture content will increase less than in steam at 100°C due to the additional inherent heat, which is transfered from steam to the fibre. However it will be enough to split hydrogen bonds, cause swelling in thickening layers, and reach the glass transition temperature in thermoplastic fibres. The moisture level is then balanced by steaming. For cotton the level of equilibrium is approx. 1% at 150°C (20% residual heat), and for polyester 0.2% at 180°C (10% residual heat). However these levels are only reached relatively slowly, so that the fibre structure remains more penetrable than it would if heating was carried out in dry air.

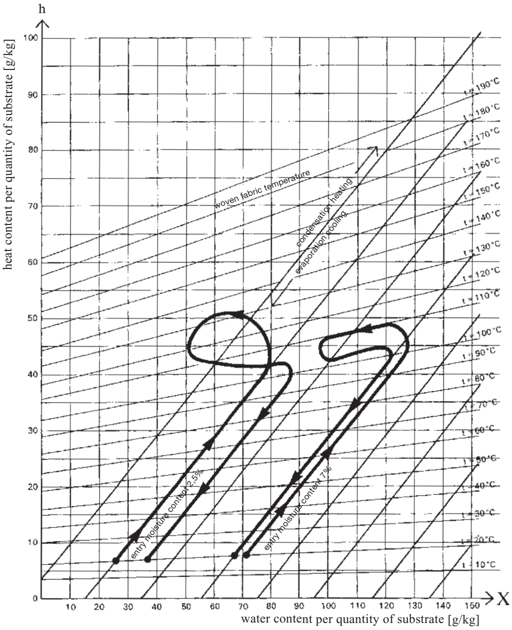

Fig. 2: h-X diagram for wet woven fabric.
[$C_{m\ woven\ fabric}$ = 1.34 kJ/kg°C]

The so-called h-X (heat content/moisture content) diagram (Fig. 2) provides a graphic representation of the changes that take place during the steaming process.

If there is a low initial moisture content of 2.5%, maximum heat is developed, resulting in a solution with a high boiling point. Temperatures in excess of

110°C cause pointless decomposure of the reduction agents used in discharge printing, for instance. For this reason the dye is only partially reduced and set, even if enough water has been adsorbed to ensure internal diffusion within the fibre. At the opposite end of the scale, a high initial moisture content of 7.5% leads to minimal heat development and a solution with a relatively stable boiling point of approx. 110°C. After the exothermic reactions have ended, this temporary temperature equilibrium can no longer be maintained. If the vapour is vaporized and cooled, the temperature of the fabric is reduced to the same temperature as the vapour to enable further water uptake. This will continue until either equilibrium is restored, or the printed fabric is removed from the vapour (according to Miles).

Steaming of garments One aspect of textile care when manufacturing finished garments from clean textiles is blocking, using →: Steaming tables; Steam finisher, garment shaper, etc. The finish can be improved if the garment is subsequently pressed, either by hand or mechanically. If the textile is steamed, the fibre becomes warm and damp, and therefore flexible and easy to shape. A smooth finish can be achieved using presses, brushes or by tensioning. The setting process is done by means of vacuum extraction or with a blower (drying).

Steaming of prints Prints are usually set or developed by steaming the various different substrates (details can be found under the relevant dye classification). The steaming process is carried out in open or sealed systems, either at atmospheric pressure or at pressure for temperatures in excess of 100°C.

Steaming of yarns, twisted yarns etc. This process is carried out by means of steam in a steam box under pressure. It is done to improve softness, quality and to avoid shrinkage (curling) during dyeing, etc. Crêpe yarns in the form of yarn packages or on weft bobbins should be steamed with extreme care (crêpe quality). When yarns are steamed, they are heat-treated, whilst at the same time being affected by moisture. If the fibre temperature and moisture level are raised, chemical reactions occur in the fibre structure. The yarn tension reaches a state of equilibrium, in other words the yarn is relaxed, stabilized, set to the correct twist, and prepared for an even dye uptake if the yarn is to be dyed. Saturated steam is an essential requirement in any temperature range for optimum thermal treatment. There are three distinctive types of steam in thermodynamics (Fig. 1).

It should be noted that even where the same type of steam is used, or at the same steam temperature, the vapour state can vary. Each time water is boiled, saturated steam is generated. In this situation the temperature at which vaporization takes place, or at which the steam becomes saturated, is dependent on the pressure. At atmospheric pressure and at sea level this temperature is approx. 100°C. When saturated steam is cooled, wet steam is formed. This type of steam has already begun to condense, making the steam visible. This type of condensate can cause staining or even water inclusion in the yarn, which damages it and prevents steam penetration. If the steam is heated further, or if the pressure is changed, superheated steam is produced. This type of steam is a poor conductor of heat. The main problem is the lack of moisture, rendering it unsuitable for yarn steaming. Superheated steam can also be produced by taking saturated steam from a steam generator and reducing its pressure. The transition phase between saturated steam and superheated steam is denoted by the saturated steam line. At this point the steam is in a state that will not cause any damage in yarn treatment. However, many yarns do not tolerate heat treatment at a temperature of around 100°C. For this reason it is necessary to create conditions in which water will vaporize at a low temperature. This can be done at a low pressure in an autoclave. According to the laws of physics, water will vaporize in a vacuum at a temperature of 50°C, for example. However the vacuum also causes the air to escape from the yarn, creating "free space" for the steam. Penetration is thus encouraged. The vacuum also removes oxygen with the air. In practice, either direct or indirect steaming (depending on the manufacturer) is used in this context (Fig. 2).

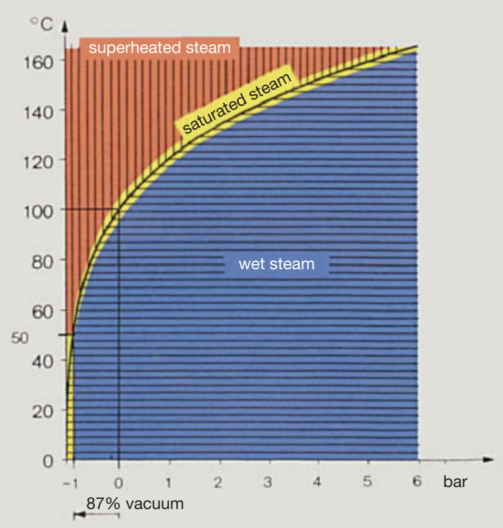

Fig. 1: Types of steam.

If the direct steaming process is used, steam will flow directly into the autoclave. With indirect steaming, steam is generated from a sealed water reservoir in the bottom of the steamer (Fig. 3). The water reservoir may also be equipped with electric heating elements, in which case a steam generator would not be required (Xorella).

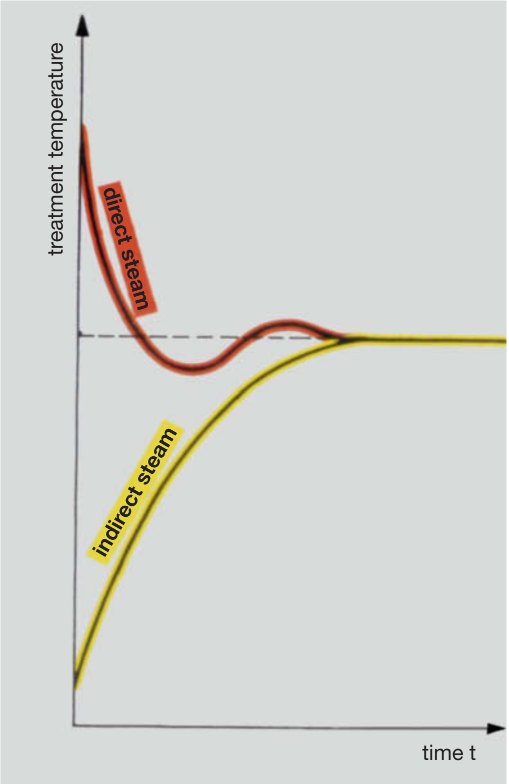

Fig. 2: Effect of indirect steam and direct steam in yarn steaming.

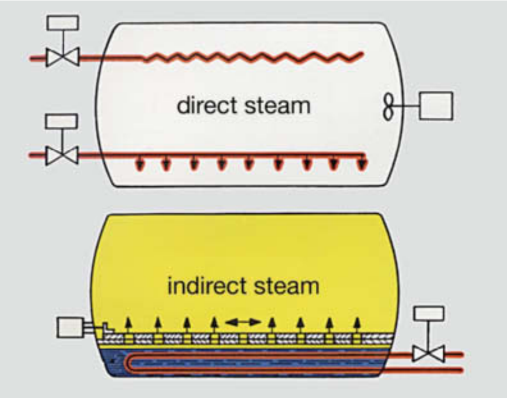

Fig. 3: Production of direct steam and indirect steam in yarn steamers.

The period of treatment in the autoclave is controlled by a program and runs automatically.

Example:

	direct	indirect
preheating	approx. 10 min	not required
vacuum	approx. 3 min	approx. 3 min
steaming	approx. 10 min	approx. 5 min
vacuum	approx. 3 min	approx. 3 min
steaming	approx. 10 min	approx. 15 min
evacuation	approx. 3 min	approx. 3 min
	approx. 39 min	approx. 29 min

Charging the equipment with cops or yarn packages is usually done automatically. Continuous running equipment and various different charging systems can be integrated into the transport system.

Steaming pad → Steam ironing dummy.

Steaming table For steaming piece goods, which are drawn across a perforated table top (with a textile cover).

Steaming temperature control Control of superheated steam with spray water as a control variable.

Steaming under pressure, fastness to Capacity of the colour shade to resist being affected by steam at high pressure, such as during setting or pleating. The sample is wound onto a copper cylinder (with adjacent fabric) and steamed under pressure in a pressure steamer or an autoclave. After steaming the steam is released over a 2 min period. Then the specimen is dried in warm air (< 60°C) without touching the individual components. There is a 4 h acclimatization period (20°C, 65% relative air humidity). Any change in colour or staining of the undyed adjacent fabric is evaluated using the appropriate grey scale for fastness testing. Steaming conditions:

light	5 min	108°C, 1.35 kPa absolute pressure,
medium	10 min	115°C, 1.70 kPa absolute pressure,
extreme	20 min	130°C, 2.76 kPa absolute pressure.

Steam ironing dummy A device which allows the steaming and drying of dresses, skirts, jackets and coats in their normal shape as worn on the body by blowing steam or hot air through them when fitted on to the dummy. Various automatic models are also available. Capacity 30–60 garment pieces per h. Mounted on a low pedestal with operating controls (lever or push-button control). With movable shoulder supports and automatic length adjustment. Grips are provided for fastening the garments and adjustment for all normal sizes is possible. Some models have exchangeable bust supports for women's dresses and jackets. Simple constructions, often in groups up to 3–5 garments on a common base (fan air supply) for drying dyed or wet impregnated pieces.

Steam jacketed pan (double-cased pan). A formerly indispensable item of equipment in the colour kitchen of a printworks to prepare thickeners for textile printing by boiling. The interior of the vessel, made of copper or stainless steel, is surrounded by a cast-iron sheath. The well-sealed space between both inner and outer walls is fed with steam in order to heat the contents of the pan. After the boiling operation is complete, the steam supply is shut off and substituted with cooling water for rapid cooling of the prepared print thickener. Steam jacketed pans for this purpose are usually provided with two mechanical agitators which keep the thickener paste in constant motion, and thus ensure a smooth consistency and uniform mixing of the ingredients. The agitators turn on their own axes and, at the same time, travel continually around the interior of the pan so that every particle of thickening agent is thoroughly mixed. These agitators work on the well-known sun and planet principle and are actuated by bevel gearing.

Steam jacketed pans are seldom required nowadays since many of the natural gums and native starches formerly used as thickeners for textile printing, and which required boiling, have been largely replaced by cold-water soluble thickeners such as alginates, starch-ethers, galactomannans, etc.

Steam lye extractor A system for the removal of caustic lye with steam after the mercerization of piece goods.

Steam mansard A type of continuous steamer which works on the Krostewitz steamer principle.

Steam precipitation A problem caused by steam coming into contact with → Condensate at a considerable lower temperature (usually in a steam main). Result: a very rapid condensation of steam occurs associated with a considerable reduction in volume thereby forming a void so that water streams in from various directions at high speed, causing a sudden braking effect and frontal collision or → Water hammer. Such events can occur, for example, in heat exchangers if an accumulation of condensate is present which has either been cooled excessively or when the steam pressure in the main is considerably higher than the steam pressure in the heat exchanger.

Steam pressure (saturated vapour pressure). The pressure (often expressed in millimetres of mercury, mm Hg) exerted by a vapour, either by itself or in a mixture of gases. All solids and liquids give off vapours, consisting of atoms or molecules of the substances that have evaporated from the condensed forms. These atoms or molecules exert a vapour pressure. If the substance is in an enclosed space, the vapour pressure will reach an equilibrium value that depends only on the nature of the substance and the temperature. This equilibrium value occurs when there is a dynamic equilibrium between the atoms or molecules escaping from the liquid or solid and those that strike the surface of the liquid or solid and return to it. The vapour pressure is then said to be a saturated vapour and the pressure it exerts is the saturated vapour pressure. There is an inverse relationship between the vapour pressure and the → Evaporation (number) since solvents evaporate resp. vaporize more quickly at increasing vapour pressures and correspondingly more slowly at a low vapour pressure. Consequently, solvents which evaporate readily have high vapour pressures and vice versa. The measurement of vapour pressure is based on the principle of the mercury barometer with the test solution in an air-free space, whereby the respective vapour pressure can be expressed directly in mm of mercury. The pressure exerted by a liquid or solid at equilibrium at a specified temperature is termed the vapour pressure at that particular temperature. Thus, at increasing temperatures, the vapour pressure obviously increases as well which, for all liquids or solvents, is always 1.0133 bar at the → Boiling point. When non-volatile salts are dissolved in water (e.g. sodium chloride), the vapour pressure decreases whilst the boiling point increases (i.e. the so-called boiling point elevation of solutions). Substances which sublime readily also exhibit a significant vapour pressure even at room temperature (e.g. camphor, naphthalene).

Steam saturation, degree of The degree of water vapour saturation in steamers.

Steam setting → Heat setting processes.

Steam starvation A partial inactivation of a steamer due to the build up of excessive condensate.

Steam trap → Steam traps. A self-acting device which, operating under steam pressure, automatically ejects condensed steam (condensate) from steam pipes, etc. without permitting the escape of steam. Various designs and systems are available, e.g. with float valve, ball valve or slide valve, bimetallic strip control (valve opens with a drop in pressure resp. temperature and closes with a rise in temperature).

Steam traps A steam trap is a device into which → Condensate from steam pipes, etc. is allowed to drain, and which automatically ejects it without permitting the escape of steam. Whilst there are many different types of steam trap, some are more suitable for a particular application than others. The condensate ejecting element and, if applicable, the actuating mechanism (float valve, thermostat, etc.) are combined in some steam traps. The various types of steam trap can be classified according to their control principle: e.g. by float valve (closed spherical float, inverted bucket type); by temperature and/or pressure (bimetallic strip, rod or liquid expansion, liquid evaporation); by temperature and flow (self-acting or non-self-acting moving internal elements); ejecting systems with self-acting variable cross-section (valves, sliders, cocks); with non-self-acting variable cross-section (nozzles, labyrinths, capillaries); ejection not self-acting (hand-operated) or self-acting (continuous and outlet venting); with purging device for clearing the entire cross-section of the ejection system by an arbitrary external influence. It is important to check the steam trap regularly for seat leakage since a gap of only 1 mm^2 allows 90

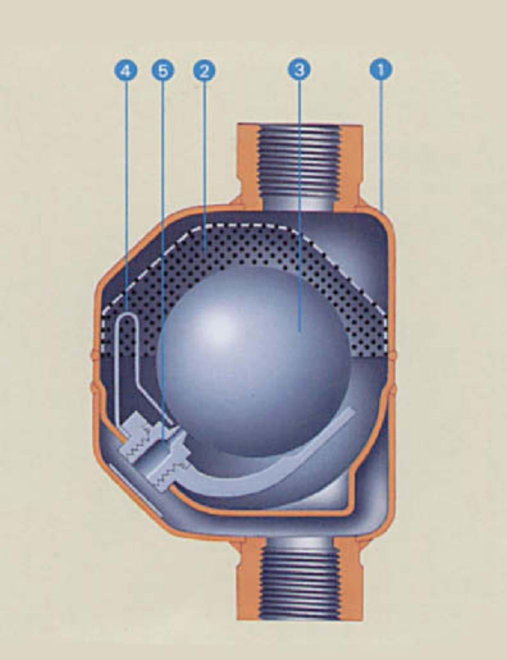

Fig. 1: Float ball condenser.
1 = housing; 2 = dirt filter; 3 = float ball; 4 = bimetal strip; 5 = valve seat.

kg of steam at 7 bar working pressure to escape in 24 h. Strainers should be fitted on the inlet side of all steam traps to prevent the entry of dirt, rust and other foreign particles, which can block orifices and cause the trap to malfunction. Sight glasses are available for fitting on the downstream side of a steam trap so that it can be seen at any time whether or not the trap is working correctly and discharging condensate.

The Float ball condenser (Fig. 1) is suitable for installation in vertical pipes (max. working overpressure 21 bar; max. operating temperature 350°C; differential pressure gradation 5/10/16/21 bar). It's working principle is demonstrated in Fig. 2.

1. During the starting phase, the bimetallic strip keeps the float ball away from the valve seat so that air and cold condensate are rapidly ejected.
2. Incoming hot condensate causes the bimetallic strip to bend which keeps the valve seat free. The float position adjusts itself according to the accumulation of condensate. The condensate is ejected continuously.
3. Due to the loss of buoyancy and the pressure gradient, incoming steam causes the level of condensate to drop and the float-ball is drawn to the exit nozzle which seals its tight. A hydraulic seal is therefore formed above the valve seat. The bimetallic strip remains below the valve seat and is not in contact with the float.

Steam trap test station A mobile production service for testing and demonstrating the working principle of various types of steam traps and systems under practical conditions at different pressures and with different quantities of condensate with/without counter pressure. Such test stations can also be installed as fixed units (see Fig.).

The test chamber is installed immediately before the steam trap. The small quantity of steam which is necessary to cover radiation losses from the pipeline and steam trap flows through a hole in the dividing wall of the test chamber. When the steam trap functions correctly the test chamber is filled with condensate. If a steam trap is blown through, the water level in the test chamber falls and the steam flows through beneath the dividing wall. The sensor of the test chamber is therefore in contact with condensate or steam. Accordingly, there is a change in the electrical resistance at the sensor. This change is fed as a signal via the sensor cable to a hand-held electronic test instrument for analysis.

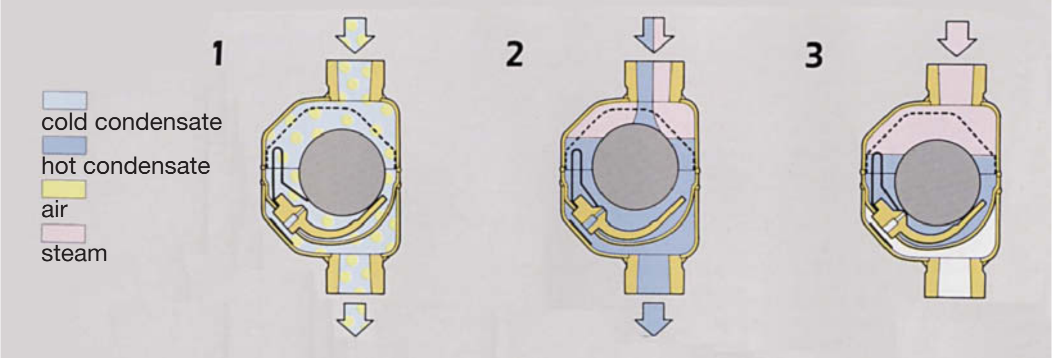

Fig. 2: Float ball condenser function principle.

Fig.: Steam trap test station for checking whether a condenser is in working order (Sarco).

Stearates Stearic acid salts, e.g. aluminium stearate, which is used as a water-repellent treatment.

Stearic acid soaps Manufactured by saponificating stearic acid ($C_{17}H_{35}COOH$). Used for scrooping in sizing and finishing (proofing grease).

Steatite, soapstone Mineral mass with a greasy feel, a derivative of → Talcum consisting of 60–85% talcum, 5–7% magnesium carbonate, 0–24% barium carbonate, 0–2% lime, 0–2% beryllium oxide. Used to remove grease stains and as tailor's chalk.

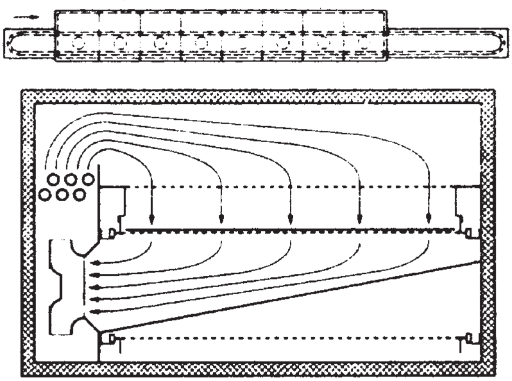

Fig.: Diagram of a steel plate conveyor drying machine.

Steel Forgeable iron, high level of strength and hardness, with 1–2% carbon and possible additives of non-iron metals (to increase corrosion resistance → Stainless steel), elastic properties.

Steel fibres → Metal fibres.

Steel plate conveyor drying machine Ventilation dryer with a high level of transport stability, consisting of edge supported perforated plates; fixed to reinforced sections with chains running along the sides. A fan blows heated air for drying over the heater into a retention chamber in which there is an even distribution of air over the whole width. (see Fig.).

Steiner Tunnel Test Method for testing the burning properties of carpets. The specimen is exposed to open flames in a tunnel. → Flammability test.

Stencil brushing Pile processing machines which can be equipped with a variety of tools for structuring the surface of imitation fur, such as stencil brushes for use after fabric has been preheated (Figs. 1–3).

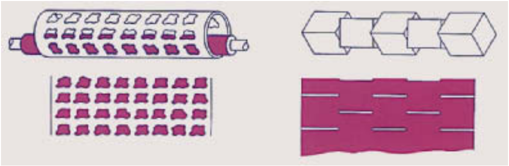

Fig. 1: Stencil brushes.

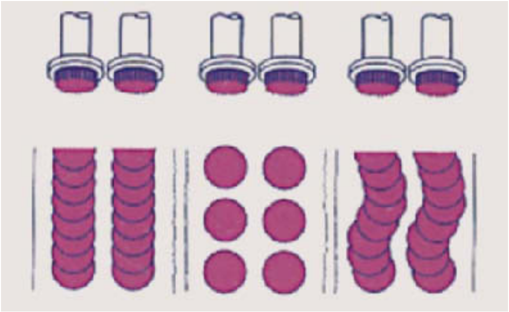

Fig. 2: Rotary brushes.

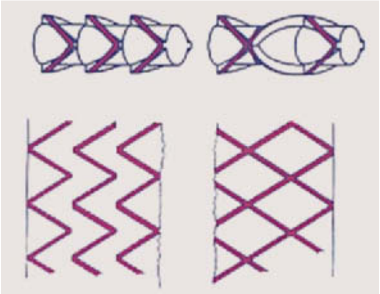

Fig. 3: Patterning devices, with drives, for geometric and floral designs.

Previous Page

Stencil raising/shearing machines The pattern is cut out of a stencil that partially covers the fabric, so that only the cut-out stencil area of the fabric will be raised or sheared.

Stencils for spray printing This type of stencil is usually made from 0.2–0.6 mm thick zinc sheet cut out in the shape of the pattern. There are various different methods of manufacturing spray stencils. The pattern can be a) cut out using a saw; b) chiselled out; c) etched (hydrochloric acid). Polyvinyl chloride film is sometimes used instead of zinc sheet, in which case etching of the pattern is not possible.

Stenter dryer → Drying systems.

Stenter emissions Emissions from thermal treatment of textile fabrics have been tested using a portable FID in numerous textile finishing companies. These tests have shown that significant mass concentrations of foreign substances can occur, particularly during thermal setting processes. For practical reasons the entire stenter is considered to be a source of emission, and this means that the overall mass flow of exhaust has to be analysed for foreign substances, which should never exceed the threshold values prescribed by TI-air for substances in categories II and III.

Experience shows that a textile treatment, which becomes volatile under process conditions, produces the most emissions during grey fabric setting. A suitable washing process can significantly reduce the level of volatile substances in the fabric, even at a high setting temperature of 220°C. However if the wash process is difficult, the volatile content of the textile is still relatively high, at 3.2 g/kg, even if the mid-range setting temperature of 185°C is used. Proofing finishes also contain a certain level of volatile substances.

A significant proportion (sometimes the greater proportion) of stenter emission is caused by the so-called constant load, which is made up of unburnt hydrocarbons from the burner. Constant load measurements are between 20 and 120 mg per normal m^3, depending on stenter age and type, the number of fields and the exhaust capacity (FID measurement, verification gas: propane). The constant load is itemized in the emission declaration in line with the 11. BImSchV (Bundes-Immissionsschutzverordnung – German Federal Immission Protection Regulation) as overall carbon levels per year. Example:

base load:	70 mg per normal m^3
average exhaust vol:	13 500 normal m^3/h
no. of operating h/year:	4500/year
annual exhaust quantity:	60 750 000 normal m^3/year
annual emission quantity from base load:	4252.50 kg/year

Suppliers of textile auxiliary substances used in resin finishing provide information in safety datasheets as to whether they contain certain substances and in what quantities, complying with:

– categories I–III of the TI-air appendix,
– the list of TLV values.

Individual emissions must be stated together with their annual quantities, in line with TI-air categories I–III, in the emission declaration. This information should be limited to the most important emissions, in other words limited to finishing chemicals used in the largest quantities, which must be itemized as individual substances in line with TI-air categories I–III. For any toxic or carcinogenic substances (TLV list) the following restriction must be observed:

---

a) cancerogenic compounds according to Number 2.3 TI-air (1997) (anorganic materials):

  class I: 0.002 g/kg with a mass flow of 0.5 g/h or more;
  class II: 0.02 g/kg with a mass flow of 5g/h or more;
  class III: 0.1 g/kg with a mass flow of 25 g/h or more;

b) organic compounds according to Number 3.1.7 TI-air (1997):

  class I: 0.4 g/kg with a mass flow of 0.1 kg/h or more;
  class II and III: 0.8 g C/kg with a mass flow of 0.8 kg C/h or more.

Stenter exhaust air treatment TI-air was published in 1986, causing more stringent emission values for volatile and gaseous organic compounds to be enforceable. Textile finishing plants must comply with the regulations stated in TI-air, because of the equipment they use, e.g. stenters.

In comparison with the version of → TI-air that was previously applicable, permissible emission values have been reduced drastically, i.e. if hourly solvent loads are exceeded, the mass concentration (mg/m^3) of the corresponding categories must be adhered to. The latest version of TI-air is a directive with stringent limitations. In textile finishing, substances in categories 2 and 3 are frequently used, which must be disposed of properly in line with TI-air. That also includes substances with strong odours, because companies are under obligation to run their plants in such a way that local residents are protected from air pollution.

In order to analyse exhaust air concentration, suitable measuring methods must be selected, among other reasons so that the plant size can be measured accurately enough for exhaust purification. A suitable method of measurement is to use an FID (flame ionisation detector). This measurement process analyses the overall carbon content of the exhaust flow and gives no information relating to individual components. Measurement should be carried out over a fairly long period. A

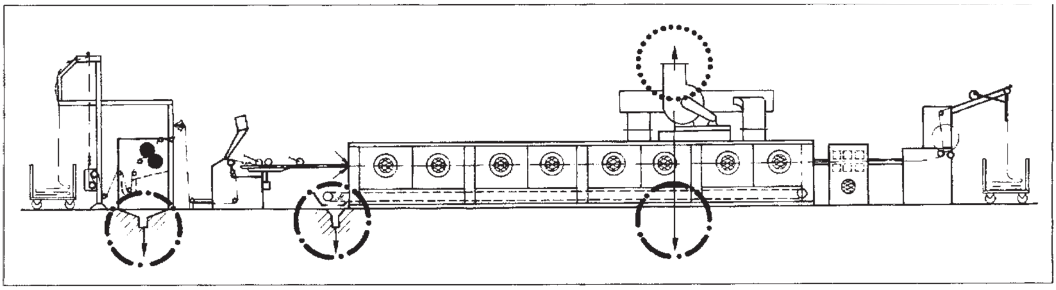

Fig. 1: Soiling of water and air in a dyer-stenter combination (by Babcock).

more accurate method of analysing individual components is to use gas chromatography in combination with mass spectroscopy. Individual components are defined selectively. To assess the measured values, the products used should be observed from a theoretical point of view based on the manufacturer's statistics. Measurements to analyse dioxins are time-consuming and cost-intensive. Waste water impurities generated by peripheral stenters should also be considered (Fig. 1).

When deciding how to dispose of stenter exhaust, the emitted category 2 and 3 contaminants should be considered in series, and because of the high volume of exhaust, the resulting overall emission of contaminants will be significant. Consideration should also be given to a suitable exhaust system (Fig. 2). The following methods are available for exhaust air cleaning:

1. Activated carbon adsorption: use of activated carbon is a state-of-the-art technique, which can be used in any situation where there is only solvent and water adsorption. Heavily polluted exhaust flows leave a deposit on the activated carbon, reducing its adsorption capacity and/or causing regeneration problems.

2. Exhaust washers with hyperfiltration: since stenter exhaust emissions consist of lint, softeners, resin and other reaction products, the use of an exhaust washer including heat recovery equipment, connected in series, is an economically viable solution. A particular point in favour of this is that it almost completely eliminates the "blue fumes" generated during fibre preparation and the associated odour problems. The high temperature of the stenter exhaust is cooled down if heat recovery equipment is used. Any lint, resin and softener content can be condensed depending on concentration, vapour pressure or saturation pressure. External air, or air from inside the room, which is passed over the heat recovery system in counter flow, preheats the system and can be directly re-routed to the stenter. Depending on the temperature of the exhaust, 22–33% of primary energy can be saved. The heat recovery equipment has a built-in cleaning system, which is cleaned during operation without interrupting production. The cooled exhaust (after it has been through the heat recovery system) is passed through an airwasher and is sprayed in counter flow with suitable washing liquids. The emit-

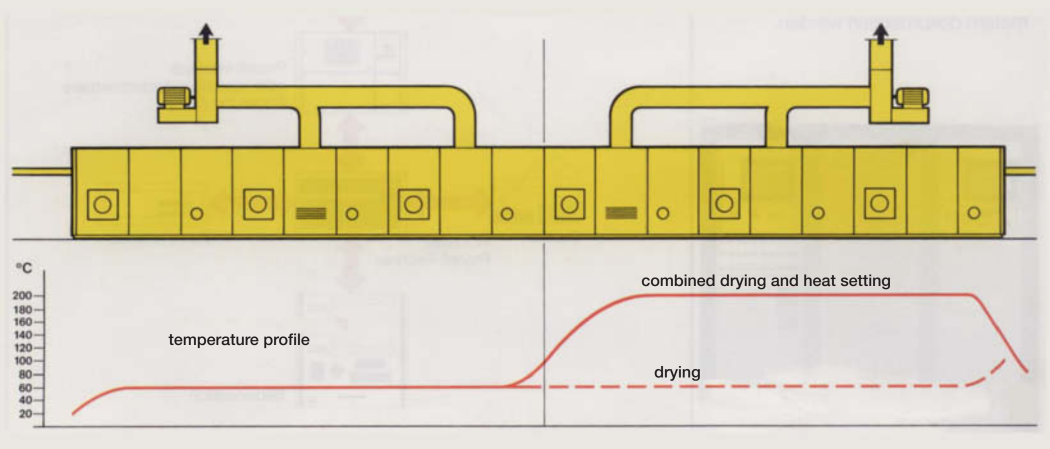

Fig. 2: Exhaust air separation as per temperature profile in the stenter (Monforts).

tents in the exhaust react with the washing liquid and are eliminated from the exhaust. The washing liquid in the washer is used as circulation water. The contaminants that have been picked up are diverted to a hyperfiltration system on the second circuit, where the solid particles are removed and the clean washing liquid is piped back into the washer circuit again. Water can be partially removed from the concentrate once it has been extracted, either by vacuum extraction or by evaporation, making it suitable for disposal.

3. Thermal post-combustion: thermal post-combustion of stenter exhaust is another method of disposing of the by-product of stenter drying.

The process of flue gas cleaning in an existing steam boiler enables combustible contaminants and odorous substances that are not naturally components of air to be removed from process exhausts, whilst recovering energy at the same time. Combustion usually has to take place with a high level of excess air, creating larger quantities of exhaust. Exhaust fans are used to remove the exhaust that is generated by means of induced draught (3000–30 000 m^3/h). During this process the stenter can reach temperatures of 50–200°C. The exhaust is piped through a specially designed circuit from the process plant to the boiler house. There is an air vent so that preheated air can be routed from the boiler house to the burner during boiler operation or used for exhaust-free heating. The burners are designed for exhaust or fresh air operation. A special burner is installed in the boiler for variable and high excess air, and it is also equipped to cope with high air temperatures, a high level of contaminants and high air humidity. The main requirement of the burner system is to optimize combustion by reducing contaminants, taking optimum levels of carbon monoxide and nitrous oxides into account. After the boiler, a heat recovery process is carried out, so that the temperature of the flue gas is kept as low as possible, thereby maximizing the recovery effect. Under certain circumstances a new chimney system is necessary for the flue gases to escape after heat recovery, because the chimney has to comply with TI-air specifications (Tab.).

There are many input and output signals to be recorded in plant control. The control system must be freely programmable to allow for variable operation and to provide adaptability to new operating conditions. It is appropriate to use this type of post-combustion if the following requirements are met:

- existing steam or hot water boiler of an appropriate size,

substance	I (mg/m^3)	II (mg/m^3)
organic hydrocarbons: paraffins, wax, spinning and texturing oils, softeners	200–2 000	< 5
dust, fibres	150– 500	< 3
carbon monoxide	0– 500	< 40
nitric oxides		< 150
formaldehyde	0– 50	< 5
hydrochloric acid	0– 10	< 10

Tab.: Stenter exhaust air measuring results (reference quantity = 3% O$_2$).
I = stenter exhaust air measured value; II = measured value in boiler exhaust gas according to Sparal machine.

Stenter exhaust air treatment

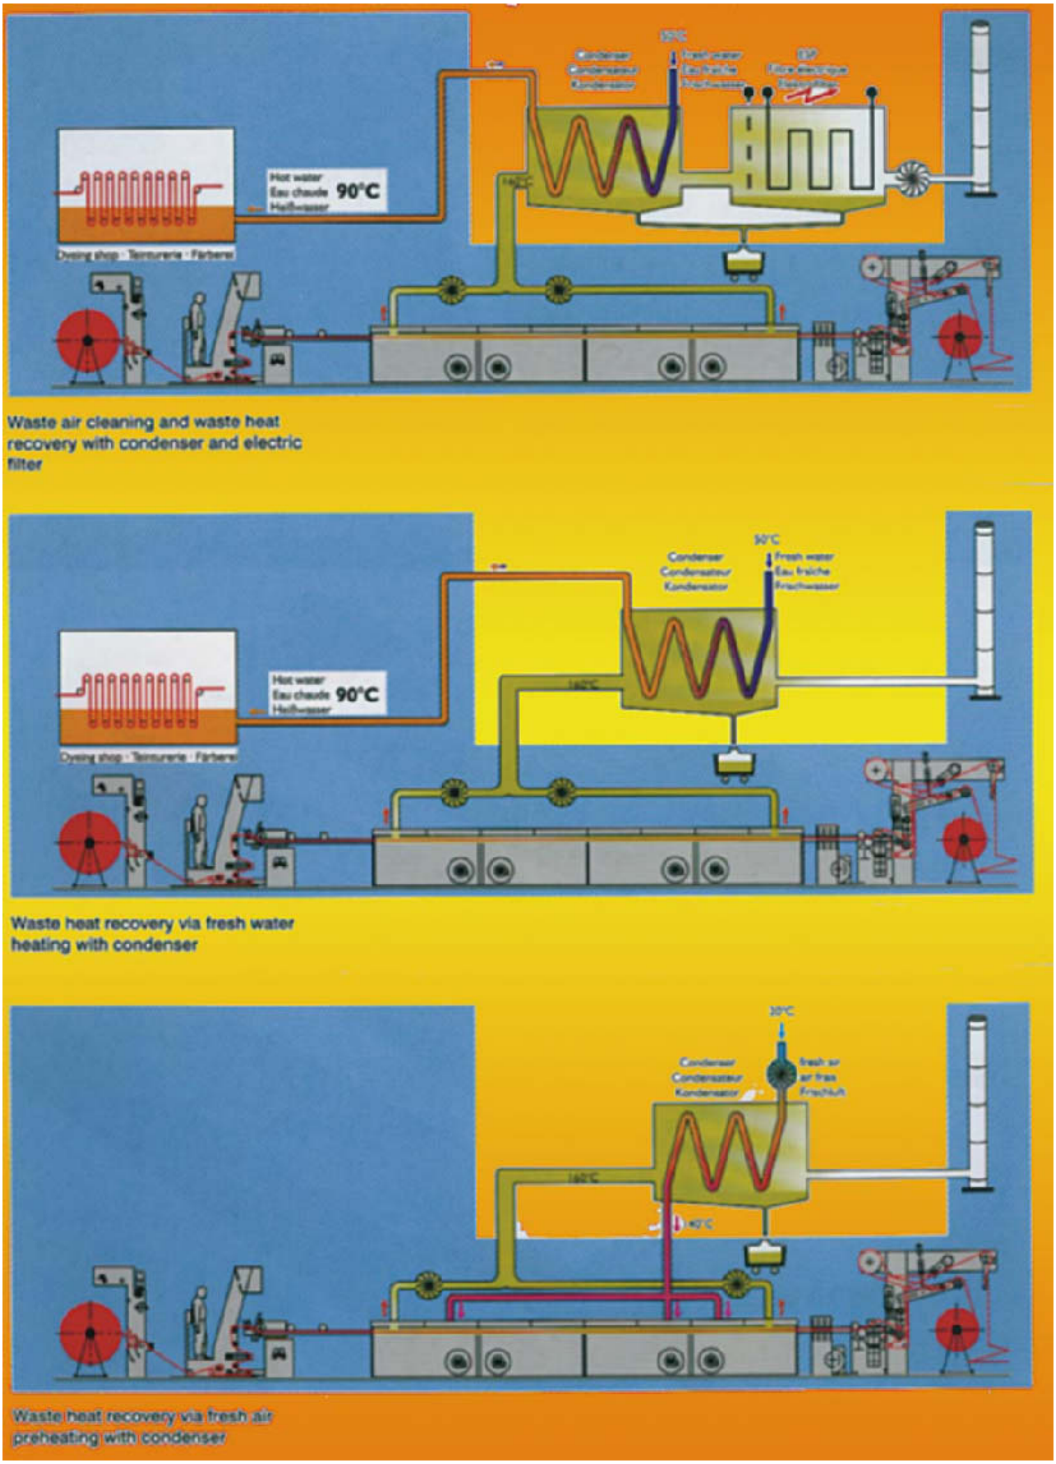

Fig. 5: Waste air cleaning and waste heat recovery.

- combustible exhaust from industrial production plants (contaminants in the form of organic compounds),
- the steam boiler must be operating while the process is running and contaminants are being emitted.

The exhaust from pure drying processes, as well as from combined drying/setting/condensation processes, can be piped away without disrupting the process by installing two fans. If the entire machine is being used for drying, both fans supply a controlled amount of humid exhaust. If drying and setting processes are being carried out simultaneously, the first fan supplies a controlled amount of humid exhaust, and the second one, oil or scrooping damper controlled, supplies enriched exhaust.

One way of achieving more economical use of energy (Fig. 3) is by combining the uniflow principle (fabric and air from front to back) up to the middle point, with the counter flow principle (fabric to back, air from back to middle). With regulation of exhaust air dampers (Fig. 4), the humidity of the surrounding air (exhaust) is detected and drying conditions can be optimized. Very low amounts of exhaust can be achieved if the behaviour curve of drying is matched. The exhaust quantity can be controlled by means of the revolutions of the exhaust mototr. Waste air cleaning/water heat recovery systems and components for waste air cleaning and waste heat recovery specially matched to Monforts machines and ranges, opening up new possibilities for energy-optimized operation of the plant as a whole (Fig. 5).

Stenter infeed assembly Device for pick-up of fabric guiding system elements at the machine's infeed point. This is an essential device for feed into the stenter entry zone. Usually consists of → Variable-tension rolls, infeed fingers and selvedge curlers to straighten out selvedges, a sensing element to make sure the fabric width is maintained accurately, and a needle device to define the fabric selvedges on a needle chain.

Stentering The process of drying textile fabrics on stenter driers; → Stenters.

Stentering and drying machine Tensioning and treatment of fabric runs with drying chambers, air supplies either vertical or parallel to the fabric, horizontal or vertical stentering chain redirection.

Stentering fabrics for printing (tensioning and straightening), to avoid pattern distortion after printing, the printed fabric is tensioned to finished size. This process involves straightening the warp and weft threads to a perpendicular position. Simple → Stenters are used, set up so that the fabric can be tensioned under slight steaming. If horizontal stripes have to be printed, such as in roller printing, these stripes are engraved approx. 2 cm askew, and the fabric has to be stentered askew to compensate for this.

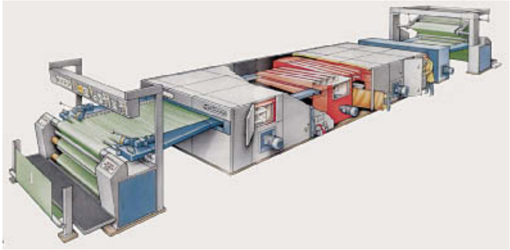

Fig. 1: A Brückner stenter frame.

Stenters Units for thermal treatment of textile fabrics, that retain and set the fabric width. They consist of an entry zone with an edge guide, one or several drying or setting zones, cooling devices for shock cooling, and an exit zone with a batching device and possibly an edge cutting device (Fig. 1). The retaining device consists of pin or clip chains, or combination chains. The air circulation and air impingement systems are comparable to those of other drying systems. However in practice there are considerable differences, because a stenter's chain system enables it to be set up specifically to suit the fabric being treated (e.g. with/without width control, with/without overfeed, clips/pins, ducted air system, etc.). Typical stenter options are varying air supplies and varying impingement types (round, oval or slit jets). Apart from essential components, a stenter dryer should have short air circuits, practically arranged heating systems, easy accessibility, and be easy to use. For knitwear finishing for instance, as well as an over-

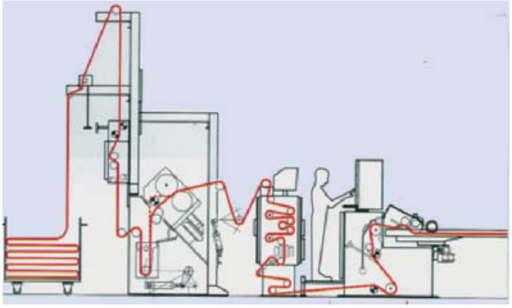

Fig. 2: Fabric preparation in front of a stenter frame.

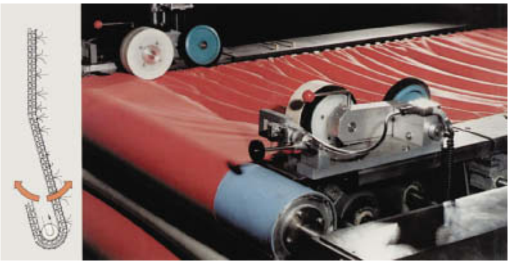

Fig. 3: Multifunctional entry zones can be modified at short notice (e.g. for coating).

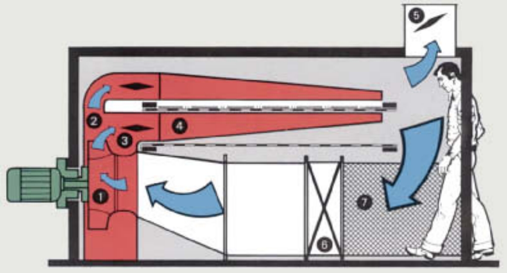

Fig. 4: A Brückner constant pressure ventilation system, here with oil circulation heating.

feed device (Fig. 3) the fabric guiding system should be relatively tension and flutter-free. Air flow control (Fig. 4) should be clear, simple and easy to use, because multi-speed motors often do not allow enough margin. If low friction tools are used, chain lubrication, which often causes oil splashes, will not be necessary. Direct gas heating can be used to direct air and any vapour in the circuit through the burner, so that any foreign substances present in the surrounding air are burnt. However this results in unknown cracking products.

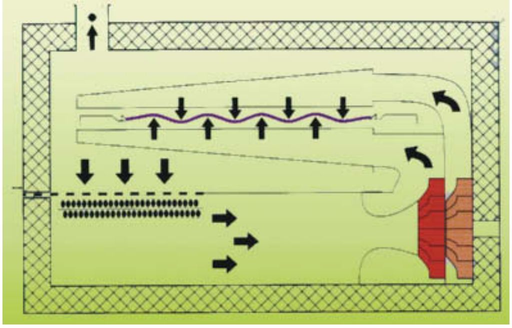

Fig. 5: TWIN-Air system.

The TWIN-Air-system (Fig. 5): Separately controlled air flow for top and bottom air. Also available with separate temperature setting for top and bottom air to supplement the system. Advantages: Reproducible fabric results at any time. Individual exact setting by speed-controlled fans even at low speeds. Ideal for delicate fabrics such as knitted goods, coated fabrics, viscose, microfibres, pile goods and silk. The TWIN-Air system is based on a Monforts patent.

There are measurement and control devices to ensure even quality of the tensioned fabric. The stenter can be equipped with electronics, which will automatically set target values for the relevant finishing process, which guarantees reproducibility for that process and the required effect (Fig. 6). Stenters are fitted with heat recovery systems, enabling approx. 80% of the exhaust heat to be put to further use. Heat exchangers usually operate on the air/air principle.

Fig. 6: A stenter control bridge with the Babcock "Dasy-Tex" process control system. The "Dasy-Tex" hardware includes local autonomous control loops, a higher-order computer, the program memory, the operator's keyboard, a monitor and a page printer.

In textile finishing, stenters cause a logistic problem in almost every factory. It is an essential prerequisite that the machine is operated properly (shrink-free fabric, exact final fabric width) to ensure fabric quality (weaves, knits). A stenter is an expensive piece of equipment, because the original purchase cost is high, it requires plenty of space, and it consumes large amounts of power. For this reason it is the only textile finishing machine to have such highly developed measurement and control systems. The stenter is one of the most highly polluting systems, next to machines that produce waste water, because of its high air throughput containing vapour that picks up diverse contaminants. Stenter emissions are regulated by TI-air specifications, but gaseous waste products are more difficult to deal with than textile finishing by-products dissolved in waste water. At the moment, stenters operating in Germany are required to be licenced, because they produce exhaust (→ Exhaust air segregation in stenters). The technical requirements for cleaning the exhaust are significant, and cost as much again as the actual purchase price of the equipment. In some areas, a licence for a new stenter is only granted if there is evidence that processes for cleaning the exhaust effectively (condensation, absorption, washing, post-combustion) have been implemented (→: Exhaust air heat recovery; Stenter exhaust air treatment).

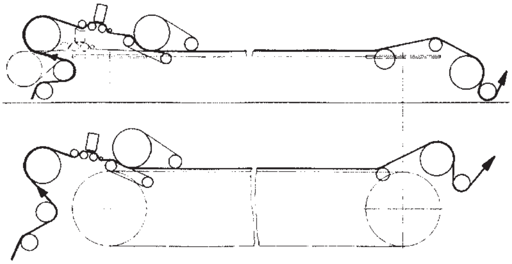

Fig. 7: *Entry and exit pin-wheel sections on horizontal and vertical chain layouts on stenters.*

Fabric should not be under tension in a stenter, they should be de-swollen, drained and dried in clearly defined dimensions, under as little tension as possible (in width and length). The selvedge grip elements necessary for these processes are not in a fixed position, but form continuous mobile chains around a vertical or horizontal axis (Fig. 7). At the inlet the chains are near to each other, gradually becoming further apart to correspond with the intended width of the fabric (Fig. 8). In stenters for drying and tensioning, the chains run through sealed boxes with heat circulation, and may be accommodated over three levels (Fig. 9). Multi-storey stenters are used almost exclusively for finishing woollen weave fabrics. The continuous chain runs in and out of several levels that are arranged one on top of the other. Straightening devices are also fitted at the fabric entry zone, to ensure that the fabric is tensioned in line with the warp or knit.

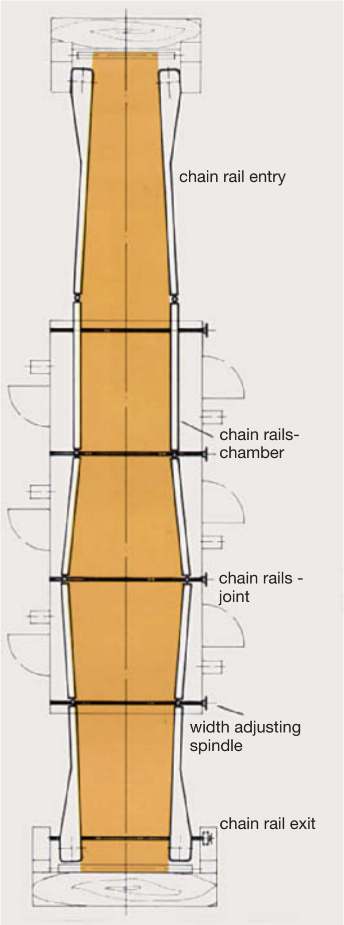

Fig. 8: Individual width adjustment in the various stenter chambers of a Brückner machine.

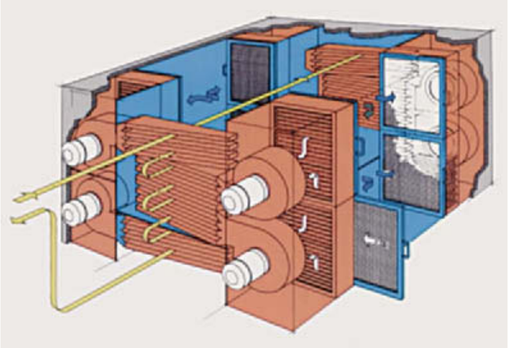

Fig. 9: The Santalucia multi-layer stenter. (yellow arrows = movement of goods; white arrows = fresh air; blue arrows = air circulation).

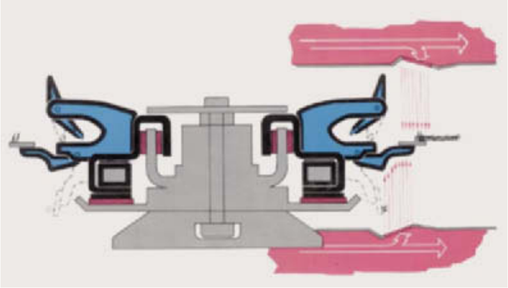

Fig. 10: Chain guides in a Krantz stenter, with flow (right) of the chain carrying goods on pins through the aerated zone and horizontal return (left) of the combination chain (pins alternating with clips).

There are various different construction methods of stenter grip elements. Depending on the type, stenters are known as clip or pin stenters (Fig. 10). The former are fitted with hammer or feeler clips. Hammer clips, a dated option, are clipped through a guide rail without taking the position of the fabric edge into account (false selvedge).

If feeler clips are used, the edge of the fabric can be

	advantages	disadvantages	main application
A horizontal stenter	entry and exit optimum with clips, highest possible tensioning forces, pins and clips possible	wide chain rails, complicated transmission, problems of curling selvedges and in selvedge trimming	universal machine, clip operation, heavy-weight woven fabrics, carpets
B vertical stenter	entry and exit optimum with pins, short spacing, highest possible drying capacity, simple and cost-effective	hardly suitable for feeler clips, higher chain bolt loading, less rigid chain rails	knitted and woven fabrics in pin operation, plastic coating, hammer clip operation
C tier stenter	high drying and heat setting capacity with little floorspace, gentle drying and aeration, 1 man operates entry and exit	fabric contact with return drums, limits to temperature separation, only hammer clips possible	heavyweight woven fabrics, especially wool fabrics, knitted fabrics, time processes
D double return stenter	high capacity, low floorspace requirement, no return drums, 1 man operates entry and exit	no feeler clips, both fabric faces once to the underside	all applications except with feeler clips

Tab.: Main applications of stenter chain versions plus advantages and disadvantages.

located by means of small rollers or hoops. They do not close until the fabric edge is in the right position between the upper and lower gripping jaw. Pins are used in the following situations: For knits, for weaves needing warp shrinking, and for woollen fabrics where clip marks are not wanted. To enable warp shrinkage during fabric tensioning, the stenter chains are set to overspeed. The fabric is fed into the machine at a slightly higher speed than the running speed of the chains. There is a special device to crimp the fabric in pleats on the pin selvedges (Fig. 11).

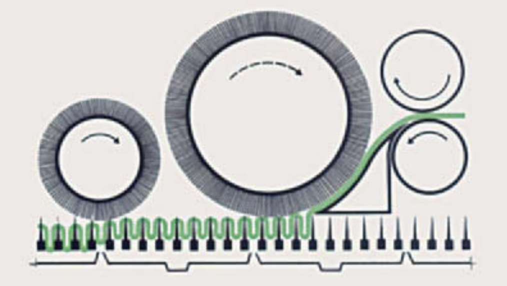

Fig. 11: Overfeed setting (Monforts).

Since the pin or clip chain is continuous (out = fabric transport; return = running empty to the single-needle area), a horizontal or vertical chain return is necessary (Tab.). This type of chain arrangement influences the design of the stenter (Figs. 12 and 13).

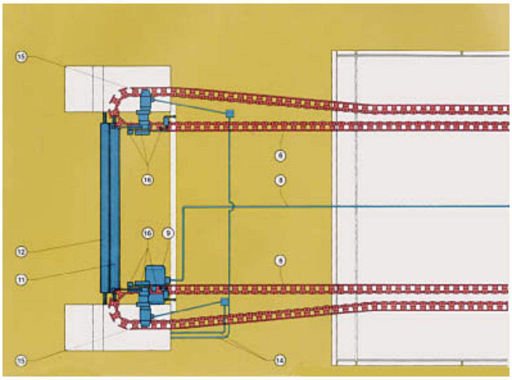

Fig. 12: A Babcock stenter with horizontal chain layout. 6 = chain; 8 = control cable; 9 = main chain drive motor; 11 + 12 = traction rollers; 14 = control cables for coordinating overfeeding and chain speed; 15 + 16 = shrinkage machine (overfeed setting).

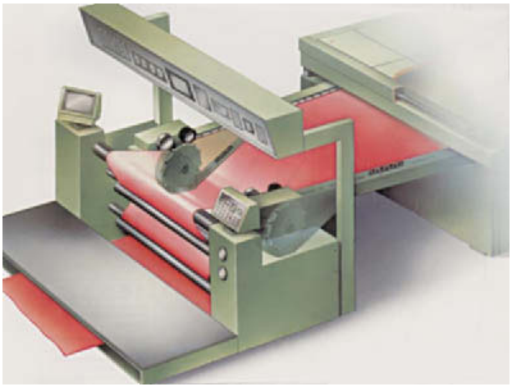

Fig. 13: Monforts Montex stenter with vertical chain layout.

If the stenter is being used as a multi-purpose system (cloth drying, knit treatment, coating), it is practical to have an adjustable operating platform in front of the entry zone (Fig. 14). Chains are often available with a combination of clip types, so that there is a choice between feeler clips or pins. To prevent the edges breaking loose from the pins, clips have been designed that hold the selvedge in position during tensioning. Combination clips can, for instance, consist of two feeler clips, one above the other, and a pin clip underneath. The fact

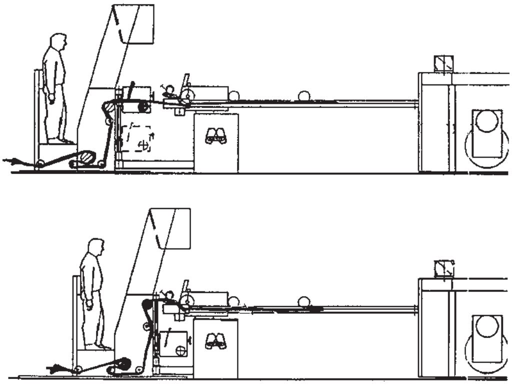

Fig. 14: The adjustable operating platform on the Monforts stenter.
Above: for coating; below: for normal drying operation.

that there are two feeler clips means that it is possible to run two lengths of fabric simultaneously in exceptional circumstances. The small holes created in the edges, caused by tensioning on needle bars, can be removed during a subsequent process, such as decatizing or calendering. The perforated edges on knitted goods can be cut off at the exit zone, using a cutting machine.

A levelling frame is a shorter version of a stenter, and they are used mainly in printing, where they are fitted with brush elements and dust filters. They operate at high speeds of up to 100 m/min and even higher, and are used for alignment of fabric with low moisture content. Jigging or Organdy stenters have side elements with continuous clip chains that move backwards and forwards (approx. 20–30 times per min).

At high fabric speeds (for clip stenters up to 200 m/min, pin stenters up to 120 m/min), the stenter must have an effective heating system. Because of the high level of water evaporation (150–300 kg/h) and the length of the heated area (3 m), the only effective method is jet ventilation, in which warm air is blown directly onto the moving fabric from above and below (Fig. 15). It is effective because the high air speed continually removes the vapour layer that forms on the fabric during drying and acts as insulation (approaching laminar flow barrier through high environmental turbulence). In general the jets are at a right angle to the fabric (Fig. 16). Counter position of the air tunnels is possible (Fig. 17).

Specialist stenters for raised and pile fabric have the option of having the jets angled so that they blow from

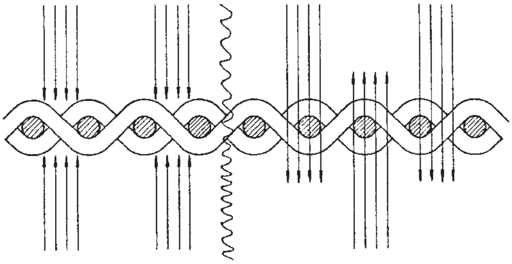

Fig. 15: Optimum (right) and less satisfactory air jet effects in the jet zone of a jet stenter.

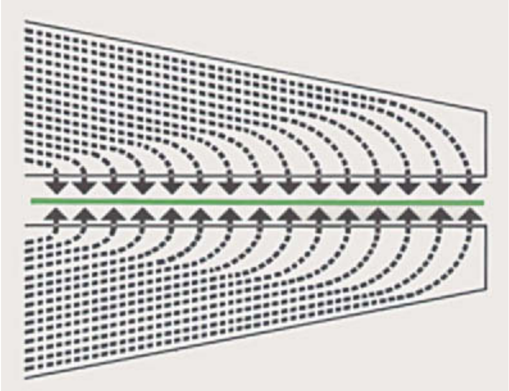

Fig. 16: Tapering jet boxes ensure that an equal quantity of air, blown at ninety degrees onto the goods, is provided at all points across the fabric web (green).

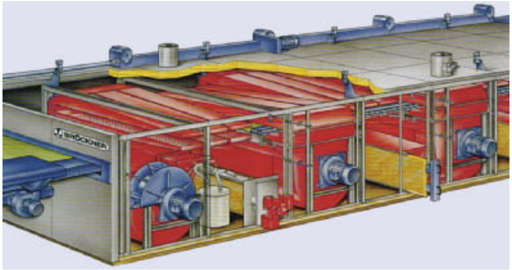

Fig. 17: Counter position of air tunnels in a stenter frame.

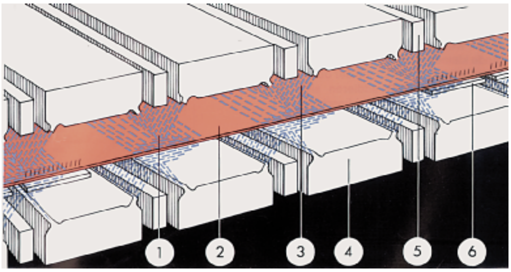

Fig. 18: The goods are transported through this Monforts drier by the air cushion generated by the angled jets.
1 + 3 = hot air jets; 2 = fabric web; 4 = jet box; 5 = throttle rod; 6 = needle slat.

a diagonal position, enabling the fabric surface to be treated without disarrangement (Fig. 18). Depending on design, the air is blown through slits or holes in the jets (Fig. 19), which affects the air path (Fig. 20).

The type of heating is always selected to suit local circumstances. Many stenters are used not only for drying, but also for hot air treatment (thermostabilization, thermosol treatment, heat setting, etc.). For machines that are often used for intermediate drying, in addition to specialist dryers, the air flow is frequently designed in such a way as to ensure even drying across the entire fabric width. For elasticated fabric, stenters with "carrier jets" are used, which carry the fabric on a cushion of air (Fig. 18). The heating system of a stenter is divided up into zones, each of approx. 3 m in length. A specific temperature can be used in each zone, independent of the other zones, enabling counter-flow drying. One method of heating the fabric up rapidly as it enters the stenter is to use infrared heating units. There are several different methods of air heating, the most effective being direct gas heating. Efficient utilization of heat is only possible in stenters that are set up to accommodate a specific width of fabric, where the same type of fabric is always run. Where high temperatures are required, such as for heat setting of woven fabric made from synthetic fibre, extra heating units can be installed. Fine mesh filters are fitted across the air flow to remove fibre dust. Nonwoven fleece can also be used as a filter. Meshes and filters require frequent cleaning.

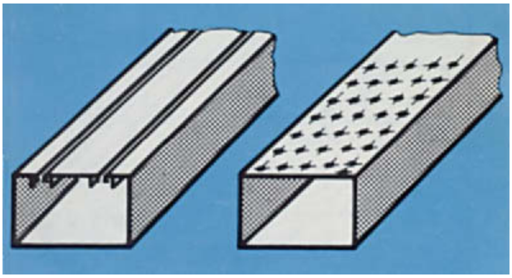

Fig. 19: Slotted and perforated jet boxes as alternatives for use in a stenter (e.g. the Facetta air conveyor jets from Brückner Trockentechnik).

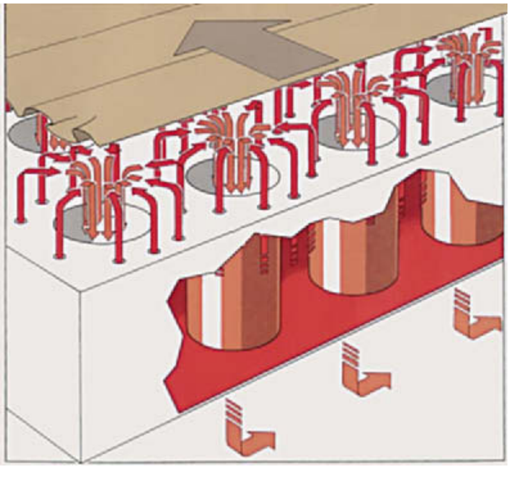

Fig. 20: The Babcock special air direction system using perforated nozzles.

Stenters for knitgoods One of the main purposes of knit finishing is to stabilize the knitgoods: the latent tension, caused by fibre type, yarn manufacture, knit structure type and quality, must be neutralized. The washing process, in which the fabric is alternately stretched and shrunk by means of fibre compression and elongation, starts to neutralize the fabric tension. This shrinkage process is important, in order to ensure that the resulting knit is free of residual shrinkage. Depending on the hydrophilic fibre content, a strong restoring force may be present after wetting/drying. This restoring force can be neither suspended nor eliminated by using a low-tension wet finishing process. For this reason deformation to length and width must be carried out in order to achieve stitch compression in the final drying process. With synthetic knits, the fibre properties have to be permanently frozen, for instance by means of heat setting followed by rapid cooling. For all other finishing processes it is essential to use as little tension as possible, and to have short fabric paths that are as direct as possible. This is the only possible way to achieve permanent shrinkage. Chemical finishing agents assist the setting process, but they cannot completely suspend latent surface tension. It is the stenter that plays a central role in this aspect.

The short, direct fabric paths required for the finishing of knitgoods limit the use of chains for fabric transport. For this reason, vertical edge guiding allows a shorter distance between the upper tensioning roller (Fig. 1, position 1) and the needle-punching device (Fig. 1, position 2) than horizontal chain guiding. In practice a 4–finger edge uncurling device (Fig. 1, position 3) ensures that the fabric is guided safely until the point of needle punching, and that the edge is fully uncurled. A homogeneous fabric appearance ensures that needle punching is carried out precisely. Needle punching is done cleanly using the vertical chain guiding method (Fig. 2), despite chain oscillation occurring after the change in direction, which is unavoidable. Vertical chain guiding requires a slimmer construction, enabling the distance between the textile and the jets to be shorter.

The machine arrangement shown in Fig. 1 is suitable for cut knitgoods that are batch rolled, batched on a dye beam or tabled. If continuous fabric is used, or if several small batches are being treated, it is practical to install a trough between the padder and the fabric feed.

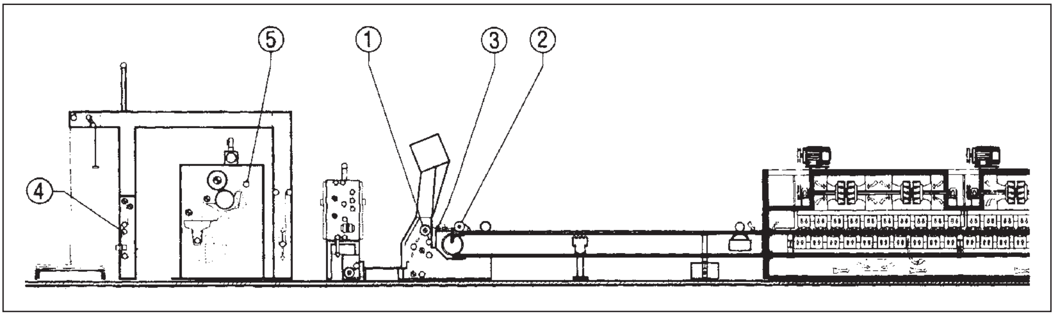

Fig. 1: Side view of a Krantz wide stenter with vertical chain layout (numbers explained in the text).

In order to achieve an even, low-tension fabric feed, the guide rollers operate at a point after central fabric control (Fig. 1, position 4). They consist of adjustable expander rollers, and ensure that the fabric is both expanded initially, and that it is in a central position. Finishing padders for knit finishing are available, and are fitted with two multi-level adjustable expander rollers as standard, one each to be used before the fabric is fed into the trough, and one before the nip. There is a compensator for light operation, developed specifically for knit finishing, which regulates speed with minimum fabric tension in comparison with standard combinations of roller compensator devices. To prevent light fabrics from sticking or wet fabrics from wrapping, an extra powered roller is installed in series to ensure a low-tension fabric path to the nipping unit (Fig. 1, position 5). In this way, the knit fabric is transported at low tension to the straightening device, which should preferably be equipped with fabric tensioning control and driven curved rollers. After the straightening process, the fabric is transported to the stenter entry zone at low tension. A powered, controllable tensioning roller assists this process. There are several expansion rollers along the fabric path, which are in a variable combination to ensure that the fabric is expanded correctly. Fine straightening of the fabric, which is frequently necessary shortly before the actual shrinking process, can be done precisely using motorized straightening rollers, or complete curved/diagonal straightening combinations with electronic sensors. The knitted fabric is guided from the driven, controllable, tensioning roller via a short route to the overfeed device (shrinkage unit) with a brush belt (Fig. 1, position 2). The specially developed brush belt pushes the fabric edges evenly into the needle bar, even at overfeed speeds > 40%. The edge tensioning can be adjusted on both sides independently or together, by means of several potentiometers. This ensures that the knit surface is even across the width of fabric, without distortion at the edges or stitch compression in the centre of the fabric.

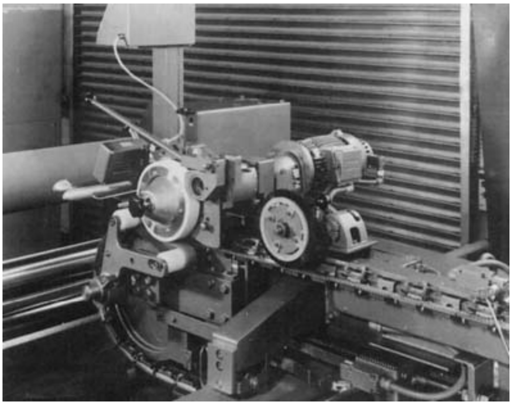

Fig. 2: A shrinkage unit.

Total relaxation of the knitgoods before drying or setting is an essential factor for residual shrinkage. It is important to maintain the correct level of fabric moisture for relaxation. When tabling dry fabric the recommended method is to install a saturated steam steamer in series with the shrinking unit. This enables even, homogeneous moisture distribution across the width and length of the fabric. At this point, applied optical brighteners can be set before the actual drying process. This method is practical in particular for finishing processes using temperature-sensitive brighteners that tend to yellow. In the entry zone infinitely variable width adjustment is carried out to stretch the fabric width slowly. In particular, articles that have undergone extreme shrinkage during pretreatment (e.g. raising, dyeing) need to be stretched without distorting the knit appearance. Fabric that has undergone shrinkage of up to 50% can be stretched properly without centre or edge breakages that must be avoided. This can be safely carried out with an entry zone length of between 4.5 and 6 m.

The spindles in the entry zone are arranged in a significantly lower position than in the dryer, to prevent contact with sagging fabric. There is a central rope to assist the transport of heavy or sagging fabric, which

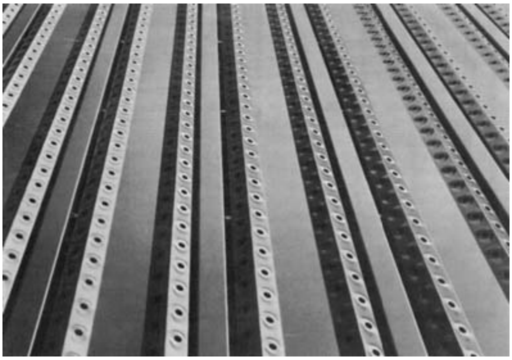

Fig. 3: View of the convey air nozzle system.

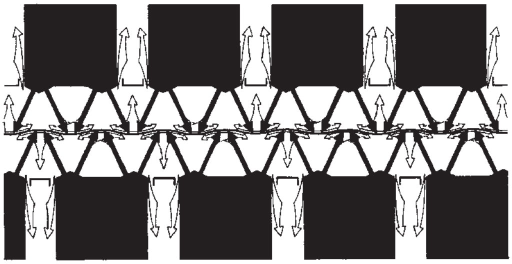

Fig. 4: Diagram showing the points of impingement of the hot air jets in the convey air nozzle system.

runs at the same speed as the chains. The edges are glued before the fabric enters the drying zone. This process is either done at the sides, or it can be done in the centre under certain circumstances, such as if the fabric has been separated into two runs. The glue is evenly dispensed onto the fabric in exact amounts, so that it can be partially dried by means of an IR drying unit connected in series.

The jet arrangement in the drying area, which operates on the basis of the convey-air system (Figs. 3 and 4), ensures a special fabric transportion. This effect causes the fabric to “float” evenly, enabling a permanent, immediate stretch and relaxation of the fabric before the actual setting process. Fabric transported in this way is relaxed during drying, setting, and also when it is cooled by the vibration caused by the air flow. Compression and shrinkage during the drying process ensures that the fabric is evenly and fully shrunk.

The arrangement of the air jets (Fig. 5), and also the vertical air outlet in a transverse position to the fabric, prevent surface fading of the knit, which is mechanically very sensitive. The quantity of air blown out can be controlled by means of speed control of the fan, and there is also a throttle valve situated on the suction side, which can be used for infinitely variable adjustment of the air quantity. The quantity of air dispensed above or below the fabric can be selected mechanically using a control valve. This valve can also be used to select unilateral air flow (Fig. 6). If the fabric run is interrupted, if there is an emergency cut-out, or when the fabric is changed, there is an automatic air flow cut-out to prevent the fabric being dried, whilst maintaining the temperature. This protects the fabric from being subjected to a direct air flow. The selection of a heating system (direct gas heating or indirect steam, oil or electric heating) is not only based on available energy resources, but also on the volatility of substances emitted from the fabric during textile finishing.

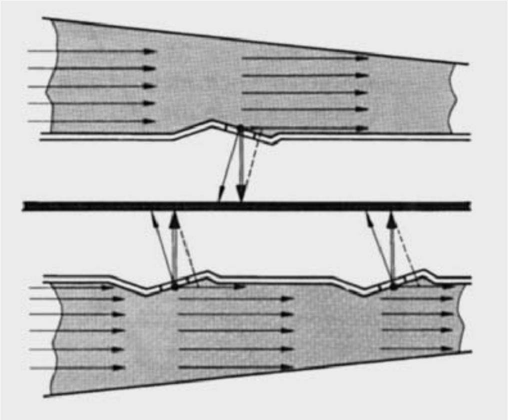

Fig. 5: Diagram of the arrangement of nozzles in the drying zone.

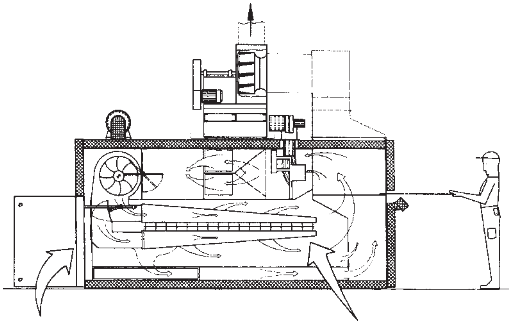

Fig. 6: Cross-section through a drying zone.

The fabric is frequently not set before washing. There are two reasons for this: the production sequence is shortened by one phase (in other words the product is completed in a shorter time), and ideally fabric should be as soft and open as possible. Generally speaking, cotton knitgoods are finished using a particularly large amount of textile auxiliaries. This can cause condensation to occur in the exhaust channels, despite effective insulation. Condensation stains on the fabric can be avoided by means of a specially designed exhaust channel system underneath the fabric run. Goods with cotton content or raised fabric generate a large quantity of lint, which can be efficiently removed from the surrounding air by the installation of a changeable filter. The filter can be cleaned during production. The drying sections have a door on both sides of each zone. Firstly the doors allow general cleaning to be carried out inside the dryer, and secondly they allow access to the jet boxes, which have openings at the ends so that they can be cleaned internally. In the transition zone between the drying room and the exit zone, there is a buffer zone with a suction slit. This is to prevent hot air escaping at the end of the dryer and the condensation of textile auxiliaries. The cooling zone in the Babcock stenter is fitted with the convey-air jet system. Relaxation is carried out with the help of vibration, and the final stage of shrinking is set by means of shock freezing. At the end of the exit zone the fabric is cut at the edges. At maximum production speed the system cuts the fabric directly at the selvedge. The cutting device pins the cut selvedge with a pinning form and sends it to a suction device. As cutting occurs directly on the selvedge outside the chain, the fabric loss is minimal. Selection of a batching device depends primarily on the production stage, the ultimate intended use of the treated textile, and the diameter of the batcher. All batching devices (Figs. 7–11) should roll the fabric consistently, keeping the edges straight, maintaining a low tension level, and without any edge curling. This objective can be achieved by;

- short distances between the point of removal after the pinning process,
- an even pressure on the batching rollers, assisted by the roller power if necessary,
- batching with defined low fabric tension.

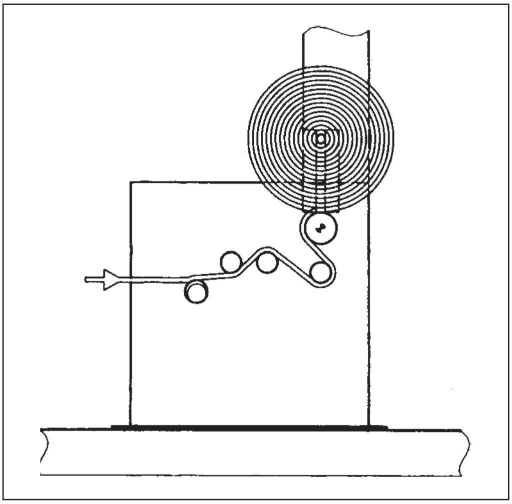

Fig. 7: A vertical rising roll batcher (Krantz).

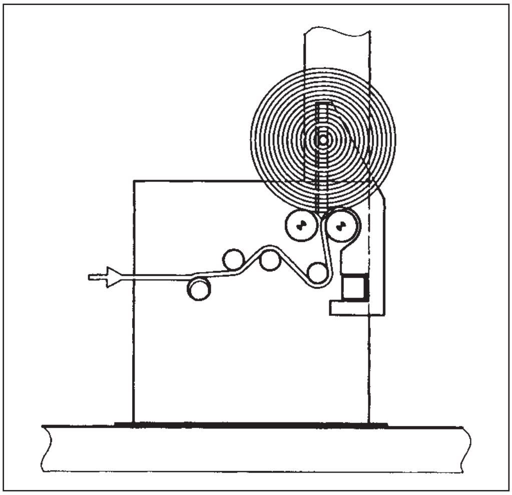

Fig. 8: A double-roller rising roll batcher (Krantz).

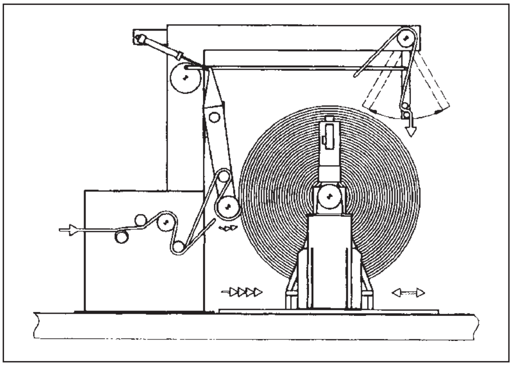

Fig. 9: A giant batch roll contact batcher (Krantz).

For batching finished knitgoods that are ready for despatch onto cardboard tubes (batch diameters of up to 400 mm), a vertical rising roll batcher is used (Fig. 7). If large runs of fabric are being roll batched, a double-roller rising roll batcher (Fig. 8) is recommended, which is powered separately to ensure even batching. If a giant batch roll of knitted fabric is being produced, a combination of a centre drive batcher and a surface batcher is used, which is known as a giant batch roll contact batcher (Fig. 9). The batching device is situated on a sliding platform, resulting in a constant, short feed path between the swivelling pressure roller and the increasing diameter of the batch roll, which is vital to en-

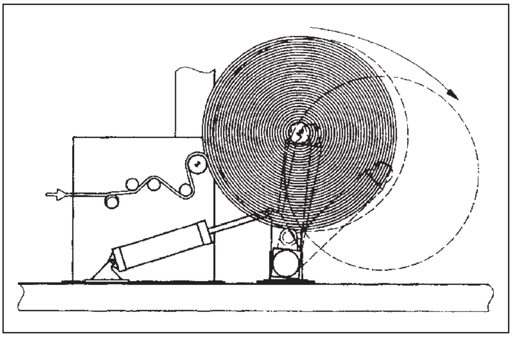

Fig. 10: A universal batcher (Krantz).

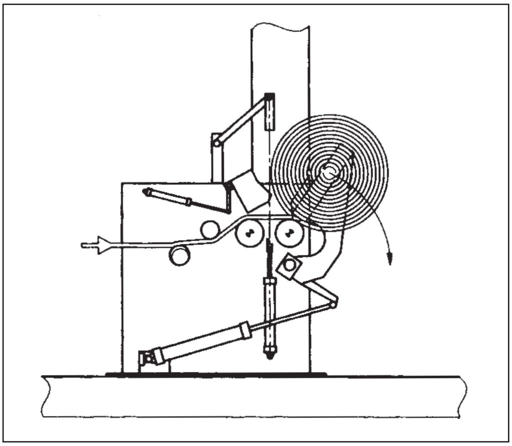

Fig. 11: A nonstop piece roll batcher (Krantz).

sure constant smooth batching. There is a tension controller to adjust the tensioning of this device. A universal batcher (Fig. 10) is used in any situation where batches of varying diameters are required. The fabric feed process is assisted by pneumatic or hydraulic pivoting arms. This batching process is suitable for all standard batching packages, from cardboard tubes to dye beam, even entire giant batch roll carriages. Batching can be carried out even at maximum production speed, without stopping the sequence or reducing the speed, by using a non-stop piece batcher (Fig. 11) for batching rolls of up to 800 mm diameter onto cardboard tubes or wooden batch rolls. Fig. 12 shows a typical two-level stenter for knitgoods, with a generous fabric area (Krantz, Bollig, Hampel and Souren); a multi-layer stenter is shown in Fig. 13.

Step-and-repeat machine The step-and-repeat machine has a print roller pre-prepared with light-sensitive paint, upon which the positive slide is placed and exposed.

Step washing For bleaching processes to be carried out properly, residual quantities of hydrogen peroxide must be present on the fabric after the reaction phase in the steamer. It is practical to immediately utilize these residues and the bleaching auxiliaries, such as surfactants and sequestering agents, in the washing process that follows. This was not possible using the counter flow washing method, which was popularly used in the past. The water flow (see Fig.) is in the same direction at the start of the washing process, with the addition of a small quantity of the overall fresh water supply depending on the type of fabric. This means improved cleaning where residual chemicals are present, and the released impurities can be completely detached

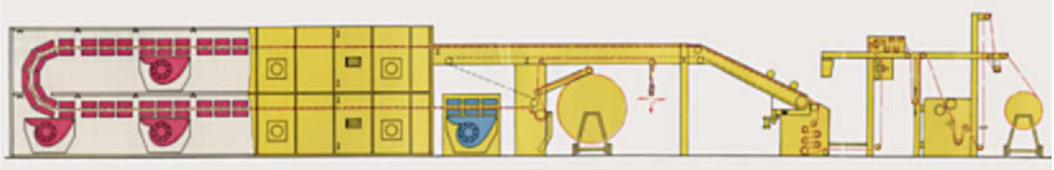

Fig. 12: A Brückner two-level stenter for the final finishing of knitted goods.

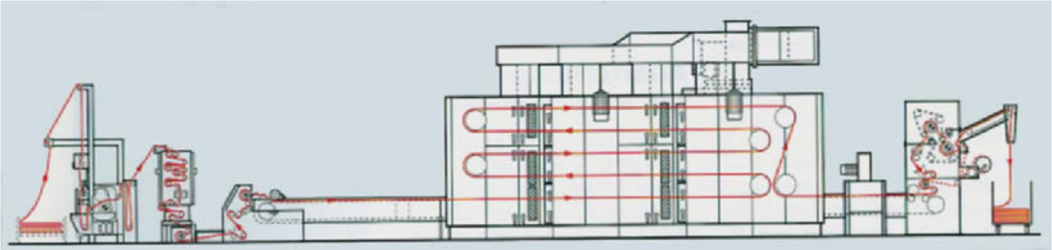

Fig. 13: Knitwear finishing (KM 16 H, Krantz).

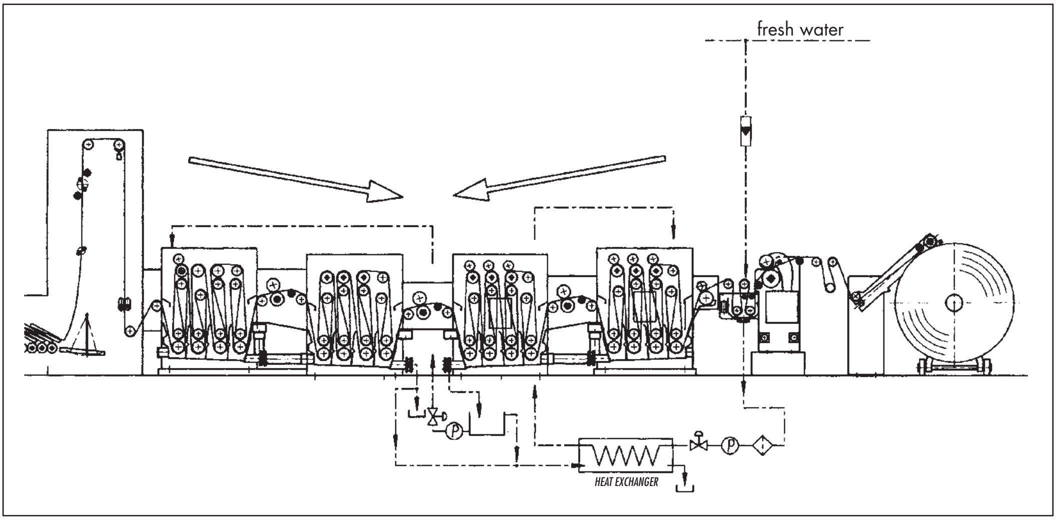

Fig.: Diagram showing the principle of step washing (Küsters).

and emulsified. It is only when this process is finished that the counter flow principle is applied, using the entire fresh water supply for subsequent soil removal.

The advantages of step washing are:

- Utilization of the residual bleaching chemicals left on the fabric after the steaming process, as well as efficient emulsifying of dissolved substances in the same flow direction, and removal and washing off of all soiling in the counter flow.
- Further improvement of reaction conditions in the steamer because of the high liquid content (if flexnip is added to counter the impregnation vat application), thereby creating better conditions for washing, which results in higher levels of absorbency.

Stereochemistry applies to the spatial arrangement of atoms within the molecule structure, e.g. →: Stereoisomerism; Isomeric compounds; Isotactic polymers.

Stereoisomerism applies to compounds having identical empirical formulae and constitutions, where the atoms are in a different spatial arrangement (spatial isomerism), and they possess different properties. There are different types of stereoisomerism, optical isomerism (→ Optical Activity), → cis-trans isomerism and conformation isomerism.

Stereoscan images If an object being examined is metallized with certain metals, it will appear almost three-dimensional under an → Electron microscope, and is caused by systematic scanning of the object during the irradiation and deflection of electrons to create the impression of a stereo image (see Fig.).

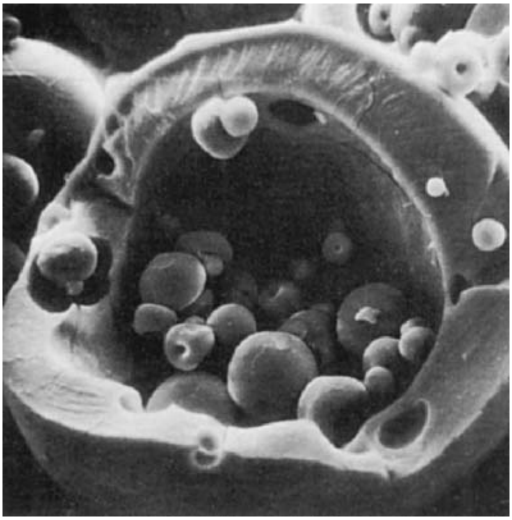

Fig.: A stereoscan image of the microgranulate formulation of an indanthren dye.

Stereospecific polymers These are → Isotactic molecules and Syndiotactic molecules, whose spatial arrangement during synthesis is formed with the aid of specifically acting catalysts.

Sterility An absence of germs (known as asepsis), i.e. no living germs are present at all. Depending on the fabric this can be achieved by dry or moist heat treatment. Usually 8 min at 120°C in an autoclave is enough (for cotton wool and bandage material), strong disinfectant can be applied (preservative), or germ-free filtration can be used (water treatment), etc. Radiation treatment is also a possibility. → Sanitized finishing.

Stick lac → Shellac.

Stiffened fabrics Stiffening → Interlinings between the top cloth and the lining, → Front fusing.

Stiffened linen Extremely strong → Buckram, board-like, hard, barely flexible, used for stiffening uniform collars.

Stiffening agents Used specifically for finishing and sizing. There are different types

I. Vegetable colloids: starches, mucilages, mosses, algae, gums.

II. Animal colloids: glue, gelatine, casein, protein sizes.

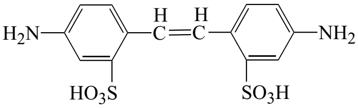
III. Synthetic colloids: polyvinyl products and similar, cellulose derivatives, synthetic resins.

Stiffness (rigidity, flexural rigidity). Flexural rigidity is a measurement of the resistance exhibited by a material when subjected to bending. It can be defined according to DIN 53 864.

Stilb Unit of → Radiant intensity per unit area. Radiant intensity is defined as the quotient of candela and square metres: $L = 1\ cd/m^2$.

Stilbene (trans 1,2 diphenylethylene)

Stock substance of stilbene dyes and numerous valuable optical brightening agents, for instance in the form of a detergent additive. The latter are usually derived from diamino stilbene disulphonated acids (a by-product of the dyeing industry), which in itself does not exhibit any fluorescing effects, but it does, if for instance the chains are extended on both sides to NH_2 groups.



Stilbene dyes → Direct dyes.

Stimulus → Colour stimulus.

Stipple engraving Dotted recesses in the pattern engraving on printing rollers. Synonymous with → Hatching.

Stitch-bonded carpets → Loop pile carpets manufactured using the stitch-bonding technique. The stitch-bonded fabrics are then bonded on the reverse side and coated.

Stitch-bonded composites (stitch-bonded fabrics), textile fabrics consisting of fibrous nonwovens or loose criss-crossed thread layers piled on each other, which are bonded with the stitches formed by warp threads that are sewn in, or they are bonded with other fabrics. Stitch-bonded composites can be sub divided into →: Stitch-bonded fabrics; Stitch-bonded thread-layer fabric; Stitch-bonded pile fabric; Stitch-bonded weft pile fabrics.

Stitch-bonded fabrics,

I.→ Stitch-bonded composites.

II. Fibrous nonwoven fabric bonded by forming stitches from warp threads that have been sewn into the fabric.

Stitch-bonded nonwovens Nonwoven fabric bonded with chain-stitch seams (stitch-bonding technique using long fibres, not sewing thread).

Stitch-bonded pile fabrics In principle the many different qualities of stitch-bonded pile fabrics can be divided into the following categories:

- type used for floor coverings,
- type used for rear window shelves,
- type used for car boot upholstery.

The requirements posed by these different uses, in a general, mechanical and specific sense, together with aesthetic and cost-related aspects, led to the development of the following range of variations. There are

- single layer needle-punched nonwoven coverings,
- multi-layer needle-punched nonwovens with a basic utility layer (reclaimed fibre),
- (single layer) pile fleece coverings with loop pile or velour-type upper side,
- combinations of single layer coverings with hard stitch-bonded fabric (reclaimed fibre).

Production technology for stitch-bonded pile fabrics is mainly based on techniques used generally in the textile fleece industry. However these techniques are modified or extended. The process sequence can basically be represented as follows:

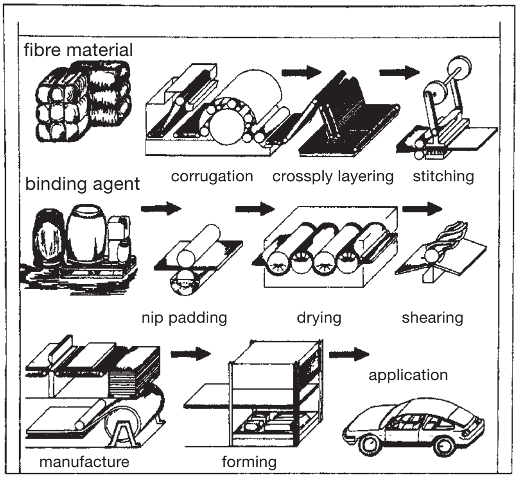


Fig.: Stitch bonded pile fabrics in a simplified flow diagram (according to Eisele).

- preparation of raw materials,
- mechanical bonding,
- finishing,
- garment manufacture
- final inspection.

The Fig. shows a flow chart.

Stitch-bonded thread-layer fabric → Stitch-bonded fabrics made from criss-crossed thread layers piled on each other as a backing material, bonded with the stitches formed by warp threads that are sewn in.

Stitch-bonded weft pile fabrics Stitch-bonded fabrics (→ Stitch-bonded composites) in which threads formed into pile loops are bonded to the backing material by means of sinker loops created by a pillar stitch chain.

Stitch bonding Mechanical oversewing of fibre nonwovens, thread-layer fabrics or textile fabrics with two parallel chain stitch seams sealed together. To carry out this oversewing, there are numerous adjacent sliding needles that are moved at the same time (with sharp points designed to pierce holes), which work with closing wire bars. The appearance of the seams, which consist of stitches, depends on the type of stitch bonding used for the warp knit fabric (→: Pillar stitch; Tricot weave).

Stitch course → Stitches arranged adjacently to one another. In standard knitting they are formed consecutively, in warp knitting they are formed at the same time. The number of stitches in the stitch course is dependent on the stitch size.

Stitch density Construction characteristic of all knit fabric types; calculated as the product of the stitch course count and the stitch wale count. This figure represents the number of stitches within an area of 100 cm^2.

Stitches Thread loops that are linked together and constitute the smallest units of → Knitted fabrics. They consist of 1 head (upper part), 2 shanks (middle part) and 2 feet (lower part); each having 4 bonding points (2 upper and 2 lower, i.e. at the top and bottom). Stitches arranged horizontally are known as stitch courses, and those in a line vertically are called a stitch wale. Depending on the side of the fabric, there can be “purl” stitches (where the stitch heads are emphasised), and “rib” stitches (where the stitch shanks are emphasized).

Stitch gauge This is the total stitch count (= needle count) per $1^1/_2$ inch (Engl.) = 3.81 cm fabric width. This stitch fineness is known as → Gauge (g), which can also be abbreviated to gg. The higher the gg number (usually between 36 and 66), the more stitches there are in the knitted fabric, it is finely woven and therefore has better elastic properties. → Cover factor.

Stitch sewknit fabrics Variant of → Malimo fabric, manufactured for instance from weft layers sewn (using pillar stitch) with woven fabric, Malimo fabric, expanded foam, fleece or knitted fabric as a basis fabric. Synthetic sewing thread is usually used. Use: imitation fur fabrics, friezé for coats, suedette, corduroy, upholstery fabrics.

Stitch wale → Stitches arranged above each other made by the same needle. The stitch wale count is dependent on the distance between the needles.

Stitch width The distance between two → Stitches, also characterized by the number of stitches per cm or inch. → Mesh number. This is important in screen gauzes, for instance.

Stochastic (Gk.), an approach based on analytical → Statistics, in which any conclusions drawn about mass phenomena or repeat sequences must take → Probability into account. Random events that occur with a certain level of stability during the course of sufficient experiments are stochastic.

Stock colour Print paste with a high concentration of dye (large quantities are usually kept in stock), used in combination with other stock colour pastes or → Reduction thickeners as mixes.

Stock pastes in printing Print pastes consisting of all the necessary chemicals except for the dye.

Stocks Solid silicon rubber compounds, which can, for example, be forced through calenders to coat fabrics.

Stock solution Analytical term for the weight of a substance dissolved in a solvent, e.g. 10 g/1000 ml.

Stock thickener (stock thickening). → Printing thickeners containing setting chemicals (large quantities are usually kept in stock), to which dye is added at a later point, in powder, paste or solution form.

Stock vat It is not possible to vat individual vat dyes in a dye bath, they need to be dissolved in concentrated form. This method is known as stock vatting.

Stock vat dyeing process Inaccurate term for → Variable temperature dyeing processes.

Stoichiometric formula (substance formula), refers to the conclusive formula of the relative atomic number in → Chemical compounds, e.g. for sodium perborate $NaBO_3$ = 1 : 1 : 3, and for sodium peroxide Na_2O_2 = 1 : 1.

Stoichiometry (Gk.: stoichos + metron = primary matter + measurement), concerns the quantitative calculation of chemical reactions that result from individual formulae or are basically derived from the same moles; e.g. 1 mole iron Fe (= 56 g) and 2 moles hydrochloric acid HCl (= 73.02 g) = 1 mole iron (II) chloride $FeCl_2$ (= 127 g) and 1 mole hydrogen H_2 (= 2.02 g), therefore the initial 129.02 g results in 129.02 g again. Stoichiometry plays an important role in the practical analysis of all chemical processes. → Titration (quantitative analysis).

Stokes (St), a unit of kinematic viscosity that is no longer used. The current SI unit is m^2/s. 1 St = 10^{-4} m^2/s.

Stone polishing In print roller manufacture, the polishing process on copper print rollers during → Copper electroplating. It occurs when agate stones (rolls) are pressed onto rotating rollers, causing the copper crystals that form vertically to be polished.

Stone-Washed-Finish Denim fabrics (→ Jeans) dyed with indigo or other dyes are sized with a large quantity of starch and manufactured into garments. Once the textile has been made into a garment it is desized immediately (30 min at 60–70°C) and then treated with sodium hypochlorite. The technique is known as "Stone-Wash" or denim finishes because pumice stones are used as an abrasive agent to achieve special effects (1 kg of stone or sand per kg of fabric). The bleaching effects can be altered by varying the pH and liquor temperature of the sodium hypochlorite bath. The higher the temperature and the lower the pH (pH 8), the stronger the bleaching effect and the attack on the fibre. There must be a compromise between the sodium hypochlorite concentration, the pH and the temperature to ensure that the fibre is not damaged too severely (see Fig.).

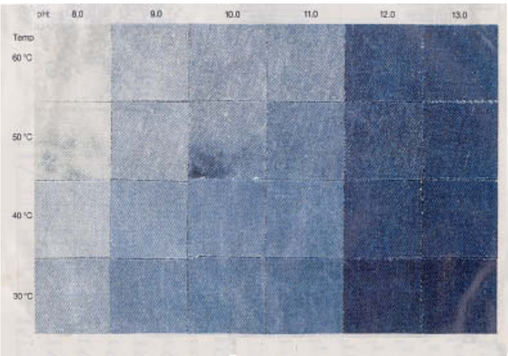

Fig.: Stone-washed finish of jeans, effect of pH and temperature (Sandoz).

The strongly abrasive effect of the pumice stones should also be taken into account; it can cause damage to the fabric, the seams and the machinery. In addition, the use of pumice stone can cause unwanted dust generation in the working environment, which generates further problems. Also the diameter of the pumice stones reduces rapidly with each wash, making it relatively expensive. Bleaching with hypochlorite is also becoming more controversial because of the waste water problem. This is a possible alternative: cellulases (enzymes) can be used for a "non-stone" technique. In this method, the jeans are desized first and subsequently treated with cellulase. Thanks to this specific effect, oxidative bleaching and the use of pumice stone is not necessary. The final result is comparable to that of the stone-wash process.

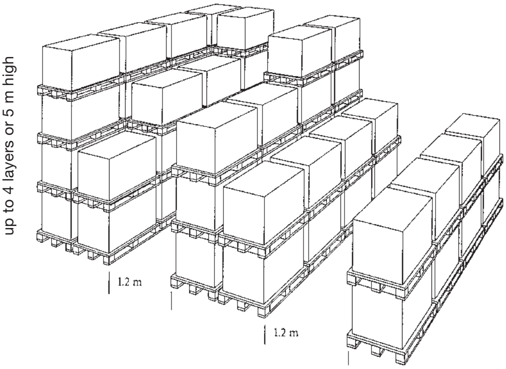

Fig. 1: Block storage, either 4 layers or up to 5 metres high.

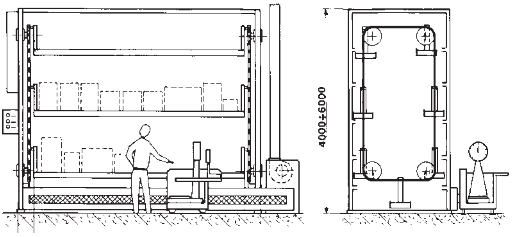

Fig. 2: A typical paternoster store for the storage of dye containers.

Storage Storage should be organized logistically; e.g. block storage (Fig. 1), high-shelf store, paternoster store (Fig. 2), etc.

Storage regulations Storage products in chemical form are categorized in storage categories according to:

1. Fire and explosion hazard: in line with the Comité Européen des Assurances (CEA) code relating to fire hazards. The criteria are the flash point, the combustion test, the drop-weight test and additional specific tests.
2. Toxicity: any properties of substances and their breakdown products in the event of fire that are toxic, detrimental to health, irritant, corrosive and caustic.
3. Eco-toxicity: Substances with properties that present a hazard to water (water hazard categories) or air (foul smelling), with respect to both the actual substances in storage as well as breakdown products in the event of fire.

The German Water Resources Law (Wasserhaushaltsgesetz) makes a distinction for stored chemicals between "hazardous substances" (§ 7a) and "substances that present a hazard to water" (§ 19g). There are specifications applying to this type of substance, relating to storage, bottling and spillage. There are also specifications for the handling, treatment and use of these chemicals, referring to how they should be handled for instance in the event of a fire, and suggesting improvements to the infrastructure.

Storage sublimation → Sublimation fastness during storage.

Storage time One element of → Throughput time. Storage time is a period during which the goods are part of a process, but do not undergo any change, i.e. there is no work in progress. This period frequently constitutes up to 80% of throughput time. Storage time is made up of the time spent physically in storage, out-time caused by technical reasons relating to the process (quality control), out-time caused by mechanical problems (defective machinery), and out-time resulting from human error.

Stored program control (SPC). The control element (in the switch box) of textile finishing machines has undergone a major change from relays to SPC, making the switch boxes visibly smaller. In practice the control valves fitted actuators must react to electrical signals. For this purpose there are electropneumatic converters, i.e. pneumatic valves with electromagnetic operation. A coil acts as a magnet, triggering a mechanism within the valve to switch from one position to another. This type of electropneumatic control system is a basic component of controlled function sequences for the appropriate unit in standard textile machine switch boxes. Occasionally a control system is made up of elements using standardized technology. Usually hybrid systems are used, e.g. pneumatics with electronics, electrics with hydraulics, etc. For this reason however, the signals need to be converted from one technology to the other within the control system, at the interfaces between each element. This means that a hybrid control system can consist of purely electrical sensor and processor elements, with a purely pneumatic or hydraulic actuator. Solenoid valves form the links between two different technologies, converting electrical signals into pneumatic signals. The electromagnetic relay is the essential factor in signal conversion, and the way in which it functions is based on efficient utilization of the magnetic effect of an electric current. As soon as current flows through a coil, it assumes magnetic properties and attracts the solenoid, which then closes the contact via the lever mechanism.

The electric relay circuit is being increasingly replaced by stored program control in modern textile machine design. In the control system (see Fig.), input signals come from the sensors, which are routed to the central unit via input boards. The signals generated by this unit are processed by output board assemblies and transferred to the actuators. The program is written using an external programming device and transferred to the program memory. The programming languages used most frequently in SPC are the contact schedule, the function schedule and the list of instructions.

Stored program control technology has become a central aspect of automation technology since its introduction at the beginning of the 1970s. It has provided

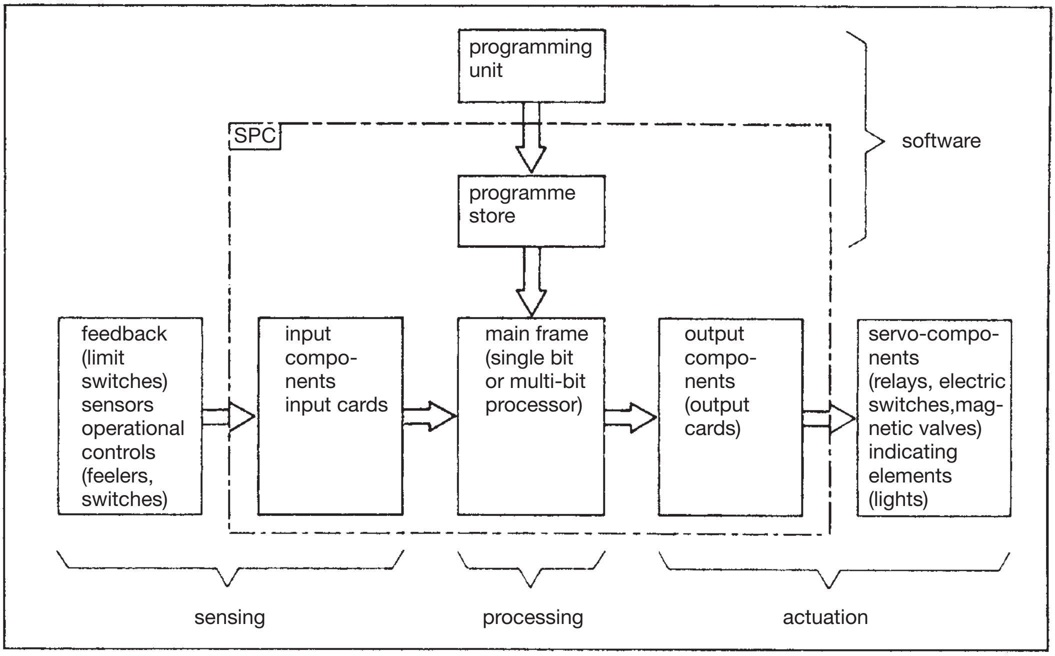

Fig.: SPC system unit.

much new impetus in automation. SPC is a computer that has been specifically optimized for "control technology". Data input into the control computer is done by means of binary signals (position switches, switches, limit potentiometers, light barriers, etc.). Data output is also in the form of binary signals, for instance via control devices that switch over, e.g. motor protection that shuts off a motor, or a solenoid valve that allows a cylinder to be released. Data in the control computer is processed using a program. In other words the SPC program is not fixed in wires or circuits, it is stored in electronic memory. A programming device is required to program this memory, as it is not self-programmable. Programming can be carried out on-line or off-line. Obviously the machine must be designed so that technicians anywhere in the world carrying out maintenance or repair to systems equipped with SPC will have portable programming devices, so that they can access factory-programmed controllers on site and modify them if necessary.

The sensors that supply the SPC with signals and the reactors that receive the signals need to be wired onto the SPC, and the pneumatic and hydraulic elements need to be connected to the solenoid valve by tubes. However this wire/tube connection is uncomplicated because it is not based on logic. There is no logic integrated into the wiring system, apart from external safety devices for humans and machinery. This means that circuit diagrams are simple and clearly defined.

Input of the actual program is done by the programming device, so it needs to be abstracted from the visible wiring to form an image that can be viewed on a monitor. Even if this image bears a resemblance to old-style circuit diagrams, the operator must be aware that it is only an image of the logical functions, a graphic representation of a Boolean logic system. Although a visual representation of a contact switch can be seen on the monitor, it does not attract a contactor. This abstraction becomes more apparent in the form of a programming tool or programming language in the application list.

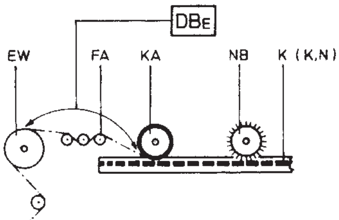
Re-wiring is made considerably easier, firstly because the programming device makes it easier to carry out changes in comparison with physical re-wiring, but in particular because it is easy to keep a record of the new program using the programming device. The state of SPC technology permits extensive documentation of SPC programs, which means that the current program version is always accessible (according to Bocksnick and Plagemann).

Store lighting (TL 84), type of lighting for colour-matching booths, defined as cool, white fluorescent light at a colour temperature of 4400 K. → Colour matching of dyed/printed samples.

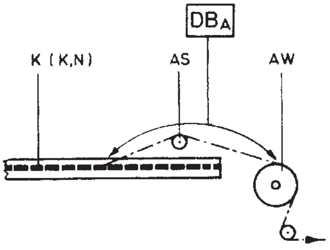
Stoving fastness Level of resistance against the influence of sulphur dioxide. The guideline applies to wool and silk, even when mixed with other fibres. The fabric sample undergoing testing must be wetted for 5 min at 25°C in soap solution and squeezed at 100% liquor uptake. Fabric sample and control sample is then exposed to an environment containing sulphur dioxide for 16 h. Fabric samples are hung for 2 h in air without rinsing. Textile mixes are rinsed for 10 min after sulphur treatment and then dried at 60°C. The result is analyzed using the grey scale method.

Straightening machine So-called fabric flattening and straightening machine, either with a horizontal span or as a tension wheel, as a type of a twin star frame. They are used for width tensioning and yarn straightening of dry fabrics and are especially important for all types of lighter fabric. Straightening machines are equipped with steam appliances and an automatic fabric entry zone (→ Expander).

With regard to the straightening machine (see Fig.) it is assumed that a long piece of fabric, e.g. 1000 m, with a constant slant "set back to the right" of only 2°, conforming to approx. 6 m by 1.80 m fabric width, is submitted to the stenter. A scanner is installed either just in front of or behind the drawing roller of the automatic straightener. As long as it is switched off, the fabric is still inclined as it leaves the stenter. When the automatic straightener is switched on, it detects the distortion and generates correction impulses in such a way that the right hand chain runs faster for a short time until the fabric is even. Then the automatic devices do not



entry (schematic)



exit (schematic)

Fig.: Stenter/straightening frame, entry and exit (schematic). DB_E = elongation area at entry; EW = intake roller; FA = finger unrolling and selvedge guider; KA = shrinkage device; NB = needle brush; K (K, N) = chain (clips, needles); DB_A = elongation area at the exit; AS = de-needling rod; AW = drawing roller.

call for any more correction; both chains run at the same speed again for a time. Then the stretched incoming fabric again exits, is detected as stretched, and correction starts afresh. In reality the correction is carried out more neatly. An even correction is permanently achieved, i.e. the right chain permanently runs somewhat faster, with correct, i.e. optimum controller adjustment. The right edge of the fabric runs 0.2% faster on average than the left, and so undergoes 0.2% more elongation.

The fabric enters into the stenter permanently stretched. During the throughput time of a point on the fabric only 12 correction impulses are given in total on 30 m in 1 min. During an impulse time of, for example, 0.3 s the right hand chain runs at 31 m/min, which corresponds to a straightening effect of 5 mm/impulse. So these 12 impulses achieve a straightening effect of 6 cm. The right hand chain covers 30.06 m on average in 1 min, the left hand chain only 30.00 m. While the left edge is pinned down with, for example, a lead of exactly 10%, it is only 9.8% on average on the right side. Then, no more elongation or shrinkage is carried out in the stenter itself, only an angular displacement. The drawing roller in principle inevitably produces a slight drawback tension, which, for example, is obtained by a lead of 1%. The left edge of the fabric is run by the chain at a speed of 30 m/min, is then stretched by 1% between de-needling point and drawing roller. The right edge of the fabric however runs at an increased correction speed of 30 m/min + 0.2%, but is then stretched between the de-needling point and drawing roller by only 0.8%. So in reality one edge of the fabric does not become longer than the edge.

Straining machine →: Yarn liquoring machine; Print paste sieving machine.

Straining of print pastes In printing the sieving or straining of print paste and thickeners before use, to remove any impurities that could cause problems.

Stramin (Italian: straminga = cheesecloth), cotton woven cloth similar to cheesecloth, usually with strong threads (made from strongly spun yarn). → Canvas.

Straw In the form of braiding straw for trimmings (on bristles, galloons, etc., sewn together for hats, bags, etc.). Straw types used are mainly wheat (light-coloured), rye (dark), maize, rice and barley. Imported from Eastern Asia and Italy. The raw material should be pale in colour and as close to white as possible. Other factors that affect the quality are, shine, matting, evenness and fineness. The only straw processed is knot-free cut straw approx. 10 cm in length (the lower part of the straw is called "pedal" and the upper part is called "punta"). Either whole straws can be processed, or they can be split into 3–7 pieces as "Liserét" (outer and pith straw), sorted according to colour, shine, length and fineness.

Streaky dyeing → Barriness.

Strength Strength is the level of resistance exhibited by a material against separation into individual pieces. In textile testing, strength usually means → Tensile strength (breaking strength, limit strength, tear strength). Depending on the type of separation process, there are different types of strength, such as → Bursting strength; Flexural strength or resistance; Tear strength; Resistance to tear propagation; Crease resistance; Flexing abrasion resistance; Loop strength, Torsional strength; Wet strength.

Strength per unit linear density The highest possible tensile force of linear density or → Tensile strength of fibres or yarns.

Stress cycle Term for load/relief cycles in the context of textile elasticity tests, e.g. knitgoods. The elasticity of a fabric can be analyzed by repeatedly measuring the force required to achieve a specified level of elongation

Stress-strain behaviour The stress-strain properties of individual fibres are frequently used to describe the condition of the fibre or to quantify fibre damage. The measurement procedure used for this is designed to analyze tension and elasticity modules in the same measurement procedure.

The resulting stress-strain curves (Fig. 1) cover three ranges:

- an elastic range according to Hooke's law (up to approx. 5% elongation),
- a plastic range (up to approx. 25% elongation),

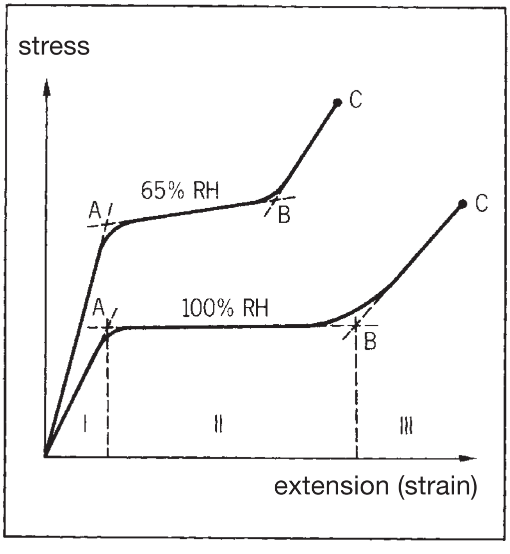


Fig. 1: The stress-strain curves for hair under differing conditions of relative humidity (RH).
I = the Hooke region; II = the plastic deformation region; III = the non-plastic deformation region; A = the Hooke limit; B = yield point; C = fracture point.

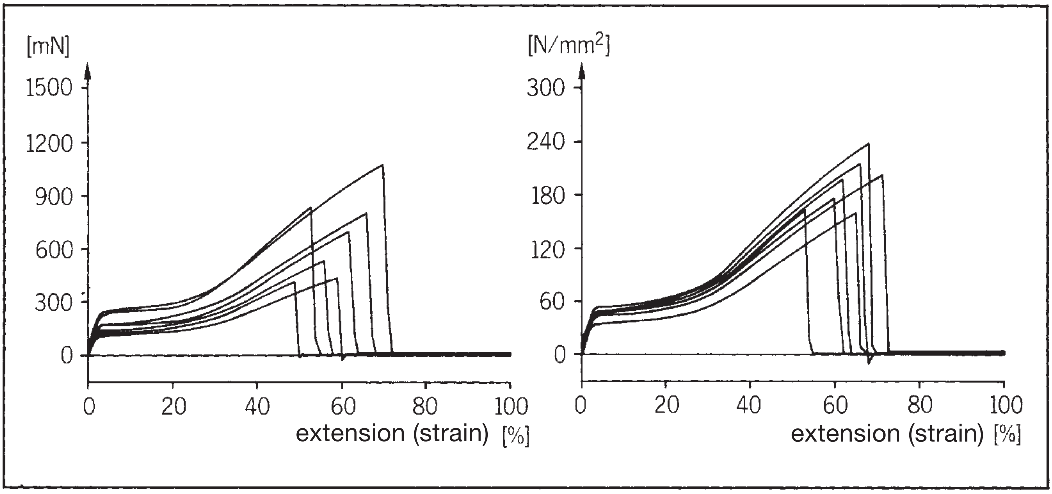

Fig. 2: Stress-strain curves. Left = tensile force; right = tensile stress.

- a "post-plastic range" characterized by a relatively sharp increase in force up to the fibre tearing point.

All three ranges are used to establish the material characteristics more precisely (Fig. 2). Hooke's law (Fig. 3) provides the elasticity module, the index values are found in the plastic range, in particular the 15% value, and the final and most important parameter constitutes the tearing point. In addition, the point of change between the plastic and post-plastic range, the gradient of the post-plastic range and the area under the different curves are all stated. These areas show the working potential of the material. For this reason, stress-strain curves provide more information than the analysis of tension and elongation.

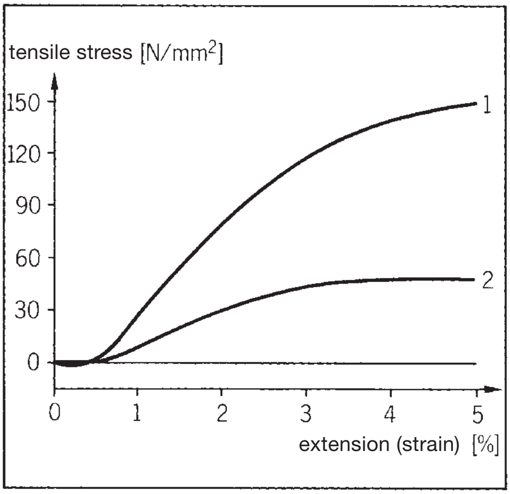

Fig. 3: The Hooke region of stress-strain curves as used to determine the elastic modulus (= Young's modulus). Curve 1 = dry hair; curve 2 = wet hair.

The stress-strain curves can be used to determine the elastic modulus. Fig. 3 shows the curves in Hooke´s law for wet and dry hair. The E-modulus are as follows:

- dry hair (60% relative air humidity): 5744 ± 469 N/mm^2
- wet hair: 2156 ± 228 N/mm^2.

(according to Busch and Schumann).

Stretch General term for elastic textiles made from stretch yarn or stretch fabric, for instance. Slimline clothes are frequently fashionable, which means that stretch garments are popular in the ladies' outerwear fashion sector. Polyurethane elastomer fibres have a better chemical resistance, a higher level of elongation and better recovery properties than rubber thread, which was commonly used in the past. For this reason polyurethane elastomer fibres have almost totally replaced rubber thread in the manufacture of particularly elastic textiles such as corsetry, support stockings and elastic tapes. They provide a new potential for swimming costumes, sport and leisure clothing, and also for the fashionable outerwear sector, because of their fineness and better textile characteristics. Elastomer fibres are primarily used as thread with other fibres wound or spun around them, e.g. in corsetry and warp-knits in general, but they can also be used in their pure form, e.g. in → Stretch cord or other stretch fabrics. The type of finish is usually dependent on the intended final use of the garment and the properties of the additional fibre used. The heat sensitivity of elastomer fibres means that the choice of finishing processes and chemicals is extremely limited. The main objectives in finishing are to produce optical elasticity, a pleasant, soft fabric handle, and sufficient dimensional stability.

Softeners that have particular lubricating properties contribute towards stretch and recovery characteristics, as well as sewability. This type of softener is particularly important for knitgoods. Effects are permanent; a high level of softness is also achieved. Non-silicone softeners that produce a soft, smooth handle should be selected in order to achieve an optimum compromise between a soft handle and lubricating effects in fabrics containing elastomer threads. The reason for this is that an excessive level of fibre smoothness can lead to slipping and also cause the polyurethane thread, which is usually not dyed, to protrude from the fibre compound. Further finishing objectives are for instance creating fullness and stiffness in corsetry, preventing cut edges from curling inwards when making up garments out of raschel fabric, and also water-proofing swimwear to speed up the drying process.

Stretch cord Collective term for different qualities of elastic cord. Depending on elasticity they are ideally woollen or cotton and textured polyamide, in addition the warp contains 2–6% elastic thread covered with textured polyamide. Example: Warp – approx. 85% textured polyamide and 15% elastomer yarn (elasticity 15–30 % depending on quality); overall composition: 80 % cotton, 16–17% polyamide, 3–4% polyurethane (elastomer fibre). Stretch cord articles need to be arranged with as little tension as possible in the warp. Pad-steam processes are a suitable and efficient dyeing option. Sulphur and naphthol dyes should ideally be used.

Stretch fabrics (elastic fabrics), elastic textiles with comfortable wearing properties (retain shape and are crease-resistant), elasticated either lengthways/ warp (ideally) and/or crosswise/weft. The yarns used for this are highly-elasticated synthetic textured yarns, elastomer and rubber thread wrapped with yarn, or core-spun yarns, frequently in the form of synthetic mix yarns, with/without natural or synthetic fibres, and also specialist wool and cotton yarns (e.g. with → Slack mercerization), etc. They can be divided into two categories:

1. Power stretch: high level of elasticity, with body-shaping properties, for corsetry, swimwear, surgical stockings.
2. Comfort stretch: lower elasticity, yield on stretching, no body-shaping properties but mould to fit the body, used in ladies' hosiery, underwear, sportswear and outerwear.

Average elongation (according to DuPont) includes reversible stretch (R%) and max. irreversible stretch (I%):

outerwear:	R = 15–25%; I = 2%.
sport-style outerwear:	R = 20–35%; I = 5%.
form-fit garments:	R = 30–40%; I = 5%.
active sportswear:	R = 35–50%; I = 6%.

Stretching and drying machines For fabric in runs:

a) for stretching without a drier → Straightening machine;
b) for stretching and drying treatment with a drier as a simple stretching and drying machine, double stretching and drying machine, multi-storey stretching and drying machine. → Stenters.

Types of stretching and drying machine:

conveyor drier,
air-stream drier,
felt calender,
stenter drier,
loop drier,
hot flue,
channel/cabinet drier,
sieve-drum drier,
drying loft,
other drier types,
stretch-drying machine,
radiation drier,
heat setting machine,
cylinder drier.

Stretching frames for screen making To ensure that screen is taut (see Fig.), the following stretch guidelines apply: Silk 2% (only when wet), polyester 3%, polyamide 5% (more practical when wet). Stretch dimensions should always be checked.

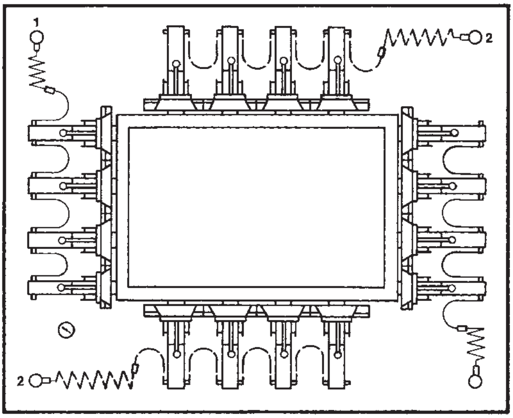

Fig.: Stretching frame for screen making.

Stretching frame systems: pneumatic with an air circulation system that supplies an equal air pressure to individual chambers simultaneously (ensures that each chamber will tension evenly). The clip carriages, which run on ball bearings, adapt automatically even at high pressure by matching the fabric stretch laterally (= necessary tension balancing). The warp and weft can also be tensioned separately. The stretching frame incorporates a manometer, so that a toothed rod on each side of the machine can be used to ensure precise mechanical tension monitoring/ overload. Tensioning clips run on ball bearings, and they adapt automatically by matching the fabric stretch laterally. The tension level can be monitored, either by recording the percentage fabric stretch using a metre stick, or by means of mechanical or electronic sag measurement. The important factor is the tensioning force applied (rather than the linear stretch as a percentage). Example: in a pneumatic stretching frame the linear density of polyester with an expansion value of 2.9 bar is tensioned; this is equivalent to exactly 10.1 N/cm warp and 10.1 N/cm weft, measured using electronic sag determination. This means that complete tensioning equilibrium is achieved. If the percentage stretch is now measured, the result will be + 2% for warp and +1.2% for weft. If this process had been done in reverse, i.e. if both warp and weft had been stretched by 2%, the weft would have had much higher N values than the warp, meaning that no equilibrium had been reached. This means that the weft yarn would have been overstretched. If this happens, the fabric recovery properties are reduced, i.e. the fabric tension achieved is relatively rapidly affected by fatigue. Measurement procedures for fabric tension/stretch:

1. linear extension and recorded stretch in %.
2. fabric tensioning forces/recording in bar.
3. electronic measurement of fabric sag in N/cm.
4. mechanical measurement of fabric sag.
5. mechanical measurement of fabric sag based on a specific weight.

Stretch principle When fabric is being dried on a stenter, its width is regulated, during which varying stretch levels can occur from the edge area to the centre of the fabric. These discrepancies have a negative effect on the fabric quality, and cause problems during subsequent processing. This discovery led to the development of a machine that ensures even stretching independently of the width before stenter drying. The fabric adheres to the roller surface, where it is stretched by the penetration of each of the two comb rollers (Fig. 1, 2b = stretched), and after it has been orientated in this way it

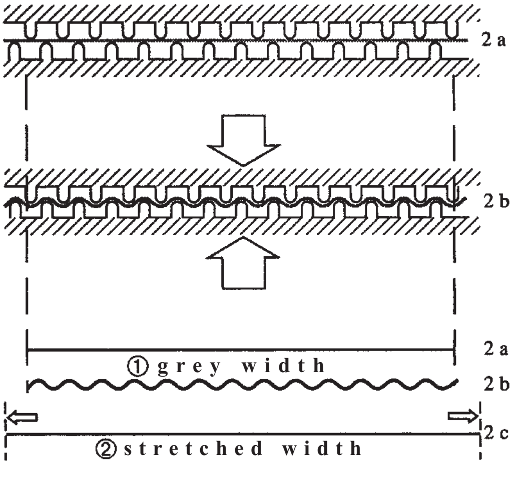

Fig. 1: Memotex process stretch principle. The woven fabric runs in between two profiled rollers (Küsters).

field of application	Memotex operation process activation in the finishing stages	Memotex process product quality optimisation
pretreatment: Memotex fibre and woven fabric orientation	– reorientation of fabric and fibres – affecting woven fabric properties	– evening out fabric tension by averaging weaving tension, with consequently better fabric run on subsequent machines – higher tear strength and therefore use of more cost-effective weft yarns (e.g. OE instead of ring yarns) – tenacity improvement – tear strength improvement – stabilising elongation, particularly with woven cotton/PES fabrics – levelling warp and weft contraction – softer, smoother handle – print quality dimensional stability
pretreatment with bleaching stage	– intensifying the bleaching process by better liquor penetration	– increasing absorbency – more uniform bleach appearance
mercerisation	– intensification of lye uptake – feeding of a narrower grey fabric width	– improving the mercerising effect by opening out the woven fabric – achieving a wider final width stable to shrinkage, i.e. better dimensional stability
chemical finishing	– more efficient chemical finishing – reduced chemical use with identical residual shrinkage – less mechanical loading of the stenter entry section	– uniform setting of the required fabric width with uniform fabric density before final chemical finishing by stretching with the Memotex machine

Tab.: Possible fields of application for a woven fabric stretching machine in the pretreatment and chemical finishing of cotton.

is passed over spreading devices and unrolled to the new width (2c = stretch width). This principle of numerous small stretch areas results in the required even stretching across the entire fabric width. A machine of this type is shown in Figs. 2 and 3.

The Tab. shows possible areas of application for cotton fabric stretching.

The realization that the fabric run has been given stretch properties as a result of a swelling process is essential if a lasting effect is to be achieved. The macroscopic orientation (paralleling) of the cotton fibres alone or in combination with synthetic fibres is almost completely set by the swelling process. Knitgoods also take up warp tension during the manufacturing process (Fig. 4), which can be compensated by overstretching of the weft. To do this, the tube of knitted fabric is stretched when wet using deflecting bars with an adjustable width (Fig. 5).

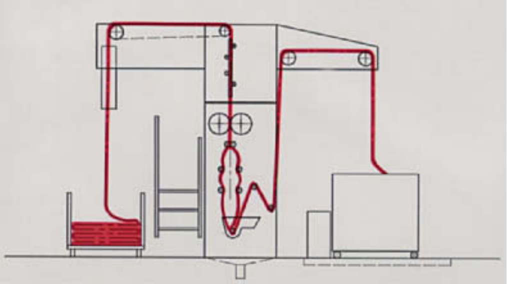

Fig. 5: A Santastretch machine for handling knitgoods tubes (Santex).

Stretch-spun fibres Synthetic threads that have been stretched during wet spinning to increase their strength and fineness, e.g. cupro filaments and high-strength viscose fibres.

Stretch yarns Yarns with exceptional elasticity, e.g. →: Textured yarns; Core-spun yarns.

Stretch yarns, dyeing Usually in the form of tubeless cross-wound yarn packages (muff) on pack system dyeing machines with a cylindrical yarn carrier in the pack dyeing system (brick-type) or a packing system onto dye tubes.

Strike Term referring to the speed of dye uptake on the substrate (→ Half-dyeing, time of). First strike is the ending, which depends on substantivity, in padder dyeing.

Strike migration test (exhaust level test), → Levelling property test. Phased dyeing in constantly boiling dye liquor to analyse absorption speed and levelling properties of dyes, as a specific type and also in combination (retarding, blocking), possibly with and without levelling agents. Method: the dye liquor is charged with dyes and additives and brought to boiling point. Then 40% of the fabric is added, with a further 10% being added after 2, 4, 8, 16, 32 and 64 min, and boiled for a further 60 min. After rinsing and drying, the levelling of each fabric sample added at different times is analysed (colour depth, shade, levelness). Variation: add 50% of the fabric to the boiling liquor, add a further 10% after 2, 4, 8, 16 and 32 min, boil for a further 30 min.

Strike-off (knocking-over), term originating from old-style hand or block printing. Colour is applied to the print block in the colour trough, and the print is then positioned on the fabric. The print is strengthened by hitting the block with a small hammer, which transfers the dye onto the fabric. Nowadays the term strike-off is used to mean the printing of a repeat run.

Strike-off machine, Impressioning machine → Roller strike-off machine.

Strike-through A phenomenon that occurs during the setting of interlinings, where parts of the bonding substance appear through the lining material.

Striking off → Strike-off.

Stripe coating In addition to the one-colour coating method for self-shaded tarpaulins (Fig.), this is another method of coating runs of awning fabrics, which is suitable for multi-colour finishes. The top coat is applied using print pastes of different colours in stripes. It is possible to vary the width of the stripes (at least 9 cm in width).

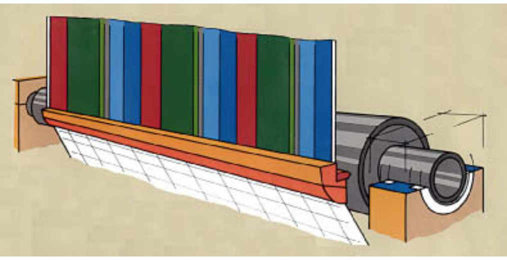

Fig.: The Zimmer Magnoroll '92 for stripe coating.

Stripiness (stripy dyeing), term for a stripy finish in dyed knitgoods, which is equivalent to warp or weft striping in wovens. It is caused by differences in yarn quality.

Stripping agent (decolourizing agent), a product for → Stripping of dyeings and prints. Reduction bleaching agents on a sodium dithionite basis are usually used.

Stripping auxiliary is used to aid the → Stripping of dyeings and printing. Has the task of supporting the brightening effect in the stripping reduction process by restricting the re-uptake of reduced, dissolved dyes. Sometimes also combined with → Fibre protective agents, principally in wool. The addition of anthraquinone might be recommended in the stripping of naphthol, vat dyes, etc.

Stripping of cationic preparations Alkaline treatment (ammonia or sodium carbonate) with 2–3 g/l of complexing agent, non-ionic wash-active substance (WAS) and anionic WAS is often successful: start cold, heat to 80–90°C within 30 min, treat for 30 min, then rinse well. Acid treatment such as in → Stripping of resin finishes is more effective. The same also applies to cationic softeners and cationic aftertreatments.

Stripping of dyeings Partial or complete stripping is used to brighten or level dyeings which turn out uneven or for re- and/or new dyeings into other, in particular, brighter or faster shades of colour. This is, however, often only possible with difficulty and incompletely, in particular for dyeings on man-made, acetate and viscose fibres. The stripping is carried out, depending on the fastness of the dyeing and stripping effect required, using processes which remove the dye again (hot soap solution, blank vat) or which destroy the dye, in which, depending on fibre type and dye class, reducing (sodium dithionite, sodium formaldehyde sulphoxylate or zinc formaldehyde sulphoxylate) or oxidising (sodium hypochlorite, sodium chlorite or potassium permanganate) agents are used. The correct setting of the pH is important to avoid fibre damage. Protein degradation products should be added for fibre protection in wool and silk. An addition of sequestering agents improves the stripping effect in metal-complex dyes. The stripping of dyeings is also possible in organic solvents. Disperse dyes in particular can be stripped easily in trichloroethylene. Tetrachloroethane is less effective.

Stripping of resin finishes for redyeing Intermicellar stored synthetic resins and/or crosslinkings of cellulose can usually only be removed with difficulty, or not at all. With fresh finishings, successes may be achieved through treatment with 4–6 ml/l of hydrochloric acid and 2–4 g/l of non-ionic washing agents at 50–60°C within 30 min, then neutralise and rinse thoroughly. At 95°C, formic acid, instead of hydrochloric acid, may also be sufficient. After removing resin, possible additional light → Stripping of dyeing.

Stripping of silk,

I. → Degumming.

II. Removal (complete or partial) of the dyes applied to the silk. The stripping process is selected in accordance with the dye used, for which the high sensitivity of the silk should be considered in particular.

Strip-Tester American device for → Shrinkage testing.

Stroboscope (oscilloscope), optical device (with tachometer) to observe fast running machine parts in operation (gearing, electric motors e.g. during spinning, winding, weaving) up to 120 000 rpm, in which motion appear stationary to the observer and/or reduced to 1% of actual speed. Device for discovering irregularities. The stroboscope also facilitates the examination of printing speeds through illumination with a regularly visible flash of light. If the frequency of the flashlight and process correspond, the illuminated article, e.g. the printed material running in the printing machine, appears to be stationary, as every flash illuminates the same printed motifs.

Strontium Sr, atomic weight 87.6, compounds of those similar to → Calcium. Properties: → Alkaline earth metals.

Structural formula In contrast to the → Configurational formula, the two-dimensional representation of the arrangement of atoms in molecules.

Structural models for man-made fibres As diagrammatically represented in Fig. 1, the various synthetic fibres can be explained with regard to the orientation of the macromolecules and their crystallinity using different structural models. In most thermoplastic polymers the groups of macromolecules can be freely rotated around their bonding axes, from which flexibility of the molecular chains results. If these fi-

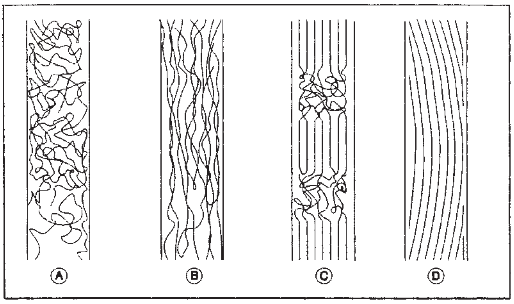

Fig. 1: Diagram showing the possible arrangements of chain molecules in the fibrils within man-made fibres as proposed by Rossbach.
A = non-orientated non-crystalline fibre polymer;
B = orientated non-crystalline fibre polymer; C = orientated partially crystalline fibre polymer; D = orientated highly crystalline fibre polymer.

bres are produced in the melt-spinning process at low spinning speeds without aftertreatment steps (drawing/heat setting), an extensively amorphous fibre polymer with completely disoriented polymer chains is obtained (Fig. 1, A). High spinning speeds and an additional drawing of the fibres firstly disentangle the polymer chains and orientate the macromolecules in the direction of the longitudinal axis of the fibre. In addition, crystalline zones are formed in the fibre, in which the extent of the crystallite formation depends on the degree of drawing (Fig. 1, C). The supramolecular atomic states in such partially crystalline polymers are characterised by the alternate arrangement of disordered and crystalline regions (→ Supramolecular structure of polymers).

The characteristic dimensions of such atomic states are in the magnitude of 3–50 nm. Certain polymers, such as poly-(m-phenyls-n-2.2-to[4-(3.4-dicarboxyphenoxy)]-phenylpropanimide) (PEI) amongst others, do not show any crystallisation power however, so that oriented, non-crystalline fine structures appear in these materials in a stretched state (Fig. 1, B). High crystalline fibre structures are chiefly produced in fibre types, in which no free rotatability of the atoms around the bonding axis is possible due to steric inhibition. This results in rigid rod-like macromolecules, which can be oriented to a stretched chain configuration in a paracrystalline order (Fig. 1, D). Typical examples are poly-p-phenyls-terephthalamide (an → Aramide fibre) and liquid crystalline polyesters. The liquid crystalline properties, which appear in these materials in solution or in melting are important in this context.

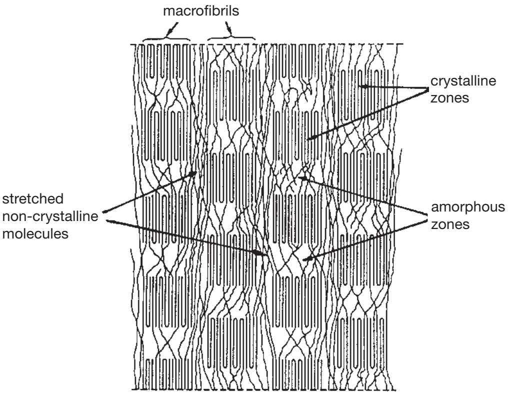

Fig. 2: The structural model of polyester fibres proposed by Prevorsec.

The individual fibrils from Fig. 1 are arranged in a three phase model in the structural model from Prevorsec (Fig. 2), consisting of unordered, amorphous zones, crystalline zones with excess chain folding and semi-crystalline interfibrillar gaps. This structural model in the main gives a good explanation of the dyeing behaviour of heat set polyester.

Structural viscosity In isothermal and reversible conditions, a reduction (without hystereses) of the apparent → Viscosity by ultimate mechanical shearing strain.

Structural viscosity behaviour Pseudoplastic behaviour, → Rheological behaviour of solutions.

Structure of textile materials Textile products, chiefly composites, have a typical structural arrangement, knowledge of which is important for the textile finisher in order to co-ordinate the finishing process of individual components on the overall concept. Floorcoverings (Fig. 1) and chiefly tyres (Fig. 2) represent complex composites in their structure.

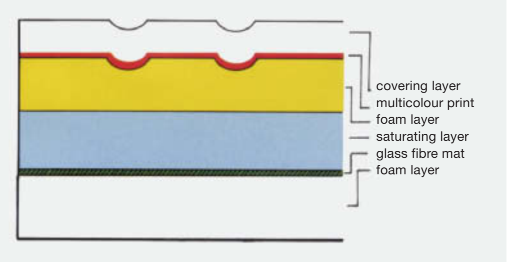

Fig. 1: Heavyweight floor covering structure.

Structure tester Measuring instrument for flat textiles, which determines the relation of fibre content to gaps using a simple throughflow measurement (air). The device reproduces a structural conductance, with which, together with fabric weight and fabric thickness, the stationary state of a fabric can be determined numerically.

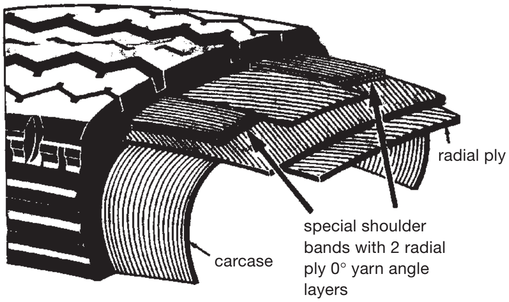

Fig. 2: Radial-ply tyre structure.

Stud roller breaking machine → Mechanical breaking.

Stuffer-box crimping → Crimp, types of.

Stuffer channel (compression channel). Is used for compressing the piece goods together in a longitudinal direction when milling on a rotary milling machine for rope treatment (Fig. 1) or in open-width washing machines (Fig. 2) to relax the fabric.

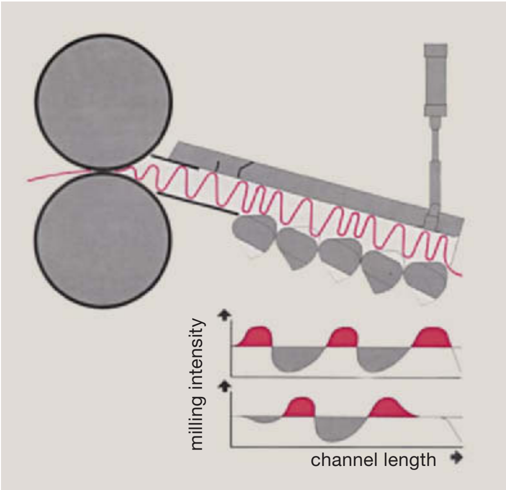

Fig. 1: Diagram of a stuffer channel in milling (Hemmer).

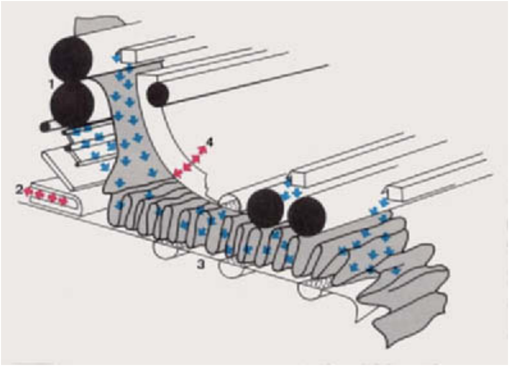

Fig. 2: The stuffer channel of an open width washing machine (Hemmer).
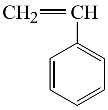
1 = squeeze roller pair which feeds the goods into the stuffer channel; 2 = hammer for stuffing the folds of goods;
3 = spray nozzle beam in the stuffer channel; 4 = moveable top plate for reducing the size of the stuffer channel.

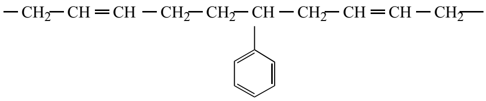
The channel floor of a stuffer channel in a milling machine may consist of milling media, which create compression and relaxation zones through an up and down oscillation motion. Its special shape and its work rhythm cause short, but intensive compressions and relaxation of fabric forms. Fig. 1 shows both final working positions of a milling channel and the corresponding compression and decompression curves, measured on the textile. The comparatively gentle increase in the pressure curve and the sudden relaxation is of particular importance. The elasticity of the fabric package is considerably increased and also its elastic recovery capability.

The even and slow increase in the pressure curve and the following steep fall show the typical behaviour of the elastic recovery in textiles containing wool. The relaxation phase, clearly flatter and longer timewise, increases the after-absorbency for liquor by opening the entire yarn and fibre lattice. The number of pressure and relaxation cycles, to which the textile is subjected in the channel, can be adapted to the desired effect by pre-selecting the working speed of the milling media. Shorter milling times are the result. The pressure and relaxation cycles during washing are expressed in a higher washing performance through the intensive, thorough kneading of the fabric.

Styrene (vinylbenzene, phenylethylene), colourless, unsaturated liquid. Technically important starting material for → Polystyrene and numerous polymer blends (especially with acrylic acid esters and/or butadiene) for coatings, chemical finishings and similar.



Styrene-butadiene rubber From a copolymer of →: Butadiene consisting of styrene; Man-made rubber.



Distinctions are made between polymerisation root and reaction temperature in these polymer blends: warm polymers and/or hot latex (at 50–80°C). Properties: shore hardness 40–90; fabric-like strength, good; abrasion resistance, good to excellent; resistance to acids, average to good; to solvents, poor (aliphatic/aromatic hydrocarbons); to oxidation, average; to ozone, solar ageing and flammability, poorer. Chiefly used for vehicle tyres.

Subcutaneous (Lat.), located under the skin (→: Cutis; Cuticle).

Subdivision of process technique in textile finishing Can be carried out in accordance with different standpoints, e.g. in accordance with type of fibre to be treated, article-specific or in accordance with the processing machines. Following a suggestion from Rüttiger, a vertical subdivision can be carried out: all processes in the basic physical operations (unit operations) and basic chemical operations (unit processes) are triggered and described by so-called primary functions. The horizontal subdivision is carried out article-specifically at the finishing processes. The processes are naturally described by very complex total functions. The advantage of the horizontal subdivision lies in the clear process description; it is, however, applied very broadly due to the variety of articles needed in textile finishing. The advantage of the vertical subdivision lies in the abstraction of coincidental process conditions to generally applicable functional correlations.

Vertical subdivision of process engineering in textile finishing:

1. Finishing areas: completed areas in the textile finishing industry, e.g. pretreatment, dyeing, printing, finishing, coating. They are characterised by type and sequence of processes to be carried out.
2. Finishing processes: extensive treatments of textiles (preparation, material conversion, processing of reaction products), according to which the textile has a particular finishing effect, e.g. alkaline scouring, peroxide bleaching, pigment dyeing, beam dyeing, thermosol dyeing.
3. Finishing steps (treatments): separate treatments of a textile, which usually run in a finishing machine or are characterised by a particular recipe formulation, e.g. padding, drying, rinsing, steaming, cold dwelling, hot dwelling under tension, hot dwelling on skeins. Represented in schematic flow diagrams by material, energy and flow.
4. Process elements (smallest indivisible functions of processes): parts of a treatment in which only an individual function or a group of positively coupled functions operate, e.g. immersing, squeezing off, controlling fabric mechanically, inking, maintaining temperature.
5. Basic functions in finishing: always recurring individual functions in the various finishing processes, e.g. heat exchange, mass transfer, stretching, wetting, swelling, shrinking. Can be described using basic general scientific and technical laws.
6. Areas of help for finishing processes: measuring and test technology (including intelligent sensors), finishing machines, automation, estimates, optimisation, systems engineering.

Sublimate Product of → Sublimation.

Sublimation,

I. (Lat.: sublimis = fine in the sense of “refining”), conversion of substance from the solid state into the vapour and/or gaseous state and vice versa without → Melting beforehand. Important behaviour of disperse dyes.

II. Sublimation of a dye printed onto a textile substrate is understood as more or less strong change in shade of colour, which can usually be put down to reductive influences of the vapour itself or even of contents of the substrate, e.g. of hemicellulose, during the steaming process or exposure to steam for too long.

Sublimation fastness during storage Resistance to dye migration (sublimation) during storage. For the test (→ Sublimation transport mechanics) the sample is laid between two metal plates with adjacent fabrics and loaded. The test specimen is treated at 120°C in the heating cabinet. The change in colour and the staining are assessed using the grey scales.

Sublimation fastness test → Sublimation transport mechanics.

Sublimation fastness tester Developed by Hoechst AG for determining the dry heat setting fastness and the temperature at the start of the sublimation. Using heating on both sides of the test specimen and 8 pairs of hot plates, between which the test specimen is laid. The weight loading can be adjusted and the temperature for each hot plate pair can be selected between room temperature and 300°C. A control device monitors and controls the temperature accurately. – Manuf.: Klaus Fischer, Bad Salzuflen, Germany.

Sublimation fastness to heat treatment Some disperse dyes (chiefly on polyester) have the capacity to enter the gaseous state directly from the solid under the effect of heat. These are thereby coloured or discoloured in blends with other fibres. On the other hand, in the heat setting of dyed polyester/cotton blend fabric it can be observed that the colouring of cotton by disperse dye under the effect of heat more or less disappears (→ Dry heat setting fastness). The temperature has a greater influence on the sublimation than the period of heating.

The evaporation and sublimation of disperse dyes play an important role during production (dyeing/finishing) and in garment manufacture. They can be described as process-determined parameters in thermosol dyeings, while they are basic prerequisites for implementing transfer printing successfully. In testing the factors which influence the sublimation of disperse dyes, it has been shown that the determination of the dry heat setting or sublimation fastness (really simple in itself) is more complex than expected.

Basis for implementing the sublimation tests (→ Sublimation transport mechanics): a sample of the dyed material is heated together with undyed adjacent fabrics by close contact with a medium, which is set at a particular temperature. The change in colour of the sample as well as the staining of the adjacent fabric are assessed using grey scales. But colorimetry can also be called upon for precise assessment. Sublimation curves, which show the course of the temperature dependent sublimation, can be obtained in this way. A disadvantage of these curves lies in the fact that the colorimetric assessment of the depth of shade deviates from the visual rating, as the human eye judges the depth of shade differently depending on the colour range. Besides the colorimetric assessment, there is the possibility of extracting the sublimated dye using dimethyl formamide and subsequent determination of the sublimated dye quantity using the colorimeter (according to Somm).

Sublimation ghosting → Ghosting in transfer printing.

Sublimation in thermosol treatment In thermosol treatment, the disperse dye is distributed differently in the fibre depending on process conditions.

Case 1 (Fig. 1): this case corresponds to a thermosol treatment on a contact fixation unit. Sequence of operations: a) setting (30 s on ironing press) using polyester adjacent fabric on both sides at 180–230°C; b) determination of the sublimated dye. Extraction using dimethyl formamide and colorimetric determination. Control type: dried dyeing. During the sublimation test, sorption, diffusion in the fibre as well as evaporation/sublimation run in parallel.

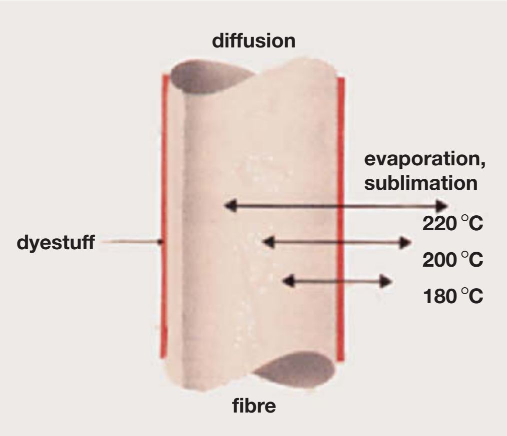


Fig. 1: Model case 1: after drying, the dye is found on the fibre (according to Somm).

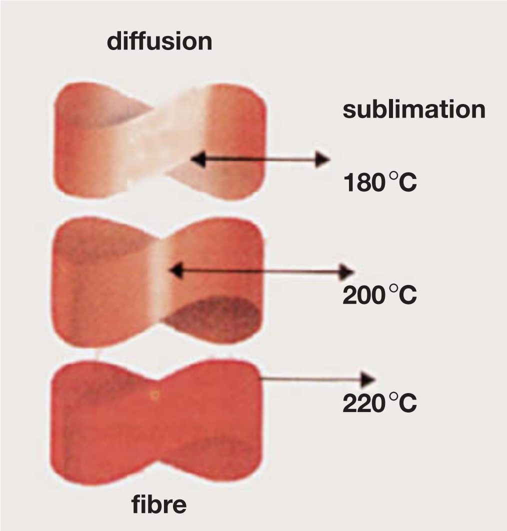

Fig. 2: Model case 2: the dye is found as ring dyeing in the fibre in accordance with the thermosolling temperature employed (according to Somm).

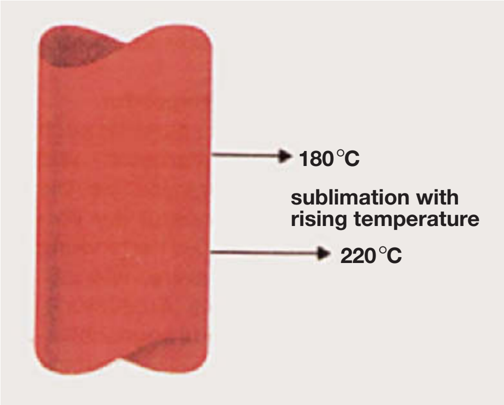

Fig. 3: Model case 3: the dye is optimally fixated in the fibre (according to Somm).

Case 2 (Fig. 2): this shows the sublimation behaviour of ring dyeings. Sequence of operations: a) setting (30 s on ironing press) without adjacent fabric, 180°C; b) reductive intermediate reduction clear; c) aftersetting (30 s on ironing press), using polyester adjacent fabric on both sides, 180–230°C; d) determination of the sublimated dye (as in case 1). In the area of ring dyeing, besides the sublimation a diffusion into the fibre core also leads to an even dye distribution. A practically ideal distribution is achieved at 220°C.

Case 3 (Fig. 3): sequence of operations: a) setting of the dyeing (215°C, 60 s on Benz dryer); b) reductive intermediate reduction clear; c) sublimation tests (30 s on ironing press), using polyester adjacent fabric on both sides, 180–230°C; d) determination of the sublimated dye (as in case 1). This case shows the ideal dye distribution and with it the actual sublimation fastness of a dye with increasing temperature.

Sublimation transport mechanics In normal sublimation fastness tests (SE-Test) an intimate sandwich is formed from a polyester sample dyed using disperse dye and a similar undyed sample. The package is heated. In the dyed fabric and in the dyed tape respectively of thickness d is the initial dye concentration c (g/m^3). A part of the dye (characterised by the hatched surface in Fig. 1) migrates into the originally undyed fabric and/or the tape during the test.

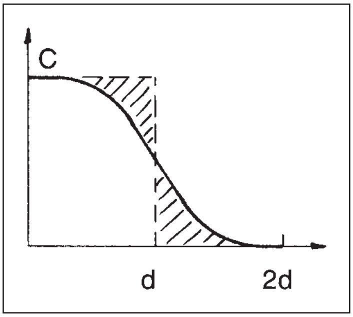

Fig. 1: Dye distribution in the sublimation fastness test (according to Gerber).

The percentage migrated is given, using the formula

$$S\,(\%) = 100 \cdot A \cdot \rho \cdot \sqrt{\frac{D \cdot t}{\pi}}$$

S = migrated dye (%);
A = contact surface (cm^2/g);
ρ = density (g/cm^3);
D = diffusion coefficient (cm^2/s);
t = contact period (s).

and corresponds to the transport mechanics by sublimation. This formula forms the theoretical background to the experimental findings, for which the percentage dye quantity migrated S increases in proportion to the square root of the experiment period t. The proportionality constant and/or the gradient of the S-R(t) lines is therefore:

$$\frac{d\,S}{d \cdot \sqrt{t}} = 100 \cdot A \cdot \rho \sqrt{\frac{D}{\pi}}$$

For its part the gradient is consequently proportional to the root of the diffusion coefficients. The mass transfer is carried out through diffusion in the polymer.

The SE-Test concerns a mass transfer in a porous body. This can be carried out both through diffusion in the polymer (direct contact of the fibres) and by diffusion in the gas phase within the pores or between the fibres. How strongly the two processes are proportionally involved in the mass transfer essentially depends on the vapour pressure of the dye in the pores and/or across the dyed fibres. Of course, the fabric structure and the pressure with which the fabric samples are pressed together also play a particular role.

The two transport processes can be distinguished in the following way in order to assess their relative importance. A stationary diffusion process is observed through a sintered glass filter (Fig. 2).

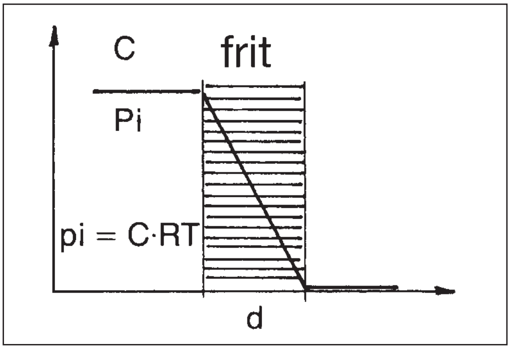

Fig. 2: Stationary diffusion through a frit (according to Gerber).

A dye solution in concentration C or a gas with partial pressure p_i is located on the left side of the sintered filter. If this is flushed with a solvent or gas on the right side so that the concentration of the diffusing components remains almost zero, a linear concentration gradient is set within the sintered filter. According to definition, the diffusion flow J (g/cm^{2}s) is proportional to the concentration gradient C/d and proportional to the diffusion coefficient D (cm^2/s).

$$J = D \cdot \frac{C}{d} \; [\text{g/cm}^2\text{s}]$$

If one then specifically assumes that the transport mechanics are carried out as gas in the pores of the sintered filter with porosity ε, the formula for the diffusion flow J_G is

$$J_G = \varepsilon \cdot D_G \cdot \frac{p_i}{RT \cdot d} \cdot \frac{M}{q} \; [\text{g/cm}^2\text{s}]$$

Sublimation transport mechanics

D_G is the diffusion coefficient of the diffusing gas in the pores and p_i/RT represents the concentration C in mole/cm^3. In order to express the diffusion flow in g/cm^2 as well, multiplication M (g/mole) is required. In order to give J_G in g/cm^2 s of the commercial dyestuff, a correction, using the diluting ratio q should be carried out as well.

If the diffusion flow J is regarded as gas diffusion

$$J = J_G$$

should thus be put. The expression:

$$D = \frac{\varepsilon}{RT} \cdot \frac{D_G \cdot p_i \cdot M}{C \cdot q} \quad [\mathrm{cm^2/s}]$$

thereby results for the macroscopically observable diffusion coefficient D.

This is consequently proportional to partial pressure p_i across the fibre, which contains the dye in concentration C (g/cm^3). It is naturally also dependent on how quickly the dye molecules diffuse in the gas and/or how large the diffusion coefficient D_G is. The gas theory makes the formulae available for the calculation of D_G. In order to determine the diffusion coefficient D, the equilibrium vapour pressures p_i should also be stated across the fibres dyed in the depth of shade C. Fig. 3 shows the apparatus used to determine p_i.

This apparatus is located in a thermostatically controlled bath. A flow of nitrogen is guided across the dyed polyester combed top, located in the tube. The equilibrium pressure p_i of the dye can be calculated from the dye quantity precipitated in the upper part. The saturation pressure p_s can also be determined according to the same process if the tube is loaded with a mixture of quarry sand and dye instead of with dyed fibres. The vapour pressure determination only succeeds however in low sublimation fast dyes. The p_i/C ratio is constant and can be replaced by the ratio of saturation value p_s/C_s. A few of the values calculated for the diffusion coefficient in the gas phase D_G and vapour pressures measured across dyed polyester fibres are compiled in the Tab.

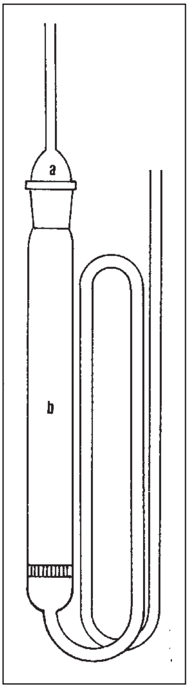

Fig. 3: Apparatus for measuring vapour pressure.
a = dyed polyester fibres;
b = undyed polyester fibres for absorbing the evaporated dye.

dye C. I. disperse	D_G [cm^2/s]	C [g/kg]	$p \cdot 10^{-3}$ [mbar]
yellow 23	0.11	68	18.66
orange 20	0.10	38	8.79
red 53	0.10	115	6.39
blue 56	0.12	62	0.93
violett 27	0.12	39	19.99
		20	11.99
		10	6.66

Tab.: The diffusion coefficients and vapour pressures of some less sublimation – fast dyes at 210 °C (according to Gerber).

The migration process may be regarded as a diffusion process in a porous body. The diffusion mathematics provided the 1st formula for the percentage dye quantity migrated. Only the expression derived for the diffusion coefficient can still be entered in this formula. If the ratio p_i/C is replaced by p_s/C_s , the following expression results for the sublimation fastness S_G (%):

$$S_G = \frac{100}{\sqrt{\pi}} \cdot A \cdot \rho \cdot \sqrt{\varepsilon} \cdot \sqrt{\frac{t}{R \cdot T}} \cdot \sqrt{\frac{D_G \cdot p_s \cdot M}{C_s \cdot q}}$$

S_G is the expression for the percentage of dye migrated across the gas phase. This expression produces the correlation between sublimation fastness and vapour pressure. Besides the dye vapour pressure p_s, a few other dye-specific parameters determine its sublimation fastness. When comparing two dyes with regard to their sublimation behaviour, not only is the vapour pressure p_s altered, but inevitably also the diffusion coefficient D_G, the molecular weight M, the saturation value C_s and the diluting ratio q. In addition to this, dye transport through the gas phase S_G, a migration through direct contact $S_{C,}$ can be considered. With a test period of 60 s this amounts to:

$$S_C = 2\,000 \cdot \sqrt{60} \cdot \sqrt{D_p}$$

The total dye transport observed in the experiment during the SE-Test is the sum of these two effects.

The sum of contact and gas phase transport calculated correlates amazingly well with the values S_{expr} determined in the experiment. The proportion S_C transferred by direct contact is also always crucial in sublimation non-fast dyes, against which the proportion S_G migrated across the gas phase can be ignored in sublimation-fast dyes. The activation energy of the migration process can be derived from the results of migration tests from the Arrhenius representation. The gradient of the Arrhenius lines is:

$$\frac{d \ln S}{d\, 1/T} = -\frac{E_A}{R}$$

whereby E_A represents the activation energy. If this concerns a sublimation-fast dye, which can practically only migrate through direct contact, the following applies:

$$S_C = 100 \cdot A \cdot \rho \cdot \sqrt{\frac{D_p \cdot t}{\pi}}$$

According to Arrhenius, the following applies for the temperature dependency of the diffusion coefficient D_p:

$$D_P = D^\circ \cdot \exp(-E_D/RT)$$

in which E_D represents the activation energy of the diffusion process. The relation

$$E_A = \frac{1}{2} E_D$$

can thereby be derived for the activation energy of the migration process E_A (in accordance with Gerber).

Sublistatic printing process → Transfer printing processes especially for several man-made fibres (in particular polyester, triacetate; less from polyamide and polyacrylonitrile). Printing on paper is carried out as a trichromatic pattern, for example, or even in customary fashionable designs and then transferred onto the fabric at temperatures of 200–210°C. Disperse dyes capable of sublimation are used as dyes, which are printed on paper as solvent-containing coloured inks by means of shallow photo-engraving rollers. The prints transferred onto the fabric from the paper are already set and do not need to be washed.

Submerged centrifuge Textile material is moistened in the basket of the → Sliding-oscillating centrifuge and then spun. It is used for soaking, impregnating, rinsing, acidifying and neutralizing. Net liquor is taken up and reused.

Submerged network test Testing of the network capacity of a surfactant on a standard cotton sample in the form of a round-cut dry substrate which is drawn under water hanging by a thread on a hook. The time that the sample requires to submerge to the bottom is measured. The network effect of various surfactants can be compared by ascertaining the particular concentration which is necessary to attain a 25 second network time. One can plot these values (log C_{25}) against the chain length abcissa of the surfactant and this yields straight lines in homologous rows. In the submerge network test, intersections in the surfactant molecule and greater chain lengths result in a reduction of the "C_{25}". However, a minimum concentration is always required for a certain network effect, irrespective of the structure of the surfactant.

Submerged path Length covered by piece goods in, for example, foulard and impregnation machine troughs in order to obtain adequate moisture.

Submerged spin process Used for dyeing continuous yarn and cross spools with reactive dye substances using the cold residual process. Cross spools are impregnated in a dye bath by a centrifuge. Commercial interest is limited to → Space dyeing.

Submerged test Testing method for water repellent impregnation of textiles (particularly yarn, activity products and knitted fabrics). Technique: weigh textile to be tested, submerge in sieve 10 cm under water for 5 minutes whilst agitating sieve to free trapped air, remove from water, allow to drip for approx. 10 minutes, weigh and ascertain water absorption.

Submerged thermosol process Follow-on process for (bleaching and) whitening synthetic fibres (also cotton mixtures): stretching process 2–5 min in hot fluorescent brightening liquor in the residence device (immersion accumulator), then squeeze out, dry and thermo fix. When fixing the fibre non-bound or diffused, whitener is thermosol fixed.

Submicroscopic fibre channels Identical with so-called intermicellar zones (→ Crystallites).

Substance (Lat.: substantia), synonym for material, "matter", constituent.

Substantive dyes → Direct dyes.

Substantivity Term originally derived from substantive dye (→ Direct dyes), which can be equated with (up)take of a dye or an auxiliary, i.e. with its ability to uptake from a liquid medium onto a textile substrate and to set. The dimension for the force with which the dye and/or the auxiliary is captured from the substrate is however, described as → Affinity. A dye must have affinity to a textile substrate so that it can show substantivity, i.e. can uptake and be set in the substrate; but it should conversely not be substantive inevitably in order to have an affinity to the substrate. Often used as a qualitative description of the affinity of a dye for a particular fibre. Substantivity is quantitatively the difference between the chemical potential of the dye in its standard state in the fibre and corresponding chemical potential in the dyebath. Affinity (μ) consists of enthalpy (H) and entropy (ΔS) in accordance with $\mu = H - T\Delta S$; if μ is negative, the reaction for temperature T runs voluntarily.

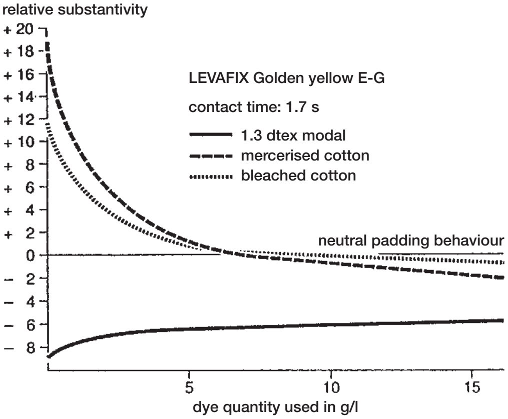

Fig. 1: Contact substantivity (%) in the squeeze nip (Bayer).

The substantivity in the nip is an important parameter in the cold-dwell process, as it causes the selective uptake of dye in the padding process and endings. Two fundamental substantivity effects can be distinguished in the pad process: positive substantivity and negative substantivity. The difference in the substantivity between cotton and regenerated cellulose is dye-specific. Dyes with higher substantivity on cotton basically result in a neutral substantivity ratio on cellulose regenerated fibres, while less substantive dyes are displaced into the negative range. Positive substantivity means that the dye concentration on the fabric is higher than in the padder liquor after the squeezing off process. Negative substantivity means that the fibre uptakes more water than dye from the padder liquor. The ratio of liquor and dye in the squeezed off liquor is constant if the substantivity is neutral. Besides the dye type, the availability of positive and negative substantivity also depends on the depth of shade, i.e. the dye concentration of the padder liquor (Fig. 1).

The negative substantivity which can be observed on viscose in certain reactive dyes also indicates a high association of dye molecules in this range for low padder liquor concentrations. Graphs, which show the percentage increase in dye uptake of the fibre as a function of padder liquor concentration, are consequently obtained when determining the substantivity. In high molecular dyes, the affinity in small concentrations outweighs the normal preference of source water uptake. These types of dye are substantively positive in bright shades.

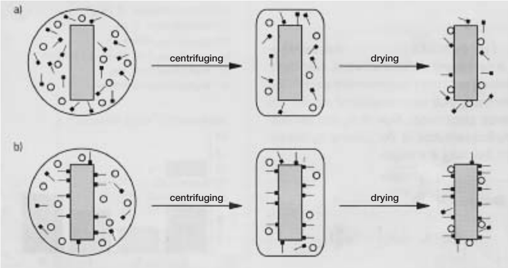

Fig. 2: Schematic diagram of the method of operation of a substance with no affinity for fibre (a) and one with affinity for fibre (b) (Henkel).

Even smaller molecular substances such as surfactants have substantivity. The action of a substance compatible with the fibre and a substance not compatible with the fibre is schematically shown in Fig. 2. No adsorption can be recognised in case a). It means that the solution constituents also remain evenly distributed when cotton samples are present in the solution. The substances compatible with the fibre are, however, adsorbed on the fibre surface (case b, filled out symbols). This results in an impoverishment of the solution of affine molecules, while the non-affine molecules (open circles) are also present in the original concentration and with the same distribution. The state after centrifuge hydro-extraction is also shown. The fibres are still surrounded by a liquid film. Both types of molecule are evenly distributed in case a). The molecules are in adsorbed and dissolved form in case b). The concentration of dissolved molecules is reduced corresponding to the adsorption. After drying, the dissolved molecules remain behind on the fibre. That is why values, which are different from zero, are also measured in case a) when determining activity, although no adsorption took place. The sum of the activities is determined from the adsorbed and non-adsorbed substance in case b).

Traditionally, the after-washing of dyeings was carried out using reactive dyes in accordance with exhaustion processes through repeated cold rinsing, scouring off and soaping and finally through hot and cold rinsing again. The reactive dye hydrolysates to be washed off, accumulate in the separate wash baths in different concentrations, but generally in a properly diluted form. The hydrolysates are very hard to eliminate in the biological wastewater treatment plant and may therefore stain the outlet channel. To remove the hydrolysates from the wastewater, they should be in concentrated form, which can only be achieved by changing the afterwash processes. Diffusion and substantivity have a large influence on the dyeing:

- The higher the substantivity, the more dye disappears and the higher the fixation yield is.
- The higher the diffusion, the quicker the equilibrium dye in the fibre/dye in the liquor will be adjusted and the quicker the dye reaches the reaction site.

A compromise has to be adopted for exhaust dyeings, as both dimensions depend on the temperature in opposite ways (Fig. 3). The diffusion speed is increased with increasing temperature and the substantivity decreases. A high substantivity and a high diffusion speed would

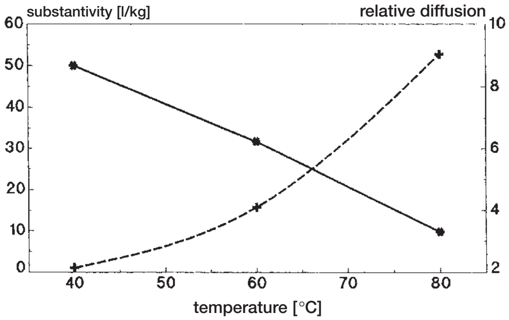

Fig. 3: Temperature dependency of substantivity and diffusion (Sigrist and Haelters).

be ideal for dyeing, but cannot be realised at the same time as a result of the opposite temperature dependency of both parameters. A high diffusion speed and a low substantivity is however required for the washing off of hydrolysates. These conditions can only be fulfilled for both parameters at higher temperatures.

Substantivity factors Auxiliaries in calculating the addition boosting of dyes in continuous dyeing to obtain end-to-end uniform dyeings.

Substituents → Substitution.

Substitute Substitute material with a similar effect to the original product no longer fit for use.

Substitution (Lat.: substituere = to replace), exchange of equivalent atoms and/or atom groups (radicals, alkyls). Example of inorganic substitution: $CuSO_4$ (copper sulphate) and H_2S (hydrogen sulphide) → CuS (copper sulphide) and H_2SO_4 (sulphuric acid). Example of organic substitution: (methane) CH_4 → $CC1_4$ (carbon tetrachloride). The exchanging atoms or atom groupings are called substituents. The product obtained is called a product of substitution.

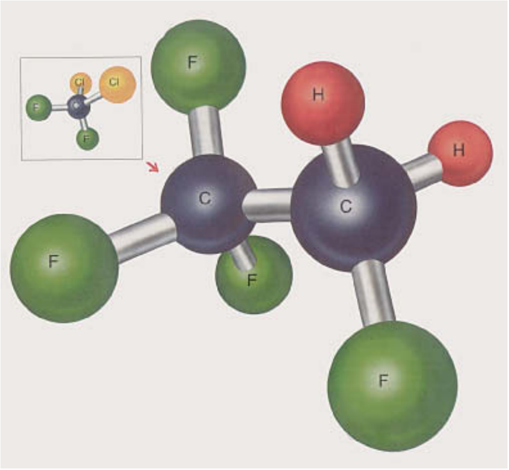

Fig. 1: The substitution of chlorine by hydrogen in a CFC compound. One fluorine is also substituted by a CF_3 group.

A chlorine and halogen substitution has taken place in Fig. 1. The new partially halogenised CFC compound is ecologically optimised and has the same technical properties as the fully halogenised CFC compound.

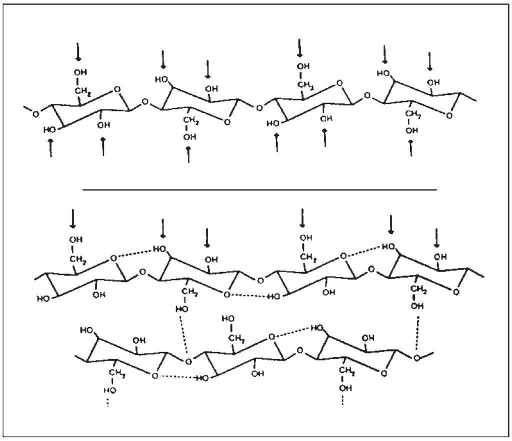

Fig. 2: The difference between the substitution of cellulose in dissolved form (above) and as cotton fibre, in which case only a part of the hydroxyl group can be substituted because the remainder participates in hydrogen bridges.

In the case of the chemical modification of cellulose, it is also called substitution in so far as the three hydroxyl groups in position C_3, C_2 and C_6 (Fig. 2) available from a chemical reaction can only be 100% converted into the diluted form of cellulose: the hydrogen of the hydroxyl groups is substituted, e.g. by an acetyl group, which results in cellulose triacetate.

Not all hydroxyl group hydrogens can be substituted in cotton cellulose because they are integrated into interchenar and intrachenar hydrogen bonds in the heterogeneous system. That is why the availability of cotton cellulose for substitution reactions is restricted.

Substitution, degree of Measurement for the complete substitution of all groups available for the substitution (100%) in a polymer module (monomer in the polymer). So when a polymer is substituted, i.e. converted, compared to the polymer (without breaking the main chain) to the available lateral chain, the degree of substitution is given in %. In cotton cellulose the degree of substitution statistically describes the conversions carried out across all the polymer chains of the three available hydroxyl groups in C_3, C_2 and C_6 position. So, a maximum degree of substitution of 3.0 can be achieved in the dissolved form of cellulose through substitution, which depends very largely on the reaction partner (see Tab.).

substituent	*DS*	*substituent*	*DS*
 $H_3C-CCl_2-C(=O)-$	*0.5*	 $H_3C-C(=O)-$	*2.4*
	*2.7*	 $H_3C-CH_2-C(=O)-$	*2.6*
	*2.8*	 $H_3C-(CH_2)_2-C(=O)-$	*2.7*
	*2.8*	 $H_3C-(CH_2)_4-C(=O)-$	*2.8*
 $HO-C(=O)-(CH_2)_2-C(=O)-$	*1.4*	 $H_3C-(CH_2)_5-C(=O)-$	*2.4*
	*0.35*	 $H_3C-(CH_2)_6-C(=O)-$	*2.2*

Tab.: The degree of substitution DS of cellulose dissolved in LiCl/dimethylacetic acid (according to various reactions).

Substrate (Lat.), basis, base, substance carrier; e.g. the fibre as a substrate for dyeing and/or dyestuff.

Subtilisine So-called extra-cellular, proteolytic enzymes (→ Proteases) made from cell walls of bacillus subtilis and amyloliquefaciens (bacillopeptidases). Have proteolytic and esterolytic activity. Hydrolytic activity qualified by an intermediary serinester involving a histidine residue and a complex network of hydrogen bonds. Temperature stability is particularly important technically (at approx. 60°C, optimum pH 10–11) under washing process conditions. Behaviour towards non-ionic surfactants relatively stable; clear activity losses in the presence of anionic surfactants or soaps.

Subtractive colour mixing → Colour mixtures.

Succinates Salts of → Succinic acid.

Succinnic acid (Lat.: acidum succinicum; therefore succinic salts: succinates), $(CH_2COOH)_2$. Large-scale technical extraction from λ-butyrolactone by oxidation with nitric acid. Is used as an initial base for dye syntheses, (ester) for malleability agents and resins. The most interesting are the sulphone succinic acid esters (sulphonated polycarboxylic acid esters and amides) for wetting and partly also washing agents.

Sucrose sebacic acid esters Sucrose mono sebacic acid esters are produced by converting 3 mole of sucrose and 1 mole of fatty acid esters (e.g. methyl stearate). The products are colour- and odourless with good detergency and emulsifying power and good biodegradability. The foaming power is lower than in → Alkylbenzene sulphonates. The products are resistant to hard water.

Suction-air drier → Drying systems.

Suction cooling In order to cool fabric or knitgoods after steaming, the fabric is passed through a cooling zone directly connected to the actual finishing operation. The cooling unit (see Fig.) consists of a circulating air fan, which blows air above the fabric guide through a nozzle system, which is drawn through the fabric by another nozzle unit below the fabric. A porous conveyor belt delivers the fabric to the plaiting down roller.

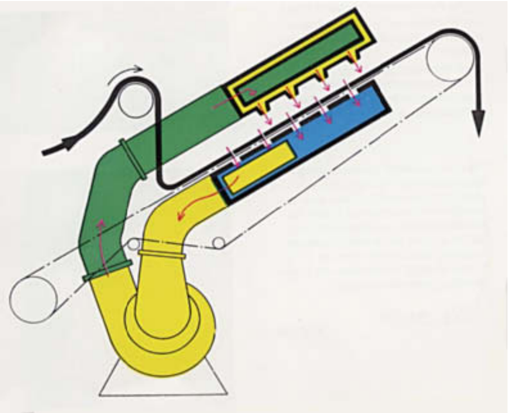

Fig.: Suction cooling at a rotary press-process (Kettling & Braun).

Suction damping of wool fabrics is used for the re-humidification by water vapour of wool and wool blend fabrics, which are completely drawn out, guided on perforated cylinders.

Suction-drum backwashing machine This works with the suction-drum system. Combed tops are washed off in the dyeing machine after being dyed and are given a subsequent softening treatment. They are also softened again before being pressed dry (in order to give them a shiny effect). Combed top washing machines are often suction-drum washing machines (Fig.).

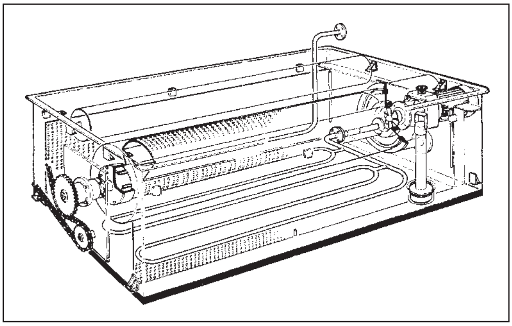

Fig.: Suction-drum backwashing machine from CMT.

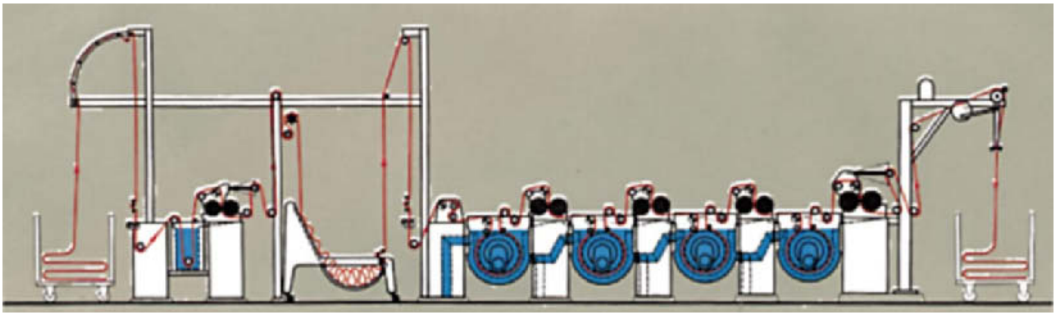

Fig.: Suction-drum washing machine (Babcock).

Suction-drum drier → Sieve-drum drier. Hot-air dryer for loose material, tow (fibre manufacturers), hank yarn, cloth and knitted fabrics. The material is sucked in through the perforated, rotating drum by airflow, soaked heavily and then dried. – Manuf.: Fleissner.

Suction-drum wash compartment This works according to the → Suction-drum washing machines principle. It is a double covered sieve drum; the interior is wide-meshed, the exterior is fine-meshed. The design of the suction-drum surface and the magnitude of the flow resistance through the holes in the drum and the screen fabric inhibit the flow of the liquor on the surfaces not covered with fabric.

Suction-drum washing machines Drum type washer with a pumped flow from the outside of the drum through the fabric and the drum covering in the interior, i.e a suction-drum with through suction. It is possible to feed through correctly fabric which has been overfed with a controlled driven drum, resulting in the tensionless transport of fabric through the drum (see Fig.).

Suction extraction system for shearing The suction (see Fig.) has 3 functions:

1. suction of the shearing dust from cutting devices and brushes.
2. straightening of the fibres suitable for shearing in the cutting device.
3. cooling of the shearing cylinder.

Suction extractor Also referred to as a suction slot device. The fabric passes across a suction slot with a slot width of a few mm. Air is drawn through the fabric by means of a vacuum pump. A suction roller, mach nozzle, Hikosaka roller, jet squeezer and OPI processes are similar suction extractors, with modified designs, for stretch fabrics.

Suction extractor for printing screens is used to remove surplus varnish during the manufacture of printing screens by dissolved solvents.

Suction of pumps Pumps work either with a suction lift or positive suction head (see Fig.).

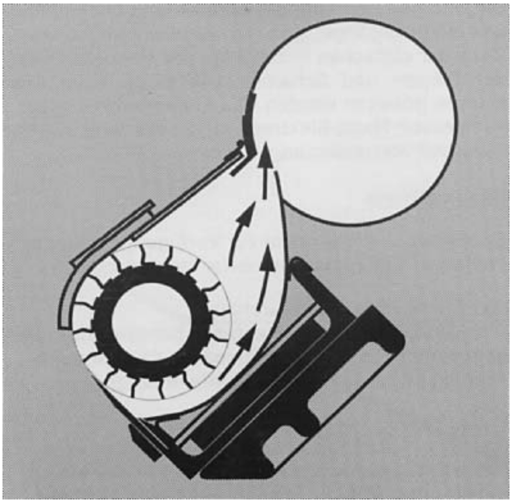

Fig.: Vollenweider Peerless three-function shearing extraction unit with fan and dust filter (straight connecting pipe between machine and fan).

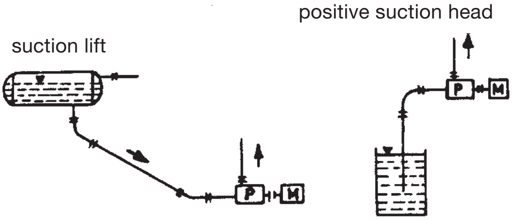

Fig.: Pumps: left with suction lift; right: with positive suction head.

Suction roller for textile webs A finely perforated stainless steel pipe, functions on both sides to transport the fabric. Fabric passes over a suction slot, with adjustable width, in the suction roller. The slot can be adjusted during a run. It can be installed either as an independently or as an inbuilt unit, complete with a water extraction machine and with a vacuum pump driven

Next Page

by a variable speed motor (a compensator roll arrangement by which fabric is transported at a speed of < 60 m/min). → Water extraction throughflow method.

Suction slot device Suction slot holder (beam) on the → Suction extractor.

Sudan Red test Microscopic detection test on fats, oil (including linseed oil, sulphonated oil) and soap that have been coloured red.

Sueded cloth A velvet-like raised cotton, wool, or wool/cotton union fabric which may also be printed. It is used for jackets, dressing gowns, etc.

Suède fabric → Imitation suede. This is an example of a simple fabric manufactured for making gloves by caustic treatment and the emerizing of cotton-warp knitted fabrics. In order to obtain a smooth surface ultra fine synthetic fibre-yarn is used.

Suède leather,

I. Roughened → Leather and is also called genuine suède leather (for example leather made from deer). It is either polished grain (e.g Nubuk) or polished velour (e.g lamb, sheep, calfskin, cow velour). Imitation suede leather → Imitation suede.

II. (suède) → Leather with a velvety rough or fluffy surface. The flesh side is cut and worn on the outside (for example Danish, suède leather). The grainy side is smoothed to obtain a special soft velvety texture (e.g Nubuk Leather).

Suède-Look “Swedish Leather” with suède characteristics, for example Duvetine and rough suede jeans material with flocked variants.

Suedette This is a five or eight stem reinforced satin material. A velvety effect is obtained by strongly roughing the right side of the fabric. Another name for this is fabric is Duvetine.

Suedine This is an imitation leather fabric with suède characteristics.

Suèding (emerizing). This is performed on the surfaces of cloth or knitted fabrics. During emerizing the fabric is covered by a thin pile that does not damage the machine or the structure of the fabric. The effect is dependent on the structure of the yarn and the surface. The shorter and thinner the fibre in the yarn, the lighter and easier it is to obtain the pile. The initial emerizing refining materials are also influenced by this.

Two different types of machinery are usually available for the mechanical variation of the surfaces: a multi roller machine for emerizing the surface or a single roller machine for → Sanding the surface. In the first instance the fabric is tensioned over four to seven rollers with emery papered rollers that turn against or with the direction of the fabric. In this way, adjustable pressure creates friction between the fabric and the emery surface. With emerizing any protruding fibre splits and results in a velvety but nonetheless lower fibre pile. The size of the emery grains is larger or smaller for each emerizing effect. Many articles are initially emerized on relatively rough wheels and are finally emerized on smaller emery rollers. A further set of rollers is needed for micro fibre-material. In practice multi roller emery machines offer more advantages for embossing than single roller emery machines:

- Knots in yarn can be eradicated and are not pulled or loosened by any subsequent adjustments.
- The emery rollers seldom heat up. This results in a longer life for emery paper.
- Power consumption is reduced because it is shared between a number of emerizing positions.

It is certainly still possible to work in a controllable sanding position with single roller machines, however in this process all differences in thickness are sanded down. This means that yarn knots are loose, and faulty fabric and selvedge can be sanded down and destroyed. Natural differences in thickness (for example tight chain thread and differences in creases) are increased. The possibilities of using this machine are decreased as a result of this. Multi roller emery machines offer more variation possibilities. Only a portion of the total power needed to emerize is transmitted to each roller. Single rollers can be used with different granules and it is also possible to choose different directions of feeding the fabric. Multi roller machines should, from now on, be predominantly used with equipment that has continually changing article programmes and that deal with specific customer requirements.

The technology employed in emerizing is largely based on that employed in sueding and it has its own individuality. The figure shows the attainment of an optimal emery effect as well as the direction of rotation relative to the direction of the fabric. For most articles the first roller runs in the opposite direction to the direction of the fabric. The weft thread is raised as a result. The second roller moves in the direction of the fabric and emerizes the raised weft thread. The third roller moves against the fabric again in order to intensify the process. The fourth and fifth rollers rotate in the direction of the fabric in order to give the emerized pile a light nap. An equally high fabric tension is employed when dealing with micro-fibre and fine fibre material.

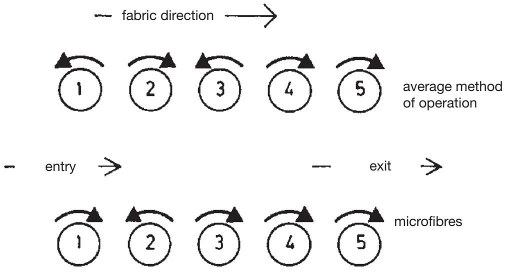

Fig.: Optimum emerizing effects; direction of emerizing roller rotation relative to fabric direction (Menschner).

The fourth and fifth rollers rotate in the direction of the fabric in order to give the emerized pile a light nap. An equally high fabric tension is employed when dealing with micro-fibre and fine fibre material.

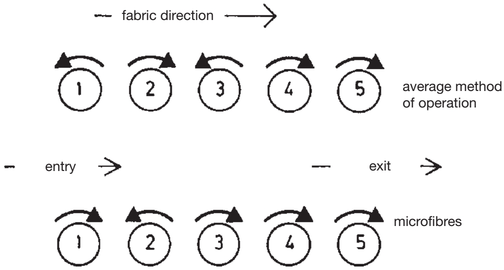

Fig.: Optimum emerizing effects; direction of emerizing roller rotation relative to fabric direction (Menschner).

The emery rollers only slightly touch these fabrics (tangentially touching).

Single roller emery machines may have either round or lattice rollers. A lot of mechanical power is used in raising, emerizing and putting a nap on the weft when using lattice rollers. Around 80–120 suitable pieces of emery paper are required for the lattice rollers. This process is not recommended for modern women's outerwear fabric. The range between being "too weak" and having "good tensile strength" is so narrow that it is no longer safe to control.

Lattice rollers, if at all necessary, are more advantageous for emerizing smooth cotton, viscose or woollen articles to make them "woolly". Round rollers are used for microfibre materials. There is less mechanical pressure on the fabric. Silk or high on Jacquard material can only be emerized with round rollers. Emerizing machines with round rollers are so quiet that only the noise level of the suction can be measured. In practice they are more beneficial whenever the single roller needs to be replaced on emery machines. The Tab. shows a summary and a comparison of the operation data.

	cylinder roller	lattice roller
fields of application	silk, low-high jaquard woven fabric lightweight women's outerwear products (100–180 g/m^2)	plain cotton/viscose or wool piece goods over 200 g/m^2 (mainly coarse graining: 80–120)
noise	very low level	high level
grain size	280/320 with lightweight women's outerwear qualities, 400/500/600 with fine-fibril polyester yarns and microfibres	80–120

Tab.: Comparison of cylindrical and lattice emerizing roller operating data.

The emerizing machine is a "cutting" tool. The hanging weft thread can be grasped and raised by large tools (80–120 granules). Result of processing using coarse grain is a denser, longer pile. If cotton or wool fabric result is too boardy and the aim is a "woolly surface", a particle distribution between 80 and 120 should be used. Wooden rollers produce the best effects here. They are therefore usually obtained using coarse paper. Light women's outerwear items between 100 and 180 g/m^2 in fabric weight should usually attain a short, dense pile. Particle distributions between 280 and 320 have proved their worth in such fabrics. Fine fibrillar polyester yarns and microfibres are emerized using 400/500/600 particle distribution. Even finer particle distributions around 600–800 are not normally used because they actually "polish" rather than emerize.

The tension of the fabric in the area of the actual emerizing field is of prime importance for a good emerizing effect. It must be adjustable and readable depending on the item. Adjusted tension values should be kept constant and automatic re-adjustments should be carried out if the material is stretched. It is especially important that tensile elements, which may take place at the input and output of the machine, do not influence the emerizing effect (according to Riedel).

The emerizing can be carried out after bleaching and before dyeing. This has the advantage that the dye result is no longer altered by subsequent emerizing (sudden change in shade). A disadvantage could be that the dyeing machine is polluted by emerizing dust or the fabric has an altered colouring behaviour. Other users carry out this dry finishing as the last processing step on the finished goods. Changes in colour are thereby partly attempted effects. The effect of a change in colour does not occur in patterned woven fabrics, shirting for example. It should rather be observed here that a subsequent resin finishing reduces the emerizing effect. A correspondingly more intensive processing during emerizing should compensate for this.

On denim fabrics the emerizing process should be carried out before the preshrinking in order to guarantee residual shrinkage values < 1% demanded. The preshrinking effect would be reduced by the fabric tension within the machine. Another area of use for emerizing is the preparation of the fabric for a subsequent raising process. The fibre capillaries loosened in the processing from the twisted yarn can be packed in the subsequent raising process more easily by the card wire point of the raising belt and further processed. This reduces the number of raising passages required. Knitted interlinings are a classic example of this case. From a textile technology point of view scrooping agent applications are required for the raising and the emerizing. These softeners may, amongst other things, already be applied in the spinning process.

Various stages, in which emerizing can take place:

1. After bleaching, before dyeing, e.g. filament woven fabrics made from polyester microfilament.
2. After bleaching, before dyeing or in the finished item, e.g. finish emerizing of outerwear materials. Depending on the organisational structure of the plant and/or the type of the effects attempted.
3. Emerizing only in the finished item, e.g. washed silk.
4. Emerizing as preparation for the raising process, e.g. interlinings.

Suèding machines (emerizing machines). Material with suède leather characteristics is produced on the emerizing machine by the emerizing rollers which split and emerize the fibre. The role of the emerizing machine can be illustrated by using the Suker and Müller SF machine as an example. A pair of draw rollers transport the fabric into the feed end as well as from the delivery end. A carrier roller ensures the cloth is guided correctly under constant tension. This is particularly advantageous in the machining of stretch fabric. The machine is built as low as possible in order for the operator to be able to carry out good visual checks on the passage of the cloth and the operational processes. Over five parallel adjustments can be made by the scaled handwheels so that fabric can be used on the emery rollers.

The setting of the fabric tension is carried out by means of the PIV-gear by a handwheel with a scale indicator, in order to provide reproducible values. The tension regulating system is tested on extremely sensitive articles and the basic machine equipment operates with a pneumatic coupling. Thin turned over seams with a thickness of only 0.25 mm can be detected without any difficulty by using the seam detection system. The process of automatic seaming can also be triggered.

Adjustments for different fabric thicknesses take place automatically. In order to keep the loss of fabric, that has not been machined, as low as possible the motors of the emery rollers are fitted with brakes which stop the emery rollers immediately when the transport of the seam is lost and accelerates the nominal revolutions per minute after the passage of seam. The part of the fabric that has not been machined is reduced to a minimum.

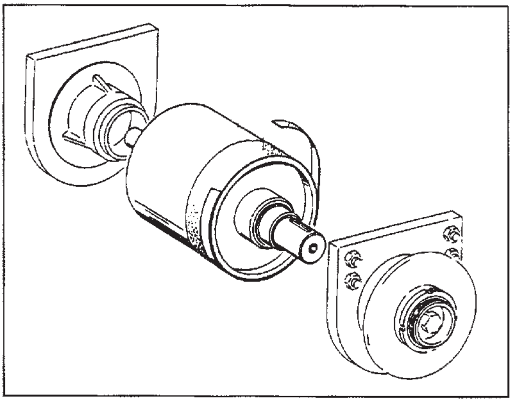

Fig. 1: A cylinder suèding roller (SMH).

The emery rollers which are wrapped in a spiral with emery paper (Fig. 1) are driven by a high performance motor and can be rotated, as desired, with or against the passage of fabric. The number of revolutions can be chosen from (950, 1200 or 1600 rpm). High frequency of contact between the fabric and process occurs as a result of the high number of revolutions and the use of the lattice roller (Fig. 2).

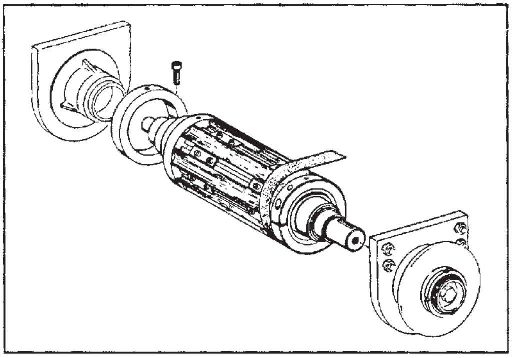

Fig. 2: A lattice suèding roller (SMH).

The emery band is classified by:

- Granulation, i.e the fineness of the granules, which limits the amount of granules per unit of area. Granulation influences the effect of emerizing.
- The type of granules influence the life of the emery coating as well as the machining effect obtained.
- Above all the embedding of the granules influences the life of the emery band.

Around 40–800 granules per unit of area are inserted. The fineness of the granules increases with an increase in numbers per unit of area. In coarse emery bands granules in textile material are embedded in fine paper. A choice is made between flocky and wet emery coatings when joining the granules to the carrier. Besides solid rollers, there are also lattice rollers that are only mounted on ledges. In addition to these rollers there are emery machines that operate according to the principle of wire roughing machines which rotate the emery machines in alternate directions (Fig. 3).

Limitations on the effects of emerizing:

- the design of the emery machines,
- the emery and grain coating,
- the speed of transport of the fabric,
- the number and direction of rotation of the emery machines,
- the fabric tension,

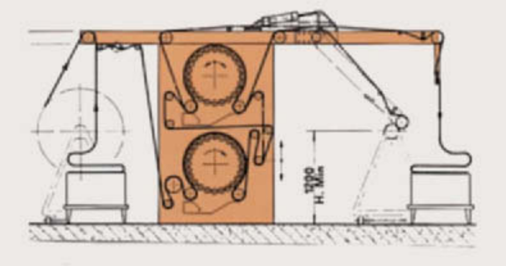

Fig. 3: A Lafer duplex raising machine with suèding rollers.

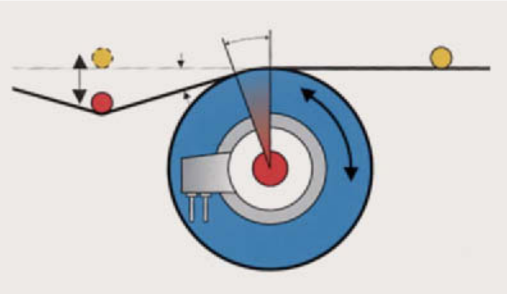

Fig. 4: Arrangement for feeding fabrics tangentially to the suèding roller.

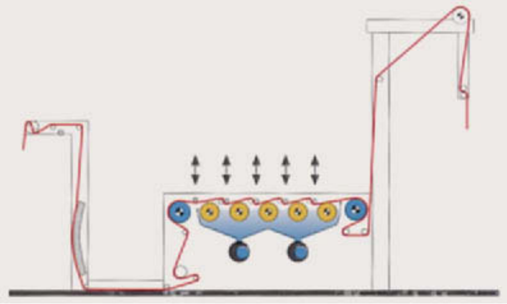

Fig. 5: Diagram of the transport of fabrics through the SF suèding machine (Menschner).

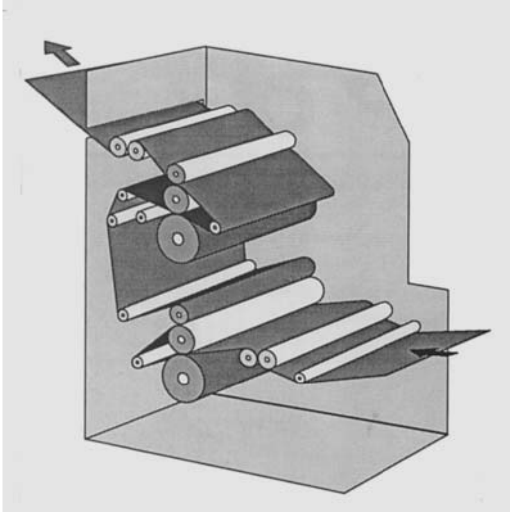

Fig. 6: A Wesero grinding machine.

– the installation of the fabric onto the emery machine (Fig. 4).

During emerizing the friction that occurs between the emery rollers and the fabric is continually measured in the emery system designed by Menschner and is kept at a constant value by a closed-loop control (Fig. 5). The power consumption of the motors on the emery roller is given as a “specific effect set point”. The angle at which the fabric enters through the emery rollers is automatically adjusted and mechanically positioned because of attrition of the emery coating and/or a change in the tension of the fabric. These adjustments continue until the optimal frictional effect between the fabric and emery roller is reproduced. One analogy draws upon the possibility of an early diagnosis of a change in the emery coating. If the required frictional is no longer obtainable, an acoustic signal indicates that there has been a change in the emery coating. Good quality reproducible fabric is continually guaranteed as a result of this. Traditional wire raising rollers can also be wrapped with emery bands instead of wire raising bands. Grinding machines work in a similar way (Fig. 6).

Suffix (Lat.: suffixus = attached). A suffix is added after the stem of a word for different chemical compounds. For example: -ase, -ate, -ide, -ite, -ose, etc. Opposite → Prefix.

Sugar alcohols (sorbitols), tetravalent-hexavalent aliphatic → Alcohols.

Sugar fibres Cuban. Raw material fibre from the waste from sugar production.

Sugars,

I. The traditional name for syrup and sugar cane.

II. Food relating to glucose, fruit, milk, maltose, etc.

III. Chemistry: can be easily combined with → Carbohydrates, mono and oligosaccharides when polysaccharides (for example starch, cellulose) do not contain sugar but consist of many simple sugars. Each type of sugar can be classified in two isomers α and β forms (→ Glucose, d-,α-, β-). Sugar and → Aglycone form → Glycosides. Simple sugars (Monosaccharides) combined with a group of aldehydes are called aldoses (C-number = bioses, trioses, tetroses, pentoses, hexoses), to which dextrose/glucose and most natural sugars also belong. Sugars within the keto group are called ketoses (for example, fruit sugars/fructose).

Suint Mainly from → Wool fat and Wool grease suint (consists of between 8 and 58%).

Sulphamic acid (sulphuric acid amide). NH_2SO_3H. Colourless crystal, odourless, non-volatile, non-flammable, disintegrates at 250°C. It has a density of 2.126 and a molecular weight of 97. It is a strong acid (very sour) and is soluble in water and alcohol. It destroys excess nitrates during diazotising: $NH_2SO_3H + HNO_3 \rightarrow H_2O + N_2 + H_2SO_4$. It is used during diazotisation and also before the coupling of naphthols (cleaner, stronger shades). Use: to analyse the presence of nitrates; boiler scale removal material (instead of H_2SO_4) in foam extinguishers where the acid carrier releases carbon dioxide from carbon.

Sulphamide ($-SO_2NH_2$), → Acid amides.

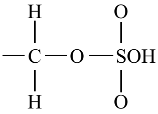
Sulphatases → Esterases.

Sulphate hardness → Water hardness salts.

Sulphates Salts from sulphuric acid (H_2SO_4; → Sulphur oxyacids), generally easily soluble (difficult in calcium, insoluble in barium and lead).

Sulphation (sulphating),

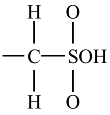
I. A reaction introducing the → Sulphonic (acid) group ($-SO_3H$) into an organic compound whereby ester originates from sulphuric acid i.e, → Sulphates with ester characteristic looping of sulphur to oxygen to carbon –C–O–S–:



$$-\overset{\displaystyle H}{\underset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}-O-\overset{\displaystyle O}{\underset{\displaystyle O}{\overset{|}{\underset{|}{S}}}}OH$$

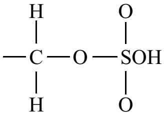
as for example is the case with fatty sulphuric acid esters. A choice is basically made between Sulphation and → Sulphonation. We only speak of → Sulphation in cases of doubt.

II. A reaction introducing the → Sulphonic (acid) group ($-SO_3H$) into an organic compound. Originating from this group are either a) sulphates by "real sulphation" or "carbon sulphation" which have a direct carbon-sulphur-bonding (they are also illustrated here as carbon-sulphonates):



$$-\overset{\displaystyle H}{\underset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}-\overset{\displaystyle O}{\underset{\displaystyle O}{\overset{|}{\underset{|}{S}}}}OH$$

or b) sulphates i.e, esters from sulphuric acid by an ester type bonding of sulphur to oxygen to carbon (also called oxygen-sulphates):



$$-\overset{\displaystyle H}{\underset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}-O-\overset{\displaystyle O}{\underset{\displaystyle O}{\overset{|}{\underset{|}{S}}}}OH$$

The concept of sulphation is often used in the generalised sense especially if it has not been made clear if → Sulphonation or sulphation or both should be used at the same time.

Sulphatoethylsulphone dye One of the most important treatments from the → Vinylsulphone dyes:

$$F-SO_2-CH_2-CH_2-O-SO_3Na.$$

Sulphenic acids A type R–SOH compound. It results, for example, from the effect of alkali on wool from the splitting of the cystine bridges:

$$R-CH_2-S-S-CH_2-R \rightarrow R-CH_2-SOH$$

and disintegrates in the separation of hydrogen sulphide from aldehyde:

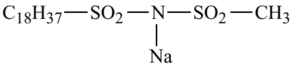
$$R-CH_2-SOH \rightarrow R-COH + H_2S$$

Sulphenic acid is very reactive.

Sulphidation (sulphidating). A reaction introducing sulphur into an organic compound whereby it forms into a sulphidation product consisting of mercaptane (R–S–H), thioether ($R-S-R_1$) and disulphides ($R-S-S-R_1$), etc.

Sulphides Salts from hydrogen sulphides (H_2 S) for example → Sodium sulphide (Na_2S). It is also an organic alkyl sulphide radical.

Sulphimides ($-SO_2-N(H)-SO_2-$), a product that originates from paraffin hydrocarbon (→ Acid amides). They are similar to sulphamides and are a high quality textile resource which has wetting and washing properties, for example:



$$C_{18}H_{37}-SO_2-\underset{\displaystyle Na}{\underset{|}{N}}-SO_2-CH_3$$

Sulphite-cellulose waste lye originates from the production of cellulose. It contains hemicelluloses, sodium lignin sulphite as an effective protective colloid, rubber, resin, glucose, tannin. Characteristics: it slows down the absorption of dyestuffs especially in light colours. Its protection colloids give wool, in high temperature alkali baths, its "weak" tanning characteristics and also in the scouring of silk.

Sulphites Salts from the sulphuric acids (H_2SO_4; → Sulphur oxyacids). They are either acid salts (e.g. → Sodium bisulphite) or normal salts (→ Sodium sulphite). Only alkali salts are soluble, and as a result have an alykaline hydrolysis reaction. Usage: they are reducers, bleachers and separators.

Sulphito- The name for the SO_3^{2-} ion coordinated as a ligand in → Complex compounds.

Sulphitolysis The separating of sulphites from disulphide compounds (→ Cystine bridges):

$$\begin{aligned} &R-S-S-R + SO_3^{2-} \rightleftharpoons R-S-SO_3^- + R-S^- \\ &R-S^- + H^+ \rightleftharpoons R-SH \\ &SO_3^{2-} + H^+ \rightleftharpoons HSO_3^- \end{aligned}$$

The maximum sulphitolysis that can been performed on wool cystines and thiol compounds (→ Cystines) is approximately pH 3.5 when unprotected and pH 4.5–5 when protected. Under similar conditions, alkali chlorinated wool with sodium sulphite and sodium dithionite is produced after treatment. The optimal bleaching of chlorinated yellow wool is also achieved.

Sulpho-acetate of alumina (aluminium sulphuric acid), which is produced from a double reaction of 1 Mol aluminium sulphate with 1 Mol of lead acetate = $A1_2(CH_3COO)_4\,(SO_4)$ or by the dissolution of aluminium hydroxide in acetic acid = $Al(SO_4)(CH_3COO)$. Alkaline salt originates from the addition of sodium bicarbonates $Al_2(SO_4)_3$ or the double reaction of alkaline sulphate with lead or calcium acetate = $AI_2(SO_4)(CH_3COO)_2\,(OH)_2$. Usage as a mordanting fluid for alizarin and Turkey red colours (especially alkaline salt) for the acid neutralisation of aniline black dye.

Sulphobetaines Used for high grade finishing. Examples include → Triethylsulphateamine, disodium salt.

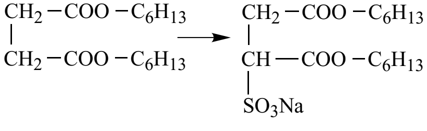
Sulphonated fatty acid esters → Fatty acid-condensation products.

Sulphonated fatty acids (fatty sulphonated acids) → Sulphonated surfactants. The reaction product of fatty acids/sulphuric acids in so doing, finally react (with the efflux of water) with a CH_2-group and which explains, with → Sulphonic acids, the direct bonding of carbon-sulphur ($–C–SO_3H–COOH$) with the fatty acids-carboxyl group. Sodium salts possess a high level of resistance to acid and alkali, form very soluble lime salts and are (for example with a mixture of → Fatty sulphuric acid esters) very active in the processes of saponifying, rinsing, dyeing, softening and modifying finishes. They are also resistant to bitter salts.

Sulphonated oil Sulphonated surfactants and similar products.

Sulphonated polycarboxyl acid esters and amides A group of high quality wetting and washing auxiliaries.

1. a) sulphonated succinic acid esters (sulphosuccinates) form the largest subgroup with extraordinary varying possibilities. $C_{6–8}$-alkyl residue have the best wettability. C_7-alkyl residue also have good washability. They are very resistant to hard water, alkali and acids. Types:

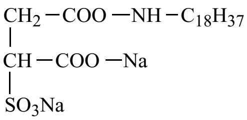


$$\begin{array}{l} CH_2-COO-C_6H_{13} \\ | \\ CH_2-COO-C_6H_{13} \end{array} \longrightarrow \begin{array}{l} CH_2-COO-C_6H_{13} \\ | \\ CH-COO-C_6H_{13} \\ | \\ SO_3Na \end{array}$$

-ester *-sulphosuccinate*

Sulphuric succinic acid esters are average to good washing auxiliaries. They are used as mild washing agents and are degradable (by comparison to other products). Sulphuric succinic acid esters from stearic acid monoethanolamides are useful for special after washing in many countries. Washing can be performed without additional electrolytes or alkali to neutralise weak acid. It can also be carried out in hard and saline water. They can be used to scour off other predominant surfactants. Disadvantages: they are in the form of a paste, sensitive to alkali, substantivity (controllable handle). $ROOC–CH_2–NaOOC–CHSO_3Na$.

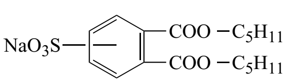
1. b) Sulphuric succinic acid amides are very active in washing. They are designed on the following principles:



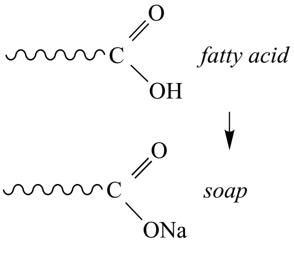
$$\begin{array}{l} CH_2-COO-NH-C_{18}H_{37} \\ | \\ CH-COO-Na \\ | \\ SO_3Na \end{array}$$

2. Sulphonated esters from tricarballylic acid ($[CH_2–COOH]_2–CH–COOH$) are very strong wetting auxiliaries.

3. Sulphonated phthalic acid esters and amide wetting auxiliaries are also very good for washing. Their design principle is as follows:

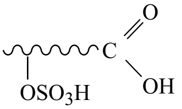


Sulphonated surfactants (sulphonated oils). The carboxyl (COOH) group is recognised as being the main insufficiency of soap:



In order to retain the features of the fats as much as possible, a corresponding change in the molecules of the → Fatty acids or → Fats (mainly castor oil or olive oil) must be made.

I. Turkey red oils: serve, above all, auxochrome dyestuff compositions. This involves the classical implementation of the sulphonic acid group $–SO_3H$ through sulphonation. The products become water-soluble and exhibit chemical → Fatty sulphuric esters wherever the sulphonic acid group has been placed in the long fatty molecules such as castor oil acids-sulphuric acid esters:



The products have uncombined chemical reactions (different degrees of sulphonation, partly C–SO_3H–bonding). The sulphonated oil from the Turkey red oil is formed through emulsifying (the name originates from its once outstanding contribution to the dyeing of Turkey Red). It is soapy, loosens up dirt, but does not possess any washing capabilities. With increasing degrees of sulphonation we may choose between a) low sulphonated oil (approximately 3–7% SO_3); b) high sulphonated oil (approximately 10–12% SO_3) c) highest sulphonated oil (approximately 19–22% SO_3), which increasingly possess wetting and emulsifying capabilities as well as increased resistance. The latter members of this formation are resistant to hard water salts, bitter salts ($MgSO_4 \cdot 7\,H_2O$), acid and alkali. Usage: are used in the dispersion of lime soap, excellent (bitter salt), finishing oils and dyeing oils (also in the boiling of liquid acids to remove colour). It is also used for wetting, levelling, full dyeing, scouring, kier boiling, desizing, chlorine bleaching, mercerization, carbonization as an emulsifier and so forth.

II → Sulphonated fatty acids: fatty sulphonated acid sodium salts are worth mentioning. They are also found in the fatty molecules of the sulphonic acid group. The sulphur is, however, directly bonded to carbon (–C–SO_3). There are also many different oils that easily form soluble lime salts in hard water besides numerous ones which have similar characteristics to fatty sulphuric esters.

III. Sulphonated tallows: These possess a proportionally low degree of sulphonation. Usage: special finishing, chemical finishing, as fat for padder tarnishing and so forth.

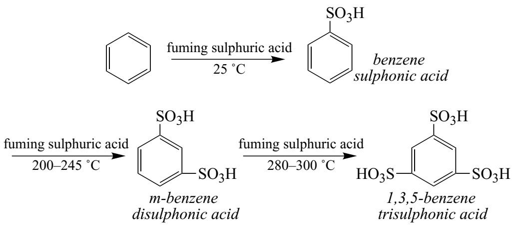
IV. Other oil products: mainly unsulphonated olein and acid oils, olive oil, ground nut oil, mineral oil or paraffin produced for the melting of wool and viscose spun fibre and when required in emulsifying combinations. Similar oil products can be used for the oiling of viscose filament yarn. Mineral oil and linseed oil can also be used as components for viscose-filament yarn-finishing as well as other oils.

Sulphonated tallows Tallow product with usually low degree of sulphonation; its natural fat properties are retained to a large extent. It is usually soluble in water. Anion active. Utilized as an avivier agent, as finishing and smoothing additives and as grease basis for matt finishing of foulards.

Sulphonation It was once a general reaction that introduced the → Sulphonic (acid) group (–SO_3H) into an organic compound. Sulphonation is only referred to in the narrowest sense if sulphur from the sulphonic acid group is immediately bonded with the carbon; type –C–SO_3H (sulphonated – type –C–SO_3Na). This structure exists for example in → Sulphonic acids, dyestuffs such as auxochrome and generally in all → Sulphones. The basic choice is made between sulphonation and → Sulphation and in cases of doubt the term sulphation is used.

Sulphonation, degree of A percentage of the organic bonded sulphuric acid and SO_3 in → Fatty alcohol sulphates and similar sulphates. Fats are water-soluble during contact with the → Sulphonic (acid) group. Acids, lime and bitter salt resistance as well as the resistance to wetting and emulsifying power increase with the degree of sulphonation. Synthetic washing materials practically have one hundred percent sulphonation and means that every active molecular substance is washed and eradicated by a soluble group. Proportionally lower degrees of sulphonation groups are sulphonated tallows which consequently obtain their softening ability from the fat characteristics. Consequently the required fatty effects are achieved by the addition of unsulphonated fatty alcohol.

Sulphonation of aromatic compounds Sulphuric acid sulphonation of aromatic compounds results in arylester sulphonation. Sulphur trioxide in sulphuric acid is joined to an aromatic ring by an electrophyllic substitution. Sulphonation occurs by the following means:



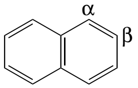
Sulphonation results over a transitional period that exists during the formation of a π complex. The attacking ion interacts with the π electron shell of the attacked aromatic compound. This reaction is reversible. The dilute sulphuric acid allows the sulphonic acids form to desulphonate. Sulphonation is easier as a result of this. An increase in time and temperature of sulphonation causes an increase in the degree of sulphonation. Previously prepared substituents (Tab.) influence the process in the normal way i.e top quality substituents direct in ortho and para positions. Second quality substituents direct in meta positions. During temperature increase the para-positions are mostly opposite to the ortho-positions. An overview illustrates the possible reaction positions during sulphuric acid sulphonation from formerly substituted aromatic compounds. Only those from the used dyestuffs are listed.

substituent	o-	p-	m-
$-SO_3H$		5%	95%
-OH	15%	85%	
$-CH_3$	15%	80%	5%
-Cl		100%	
-NH-Ar		100%	
-COOH		14%	86%

Tab.: The formation of sulphonic acid as a percent according to the availability of substituents.

The following requirements must be adhered to in sulphonation:

- Never put two sulphuric acid substituents in an ortho-para position to each other.
- Two or more substituents can become strengthened or weakened. In the latter case isomers are mainly formed side by side.
- The influence of the hydoxyl group outweights all the other substituents.
- Amide groups lead the sulphonic acid groups into their para and ortho positions.
- Second quality substituents make sulphonation harder. There is very seldom a substitution in the meta position.
- Phenol that leads the sulphonic acid group, initially into a para position and finally into an ortho position, can easily be substituted.
- Naphthalene sulphonation is strongly influenced by temperature; below 65°C the sulphonic acid group forms the α position, under 120°C it forms the β position.



1- naphthol becomes 1-naphthol-4-sulphonic acid; sulphonation of 2-naphthol takes place in mild conditions to 2-naphthol-1-sulphonic acid vigorous under conditions 2-naphthol-8-sulphonic acid and 2-naphthol-6-sulphonic acid.

- Sulphonation of anthraquinone takes place in vigorous conditions. Disulphuric acid forms as well as monosulphuric acid. The second sulphonation always takes place on the other benzene nucleus. Further sulphonation does not occur.

Sulphones (R_2–SO_2). Oxidation product of → Thioethers.

Sulphonic (acid) group (SO_3H). Monovalent. Characteristic of many textile auxillaries and numerous dyestuffs (auxochrome).

Known as a → Sulphuric acid extract of an hydroxyl group. Interaction of the sulphonic acid group occurs during → Sulphation (sulphonation). It consists of mainly water insoluble organic compounds which effect its water solubility.

Sulphonic acids Aliphatic and aromatic compounds have a wider variety with the water-soluble sulphonic acid group ($-SO_3H$). They are in acidic form, for example, as acidic dyestuffs, sodium salts, direct dyestuffs and are very valuable textile auxiliary components (→: Fatty acid condensation products; Sulphonated fatty acids). In contrast to fatty sulphuric esters, sulphur is directly combined with a carbon atom (–C–S–). These also include “C- sulphonates”, alkyl sulphonates, “real” sulphuric acid and alkyl sulphuric acid metals in the form of sulphonates (as salts). They are made up from paraffin carbo-hydrogen (through sulphonation with SO_2 and CO_2 or sulphuric chloride SO_2Cl_2) and initially change to sulphuric chloride (Mersol.-type: $R–SO_2Cl$), which are saponified with caustic alkali to form Mersolate (cleaning auxiliaries, wetting auxiliaries, etc).

Sulphonium compounds Sulphur-complex, similar to → Oxonium compounds in which oxygen interacts with sulphur. Sulphonium compounds are taken from the coordinative four-valency sulphur and are substituted three times with alkyl. As a high-grade finishing product Sulphonium compounds contain a lot of cellulose (e.g. disodium salts from tris (β-sulphurethyl) sulphonium). sulphonium compounds behave similarly to quarternary ammonium compounds and form strong hydrate bases similar to sodium hydroxide. The colouristic characteristics of sulphonium compounds have until now been similar to phthalocyanine-complex in sulphonium compounds (→ Phthalocyanine dyestuffs).

Sulphonyldiethanol Originates from di-vinyl sulphone when poured into a watery alkali solution:

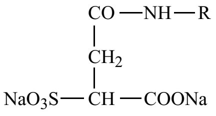
$$CH_2{=}CH-SO_2-CH{=}CH_2 \xrightarrow{OH^-}$$

$$OH-CH_2-CH_2-SO_2-CH_2-CH_2-OH$$

Sulphonyldiethanol serves as a linking auxiliary for cellulose, for example for the non-iron finishing of cotton. (→ Bis(β-hydroxyethyl)-sulphone).

Sulpho salts Known as double sulphides. They originate from oxygen salts produced by changes in sulphur as opposed to oxygen, for example urea $CO(NH_2)_2$, sulphur urea $CS(NH_2)_2$.

Sulphosuccinamates Foaming agents and emulsifiers of the general formula:



$$\begin{array}{l} \quad\;\; CO-NH-R \\ \quad\;\; | \\ \quad\;\; CH_2 \\ \quad\;\; | \\ NaO_3S-CH-COONa \end{array}$$

sodium sulphosuccinamate
(R = organic residue)

These differ from most surface-active compounds through two ionisable groups: sulphonic acid group and carboxyl group. The consequent bifunctionality in interaction with the amide group yields specific characteristics which predestine them for use in emulsion systems. Thus certain sulphosuccinamates are used alone or in mixtures with e.g. potassium oleate sulphate or sodium lauryl sulphate as an emulsifier for latex compounds, as well as as an emulsifying and foaming additive in the manufacture of foamed carpet backing coatings.

Sulphosuccinate → Sulphonated polycarboxylic acid esters and amides.

Sulphoxides (R_2–SO), oxidized → Thioethers.

Sulphoxylates (formaldehyde sulphoxylates, formaldehyde sulphoxylic acid salts, oxymethane sulphinic acid salts) formed from formaldehyde and sodium dithionite or (in acid solution) through the reduction of formaldehyde disulphite with zinc dust. Used as highly effective reducing agents – frequently used in heat – for stripping, in vat dye printing, as discharge agents, as kier boiling assistants (preventing oxycellulose), etc.

I. Sodium formaldehyde sulphoxylate: ($NaHSO_2 CH_2O \cdot 2\,H_2O$) mostly 98–99%, stable (if protected against moisture and heat), soluble in cold water; used as: deoxidant in cloth printing (vat dyes), discharging of direct and naphthol dyeings.

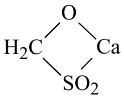
II. Sodium sulphoxylate stabilised with acetaldehyde and ammonia. At around 70°C it already exceeds the upper vatting limit of vat dyes. Has a higher negative redox potential than sodium dithionite, i.e. not suitable for dyes sensitive to over-reduction.

III. Zinc formaldehyde sulphoxylates:

a) Primary salt [$Zn(SO_2CH_2OH)_2$], water-soluble; used for: stripping of dyeings, deoxidant in vat-dye printing, discharge printing of acetate fibres, etc.
b) Secondary salt [$Zn(SO_2CH_2O)$], not soluble in water, soluble in ethanoic acid or formic acid bath; used for: stripping of dyeings, discharge agent.

IV. Zinc acetate aldehyde sulphoxylate: oxyethane sulphinic acid zinc: [$ZnSO_2(CH_2OH)_2$], difficult to dissolve in water, used for: stripping.

V. Calcium formaldehyde sulphoxylate: deoxidant for printing with vat dyes.



VI. Glucose sulphoxylate.

Sulphur (Lat.: sulfur). Chemical symbol: S. Atomic weight 32.06. Sulphur is bivalent, quadrivalent and hexavalent. Yellow rods, chunks or powder (always containing sulphurous acid), brittle, stable in air (density 2.06). Insoluble in water, low solubility in alcohol, ether, benzene; soluble in carbon bisulphite; burns when ignited with a blue flame (melting point at 114.5°C) (to form sulphur dioxide SO_2). Used as bleaching agent (wool, straw), vulcanisation, etc.

Sulphur bridges →: Cystine bridges; Wool chemistry.

Sulphur determination for wool → Benedict-Denis reagent.

Sulphur dioxide SO_2. Molecular weight 64. Colourless gas (steel cylinders) with a suffocating odour, toxic, non-combustible (occurs when → Sulphur is burned); also liquid (H_2SO_3, molecular weight 82, salts: sulphites, hydrogen sulphites). Colourless, weak acid, pungent odour. When air is included, slow oxidation to form sulphuric acid (store well sealed). Addition of small amounts of alcohol improves storage properties; acid reaction. In the dissolved state, SO_2 is present in water, only to a small extent $SO_2 + H_2O \rightarrow H_2SO_3$. Used for: bleach (wool, silk, cellulose, etc.); antichlor; after-treatment after potassium permanganate bleaching (dissolving manganese dioxide); stain remover (for berry and fresh fruit stains). Must be well rinsed out of cellulose goods (formation of sulphuric acid).

Sulphur dyeing A distinction must be made between normal and modified types of sulphur dyes. For normal types, storage time is limited. Even when stored in cool, dry conditions, auto-oxidation can occur with individual products. Individual dyeings likewise have limited lives; changes of shade. In the case of modified types, observe the manufacturer's instructions. Dissolving regulations: observe the details provided by the manufacturer. Normal types should be boiled with 1 to 3 times the amount of sulphur sodium crystals. This solution must be filtered before being added to the dye bath. Modified types, on the other hand, are water-soluble or can be diluted with water. Dye baths: use soft water. In the case of standing baths, monitor the salt content. Sulphur dyes take up relatively slowly, and therefore pose no levelling problems, unlike vat dyes. Oxidation: where rinsing and/or hanging are not sufficient, baths with hydrogen peroxide are used. The use of dichromate is prohibited by law in Germany. Oxidation through steaming does not occur often. After-treatment: for some dyes, metal salts (copper) increase fastnesses, although changes of shade occur. Metal salts reduce the absorbency of the goods. Improvements in fastness which are resistant to washing can be obtained through after-treatment with nitrogen condensation products. Sulphur black dyeings should be alkaline finished (pH 8–8.5), or else sodium acetate or sodium formiate should be added to the last rinsing bath. In this type of dyeing, there is the risk of sulphur separating, which converts into sulphuric acid, causing a weakening of the fibre. Sulphur dyes can be applied by both the exhaust method and the pad dyeing method. However, there is little interest in the discontinuous pad dyeing method. Modified types are recommended for pad dyeing methods.

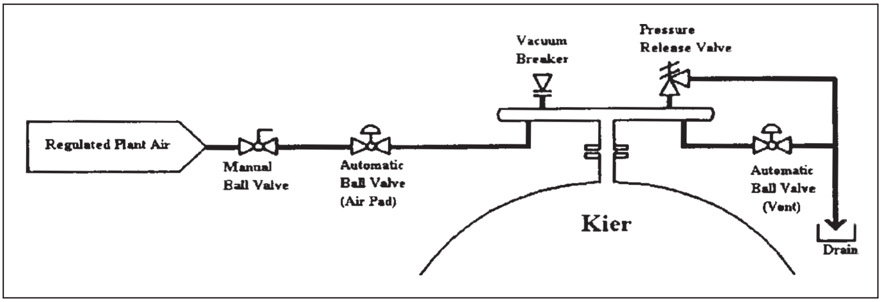


Fig. 1: Typical jet dyeing machine for the "Nitro"-process of sulphur dyeing.

I. Dyeing of cellulose fibres:

a) Exhaust dyeing. Normal types: observe the manufacturer's details precisely. Additions of sulphur sodium and salt vary depending on the dye, as does the dyeing temperature. Modified types: partly reduced and leuco forms behave like normal types during dyeing. Additions of reducing agents can be reduced. Thiosulphuric acid derivative types have no affinity; this occurs only when sodium sulphide or sodium sulphydrate are added, through reverse transformation to the mercapto form. Baths with sulphydrate are less alkaline, which has a favourable effect on the handle of dyed goods, this being particularly important in the dyeing of regenerated cellulose fibres (cupro, viscose). Instead of sulphide, glucose can also be used as the deoxidant. However, it must be noted that the dyeing must then take place in a closed system at a minimum of 90°C, since glucose can only develop its reducing characteristics under these conditions. A further reduction of the sulphur content in waste water is possible through the choice of low-sulphur dyes, but their substantivity to cellulose is less than that of normal sulphur dyes. This situation is solved in terms of process engineering in that after dyeing, before oxidation, the dye liquor with the low-sulphur dyes is cooled to at least 60°C before the rinsing process is started.

b) Pad dyeing method. Normal types: the preparation of dye solutions is so laborious that liquid sol types are preferred for this process. An important method for this is the pad-steam method: padding with dye, intermediate drying, padding through polysulphide solution, steaming, rinsing, oxidation and rinsing again. Further possibilities are provided by the thiosulphuric acid derivative types: in the pad-roll, cold dwell and thermosetting methods.

II. Dyeing of wool and silk: sulphur dyes have not found practical use for either wool or silk. Lowering the dyeing temperature and adding fibre preserving agents do not entirely prevent poor handle and fibre damage.

III. Nitrogen inerting during sulphur dye application: The "Nitro" exhaust dyeing process (Fig. 1) utilises nitrogen, one of nature's most abundant and inert elements, in order to minimise the amount of chemical reducing agent required for the application of sulphur dyes.

Nitrogen makes up 78% of the air and is used in a number of industries to protect various materials from the detrimental oxidative effects of atmospheric oxygen. For example, nitrogen is used in packaging by the food and beverage industry, for the preservation of coffee, snack foods, juices and wine. Controlled atmosphere technology employs nitrogen to maintain the freshness of fruits and vegetables during storage and transportation.

Oxygen in the air hinders at the chemical reducing system in the dyebath lowering the stability of the "leuco" dye and thereby increasing the likelihood of premature oxidation leading to bronzy unlevel dyeing. As in the case of vat dyes, excess reducing agents are generally required to avoid these problems. By simple inerting methods, the "Nitro" process purges the dyeing vessel of atmospheric oxygen and thus decreases the amount of chemicals required for dyestuff reduction. The nitrogen purging process can be implemented for as little as $0.0025/lb. of fabric dyed while reducing chemical cost by approx. $0.03/lb. as compared to many Sandozol RDT type applications. The decrease in chemical usage leads to lower BOD and COD loads while nearly eliminating sulphides in the waste

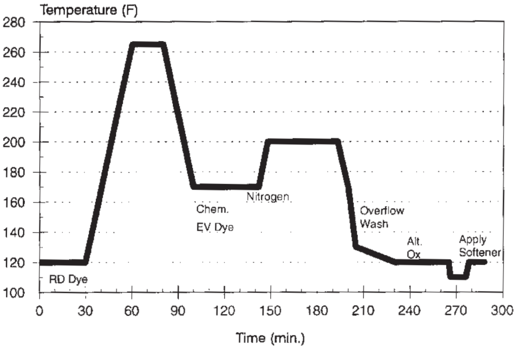

Fig. 2: Diresul Black 4G-EV-Jet application: Foron RD/ Diresul EV 1 bath, 2 step dyeing procedure.

streams. In addition to chemical cost savings and minimal environmental impact, the "Nitro" application process utilises fast chemical and dye additions as well as rapid heating rates to cut as much as 1 hour 15 min off typical classical sulphur dyeing cycles (Fig. 2).

Sulphur dyeing from standing bath Even with salt, sulphur dyes exhaust only incompletely, which is why in the case of deep shades, one usually works with standing baths. Analysis of the cooled liquor by spindling with areometers. Experimental values for medium dyeings up to 3–4° Baumé, for dark ones up to 5–6° Baumé, and for black liquors up to 8° Baumé.

Sulphur dyeings (black)-storage stability testing Moisten a dye sample of at least 10 g with as small an amount of distilled water as possible (beaker), centrifuge, dry at 90°C (drying chamber), moisten again and then continue in this way (repeat the whole procedure 10 times). Then place the sample in cold water and boil for 30 min (replace evaporation loss), take out, add barium chloride solution to the water used for boiling; any clouding which occurs indicates sulphuric acid ions, and thus endangered storage stability.

Sulphur dyes Due to its favourable price, combined with good fastness of dyeing (exception: fastness to chlorine), this class of dyes is still of great importance, despite the environmental problems associated with the dyeing method. The range of dyes covers, above all, muted shades; more lively colours are missing, particularly red shades. Manufacture of sulphur dyes through fusing together elemental sulphur and aromatic compounds containing nitrogen, or boiling them with polysulphides in water or solvents. Usually, this results in mixtures of various products, or more rarely well-defined compounds. The reaction mechanism is not clear in every case, nor is the precise constitution. Sulphur dyes are insoluble in water and are dissolved through alkaline reduction with sodium sulphide or sodium dithionite and caustic soda, the so-called sulphydryl form, generally also called the leuco form (principle: $=C=O \rightarrow \equiv C{-}OH \rightarrow \equiv C{-}SH$). The sodium salt which forms ($\equiv C{-}SNa$) goes onto the fibres and is once again fixed, water-insoluble, on the fibre through subsequent oxidation. With sulphur dye types as dyes which had already been partly or wholly reduced, and mixed with dispersants and stabilisers (so-called sol types), laborious dissolving was no longer necessary. Sol types are on the market mainly in liquid form. These types were followed by the thiosulphuric acid derivatives (→ Bunte salt dyes) as the non-affinity form, which only goes onto cellulose after the addition of sodium sulphide or sodium sulphydrate.

Sulphur dyes, field of application Of great significance for cheap staple goods or heavy fabrics of cotton in muted shades (Manchester, velvet, rucksack fabric, tent fabric, lining materials, apron materials, work clothing, etc.) which are fast to washing, light and abrasion. Of less importance on regenerated cellulose fibres (losses in handle and lustre).

Sulphur dyes in printing Their use is restricted mainly to black brands. Printing paste similar to that for → Vat dyes.

Sulphur dyes in resist printing → Vat dyes in resist printing.

Sulphur oxyacids $H_2S_2O_3$ = thiosulphuric acid. Salts: → Thiosulphates ($Na_2S_2O_3$) as antichlor, for titrimetric analysis, etc. $H_2S_2O_4$ = (formerly) low sulphurous or hydrosulphurous acid, or (these days) dithionic acid. Salts: hypo- or hydrosulphides, these days dithionites ($Na_2S_2O_4$), as strong reducing agents. H_2SO_3 = sulphurous acid. Salts: → Sulphites (Na_2SO_3), hydrogen sulphites ($NaHSO_3$), as reducing agents. H_2SO_4 = sulphuric acid. Salts: → Sulphates (Na_2SO_4), hydrogen sulphates ($NaHSO_4$), potassium aluminium sulphate [$KAl(SO_4)_2$]. H_2SO_5 = oxysulphuric acid, peroxy(mono) sulphuric acid (→ Caro's acid). $H_2S_2O_8$ = poly- or persulphuric acid, peroxydisulphuric acid; salts: → Persulphates ($K_2S_2O_8$), as oxidation agents. $H_2S_{2(-5)}O_6$ = polythionic acids.

Sulphuric acid (oleum), H_2SO_4. Molecular weight 98.04. Salts: sulphates. Thick, oily liquid; colourless to weak brown colour, odourless, highly corrosive to the skin (wounds difficult to heal), highly hygroscopic (store well sealed); strong acid, displaces (due to its being not easily volatilised) most other (more volatile) acids from their salts; dissolves metals (with hydrogen formation). When sulphuric acid is diluted with water, always add the sulphuric acid slowly into plenty of cold water in a thin stream and not the reverse; heating (up to 120°C) , sometimes explosive spraying around. Used for: carbonisation; wool dyeing (besides sodium sulphate); developing of leuco vat ester dyes; frequently for acidifying (particularly in bleach); as accumulator acid (20–30%), etc.

Sulphuric acid solubility test,

I. In cold concentrated sulphuric acid, the following are soluble: natural silks, cellulose fibres; acetate, triacetate, polyamide, polyurea, polyester, polyacrylnitrile fibres; some modacrylic fibres, polyvinyl alcohol fibres, polyurethane fibres, rubber threads. Insoluble: wool; casein, PVC, polyvinylidene chloride, polyethylene, polypropylene, polytetrafluor ethylene fibres.

II. In boiling concentrated sulphuric acid, the following are soluble: wool; natural silk; cellulose, acetate, triacetate, casein, polyamide, polyurea, polyester, polychloride, polyacrylonitrile, copolymer, PVC, polyvinyl alcohol, polyethylene, polypropylene, polyurethane fibres; rubber threads. Insoluble: polytetrafluor ethylene fibres.

Sulphurized phenols → Fat-free aromatic products.

Sumach Products containing tanning agents, ground leaves of varieties of rhus, or viscous light brown solution of 20–36°Baumé (= sumach extract), also solid mass. Originates from southern Europe. Tannin content 18–28%. Used as a tanning agent similar to → Tannin; for weighting silk.

Summation parameters Textile waste water can contain a large number of different substances which are alien to water; these include inorganic substances, e.g. neutral salts such as sodium chloride, but also heavy metal ions and – not least – ions from sulphur chemistry, such as sulphide, sulphite and sulphate, which frequently occur as secondary products of reducing agents. These inorganic substances can usually be identified and determined at reasonable expense using classical methods. However, for the analytical characterisation of the numerous organic individual substances in the waste water, one of the so-called summation parameters are frequently used (→ Waste water evaluation).

Organic water pollutants consist of numerous individual substances which can be determined only at considerable expense, if at all. The advantages in using summation parameters lie in considerable savings in work and costs, but the corollary disadvantage is undifferentiated information.

Some of the important summation parameters for assessing waste water are:

- → TOC: total organic carbon. Method: combustion analysis.
- DOC: dissolved organic carbon.
- COD: → Chemical oxygen demand. Method: oxidation with dichromate.
- BOD: → Biochemical oxygen demand. Method: biochemical oxidation.
- → AOX: Adsorbable organic halogen. Method: adsorption on carbon, combustion, determination of HCl or HBr.

Provided below is a list of the most important determination regulations for summation parameters, adherence to which in accordance with the DIN standard is to be regarded as relevant in relation to water analysis from textile areas. The expenditure on measurement and the measurement methodology is not discussed here.

– pH	[1]
– determination of acid and base capacity	[2]
– Suspended matter	[3]
– chemical oxygen demand (COD)	[4]
– biochemical oxygen demand (BOD)	[5]
– determination of halogen compounds (adsorbable organic halogen: AOX; purgable organic halogen: POX; extractable organic halogen: EOX)	[6, 7]
– carbon (total organic carbon, total inorganic carbon, total carbon)	[8]
– total nitrogen, phosphorous, sulphur	[9]
– heavy metals content	[10]
– hydrocarbons and aromatic compounds	[11]
– surfactants	[12]
– colour	[13]
– toxicity to fish	[14]
– other substances which pollute waste water	[15]

As summation determination, these methods are largely sufficient for monitoring adherence to the limit values which are required by law. However, they cannot make meaningful statements about which chemical type leads to the measurement result, i.e. it is not possible to trace back to a process stage the cause of the pollution of the waste water. The methods listed are to some extent very time-consuming, and not suitable for in-line or on-line process monitoring. Further methods for identifying and characterizing pollutant substances are essential. Determination of the summation parameters does not permit any statements about the possibilities for specific removal of any pollutants. Only the use of specific methods of analysis enables a diagnosis of which stage of a production sequence results in pollution of exhaust air or waste water. (according to Schollmeyer).

Sunflower pectin as thickener The pectin obtained from sunflowers is of interest for technical purposes on account of low prime costs. For printing with dispersion, acid and reactive dyes, sunflower pectin with a finishing level of 33% and a uronic acid content of 73% can be used rheologically. When flowing, sunflower pectin solutions behave as non-Newtonian liquids with plastic-pseudoplastic viscosity in a broad span of speeds and transverse stress. At concentrations of over 5%, solutions lose their flowing properties and convert into gels. The apparent viscosity has a negative temperature coefficient, and reduces with storage time. Neutralization lowers viscosity.

Sunn fibre South Asian → Bast fibres, water-retted, coarse and hard. Used for cords and ropes.

Superabsorbers → Absorbent compounds such as highly absorbent polyacrylate powders, can be used in the hygiene sector for the absorption of wetness which occurs suddenly (see Fig.).

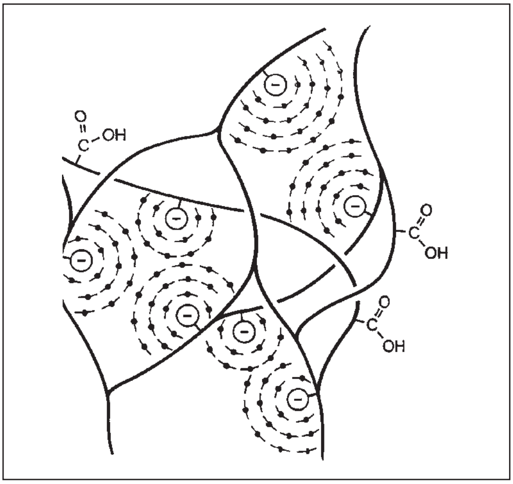

Fig.: Structure of a superabsorber (Favor-Hydro-Gel).

Supercontraction Shortening of (e.g.) fibres to less than their original length (see Fig.). Can be reversible or irreversible. In the case of keratin fibres, it is based on the splitting of cystine and hydrogen links. The starting points for the various theories concerning the chemical reactions which occur during fixing are based on the observations by Astbury and Woods (1933). They investigated the behaviour of wool fibres which were stretched by 40%, exposed to steam for varying lengths of time, and then relaxed in steam. If the steaming time in the elongated state was less than 15 min, after 1 hour's relaxation in steam the fibre shrank to a length which was shorter than its original length. Astbury and Woods called this phenomenon supercontraction. In the case of a steaming time of more than 15 min, after relaxation the fibre length was longer than the original length. This phenomenon was termed permanent setting.

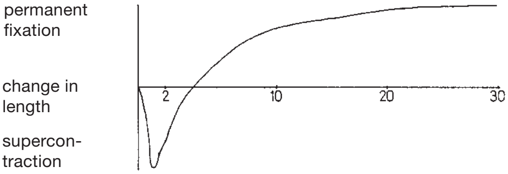

Fig.: The change in length of wool fibres, which have been stretched by 40%, following immersion in steam and subsequent relaxation in steam (according to Astbury and Woods).

Astbury and Woods explained supercontraction and permanent setting as follows: When boiling water or water vapour act on a stretched wool fibre, they quickly break up the links which stabilise the unstretched state, because they are under tension as a result of elongation. If the fibre is relaxed at this stage, then the remaining stabilising links are no longer sufficient to maintain the unstretched state; the fibre contracts to less than its original length. If the steaming time in the elongated state is extended, new crosslinks form, which stabilise the elongated state. With increasing steaming time, the stabilising crosslinks predominate, giving rise to permanent setting. However, Astbury and Woods did not state which crosslinks might be involved in the setting mechanism.

In 1936, J. B. Speakman proposed a theory of the chemical mechanism of wool fixing. Following his experiments, in which he investigated the influence of water, steam, alkalis and reducing agents on the setting of wool fibres, he concluded that the disulphide links are split by the action of steam:

$$R{-}S{-}S{-}R + H_2O \rightarrow R{-}SH + R{-}S{-}OH$$

Through this splitting, the wool fibre becomes capable of being deformed, because stabilising crosslinks between the individual polypeptide chains are eliminated. The setting of the fibre takes place via new stabilising cross-links between the sulphonic acid residue which is formed during splitting, and free amino acids.

Supercritical systems Certain gases such as CO_2 or NH_3 whose normal boiling points lie at low temperatures (e.g. NH_3 at –33.4°C) can, through compression at high pressures (p_k 111 bar, critical density 0.24 g/cm^3 for ammonia), assume relatively low viscosities which are comparable with gases.

In the Fig., pressure p_E, at which liquefaction begins, is the vapour pressure. According to the second law of thermodynamics, the areas above the line CDE and below the line ABC must be equal. If for each isotherm, in each case the points E at the beginning of liquefaction of the gas and the points A for the end of liquefaction are connected to one another, then the result is a range within which a conversion from the gaseous phase to the liquid phase takes place (shaded zone in

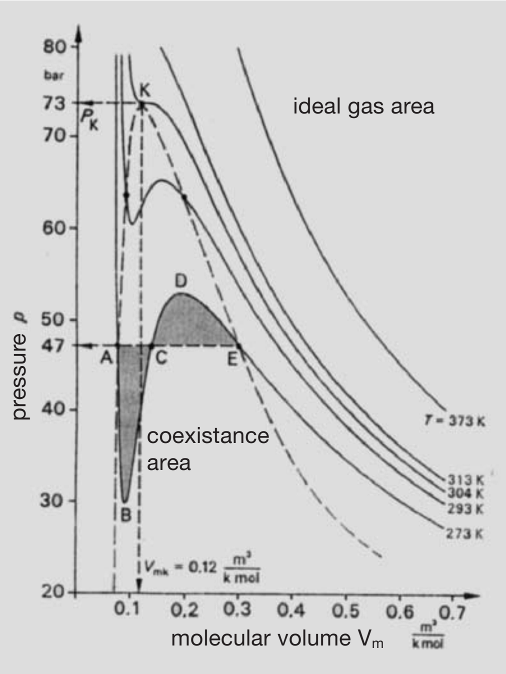

Fig.: Isotherm progressions for carbon dioxide in the p,V diagram.

the Fig.). To the left of this area there is only the liquid phase, and to the right, the gaseous phase. In the coexistence zone, both phases are present. In the case of water, these zones are: superheated steam (pure gaseous state), dry saturated steam (binodal curve) and wet steam (within the liquefaction zone). The highest steam pressure point is the critical point K. The corresponding temperature is the critical temperature T_k. This is the turning point of the corresponding isotherms. The corresponding values are the critical pressure p_k (for CO_2, p_k = 7.38 MPa) and the critical volume V_k (for CO_2, V_{mk} = 0.1275 m^3/kmol). Above point K, liquefaction solely through compression (smaller volume and higher pressure) is not possible.

In the development of environmentally friendly finishing processes in the textile industry, using supercritical carbon dioxide, essentially only the solvent characteristics of the supercritical fluid are exploited (e.g. in the dyeing of polyester with dispersion dyes from supercritical CO_2). However for some applications, for example in pre-treatment, a supercritical system should be chosen which itself has a chemical reactivity. The critical data for ammonia lies in a technologically manageable range, so that it can be used as a reactive and simultaneously solvent medium. One could expect that, for example, with waxes and lignin constituents, ammonolytic reactions could be achieved, which would lead to easily soluble (i.e. extractable) products. Beyond that, structural changes in cellulose towards mercerization effects are conceivable. (according to Schollmeyer).

Superheat Specific heat of → Steam at constant pressure and superheat temperature, less the saturated steam temperature.

Superheated steam → Steam.

Superheated steam dyeing Continuous dyeing of woven cotton fabrics with reactive dyestuffs is normally carried out by either a pad-dry chemical pad steam or pad-dry-thermofix process. In both cases the dye liquor is applied in a pad trough, and the fabric passed through the padder. Infrared driers are used for predrying and hotflues for final drying. Fixation of the reactive dye is then achieved by a second stage of chemical padding or steaming or a further hotflue treatment of thermofixing (Fig. 1). The pad-steam route is a difficult process to control. In both these processes, to ensure high quality dyeing results (level appearance, no side-to-centre shading, no two-sideness), the dyeing dryers or hotflues work with low-intensity air circulation. Drying and thermofixation take place in an air atmosphere.

The Babco-Therm drier developed by Babcock is a superheated-steam drier. It continuously dries and fixes dyed cotton fabrics in 100% superheated-steam atmosphere. As can be seen from Fig. 2, as the fabric enters the drier it is heated to 100°C dew-point temperature within 1 second by condensation of the superheated steam. Unlike air drying, the drying here takes place at this temperature of 100°C. Thanks to the constant

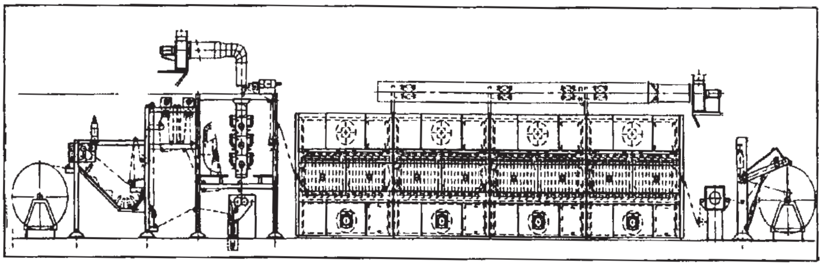

Fig. 1: Conventional pad-dry-thermofix range with infrared drier and hotflue.

Superheated steam in the print steamer

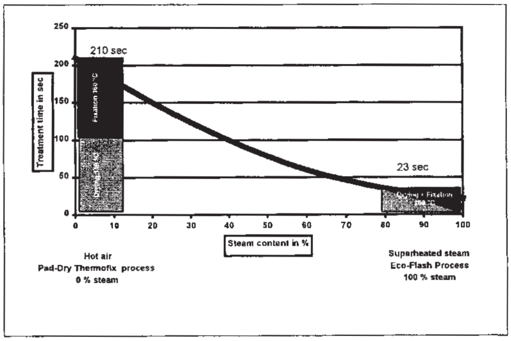

Fig. 3: Correlation between treatment time and steam content.

high temperature of the fabric, dyestuff fixation proceeds so quickly that the process takes place in parallel with the drying process and is completed by the end of the drying process. The correlation between total treatment time and steam content is shown in Fig. 3. Drying and fixation are reduced from 210 s. in air drying with the pad-dry thermofix process to 23 s. in superheated steam drying, the so-called Eco-Flash process. This process (Fig. 4) was developed in co-operation with BASF. The significant reduction in treatment time to around 20 s. as a result of the new process is of great importance for process management, production costs, etc. Special mention must also be made of the reduced tendency to migration.

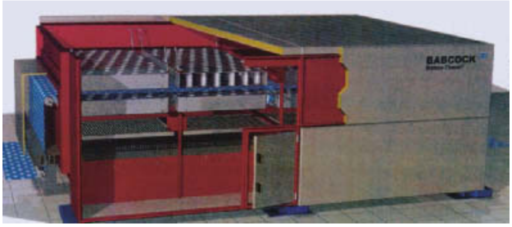

Fig. 4: Inside of the Babco-Therm.

Superheated steam in the print steamer This is 100% water vapour at an atmospheric pressure of 1 bar and a temperature of over 100°C. This steam is not saturated.

In the steamer, the dry and cool goods are heated up rapidly to 100°C through the superheat energy of the steam and the condensation heat which is released.

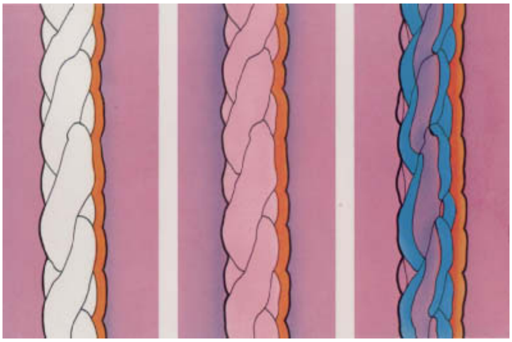

Fig. 1: The warming-up phase: the result of condensation from the steam onto the substrate during its entry into a steamer (by Babcock).

Then the excess condensation evaporates (the evaporation speed is determined by the degree of superheat of the steam), with the temperature remaining constant, until the moisture content of the printed goods has reached an equilibrium with 100 % relative humidity at a temperature of 100°C (Fig. 1). Only then does the temperature rise, with the dampness of the goods decreasing, until the set fixing temperature is reached (Fig. 2). The dampness of the goods is then in equilibrium with the absolute humidity of the setting atmosphere. Once the goods have reached the temperature of the fixing medium, which is rapidly the case under the influence of steam, the setting phase has been reached. No hard and fast boundaries can be drawn between the heating and setting phases. In almost all cases, these two phases will overlap.

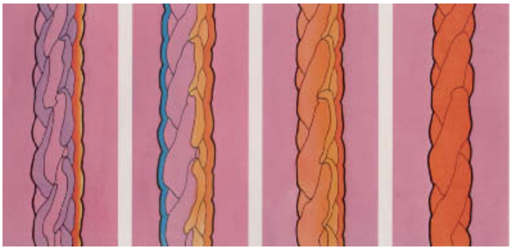

Fig. 2: The fixation phase: both the humidity and the temperature of the goods are in balance with the analogous parameters for the steam (by Babcock).

Superimposed yarn layer Bonded yarn fabrics which are arranged randomly or deliberately.

Supermicrofibres The so-called supermicrofibres are finer than → Microfibres by a power of ten; supermicrofibres are obtained by dissolving out the polyester "islands" in "islands in the sea" technology (see Fig.).

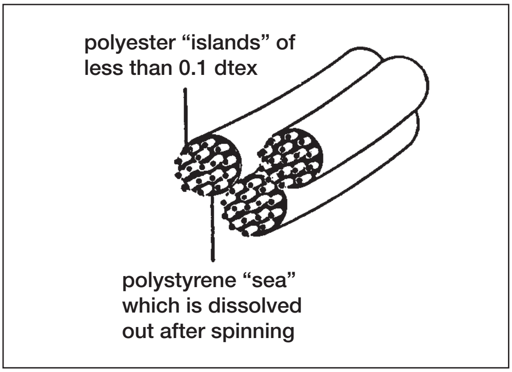

Fig.: "sea island" technology for producing super microfibres (0.1–0.3 dtex).

Superpolyamide fibres Carothers (the inventor of the polyamide 6.6 fibre), used this name to denote all fibre-forming polyamides with a molecular weight over 10 000.

Super-Sat system In the impregnation device developed by Babcock, the reduction of the liquor content is achieved by means of a liquor nip between the goods and the deflecting roller (see Fig.). The liquor is fed into the nip, with sufficient excess and distributed evenly over the width. Through the excess pressure in the liquor, which arises when the goods travel around the deflecting roller, the liquor is forced through the goods. This takes place by guidance of the goods, once from the reverse and once from the right side of the goods. This way, despite the short contact time, intensive liquor exchange is achieved. There is no longer any need for a penetration section following on from impregnation. This in turn enables the combination of the "Super-Sat" system with various steamers as reaction chambers. As a result of the low liquor content and the rapid liquor turnover which results, the goods can flow from the hot pre-wash into the impregnation unit, without cooling. Heating the liquor encourages its penetration into the fibre, but as a result of the rapid liquor renewal, this causes auto-decomposition of the liquor. The fabric can be loaded with liquor to between approx. 100% and its maximum carrying capacity. The amount of liquor carried along can be limited by means of a squeezer mechanism, a laying-on roller or a doctor blade. The excess liquor which is not taken up by the goods in the liquor nips is fed back, by a manually operated or automatic filter, into a small liquor collection vessel, and from here it is pumped back into the unit. Also, the liquor which drips off the goods on the way to the steamer and in the steamer inlet is fed back to the liquor collection vessel. No chemicals are lost. The level in the liquor collection vessel is kept constant through controlled addition of fresh water. The impregnation liquor is mixed and diluted in a mixing vessel through which the fresh water and a partial flow of the recirculated liquor is directed. The desired concentration, related to the weight of goods put through, is achieved by means of a dosing device. Manuf.: Babcock.

Superwash A quality term defined by the International Wool Secretariat (IWS) for wool articles which have been finished to be resistant to machine washing. These articles must fulfil certain conditions in relation to their fastness to light and wetness, relaxation shrinkage and felting shrinkage. Articles which conform to the Superwash standard (Tab.) can be washed in any washing machine at up to 40°C without suffering any impairment to their appearance, handle or dyeing.

In the class of possible care labels (see Fig.), truly felt-free woollen articles are only those which have the term Superwash added to the wool seal.

Superwash process Synthetic resin-based finish for felt-free and low-shrinkage wool articles, which enables the → Superwash standard to be fulfilled. The basis is the IWS-CSIRO chlorine/Hercosett process and the Dylan GRB and GRC processes. In comparison with the oxidative methods, based on synthetic resins a felt-free effect is achieved which was previously unobtainable without impairment of the fibre characteristics (→ Antifelting finish). The designation Superwash ap-

plies to all woollen articles which conform to the IWS machine washing test conditions, regardless of what method was used to achieve the effect. Since the trend is increasingly away from dry cleaning towards washing, Superwash finishing for trousers is gaining in importance.

Suppleness Suppleness is a characteristic property of a material; the opposite characteristic is brittleness. The suppleness resp. brittleness of a material is dependent, among other things, on the transverse strengths of a material. →: Knot breaking strength; Loop breaking strength; Torsional strength. Flexurally limp fabrics are very supple.

Supramolecular structure of polymers Synthetic fibres exist in the glass state and – depending on their previous thermal history and the acute temperature – represent viscoplastic, plastic or highly viscous supercooled melts. Their textile mechanical or dyeing behaviour depends heavily on the supramolecular structure of the polymers, large numbers of which form layers together to form the fibre. There are notional models of the supramolecular structure, which result from various physical-chemical measurement methods. The older notion of the “fringed micelle” has been superseded by the model of chain folding over and the notion of the crystal with statistically distributed imperfections (→ Structural models for man-made fibres).

Fig. 1 shows a schematic 2-dimensional representation of the supramolecular structure of oriented polyester after crystallisation at high and low temperatures (tempered). In principle, the non-crystalline areas are made up of the following types of chains (see Fig. 2): chains which connect the crystallites (t_1, t_2), those with

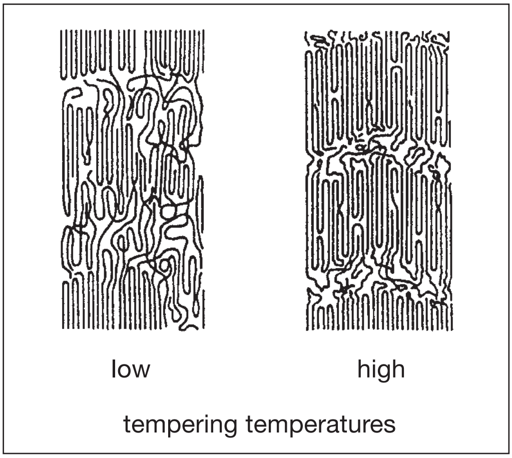

Fig. 1: Schematic illustration of the structure of oriented polyester after crystallisation at different temperatures (according to Fischer and Fakirov).

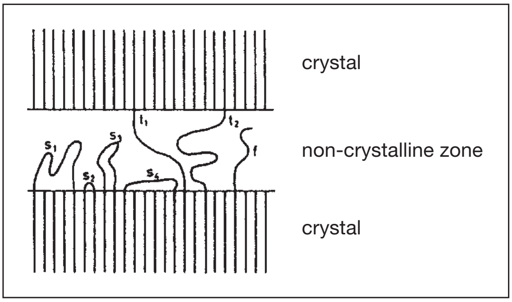

Fig. 2: Schematic illustration of the different chain types of the non-crystalline zone.

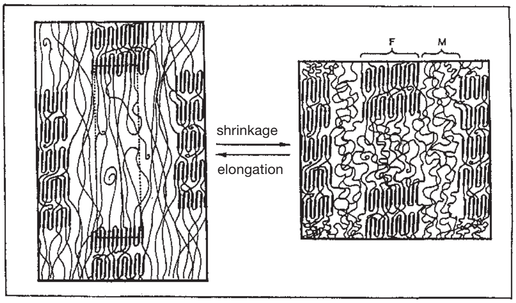

Fig. 3: Model presentation of the structure of synthetic fibres in the stretched and shrunken state (according to Berndt). F = fibrils (molecule chains arranged in crystalline and non-crystalline layers); M = matrix (continuous molecule chains only partially crystallised).

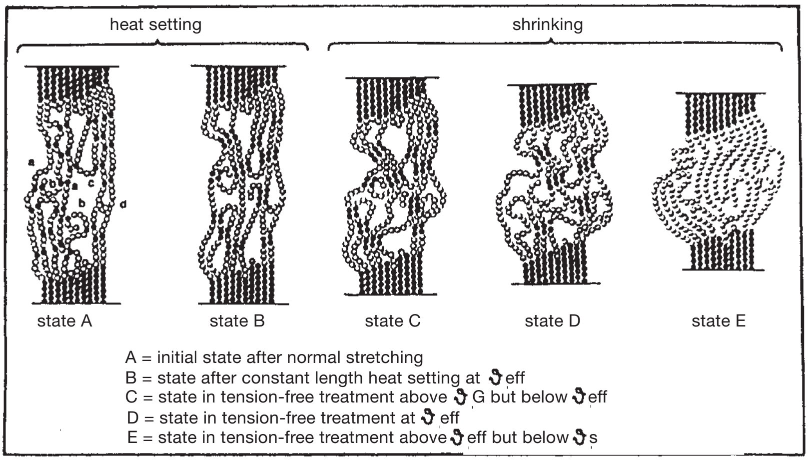
a free end (f) and loops (s_1–s_4), with the borderline case of sharp folds being included.

The fibre structure model shown in Fig. 3 provides a schematic representation of the arrangement of the molecule chains in the fibre interior in the stretched and shrunken state. Since the long period of a fibre, i.e. the main focal distance between the crystal layers, does not change analogously to the fibre in the shrunken state, it must be assumed that for most synthetic fibres, the fibre structure model shown in Fig. 3 applies. According to this, a synthetic fibre can be thought of in structural terms as a matrix (M) with more or less well-ordered molecule chains running in a longitudinal direction, integrated into which are fibrils (F) in which molecule chains run through crystallised and non-crystallised regions in layers. Shrinkage of up to 50%, which can be reversed again by stretching, can be explained by the convolution of chain molecules in the matrix between the fibrils.

Fig. 4 illustrates the synthetic fibre structure in the bead model according to Berndt. The crystalline layers of the fibrils are symbolised in the model by black beads, whilst the white ones represent non-crystalline areas. Directly after fibre manufacture, in general, state A pertains: the molecule chains, which in the melted mass are present in the convoluted state and which is more favourable in terms of energy, are oriented during spinning and stretching. Besides the relatively large and thus stable partially crystallised fibrils, crystallites which are less thermally stable also form in the matrix. Furthermore, the majority of the tensions applied during stretching are blocked by freezing of the chain movement.

State B describes a thermoset fibre after length-constant thermal treatment and cooling. In the case of fixing, generally no uniform crystal size spectrum forms, since the stable crystallites remain preserved and the relatively high cooling speed as well as the tensions acting from outside prevent place-changing processes in the molecule chains, through which distorted crystallites with low thermal stability also arise.

States C to E illustrate the current state of the set



A = initial state after normal stretching
B = state after constant length heat setting at ϑ_{eff}
C = state in tension-free treatment above ϑ_{G} but below ϑ_{eff}
D = state in tension-free treatment at ϑ_{eff}
E = state in tension-free treatment above ϑ_{eff} but below ϑ_{s}

Fig. 4: Model presentation of the change in state of the non-crystalline fibre proportion between the fibrils in heat setting and in thermomechanical analysis (shrinkage measurement) according to Berndt.

specimen (B) in the case of tension-free treatment with successively rising temperature.

State C shows clearly that where the transformation temperature is exceeded, the chain segment movement increases, through which the blocked restoring forces in the molecules are released. The molecule chains aim towards the convoluted state, which is more favourable in terms of energy, and which is associated with place-changing processes for the chain segments, i.e. with material shrinkage. With further temperature increases, these place-changing processes proceed further, until the fibrils and the cross-linkage points formed during setting prevent further shrinkage.

In state D, the crystallites which are initially less thermally stable during further heating are melted open, and the tensions which were blocked are released. The result is renewed shrinkage.

In state E, the heating process is continued with a rate of heating which lies above the speed of crystallisation, through which the thermally more stable cross-linkage points are also dissolved. The material between the fibrils can become disoriented and tend towards optimum convolution. In this state, only the crystalline layers in the fibrils prevent deliquescence of the fibre, which is finally reached after the fibre-specific melting temperature ϑ_s has been reached. (according to Schollmeyer and Berndt).

Surface active compounds Chemical compounds which are dissolved or dispersed in a liquid, and are preferably absorbed at a boundary surface. The molecule of these compounds has at least one group which effects an affinity to surfaces with an expressed polarity, through which the solubility in water is limited, as well as a residue which has little affinity to water. The products which are used in practice are mostly mixtures of such compounds (→ Surfactant).

Just as at the water/air and water/oil interfaces, the surface tension at the water/solids interface also is lowered through the absorption of surfactants which are dissolved in the aqueous phase. The solid/liquid interfacial surface tension cannot be measured directly, but the lowering of it, which is caused by surfactants, is expressed in the effect on wetting (→ Wetting process). Since a wetting process is equivalent to the formation of a solid/liquid interface instead of a solid/gaseous interface, this process is encouraged by a lowering of the solid/liquid interfacial surface tension. In the specific case of a drop of liquid lying on a flat solid surface, this can easily be shown using Young's equation, which places the spontaneously occurring wetting angle in relation to the interfacial tensions which are present in the system (see Fig.).

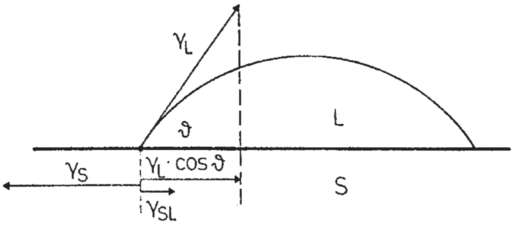


Fig.: Explanation of Young's equation of interfacial tension.

$$\gamma_S - \gamma_{SL} = \gamma_L \cos \vartheta$$

γ_S and γ_L are the surface tension of the solid S or the liquid L, whilst γ_{SL} stands for the interfacial surface tension between S and L. If the liquid is water and a surfactant is dissolved in it, then γ_L and γ_{SL} are lowered by the adsorption of the same, whilst γ_S remains unaffected. From the equation, it can be seen that the wetting angle thus becomes smaller. This can lead to the situation where $\vartheta = 0$, and the liquid thus spontaneously spreads over the surface.

Surface active detergent Within a detergent or washing powder, the pure organically active components: → Detergent raw materials or → Soap (→ Surfactant). The proportion of a surface active ingredient is given in %; e.g. 30% pure alkyl-aryl-sulphonate or alkyl-sulphonate or aliphatic alcohol sulphonate, etc. Although the presence of surface active ingredients plays an important part in the effectiveness of → Detergent it would be a mistake to judge a detergent in practical or even theoretical terms according to this aspect alone. Significant differences exist between surface active ingredients derived from the same group of substrates. Further, the mixing of surface active ingredients may result in a synergistic improvement in the washing performance of the individual components, or conversely a decline in the washing performance. Finally, other components (→ Builders) in particular may produce an improvement in performance. Objectively conducted washing or cleaning investigation with → Soiling test is decisive in arriving at a comparative assessment of value.

Surface activity Characteristic of → Surfactant, which occurs at the interfaces of two phases. → Capillary activity.

Surface analysis Strictly speaking, the surfaces of textiles represent 3-dimensional formations, with a thickness of a few nm, which is sufficient for accommodating a few molecular layers. This surface also determines a range of characteristics such as wettability, adhesion, diffusion, bio-compatibility and optical characteristics such as lustre. Analytical methods exist for characterising these surfaces. → Photometer microscopy allows the analysis of fibre surfaces and fibre cross sections, and the detection of dyed or fluorescent substances on these surfaces, or of materials marked with fluorescent dyes. Thus the evenness of the distribution of polymer UV absorbers on the surface, or of polymer coating add-ons for wool with a Superwash finish can be analysed, just as the silicone or fluorohydrocarbon coating add-ons can. For measuring the size of the specific surface of materials, there is the Brunauer, Emett and Teller nitrogen absorption/desorption method, which also provides information about pore size distribution, e.g. depending on the pretreatment of the material. The → Scanning Electron Microscope permits visualisation of the surface, with high depth of field, and quite specifically permits determination of the scale edge height of keratin fibres. With the addition of energy-dispersive → X-ray fluorescence, electron microscopy also allows the detection of elements such as sulphur and chlorine, but also of heavy metals such as chromium on the surface. → Infrared spectroscopy, which provides detailed information on the chemical structure of compounds, can be carried out in a surface-sensitive technique, that of attenuated total reflectance. Thus in particular the effect of a bleach on wool fibre can be tracked kinetically. Using polarised infra-red radiation, information about the orientation of macromolecules in thin layers can be obtained. The method with the least depth of information is → X-ray photoelectron spectroscopy. It allows tracking of the decomposition of fatty acids bound in an ester-like manner on the surface of the wool, as well as the UV damage to the surface of the wool through the effects of weather, and the modification of the surface of the wool in the case of chlorine treatment compared with corona treatment. → Spectroscopy.

Surface batcher,

I. Used for the production of → Giant batch rolls, the drive for which operates tangentially at the periphery of the winding machine and thus, regardless of the size of the yarn package, ensures the same speed and tension of goods.

II. Winding device with the drawing roller, held in two swing arms, rising with increasing diameter of the yarn package. → Batching drives.

Surface energy, free Work which needs to be performed in order to structure the surface of a liquid isothermically or reversibly, or to enlarge it. The result is in the form of an increase in the free energy of the system. Expressed in joules. → Surface tension.

Surface finishing The fundamental construction of the handle and quality of fabrics is effected by working methods in wet finishing which are adapted to the type of goods. Dry finishing tasks, on the other hand, have to develop further the effects created by wet finishing, and complete them. It is only through the combination of wet and dry finishing that aspects (appearance and handle) and wearability of the finished goods are ensured. Although the operational sequence in dry finishing for achieving “needle readiness” of e.g. wool is fairly firmly associated with “shearing, pressing, shrinking, decatizing”, at least with the bare-finished worsted goods, which are important in terms of quantity, and gives rise to continuous line concepts, fashion influences nevertheless demand new process steps or other sequences in dry finishing. The goods can come into contact with dry finishing not just at the end of textile finishing; in pretreatment too, special surface finishing steps such as singeing, emerizing, brushing or roughening can be applied to the dry or wet goods, in order to shape the quality.

If one disregards singeing for the moment, then all aspects in the surface finishing of woven fabrics are achieved by means of mechanical influences on the fibres. If the results of shearing and roughening are perceived mainly by touch, then human beings register aspects which come about through pile rotation (lustre) or friezing primarily visually. If the skin is a sense organ for perceiving complex sensations such as the handle of goods, then when inspecting the surface, the eye perceives a certain surface with the aid of its two-dimensional matrix of light-sensitive elements. Through an irregular displacement of this area over the entire surface in rapid sequence, there arises in the optic nerve an assessment, based on comparison, of the evenness or unevenness of the surface of the textile. Here, the optic nerve acts as a complex computer, which can record certain structural features at high speed, and which conveys to the conscious mind strongly reduced data such as “matt, glossy, silky, sandy, grainy, rough, smooth, level, unsettled, with islands”, as designations for aspects. These visual perceptions are supplemented by the aspects perceived in a tactile manner by the skin (and possibly acoustically by the ears), such as “hard, soft, full, thin, limp, wiry”, etc., to form impressions of the goods, which are principally brought about by surface finishing. The fact that in the literature concerning finishing machines and processes no uniform sequence is to be found, is connected with the fact that individual work sequences (dry and wet treatments) overlap one another in multiple ways. The fabric, which is often used as a “guide” for arranging the treatment steps, sometimes passes through the same machine several times in different stages of its manufacture (e.g. in wet or dry roughening). The DIN 61 704 specification has therefore been proposed as a classification principle. In the case of the processes of providing aspects, which include e.g., wet brushing, this type of classification can result in problems. In the systematization of the finishing processes for woven fabric, the concept of surface finishing with mechanical means is therefore used only in the processing of dry goods (singeing, shearing, brushing, roughening, emerizing, pile rotation, friezing) (Fig. 1), whilst wet roughening and wet brushing are classified under fixing processes, since the inevitable drying process is important for the preservation (fixing) of the finishing effect of this fixing process.

Surface finishing

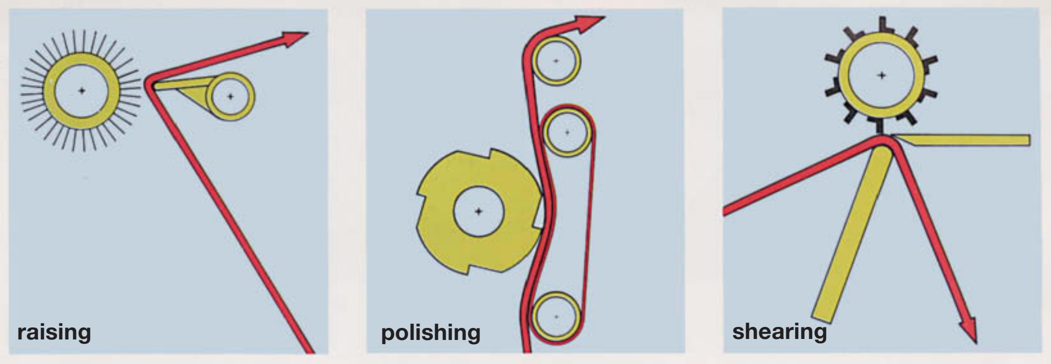

Fig. 1: A comparison of the processes for finishing surfaces by raising, rotary polishing and shearing (by SMH).

In the case of shearing, pile rotation and singeing, these are separation processes of individual fibres, whose countless macromolecules are split or slide past one another by the action of external mechanical forces and/or heat. In the case of a knife cut, the wedge surface of a blade forces the material "fibre" apart, as happens in practice e.g. when pile tubes, which are formed by the pile weft during weaving, are cut open to produce corduroy (Fig. 2). In the shearing cut, two blades are used, which move relative to one another (i.e. in absolute terms, one blade can be stationary). Shearing forces bring about the separation of the fibre material which is to be processed, with frictional energy occurring in the form of heat. In shearing, there is a separation into processed work piece and waste, through the flow of the material. In this way, the result is either a shortening of the projecting fibre pile of a woven fabric, or – in the case of improper work – a splicing of the fibres lying in the direction of the force which is applied. The situation for pile rotation is similar. With the aid of grooves which are milled into a rotating heated cylinder, fibres which rest tangentially on the pile rotor along their fibre axis, are very often caught, and therefore split and flattened (Fig. 3). This mechanical "flattening" of the surface of the woven fabric causes higher light reflectance, and thus lustre.

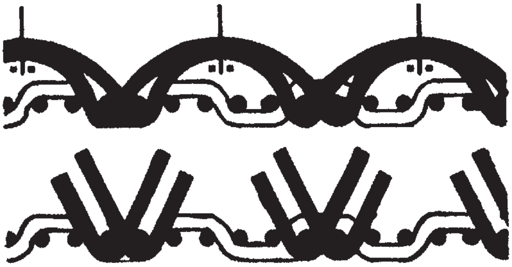

Fig. 2: Corduroy with V-ties.
above = not cut open; below = cut open.

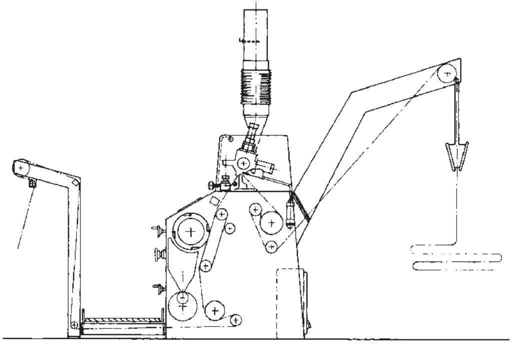

Fig. 3: A Sellers polishing and shearing machine.

Since fibres naturally burn relatively poorly, for singeing off fibre ends which project from the surface, high ignition temperatures have to be used, in the form of an open flame. On ignition, there is then briefly a chemical equilibrium between combustion (exothermal oxidation with flame formation through ignition of the gases which have occurred in the fibre interior through pyrolysis) on the fibre surface, and endothermic decomposition of the fibre substance (pyrolysis) in the fibre interior. In order to keep the flame out of the fabric body and restrict it to the projecting fibre ends, air has to be blown through the fabric against the flame, on account of the necessary high temperature. One can thus state: surface finishing of woven fabrics can be effected by mechanical means and/or by heat (Tab.).

One method of structuring the surface of the woven fabric is screen shearing, where a rotary screen with apertures left open rolls over the textile fabric like a rotary printing roller, and the parts which are not pressed down are shorn more or less heavily. The use of brushes opens up an almost unlimited field of effects which can be achieved. Brushing can be rotating,

finishing process	the effect of heat	the effect of mechanics

shearing	+	++
rotary polishing	+	+
singeing	++	–

Tab.: The effect of heat and/or mechanics during surface finishing.

changeable, on the spot, anti-clockwise and clockwise, acting jointly or alternately, and also with or without a screen, with rotation and belt brushes being used. Brushing can be with the nap or against the nap, and optionally also in the warp or weft direction. The numerous furnishing fabrics with patterns in different pile positions, as well as the endless diversity of fake furs, in combination with the variables of the fibres and colorations used, yield goods whose final appearance – once processed – are hard even for an expert to distinguish from natural fur.

In contrast to embossing on an embossing calender, where work is carried out with a heated roller, the embossing of pile articles is in accordance with a different scheme. The goods being treated are heated with an infra-red field on the pile side, to a temperature which makes deformation of the pile possible, and are then structured under pressure with a cold embossing shell. The pattern which is thus obtained has affected only the pile, and left the back of the goods in its original state. The goods remain soft and flowing. A prerequisite for this process is the use of pile fibres which permit plasticisation. Included in the field of suede embossing are the silk finish embossings or crêpe patternings. For silk finish embossing, the steel roller is given the finest flutings at a certain angle to the warp or weft thread. On the fabric, the embossing of the finest lines yields a refraction of light which lends the goods a silk-like lustre. A polyamide fabric or product, for example, only becomes usable for underwear in the first place with a silk finishing roller and a corresponding temperature. The transparency of the fabric is lowered and at the same time the handle is improved. The term “chintzing” is used for making something glossy. In the original sense, the gloss effect on the fabric was achieved through the friction of a steel roller against a flexible roller, e.g. cotton or paper roller. Since the introduction of polyamide roller casings as a counter roller for a steel roller, through the use of corresponding temperatures and contact pressures an effect is achieved which is similar to chintz, with a corresponding compression of the goods.

Recently an important finishing process has made its mark, which – in accordance with the effect achieved – is called “peach skin finish”. This is a soft, pliable and velvety effect, e.g. on the following fibre materials: for pure cotton and for the blends polyester/cotton, polyester/viscose, polyamide, polyamide/cotton, polyamide/viscose, wool and blends of polyester/wool. The mechanical effect is achieved through emerizing. On cotton articles and denim, a soft handle and the desired suppleness can be achieved through processes in which the weight of the product is reduced. This process includes the action of cellulose enzymes (stoneless stone-washing process), or the enzymatic decomposition in accordance with the Knit-Elle-es process from the firm Shikibo, in which a smaller loss of strength is noted. In the case of textiles produced from polyester fibres, the aforementioned effect can be achieved through controlled hydrolysis of the surface, on the basis of a treatment with alkaline solutions. Besides the better handle, strength is reduced, the pilling tendency is likewise reduced, and the wetting capability is increased to some extent (alkalisation).

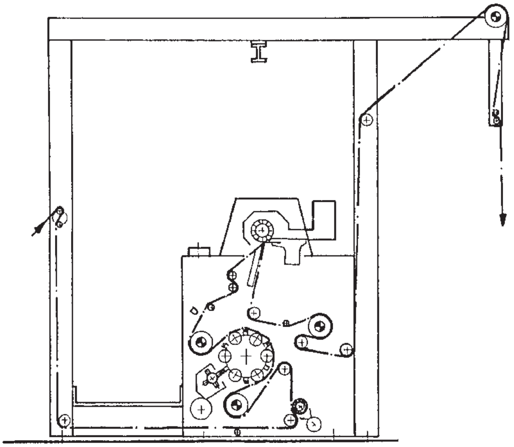

Fig. 4: The combination of central cylinder raising and shearing in a Sistig-Menschner raise-and-shear unit.

Also popular among users are warp-knitted velvets of viscose, acetate or triacetate, which can be printed after emerizing or roughening (Fig. 4), shearing and thermosetting; embossing effects on the surface of the goods can also be achieved through goffering or calenders. Crêpe effects on cotton textiles are already known from the nineteenth century; on textiles made of synthetic fibres, similar effects can be achieved through the application of strongly swelling chemicals, e.g. phenol-based. For textiles made of synthetic fibres, predominantly mechanical methods are employed. Embossalon is the name for a goffered warp knit fabric manufactured from polyamide; in appearance, it resembles fabrics (satin and crêpe) of textured filament yarns. A flat surface is usually achieved through calenders.

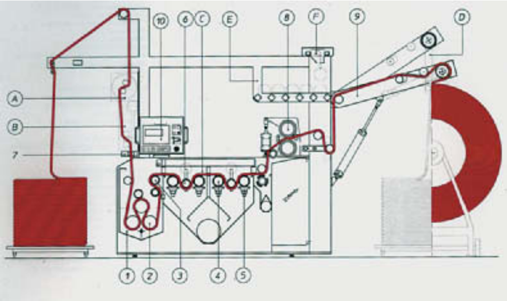

Fig. 5: Wet suèding (Sperotto Rimar, Plurima). Composition of the machine: 1 = impregnation tank; 2 = drawing rollers; 3 = tension control device; 4 = suèding rollers; 5 = tanks for the dipping of the suèding rollers; 6 = penetrating rollers; 7 = automatic seam detector; 8 = squeezing unit; 9 = fabric delivery and collecting unit; 10 = control panel. Optional devices: A = double fabric spreader positioned on the inlet side; B = centering device positioned on the inlet side; C = oscillating transverse motion of the suèding rollers; D = fixed-length flat and variable length "A" frame plaiter (it can be combined with the batcher); E = spare suèding rollers complete with relevant roller holder suitable for storage; F = hoisting unit for the rapid replacement of the suèding rollers.

A range of surface effects is achieved through special printing pastes which foam up under the action of temperature, through printing with delustring products, possibly in combination with a high-lustre surface. Through printing with special resins and hydrophobic products, chintz or crêpe effects with colour nuances and the like are achieved. Textiles which are patterned with a metal film are regularly in demand. This film is applied to the textile with a technology similar to thermoprinting. An appearance similar to brocade can be achieved in e.g. knit fabrics with a relief-like surface, in that a metal film is fixed only on the thread sections projecting upwards. Technologies with which one can achieve a crumpled or broken visual appearance on woven fabrics of synthetic and natural fibres are widespread. The term "crash" is used to refer to textile fabrics which have marked folds or break surfaces, with these being less parallel and more or less running in the warp direction. For the so-called "crinkle" effect on woven fabrics of synthetic fibres, an unsettled "rumpled" appearance without marked fold breaks is characteristic. This effect is achieved on various types, from mechanical, repeated wrinkling with steam by means of a so-called "cannon", down to processing in a hank dyeing machine under specific conditions. Woven fabrics with a crinkle finish, manufactured from polyester microfibres, are particularly sought-after for sports clothing. Very soft handle can be achieved by wet suèding (Fig. 5) (according to Schiffer and Rothova, as well as Kittan).

Surface fluoridation For increasing the substrate adhesion in manufacturing processes such as gluing, coating, laminating, lacquering and printing. Adhesion depends on various factors, above all on the polar nature of the surface, which enables mechanical bonds. For this reason, polymer materials are treated with oxidation processes, which are divided into corona discharge, low-pressure plasma and chemical processes. All methods have more or less disadvantages. Chemical methods have proved their worth only in tightly circumscribed applications (e.g. liquid mordants), or else they require a high expenditure on monitoring and maintenance (such as ozone treatment). Low-pressure plasma technology is characterised by a complex combination of vacuum, high frequency and gas technology, which comes down to careful training of plant operators. The continuous plasma pre-treatment of runs of materials has not yet been sufficiently investigated. Depending on the condition of the run of material (above all in the case of thicknesses > 1 mm, or with higher porosity), corona pre-treatment is very susceptible to faults. In the area of the dielectric, fires frequently occur, which bring with them short circuits in the pre-treatment station. Furthermore, only one side of the run of material can be activated by the corona discharge. Often, the desired high surface energy is not achieved.

Another pretreatment method is continuous surface fluoridation of runs of materials (see Fig.). The surface of textile runs is briefly exposed to elemental fluorine, diluted by an inert gas, in a continuous process in a reaction chamber suitable for the process. The parameters of contact time and fluorine concentration influence the surface energy of the textile. The surface effect which can be achieved additionally depends on the chemical condition of the fibres. Due to the high reactivity of the element fluorine, all textiles which consist of polymer fibres and which have substitutable hydrogen atoms can be activated with fluorine. Through this, the surface energy of the textile material is raised in such a way that excellent adhesion to other polymers (e.g., printing dye pastes, adhesives) is achieved. What is decisive for this effect is the extremely high oxidation potential of fluorine, which can develop extremely effectively even when heavily diluted. The polymer surfaces are permanently atomically changed, with the hydrophilic nature rising up to non-wettability with

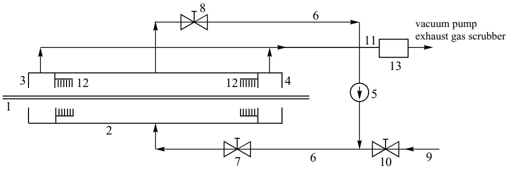

Fig.: Sketch showing the principle of a system for double sided surface fluoridation.

water. The intensity is comparable only with that of plasma gas. The high reactivity is explained by the interaction of the low dissociation energy of the fluorine molecule and the very strong bonds which fluorine achieves with other atoms. Furthermore, the fluorine atom is relatively small, so that the spatial relations in compounds of fluorine permit high co-ordination numbers of the respective central atom. The fact that this fluoridation technique is feasible on an industrial scale is due to the astonishing development in chemical engineering over the last 20 years, which enabled fluorine to become, not just an important starting material, but even a great technical event. However, to categorise fluorine as "hazardous" reflects a widespread prejudice which arises from lack of knowledge about this chemical element. No mention is made of the hazardous nature of the ozone which is released in the corona pretreatment, for which, incidentally the same maximum threshold limit value in air (0.1 ppm) has been set as for fluorine or hydrogen fluoride. But ozone (as animal experiments have shown), is far more toxic than fluorine or hydrogen fluoride. Since fluorine makes its presence felt well below the permitted limit concentration of 0.1 ppm in the ambient air, through its intense, characteristic smell (reminiscent of heavily chlorinated water), there are no references to incidents of poisoning in relevant literature.

The fluorine, which is purchased in steel pressure bottles, is diluted in a corresponding extraction and dosing device with inert gas (nitrogen, inert gas or compressed air) to a certain concentration. This fluorine /inert gas mixture is supplied to the system via the line (9). After the reaction chamber (2) has been filled with diluted fluorine, the mixture of fluorine and inert gas is circulated through the reaction chamber (2) by means of the pump (5) via the line (6) and the two shut-off valves (7, 8). The textile goods which are to be subjected to surface pre-treatment are fed into the chamber (2) via the entry air lock (3), and leave it via the exit air lock (4). Via the line (11), the air locks (3, 4) are kept at low pressure, via an intermediate catalyst (13) followed by a vacuum pump with a connected gas scrubber, in such a way that neither fluorine nor hydrogen fluoride can get into the ambient air. The flow resistors (12) which are placed upstream of the airlocks also contribute to this (9 = fluorine gas supply; 1 = fabric; 10 = dosing valve) (according to Milker and Koch).

Surface hairs → Kemp.

Surface lacquering Surface lacquering of membrane materials is a measure for extending life; it extends the service life of stationary membrane roofs to 15–20 years, depending on the place and manner in which they are deployed, and also has a positive influence on the visual aspects and the cleaning behaviour. Compared with the overall thickness of the material, the lacquer layer consists only of a thin skin of approx. 4–20 µm (see Fig.), and as a rule is constructed of polyacrylates. Advantages:

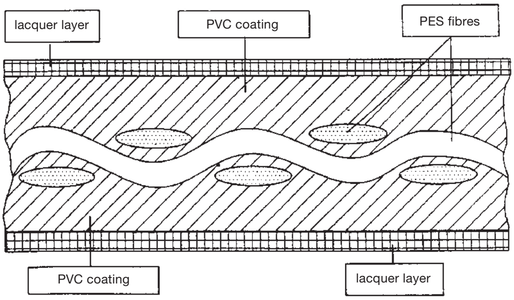

Fig.: Diagram of the structure of a membrane material with surface lacquering.

- protection of the membrane from environmental effects,
- improvement of the dirt-repellent effect,
- protection of the PVC mass against losses of formulation constituents, such as softeners,
- good scratch resistance of the surface,
- good high frequency heat-sealing properties,
- good temperature stability of –30° to +80°C,
- good adhesion on PVC coating.

Surface modification of fibres Due to their great variability, physical processes are increasingly opening up possibilities for specific modification of surface characteristics. For technical textiles in particular, such techniques can be of great interest, since through UV laser radiation, plasma modification and plasma polymerisation, adhesive, adsorptive, biological and visual fibre characteristics can be influenced or achieved (→: Plasma treatment; Corona treatment). In laboratory trials, methods using radiation with → Lasers have proved their suitability, and in principle have the advantage over plasma technology that they are simpler in terms of equipment, and more variable. Treatments of fibre material using UV lasers result mainly in morphological modifications, besides a few examples of laser-chemical treatments (graft co-polymerization). On the other hand, CO_2 lasers in the infra-red spectral range represent powerful systems, suitable for industry, which in commercially available forms are suitable for heat treatment of textile fibre materials; pure surface treatments and surface modifications have not yet been achieved, due to the low absorption of the polymers at the laser wavelength. All important fibre substances and many reactive substances, however, have strong absorption bands in the spectral range of 3–10 µm, e.g. polyethylene terephthalate is highly absorbent at 9.7 µm. One possibility for making use of these absorption characteristics is seen in the emission spectrum of CO_2 lasers: CO_2 lasers have two broad emission bands in the range of 9–11 µm (in the interests of a high performance yield, commercial lasers are adjusted to 10.6 µm), which are technically variable through corresponding modification of the laser resonator. In this case, one may anticipate considerably higher absorption of the optical energy by the fibre substance or by reactive substances. On this basis, three possibilities for deliberate surface modification are conceivable:

1. Through optical activation of the substrate surface, for example, there is the possibility of a laser-induced deposition of reactive substances with specific desirable characteristics, from a gaseous or liquid environment.
2. With a corresponding adaptation in the infra-red spectral range, it is conceivable to achieve depositions of surface-active media through activation of reactive gases.
3. In conjunction with a pulsed operation of the laser, one can reckon on morphological surface modifications, similar to known effects which are achieved with UV lasers. (according to Schollmeyer).

Surface phenomena of fibres for composites The interactions between reinforcing material (high-modulus fibres) and polymer matrix (ductile with high fracture toughness) determine to a large extent the processing and end characteristics of the resulting composite material. Interfacial or boundary layer characteristics are due on the one hand to morphological parameters (e.g. specific surface of the reinforcement material, coarseness), and on the other hand to the nature and size of the interacting forces originating from the components. Deliberate influencing of the boundary layer characteristics via the interacting forces presupposes the allocation of the nature and size of the interaction to the chemical and physical structure of the components. The significant role of boundary layer characteristics in relation to the manufacture of composite materials and characteristics is shown in Fig. 1. Here, the considerations start from the basis of a three-phase model, of reinforcement material/boundary layer/matrix. In this model, the interaction is achieved on the one hand via adhesion processes (or chemical reactions) at the interface between the fibre and the boundary layer, and on the other hand via the mutual influence of the boundary layer/matrix [e.g. hydrophobic interaction, diffusion processes, formation of quasi-IPN (inter-penetrating polymer networks)].The model thus follows theoretical concepts, according to which a high composite material strength presupposes a strong adhesion to the reinforcement material/boundary layer and boundary layer/matrix interfaces. It should be possible to influence the fracture toughness of composite materials with ductile matrices and high-modulus intercalation components through boundary layers whose modulus of elasticity lies below that of the matrix.

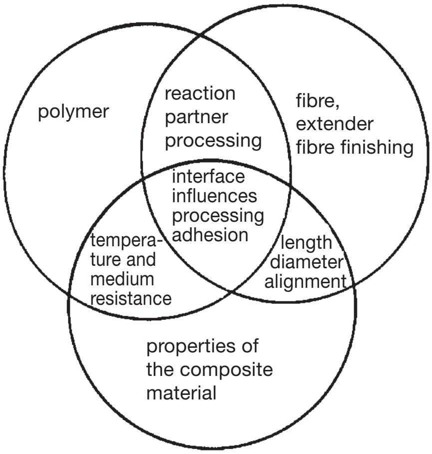

Fig. 1: The effect of influences operating at the interface on processing properties and composite properties.

The attempt to implement this concept takes account of the influence of surface parameters of the reinforcement materials on boundary layer characteristics. Targeted alteration of the surface characteristics of reinforcement materials can be effected through suitable modification (microscopic characteristics), influencing the characteristics of the boundary layer through compatibility mediators and modified binders (mesoscopic quantities), matrix modifications and their correlation to macroscopic composite material characteristics. Physical-mechanical modelling of interacting forces is currently under development. The multi-component systems which are to be investigated are difficult to access. In order nevertheless to make the composite material characteristics accessible to scientific investigation, it is necessary to work with approximation methods which are not completely secure.

Above all, electrostatic interactions at solids boundary surfaces are accorded importance for adhesion, as the effective surface forces of polymers which come into contact. For this, the presence of a potential difference at the phase boundary is necessary. The energy of corresponding interactions is due e.g., to the acidity or basicity of the components involved.

$$\mathrm{MOH} + \mathrm{HXR} \rightleftharpoons \mathrm{MOH_2^+} + \mathrm{XR^-}$$

$$\mathrm{MOH} + \mathrm{YR} \rightleftharpoons \mathrm{MO^-} + \mathrm{YHR^+}$$

MOH = inorganic oxide or hydroxide
HXR = organic acid
YR = organic base

According to the Lewis theory, in the event of contact between electron acceptors and electron donators, an electron migration takes place, which leads to electrostatic interaction between the partners. In the case of adsorption of surface-active substances from aqueous

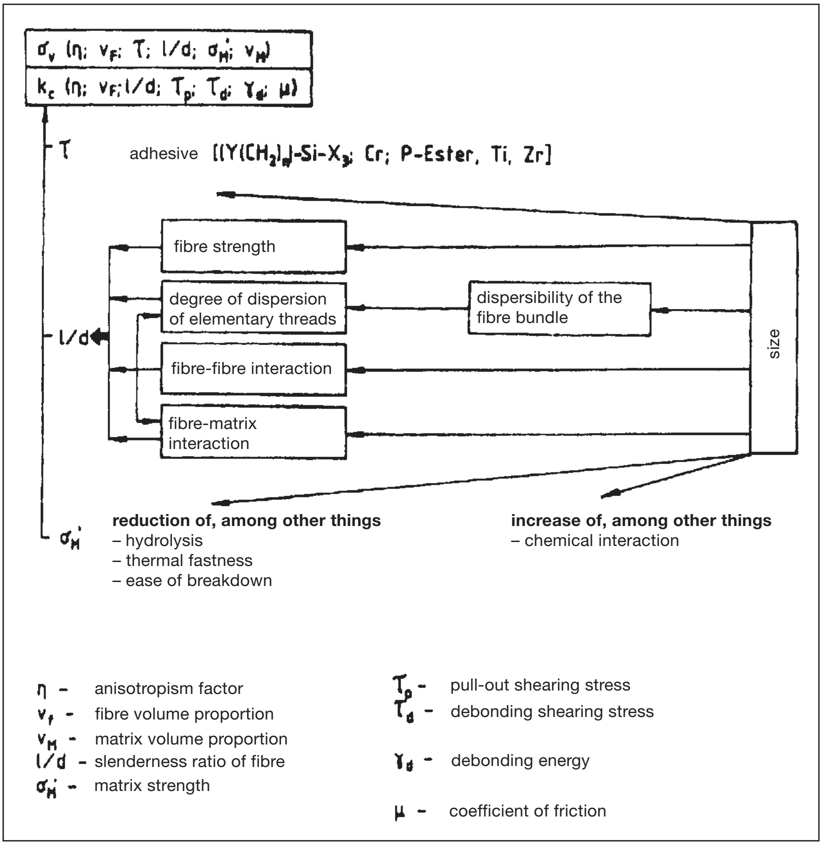

Fig. 2: The influence of the size on the properties of fibre and composite.

media onto polymers or reinforcement materials, interactions play a role in which the decrease in free enthalpy is based on entropic effects. This entropic effect is attributable to the fact that in the immediate surroundings of polar molecule groups, there are water structures with a higher order than in pure water. Since under normal conditions, reinforcement materials retain adsorbed water in a swell layer in their surface, the presence of surfactants is associated with an influence on these hydrophobic interactions. Wetting measurements and electrokinetic measurements (zeta potential) can be applied for surface characterisation.

The surface modification of reinforcement materials must fulfil two tasks:

1. First and foremost, modification is necessary in order to enable textile processability of the fibre substances. Thus in general it is necessary to apply gliding agents and binders, as well as anti-static agents.
2. In composite material, modification represents the connecting link between fibre and matrix. It thus influences the working of fibres into the matrix (wetting, dispersion, fibre disintegration), the fibre/matrix interaction via adhesion agents, as well as – in some cases – the matrix characteristics themselves.

For this reason, each sizing agent and/or each finish represents a system (Fig. 2), which consists of at least, adhesive media, gliding agents, binders and film formers, and which must be optimised in accordance with the complex profile of requirements. With the amounts of these substances which are usually applied, the result is modification layer thicknesses of the order of 100–500 nm. This layer thickness can no longer be neglected in a real composite material.

To achieve fibre/matrix adhesion, hydrosilicons are used as reinforcement materials. Fig. 3 shows the primary reactions which take place. First of all, hydrolysis of the trialkoxy groups takes place. The hydrosilicon groups formed react with the glass surface via hydrogen links, and then form covalent bonds. The second function (–Y) of the hydrosilicon must be selected such that a strong interaction with binder and matrix, and thus a mutual penetration, is possible. The resulting boundary layer with chemi- and physio-sorbed hydrosilicon and an interdiffusion layer is shown schematically in Fig. 4.

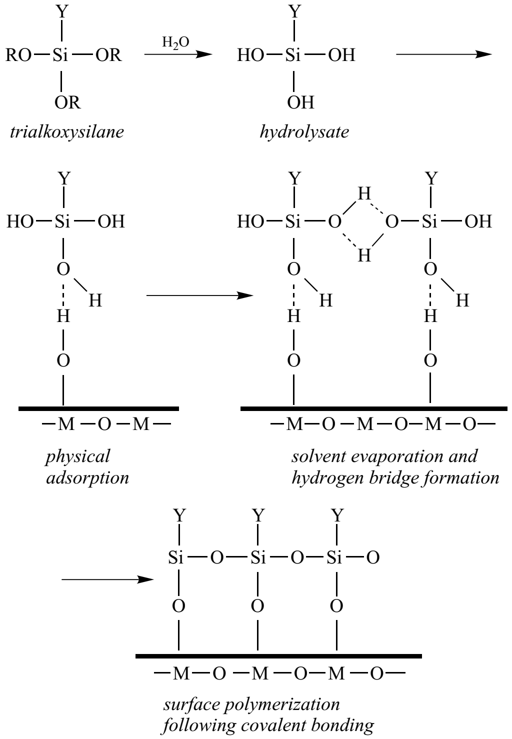

Fig. 3: The binding of silane adhesives to mineral surfaces.

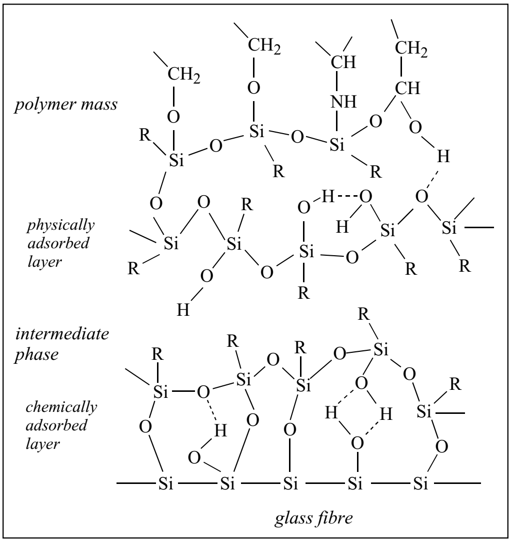

Fig. 4: Structure of the interface between fibre and polymer. (left) = description of layer; (right) = chemical structure (diagram).

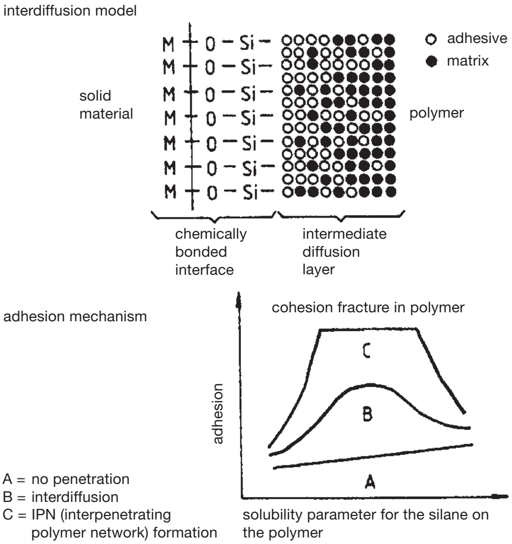

Fig. 5: Model of interdiffusion and mechanisms of adhesion.

In this concept, Fig. 5 shows the connection of adhesion and the solubility parameters of sizing agent and polymer matrix. It is clear that good adhesion is achieved through interdiffusion or the formation of quasi-IPNs. Interaction, interdiffusion and IPN formation are influenced by the structure of the adhesion agent. (according to Jacobasch).

Surface potentials The properties of the fibre and soil during washing (greying) determine the surface potentials of fibres, which are dependent on the medium used.

In tetrachloroethylene, the negative surface potential becomes greater as the concentration of anionic dry-cleaning detergents increases (Fig. 1, RV.OR I). However, when the fabric‘s greying behaviour is interpreted, it must be taken into account that dry-cleaning

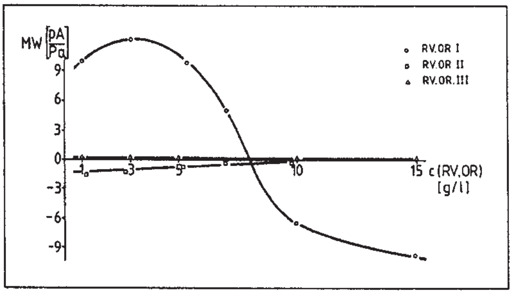

Fig. 1: Measured surface potential values for cotton in tetrachloroethylene in relation to the type and concentration of the dry-cleaning detergent (RV.OR I and II are anionically active, RV.OR III is cationically active).

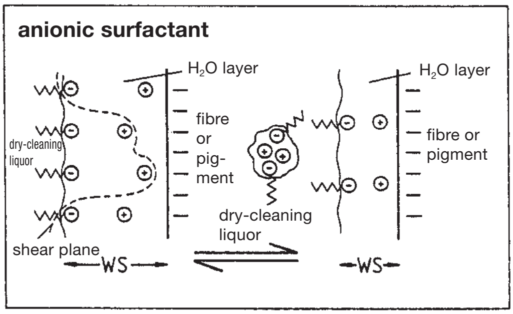

Fig. 2: Proposed model of the structure of surface charge in the adsorption layer (WS) of water at the fibre surface and its shearing due to dry-cleaning mechanics.

liquor also contains small quantities of water, which could exert an influence on the surface potential (Fig. 2). This can lead to the surface potential deviating from the expected values (Fig. 1, RV.OR II and III).

Surface print Prints with a greater colour intensity resulting from the concentration of dye printed onto the fibre surface. This effect is achieved by using suitable thickeners, which should be in combination with semi-emulsions if reactive dyes are used. For any other type of dye, thickener combinations containing starch should be used.

Surface printing machine The pattern is printed by means of raised relief-type printing elements. In contrast to → Roller printing machines, the surface printing machine can print all wovens using the same rollers. The only difference is that print paste application to the print rollers is varied with a paste application device. In addition to this, a surface printing machine requires less pressure than a roller printing machine. Up to eight dyes can be used. The main components of the machine are: printing cylinder, lift lever for printing cylinder, print rollers, colour box for dye pastes, and felt for paste transfer (dye cloth). Hollow cylinders with the pattern in relief (raised) are used as print rollers. Relief printing technology is not important in the textile printing industry any longer; however it is still used frequently for printing wallpaper. The same principle is also used for carpet printing machines.

Surface, specific This term is applied to fibres, and is used to define dyeing properties, for instance. The surface of crystallites in polyamides or polyurethane (see Fig.) to which test dyes (e.g. acid dyes with certain chemical structures) can be applied.

Surface temperature measuring instruments,

Surface tension,

I. The tension present at different interfaces (soil/wash liquor, fibre/soil, fibre/dyeing liquor, water/benzine), which is as a force acting against the wetting/penetration process. This could be the surface strength of a water droplet, which causes cohesion and prevents it from breaking up. Another example is penetration of air bonded to the fibre capillary into the fibre surface (for 1 g of cotton cellulose approx. 5000 m^2). A high level of surface tension at the interface therefore causes poor wetting. The wetting/penetration properties are increased proportionally as a result of the surface, interface and capillary-active products counteracting the tension. Interfacial tension is defined as the force per linear unit resulting from free interfacial energy, which is numerically equal to free interfacial energy/interfacial unit, expressed in N/m or mN/m. It is measured using →: Electrokinetic interface potential; Interfacial tensiometer.

The interface tension can be lowered in some substances using sodium oleate solution, soap (30.4 g/l at 22°C), etc. a) compared with water; b) compared with soap in mN/m:

air	a) 72.4; b) 30.4
chloroform	a) 29.4; b) 2.09
carbon tetrachloride	a) 43.4; b) 1.64

Lowering of surface tension at interface (in mN/m) and wetting angle of:

1. Ceresin/water using the following additives:

solution	wetting angle	surface tension (mN/m)
pure water	110°	72.8
5 g/l anionic wetting agent	65°	38.1
5 g/l soap (sodium oleate)	46°	26.0

2. water/acetate spun fibres:

solution	wetting angle	surface tension (mN/m)
pure water	55°	72.8
5 g/l anionic wetting agent	35°	38.1
5 g/l soap (sodium oleate)	0°	26.0

Surface tension is defined according to German standard DIN 53 914, using a tensiometer with a plate, ring or bar and a film is formed with liquid. The tensiometer is moved in such a way that increasing tension is exerted on the film, which is ultimately broken. The force acting at this moment is measured. Calculation formula:

$$\sigma = {}^{K}/_{2L}\ \text{mN/m}$$

K = force measured,
L = circumference of plate/ring, or length of bar.

II. Force resulting from free → Surface energy, per linear unit. Numerically it corresponds to the free surface energy per surface unit, expressed in J/m^2 or N/m. The liquid state forms the transition phase between the gas state and the solid state. A liquid consists of particles (atoms, ions, molecules) in relatively free motion. Forces of attraction, which are stronger than in a gas, cause a certain level of order. The particles move together as closely as their specific volume will permit. The forces of attraction in liquids are known as cohesive forces. One effect of cohesion is the ultimate tensile strength of a liquid film. Liquids have viscous properties, which means that they resist flow. Unlike gases they have a stable volume, can barely be compressed, and usually have a phase interface (surface).

Since particles in the surface layer are unilaterally attracted inwards, the liquid tends to form the smallest surface possible (Fig. 1). Surface tension is a measurement of the forces that cause reduction in surface size. It can be defined as the quotient of an increase in energy and an increase in surface area:

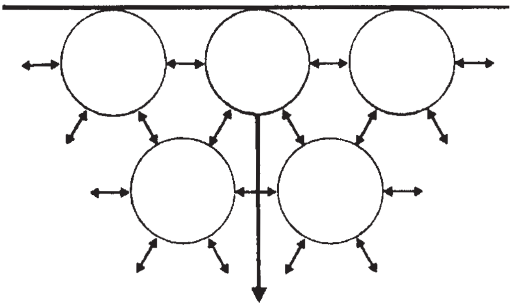

Fig. 1: The forces of attraction between water molecules. A molecule at the surface is affected only by forces from the side and from within the liquid. The resultant force on the molecule is one that is directed inwards, and represents the surface tension.

$$\sigma = \frac{\text{increase in energy}}{\text{increase in surface area}}$$

If there are differences in concentration within a solution, the heat migration of the dissolved particles causes any differences in concentration to balance out eventually. This levelling of concentration is known as diffusion. Surface tension counteracts concentration levelling by evaporation of the liquid molecules as they move into the gas phase. In other words, surface tension is the force that counteracts expansion of a liquid surface, because the molecules within the liquid are subject to inward forces of attraction caused by interactive molecular forces. In an ideal situation, this means that droplets will be spherical in shape, i.e. the smallest surface area for the maximum volume (Fig. 2).

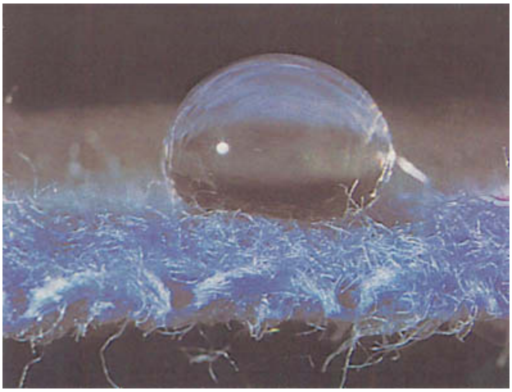

Fig. 2: A water droplet retains its surface tension when in contact with a waterproofed fabric, i.e. in the absence of wetting (by Wunder).

The high surface tension of water can be lowered by adding surfactants in low concentration. The degree to which surface tension is dependent on temperature is lower than its dependency on vapour pressure or viscosity. For this reason it can be observed that liquids with a high surface tension will evaporate more slowly at the same temperature than those with lower surface tension. The concentration dependency causes considerable interfacial tension gradients at the point where surface/interfacial tension is generated (Fig. 3). These gradients in turn cause interfacial currents. This phenomenon is known as the Marangoni effect. A simple example to illustrate this is n-heptane (surface tension

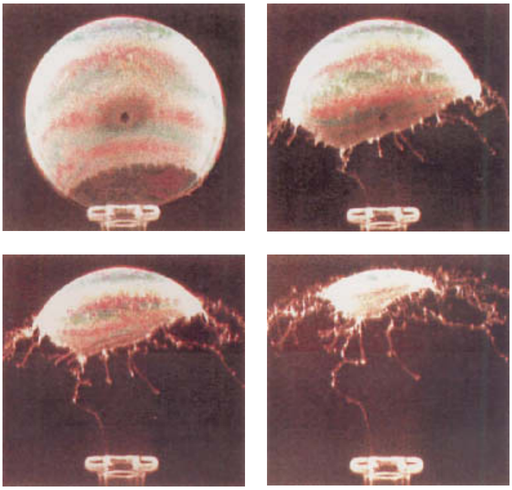

Fig. 3: High-speed cinematography is used to observe phenomena resulting from surface tension (here, the bursting of a bubble) (by Henkel).

$\sigma = 0.0203$ N/m) and benzene ($\sigma = 0.0288$ N/m). A drop of benzene on a thin film of n-heptane will not spread out, because benzene has a higher surface tension than n-heptane, even though both liquids can be completely mixed. In reverse, the benzene film spreads out almost explosively as a result of the n-heptane droplet spreading. If an interfacial tension gradient occurs, it causes surface currents, which result in surface renewal. The above phenomena can be systematically classified, the surface renewal being a micro-effect, and where the interface is affected it is a macro-effect. Surface renewal or micro-effects arise if the depth of the liquid layer is significantly greater than the depth to which interfacial currents occur.

The static surface tension can be measured using the Wilhelmy method. The dynamic surface tension is measured using a device based on the maximum bubble pressure method in an aqueous solution, depending on the speed at which the new preparation/air interface (measured in Hertz as bubble-forming frequency) is formed (Fig. 4).

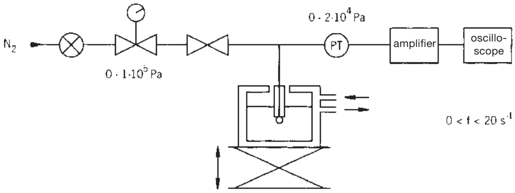

Fig. 4: Measuring dynamic surface tension by the maximum bubble pressure method.
PT = pressure transformer (induction system).

Surface tension meter Measuring instrument for determining the → Surface tension of liquids and solid matter. In order to determine the dynamic surface tension of liquids two capillaries of varying lengths are placed in the solution to be measured, releasing a defined flow of air. The differential pressure between the capillaries is recorded electronically and transferred to a computer for evaluation (Fig. 1).

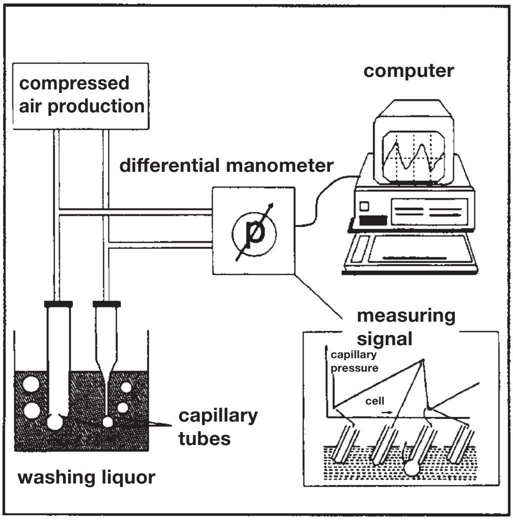

Fig. 1: On-line surface tension meter, design and measuring principle (wfk).

The measuring technique is based on the change in the maximum bubble pressure. When a capillary with gas bubbles escaping from its lower end is submerged into a solution containing a surfactant, the shape and size of the bubbles change according to the surface tension of the solution. High surface tensions, i.e. low surfactant concentrations, produce large bubbles, whereas low surface tensions produce small bubbles. Also the pressure which is necessary to create bubbles changes, high pressure being associated with a high dynamic surface tension. The use of an additional wide capillary means that measurements can be taken independently of the submersion depth.

Tensiometers are suitable for measuring in washing liquors, as they enable changes in concentration above the critical micelle formation concentration (CMC) to be recorded, as opposed to measurements of static surface tension (Wilhelmy or ring method). Also, in addition to the surfactant quantity, other parameters concerning the technical application of the washing liquor can be measured such as the amount of dirt, dirt-bearing capacity and remaining amount of washing power (reserve washing power).

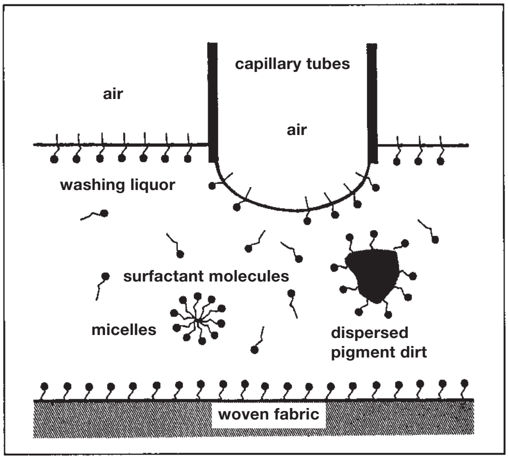

Fig. 2: Adsorption behaviour of surfactants in washing liquors (wfk).

Surfactant molecules in the washing liquor occur individually as well as in the form of micelles (Fig. 2). Free surfaces at the interface between air and water, water and fabric, and water and dirt are occupied by surfactants in physical-chemical balance. The gas bubble forming constantly at the end of the capillary represents an imbalance due to the enlarging interface. Surfactants continuously accumulate at this interface. This process is diffusion-controlled; the more surfactant is present in the solution the more quickly the process takes place. The micellar-bound surfactants also participate in this dynamic process, whereas the surfactant elements in the liquor are adsorbed to a greater degree by the dirt. This explains why increasing pollution of the liquor increases the measurable dynamic surface tension at an initially identical operating concentration. The differential pressure recorded with the on-line tensiometer increases with falling dirt-bearing capacity accordingly (Fig. 3) (Krüssmann Principle).

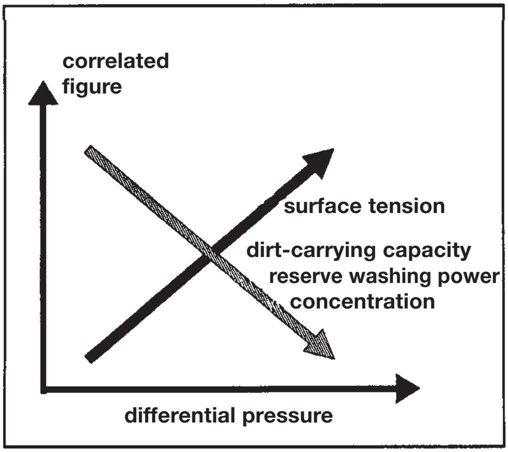

Fig. 3: Qualitative correlation between differential pressure, dynamic surface tension, surfactant concentration, reserve washing power and dirt-carrying capacity (wfk).

Surface water,

I. Fresh water originating from natural or artificial sources above ground (e.g. stream, river, lake, pond, reservoir). Temperature and composition are usually extremely varied (self-cleaning frequently takes place with the help of bacteria and fish. Some impurities dependent on origin, season, temperature, water management, usually has more organic substances and less salt than → Ground water. Floating colloid substances that cloud the water originate from micro-organisms, dirt, clay, earth, humus, products of protein decomposition, etc. Colour and reaction varies greatly depending on the level of impurities and the type of ground.

II. → Adhering water.

Surfactant Surface active substance.

Surfactant additives Additive in a detergent that causes the product to have further properties, but has nothing to do with the washing action. Examples are optical brighteners, corrosion inhibitors, anti-electrostatic products, dyes, perfumes and bactericides.

Surfactant analysis Surfactants are used in almost all processes in textile manufacture, pre-treatment and finishing. Examples of problem areas in surfactant analysis are:

- The analysis of surfactants in textile auxiliaries during inspection of raw materials, with the objective of analysing both qualitative and quantitative product composition. One advantage is that it is possible to analyse extraneous substances, the other is that it is possible to compare two products.
- The importance of checking the concentration of surfactants in aqueous liquors becomes greater when waste water is being monitored. But it is also essential to be aware of surfactant concentration in this type of medium during production, so that errors can be avoided.
- Investigating changes in the chemical structure of surfactants, for example during drying and setting processes, plays a crucial role in waste water and exhaust analysis. It is also important for detecting alterations in behaviour to surfactant properties in textile process sequences.
- If the surfactant distribution during softening is checked for evenness, it is possible to optimise the process parameters and thereby minimise application of the product.
- Analysis of residual surfactants on the fibre surface is useful, meaning, for instance, that problems arising after washing phases in process sequences can be avoided.

With regard to minimizing contaminants in waste water, there will be new, more stringent requirements for specific surfactant analysis in the future (→ Surfactant biodegradability, evaluation of). The law applying to detergents and cleaning agents stipulates stricter requirements for products “that have been applied to surfaces in line with specifications, which are for the most part removed in a single cleaning process using the products implied in paragraph 1, which in practice can subsequently be detected in water” (and this includes numerous substances used in textile finishing). Because of the composition of aqueous liquors or fabric coatings used in the textile industry, methods of analysis must be found that are minimally intrusive, or other possible methods must be found, such as the selective separation of surfactants from the medium concerned. The Fig. illustrates one possible separation method, using solid phase extraction as an example. In the case of normal liquid/liquid extraction, the distribution equilibrium of the substance being analysed in two non-mixable liquids is utilized as a separation effect. However, in solid phase extraction, the selective interactions occurring between the substances under analysis and a chemically modified silica sorbent are used. This process is already used for biochemical purposes, e.g. for separating surfactants from proteins. The surfactant molecules are smaller, and are therefore retained in the gel, whereas the protein molecules can pass through almost without hindrance. The contents of the column are eluted with methanol, for example, making it possible to recover the surfactants for specific analysis.

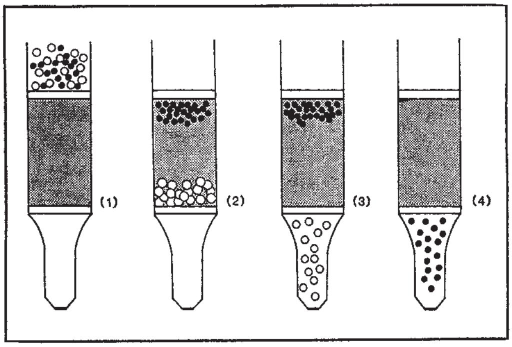

Fig.: The principle by which surfactant and macromolecules are separated using solid phase extraction (DTNW).
Black dots = surfactant molecules; white dots = macromolecules; 1 = delivery of the solution containing the substance;
2 = separation of surfactant and macromolecules;
3 = rewash; 4 = elution of the surfactant molecules.

These molecules are chemically dipolar, and utilizing this characteristic property, as well as the associated physical/chemical property changes, where the critical micelle concentration is exceeded, is one possible method of surfactant analysis. Another method is to use the criteria that are dependent on the chemical structure of the surfactants for analysis. The table shows the methods that are usually used, and ways in which they can be implemented for qualitative and quantitative analysis.

methods		analytical quality	analytical quantity

HPLC = High pressure liquid chromatography

It is difficult to analyse detergents and cleaning agents using a generalized formula. As ion exchangers, there are some types that are suitable for surfactant exchanger chromatography. To use this method, it is assumed that the detergent product containing the surfactants is alcohol-soluble, and exchanges ions at double rate (dissolved in an isopropanol/water mix). Non-ionogenic surfactants are contained in the fluate, while the anionic components released into free acid by cation exchangers can be found in the sorbate. The acids, which are bonded at different levels of firmness, can be released by means of eluation agents of appropriate strengths, and then analysed. This separation process provides the four fractions without the need for a preliminary qualitative/semi-quantitative test: (fluate) non-ionogenic surfactants, (1st eluate) soap, (2nd eluate) hydrotrope and chloride, (3rd eluate) anionic surfactants. The components are extracted in their entire form (i.e. not broken down), and the first step is an optical inspection (IR, UV). Multi-component mixes in the individual fractions can be differentiated for instance by hydrolysis and inspection of the cleavage products, separation of components for which saponification is not possible, etc. (according to Knopf and Denter).

Surfactant biodegradability, evaluation of In order to discuss the biological degradability (→ Biodegradation) of a substance, it is essential to understand what is meant by it. There are two important terms that have been used as analysis criteria for a relatively long time, especially for surfactants: primary degradation and ultimate degradation (see Fig.).

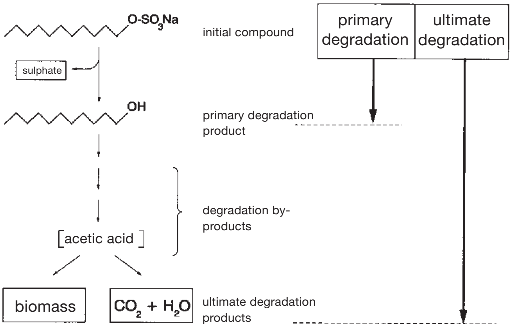

Fig.: Terms of evaluation of biological degradability (example: fatty alcohol sulphate).

The degradation of any chemical compound is a multi-phase process, in which the first stage is conversion of the initial compound into the first degradation product by the degradation organisms. Since the initial substance loses its chemical identity and usually also its primary matter properties (e.g. for a surfactant its surface-active effect and therefore its foaming properties) in the very first phase, the disappearance of the initial compound is referred to as primary degradation. Surfactants form an excellent example because even primary degradation frequently has significant ecological consequences. It has been proven that for a number of anionic and non-ionogenic surfactants, the loss of surface-active effects, i.e. primary degradation, is linked to a drastic reduction in toxicity affecting aquatic organisms. This means that it is certainly of ecological relevance with respect to the European minimum degradation specification of at least 80% for anionic surfactants (under defined test conditions). However the aim should, of course, be to achieve total degradability of any chemical compound released into the environment, rather than simply ensuring that any undesirable properties become ecologically non-toxic.

Ultimate degradation means the biodegrading process up to its final stage, in other words up to the point at which the initial compound is converted to the final product of biodegradation. The final products are mineral oxidation products – carbon dioxide, water, possibly inorganic salts, and the organic material converted (assimilated) into bacterial biomass. Proof of the ultimate degradation of a chemical constitutes a reliable basis for the assumption that neither the initial compound nor any by-products generated during degradation will remain in the environment, thereby representing a long-term ecological risk.

Analytically, the primary degradation of a test compound can be tracked by means of an appropriate (group) specific analytical process. Ultimate degradation however is analysed using substance-specific → Summation parameters.

1. Primary degradation: analysis specific to substance (groups).
   a) a-surfactants (anionic surfactants): MBAS degeneration (methylene blue active substance);
   b) n-surfactants (non-ionic surfactants): BiAS degeneration (bismuth active substance);

legal foundation	degradation	screening test	simulation test
EEC instructions or national laws for a-, n-surfactants	primary degradation (≥ 80 %) – MBAS degeneration – BiAS degeneration	screening test OECD 301 E	OECD confirmatory test
EEC instruction 79/831 or chem. law (1982) for new substances	ultimate degradation	OECD test for ready biodegradability:	
	– C degradation	modified screening test OECD (> 70 %)	coupled units test
	– BOD	GF test (> 60 %)	–
	– formation of CO_2	CO_2 evolution test(> 60 %)	

Tab.: Important degradation test methods of surfactants.

   c) c-surfactants (cationic surfactants): DSBAS method (disulphine blue active substance).
2. Ultimate degradation: Summation parameters.
   a) mineralization: O_2 consumption (BOD); formation of CO_2;
   b) mineralization + assimilation: DOC degeneration (Dissolved Organic Carbon).

Test methods have been developed for evaluating surfactant biodegradability that can be used universally, are recognized internationally, and are based on standard test specifications. They can be divided into two categories, screening tests and simulation tests (Tab.).

Surfactant biodegradability tests Surfactant biodegradability (→ Biodegradation of surfactants) is usually analysed according to two biological processes:

1. Selection test (screening test OECD 301 E).
2. Confirmation test (OECD confirmatory test).

Both of these tests feature in the Detergent and Cleaning Agent Law in Germany, for instance. Any surfactant achieving at least 80% biodegradability in the selection test is considered to be biodegradable. The selection test is a simple static version of the “shake-flask” test. The concentration range is quantified in mg/l. The substance is set off with a mineral-based nutrient salt solution and then injected with waste from a purification plant. The concentration curve of the surfactants is monitored over a period of 19 days. At the same time, the biodegradation properties of two standard substances are tracked (lauryl alcohol sulphate after 14 days 92%, tetrapropylene benzene sulphonate after 19 days 35%). If the surfactant biodegradability is lower than 80% in the selection test, or if the test result is unclear, the confirmation test must be carried out. The confirmation test is a model based on a biological purification plant, which represents a continuous process. An artificial nutrient base is used (meat extract + peptone). In this test, concentrations are higher by a factor of 4 than in the selection test. Waste from a purification plant is injected into the test environment, in the same way as the selection test. After approx. 2 weeks activated sludge is formed, and the remainder of the surfactant is monitored analytically (mean value of 14 measurements over a period of 3 weeks).

Anionic surfactants can be detected by means of methylene blue in the form of methylene blue active substance (MBAS). Non-ionogenic surfactants are recorded as bismuth active substances (BiAS). The methylene blue method is based on the fact that where anionic substances are present, cationic methylene blue forms blue salts that can be extracted using chloroform. The concentration can be determined photometrically. Surfactants on a phosphoric acid ester basis form an exception. To analyse non-ionogenic surfactants, they are enriched by blowing through acetic ester, and then precipitated in a bismuth complex with a modified Dragendorff reagent (sodium bismuth iodate + barium chloride + acetic acid). The bismuth content is analysed after being dissolved using pyrrole idinthiocarbamate, by means of potentiometrical titration. The limits and accuracy of this test have recently been discussed in great detail.

It is not only the level of biodegradability that is analysed in the confirmation test, the elimination potential can also be partially analysed. If surfactants are properly adsorbed by the activated sludge, the test method does not detect them. This phenomenon occurs with alkylphenolethoxylates (APEO), and for this reason they were believed for a long time to be biodegradable. Adsorption of surfactants into sewage sludge should in principle be regarded positively, and is usually required. It is one of the essential cleaning mechanisms in the purification plant. However it is only acceptable if the by-products resulting from decomposition are harmless.

Surfactant degradation → Biodegradation always begins with an oxidative attack (see Fig.). Non-branching side chains can rapidly be split up into units of acetic acid. The rings are opened at a slower rate, and finally desulphonation occurs.

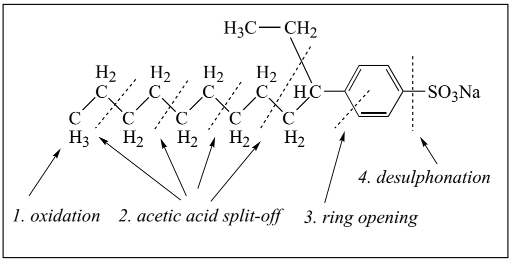

Fig.: Biological surfactant degradation.

If the biodegradability potential is being tested, the “chocolate marshmallow – black bread” model should be used for test nutrients: mixed nutrients, derived from surfactants that biodegrade easily and those that do not, provide realistic results in a simulation test, i.e. biodegradability levels similar to those occurring in practice. The → Screening test OECD 301 E is actually cheaper than simulation tests, but very stringent conditions are required. Examples of these are:

- modified OECD test;
- GF test (water-soluble);
- block test (not easily soluble).

In the screening test there is only one C source; mineralization is only necessary if a few bacteria are present. For this reason, screening tests are designed for long-term use. It is often claimed that surfactants can be “biodegraded rapidly and easily under real environmental conditions”. This comment relates to primary degradation, which causes the substance to lose its surfactant characteristics. However, this needs to be followed directly by secondary degradation down to CO_2 and H_2O, in other words it must be completely degraded to waste water that contains no metabolites. “Hard” metabolites, which exhibit resistance to secondary degradation, can increase in concentration. For this reason, a metabolite test acts as a “magnifying glass” to home in on an area that was unclear in the standard test (see above), all of which serves to highlight primary degradation.

Using the compost method is not a suitable way of measuring surfactant biodegradability, because adaptation is possible within this microbiological zone, because the timescale is greater. Adsorption can take place while surfactants are still in the settling tank, before they even arrive at the biodegrading stage of the purification plant. Therefore a distinction must be made between adsorption into the sewage sludge and elimination. Since cationic surfactants adsorb efficiently, they can be deposited together with the sludge without the need for a biodegrading process.

Surfactant foaming capacity → Foaming power of surfactants.

Surfactants As defined by the German Detergent and Cleaning Agent Law (Waschmittelgesetz), organic polar compounds with at least one hydophobe residue and a hydrophile group. The term identifies water-soluble compounds which are used for wetting, washing, emulsifying and dispersing, accumulate on border surfaces and which reduce the border surface tension. The term surfactant is not identical with detergent, as the latter are washing agents which, among other substances, contain surfactants. Surfactants are therefore → Surface active compounds whose molecules demonstrate a lipophile (hydrophobe, i.e. water repellent = fat tolerant) organic residue, symbolized in Fig. 1 by rods, and a hydrophile (lipophobe, i.e. water friendly, fat intolerant) group, symbolized in Fig. 1 by a circle.

Fig. 1: Diagram of the structure of a surfactant. Sphere = hydrophilic; rod = hydrophobic.

The hydrophobe group is usually understood to contain a hydrocarbon residue with alkyl and/or aryl components. Characteristic of the hydrophobe group, as a component of the surfactant molecule, is that it behaves in a watery medium as if it were being forced out. It should be remembered that in any case van-der Waalssche attraction forces are in play, between a hydrocarbon chain as the preferred model of a hydrophobe group and the water molecules which are in contact with it. On the other hand the water molecules exert even stronger attraction forces on each other and therefore have the tendency to displace the hydrocarbon chain. This explains why the size of the hydrophobe groups plays an important role in the solubility of the surfactant.

According to the molecule structure, surfactants have an ionogenic or a non-ionogenic character which is determined by the hydrophile group in the molecule. Products are therefore classified as ionogenic and non-ionogenic. The former are divided into anionic, cationic and amphoteric surfactants. These all contain a hydrophile group which is able to dissociate into ions which are known as tensiodions and gegenions. The surfactant acquires a hydrophobe and a hydrophile residue and bears surfactant properties.

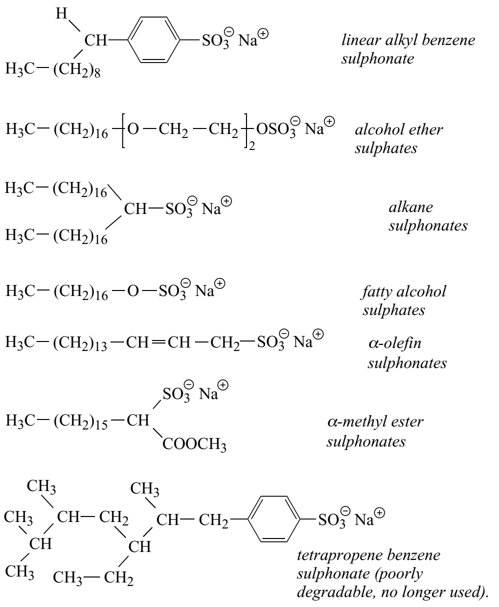

Fig. 2: Examples of anionic surfactants.

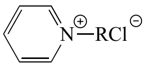
Anionic surfactants (Fig. 2) are identified by the fact that they contain an anionic, usually a $–COO^-$-, $–SO_3^-$-, $–OSO_3^-$-group, at the last constant carbon atom of a hydrophobe chain. They are therefore salts of alkyl carbonic acids ($R–COO^-H^+$), alky sulphonic acids ($R–SO_3^-H^+$) or sulphuric acid with higher alcohol levels ($R–O–SO_3^-H^+$). Cationic surfactants are predominantly derivatives of ammonia, generally alkylamines or substituted pyridine compounds which are usually quaternized.

e.g. $R{-}\overset{\oplus}{N}(CH_3)_3Cl^{\ominus}$ *or*



The amide acid, polyalcoholester (sugar ester) groups belong to the non-ionogenic surfactants (Fig. 3), as well as the ethane oxide adducts group, which is very important as far as application techniques are concerned, and whose polarity is based on the accumulation of ether groups in the polyethene oxide chain.

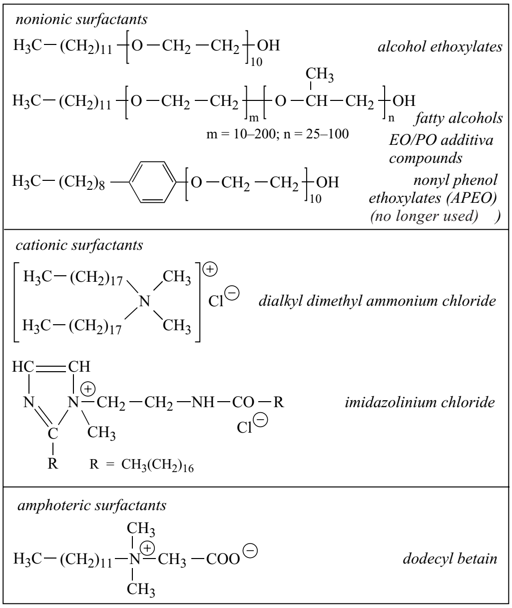


Fig. 3: Examples of nonionic, cationic and amphoteric surfactants.

Amphoteric and hermaphrodite ionic surfactants contain an anionic and a cationic group in the molecule (see Tab.). If both ionic groups are strongly disassociated, they are referred to as hermaphrodite ions. The degree of their dissociation in water is only influenced slightly by the pH value of the solution. In the case of slightly dissociated groups, the molecule reacts in acetic solution like a cationic surfactant, whereas in alkaline solution it reacts like an anionic surfactant and is known as amphoteric.

hydrophobic	hydrophilic	counterion	type	examples
alkyl-, alkyl aryl-	$-COO^{\ominus}$	$Na^{\oplus}$	anionic	soaps carboxylate
alkyl-, alkyl aryl-	$-SO_3^{\ominus}$	$Na^{\oplus}$	anionic	sulphonates

Tab.: Surfactant classification with examples.

The → HLB value describes the intensity relationship between polar and apolar molecule elements of a surfactant. It is determined by the type and size of the hydrocarbon chains as apolar representatives and the height of the dipole in the polar element. Thus a long straight-chained hydrocarbon element has a greater intensity than a short branching hydrocarbon chain. In the polar range an ethene oxide group is less intensive, carboxyl, phosphate, sulphate and sulphonate groups being more intensive, in descending order of intensivity. The HLB value determines:

- solubility of the surfactant
- emulsion properties of the surfactant
- dirt-bearing properties of the surfactant.

With non-ionogenic surfactants the HLB-value can be registered quantitively by codes for the hydrophile as well as for the hydrophobe (lipophile) ranges. With ionogenic surfactants, this has to date not proved to be adequately possible, as in this case other properties also determine surfactant-typical behaviour, which are not included in the HLB value. The HLB value is mainly of qualitative significance. Dividing the HLB value into a scale of 20, textile washing agents have an HLB value of 13–18 (1 = water insoluble, 20 = water soluble).

The solubility of surfactants is defined as saturation concentration in balance with a second phase, which either consists of the pure surfactant or of a defined hydrate of the same, or at least is surfactant-rich and low in water. Thus the second phase can be

- crystallized surfactant or stoichiometric surfactant hydrate or
- a fluid mixing phase of constantly variable composition.

The first of these is found mainly but not exclusively with ionogenic surfactants, the second particularly with non-ionogenic surfactants. The solubility of surfactants in water depends above all on the hydration of the hydrophile group. Thus the following characteristic behaviour of surfactants towards water as a solvent can be expected: the hydrophile group tries to achieve solubility of the surfactant in water and is successful if the hydrophobic residue is not too large. The hydrophile group therefore prevents separation of the hydrocarbon phase. The system tries, however, to reduce the energy-filled interface between hydrocarbon and water to a minimum with simultaneous maximum contact between water and the hydrophile group which leads to accumulation at the interface areas or to aggregate formation (micelle formation). The solubility of surfactants depends on both concentration and temperature. Typical surfactant phenomena are the Krafft and cloud points.

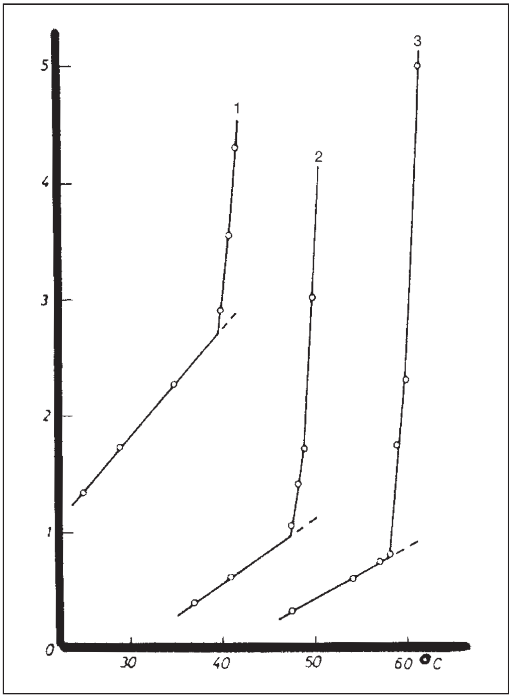

Fig. 4: The solubility in water (in 10^{-3} mol/litre) of sodium alkane sulphonates as a function of temperature. 1 = C_{14}; 2 = C_{16}; 3 = C_{18} .

The solubility temperature curve of ionogenic surfactants (Fig. 4) demonstrates a peculiarity which is connected with the formation of aggregates (micelles). The curves demonstrate turning points which move towards higher temperatures and smaller concentrations with increasing chain length. This turning point of the solubility curve is known as the Krafft point. It indicates the temperature above which the solubility of surfactants increases enormously. This increase is caused by the fact that above this Krafft point micelles are created which are considerably more soluble than surfactant monomers. The solubility curve is “cut” precisely at the Krafft point by the critical micelles concentration curve (Fig. 5).

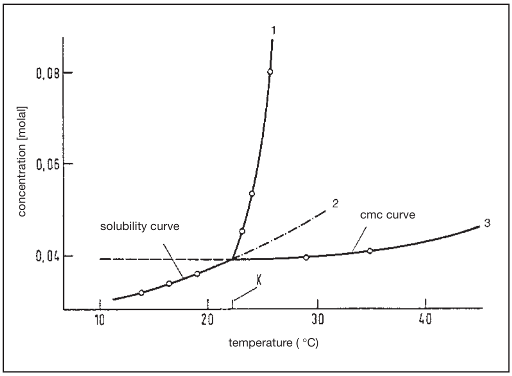

Fig. 5: Schematic phase diagram of a surfactant near the Krafft point.

The use of surfactants is only viable above the Krafft point temperature. The height of the Krafft point increases with increasing chain length of the hydrophobe group. The height is reduced if the hydrophobe group is branched. The type of hydrophile group and its inverse ions also has an impact on the location of the Krafft point. The addition of electrolyte increases the temperature of the Krafft point.

Non-ionogenic surfactants, which form a clear solution in water, demonstrate particular properties as opposed to other surfactants. When the temperature is increased and when a certain relatively precisely-defined temperature characteristic of that particular surfactant is exceeded, the solution becomes cloudy and the solution separates into two fluid phases. This temperature is known as the “cloud point”. The reason for the occurrence of this phenomenon probably has to do with hydration of the hydrophile non-ionogenic groups. This hydration is exothermal; with increasing temperature partial dehydration takes place and this causes formation of a new phase (Fig. 6). The fact that the cloud point is almost independent of the overall concentration of the surfactant confirms this explanation. The cloud point can be influenced by additives. This can be caused by additives being stored in the micelles, thereby changing their properties, or by changes to the properties of the water, i.e. the environment of the micelles. This mechanism applies in particular to the addition of electrolytes which generally transpose the cloud point to lower temperatures with increasing concentration.

The impact of the hydrophobe and the hydrophile group is due to the fact that the cloud point increases with increasing length of the ethene oxide chain (hydrophile group) and decreases with increasing length of the hydrophobe element. Interface activity is the prop-

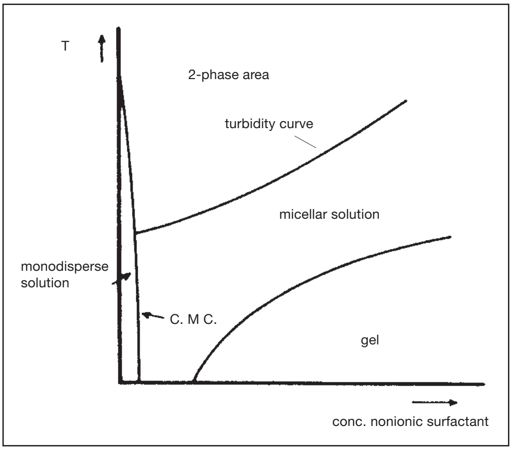

Fig. 6: Surfactant/water phase diagram (schematic).

erty of drifting out of a solution to the border area of a liquid and reducing the surface tension. The bifunctional structure of surfactants means that their concentration at the interface is up to several thousand times as great as in the solution. Orientation of the surfactants occurs simultaneously. The apolar molecule element is constantly directed towards the apolar medium, whereas the polar molecule element is constantly directed toward the polar medium. Due to the interface activity of surfactants, the surface tension of water is, for example, significantly reduced. In addition, hydrophobe, largely apolar solids in watery media are hydrophiled to a greater or lesser extent by the attraction of the hydrophobe group of surfactants, caused by van der Waals interaction. With polar solids (such as metal oxides) the hydrophile group can react directly with the solid surface during adsorption of surfactant ions, causing the hydrophobe group to be oriented towards the aqueous phase. In the case of higher surfactant concentrations a second layer can build up on the hydrophobe absorption layer, the hydrophile groups of which tend towards the aqueous phase.

The adsorption of surfactants depends to a large extent on the class and the constitution of its hydrophile and hydrophobe elements. Quantitative relationships between surfactant constitution and marginal activity have not been established in any numbers, the most important of those established being the rule defined by Traube. This rule states that an n-alkyl surfactant in aqueous solution, in which only the alkyl chain was extended by a CH_2 group, reduces the surface tension in the same way as the non extended surfactant in triple concentration. The Traube rule applies to non-ionogenic and ionogenic surfactants alike. It works on the assumption that chain extension does not cause any significant differences in hydration. The validity of the rule is limited to a certain chain length, above which surface tension increases again. A further limit is formed by the critical micelle formation concentration (aggregate formation), as the surface tension does not change above this concentration. Comparison of homologous rows of alkyl sulphates and alkyl sulphonates has shown that, with alkyl sulphates, the oxygen atom derived from the fat alcohol contributes as much to reducing the surface tension as a CH_2 group of the alkyl chain. Fig. 7 shows the surface tension curves of sulphate and sulphonate with identical alkyl chain lengths.

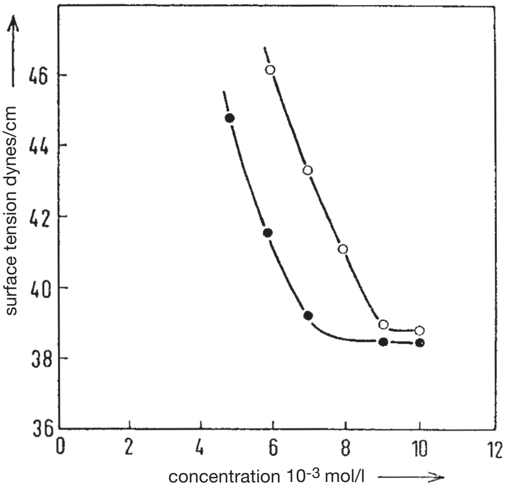

Fig. 7: Surface tension of aqueous solutions of sodium dodecyl sulphate (black dots) and sodium dodecyl sulphonate (white dots) at 27°C relative to concentration.

In addition to adsorption capability in marginal areas in order to keep the contact surface of the hydrophobe element as small as possible, dissolved surfactants beyond a certain concentration and beyond a temperature which is specific to each surfactant, i.e. the Krafft point, can amalgamate. A characteristic of micelle forming surfactants is that they form micelles in solutions at a certain concentration which corresponds approximately to the concentration at which adsorption in the phase margin has reached its saturation point. This concentration is known as the micelle critical formation concentration (CMC). Micelle formation is an expression of the fact that, with concentrations above the CMC, it is more favourable in energy terms to remove the hydrophobe chains of the surfactant from contact with the hydrophile volume phase, by bringing the surfactant molecules in the volume phase together, instead of bringing further molecules into the already saturated adsorption layer. According to a standard criterion, a surfactant is counted as being adequately pure

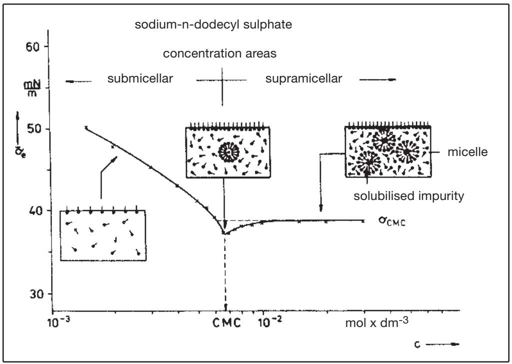

Fig. 8: (Equilibrium) surface tension/concentration isotherms of the aqueous solutions of an impure sodium dodecyl sulphate (SDDS). The concentration conditions of the SDDS and the surface active impurities in the various concentration areas: a) submicellar concentrations; b) CMC and c) supramicellar concentrations are schematically illustrated.

if no minimum occurs in its balance surface tension(σ_e) concentration(c)-isotherms (Fig. 8). The occurrence of the minimum can be explained in thermodynamic terms by the fact that the main component is no longer absorbed when the CMC is exceeded, but a new phase, the micellar phase, is introduced instead. In the first instance this does not apply to contamination, since, as a residue of the hydrophobic original product, this generally does not form micelles itself. When the CMC is exceeded, the contamination is initially further absorbed at the solution surface, which can cause the surface tension to be further reduced. Not until an adequately large number of micelles is present in the solution, are contamination molecules increasingly locked into the hydrophobe interior of the micelles. This process is known as solubilisation.

These micelles are reversible aggregates which decompose again into surfactant monomers when the solution is diluted. The example of an anionic micelle in water shows (Fig. 9) that the outer layer consists of the hydrophile, polar group, which is therefore surrounded by water. The micelle core is formed by the hydrophobe hydrocarbon chains which are in an unordered fluid state. The positive inverse ions of the anionic surfactant partially surround the micelle with a diffuse layer. The structure of a micelle of non-ionogenic surfactants is identical with the exception of the diffuse layer.

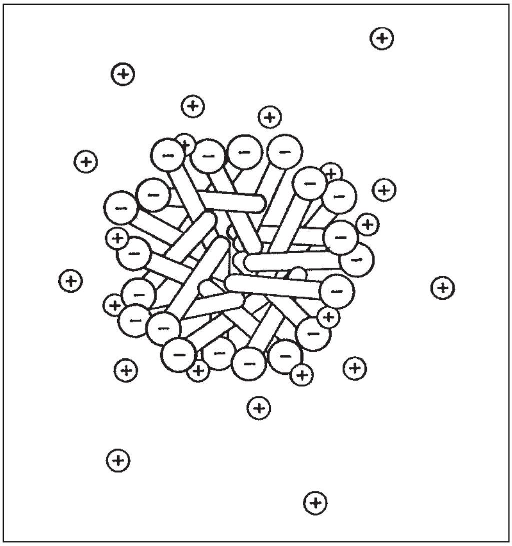

Fig. 9: The formation of a micelle by an anionic surfactant in water.

The number of surfactant monomers dissolved in a micelle, i.e. its aggregation number as well as its size, are determined by the length of the hydrophobe hydrocarbon element of the surfactant; it is therefore limited in the upward direction. If the concentration is increased, the number of micelles increases accordingly. The micellar system is in a state of thermodynamic balance so that permanent exchange takes place between the micelles and individual dissolved surfactant monomers. Depending on the surfactant concentration, a series of physical properties of the solutions provide information on the critical micelles formation concentration. The example of sodium dodecylsulfate demonstrates that a turning point occurs at the same concentration for all of the listed properties so that the critical micelle formation concentration must be located (Fig. 10).

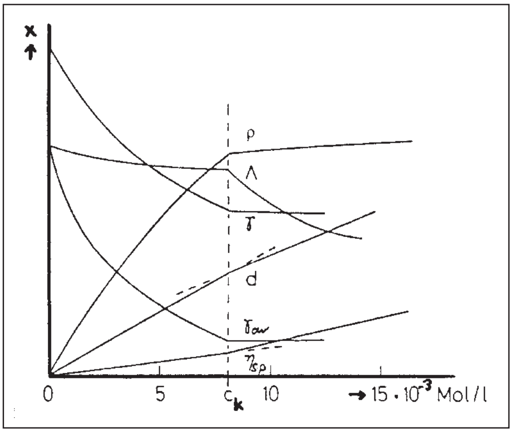

Fig. 10: Various properties (x) of aqueous solutions of sodium-n-dodecyl sulphate in relation to concentration. ρ = *osmotic pressure;* Λ = *equivalent conductance;* γ = *surface tension;* γ_{ow} = *interface tension with respect to n-heptane; d = density;* η_{sp} = *specific viscosity. The ordinate scale is arbitrary.*

In the first instance the length of the hydrophobe chain has an impact on the value of the critical micelle formation concentration. With increasing hydrocarbon chain length, the value of the micelle formation concentration is reduced. Branching of the chain causes the value to increase. The addition of electrolyte causes the critical micelle formation concentration of ionogenic surfactants to be reduced significantly. The influence of this is slighter in the case of non-ionogenic surfactants. Mixed solutions of ionogenic and non-ionogenic surfactants result in particularly low critical micelle formation concentration values. The influence of temperature on the critical micelle formation concentration is relatively slight. At a temperature increase of 50°C above room temperature it increases by approx. 30%.

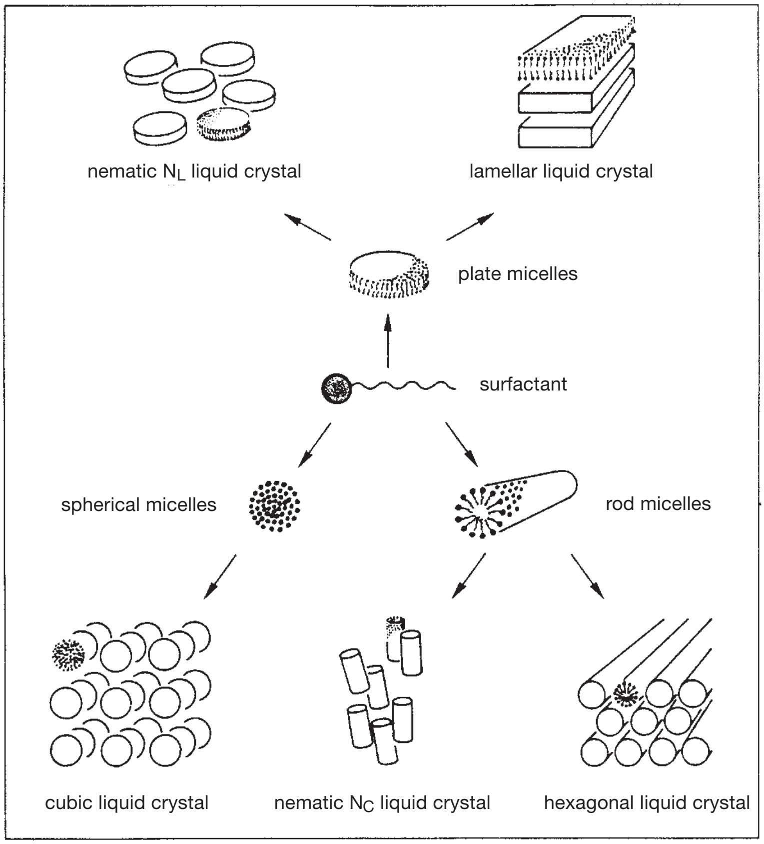

Fig. 11: Aggregation of surfactants into micelles and lyotropic liquid crystals (Henkel).

The forms of micelles depend on concentration (Fig. 11). At the critical micelle formation concentration, ball or spherical micelles form in the first instance. The cylindrical micelle form is predominant at higher surfactant concentrations. If this concentration increases still further, the surfactants accumulate to form large surfaced lamellae. A surfactant solution has the highest degree of washing and dispersion effects in the laminar state. If the surfactant concentration is further increased, the aggregates become larger or their number increases; in most cases both at a high concentration. Due to the interaction between the aggregates so-called mesophases are formed above a certain concentration. In these the individual aggregates can still be recognised as such. They arrange themselves in geometrical fashion in such a way that repulsion between individual parts is minimal, i.e. a variety of structures is formed depending on the structure of the aggregates. Thus, cubic phases result from ball or spherical micelles, hexagonal micelles develop from cylindrical ones and lamellar phases develop from wafer shapes. The aggregates in the mesophases are seen as liquid crystals due to their crystalline arrangement.

One of the most important properties of micellar solutions is their capacity to dissolve non-soluble or only slightly soluble substances by inclusion of these in the hydrophobe cores of the micelles. This process of dissolving into micelle cores is known as solubilisation. Dissolving by means of solubilisation should be differentiated from dissolving by means of hydrotropic substances. In the case of hydrotropium dissolving a substance, which is only slightly soluble or non-soluble in water, takes place by means of concentrated solutions of a not necessarily surfactant like body, solubilisation representing dissolving by means of a diluted solution of a micelle-forming surfactant. Also, solutions which originated through solubilisation should be differentiated from emulsions. Surfactant solutions with and without solubilised material have the same phase characteristics; they are thermodynamically stable, as opposed to emulsions. The tight tolerance value for adsorption of the solubilised substances represents a further difference to emulsions. The quantities of material which can be solubilised depend on the type of surfactant as well as on the type of material to be solubilised. Branching generally opposes solubilisation in the hydrophobe range of the surfactant molecule. Solubilisation of dirt particles represents an important factor in the washing process.

The purpose of surfactant application in the textile finishing industry can either be its own effect, as is the case in the use of washing and cleaning agents or their auxiliary effect during finishing with other materials, when they facilitate or help to improve the application of a finishing agent as a net, disperser, emulsifying, equalising agents, etc., developing a protective effect and rendering some processes possible due to their specific properties. The first range of application is determined by the hydrophile group. Thus cationic surfactants are mainly used as softeners, whereas anionic or non-ionogenic surfactants are used as net, dispersing, emulsifying or equalising agents, etc. The hydrophobe group also determines its own range of application. Surfactants with a long non-branching hydrocarbon chain have, for example, an intensive washing and cleaning effect. Whereby, on the other hand, the hydrophobe element is short-chained and branched, the surfactants are particularly good as network agents or emulsifiers.

Surfactant stability to hard water Definition of the level of resistance exhibited by surfactants in the presence of hard water. Hardness caused both by calcium and magnesium is taken into account, with a ratio of 17 : 3. Detection characteristics: breakdown of the bond between surfactant and alkaline earth ion, or change in colloidal state caused by ionic forces, salt effects, etc.

Surfactant toxicity If surfactants are ingested orally, they are not particularly toxic to mammals. The Tab. shows the acute toxicity levels of both surfactants and soaps most commonly used in industry. A range of substances having different chain lengths are listed under each heading; testing was carried out under varying test conditions, using different test organisms of the same generic type. For this reason, there is a wide spread of results. However there is a stronger toxic effect on aquatic organisms, which are subject to physical contact rather than oral ingestion, as is the case with mammals. They have extremely thin, delicate membranes inside the gill, which are damaged by surfactants in high concentrations. In the worst cases recorded, even concentrations of a few mg per litre have been observed to cause acute toxicity. Sodium dodecyl sulphate even has anti-shark properties. In the case of LAS, the level of aquatic toxicity increases proportionally to the length of the side chain, i.e. fat solubility. Similarly, biodegradability becomes better, and so a compromise in chain length must be found in order to develop surfactants that are particularly environmentally friendly. Therefore surfactants with low toxicity and high stability could be developed to counteract oil spills caused by tanker accidents at sea. However, ecologists are extremely sceptical as to whether the advantages of using surfactants (rapid oil dispersion) would actually outweigh the disadvantages (additional water pollution). With non-ionogenic alkylphenol ethoxylates (APEO, Tab.), biodegradation begins on the ethoxyl side, so that nonylphenol is formed as an intermediate product, which takes significantly longer to biodegrade. This product has a higher level of toxicity for aquatic organisms. For this reason, APEO is not used in detergents and cleaning agents in Germany.

Suri (alpaca) fibre Fine animal hair originating from a species of South American camel. From a quality point of view, it is the best type of → Alpaca fibre, having an even colour shade and even linear density (approx. 25 µm, about 90–110 scales per mm).

Surikome printing Ancient Japanese technique, a multi-coloured version of → Kasuri dyeing.

Surplus liquor application → Liquor application in

Substance	mammals LD_{50} mg/kg	fish LC_{50} mg/l	bacteria LC_{50} mg/l	algae LC_{50} mg/l	daphnia LC_{50} mg/l

Tab.: Acute toxicity of surfactants.

a greater quantity than can normally be achieved on a padder. The surplus is the amount of surface water that can be held as an intermediate volume (e.g. in a pile), where the water could be removed by squeezing. Various surplus liquor processes have been developed and implemented in fabric pre-treatment. The Menzel Optimax machine, for example, operates with a "split" padder, to strip off the surplus liquor up to the surplus application value (110%). The Babcock Super-Sat system impregnates up to the surplus liquor application value in the nip of the deflecting rollers. The Küsters Flexnip machine uses a type of aquaplaning effect for surplus liquor application.

Suspending power Property exhibited by certain substances of holding solid particles in → Suspension.

Suspending property → Soil suspending property.

Suspension Dispersion is a generic term for all dual phase mixes. Dispersion from a solid phase (e.g. "dispersion" dye) and a liquid phase (e.g. dye liquor) is known as suspension.

Suspension centrifuge → Centrifuges.

Suspension drying,

I. (screen printing). Before fabric that has been printed using the flat-screen technique can be processed further, the print paste must be completely dry to avoid smudging. For this purpose suspension dryers are used, which are mobile or static systems. If there is good air circulation, the fabric will dry rapidly enough, or the air can be heated to speed up the drying process. Another option is to dry out the humidity in the ambient air by using a silica gel filter, which produces good results.

II. → Drying systems.

Suspension drying in screen printing Obsolete drier used in screen printing, on which the fabric was hung in loops from drying rods. Air was circulated slowly from top to bottom.

Suspoemulsion A mixture of anionic and non-ionogenic emulsifiers or anionic dispersants, with specific stabilizers and de-foamers. With a suspoemulsion, it is possible to combine biocides with varying physical and chemical properties, because it has a mixed structure.

SWA Soil Water Air. Refers to → Ecological problems in textile dyeing, printing and finishing. There is an SWA group in Basle, Switzerland (Basler Chemie). It is mainly Swiss textile finishing professional organizations that are involved in SWA group textile finishing.

Sweat (perspiration). Consists of 98% water; $^3/_4$ organic salt residue (sodium chloride, phosphates, sulphates, potassium, calcium, magnesium); the rest is made up of organic compounds (urea, uric acid, neutral fats, volatile fatty acids, cholesterol, lactic, citric and amino acids, etc.). The sodium chloride content is usually in excess of 0.5%. Usually acidic to begin with (pH 4.5–6), however it moves into the alkaline range after a few hours (particularly if the diet consists mainly of vegetables). The composition of sweat is dependent on lifestyle, time of year, diet and general health. Human sweat glands produce between 0.2 and 2 l of sweat per day (→ Clothing physiology). The penetrating odour of sweat is caused by the growth of different types of bacteria that cause the protein compounds in sweat to be broken down. Biodegradable components in finishes and the fact that sweat is becoming increasingly alkaline provide ideal conditions for the bacteria to develop. Types of germs that have been detected in sweat include yeast, aerobic germs (sarcina), bacillaries, staphylococci and even pathogenic bacteria (which can cause disease).

Sweated wool → Skin wool treated using the sweating process (sweating: controlled rotting process, the oldest biological method of dewooling). → Mazamet wool.

Swelling Limited solubility (solution = infinite swelling). A fibre swells if it has the capacity to store substances in liquid or vapour form on a temporary basis. This increases the volume of the fibre, which is frequently associated with shortening of the fibre (transverse swelling). In some cases the fibre can also become longer as a result of swelling (longitudinal swelling). After the liquid is extracted or discharged, the fibre will return to its original volume. The temperature of the liquid (e.g. water or solvent), the size of the particles and the pH (acid or alkali) also have an influence on the fibre's absorbency and swelling capacity. Natural fibres have a better swelling capacity or hygroscopic properties (absorbency) than synthetic fibres, because natural fibres have larger cavities, whereas the swelling potential of synthetic fibres is dependent on the chemical substance and the method of manufacture (ratio of crystalline zones). Each swelling process is a preparatory stage towards becoming a solution. The lower the packing density, the more amorphous areas there are, and the more cavities they contain, the easier it is to dissolve a fibrous material. If the liquid or solvent penetrates through the amorphous areas and between the crystalline zones, temporary (reversible) swelling occurs. Permanent swelling occurs when the solvent penetrates the crystalline zones, which can cause damage. Widening of the pores caused by the swelling agent is dependent on two factors:

1. the type of swelling agent.
2. the morphological fibre structure.

I. Cellulose fibre swelling: viscose exhibits a high swelling capacity in water. The water penetrates into the fibre pores, which is not caused by capillary effects alone. The absorption of water is a consequence of molecular solvation forces originating from the free, unbonded hydroxyl groups in the glucose. Swelling in water takes place, therefore, primarily in the amorphous areas of the fibre, which is why it is known as intermicellary swelling. The volume increases in parallel with water swelling. This can be seen from the increase in diameter of the fibre, but not so clearly when the fibre is in solution (Fig. 1). This anisotropy is closely linked with the degree orientation of the crystallite towards the fibre axis.

Fig. 1: Model showing a fibre which has been swollen in water (according to Hermanns).

The water penetration causes the paralleled molecule chains, which are not very strong, to be forced apart. This forcing apart can cause chain shifts even in the structured areas, because the boundaries between the amorphous and crystalline regions are fluid. Water penetration is not possible because of the high level of hydrogen linkage bond crosslinking. As the fine structure of the fibril threads after deswelling (drying) is not significantly altered, water swelling can also be termed reversible. After each swelling process followed by drying, there is a slight decrease in water absorbency. For this reason, free hydroxyl groups must have already undergone saturation, a slight rearrangement of the hydrogen linkage bonds, after the deswelling process. The extent of swelling for cellulose in an alkaline solution is greater than in pure water. In contrast to water, swelling in an alkaline solution occurs, to a certain extent, in the crystalline areas, as well as in the amorphous areas. This intramicellary swelling is irreversible when the alkali concentration is above a certain level, and it can ultimately result in deterioration of the fibre structure.

Influence of the absorbed quantity of sodium hydroxide on structural changes in cellulose (→ Mercerization):

– 0–9%	unchanged cellulose,
– 9–12%	unchanged cellulose and soda cellulose I,
– 12–20%	soda cellulose I,
– 20–45%	soda cellulose II.

The extent of cellulose swelling in an alkaline medium depends on the quantity of water absorbed, which in turn is dependent on the alkali concentration in the solution.

The first theory on cellulose swelling can be credited to Neale. He categorizes cellulose as a weak monobasic acid (pH 13.7). It reacts with alkalis, forming salts:

$$\text{cell–OH} + Na^+ + OH^- \rightarrow \text{Cell–O}^- + Na^+ + H_2O$$

The salt dissociates into the counterions (Na^+, K^+), which are fairly mobile, and into the cellulose anions. It is not possible for the counterions to revert to a liquid state because of the membrane potentials that occur. They remain in the swelling water contained within the amorphous and crystalline areas, where they resist any further penetration of alkali. The level of resistance increases in proportion to the alkali concentration in the liquid phase, which means that the difference in ion concentration is increased in both phases. The osmotic swelling pressure also increases as the alkaline concentration increases, until the alkaline concentration reaches the maximum cellulose bonding level. If the alkaline concentration continues to increase, the amount of free alkali in the fibre will also increase, so that an assimilation of ion concentration in both phases occurs.

However the theory described does not explain the varying swelling behaviour of cellulose in different metal hydroxide solutions (KOH, NH_3OH). Chédin and Marsaudin discovered that swelling is triggered when the hydrate water of the solute metal hydroxide is substituted with hydroxyl groups, as shown by the following:

$$\begin{gathered}\text{cell–(OH)}_3 + Na^+ + OH^- \cdot n\,H_2O \\ \rightarrow \text{cell–(OH)}_3 + Na^+ + OH^- \cdot (n-3)\,H_2O + 3\,H_2O\end{gathered}$$

If hydrated ion pairs are adsorbed by the cellulose, three water molecules are detached from the hydrate water and replaced by three alcoholic cellulose end-groups. The water molecules that are now free have a greater volume than the hydrate water of the Na ion, and therefore cause the fibre to swell. The hydration tendency of the metal ions decreases in the following sequence:

H → Li → Na → K → Rb → Cs → NH_4

The swelling tendency of regenerated cellulose fibres is lower in electrolytic solutions than in pure water. This is because some of the ions (salt) penetrating the fibre together with the water are adsorbed by the fibre, which reduces the water bonding properties of the freely accessible hydroxyl groups. As the ions of different elements are adsorbed at different rates by the hydroxyl groups in the cellulose, the water bonding properties and therefore the swelling potential of cellulose varies in different electrolytic solutions. Ions with a larger ionic radius are bonded less strongly than ions with a smaller radius. On this basis, the swelling of cellulose in electrolytic solutions containing the following cations increases in the sequence:

Cs → Rb → NH_4 → K → Na → Li

Energy is released during water swelling, as well as during swelling in alkaline solutions. The heat of reaction, i.e. the freed energy, varies in quantity. For water swelling, the amount of heat is 15 J/g cellulose, and for alkaline swelling (NaOH 7.4%) it is 28 J/g cellulose.

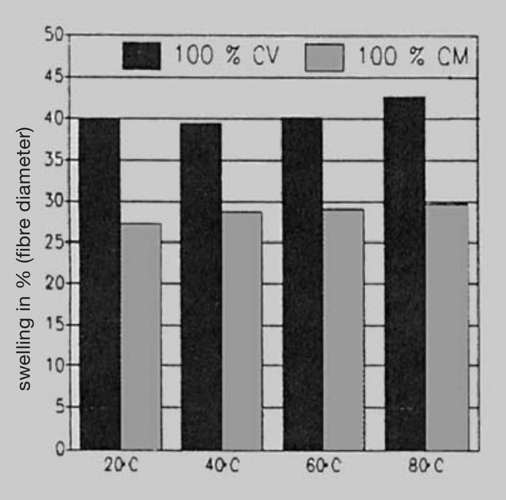

Fig. 2: The influence of temperature on the swelling of viscose and modal fibres (1.3 dtex, pH 7).

Any external energy source in the form of an increase in temperature would in theory have a negative effect on the swelling process, since exothermic reactions are taking place, which produce their own activation energy. With viscose fibres however, the water swelling increases slightly as the temperature of treatment is raised (Fig. 2).

On the other hand, the properties of equilibrium swelling are exactly the opposite in a concentrated caustic soda solution (250 g/l), in other words the extent of swelling decreases as the temperature rises (Fig. 3). The concentration of alkali during viscose fibre dyeing with reactive dyes does not reach these levels.

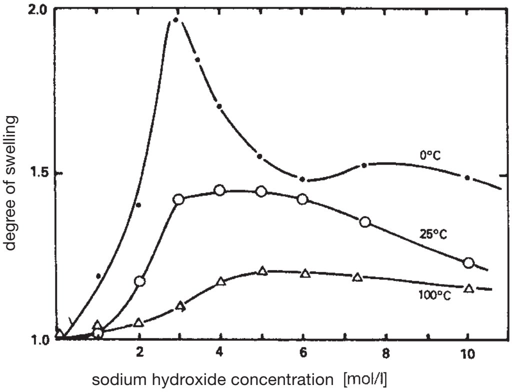

Fig. 3: The equilibrium swelling of cotton in solutions of sodium hydroxide.

However, the water swelling results stated above contradict the opinion of dye and fibre manufacturers, who are of the opinion that cellulose swelling is at its highest when the temperature is low. Experiments have been carried out to test through flow in vat dyeing of viscose filament yarn packages at varying temperatures and pH levels, which confirm this controversial point of view.

The construction or twist of the yarn also influences the extent of swelling. If the yarn only has a slight twist, it will swell to a much greater extent than a ply yarn. To compensate for this effect, packages of yarn such as viscose filament (ply-yarn) are wound very loosely, so that the yarn, which has a high swelling capacity, has enough space to swell. This prevents a situation where the pressure on the inner yarn layers caused by the change in volume after swelling results in an uneven flow of the dye throughout the entire yarn package.

II. Swelling as an indicator of a chemical reaction: a chemical reaction is not directly visible. However it can be followed indirectly. There are various different possibilities: the temperature curve, the change in pH or redox potential, the formation of a precipitate or a gas, a change in colour, or another indicator that does not display the reaction itself, but merely constitutes a signal. A change in shape resulting from a chemical effect is also no more than an indicator of the reaction itself. There are two types of reaction that can cause a change in shape, corrosion and swelling. Both of these processes play an important role in microscopy: One in metallography, and the other in fibre microscopy. A swelling object becomes larger in volume if it absorbs a liquid swelling agent. In other words a xerogel becomes a gel if it reacts with a swelling agent. A xerogel is a very dry gel. Many pre-prepared foodstuffs are xerogels, which are converted to gels, usually hydrogels, during cooking. Rice and all dried pulses are xerogels, and bread is a hydrogel, which becomes a xerogel as a result of ageing. Textile fibres also consist of xerogels which, if the substance is cellulose or keratin, can only be dyed and finished in the form of a swollen hydrogel. There is a linkage, even though narrow, between the properties of the fibre in the dyeing bath and the swelling reaction under the microscope, provided that the dye liquor and the swelling agent are chemically similar.

Swelling can be isotropic or anisotropic in character. Amorphous bodies, such as gelatine, glue, gum arabic, agar agar, pectin, cellulose ether, swell isotropically. An increase in volume occurs all round without a preferred direction of expansion. However, when fibres are exposed to a swelling agent, they behave anisotropically, virtually shrinking as they swell primarily in width. Both types of swelling are shown diagrammatically in Figs. 4 and 5.

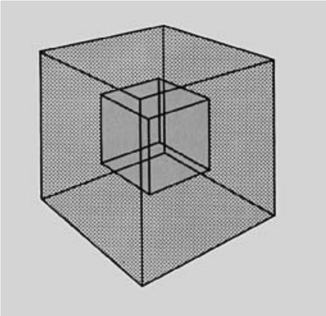

Fig. 4: Isotropic swelling.

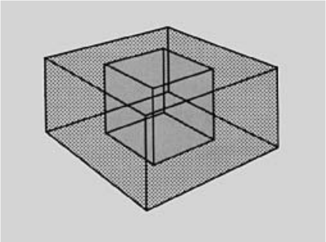

Fig. 5: Anisotropic swelling.

An object only swells anisotropically if its macromolecules are ordered in some way; in other words anisotropy is an indicator of order. This can be demonstrated by means of a simple model. The model consists of straight sticks, the system of order being that the sticks, which are equidistant from and parallel to each other, form a bundle. It is also assumed that the sticks exhibit mutual attraction. The bundle has a certain level of stability. The swelling agent, represented here as particles in free motion, is located outside the bundle, and is attempting to penetrate the lengthways cavities between the sticks from the narrow side. For its entry to be successful, the particles of the swelling agent must interact with the sticks. This neutralises the forces that act between the sticks, the swelling agent can fill up the cavities, and as the process continues the bundle expands in width. The bundle of sticks behaves as an object that swells anisotropically (Fig. 6).

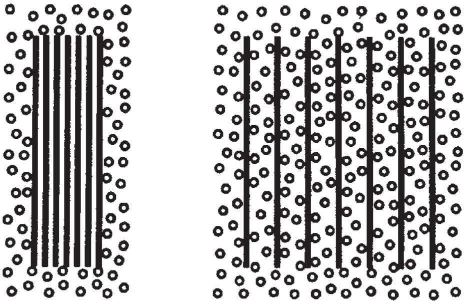

Fig. 6: Proposed model of swelling. The elements of the model are rods; these enter into an interaction with the swelling agent which results in a lateral swelling of the bundle of rods.

The bundle can be stabilized by means of linkages, which cause widthways expansion to be limited or impossible. It would be thought that the crosslinkages could be forced apart if the appropriate action was taken, which would be reflected in the swelling behaviour. It would be assumed that the stick model would ultimately be partially or totally destroyed. The further decomposition progresses, the more the substance dissolves instead of swelling. Variations in the stick model that represent these different possibilities are shown in Figs. 7–9 (according to Bigler).

Cuprammonium, the so-called Swiss reagent, has been used for almost 100 years as a solvent for cellulose. As soon as cellulose comes into contact with a solution of copper (II) hydroxide in concentrated ammoniac ($Cu(NH_3)_4(OH)_2$), it dissolves rapidly, forming a complex up to the highest mole weight ever recorded. The hydroxyl groups in positions 2 and 3 of the cellulose react with complexed copper ions. The intramo-

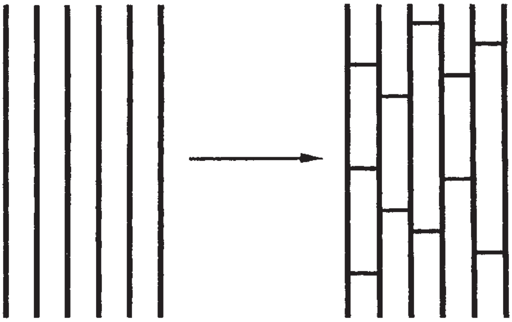

Fig. 7: Stabilization through cross-linking.

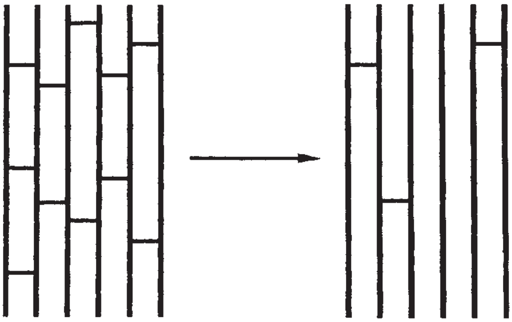

Fig. 8: Breakdown of the crosslinkages.

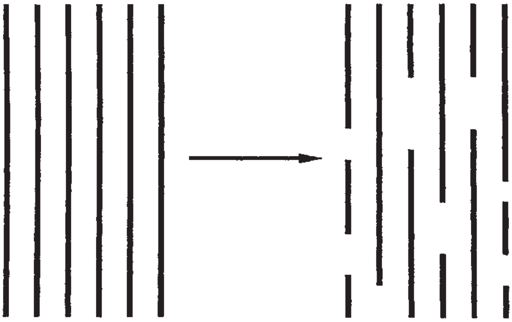

Fig. 9: Break-up of the model.

lecular hydrogen linkages are dissolved, which means that the cellulose loses its stiff quality. Conclusions can be drawn from the dissolving behaviour of dyed and undyed cellulose in cuprammonium, regarding the fibre/dye bond. In addition, these properties can be regarded as an indicator of the cuticle condition in the cotton fibre. The insolubility of cuprammonium, when bifunctional reactive dyes are used, is caused by two reactive dye groups reacting with the cellulose to form a crosslinking bond. However there is no adequate explanation of why, only the crosslinking is the reason for insolubility in cellulose dyed with bifunctional dyes, because cellulose dyed with a dichlorotriazine dye and set on one side only (recognizable because of the large quantity of unreacted chlorine) is just as insoluble in cuproammonium as cellulose that has been treated with fully reacted DCT dye. Complex Cu ions from the cuprammonium can be sterically prevented from affecting the fibre by means of bonding the dye to the fibre, which is the reason for insolubility. For this reason, it would be easy to reach the wrong conclusion that crosslinking is the cause. Yet it makes no difference whether crosslinking occurs or not. Therefore fibres dyed with a concentrated bifunctional vinylsulphone dye with good setting properties (C) swell less strongly than fibres dyed with a monofunctional vinylsulphone dye with lower setting properties (E), or a heterobifunctional reactive vinylsulphone/DCT dye (D) (Tab.).

Fibres dyed with Remazol Black B swell very little in cuprammonium. The fibres treated with Cibacron

	solution	swelling	begins to swell or dissolve	after 15 minutes
A	+	+	after 2 seconds	entirely dissolved
B	+		immediately	entirely dissolved
C	-	+	after 90 seconds	slight swelling
D	-	+	after 30 seconds	moderate swelling
E	-	+	after 30 seconds	moderate swelling

Tab.: Test on the swelling behaviour of samples A to E. A = raw goods; B = blank dyeing; C = Remazol Black B (Hoechst) (200 g/l; fixation ratio 92%); D = Cibacron Marine C-G (Ciba Geigy) (50 g/l; fixation ratio 91%); E = Remazol Black GK (Hoechst) (200 g/l; fixation ratio 40%).

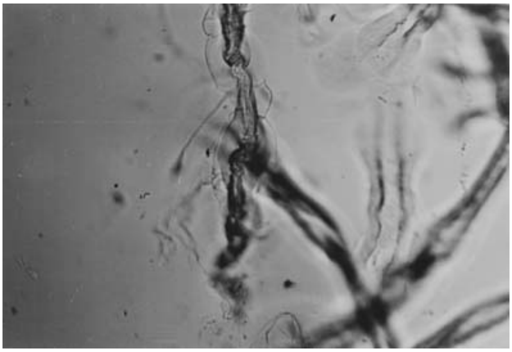

Fig. 10: Solubility in cuprammonium as endless swelling. Raw goods after 60 s: the fibres dissolve particularly rapidly at their cut ends.

Fig. 11: Solubility in cuprammonium as endless swelling. Blank dyed sample after 10 s: the dissolving process here is also connected to a swelling process, as shown in the photograph.

Fig. 12: Cibacron Marine C-G (Ciba Geigy) after 15 min. The fibres are entirely swollen but no dissolving has taken place.

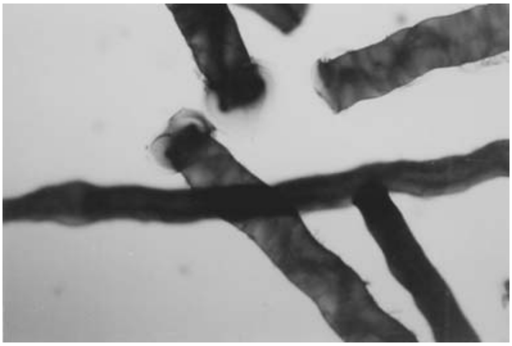

Fig. 13: Remazol Black B (Hoechst) 200 g/l after 90 s. The fibres are only beginning to swell slowly. The fraying at the cut ends (mushrooming) is clear to see.

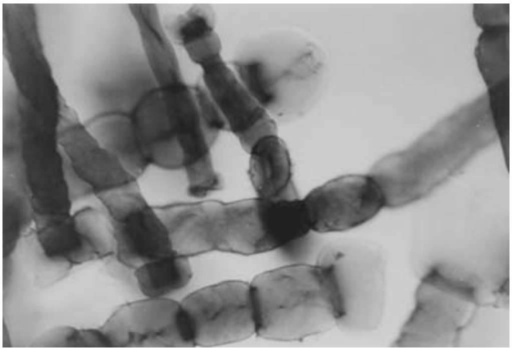

Fig. 14: Remazol Black GK (Hoechst) after 15 min. The ligatures show more clearly why the fibre diameter has increased.

Marine C-G or Remazol Black GK swell faster, and when the swelling process has finished they have a wider sectional expansion. In contrast to untreated fibres and the control sample fibres, the dyed fibres do not dissolve in the cuprammonium reagent (Figs. 10–14).

Swelling agent in dyeing → Carrier.

Swelling agent in printing The absorbency of print pastes is frequently limited in regenerated cellulose fibres, and for this reason swelling agents are added to the print paste, or a → Carrier is used, as is the case for polyester dyeing. For acetate filaments the following swelling agents are used: triacetin or triurea and salicylic acid. For synthetic fibres, using a swelling agent as a print paste additive presents problems, because fibre swelling and therefore dye uptake is uneven as a result of the uneven application of print paste. Swelling agents can also be used as setting accelerators. Setting accelerators, e.g. alkylphenol-based, can be useful for setting processes using superheated steam, hot air or contact heat on hot cylinders.

Swelling anisotropy The fibre swells significantly more strongly in diameter as opposed to length.

Swelling as a precondition for finishing Cellulose fibre swelling is of primary importance for the finishing of these fibres. Cellulose is a substance that does not melt. Because of this, chemical reactions are only possible via the swelling solution, which can be used to penetrate inside the fibre to the cellulose molecule. In this way it is possible to involve the substances in the swelling solution in the reaction. Failing to take this fact into account can lead to an unsatisfactory result from dyeing and resin finishing processes. It is essential to have an overall picture of the complex histological and morphological structure, in particular of cotton fibre. Cellulose fibres can absorb water either by direct contact with the water or from environmental air humidity. The water penetrates as far as the intermicellary cavities. The path travelled by the water inside the fibre to reach these cavities, taking into account the relative size of the molecules, is narrow and extremely long. The diameter of the most important structural molecules is approx: cellulose molecule as the smallest unit: 0.5 nm; cellulose fibrils: 10–20 nm; fibril bundle: 0.1–0.2 µm.

As the cellulose absorbs the water, it heats up significantly enough to be measurable, which signifies an exothermic reaction. An equilibrium with the atmospheric humidity is reached, depending on the humidity level. The difference between the humidity in contact with 100% saturated humidity, which occurs in close proximity to the body because of sweat secretion, and normal air humidity of about 65%, results in precipitation, whereby the moisture from the human skin is transported outwards. This is particularly important for wearing comfort in clothing.

During the dyeing process, the dyes are intercalated in the fibre by means of the swelling solution. Reactive dyes are chemically bonded to the cellulose molecule. It takes a certain amount of time for the swelling solution to transport the dye, however it is still relatively fast if the fibre can be treated with solutions containing all the substances necessary for the reaction. If the fibre is already swollen, exchange can only take place according to the laws of osmosis, which requires much more time and makes continuous processes difficult.

If crosslinking takes place while the fibre is wet, the treated fibre will be wet crease resistant. If moisture levels are controlled, dry crease resistance can be achieved. The optimum combination of a good dry and wet creasing angle can be achieved with a water content of 6–8%. The moisture limits are very close together, because if the moisture level is in excess of 8%, it causes the dry creasing angle to drop sharply. By this means the necessary parameters for a good wash-and-wear finish can be controlled. It is not enough just to regard the chemical process as the important factor, it is also essential to take physical conditions into account, particularly the swelling of the cellulose and the consequences resulting from it. For instance, wet crease resistance is not only a result of chemical crosslinking of the amorphous cellulose regions, but also of physical processes.

The speed of the swelling reaction can either be determined by the diffusion speed of one or several components crosslinking into the substrate, or by the speed at which the intermolecular and interfibrillar cellulose forces are released. In the first situation, the swelling is controlled by diffusion, and in the second the diffusion is limited by the swelling process.

The swelling kinetics can be analysed by measuring the increase in weight of the cellulose fibres during crosslinking, as increase in volume (= swelling) is proportional to increase in weight. The relative swelling f_Q of the fibre can therefore be calculated using the following formula:

$$f_Q = \frac{G_t - G_0}{G_\infty - G_0}$$

f_Q = relative fibre swelling
G_t = weight of fibre at time t
G_0 = weight of fibre before reaction
G_∞ = weight of fibre at time $t \to \infty$.

In series 1 and 2 (Figs. 1–2), the swelling speed increases in line with the water content in the crosslinking solutions. It increases particularly in experiments with between 30 and 50% water. The S-shape of the relative swelling curves shows that the swelling process is not, or not solely, defined by the diffusion speed of the crosslinking components, but is probably dependent on the speed at which the interfibrillary interactions are broken. If the swelling process was diffusion-controlled, the relative swelling speed up to $f_Q \leq 0.4$ would have to show a linear dependency of $t^{1/2}$, which can be almost reached if the level of water is very high. In crosslinking solutions without hydrochlo-

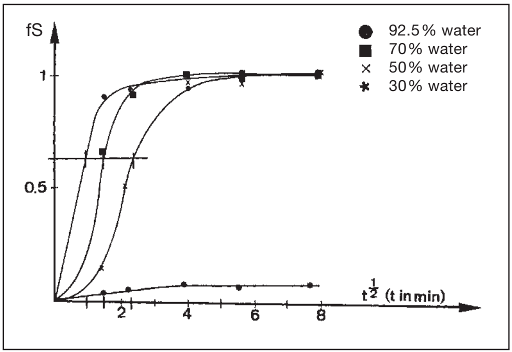

Fig. 1: The relative swelling rate of a viscose fibre, series 1 (7.5% formaldehyde, 92.5; 70; 50; 30% water, remainder acetic acid) (according to Annen).

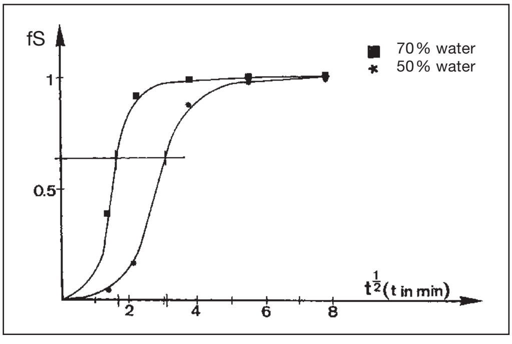

Fig. 2: The relative swelling rate of a viscose fibre, series 2 (14% hydrogen chloride, 7.5% formaldehyde, 70% or 50% water, remainder acetic acid) (according to Annen).

series	H_2O %				
	92.5	70	50	30	18
1	1.2	2.0	6.0	$3 \cdot 10^3$	–
2	–	3.2	10.2	$> 10^3$	$> 10^3$

Tab.: Relaxation time in swelling t_q (in minutes).

ric acid (series 1), the swelling speed is higher than for equivalent experiments with hydrochloric acid (series 2). In series 2 it is not possible to determine the equilibrium value of the experiments with 18 and 30% water, because the fibres hydrolyse before they reach the swelling parameter.

By definition the relaxation period during swelling is the time required for the fibre to swell to 1 – 1/e of the final swelling value (Tab.). The swelling curves are cut at $t^{1}/2 = \tau_Q{}^{1}/2$ and run parallel with the $t^{1}/2$ axis in the diagram $f_Q = \Psi(t^{1}/2)$ where $f_Q = 1 - 1/e$ (Figs. 1–2).

The swelling properties of human hair form important criteria both for the evaluation of diffusion processes, as well as monitoring reversible and irreversible structural changes. In Fig. 3 the chronological sequence of swelling during a sulphite permanent wave process is shown. The influence of temperature on the swelling is clearly visible. There is a surprising result – there is an increase in swelling while the hair is being rinsed after reduction, which is caused by osmosis. This leads to irreversible hair damage.

Swelling capacity Swelling capacity or swelling potential means the capacity of textile fibres to absorb water or other substances such as solvents, in liquid or vapour form, and to store it temporarily. To measure absorption and swelling capacity, the moisture uptake or water uptake and water retention capacity are measured. The moisture uptake is calculated as a percentage of dry weight (under normal atmospheric conditions). Moisture levels can be measured by determining the dry weight by drying out the fibre, or by means of electrical or physical processes.

Swelling fixation (swell thermosetting), term for thermosetting using hot water, saturated steam or aqueous solutions at 20–110°C with swelling agents.

Swelling-induced fabric relaxation The cotton fibre within a yarn or fabric is primarily subject to longitudinal tension during the manufacturing and finishing processes. Wet treatment causes the cotton fibres to swell to a greater or lesser degree, and causes the threads or the run of fabric to stretch lengthways. In this way, the tensile energy becomes more intense in the swollen fibres, and distortion is initially prevented in the subsequent drying or deswelling processes. According to this principle, high levels of latent tension can build up during wet treatment of cotton fabrics under tension. If the deformed fabric is then subjected to a tension-free wet process, the water triggers anisotropic swelling behaviour, which means that the cotton fibre undergoes an extreme expansion in cross-section as opposed to an increase in length. The take-up and twist of the yarns in the fabric is increased, and as the fibre

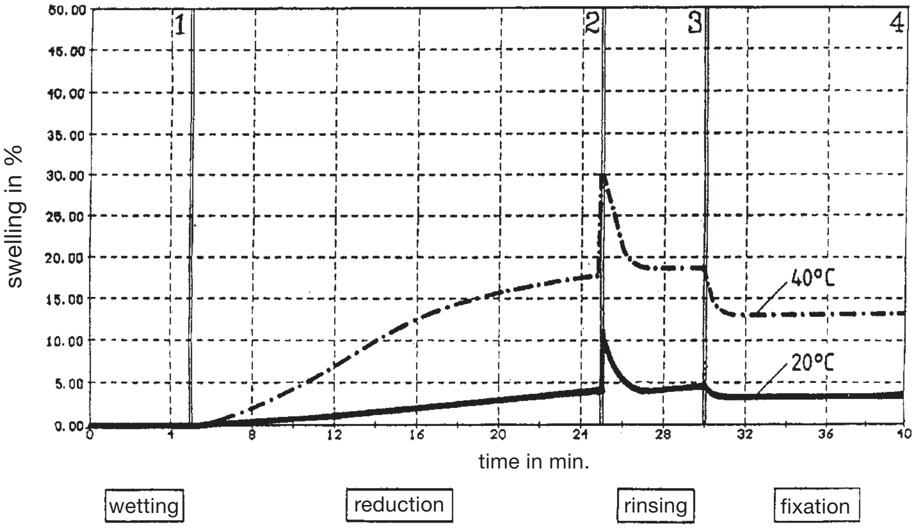

Fig. 3: The swelling curves in a sulphite permanent wave at two different application temperatures.

swelling progresses, freedom of movement of the fibres and yarn becomes restricted. During tension-free water treatment, the hydrogen linkages can be suspended and the deformation reversed. A deeper level of swelling, and suspension of interactions or new formations during deswelling, can only be achieved by using an alkali treatment. This method of stabilization is permanent, in contrast to subsequent water treatment.

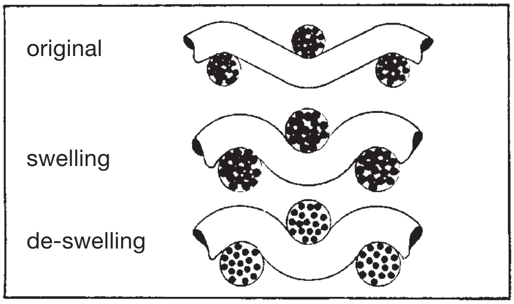

Fig. 1: Diagram of the shrinkage mechanism.

Woven fabric consists of two thread systems that cross over each other. During swelling the take-up and twist, or ondulation, of a thread system needs to increase in order to adjust to the growth of the yarn cross-section of the other thread bundle. It is not possible for the yarn to stretch for reasons of energy, as the fibre only has a small zone of elasticity. As a result, the number of warp and weft threads increases (Fig. 1).

Mercerization means causticizing at an alkali concentration of 28–32° Bé under tension. If the fabric or yarn is tensioned during the swelling process, the lustre is also increased. This lustre occurs as a result of the fibre being pulled smooth, and because of the change to the cross-section. The kidney-shaped cross-section of the cotton fibre becomes almost round as a result of mercerization. This causes increased light reflection in the fibre, which manifests itself as an increase in lustre. In addition to this, mercerization also significantly increases swelling capacity and tear strength, although improved tear strength results in worsening of elasticity.

As an alternative to treatment with a caustic soda solution, pronounced swelling in cotton can be achieved using liquid ammoniac. The Sanforized Company (Cluett Peabody Company) uses a process that consists of an ammoniac treatment machine with a subsequent sanfor system. The use of ammoniac results in further effects and economic advantages, as well as similar positive changes to the properties of the material. The speed and extent of the swelling and shrinkage processes are dependent on

- the particle size of the swelling agent,
- the viscosity of the swelling liquid
- the pretreatment of the cotton fibre and the fabric.

Liquid ammoniac (NH_3) has a lower viscosity and surface tension than cold caustic soda solution. The capacity of caustic soda solution, which is relatively viscous, to wet grey fabric without any added auxiliaries is poor. The NH_3 molecules are small in comparison to the relatively large ion hydrates of caustic soda which react with the fibre, and they can reach the fibre structure much more rapidly.

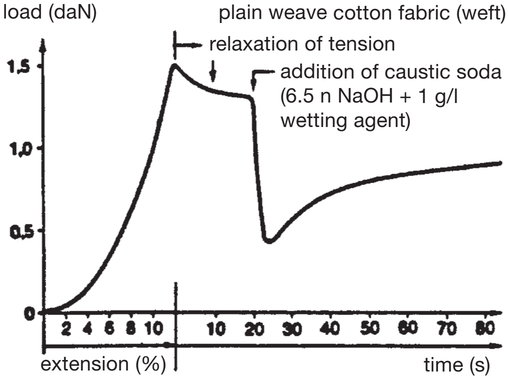

Fig. 2: The inversion effect during mercerization at constant fabric length.

If caustic soda solution is added to a cotton fabric that is subject to a specific tension, the initial result is relaxation caused by tension release. It is only after a few seconds that the swelling forces start to occur (Fig. 2). If water is added to the cotton fabric during the relaxation phase (Fig. 3), it can be observed that water alone has the capacity to accelerate the tension relaxation to a great extent. It can be assumed that the water, which diffuses into the fibre structure more rapidly than Na^+ and OH^-, initially triggers relaxation by opening the H linkages, so that the caustic soda solution (NaOH), which diffuses subsequently, reaches the crystalline zones in the fibre and starts the contraction process.

The treatment of cotton both in liquid ammoniac (NH_3) and caustic soda solution produces pronounced swelling effects. These are caused by the splitting of hydrogen linkages between the OH groups of the cellulose molecules within and between the fibre crystallites and the formation of cellulose swelling agent adducts. This causes a change in the external fibre shape and a greater or lesser degree of fibre shrinkage. This is a consequence of the significant increase in fibril width due to the formation of adducts with the swelling agent and the relaxation of chain molecules which are highly orientated. Liquid ammoniac has a less pronounced

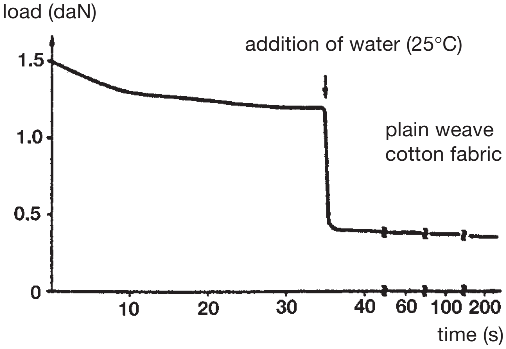

Fig. 3: Accelerated relaxation of tension by the addition of water.

swelling effect than caustic soda solution at room temperature; an increase in temperature causes the level of swelling to decrease. Cotton shrinks much more in caustic soda solution than in liquid ammoniac, however, the shrinkage forces that develop in ammoniac are non-uniformly higher. If the temperature in the caustic soda solution is raised, the shrinkage forces are reduced. A temperature dependency can also be detected using liquid ammoniac. At temperatures below 33°C the shrinkage forces are significantly greater. The reversal of shrinkage force when the caustic solution temperature is raised is relative to the degree of swelling, which reduces. The fact that the ammoniac system produces more pronounced shrinkage forces is caused by the more extreme relaxation processes.

X-ray analysis shows that the basic reactive units in intracrystalline swelling are not individual cellulose chain molecules, but layers of polymer chains. The NH_3 molecules or the hydrated ions in the caustic soda solution only penetrate between the layers of the crystal lattice that remain intact by splitting the hydrogen linkages. The result is the formation of defined cellulose/swelling agent complexes. The water molecules in the solvate shells of the NaOH ions are replaced by OH groups from the cellulose, and the NH_3 molecules are bonded to the cellulose OH groups via hydrogen linkages. If natural cellulose is treated with NH_3 at temperatures in excess of 30°C, the NH_3 cellulose I complex is formed, and at temperatures below 30°C the NH_3 cellulose II complex is formed. Extreme intercrystalline swelling also occurs. If the yarn or fabric is constructed in such a way as to constrain the swelling, the ammoniac swelling value can be drastically reduced. With 20% caustic soda solution between 15°C and 80°C, cellulose forms the NaOH cellulose I complex, and at temperatures in excess of 80°C the cellulose II/III complex is formed.

The low swelling level of cotton in liquid ammoniac is caused by the less pronounced expansion of the crystal lattice because of the relatively small NH_3 molecules. The degree of swelling decreases as the temperature rises. Firstly this effect can be explained by a reduced absorption of caustic soda solution and water, and secondly if the temperature is higher the cellulose II/III complex can occur with a lower level of water accumulation. The NH_3 molecules are more efficient at holding the crystallite layer system together with H linkages than the hydrated NaOH ions. This explains the low level of plasticity, the greater development of shrinkage forces, and the lower expansion capacity of the NH_3 cellulose complex.

Removal of the swelling agent causes the cellulose swelling agent adducts to be destroyed. The fine structure of the fibre is reformed. After the caustic soda solution is washed out at a low temperature in a tension-free state, cellulose II is usually formed. If the washing temperature is high, and tension is applied, the fibre reverts to cellulose I. If ammoniac is removed by vaporization, the cellulose III lattice is usually formed. Cellulose III is not stable in the presence of water; if ammoniac residue is removed in a short steaming process, cellulose III reverts to cellulose I. NaOH mercerization results in a higher level of shorter and narrower crystallites. NH_3 treatment also reduces the size of the crystallites, however the conversion of cellulose III into cellulose I leads to crystallite enlargement. X-rays have shown that after caustic soda or ammoniac treatment, the fibre area where there is little ordered structure has increased by a factor of 2 or 3. Primarily with the ammoniac process, and particularly in the case of cellulose I, there is a large increase in small pores in the fibre, which can be seen from the fact that the fibre is inaccessible for larger dye molecules.

From a morphological point of view, swelling treatments result in

- thickening of cell walls,
- reduction in lumen size,
- an almost round fibre cross-section
- elimination of fibre convolution.

However all these changes are not pronounced in fabric/yarn treated with ammoniac.

Strength is increased as a result of mercerization processes; this is linked with the higher orientation of the crystallites within the macrofibrils. The mercerization process means that dimensional stability is increased, in some cases even without losing fabric length and width. The basic principle that causes alkali treatment to be effective is the reduction of textile tension by splitting and reforming H linkages in the cotton fibre, as a result of which the fibre adopts a low-energy state to suit its shape. Ammoniac treatment can be used for efficient stabilization of particularly thick and heavy fabrics. However after the liquor has been washed out and the fabric has been dried by means of deswelling, the textile adopts new tensions. In this situation it is more effective to remove the ammoniac by drying and steaming, since it occurs in a deswollen state (according to Bredereck).

Swelling kinetics and thermodynamics
Swelling and dissolving are mixing process. Solution is referred to if unlimited mixing of the liquid and the polymers is possible, swelling if there are limitations to mixing. Mixing only occurs voluntarily if the change to the free enthalpy ΔG is negative. In sealed systems with constant pressure, the following applies for ΔG:

$$\Delta G = \Delta H - T\Delta S$$

Therefore whether or not mixing takes place depends on the size and mathematical sign of the mixing heat ΔH and the mixing entropy ΔS. Entropy is dependent on how freely the molecules move. In solid polymers the long chain molecules are extremely strongly fixed. If the polymer is mixed with a liquid, the molecules start to move freely; they can change position in relation to each other, and the individual molecule can bend, twist or curl up. If polymers are mixed with liquids, entropy will generally increase. A rise in temperature increases the value of the negative term $-T\Delta S$, and for this reason has exactly the same effect as a positive entropy change regarding swelling or solution. If ΔG is negative, either ΔH must be negative, i.e. heat is released during the dissolving process, or if it is positive, it must have a value lower than that of $T\Delta S$. If non-polar polymers such as rubber or polyethylene are mixed with liquids, physical bonds such as van der Waals and London forces between polymer molecules and between liquid molecules are broken and replaced with similar bonds between the molecules of the polymer and the liquid. To break these bonds heat is absorbed; while bonds are forming, heat is given off. Depending on which of these processes is dominant, the fibre swelling process is either exothermic or endothermic. If ΔH is positive, the following equation applies to the mixing enthalpy of non-polar polymers:

$$\Delta H = V_M \cdot \vartheta_L \cdot \vartheta_P(\delta_L - \delta_P)^2$$

V_M = volume of mixture;
ϑ_L, ϑ_P = fractional volume of solvent or polymer;
δ_L, δ_P = solubility parameters of solvent or polymer.

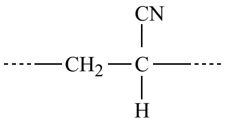
The solubility parameter is a measurement of the intermolecular forces of attraction, which must be overcome during the dissolving process as well as during vaporization; it can be calculated by use of the following equation:

$$\delta = \left(\frac{L - RT}{V^*}\right)^{1/2}$$

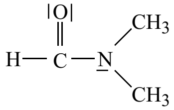
L = molar heat of vaporization;
V* = mean mole volume at temperature T;
R = general gas constant.

If the positive value of ΔH is low, $\delta_L - \delta_P$ is also small, and δ_L and δ_P must be similar in value. If $\delta_L = \delta_P$, the mixture is defined by the entropy term alone. Another way of expressing this: like substances dissolve in each other. Until now, the observations have applied strictly to non-polar polymers. For polymers that contain polarized groups, strong bonds exist between the molecules, which can be explained by hydrogen linkages or dipolar interactive effects. Much higher levels of energy are necessary to split bonds of this type than are required to split the forces between non-polar polymer molecules. For this reason, liquids that are strongly polar themselves are used as solvents, which give off heat while they interact with the polymers. This process is known as solvation, which according to Brønstedt can be described as an acid/alkali interaction: If the polymer contains acidic groups it will be solvated by alkaline liquids and vice versa. Obviously no proton transition occurs in this situation; the process can be more accurately described as electrostatic interactions between polarized molecules.

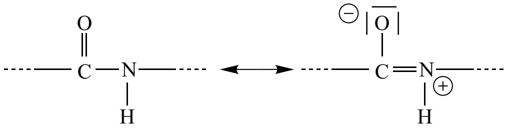
Polyacryl nitrile, for example, contains acidic hydrogen atoms caused by the inductive effect of CN groups, and it dissolves in alkaline liquids such as dimethyl formamide, where the C=O group behaves like a proton acceptor.



$$\cdots - CH_2 - CH(CN) - \cdots$$



There are polymers that contain both acidic and alkaline groups. According to Pauling, the carbon amide groups in polyamides are structured as follows:

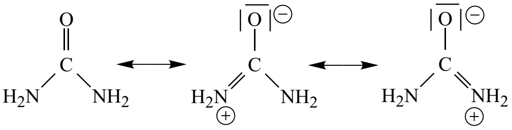


(approx. 40% double bonding properties)

The electron pair at N is not free. For this reason it no longer exhibits any alkaline properties. On the contrary, the C=O group has alkaline properties, and the

N–H group has acidic properties. However the proton acceptor property of the C=O group is much stronger than the proton donator property of the N–H group. For this reason, acidic liquids, such as formic acid and phenols are primarily used as solvents.

The interchenary forces of attraction in polyamides can be better described as dipolar interactions than H linkages. The interaction of urea with polypeptides and proteins is also caused by dipolar forces, as urea exhibits its polar elements in its mesomeric limit form.



The free motion of the molecules is limited by the solvation process, which lowers the ΔS value. In addition, the polymer becomes less polar as the acidic and alkaline groups neutralize. The solvated polymer now behaves almost like a non-polar polymer, and only mixes with the liquid if the solubility parameters of the liquid are not too different from those of the solvated polymer. Analysis of the glass transition temperature and swelling properties are among the most important physical/chemical methods that characterize the crosslinking potential of polymers. Crosslinking of polymers raises their glass transition temperature. This displacement is insignificant for low levels of crosslinking, such as is used in cotton finishing. It is only at higher levels of crosslinking that this displacement becomes more significant. Furthermore the displacement of the glass transition temperature with an increasing level of crosslinking is not independent of the chemical composition of the polymer concerned, so that this method is not universally applicable. If a non-crosslinked polymer is soluble in a liquid, once it is crosslinked it will only swell in that solvent. Swelling measurements provide three types of information about crosslinked polymers:

- quantity of polymer that is not incorporated as a covalent part of the polymer network, and can therefore be extracted as a sol fraction,
- molecular weight of sol fraction,
- swelling level of insoluble gel fraction.

Under normal circumstances the swelling ratio is as follows:

$$\frac{\text{volume of swollen gels}}{\text{volume of non-swollen gels}} = q$$

The sol fraction is denoted thus:

$$\frac{\text{weight of extracted polymers}}{\text{initial weight}} = s$$

The analysis of sol gel is used on cellulose crosslinked with formaldehyde; the apparent crosslinking density, measured using the gel fraction in cuen. The formaldehyde content of the sample increases, with the variation depending on the type of crosslinking process. Since the swelling of cotton with solute reagents is so important, there are many known methods of analysing the swelling. In most cases the increase in fibre weight is measured. The actual swelling parameter in a thermodynamic sense, i.e. the volume effect that is additional to the superficial adsorption effect, is only defined in methods where the change in volume is measured directly (if there is uptake of a substance into a solid body, it is known as adsorption, if the volume effect outweighs the superficial effect). There are only a few reagents that, independently of their chemical nature, have particular physical qualities that enable them to react anyway with the cellulose hydroxyl groups in the morphological structure of a cotton fibre without the presence of additional swelling agents. Dimethyl sulphate, for instance, is very effective at methylating cotton cellulose in the presence of sodium hydroxide, because the reagent is liquid, and once it has caused swelling in the insoluble cotton substrate, it can diffuse away to the hydroxyl groups of the cellulose. In the same way, formaldehyde in gas form in the presence of gaseous hydrochloric acid is capable of crosslinking cotton fibres very evenly, because the diffusion of the reagent and catalyst in a gaseous state at a specified level of fibre moisture occurs rapidly and penetrates right into the morphological fibre structure.

In both cases, the volume effects that accompany diffusion and adsorption of the reagent cause more hydroxyl groups in the cellulose to become accessible for reaction than the number of hydroxyl groups on the surface of the solid body, e.g. on the capillary walls. But even in the case of the gas phase crosslinking described, the presence of an agent that influences the hydrogen linkage system in the cotton, such as water vapour, is necessary to enable a reaction to take place.

In a similar way most chemical reagents need a solvent as a partner for the reaction with cellulose, which prepares the solid substrate, i.e. which causes swelling to allow diffusion of the reagent into the hydroxyl groups. To achieve this, the solvent itself must diffuse into the pores of the fibre, split the hydrogen linkages of the cellulose, and build new linkages to the substrate. It is only then that further high-volume solvent molecules can penetrate into the solid and break further hydrogen linkages. Known solvents have varying levels of suitability for this process, as a result of various factors. The surface tension of different solvents has a strong influence on their interactive potential with fibres. Water has by far the highest surface tension (0.073 N/m), and is retained more strongly by hydrophilic fibre surfaces than for instance acetic acid (0.027 N/m). For this reason, when methods such as centrifuge swelling are used for comparing the swelling capacity of cellulose in different solvents because of the varying adhesion potential of liquids to the fibre surface, apparent effects that have nothing to do with swelling are measured.

Obviously the diffusion processes that are essential for fibre swelling are dependent on the size of the molecule. Two simultaneous processes are occurring at different speeds while a solvent is acting on cotton fibres, for example:

a) Rapid diffusion in interfibrillary cavities in the accessible areas of the micro-fibrils and elementary fibrils, which seems to be independent of the molecular size of the solvent.

b) Further rapid penetration into the elementary fibrils is only possible with cotton if there are sufficient small molecules, such as water or methanol. Classification according to molecule size is only practical if the molecules have similar capacity to split hydrogen linkages. The capacity of solvents to split hydrogen linkages varies greatly. This means that the degree to which cotton is accessible for methylation is dependent on the swelling effect of the solvent used. If the fibre is treated with diazomethane in ether, only the surface of elementary fibril systems, which on average appears to consist of four elementary fibrils, is methylated. In contrast, if 2-molar caustic soda solution and dimethyl sulphate are used as a methylation agent, a much more extensive methylation of the surface of individual elementary fibrils is possible. This is because the aqueous alkaline solvent is able to separate the elementary fibrils from each other, which are bonded by means of strong hydrogen linkages. This is not the case if ether is used. In the situation described, the ether could only penetrate the morphological structure of the fibre to a certain extent because it was saturated with a small amount of water. On this principle, the extent of interaction of an organic solvent with the hydroxyl groups and acetal oxygens present in the cellulose can be increased by adding substances with a higher capacity for splitting hydrogen linkages.

Because of cotton's complex physical, morphological and supermolecular structure, non-ambiguous measurement of swelling is almost impossible. Length measurements of the swelling fibres have to be classified as unsatisfactory, because cotton fibres exhibit swelling anisotropy, i.e. they swell much more in the direction transverse to the fibre axis than longitudinally. For this reason, care has to be taken to measure the fibre expansion in width or cross-section. However, as the cotton fibres are non-uniform, it is very difficult to record the results. Warwicker's work showed that in order to analyse the transverse swelling it was necessary to take 200 individual measurements at the widest point of the fibre for each swelling. In addition to this, measurements of the change in width are not necessarily representative of the overall swelling process, because the fibre mass does not only extend externally, it can also extend into the lumen of the fibres. This effect can only be detected under a microscope, by means of complicated measurement of the increase in cross-sectional area of the fibre. However the methods that analyse an increase in fibre volume are suitable for relative measurement; absolute measurement of fibre swelling does not appear to be possible using current processes, because the morphological structure of the cotton fibre is irregular. In literature on this subject there appears to be some confusion whether the diffusion of various different types of swelling agent into the fibre fibrils causes changes to the x-ray structure or not. The varying statistics result mainly from the swelling conditions, which are sometimes very different from each other. The x-ray structure of cotton fibres was analysed in the presence of swelling agents of varying strengths and after their removal. A comparison was made with the increase in volume of the fibre. It became apparent that even with swelling at a maximum, there was a residual flexing effect. According to Warwicker, although swelling of the elementary fibrils is possible, using

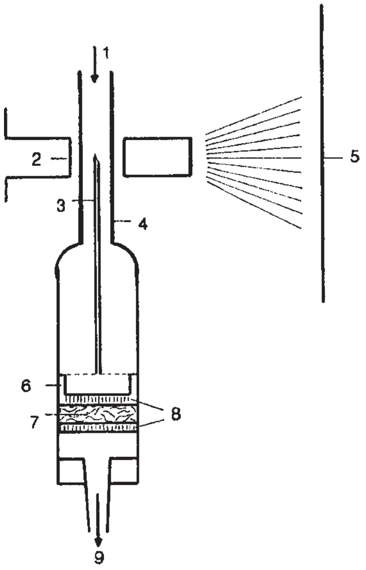


Fig. 1: Swelling volume measuring device for pressed cotton fibres (according to H. K. Rouette and Kalyana Raman).
1 = addition of swelling agent; 2 = projector; 3 = pointer; 4 = glass vessel; 5 = screen; 6 = piston; 7 = cotton fibres; 8 = porous plates; 9 = drain for swelling agent.

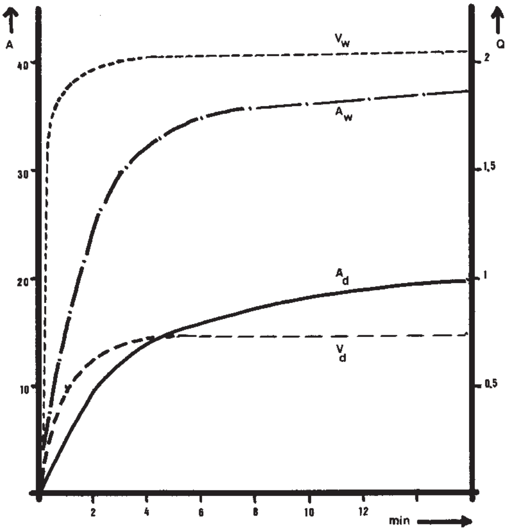

Fig. 2: Comparison of the swelling kinetics of cotton in crosslinking liquor following the detwisting rate method (A) and the swelling volume method (Q).

Form D process and form W process: crosslinking of cotton.

caustic soda solution for instance; it is not possible to completely separate all cellulose molecules, because the van der Waals forces within laminar cellulose chain units are too great. Warwicker's work showed that recording the x-ray structure is a suitable method of describing a swelling process in an aqueous swelling medium in a state of equilibrium swelling.

The yarn untwist count is a measurement of swelling and to a lesser extent for tension relaxation of cotton fibres in an appropriate swelling agent (Fig. 2). It is not possible to distinguish these two phenomena clearly. Cotton yarns in liquids that cause particularly slow swelling (dimethyl formamide) do not untwist completely within the prescribed test period of 3 min, i.e. they do not reach the level of equilibrium. For this reason it is recommended that the number of twists until it becomes completely motionless are taken into account for an absolute analysis, i.e. the overall kinetics of swelling should be observed. Although the untwisting rate of yarn is indirectly caused by an increase in volume from the swelling, a more direct method must be used for an exact measurement of the increase in volume (Fig. 1). One method of measuring the swelling of polymers allows the swelling speed in solvents to be analysed. The increase in volume of a sample that is both in contact with the swelling agent and with mercury has the effect of displacing the mercury. This transitory displacement is measured using a calibrated capillary. With the help of this device made by Vavruch, it was established that the swelling curves of sephadex gels in water form an S shape. The overall swelling process can be divided into three phases:

1. Induction period.
2. The diffusion of the solvent molecules into the gel becomes the phase that determines the speed.
3. The restriction of this diffusion becomes the dominant factor.

In the middle part of the swelling/time curve, the process can be described using a kinetic equation of a reaction of the first order.

The swelling kinetics of modal fibres in water (Fig. 3) dependent on temperature is scarcely different from that of cotton (Fig. 4) or viscose (Fig. 5): Although swelling is an exothermic process, after 20 min at a higher temperature, a higher level of swelling in water is always achieved than at room temperature. Presumably this effect can be linked with the fact that the actual heat effect caused by swelling is superimposed by the decomposition of the water clusters, which means that the water can penetrate more efficiently into the fibre. This is because the swelling substance consists of smaller, more mobile molecules that can penetrate further into the fibre.

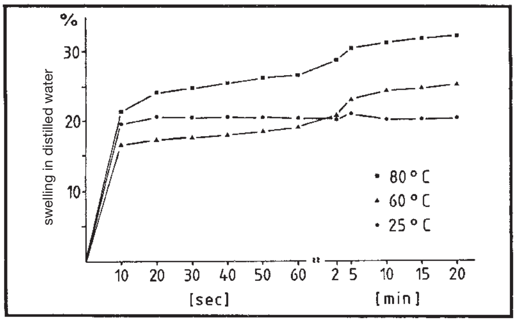

Fig. 3: The swelling of modal fibre in water at various temperatures (by DITF).

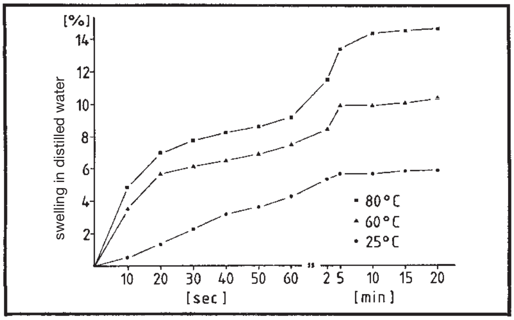

Fig. 4: The swelling of cotton fibre in water at various temperatures (by DITF).

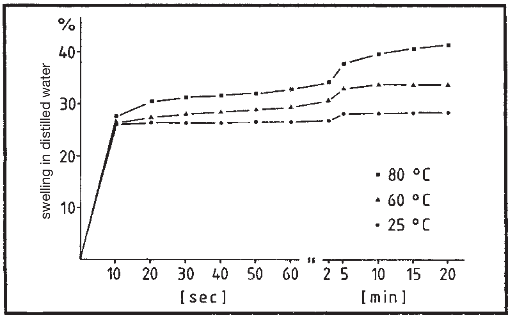

Fig. 5: The swelling of viscose fibre in water at various temperatures (by DITF).

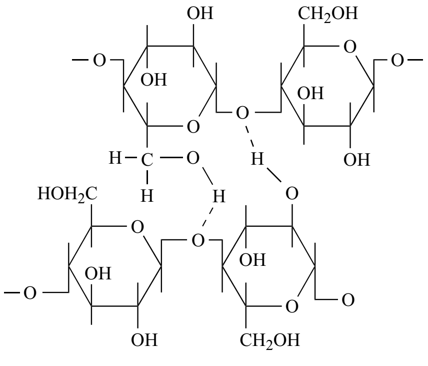
A swelling process can be divided up into a dynamic initial phase that is driven by kinetics, as well as a dynamic equilibrium phase that is based on thermodynamics. The state of the polymer chains in the crystalline zones, which are facing each other a minimal distance apart, is determined by van der Waals forces and hydrogen linkage bonds. The hydrogen linkages, where the H atom of a polarized molecule forms a linkage to the adjacent electro-negative atom, can be categorized as electrostatic interactive effects. If a proton belongs to two atom structures of maximum size, energy can be gained.

Between the two immediately parallel polymer chains, an electro-positive H atom links with two oxygen atoms with a high level of electro-negativity; oscillation takes place between the two oxygen atoms. The separation energy is between 20 and 40 kJ/mol. Segments of two cellulose molecule chains with formation of hydrogen linkages:



The van der Waals or London interactive effects are intermolecular forces that are important for crystallite formation. This bond results from the fact that even completely apolar molecules are subject to a temporarily altered dipolar moment as a result of electron motion. Although the separation energy of each bond is only 20 kJ/mol, the high number of these bonds causes adsorption forces to be generated. There are intermicellary cavities between the fibrils. As the cellulose molecules in these regions are amorphous (unstructured), there are hardly any polymer chains that are a minimal distance apart. For this reason only a few partial valency bonds can form. The numerous functional alcoholic groups and the amorphous structure of the intermicellary regions cause cotton to have a high affinity to water. This is apparent from the fact that it is highly hydrophilic and has a high level of water retention. Cotton has the capacity to absorb up to 11% humidity from the air, and to bond physically up to 45% of its dry weight in water. In water a swelling of the fibre occurs. As the fibre has an anisotropic structure, there is a high transverse swelling of approx. 28% as opposed to longitudinal swelling of approx. 1%. The water can penetrate the crystallite structure of the cotton fibre and split up the physical interactions in the intermicellary regions. The fibrils can slide past each other, i.e. the water penetrates the areas where there is less structure and forces the fibrils apart. On drying, the hydrogen linkage bonds reform and the van der Waals forces become effective again. This new orientation depends on the angle of the fibre axis in relation to the direction of strain. In other words, if a cotton fabric is turned while it is in a wet or swollen state, the H linkages will form in the deformed state. If the fabric has sufficient opportunity to relax, the newly formed physical interactive forces stabilize the relaxed dimension during deswelling.

Cellulose has the capacity to take up water via the H linkage links. Since no shift of the valency electrons occurs, the process is known as type 2 hydration. Because of the hydrogen linkage bonds, a relatively solid solvate shell forms around the cellulose molecule, i.e. the water dipoles can be deposited on the polymer. In thermodynamics the progress of a reaction is defined by the interaction of activation energy, enthalpy and entropy. If a solvated, inorganic molecule changes in water, it is not only the entropy change of the molecule that should be taken into consideration, but also the change to the solvation water. If a macromolecule only bonds with a little water, the water entropy increases. If cellulose dries, energy must be extracted from the surroundings in order to split the state fixed by means of hydrogen linkages. Enthalpy, the driving force of the reaction, can be termed endergonic. According to the Gibbs-Helmhotz equation, the free energy acquires a positive value.

$$\Delta G = \Delta H - T \cdot \Delta S$$

$$\Delta G > 0$$

ΔG = free enthalpy, driving force of reaction;
ΔH = size of energetic state, degree of reaction heat or enthalpy at constant pressure in kJ/mol;
ΔS = entropy change, controls the state of order of a system;
$T \cdot \Delta S$ = energy used to create order.

The water accumulation can be described as follows:

$$(C_6H_{10}O_5)_n + (H_2O)_n \rightleftharpoons (C_6H_{10}O_5)_n \cdot (H_2O)_n$$

The increase in volume causes the entropy of the system or the cellulose to become greater.

$$S = K \cdot 1n\ (M)$$

K = Boltzmann constant;
M = possible number of states.

The system aims to reach a state of maximum stability, the driving force of the reaction decreases; this is known as exergonic.

$$\Delta G = \Delta H - T \cdot \Delta S$$
$$\Delta G < 0$$

When water accumulates on cellulose, energy is released. This energy appears in the form of reaction heat or enthalpy. The preceding sign is negative, and the reaction can be termed exothermic.

$$\Delta H = \Delta G + T \cdot \Delta S$$

The crystalline structure of cotton fibre is fixed by means of H linkage bonds while the fibre is at air humidity level. The solvate shell around the cellulose molecule is also formed as a result of this bond. However, to enable swelling and water accumulation, the hydrogen linkage bonds of the micellary formation need to be split. Energy must be available, even if only a small amount, to break these partial valency bonds. If the cotton is in an aqueous medium, there is more energy available because of reaction heat to split the H linkage bonds in the micellary structure.

Swelling liquid (absorption liquid), bonded liquid that is generated in the amorphous regions and on the surface of the crystalline areas of fibres as a result of accumulation or addition of liquid molecules. If polar liquids accumulate, partial valency bonding occurs.

Swelling of rubber-covered rollers Rollers that have an elastomer coating are subject to dynamic and/or chemical stress during operation. Since the main component, rubber, is organic in nature, it means that the ageing process (as with all organic materials) begins shortly after manufacture. These ageing processes vary greatly depending on the type of elastomer, and in most cases it is so slow that it is not possible to detect by short-term observation. In addition these processes are extremely dependent on the compound structure and development factors. Chemical stress can be caused by interaction with the active medium (or a component of that medium) and components in the rubber mix. These are the physical processes of swelling, or vice versa of extraction (see Fig.), which occur primarily in the organic phase (with the exception of water). However they can also be based on chemical reactions, and in the worst case scenario they can be caused by a combination of the two.

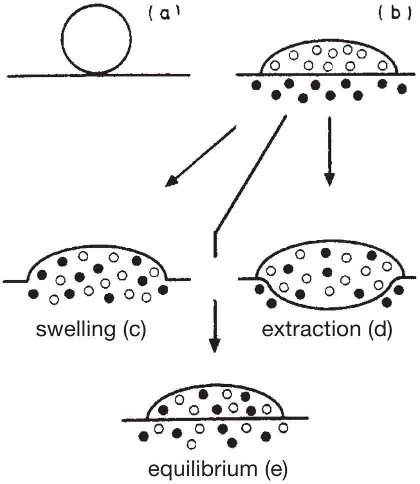


Fig.: Diagram of the swelling of rubber-covered rollers.
a) no wetting = no interaction; b) wetting = the possibility of interaction; c) swelling = penetration into the rubber; d) extraction = leaching out from the rubber; e) equilibrium = penetration and leaching.

The German standard DIN 7716 contains a summary of general guidelines for the cleaning and maintenance of rubber products, in particular where the expected storage time is in excess of 6 months. The basic ideas can be applied fully to rollers, but the guidelines do not include storage requirements specific to rollers.

Rubber-coated rollers used as elements of a machine are subject to continuous operating stress. For this reason it is advisable to monitor their condition and functioning capacity constantly by means of (preventative) maintenance.

Swelling of textiles, measurement of In order to characterize the changes in the properties of cellulose caused by caustic soda solution, several methods can be used. These methods frequently only simulate secondary states of cellulose, i.e. the swelling state in the absence of the swelling medium, after the caustic soda solution has been washed out.

There are different types of swelling measurement:

I. Woven fabric swelling: The fabric sample is placed between two glass plates, weighted with 2 kg and pressed for 3 min. The thickness of the sample D_0 is measured. Then the sample is placed in the measuring gauge between the carrier and the stamp, which transfers the change in thickness of the sample caused by the effects of swelling directly and continuously onto an iron core of two inductive coils. The inductivity of the coils changes direction when the iron core moves. The current generated is transferred to a recorder, where the signal can be amplified as required. Any change in the current is directly proportional to the change in sample thickness ΔD. The swelling at a specific time t can be calculated as follows:

$$Q_t = \frac{\Delta D}{D_0} \cdot 100$$

Advantage: Rapid, simple, time-related recording of the swelling sequence and of the smallest and most rapid swelling process.

II. Microscopic measurement of the fibre width is carried out on relatively long fibres. This is an awkward method, and it is not possible to record the time-related sequence. At least 200 measurements must be taken for statistical reasons.

III. Laminar thickness swelling measurement, carried out on punched cellulose sheets: visually inaccurate, time-related tracking not possible.

IV. Compressed cellulose platelets; swelling is measured using a vertical microscope.

V. The change in volume of a compressed cotton fibre layer is transferred to a stamp that is linked to an indicator.

VI. Yarn detwist test, where the yarn untwisting rate in the swelling medium is measured. Unsuitable for low levels of swelling.

Swelling of wool in formic acid Formic acid swelling has been proposed as a method for analysing the level of crosslinking in wool. This process is a gravimetric analysis of the quantity of formic acid absorbed by the wool fibre. This method can be used for instance in order to assess the extent to which the wool is crosslinked by bifunctional reactive dyes. Overall three materials were tested. 4 parallel wool samples, of 0.3 g each, were weighed exactly in a 100 ml glass beaker containing 40 ml formic acid (98%, density 1.22) and left for exactly 15 min. After 12 min the samples were stirred once using a glass rod. After the 15 minute period had expired, the swollen wool was removed using the glass rod, allowed to drip-dry and transferred to a centrifuge tube. This centrifuge was previously packed with 2 g of cotton wool, which half filled the tube. There is a paper filter on the cotton wool, to ensure that the wool and the cotton wool are kept separate. Finally hydro-extraction was carried out in the centrifuge at approx. 8000 rev/min. After the centrifuge process, the wool soaked in formic acid was transferred to a weighing bottle and weighed. Finally the dry weight of the wool was established by drying overnight at 105°C in a drying oven. The swelling capacity of the wool in formic acid is given as a volume fraction of the wool.

$$V = \frac{W_W/d_W}{(W - W_W)/d_A + W_W/d_W}$$

W_W = initial dry weight of wool;
W = damp wool after centrifuge treatment;
d_W = density of wool (1.3);
d_A = density of formic acid (1.22).

As can be concluded from the results (see Fig.), the swelling capacity of wool dyed with reactive dye with a high crosslinking effect (C) is between the values for untreated wool (A) and the values for (B), which was dyed with a low crosslinking dye. For this reason, formic acid swelling is not suitable for analysing the level of swelling in wool after reactive dyeing using α-bromacrylamide dyes (according to Werkes).

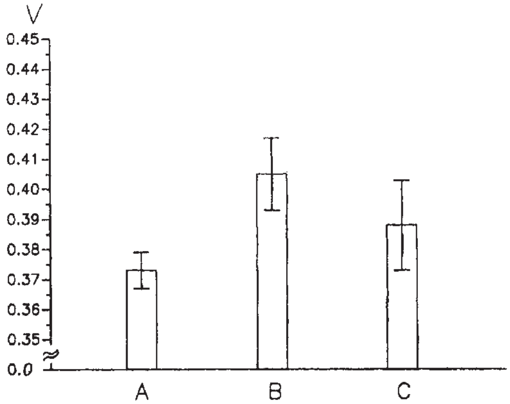

Fig.: The swelling in formic acid of dyed and undyed wool, with indication of the confidence range for a statistical certainty of 95%.
A = untreated fabric, HBL 41%; B = fabric dyed with 10% by weight Lanasol Red B (Ciba Geigy), HBL 17%; C = fabric dyed with 10% by weight Lanasol Red G (Ciba Geigy), HBL 9%.

Swelling-resistant finish The high swelling capacity of synthetic fibres made from regenerated cellulose is the cause of reduced mechanical properties while the fibre is wet. Water-repellent finishes can only delay swelling but not prevent it. Since more utility properties than just reduced swelling capacity are expected of regenerated cellulose products, swelling-resistant processes are no longer particularly significant. Reduced swelling can be achieved at the same time as good crease recovery properties using crease-resist finishes (→ Resin finishing). All other types of process are today only of historical interest, such as → Formaldehyde finishes. Not only regenerated cellulose fibres show a reduction in swelling, for instance if dried several times, it can also apply to natural fibres, and it can be assumed that this effect derives from a change to the fibre structure.

Swelling test for cotton (soda swelling process), microscopic test for chemically damaged cotton. Treatment of cut fibres between object carrier and cover glass with caustic soda solution (density = 1.26). Results: circular, sector-type protuberances = healthy cotton. Some degree of protuberances that have disappeared, with broadened ends = start of damage (permitted damage threshold). Nothing but swollen cylinders = extreme damage (e.g. resulting from too much bleaching). This sampling method for swelling is a certain test for any cotton damage, which is more reliable than other possible methods such as Fehling's solution, methylene blue count, silver test.

Swelling test for wool Microscopic test for (un)damaged wool. Treatment between cover glass and object carrier with ammoniac caustic potash solution (20 g pure potassium hydroxide in 50 ml pure ammoniac, density 0.857, dissolved during cooling). Results: After 1–2 min slowly growing "ulcers" appear over the entire length of the fibre = acid-damaged wool; if this phenomenon only appears after 8–10 min = healthy wool (→ Sodium hydroxide process).

Swelling time of polyester fibres in hydrothermic treatments One of the most important process-related parameters in textile finishing processes is the amount of time the fabric spends in the medium used for treatment. For reasons of economy, this duration should be as short as possible, and for technical reasons related to quality assurance in production, it needs to be relatively long. Because of this discrepancy it is essential to be sure, after each time the fabric is treated, that the treatment has been successful from a technical point of view. For heat-setting processes involving synthetic fibres, success can be gauged by tension relaxation and subsequent crystallization, which can be monitored afterwards with pretreated polyester fibres.

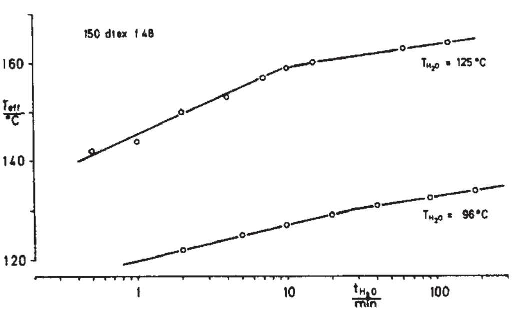

Fig. 1: The effective temperature of hydrothermic treatments of polyester multifilament yarn (according to Berndt).

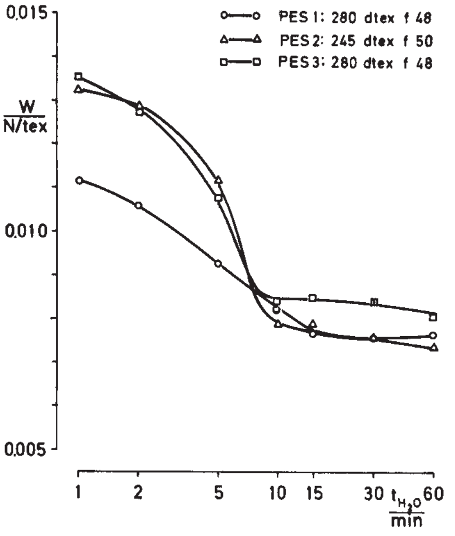

Fig. 2: The working capacity between 5% and 10% extension of various polyester filament yarns which have been pretreated with free shrinkage in water at 98 °C (according to Berndt).

With hydrothermic treatment the softening effect of the water is superimposed on the purely thermal effect. To achieve this softening effect, as well as reducing friction between the fibres, the water has to diffuse into the fibres. If the "hydrofixation" of the polyester fibres is tested using differential thermoanalysis dependent on the duration of treatment in the medium, which is water at a constant temperature, the result is the relationship shown in Fig. 1. Regarding the effective temperature, two linear logarithmic periods of time are observed, which reflect the increase in crystallization speed. From this result it can be concluded that in the first period the speed of crystallization can be established from the diffusion of the water into the fibres, because if the fibre structure remains identical the diffusion speed increases in line with the temperature. In the second time period however, the crystallization speed is independent of the treatment temperature, as is the case with setting in hot air. If the slopes of the curves in the first period are extrapolated to an effective temperature value that is equal to the treatment temperature, then in both cases, the result will be approx. 2 s treatment time, which should be equal to the time taken for the fibres to heat up in the treatment medium (water). The deviation points in the curves in Fig. 1 represent the times at which water absorption into the fibres reached equilibrium point. For the fibres in this test, this occurred after 10 min at 125°C, and after approx. 30 min at 96°C. The structural changes to the fibre shown at the effective temperature with hydrothermic treatment was monitored using a classic textile testing method, the stress-strain behaviour test.

In Fig. 2 the working properties of polyester filament yarns, that were pretreated hydrothermically at 98°C at different times with free shrinking are shown. In this case there are also two characteristic curve sections, from which the first section shows short dwell times that can be explained by the increasing absorption rate of the fibres. On this principle the deviation point in these curves shows the point in time at which the fibre swelling has finished. However this point is certainly not defined only by the single filament titre - even though the cross-section is round, no correlation has been found between the swelling time and the titre; it is dependent on structure.

It has been established that alteration to the structure, and therefore also the shrinkage of hydrothermically treated polyester fibres has to be divided into three phases:

1. The heating up phase, which only lasts a few seconds, and during which a change to the material occurs, as in hot air.
2. The diffusion phase, which lasts for several minutes, depending on the temperature of the treatment medium, titre and structure of the fibre.
3. The dwell phase, in which the fibres have swollen to saturation and subsequent crystallization eases off exponentially to the treatment time.

The first two phases are particularly important in textile finishing. In the first phase the shrinkage is created, depending on the treatment temperature, and in the second, after-shrinking occurs depending on the rise in effective system temperature. After the swelling process has finished, this temperature is about 35 K above the temperature of treatment. Stabilization of the fibre structure also occurs as a result of subsequent crystallization, which is basically completed during balanced swelling (Heidemann, Berndt and Stein).

Swelling, water of (swell water), water taken up by the fibre adsorptively by means of actual → Swelling, which can only be eliminated by the effect of heat (drying). There are two different types:

I. Water that is bonded chemically by means of hydrogen linkages (the most difficult type to remove, usually only present in small quantities. Exception: wool).

II. Water that has accumulated in the amorphous regions of the fibre, which determines the actual swelling of the fibre.

Swell process nonwovens → Nonwovens made from fibre fleece; bonded by the effects of a swelling agent (e.g. cotton felt).

Swimming roller (S roller), roller construction where the roller floats on a hydraulic cushion. In many textile finishing processes, squeezing is required. As well as separating liquor off, this process is also used to transport the fabric. The intention is to remove substances from the fabric or to add something. Both actions need to take place as smoothly as possible. In textile washing machines it is frequently the case that the fabric run is squeezed unevenly, usually with better results at the edges. In addition to this, the concentration of liquor to the right and left of the fabric run is often not evenly concentrated around the fabric itself. The consequence of this is a higher exchange of substances at the edges of the fabric. In order to keep the deviation within acceptable limits, squeezing units with rollers should be installed at certain points of the finishing process to ensure that any deflection is corrected. Wrapped or angled rollers can be used for correcting deviation. Deviation correction using S rollers (Küsters) was developed in 1956 as a follow-up to the built-in squeezing element with stabilizing rollers (Fig. 1). This squeezing element made it possible, even in the early 50‘s, to adjust a nip evenly or deliberately unevenly. As a result of specific disadvantages, such as pressure elements external to the roller and above the fabric run, the S roller system used today was devel-

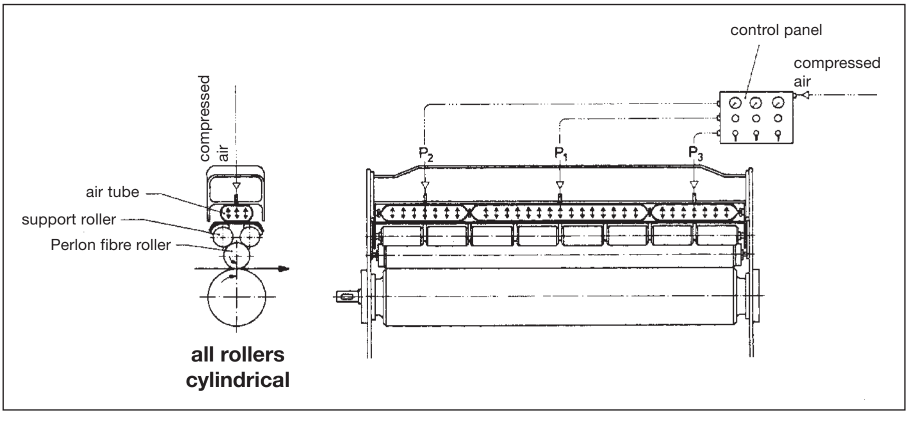

Fig. 1: Diagram showing the principle of the squeezer installation component of the year 1956 (Küsters).

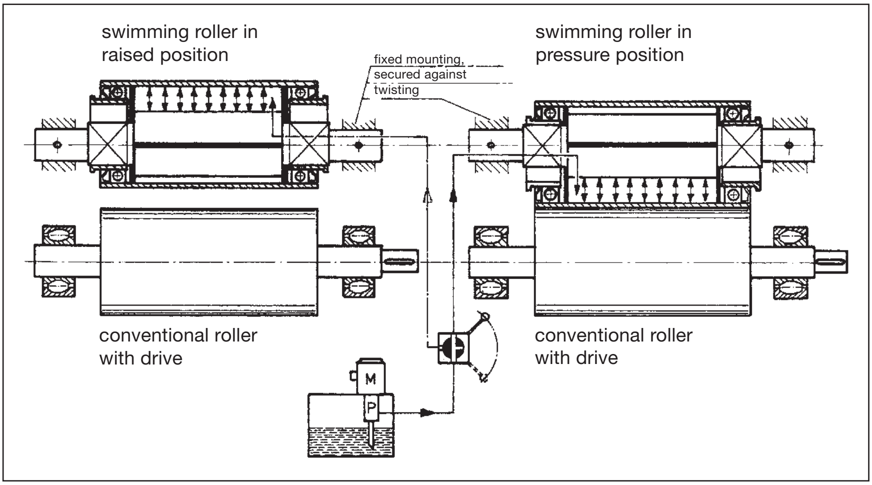

Fig. 2: Diagram showing the principle of a swimming roller as in the old system from the 1950s (Küsters).

oped, where the pressure elements are contained within the roller. The first rollers of this type only had a hydraulic pressure chamber (without individually adjustable bearing pressure). Although these rollers were along the lines of a conventional cylindrical roller, the flexing potential was limited (Fig. 2). Despite the elastic roller coatings, the system put the fabric seams under stress. Instead of a fixed pivot bearing, pneumatic pressure cylinders were used and the lifting gear inside the roller was rigid. It was only with this configuration that the way was clear for a pressure roller as shown in Fig. 3.

The operation of the hydraulic chamber and the bearing pressure can deflect every S roller positively or negatively, or allow the flexible line of a conventional roller to be followed whilst applying even pressure. The extent of linear pressure deviation depends on the construction of the conventional roller. For many processes it is sufficient to operate using only one S roller in the padder or drying system. This applies to drying (water extraction), application of substances that are invisible or not easily visible, treatment of pile articles or printed fabric, and low-temperature dyeing by rolling (side balancing in batch) (Fig. 4). The situation is different in processes with a rapid reaction, such as before a hot flue or steamer, and during drying. Here the most important factor, as before, is that articles are smooth and identical on both sides. To ensure that this is so, the rollers must have an identical diameter, hardness, quality and roller arrangement. These requirements apply to a dye padder with two S rollers arranged horizontally (Fig. 5). The two rollers are carefully

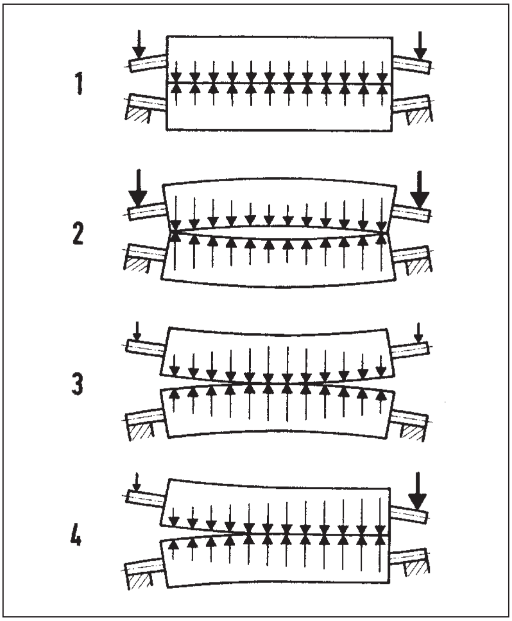

Fig. 3: Possible settings for the nip between the paired rollers of a swimming roller, once it had become feasible to replace the fixed pivot bearing with pneumatic pressure cylinders (Küsters).

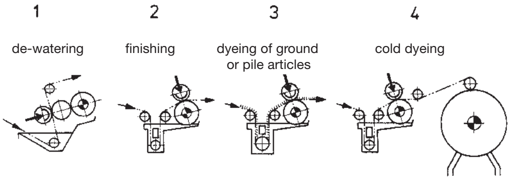

Fig. 4: Diagram showing the application of swimming rollers to various wet processes (Küsters).

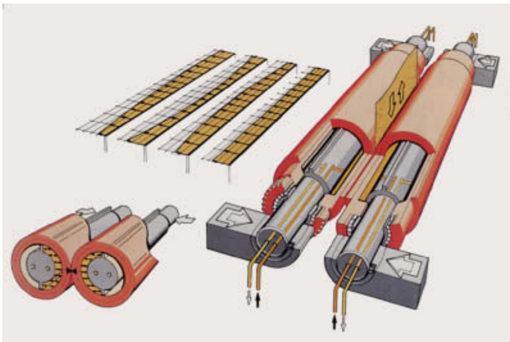

Fig. 5: Diagram showing the application of swimming rollers mounted horizontally (Küsters).

joined together. This is because of the bending behaviour of the two S rollers against each other. When interaction takes place between a conventional roller and an adjustable roller, the conventional roller deflects under pressure. In order to keep deflection at a low level, this roller must have a specific diameter. The adjustable roller should be a little inflexible, so that it can follow the bending line of the conventional roller.

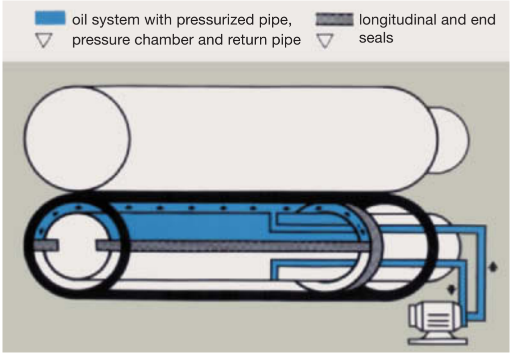

Fig. 6: Finishing padder with a swimming roller mounted vertically below the conventional squeeze roller (Küsters).

The conventional roller deflects when the linear pressure is even, and must deflect even more if a higher level of squeezing is required in the centre of the roller. On this principle, pairing a rigid roller with a highly flexible roller will create the ideal joint. However, a joint formed between two adjustable S rollers is different. In this situation the controlled deflection of the two rollers combine. If the squeezing effect in finishing processes needs to be particularly even, a floating roller with a conventional roller, arranged vertically, is the ideal combination (Fig. 6) (according to Itgenhorst).

Swivel batcher Swivelling → Batching device for screen printing with axle drive and two operating points, which can be varied and used alternately by swivelling. Ensures that the batch is changed quickly and that the fabric runs evenly.

Synchronization (Gk.: synchronos = at the same time), making two processes or machines operate simultaneously; for instance the assimilation of fabric running speeds of a serial combination of machines in a continuous production line, by modulating the electricity supply (voltage or frequency) of each motor, e.g. by means of a → Compensator roll device. This type of synchronization to reduce voltages can also be installed in an individual roller vat between every deflecting roller (Fig. 2).

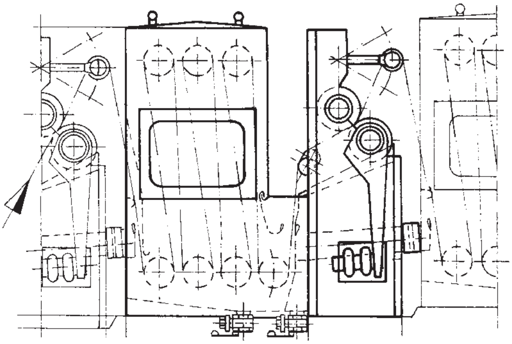

Fig. 1: Synchronization achieved between two roller vats using compensator rollers which supply information to the drive motors.

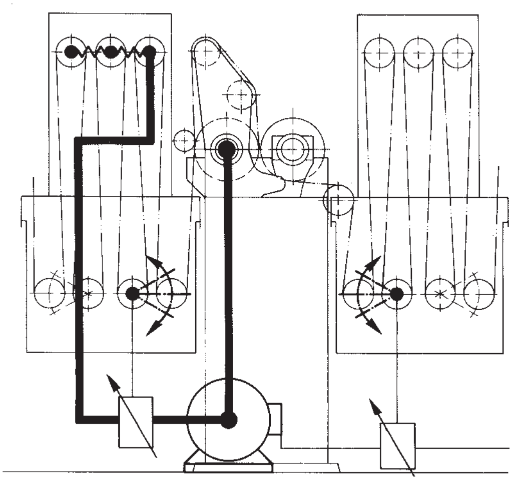

Fig. 2: Synchronization of the movement of goods from one loop to the next in a Babcock roller vat.

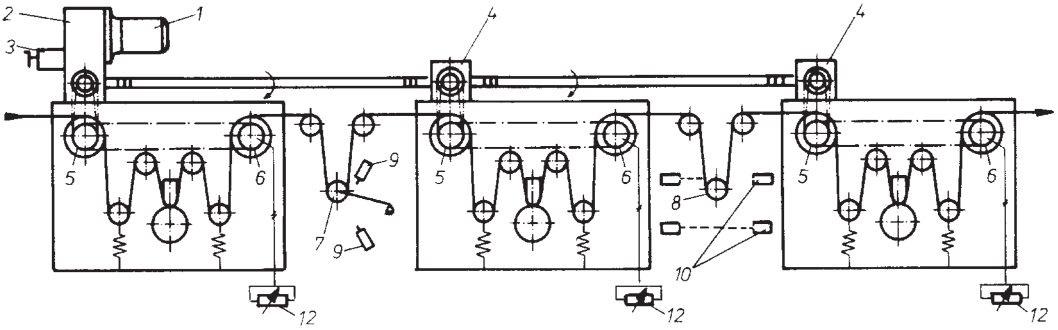

Fig. 1: Two-position control. 1 = three-phase AC motor; 2 = steplessly adjustable transmission; 3 = manual adjustment; 4 = angular transmission; 5 = electromagnetic clutch; 6 = electromagnetic friction clutch; 7 = compensator roller; 8 = dancer roller; 9 = terminal position switch; 10 = photoelectric barrier; 11 = actual value sensor; 12 = potentiometer.

Synchronization control The finishing of textile fabrics (wovens, knitgoods, nonwoven fleece, etc.) can be carried out profitably using finishing lines, in which the necessary machinery for the different finishing processes are set up in series in the appropriate order for the production phases (continuous lines). The devices for transporting the fabric have to be synchronized with each other in all machines, in such a way that the fabric speed is identical at every point in the line, and there is no area in or between machines where the fabric tension reaches unacceptable levels. The usual type of solution for these functions consists of two and three-point control devices (Figs. 1 + 3).

The problem of synchronization control occurs in all technical areas in which materials being processed in plants with several drive systems for transporting the fabric are processed in continuous production. Various different options have been developed over the course of time to solve this problem. The most commonly used method for this purpose is to use direct current drives. The direct current motor is a component of the automatic control system closed loop. The number of revolutions can be adjusted using the excitation flow or armature voltage as a variable. Because of similar control possibilities, the control loop can be set up for almost any timing, depending on the design of the controller. The reliability of the control loop is almost limitless, and has an outstanding quality of control. The oldest type of synchronization control is driven from a single point by means of a drive shaft. Bevel gears are used for fine adjustment between different sections of the plant. The bevel gears are controlled by compensator rolls or dancer rolls.

Direct current drives are not sensitive to load variation if the armature voltage is used as a control variable. Furthermore, additional gears are superfluous because direct current machines have such a wide speed range. Significant disadvantages of direct current control (Fig. 2) are the high costs. The complicated structure of direct current machinery means that the cost of acquisition is significantly higher than for comparable three-phase machines. First the alternating current network needs to be converted to a direct current network (Ward-Leonard system or thyristor control). Direct cur-

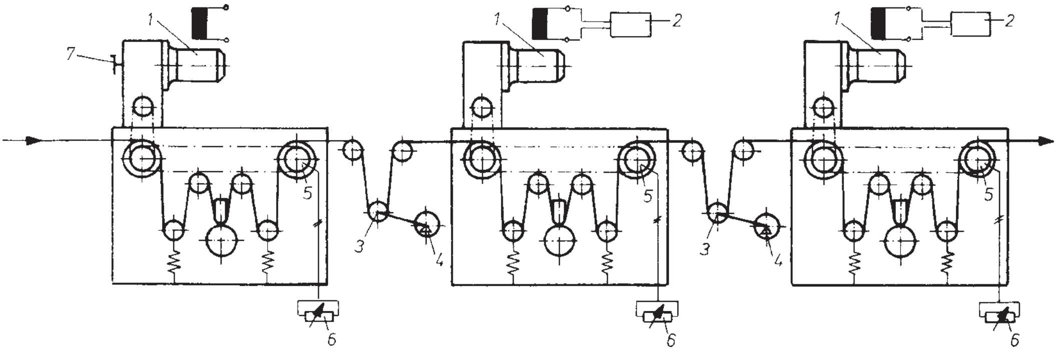

Fig. 2: Continuous control with a DC motor as fabric drive. 1 = DC motor; 2 = controller; 3 = compensator roller; 4 = actual value sensor; 5 = electromagnetic friction clutch; 6 = potentiometer; 7 = manual adjustment.

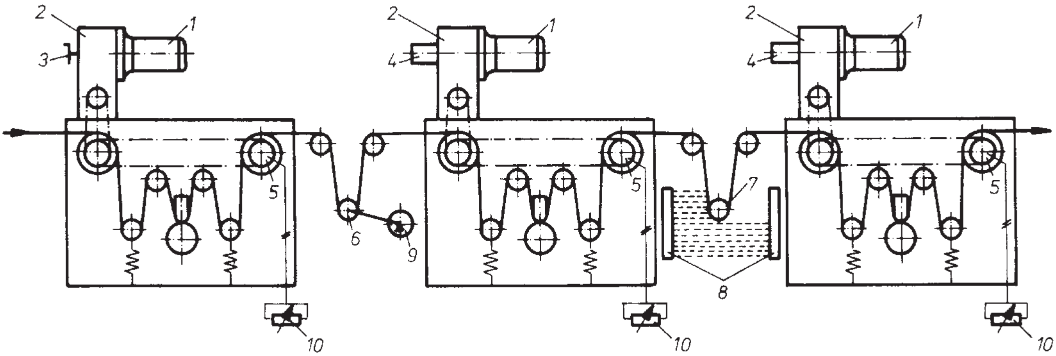

Fig. 3: Three-position control. 1 = AC motor; 2 = steplessly adjustable transmission; 3 = hand wheel for ground fabric speed adjustment; 4 = servomotor; 5 = electromagnetic friction clutch; 6 = compensator roller; 7 = dancer roller; 8 = analogue measurement light curtain; 9 = actual value sensor; 10 = potentiometer.

rent machines have various working parts (e.g. collector and brushes) that require more maintenance. In addition to this, direct current machines take up more space than three-phase equipment with the same power rating because of their construction.

Because of the high costs of direct current equipment, lower priced drive units have been developed. The two jobs done by the direct current machine, transforming electrical energy into mechanical energy and enabling the revolutions to be adjusted, became separated during the course of this development. A three-phase motor replaced the direct current motor for transmitting energy. Speed adjustment is carried out by means of an infinitely variable gearbox, in connection with an appropriate adjustment device. During the course of time, various different processes were developed on the basis of this principle. The differences between these processes are essentially only the construction of the infinitely variable gears and the type of set point sensor. Due to the inertia of the gear components and the final set speed of the servo motor, greater time constants occur than with direct current control. For this reason, the blocks consisting of three-phase motor and gears as a single unit are popularly replaced with frequency-controlled three-phase motors. An appropriate impulse from the compensator roll increases or reduces the frequency of the three-phase current supply in a frequency transformer. The correct type of motor reacts with a correspondingly higher or lower speed.

Syndets → Synthetic detergents, prepared for sale in the form of "ready-to-use detergents" for specific uses. Word origin based on abbreviated English form of synthetic detergents. There are different types of synthetic detergent:→ Mild washing agents, Special washing agents and Heavy duty detergent. Build up of:→ Surfactant: a) combined with each other or with → Soap; b) with → Builders, in liquid, paste or solid form. Available in solid form (usually for household use) as powder, scales, flakes, hollow balls or pieces. Use: primarily in the household and in commercial laundries, also for textile auxiliaries, dry cleaning detergents, etc.

Syndiotactic molecules Macromolecules in which the light hitting one structural element rotates in one direction, which always follows another structural element that rotates polarized light in the other direction, so that both structural types alternate systematically throughout the whole molecule. This type of molecule occurs in modified synthetic fibres, for instance → Isotactic polymers.

Syneresis (Gk.), contraction; term applying to self-drying in foaming; → Foam performance evaluation.

Synergistic (Gk.), concurrent influence causing increased interaction, i.e. more than the additive effect of a combination at a specific ratio, e.g. in the case of well-proportioned mixtures of surface-active substances. → Synergistic effect.

Synergistic effect Effect that causes a combination of two surfactants for example (or other substances) to achieve a specific effect even at a low concentration within certain interactively defined concentration limits in a solution. The concentration is lower than the mix-ratio concentration that corresponds with the linear dependency for this effect. Any substances involved in this effect can also be compounds/mixes.

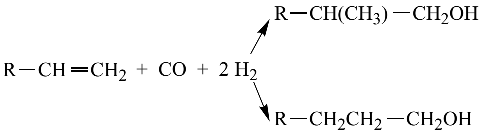
Synthesis (Gk.), adding individual components together. Chemical compounds structured from elements or low-molecular to high-molecular compounds. The simplest example is the well-known synthesis of water from hydrogen and oxygen gas: $2\,H + {}^{1}/_{2}O_2 \rightarrow H_2O$. In technical chemistry, synthesis is taken to mean a controlled reaction sequence that results in a planned amount of a chemical compound.

Synthesis alcohols Synthesis alcohols are important as a basis for textile auxiliaries. The following important examples must be mentioned:

1. Synol alcohols (synthesis alcohol): these are pro-

duced as a result of carbon dioxide and hydrogen in the presence of a catalyst at 175–200°C and 18–25 bar pressure, according to the principle: 17 CO + 20 $H_2 \rightarrow C_6H_{13}OH$ (+ C_6H_{14} + 6 H_2O + 5 CO_2). The result is over 50 % normal, non-branched alcohols (mostly ethanol) with $C_{2–20}$, as well as hydrocarbons, esters, fatty acids and aldehydes. The formations that are of importance for textile auxiliaries, $C_{10–20}$, constitute approx. one-third.

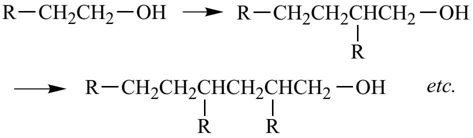
2. Oxo alcohols: These form when carbon monoxide and hydrogen accumulate simultaneously on → Olefins, in the presence of a catalyst at 50–200°C and 20–300 bar pressure as follows:



$$R{-}CH{=}CH_2 + CO + 2\,H_2 \rightarrow R{-}CH(CH_3){-}CH_2OH$$
$$R{-}CH{=}CH_2 + CO + 2\,H_2 \rightarrow R{-}CH_2CH_2{-}CH_2OH$$

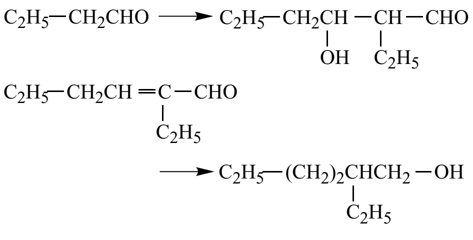
The result consists of approx. 80% alcohols, as well as higher condensation products and carboxylic acids. Fatty alcohols, fatty alcohol sulphates, acrylic acid (acrylic ester/amides), etc. can be manufactured using this method.

3. There are many other known types of synthesis, such as the large-scale Wacker condensation of alcohol molecules at high temperature, based on the following principle:



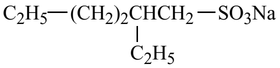
$$R{-}CH_2CH_2{-}OH \longrightarrow R{-}CH_2CH_2\underset{\substack{|\\ R}}{C}HCH_2{-}OH \longrightarrow R{-}CH_2CH_2\underset{\substack{|\\ R}}{C}HCH_2\underset{\substack{|\\ R}}{C}HCH_2{-}OH \quad etc.$$

This synthesis results in alcohols with branched chains and a higher number of molecules with $C_{8–12}$ (ethylhexanol, butyloctanol) as a wetting agent. Another important type of synthesis is based on higher aldehydes derived from ethyne and their condensation. This synthesis can also lead to ethylhexanol as follows:



$$C_2H_5{-}CH_2CHO \longrightarrow C_2H_5{-}CH_2\underset{\substack{|\\ OH}}{CH}{-}\underset{\substack{|\\ C_2H_5}}{CH}{-}CHO$$
$$C_2H_5{-}CH_2CH{=}\underset{\substack{|\\ C_2H_5}}{C}{-}CHO$$
$$\longrightarrow C_2H_5{-}(CH_2)_2\underset{\substack{|\\ C_2H_5}}{C}HCH_2{-}OH$$

The sulphate of ethylhexanol is a basis for high-quality wetting agents:



$$C_2H_5{-}(CH_2)_2\underset{\substack{|\\ C_2H_5}}{C}HCH_2{-}SO_3Na$$

Synthetic colloids Different types of → Colloid consisting of plastics or synthetic resins, which can be used in finishing technology as a stiffening agent for sizes, proofing, print thickeners, etc.

Synthetic detergents Non-manufactured → Wash-active substances resulting from a technical process (they also contain the by-products formed during manufacture).

Synthetic dyes,

I. This term can be used to mean man-made dyes (also covers the old-fashioned aniline and tar dyes). They are manufactured using chemical synthesis. They should not be regarded as the opposite of natural dyes, because they are both structured according to the same rules of dye chemistry.

II. As opposed to → Natural dyes, which are obtained from plants or animals, synthetic → Dyestuff is manufactured on the basis of a chemical reaction involving basic material that was originally obtained from mineral oil (formerly coal). Typical natural dyes such as indigo are manufactured in large quantities in the same way as synthetic dyes.

Synthetic fatty acids and natural fats → Fatty acids, synthesis of.

Synthetic fibres (synthetics) → Fibres spun using various different processes from high-molecule, chain-structured substances manufactured synthetically, composed of low-molecule modules of the following main synthetic fibre groups:

I. Polymer fibres, e.g. polyacrylonitrile, polyethylene, polyvinyl chloride.

II. Polycondensation fibres, e.g. polyester, polyamide.

III. Addition polymer fibres, e.g. polyurethane.

Since it is possible to select the raw material for the fibre, and also to produce fibres and yarns with greatly varying properties using different processes, synthetic fibres suitable for almost every textile purpose can be manufactured. As it is also possible to mix synthetic fibres with each other or with other fibres of chemical origin or natural fibres, or to combine individual textile parts made from different types of fibre, the development of synthetic fibres is likely to be ongoing. In the long term the textile industry will be forced to prepare itself for a continuing increase in the production of synthetic fibres because worldwide fibre requirements are rising rapidly. For the finishing sector this means that new problems and new finishing processes are always appearing, for example in dyeing, easy-care and resin finishing.

The main synthetic fibres are →: Polyester fibres; Polyamide fibres; Polyacrylonitrile fibres. A variety of fashionable effects can be achieved with modification, which opens up new opportunities for people in the textile finishing trade. Synthetic fibres are in competition with natural fibres on the textile market. As it is no longer a problem to make synthetic fibres similar in price and quality to natural fibres, the decision to use a synthetic fibre, which is financially of interest, is usually decided on the basis of specific properties. Frequently a particular market or fashion is made accessible by the use of fibre mixes (such as wool/polyester or cotton/polyester), or by means of modification, for example textured, profiled or dual-component fibres.

Synthetic fibres for technical applications Synthetic fibres have expanded enormously in type in the second half of the twentieth century. The classic first generation fibres at the beginning of the 1950s were essentially only polyester, polyamide and polyacrylonitrile. However from the end of the 1960s specialist modified fibre types with a complex chemical and physical structure (second generation fibres) with specific property profiles followed. Fibres with even greater homogeneous properties, in which various different polymers are combined (dual-component fibres and polyblends), form a further stage of this development. Since then, a variety of fibres, with more than 5000 brand names based on the three classic fibre polymers, as well as polyurethane and polypropylene, have become available.

Synthetic fibres with new chemical and physical structures were developed and manufactured particularly in the 1970s and 80s. This was initiated by requirements that are usually less important in the field of traditional textile applications (clothing, domestic and household textiles): a high level of strength, a high E modulus, a high level of thermal stability, low flammability and good chemical resistance. Because of these property profiles, these “non-conventional” fibres are particularly suitable for technical applications, a field that is constantly on the increase.

This includes the following fibre polymers:

name	structural formula
PMI	PPTA	
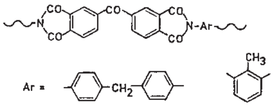
poly-(p-phenylene-co-3.4’-diphenylether-terephthalamide) (PEA)

highly crystalline, chains straight

poly-4.4’-diphenylmethane trimellitic imidamide (PAI)

non-crystalline

poly-(4.4’-diphenylmethane-co-2.6-toluylene-benzophenone-tetracarboxylic acid) (PI)



non-crystalline

poly-2.2’-m-phenylene-5.5’-bisbenzin imidazol (PBI)

non-crystalline

poly-p-phenylene sulphide (PPS)

partially crystalline, chains folded

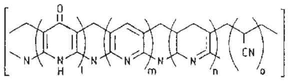
poly-ether-ether ketone (PEEK)

partially crystalline, chains folded

polytetrafluoroethylene (PTFE)

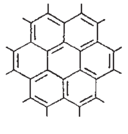
crystalline, chains folded or straight

oxidized polyacrylic fibre (OPF)

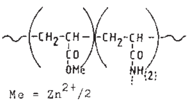


non-crystalline

polymer carbon (polycarbon) (carbon fibre)

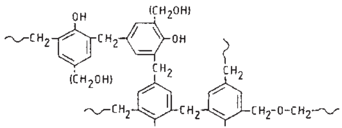


poly (acrylate-co-acrylamide) (P-AAcMe/AAm)



non-crystalline

phenole formaldehyde fibre (P/F)



non-crystalline

poly (tetramethylene adipamide) (PA 4, 6)

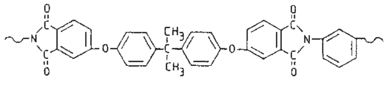
$\sim NH-(CH_2)_4-NH-\underset{\underset{O}{\|}}{C}-(CH_2)_4-\underset{\underset{O}{\|}}{C}\sim$

partially crystalline

poly (4.4'-diaminodiphenylsulphone terephthalamide) (PA pDPSO, T)

partially crystalline

poly (m-phenylene-2.2-bis [4-(3.4-dicarboxy-phenoxy)]-phenylpropaneimide) (PEI)



non-crystalline

poly(p-phenylene-oxadiazole) (POD)

partially crystalline

polyacrylonitrile (PAC, PAN)

$\sim CH_2-\underset{\underset{CN}{|}}{CH}\sim$

partially crystalline

The polymers demonstrated belong to various different classes with regard to chemical structure and fine structure. Some are linear polymers with aliphatic, aromatic or heteroaromatic structure elements. The melting and/or glass transition temperatures, which in most cases are high, are reached by means of intensive intermolecular interactions and/or chain rigidity for these fibre polymers. The other type consists of covalent crosslinked polymers, of which there are various different types (Fig. 1):

- one-dimensional crosslinked polymers (conductor polymers), in an ideal situation in the form of oxidized polyacrylonitrile fibres,
- two-dimensional crosslinked polymers (surface polymers), which occur in carbon fibres,
- polymers that are crosslinked in all spatial dimensions (three-dimensional), which can be realized in phenol-formaldehyde polymers and poly(acrylate-co-acrylamide).

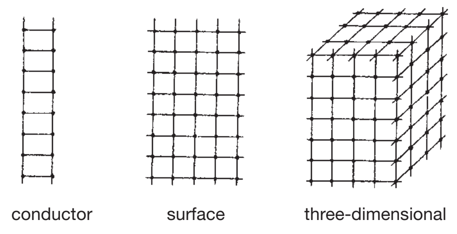


Fig. 1: Types of crosslinking of fibrous polymers (according to Roßbach).

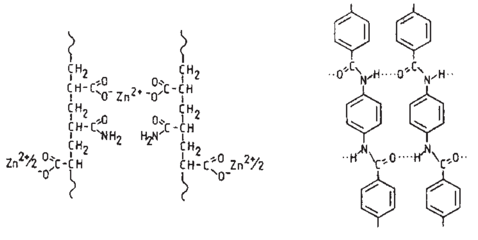

Fig. 2: Structural stabilization due to ionic and secondary valency bonding of special synthetic fibres (according to Roßbach).

As well as covalent bonds, ionic bonds (salt linkages) and partial valency bonds (e.g. hydrogen linkages) can function as crosslinking points (Fig. 2). Typical examples in the field of specialist fibres, where this type of non-covalent crosslinking points are particularly important, are fibres based on poly(acryl-co-acrylamide) (with Zn linkages) and poly-p-phenylenterephthalamide (with three-dimensional regular formation of hydrogen linkages) (according to Roßbach).

Synthetic filaments Dated term for → Elementary filament made from synthetic fibres, →: Filament; Capillaries; Fibrils, single end threads; but also for → Filament yarn.

Synthetic filament yarn → Filament yarn made from synthetic fibres.

Synthetic finishing agents → Synthetic colloids.

Synthetic leather (synthetic suede), term for →: Imitation suede; Artificial leather banned on the grounds that the term is anti-competitive.

Synthetic monofilament Monofilament made of synthetic fibre with Ø > 0.1 mm.

Synthetic resin exchanger Synthetic → Organoliths.

Synthetic resins (for textile finishing) Group of → Plastics with resin quality, insoluble in water, not infrequently also insoluble in organic solvents, which improve the efficiency of textiles significantly. Classification is analogous to plastics, so that synthetic resins can also be found classified under polymerization, polycondensation and polyaddition products. According to the German Federal Immission Protection Regulation (Bundes-Immissionsschutzverordnung – BImSchV), synthetic resins are substances and preparations that can react primarily with themselves in coating and impregnation, or steeping, such as

- melamine resins,
- urea/formaldehyde resins,
- phenol resins,
- polyester resins.

Monomers that are not able to react with themselves are not categorized as synthetic resins. Use: auxiliaries in all aspects of textile finishing, for resin finishing, wet crease-resistant, hydrophobic, slip-resistant and anti-snagging finishes. Permanent handle, stiffening, weighting, backcoating finishes; hat stiffening; permanent embossing, Schreiner, chintz effects; sizing; coating; laminating; permanent impregnation; nonwoven fleece impregnation; flocking adhesive; binding agents for pigment printing, etc.

Synthetic rubber Synthetic rubber is superior to natural rubber (→ Caoutchouc) in certain qualities (higher gas permeability, more resistant to oils and chemicals), while natural rubber is distinguished by its superior adhesive properties to fabric and metals (→ Latex). However chloroprene and silicone rubber also have good adhesive properties. Typical examples are butadiene polymers, chloroprene polymers or mixed polymers (→ Polyblends), e.g. made from ethylene-propylene-diene, isobutene-isoprene, butadiene-acrylonitrile, butadiene-styrene or sulphochlorinated polyethylene.

→: Butadiene-acrylonitrile-rubber; Styrene-butadiene rubber; Epichlorohydrine rubber; Isoprene; Polyester elastomers; Polyurethane rubber; Silicone rubber.

Synthetics This applies to

I. → Synthetic fibres.

II. → Synthetic detergents.

Synthetic suede → Synthetic velours.

Synthetic thickener Weakly crosslinked copolymers of oleofinic monomers containing carboxyl groups with a high molecular weight, which act as polyanionic bodies in the range of pH 7–10 as thickeners with similar rheological properties to an → Emulsion thickener. A particular high rate of swelling takes place in this pH range, and therefore the capacity to form a hydrate shell (Fig. 1) (increase in volume of approx. 100 times). Partial loss of solvate shell (Fig. 2) in line with increasing shear stress (→ Rheology), causing reduction in viscosity (steeply dropping viscosity curve with protracted → Flow limit). Synthetic thickeners are extremely sensitive to electrolytes and are subject to the salting-out effect. They are also sensitive to bruising.

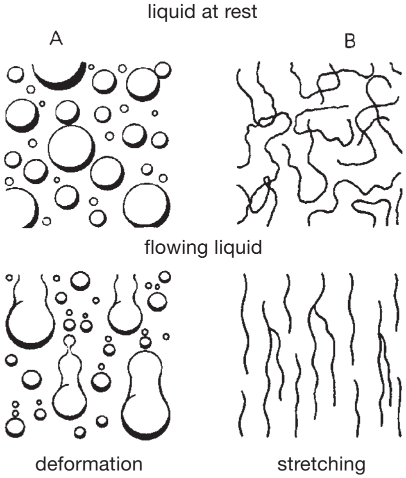

Fig. 2: The deformation of benzin droplets.
A = in benzin emulsion and stretching of thickeners; B = in synthetic thickeners at high shear stress.

Synthetic velours A term covering the following: synthetic leather knit (synthetic leather), imitation suede, imitation leather, microfibre whirled pile, synthetic leather, synthetic suede, suede imitation. "Leath-

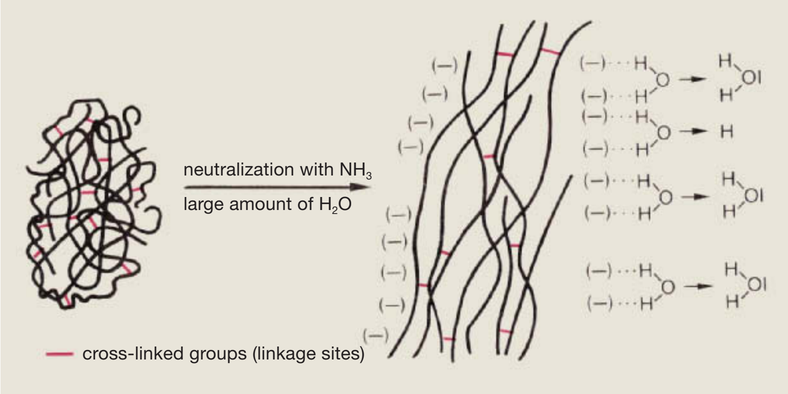

Fig. 1: Molecule packets of synthetic thickener.

er imitations and synthetic leather" is the only generic term considered by the association Verband Deutscher Lederindustrie und Kunstleder to be freely applicable. Synthetic velour is available in different strengths and with different surfaces (velours, nubuk, nappa-type). It can be dyed, printed, perforated, embossed, embroidered, pleated, etc. Other properties are for instance wool-type velour surface (extended knops) or velvet-type nubuk characteristics, extending to microfibre cross-section varieties, other handle and lustre trends, as well as even higher abrasion resistance. Manufacturing principle of synthetic velours: → Imitation suede.

Synthetic washing agents → Syndets, i.e. washing agents manufactured from synthetic detergents.

Synthetic waste water Used to analyse biodegradability in line with the Detergent and Cleaning Agent Law. Manufacture of 24 l (amount for one day) of a solution, containing the following components per litre of drinking water: 160 mg peptone, 110 mg meat extract, 30 mg urea, 7 mg sodium chloride, 4 mg calcium chloride ($2\,H_2O$), 2 mg magnesium sulphate ($7\,H_2O$); analysis of biodegradability at 20 ± 2°C using → MBAS.

Synthetic waxes (artificial wax, man-made wax), used as additives in sizing, finishing, waterproofing, etc. There are different types depending on their origin:

I. Solid → Polyethylene glycols: products of this type are soft or hard waxes, which almost always have water-soluble properties.

II. Montan wax or paraffin oxidation products (→ Fatty acids, synthesis of) in the form of esterized (and natural) fatty acids and alcohols, with or without further additives, also as soft and hard waxes with widely varying melting points (approx. 70–100°C), dark and light in colour, varying solubility, can usually be saponified and emulsified (e.g. in boiling water without alkali water-in-oil or oil-in-water emulsion).

They are used in a non-saponified or emulsified form for sizing, specialist preparations, finishes, hydrophobization. Type I and II products give textiles a soft handle, but frequently insufficient bulking elasticity.

Syrup formation Practical term for the secretion of droplets that occurs near boiling point or when the dyeing process is complete, e.g. of many non-ionogenic levelling agents in dyeing with 1 : 2 metal complex dyes. The dye liquor appears to be clear as water on extraction, when the fabric is unpacked from the machine and during cooling, the addition compound of dye/levelling agent begins to flow out. If this flowing "syrup" begins to dry, it can lead to non-fast, uneven dyeing.

Systems (Gk.: combination), from a cybernetic point of view, systems are structures consisting of elements and components linked by relationships. They can be homogeneous or heterogeneous, static or dynamic, open or closed.

In contrast to linear thought of a monocausal type, a feedback system thinks in complex causalities. A control loop is a system that consists of a sensor, a microprocessor (target/performance comparison) and an actuator linked together. A system has a transparent structure (atomic system, planetary system), of which it is not necessary to recognize all the elements, but their effects must be calculable. The biological structures of a chaotic system (e.g. chaotic layers) on the other hand is not transparent, and require a large amount of computer power to control them.

In 1987 Lehn described the systems of supramolecular chemistry (Fig. 1). Polymer systems interact with one another. Enzymes, for example, function according to the "key-lock" principle. Proteins are generated as the final product of amino acid monomers during biosynthesis. These receptors with a specific detection capacity for their substrate, form an "active pocket" of supramolecules by enclosing functional groups of the substrate, which are formed either for detection, transformation or translocation.

Systems can be classified according to the aggre-

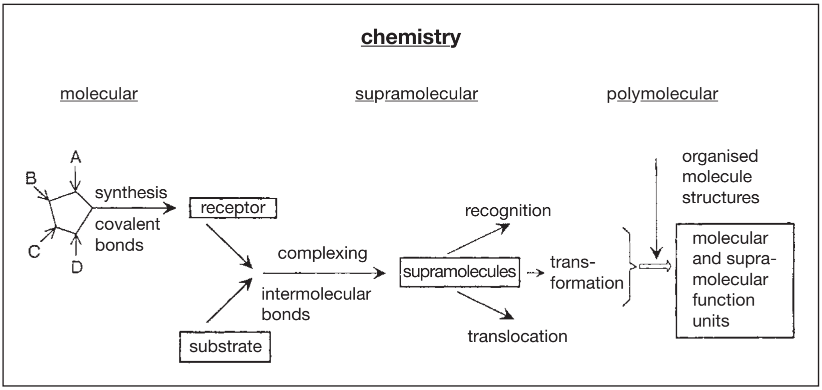

Fig. 1: Schematic explanation of the connection between molecular and supramolecular chemistry (according to J.-M. Lehn).

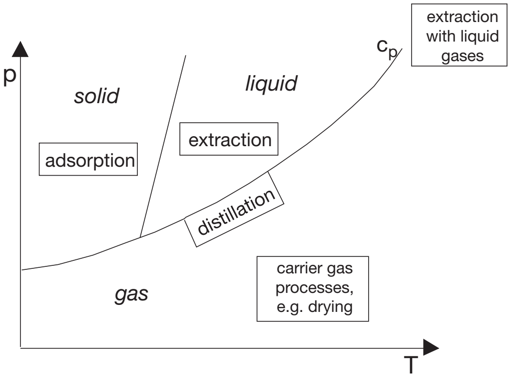

Fig. 2: System of aggregate conditions (according to Schollmeyer).

gate state in which the system's processes occur (Fig. 2). The three aggregate states are calculated by defining the ordinate system pressure and the absolute system temperature on the abscissa. Depending on the process parameters in textile finishing, typical processes occur within this system, such as

- adsorption,
- extraction,
- distillation,
- drying.

The use of supercritical states in this system is new (extraction with liquid gas).

Systems of units The SI unitary system (→ SI System of Units, SI = Système Internationale d'Unités) has been applicable in Germany since 1970 for business and official use, according to the law governing units of measurement. This law has been introduced internationally throughout the industrialised regions of the world for the purposes of standardization.

System washing agents Usually household detergents, containing dirt-dissolving agents and optical brighteners, the detergency power of which takes effect at different temperatures in one operating cycle.

SZ New term for referring to the Swiss Patent.

T

T Abbrev. for temperature.

t,

I. Abbrev. for time.

II. Abbrev. for weight unit, ton.

TA,

I. → Triacetate fibres, → Textile fibre symbols, according to the → EDP key system, → CTA.

II. Ger. abbrev. for "Technische Anleitung" (Technical Instructions); →: TI-waste; TI-noise; TI-air.

Ta Element symbol for tantal (73).

Table adhesives These are designed to glue fabrics on to flat screen printing tables. Temporary adhesives behave neutrally towards the print application, fabrics of every type and the various dyes. The fabrics can be bonded together on a backing fabric or previously on a bonding machine independent of the table. →: Flat screen printing; Table printing.

Table printing → Flat screen printing. High-quality, multi-coloured prints, e.g. in small runs on silk (e.g. scarves), are printed on tables with a moving film printing carriage (Fig. 1).

The carriage takes its direction from the repeat rails which run along the edge of the table (Fig. 2). The flat templates are printed through one after the other; initially one pattern is printed over another without intermediate drying. When all the individual colours have been applied, (Fig. 3) the fabric is stripped from the rubber conveyor (Fig. 4) and passed on to the vertical drier (Fig. 6) whilst the conveyor passes through a

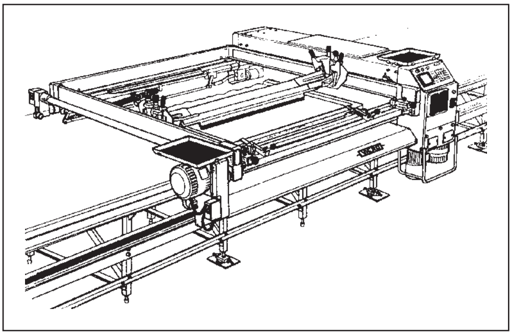

Fig. 1: Viero table printing carriage.

Fig. 2: Table printing room with electrically heated tables and typical repeat edges (by Sigma).

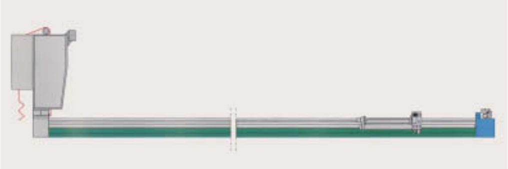

Fig. 3: Side view of a modern table printing device with glueing device, conveyor belt for transportation of the printed fabrics and drying chamber.

Fig. 4: Feeder and glueing device for fabrics to be printed (Viero).

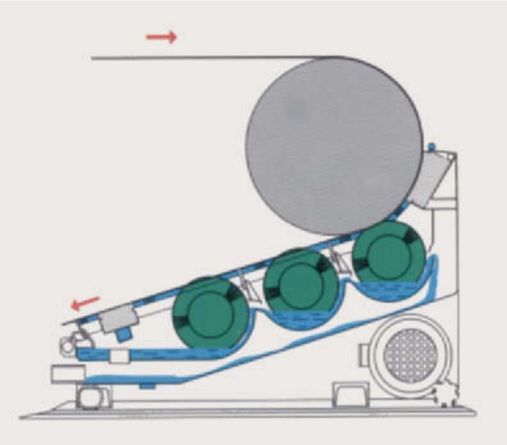

Fig. 5: Rubber blanket washing range at the end of the table.

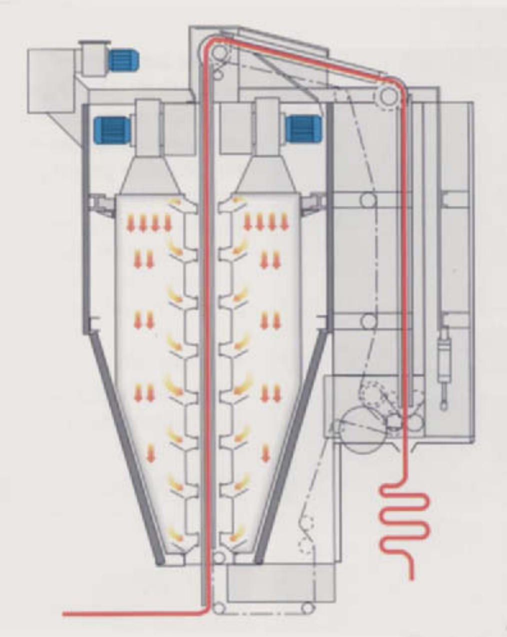

Fig. 6: Vertical drying device for printed goods (Viero).

washing process (Fig. 5) after the printing line and possibly under the print table.

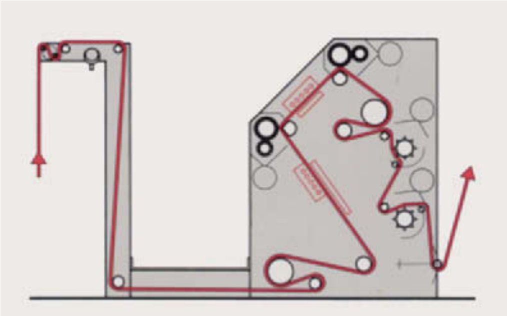

Fig. 1: Menschner table raising machine.

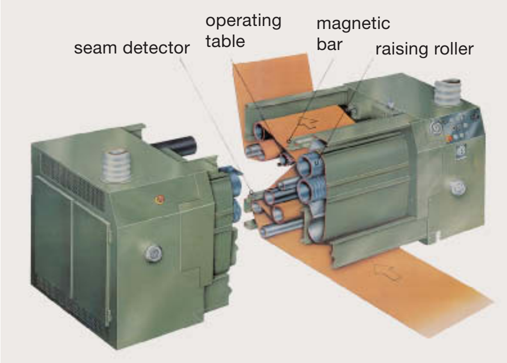

Fig. 2: Sucker-Müller PRN table raising machine.

Table raising machine Used for polyester fabrics, velours, velvet and imitation furs. Depending on the fibre material, the pile is rendered thermoplastic (Fig. 1) using infra-red heaters before passing over the table. The temperature, i.e. the intensity of radiation, can be regulated. The material passes over the table (Fig. 2) so that the raising roller runs against the direction of pile of the fabrics.

Table raising/polishing/shearing machine Raises, polishes and shears in a single run. Both sides of the material can also be processed in a single run without the use of a turning device (back-to-back). An electrically-heated polishing cylinder with beaters ensures lustre. The shearing table can be replaced by a roller for heavily-coated or reverse-side-coated articles for example.

Tablet test → Pill test.

Table washing device in flat screen printing Appliance for cleaning the printing table surface after printing. An electrically-driven brush roller scrubs the table surface whilst water flows into it from spray pipes. The liquid is wiped from the table surface by a double doctor blade in contact angle of approx. 30°.

Tabriz carpets Thin Persian knotted carpets with short, smooth woollen tufting. Precise, richly decorated, fine patterns in light colour on background colours of sand, red, matt blue and natural white. Also produced as medallion and hunting carpets. 220 000–250 000 Persian knots per square metre.

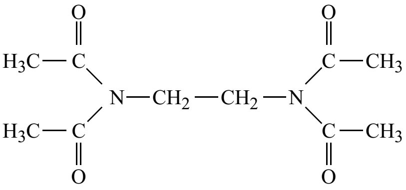
Tachometer Revolution (speed) counter for measuring revolutions of machine shafts, rollers, drums etc. Produced as tachometer for measuring number of revolutions per minute and as an automatic counter for any other period of time. Available in various versions for manual use (checks), fixed installation (works checking of pieces or meter count), the latter also provided with electrical contacts, and registration unit etc.(→ Oscilloscope).

Tackiness index Measure of speed of action of a paper printing paste. This is determined by means of an inkometer or → Tackoscope and depends largely on the amount of binder contained. The tackiness index is a relative figure which is influenced by the experimental set-up.

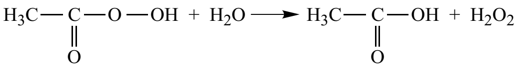
Tackoscope Serves to measure relative → Speed.

Tacticity → Isotactic polymers; syndiotactic molecules.

TAED Short form for the chemical compound N,N,N,N,-tetraacetylethendiamine ($C_{10}H_{16}N_2O_4$) with the structure formula



Manufactured on an industrial scale by converting ethendiamine with anhydride acetic acid; degree of purity over 99%. Colour and aroma free rhombic crystals. Melting point 156–157°C. Easily dissolved in ethanol and a little ice vinegar, less easily dissolved in benzene, difficult to dissolve in petroleum ether. TAED is an important bleaching activator for detergents with bleaching systems on the basis of inorganic oxygen carriers. TAED activation of perborat bleaches has proved particularly useful in practice. This process is accelerated in relation to the temperature by the presence of TAED. At moderate temperature perborat and TAED react with each other in the washing bath to form intermediary → peracetic acid by residual acyl which has separated from the TAED combining with H_2O_2. As peri acetic acid is an unstable compound, the following disintegration reaction occurs almost immediately:



$$H_3C-\underset{\underset{O}{\|}}{C}-O-OH + H_2O \longrightarrow H_3C-\underset{\underset{O}{\|}}{C}-OH + H_2O_2$$

Thus in the lower temperature range TAED produces a significant bleaching effect in the washing bath which at 60°C corresponds virtually in terms of performance to the bleaching effect achieved by perborat at boiling point. The TAED-Perborat bleaching system kills off microbe germs at 40°C and therefore produces hygienic washing results. As far as textiles and dyeing processes in the bath are concerned, this system is no more aggressive than perborat bleaches on their own. Accelerated bleaching at low temperatures is a realistic consideration for practice as it saves energy and time and eliminates the necessity to raise the temperature to boiling point each time. After a short washing time at 60°C the system virtually eliminates stains.

Taffet → Taffeta.

Taffeta (taffet). Smooth, usually shiny fabric (made of silk or acetate) in plain weave and single colour, in different colours (glacé taffeta) in changeant, etc. Light taffeta is known as → Muslin. Used for blouses, dresses, linings, etc.

Taffeta weave Plain weave in silk ware. → Weave.

Tagal Interlaced fabric for hats, bags, arts and crafts, fabricated from → Manila fibre.

Tailing Gradual transition from dark to light shades of the same colour tone in textile printing and dyeing. In the course of this transition one or both edges (listing, side-to-side shading) or the end (ending) of a batch demonstrate lighter or darker colouring as compared with the centre of the fabric. This is usually not desirable but is sometimes consciously exploited in printing and dyeing to achieve fashionable special effects. The causes can originate during a number of stages of the fabrication process:

I. During the fabric manufacturing process:
- differing tensile stresses on the warp beam;
- uneven sizing application, uneven drying or overdrying;
- thick selvedges;
- differing warp and weft thread densities.

II. During pretreatment:
- saizing residue on the fabric;
- uneven mercerization, can be monitored by means of staining, microscopic tests or swelling value determination;
- differing degrees of whiteness caused by oxidative damage to the fabric;
- alkali and acid content, can be determined by means of titration;
- singeing damage;
- distortion of the fabric.

III. During dying:
- squeezing differences caused by differing pressure in the centre and at the edges of the squeezing rollers;
- changed degrees of hardness of the roller coverings or their deformation (wear);
- uneven liquor level in the pad bath, immersion period (prevention of runback);
- uneven padder liquor temperature;

- uneven distribution of padder liquor over the width of the chassis.

IV. During drying and dye setting:

- migration processes (fabric appearance, dye penetration, changes in colour shade, dual-sidedness) caused by uneven drying conditions;
- uneven setting in thermosol plants over the width (particularly frequent in the case of very high temperatures);
- uneven heat transfer over the width caused by a) influx of cold air as a result of defective or open doors; b) improper adjustment of valves; c) blocked sieves in the air circulation and venting systems;
- uneven steamer conditions;
- air pockets;
- indequate supply of fresh water in the water lock;
- too long exposure to air between padder and steamer or steamer and rinsing tank.

V. During final finishing:

- unevenly applied finishing liquor;
- differing condensation conditions.

It is important to recognize unwanted tailing and ending as quickly as possible. Using dye measurement devices on running strips, it is possible to detect tailing and ending at an early stage, making immediate correction possible for continuous dyeings. The → Formatted piece method is important for rotary film printing. Other possibilities are measuring and regulating application dampness, measuring and regulating a pre-drying shaft and monitoring temperatures in dry heat aggregates. (→ Sewing test in listing).

Tailing and listing In textile printing and dyeing the gradual transition of a colour shade from dark to light in textile printing and dyeing → Tailing.

Tailing in continuous dyeing Modern padding mangles work with the least dye liquor quantities in the trough, liquor circulation and dosage equipment when reactive dyes and alkali are used. Partial hydrolysis of the reactive dye may take place in the trough, and if there is not sufficient mixing, it will take time to establish an equilibrium between dye supply at the fabric surface, rate of hydrolysis and dye absorption at the beginning of the continuous dyeing process. The colour intensity may be greater at the start than, for example, after 500–700 m (equivalent to 10–15 min dyeing time) (Fig.).

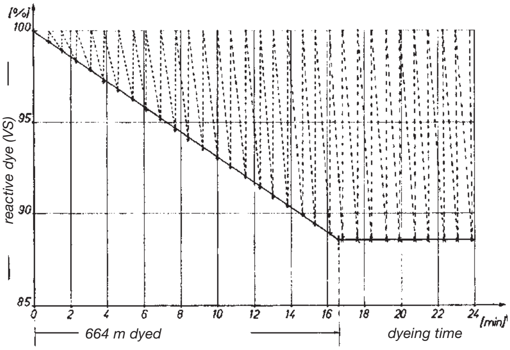


Fig.: Colour intensity variations up to a state of equilibrium in the padder.
VS = vinylsuphone dye.

The steep sides of the peaks occur as a result of additional dosing and represent extreme dye strength differences. These should not become obvious until after the 10th add-on dose when the max. dye strength differences exceed 5%. Dye strength differences below 5% can be recorded easily with the aid of transmission measurement, whereas visual assessment by a person has its limitations. Thus tailing would become visible after approx. 300 m corresponding to a dyeing time of approx. 8 min. The chemical processes in the dye trough must be included in the equation. From the chemical point of view, a hydrolysis balance establishes itself during the dyeing process. Whilst this balance is establishing itself, there is a corresponding tailing on the fabric. After the hydrolysis balance has established itself the dye strength remains constant during the remaining dyeing process. Whilst the hydrolysis balance is forming, the liquor in the trough increasingly accumulates reactive dye hydrolysate. The formation of hydrolysate is an alkali-consuming reaction which has little effect on the overall alkali concentration of the pad liquor. On the other hand the additional dosing liquors always have the same dye concentration corresponding to 100%. At the boundary between the residual liquor and the additive liquor the hydrolisate formation changes increasingly in the direction of the add-on liquor. This explains why 100% dye strength or a dyestuff with 100% reaction capacity cannot be achieved. The line of the curve would therefore have to run close to the actual curve until hydrolysis equilibrium has established itself. The new line of the curve would result in different liquor take-up by the fabric during passage through the trough resulting in tailing of the dyed fabric and the resulting changed liquor total in terms of time and the associated dye concentration difference (according to Dienst).

Tailor's canvas →: Buckram; Linen interlining.

Tailor's chalk This is used for marking measurement and pattern details on fabrics. It usually consists of finely pulverised clay or in the form of small plates cut with sharp edges (coloured ones with the addition of mineral dyes), also made of soapstone and talcum.

TAK dyeing Serves to produce multi-colour effects on carpets. Background colour is first applied to a strip of carpet up to 5 m wide by first dipping/squeezing. Then up to four further batches of dye are floated over the width of the carpet strip using special equipment. To fix the dye, the carpet strip is subjected to steaming and then rinsing processes. This process produces a blotchy effect which has a similar appearance to → Space dyeing. The dye solution is distributed over the carpet strip in snake-like patterns by means of special mobile spreader. Multi-colour effects are achieved by means of multi-colour processes. – Manuf.: Küsters.

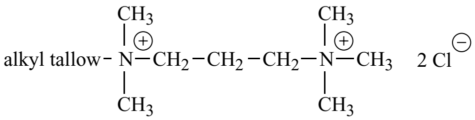
Talc → Talcum.

Talcum (light white, magnesium silicate, talc), $3\,MgO \cdot 4\,SiO_2 \cdot H_2O$. Density 2.7–2.8. Flaky or crystalline substance, shiny appearance like mother of pearl, (non) transparent, colourless or light white in colour, soft and greasy to touch, not soluble in water. It is characterised by its property of rapidly absorbing moisture. Utilized as Detachier powder (sometimes with the addition of dyeing agents), to prevent the formation of rims, to remove grease stains (scatter and iron over); to dehumidify wet-treated (glacé) leather gloves; to powder rubber items or plastic-covered textiles (to prevent sticking); to whiten white felt hats; as a filler for finishing agents, etc.

Tall oil Bi-product of cellulose production in accordance with the sulphate process. Raw tall oil consists of predominantly 45–70% fatty acids and 20–50% resin acids (usually abietine acid), strongly coloured, with an unpleasant smell. Refined tall oil contains mainly only resin acids. Tall oil is one of the cheapest capillary-active substances. Soaps made of tall oil have unusual emulsifying, moistening and cleansing properties but this has to be balanced against the unpleasant smell. Used in sulphurising, estering, condensation, oxyethylising products, also for moistening, smoothing and textile aids.

Tallow (suet). Fat originating from abdominal cavity of cattle, goats, sheep, mutton. Yellowish white in colour, hard and brittle; mild smell and taste. Melting point 37–41°C (mutton tallow). Dissolvable in ether, petroleum, turpentine, alcohol 1 : 5 (heated). Used to manufacture soap for smoothing, dressing etc.; has a slight dulling effect on colours. Composed of fatty acids with traces of glycerine, 32–50% fatty acid, 14–31% stearic acid, 3% myristine acid (beef tallow), 3% linoleic acid (beef tallow).

Tallow-alkyl compounds Dialkyl tallow- (→ Imidazolinium compounds) and Diquarter compounds such as for example N-alkyl tallow-pentmethyl-propendiamindichloride represent interesting avivage raw materials.



$$\text{alkyl tallow}-\overset{CH_3}{\underset{CH_3}{\overset{\oplus}{N}}}-CH_2-CH_2-CH_2-\overset{CH_3}{\underset{CH_3}{\overset{\oplus}{N}}}-CH_3 \quad 2\,Cl^{\ominus}$$

N-alkyl tallow-pentmethyl-propendiamindichloride

Tallow fat alcohols → Fatty alcohols with 14, 16 and 18 C atoms.

Tallow fat amines → Fatty amines with 14, 16 and 18 C atoms.

Tallow soap → Sodium stearate. Derived from congealed fish-oils. Utilized inter alia as a substitute for → Marseilles soap, in particular for soap soda rollers. When subjected to high temperatures, it is known to result in a tacky substance (turbidity point, deterioration point 65–70°C). 0.25% solution of pure tallow soap has a pH value of 9.2; degree of hydrolisation at 90°C = 13%. It is suitable for washing temperatures of 40–60°C.

Tallow sulphonate Tallow product with usually low degree of sulphonization; its natural fat properties are retained to a large extent. It is usually soluble in water. Anion active. Utilized as an avivier agent, as finishing and smoothing additives and as grease basis for matt finishing of foulard.

Tamarind pectin Fine, white powder derived from cold-processed tamarind seeds and kernels (with husks removed) (India, Sri Lanka, Burma). The powder is odourless, differs significantly from other fruit pectin and is 99.87% soluble in alcohol. Does not result in a blue coloration with iron but produces a deep blue or bluish black coloration using tamarind kernel flour which contains particles of husk, cream-coloured, or frequently even brown or reddish brown and possessing a typical odour. Use: as a sizing material due to its viscosity, gelling and film formation capacities. It has a better sizing capacity than maize starch; also as a finishing agent (recommended as very successful on cotton); in screen printing (2% paste does not drip, producing a rubber-like paste with sodium tetra borate).

Tambour,

I. Smooth, hollow roller (printing cylinder; presser roller), sometimes bombarded with rubberised wool or woollen felt fabric in Rouleaux print. Driven by means of pressure rollers.

II. The central, large cylinder on raising machines and in spinning machinery (carding, combing machines).

Tandem rolls Term used to describe two heated steel rollers in roller coating.

Tandem units Two identical elements are utilized twice in succession in a machine. Examples are the tandem rotary milling machine, a milling machine with dual rotary milling units which the fabric passes through one after the other on each rotation, or the coating machine with two coating heads (see Fig.).

Tangential washing machine → Horizontal washing machines used for washing linens.

Tangling → Air entangled yarns.

Tanner Dirt contaminated scum formed when scouring woollen goods in the scouring or milling machine.

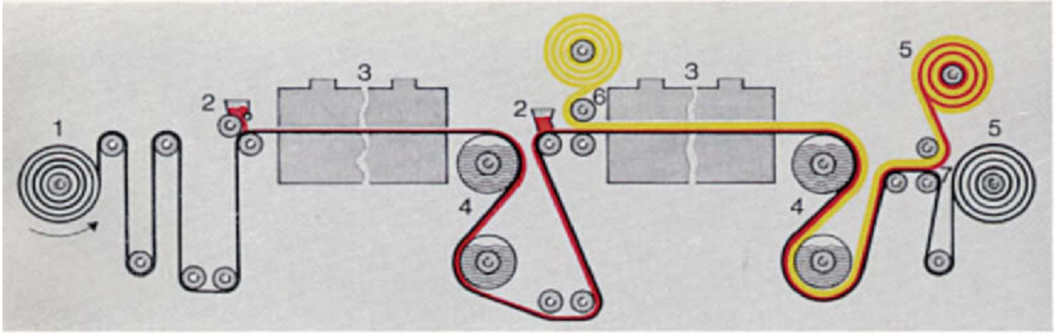


Fig.: Tandem units with two paint heads (by Bayer).
1 = unrolling; 2 = coating heads; 3 = drying tunnels; 4 = cooling cylinders; 5 = take up; 6 = laminating roll; 7 = separation;

Tannic acid → Tannin.

Tannic acid solution 5 g tannin in a water bath dissolved in 100 ml water. For finishing analysis during which glue, protein, starch, slime produce precipitants (glue precipitate dissolves partially in diluted hydrochloric acid).

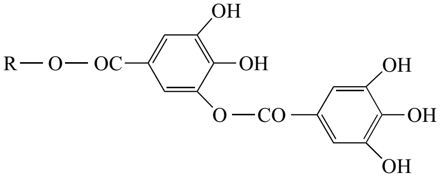
Tannic acid/tartrate emitic aftertreatment of polyamide Dyeing carried out with acid and metal complex dye substances has improved wet-fastness characteristics (water, sweat and washing fastness). Work process: Rinse after dyeing and treat with 2% tannin and 1% acetic acid (80%) for 15 minutes at 70°C. After the tannic acid has been absorbed, add to the same bath 1% cracked wine lees (potassium antimony(III)-oxide of tartrate) solution and continue treatment at same temperature for 15 minutes and rinse.

Tannic acid/tartar emitic mordant Dyeing stain with sufficient uptake and fixing of cationic dyeing substances on cellulose fibres, particularly for medium to dark colourations. Used before dyeing with cationic dyestuffs in the dyeing of cellulose, wool and silk.

Tannic mordant → Tannic acid/tartar emitic mordant.

Tannic mordant substitutes have the advantage, compared with → Tannin, of single bath staining and dyeing without metal salt follow-up treatment. Usually sulphured phenols or → Thiophenols. They serve as Reserving materials for wool and cotton and to improve fastness of polyamide dyeing.

Tannin (gall tannic acid, tannic acid). A natural tanning substance with differing composition depending on its origin (polygalloyl-glucose). Acts like mild acid on the basis of many phenolic OH groups. Density 1.35. Light powder, white to light yellow or brown; crystal needles (needle tannin); foamy mass (foam tannin, almost chemically pure); brittle, glassy flakes (flake tannin); all of these having the typical smell and acetic taste. It is a colloid, soluble in one part water (acid reaction) or two parts of alcohol as well as in glycerine and related substances. It has a strong tanning effect; 0.5% solution precipitates glue and gelatine; in combination with metal salts (iron, copper, mercury, lead) it forms insoluble or barely soluble tannins and in combination with cationic dyeing substances it forms insoluble colour varnishes. The staining properties are derived from the presence of residual gall acids:



High-quality tannin contains 65–76% tannic acid (best quality 75–80%), "water tannin" 26–60%; "alcohol tannin" (expensive) is cleansed with alcohol. Used for staining (superseded by → Thiophenols) for cationic dyestuffs (particularly water tannin); for colour varnish fabrication (colour fastness increase as an after treatment); decrease in the affinity of wool against certain colour substances.

Tanning Process for refining animal skins or pelts to make leather. It is carried out using → Tanning agents and works on the principle of starting with tannage from weaker solution and finishing with concentrated tannage solutions:

I. Using plant-based substances (bark or red tannage): usually in concentrated water-based solutions using vigorous mechanical movement, within a few days. Calf leather is tanned using willow bark, re-fatted with birch tar resin and then dyed with aluminium potassium sulphate and sandalwood.

II. Using mineral-based substances (mineral tanning): a) chrome tanning often with ready-to-use chrome products or with chrome alum or sodium dichromate. Chrome leather is pale bluish green. b)

White tanning (for white leather): Weak tanning action, leather shrinks slightly in hot water, can be swelled with dilute acetic acid. Soak in water-based solution of aluminium potassium sulphate and sodium chloride.

III. Using fats (fat or chamois tanning): by kneading with fish oil which oxidises during subsequent air-storage and can no longer be washed out. Excess residues are pressed out, or the skin is washed in sodium carbonate. Finished chamois leather is light cream in colour, supple and washable.

IV. Using synthetic products on the lines of I.

V. Combination I + IIa, I + IV, etc. Further treatments for improving and softening are known as dressing.

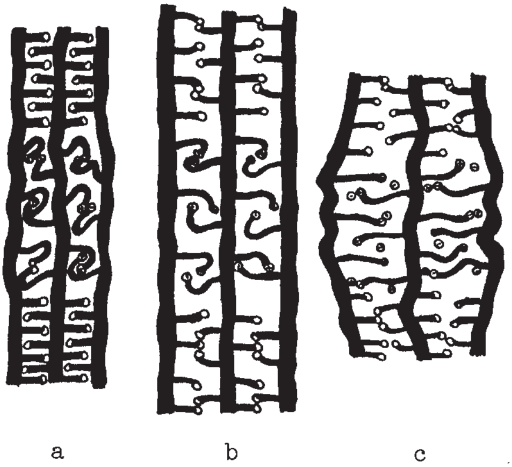


Fig. 1: Collagen swelling behaviour.
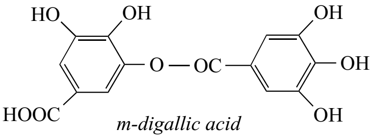
a = fibrils dry; b = fibrils swollen in neutral water;
c = fibrils swollen in acidic water.

Tanning is the most important and indispensable treatment for converting raw skins into leather. The collagen fibres normally have a high swelling capacity (Fig. 1). They swell quickly in water or acidic and alkaline solutions due to penetration of hydrogen and hydroxyl ions into the unstructured areas. The collagen molecule itself also swells. Such methods prevent the skin fibres, which consist of collagen chains, swelling due to water absorption or shrinking due to water loss. The collagen thus achieves hydrothermal stability. Hydrothermal stability is defined by the property of not shrinking when heated in a water-based medium until a certain characteristic temperature is reached. This temperature is the so-called "shrinking temperature". It is a measure of the forces which the structural order withstands, a phenomenon of denaturing and depends on the type and age of the collagen. In the case of untreated collagen the shrinking temperature is within the range of 40–60°C. Untanned collagen is therefore unstable in hot water and as such is unsuitable for use or for direct processing. The skin has to be tanned to stabilise the collagen. During the tanning process various chemical compounds (tanning agents) react with those protein groups capable of reaction. The incorporation of cross linkages gives the collagen a greater degree of strength which it does not naturally possess. The shrinking temperature is increased as the tanning process progresses thus improving the stability of the collagen when exposed to heat, enzymes and chemical influences. Swelling of the collagen in water, acid or alkaline is also reduced.

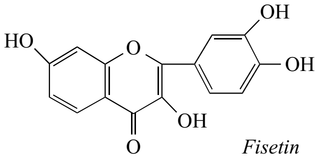
The tanning agents are divided into 4 types according to their various mechanisms: The crosslinking with vegetable-based tannages is carried out using the hydrogen bonding between the phenol hydroxyl groups in the tanning substance and the amide groups in the collagen. Two types of vegetable-based tannages are used.

1. Hydrolysable tanning agents: In the tanning agent molecule the benzene rings form large complexes with the aid of oxygen atoms. These include depside-, gallotannins and ellagi-tanning. They are esters of phenol carboxylic acid.



m-digallic acid

2. Condensed tanning agents: Multi-hydroxy phenols are joined together with the aid of carbon atoms as an ether bond to form a higher-molecule polyphenol.



Fisetin

The two types of vegetable-based tanning agents are used to process lower shoe sole leather, plain leather, drive belt leather, as well as some upper shoe and fine leather. Tanning with mineral tanning agents is carried out using complexing agents. Previously aluminium salt was used for tanning and this resulted in so-called "white tanning". Iron and zirconate tanning agents were also used. When chrome salts were introduced in tanning, the other mineral-based substances were no longer of interest with the exception of aluminium and zirconium. In chrome tanning the chrome salts react with the collagen carboxylic groups. The complex bonds are strong. Chrome salts are found in nature in chromite. The chrome is 2-, 3- or 6-valent in its compounds; only the compound with the 3-valent chrome can react with the skin fibres. Chrome compounds in an alkaline state are used in the tanning process. The more –OH groups are present in the chrome complex, the greater is the tanning action (Fig. 2).

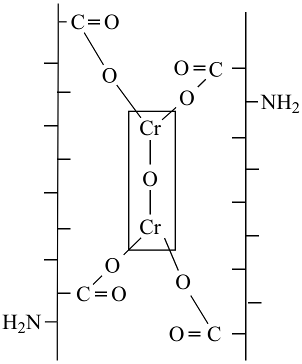


Fig. 2: Chrome tanning mechanism, crosslinking by principal valency bonding via COOH groups.

When tanning with synthetic tanning agents, no crosslinking occurs but secondary valency bonding by means of electrovalent salt linkages in the sulphonate acid groups with the NH_2 groups of the collagen (Fig. 3).

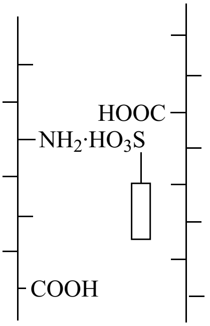

Fig. 3: Mechanism of tanning via salt bridges.

These tanning agents include polyphosphoric acids, complex poly-acids and lignin sulphonate acids. In aldehyde-based tanning agents, e.g. aldehydes, quinones, the tanning action is based on principal valency crosslinking. The tanning substance reacts with the free amino groups (NH_2) of the collagen (Fig. 4).

Polyfunctional compounds which are able to react simultaneously with several reactive centres of the collagen thereby causing crosslinking are generally known as tanning agents. Thus formaldehyde, di- and polyaldehyde and quinone form covalent bridges between two ε-amino groups of the lysine and hydroxylysine.

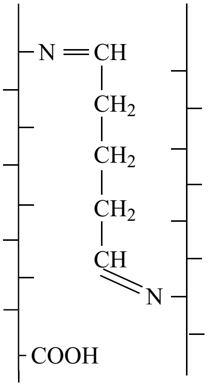

Fig. 4: Mechanism of tanning with bifunctional aldehydes.

Tanning agents (tannic acids), substances with a tanning effect, soluble in water and as colloids; have an unpleasant taste; prevent rotting; precipitate glue and protein solutions and convert animal skins into leather; with lead salts they mostly result in insoluble precipitates. The presence of numerous phenolic-OH groups in the molecule is characteristic. Differentiation is made between:

I. Hydrolysable tanning agents (ester-like properties), usually derived from gallic acid (e.g. tannin).

II. Condensed tanning agents (with carbon bonds) from natural sources are, for example, catechu, oak bark and of similar synthetic origin, for example condensation of formaldehyde and phenol and naphthalene sulphonic acid. In a sense, sulphite cellulose lye can also be regarded as a tanning agent.

Tannin stains Removal: a) Warm glycerine; b) 20% solution of tartaric acid (warm/hot); c) isopropanol (hot).

Tape fibres Spliced, slit or split fibres. Fabricated of sheet materials, → Tape yarns or flat threads, cut lengthwise or through lengthwise split fibrils, and cut into staple fibre lengths.

Tapestry carpet Chain pattern, machine woven tufted carpet in loops (Brussels tapestry) or velour form (tapestry velour). Patterns are produced using chain dyeing technique.

Tapestry carpets, tapestries → Flat carpet with representations of hunting scenes, historical events; modern non-naturalistic motifs are usually also used as wall hangings.(e.g. → Gobelin).

Tape yarns → Extruded tape cut from foils or tape strips. After cutting, they are hot stretched monoaxially and thermoset. A new process is based upon mono- or bi-axially hot stretching, thermofixing and then lengthwise slitting.

Tape yarns, stretched Stretched → Tape yarns in degrees of fineness ranging from 300–3000 tex.

Tarpaulin Jute double linen for sacking, linings, etc. Coatings can be applied for certain purposes.

Tarpaulin coating Lorry and container tarpaulin covers are woven of strong polyester yarns in Panama or Plain weave (→ Transport tarpaulins). The tarpaulin fabrics are coated to a weight of 600–800 g/m^2 with polyvinyl chloride which is coatable after plasticising and can be subsequently gelled.

A tarpaulin fabric coating system (see Fig.) consists of the following main system groups:

1. Preconditioning unit: This unit is necessary to reduce residual humidity as much as possible in order to prevent bubble formation and water inclusion in double-sided coating.
2. First coating unit: This is designed for single-sided coating of closed fabrics and for double-sided coating of fabrics with open weave.
3. Second coating unit: For production speeds of over 25 m/min it is advisable to use a double vertical drier. This unit also includes an embossing calender which can be equipped with two steel embossing rollers for various finishes on each side of the coated substrate, e.g. high-gloss finish on one side and matt finish in order to prevent clinging on the other. In this case one of the rollers is a “swimming roller” in order to prevent sagging.

Tarpaulin, heavy canvas Sailcloth made of hemp and/or linen and jute, with waterproof impregnation or multiple tar coating, for tarpaulins, tents and the like.

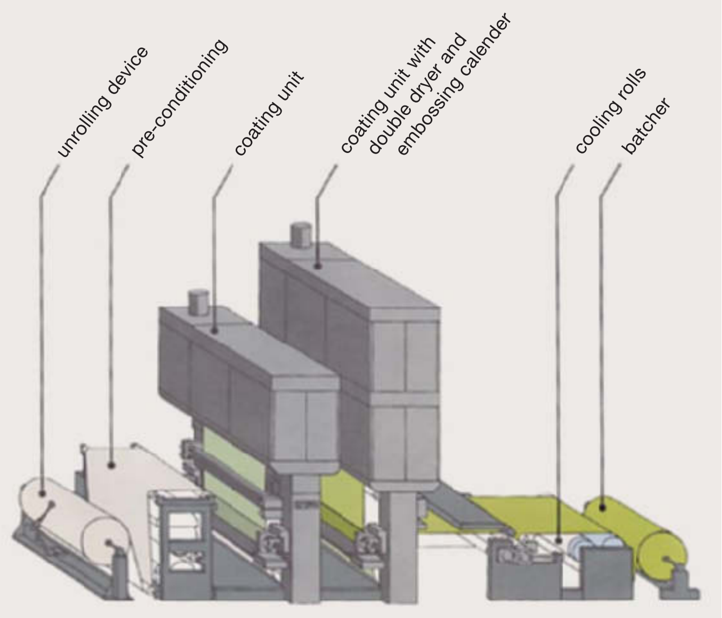

Fig.: Tarpaulin coating unit (Stork).

Tar stains (tar). Usually brownish black, sticky when warm, sharp edges, becoming harder, more brittle, and therefore easier to remove the longer the stains are left. Removal: a) benzene; b) benzene/carbon tetrachloride (or tri-, tetrachloroethene) 1 : 1, possibly with glycerine (= dye protection) in equal parts; c) carbon disulphide or acteone; d) chloroform (ether)/carbon tetrachloride; e) benzene/carbon tetrachloride 1 : 5 with diethyl ether/ethanol. If this does not produce satisfactory results, soak with concentrated grease-solvent soap (possibly overnight). Rework yellow stains: a) 3% ammoniac; b) (silk) 20% sodium tetraborate solution, possible reductive post-bleach; c) particularly for brown residues: Mixture of 75% oleic acid and 25% carbon disulphide, rinse with pure solvent.

Tartan Scottish tartan pattern, Scottish cloth.

Tartan fabrics (plaid fabric). Does not denote origin but is a generic term for all boldly-checked fabrics with predominantly green, red and blue colour shades. Woollen tartan fabrics can be fabricated from carded yarn or worsted filaments; important is the strong patterning. There are distinct summer and winter weights. The most frequent weave is the 1 : 4 twill, in same-sided twill as well as Plain weave. Worsted tartan fabrics are usually sheared; those made of carded yarn have a clear surface to lightly milled, occasionally also finished with long combed finish, causing the colours to flow delicately into one another. Used for dresses, skirts and coats.

Tartaric acid (dioxy succinic acid), $C_4O_6H_6$ molecular weight 150; density 1.759. Salts = tartrates. Large, colourless crystals, stable when exposed to air, odourless, nonpoisonous. Soluble in water with acid reaction, soluble in alcohol and ether. Water-based tartaric acid solution is dextrorotatory. Tartaric acid is a strongly dissociated acid (1% solution pH 2.1; 10% solution pH 1.6). Has a harmful effect on fibres when they are subjected to solution steam; reducing agent. Softening of textiles and silk scroop fabrication (silk, viscose); preservation agents (finishing agents for protein-based substances); spotting agents (lightening, freshening, etc.).

Tartrates Salts of → Tartaric acid.

Tasar → Tussah silk.

Tassel Tuft of threads or

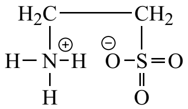
looped threads, bound together at one end. These are counted amongst → Trimmings.

Tatami mats Smooth floor covering, frequently used in Japan, made of Tatami straw. This is derived from Tatami grass, a type of rush cultivated in Japan, China and Taiwan.

tato Abbrev. of the German Tagestonne day-ton(s), tons/day.

Tatty-Look Fashion direction which values a worn appearance of clothing. Worn effects can be achieved by irregular contact drying, emerising or dripping of chemicals, etc. onto the fabric.

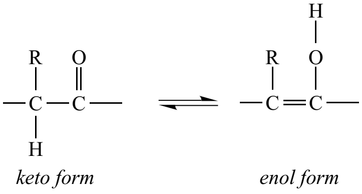
Taurine (amino ethane sulfo acid).



Molecular weight 125, melting point over 240°C, white crystals. It is easily soluble in water (neutral) and alkali, not in alcohol or ether. Originally derived from → Gall extract. Reacts like ester with cellulose hydroxyl groups (acid dye substance affinity). By-product of dye substance synthesis. It is used for detergent synthesizing and for animalisation of cellulose.

Taurocholic acid → Gall extract.

Tautomerism Organic compounds, in which two isomeric-structure forms merge partially, like keto- and enol forms (→ Ketones) when in dyeing vats, known as tautomerising. keto-enol-tautomerism causes a shift in the chemical combination:



As opposed to mesomeric (→ Mesomeric resonance), in which electrons change their position in the isomers, in tautomerism an atom (hydrogen) is displaced.

Tb Element symbol for terbium (65).

TC,

I. “Total Carbon“ = total carbon content (term used in biological effluent cleansing. (→ TOC).

II. Abbreviation for “Toxic Concentration”, i.e. in the case of gases, the concentration at which any → Toxic effect on humans is demonstrable.

Tc Element symbol for technetium (43).

T-Carbate Substituted dithiocarbamate, which at pH 5 in acetic, tartaric solution is a suitable reagent for quantitative precipitation of metal traces (including cobalt, copper, nickel, platinum, precious metals, lead, manganese, iron, zinc, vanadium, chrome, molybdenum), whereas titanium, aluminium and earth alkali do not precipitate. It is used for spectral analysis of heavy metal traces in incinerated cellulose materials.

TCF process (textiles continuously formed). Direct technique for fabrication of spun fleeces and spot-bonded nonwovens fabricated of viscose. Spun threads contain the components hydrozyl methyl cellulose xanthate (HMCX), cellulose and caustic cellulose in concentrated ringed layers. The thermoplastic component is HMCX, which has a sticking effect during hot calendering of the spun fleece and is transformed into cellulose during the process. A bonding agent is not required.

Td Abbreviation for tighter denier, obsolete → Linear density of fibres and yarns

Te Element symbol for tellurium (52).

Tearing Tester Elmendorf Used to establish initial tearing and further tearing values (= Elmendorf values) of particularly highly refined cotton fabrics by applying a strain with pendulum stroke testers.

Tear strength The force necessary to tear or tear through a strip of fabric in the direction of its length. Measurable with special clips on the tensile strength tester, where values can be read directly from a scale.

Teasel cards Dry teasel plant heads for rod teasel machine and roller card raising machines. → Raising machines.

Technical and professional organizations The following list contains the most important technical organisations and institutes in German-speaking countries. Further information and addresses are obtainable from the Gesamtverband der deutschen Textilindustrie e.V. (Gesamttextil) (Umbrella Association of German Textile Industry).

I. German textile reseach institutes:

- Bundesanstalt für Materialforschung und -prüfung (BAM) (Federal Institute of Material Research and Testing), Fachgruppe Textilien und Leder (Specialist Department for Textiles and Leather), Unter den Eichen 87, Berlin.
- Deutsche Institute für Textil- und Faserforschung (German Institutes for Textile and Fibre Research) Stuttgart/Denkendorf, Körschtalstr. 26, Denkendorf:
  - Institut für Chemiefasern (Institute for Chemical Fibres) (Chf),
  - Institut für Textilchemie (Institute for Textile Chemistry) (Tch),
  - Institut für Textil- und Verfahrenstechnik (Institute for Textile and Textile Processing Technology) (ITV).
- Deutsches Institut für Normung e.V. (German Institute for Standards) (DIN) (Normenausschuß Textil und Textilmaschinen) (Standards Committee Textiles and Textile Machines), Burggrafenstr. 4–10, Berlin.

- Deutsches Teppichforschungsinstitut e.V. (German Carpet Research Institute) (TFI), Germanusstraße 5, Aachen.
- Deutsches Textilforschungszentrum Nord-West e.V. (German Textile Research Centre) (DTNW), Frankenring 2, Krefeld.
- Deutsches Wollforschungsinstitut an der TH Aachen e.V. (German Wool Research Institute at the Technical University, Aachen) (DWI), Veltmanplatz 8, Aachen.
- Faserinstitut Bremen e.V. (FIBRE) (Fibre Institute Bremen) (Cotton Exchange), Wachtstraße 17–24, Bremen.
- Forschungsinstitut für Reinigungstechnologie e.V. (Research Institute for Cleaning Technology) (wfk, Wäschereiforschung Krefeld) (Laundry Research Krefeld), Adlerstraße 42, Krefeld.
- Hohensteiner Institute (Hohenstein Institutes), Schloß Hohenstein, Bönnigheim:
  - Bekleidungsphysiologisches Institut Hohenstein e.V. (Clothing Physiological Institute) (BPI),
  - Forschungsinstitut Hohenstein (Research Institute) (FI),
  - Forschungsstelle Textilreinigung e.V. (Research Centre for Textile Cleaning) (FTR) (based in Krefeld).
- Institut für Nähtechnik e. V., Jülicher Str. 336, Aachen.
- Institut für Makromolekulare Chemie und Textilchemie (Institute for Macromolecular Chemistry and Textile Chemistry) (IMTC), Mommsenstraße 13, Dresden.
- Institut für Textilmaschinen TU Chemnitz (Institute for Textile Machinery at the Technical University of Chemnitz (ITM), Reichenhainer Straße 70, Chemnitz.
- Institut für Textiltechnik der RWTH Aachen (Institute for Textile Technology of the RWTH Aachen (ITA), Eilfschornsteinstraße 18, Aachen.
- Institut für Textil- und Bekleidungstechnik TU Dresden (Institute for Textile and Clothing Technology at the Technical University Dresden (ITB), Mommsenstraße 13, Dresden.
- Sächsisches Textilforschungsinstitut e.V. (Textile Research Institute of the State of Saxony) (STI):
  - Forschungsinstitut für Textiltechnologie Chemnitz GmbH (Research Institute for Textile Technology Chemnitz Ltd.) (FIFT), Annaberger Straße 240, Cheminitz;
  - Institut für technische Textilien GmbH (Institute for Technical Textiles Ltd.) (ITT), Hohe Straße 6, Dresden.
- Textilforschung Bielefeld e.V. (Textile Research Bielefeld) (TF), Am Bahnhof 6, Bielefeld.
- Textilforschungsinstitut Thüringen-Vogtland e.V. (Textile Research Institute) (TITV):
  - Textilservice GmbH Greiz (TS), Zeulenrodaer Straße 42, Greiz;
  - Textilforschung Plauen GmbH (Textile Research) (TFP), Morgenbergstraße 41, Plauen.

II. European associations:

- Aachener Textilzentrum e. V., Veltmannplatz 8, Aachen.
- Bundesverband der deutschen Bekleidungsindustrie (Federal Association of German Clothing Industries) (BDI), Mevissenstraß, Cologne.
- Gesamtverband der deutschen Textilindustrie (Gesamttextil) e.V. (Umbrella Association of German Textile Industries), Schaumainkai 91, Frankfurt am Main.
- Gesamtverband der deutschen Textilveredlungsindustrie (Umbrella Assocation of German Textile Finishing Industry) (TVI-Association) Schaumainkai 91, Frankfurt/Main.
- Schweizer Verein der Chemiker und Coloristen (Swiss Association of Chemists and Colourists) (SVCC), Postfach 262, Zürich.
- Schweizer Verein der Färber (Swiss Association of Dyers) (SVF), Gossauerstraße 129, Herisau.
- VDI Gesellschaft Textil und Bekleidung (Association of German Industry Textile and Clothing) (VDI-TXB), Graf-Recke Straße 48, Düsseldorf 1.
- Verein Deutscher Textilveredlungsfachleute (VDTF), Weinbrennerstr. 4, Schwetzingen.

III. Institutes and associations:

- Ahmadabad Textile Industry's Research Association (AITRA), P.O. Polytechnic, Ahmadabad 380 015, India.
- American Associations:
  - American Association for Textile Technology (AATT), POB 99, Gastonia, NC 28 053, U.S.A.
  - American Association of Textile Chemists and Colorists, (AATCC), POB 12 215, Research Triangle Park, NC 27 709-2215, U.S.A., promotes the Wet Textile Industry. It has worked for 70 years with dyers, finishers, educators, students, chemists, mill superintendents, laboratory technicians, management executives and others who are involved with the application of chemistry textiles.
  - American Fiber Manufacturers Association (AFMA), is a domestic trade organization representing U.S. producers of more than 90 percent of the domestic production of manufactured fibers, filaments and yarns.
  - American Polyolefin Association (APA) is a U.S. based organization dedicated exclusively to promoting polyoloefin textile and ancillary products. APA and ist member companies open and broaden opportunities for polyolefin use in apparel, automotive, home furnishings, industrial, technical and related markets.
  - AMTEX, the American Textile Partnership (between the Department of Energy, the DOE laboratories, other federal agencies and universities.
  - Cotton Incorporated, with headquarters in New York City and eight other offices the world. Cotton Incorporated is a research and promotion company funded by U.S. cotton producers and importers of cotton goods into the United States.
  - Dallas Textile Club, nearly 200 active and honorary members representing the textile industry and related

  fields. Promoting cooperation to enhance the professional, social and personal development of each participating member.
  - National Textile Center is a group of four universities: Aubrun University, Clemson University, Georgia Institut of Technology, North Carolina State University, located in the heart the U.S. textile industries manufacturing base. Sharing human resources, equipment and facilities, mission goals are accomplished through innovative research and collaborative partnerships.
  - Textile Institute, U.S.A. The mission of the Textile Institute is to promote professionalism in all areas associated with the textile industries worldwide. Industrial and commercial operations from fibre production to the use of product by individual and corporate consumers.
- Associatión Española de Quimicos y Coloristas Textiles (AEQCT), c/o Joaquin Vidal Artes, Paseo General Mola 35, Barcelona 9, Spain.
- Association Internationale des Laboratoires Textiles Lainiers, 19 Rue du Luxembourg, B-1040 Bruxelles.
- Association Interprofessionelle pour la Formation Permanente dans le Commerce Textile, 69 Rue de Richelieu, 75 001 Paris, France.
- Associazione Italiana di Chimica Tessile e Coloristica (AICTC), Viale Sarca 223, 20 126 Milano, Italy.
- Associazione Italiana di Cinematografia Scientifica, Via Alfonso Borelli 50, 00161 Roma, Italy.
- Associazione per lo Sviluppo di Studi e Ricerche nell'Industria Tessile Laniera Oreste Rivett, Piazza Lamamorra 5, 13 051 Biella, Italy.
- Australian Wool Corporation, Wool House, 369 Royal Parade, Parkville, Vic 3052, Australia.
- Bombay Textile Research Association (BTRA), LB Shastri Marg, Ghatkopar, Bombay, India.
- Canadian Apparel Manufactures Institute, 141 Laurier W, Ste 804, Ottawa Ont. K1P 5J3, Canada.
- Centre de Perfectionnement des Industries Textiles Rhône-Alpes (CEPITRA), 55 Montée de Choulans, 69 323 Lyon Cédex 1, France.
- Centre International d'Etude des Textiles Anciens (CIETA), 34 Rue de la Charité, 69 002 Lyon, France.
- Compagnie Française pour le Développement des Fibres Textiles (CFDT), BP 1699, Couala, Cameroon.
- Costume Society of America (CSA), 55 Edgewater Dr, POB. 73, Earleville, MD 21919-0073, U.S.A.
- Educational Foundation for the Fashion Industries (EFFI), 227 W 27 ST, New York, NY 10 001, U.S.A.
- European Association for Textile Polyolefins (EATP)/Association Europénne des Polyoléfines Textiles, 4 Av. E. van Nieuwenhuyse, B-1160 Bruxelles.
- Federation of Asian Professional Textile Associations, objectives are to develop fraternity among members of the professional textile associations of the Asian region, upgrade technologicla status, organize conferences and programs for improving interaction between Asian countries. Approx. 10 member associations are representing thousands of textile and clothing professionals.
- Institute of Textile Science, c/o Dominion Textile Inc, POB 6250, Montréal, Qué. H3C 3L1, Canada.
- Institute of Textile Technology (ITT), POB 391, Charlottesville, VA 22 902, U.S.A.
- Instituto Nacional de Tecnologia Industrial (INTI)/National Institute of Industrial Technology, Av Leandro N. Alem 1067, 1001 Buenos Aires, Argentinia.
- Internationale Föderation der Vereine der Textilchemiker und Coloristen (IFVTCC)/International Federation of Associations of Textile Chemists and Colourists, Hollenweg 8 a, CH-4153 Reinach.
- International Textile and Apparel Association (ITAA), POB 1360, Monument, CO 80 132, U.S.A.
- International Wool Secretariat (IWS), Wool House, 6–7 Carlton Gardens, London SW1Y 5AE, UK
- Irish Textiles Federation Confederation House, Kildare St, Dublin 2, Ireland
- Malaysian Textile Association membership from all sectors of the textile and apparel manufacturing, covering the fibre, spinning, weaving, knitting, garment-making, industrial textile/accessories
- National Council for Textile Education (NCTE), POB 391, Charlottesville, VA 22 902, U.S.A.
- Norsk Tekstil Teknisk Forbund (NTTF), Lars Hillesgt 34, 5000 Bergen, Norway.
- Shanghai Textile Ingineering Society, 197 North Wulumuqi Rd, Shanghai, China.
- South India Textile Research Association, POB 3205 Coimbatore 641 014, India.
- Tecnotessile/Centro di Ricerche, Via Valentini 14, 50047 Prato, Italy.
- Textile Academy, Ying Jia Fen, Beijing CA: 9444, China
- Textile Institutes (TI):
  - TI China Liason Office, 18 Guang Wie Road, Guangzhou 5 100 030, China.
  - TI Czech Republic National Office, Na Ostrove 1165, 562 23 Usti nad Orlici, Czech Republic.
  - TI India National Office, 308 Raheja Centre, Avanashi Road, Coimbatore 641 018, India.
  - TI International Headquarters, 10 Blackfriars Street, Manchester M3 5DR, United Kingdom.
  - TI Poland National Office, Institute of Natural Fibers, Wojska Polskiego Str 716, 60 630 Pozna, Poland.
  - TI Turkey National Office, Byksehir Kltr Merkezi, 8 Medidiyeky, Istanbul, Turkey.
  - TI USA National Office, 2207 Concord Pike, Wilmington, DE 19 803, U.S.A.
- Textile Research Council (TRC), 2 First Av, Sherwood Rise, Nottingham NG7 6JL, United Kingdom.
- Textile Society of Australia, 594 Saint Kilda Rd., Melbourne, Vic 3004, Australia.
- Textilpari Müszaki és Tudományos Egyesület (TMTE)/

Hungarian Society of Textile Technology and Science, Fo utca 68, 1027 Budapest, Hungary.

- Trade Associations:
  - American Apparel Manufacturers Association (AAMA).
  - American Association of Textile Chemists and Colorists (AATC).
  - American Fiber Manufacturers Association (AFMA).
  - American Society of Mechanical Engineers (ASME) – Textile Ingineering Div., represents U.S. producers of manufactured fibres, filaments and yarns
  - American Textile Machinery Association (ATMA), working on improve conditions within the textile machinery industry of the U.S.
  - American Textile Manufacturers Institute (ATMI), is the national trade association for the U.S. textile industry.
  - Ayrshire Textile Group, helping strengthing the textile industry's profile and competitiveness in the UK and worldwide.
  - Carolina Hosiery Association (CHA), representing hosiery manufacturers and suppliers in the Carolinas.
  - China Garment Enterprise Association, social economic organization of the China garment industry.
  - Consortium on Competitiveness for the Apparel, Carpet and Textile Industries (CCACTI).
  - Embroidery Trade Association (ETA), developing solutions to the challenges of running an embroidery company.
  - Garment Contractors Association of Southern California Inc. (GCA).
  - German Apparel Association, an independent forum for European fashion and textile business.
  - Honduras Apparel Manufacturers Association.
  - International Apparel Federation (IAF), the representative organization for apparel manufacturers worldwide.
  - International Swimwear and Activewear market (ISAM).
  - Korea Textile Communication, providing up-to-date accurate and reliable information about the Korean Textile Industry.
  - Japan Cotton Promotions Institute, promoting cotton fabrics and fashions in Japan.
  - Malaysian Textile Manufacturers Association (MTMA), important and indespensible guiding forces in the Malaysian Textile Industry.
  - Nottingham Derbyshire Clothing and Textiles Association.
  - San Francisco Fashion Industries (SFFI), representing the Northern California Apparel Industry Trade Association.
  - Silk and Rayon Printers and Dyers Association of America, providing members with ideas and innovations in textile processing.
  - The Scottish Textile Association, promoting Scottish manufacturers and textile services throughout the world
  - Southeastern Apparel Manufacturers and Suppliers Association (SEAMS)
  - Taiwan Textile Federation (TTF)
  - Textiles from France
- Union of Textiles, Clothing and Leather, Rakovski 198, 1000 Sofia, Bulgaria
- Wuhsi Academy of Textile Engineering, Iiande Rd, Wushi 214004, China

IV. German universities with international education curricula in textile and garment technology and management:

- Institut für Textiltechnik, RWTH Aachen, Eilfschornsteinstraße 18, 52062 Aachen, Telefon 02 41 80 56 21, http://www.ita.rwth-aachen.de/~vth index.html; European Master of Science
- Technische Universität Dresden, Institut für Textil- und Bekleidungstechnik, 01062 Dresden, Telefon 03 51/ 4 65 83 70, http://www.tu-dresden.de; Master of Science in Textile and Clothing Engineering
- Fachhochschule Niederrhein, Textil- und Bekleidungstechnik, Webstuhlstraße 31, 41065 Mönchengladbach, Telefon 0 21 61/18 67 02, http://www.fh-niederrhein.de; Bachelor of Science in Textile and Garment Management and Master of Science in Textile and Garment Management (in English language only)
- Fachhochschule Reutlingen, Hochschule für Technik und Wirtschaft, Alteburgstraße 150, 72762 Reutlingen, Telefon 0 71 21/27 12 55, http://www.fh-reutlingen.de; Executive Master of Science in Global Textile Marketing
- Fachhochschule Albstadt-Sigmaringen, Jakobstraße 6, 72458 Albstadt-Ebingen, Telefon 0 74 31/57 92 13, http://www.fh-albsig.de; Master in Textile and Clothing Technology (TCT).

Technical grease solvents → Fat-solubilising soaps.

Technical guideline concentration A technical guideline concentration for hazardous substances and their concentrations (in the form of gas, vapour or suspended matter) in the air taken as a reference value for the introduction of appropriate protective measures at the workplace and the monitoring of exposure levels. It applies particularly to carcinogenic substances which have been removed from the MAK (maximum workplace concentration) list and included in the TRK (technical guideline concentration) list. Technical guideline concentrations are only allocated to hazardous substances for which no MAK limit, based on industrial toxicology, can be specified at present (→ Carcinogenic substances). The observance of technical guideline concentrations is intended to reduce health risks at the workplace, although these cannot be entirely excluded. No technical guideline concentrations have been adopted in the USA where the → TLV (threshold limit value) applies as far as possible in industrial practice, even for carcinogenic substances.

Technical organizations → Technical and professional organizations.

Technical textiles Frequently used term for textiles used for technical purposes, for preventive or auxiliary functions in consumer and utility goods as well as in the production of goods and services (→ Industrial textiles). These are textiles, whose fibre substance and form, texture or weaving technique, impregnation, coating, rubberising or composite construction render them independent technical products, are used in technical products, or demonstrate technical or special industrial properties. They may completely lose their textile character in the following phases of manufacture and use.

Technical textiles can be systematically categorized as follows:

1. construction textiles
1.1 geotextiles for underwater and underground construction
1.2 textiles for civil engineering (Figs. 1–2) (reinforcing, roofs and tents)
1.3 agro textiles (Fig. 3)
1.4 floor coverings
1.5 screening and sound insulation
2. medicinal textiles
2.1 hygiene articles and cosmetic articles
2.2 hospital linens
2.3 surgical articles and dressings
3. industrial articles
3.1 composite fabrics as alternative materials (Fig. 4)
3.2 rope articles, hose piping, cables

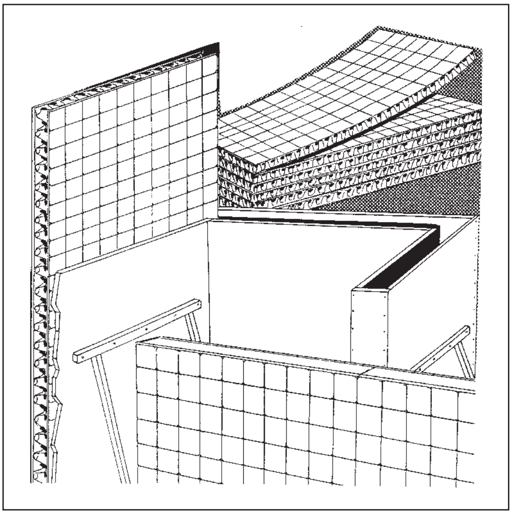


Fig. 1: Light partition walls for trade fair construction, can be rapidly installed and dismantled because of their honeycomb textile structure and easy to both store and transport (by TexTec).

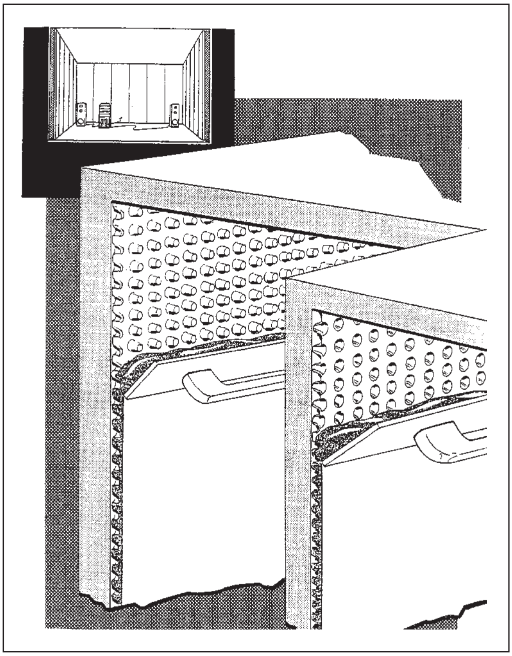

Fig. 2: Sound insulation walls made from composite material (by TexTec).

3.3 nets, belts, webbing, fastenings
3.4 filter fabrics and sieves
3.5 polishing textiles (sanding, cleaning cloths)
3.6 roller coverings
3.7 packaging material
3.8 dyestuff carriers
3.9 circuit boards
4. mobile textiles
4.1 automobile interior design (Figs. 5–7)
4.2 transportation tarpaulins (Fig. 8)
4.3 aviation and space travel
4.4 tyres, V-belts and drive belts
4.5 transport belts, conveyor belts
4.6 seals, brake linings
5. protective textiles
5.1 defence textiles
5.2 technical goods
5.3 heat, cold, fire, chemical protection
5.4 weather protection and sport clothing
5.5 cleaning textiles
5.6 safety clothing.

Technical textiles frequently demonstrate three-dimensional properties, as is demonstrated by the structure of a drainage pipe (Fig. 9) or by the differentiated construction of a tyre (Fig. 10). This type of textile construction has to be reinforced in order to fulfil the profile requirement. Reinforcement is often carried out mechanically, e.g. by means of stapling (Fig. 11) or by

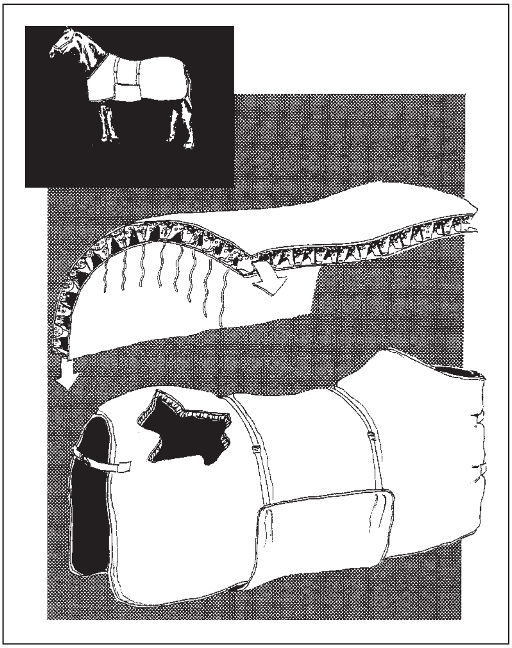

Fig. 3: Three-dimensionally fixed textile structure serving as a layer of insulation in water vapour permeable horse blankets (by TexTec).

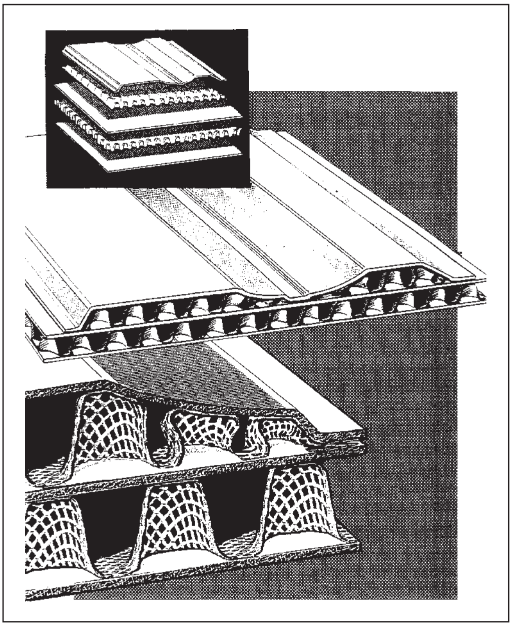

Fig. 4: Moulded textile nets, set three-dimensionally as prepreg and used as a construction material in the insulation industry (by TexTec).

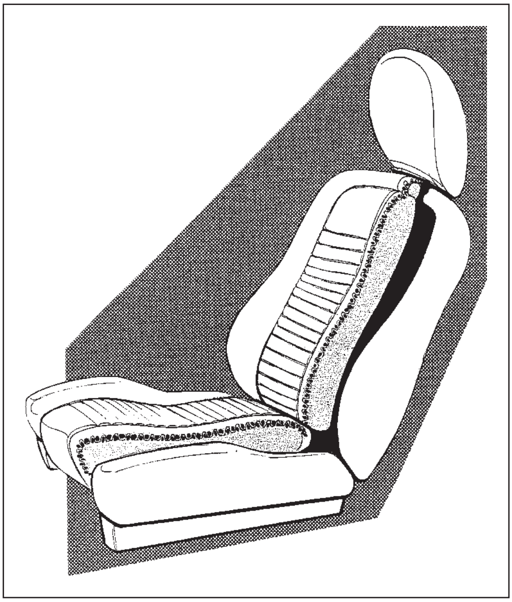

Fig. 5: Cross-section through a car seat (by TexTec).

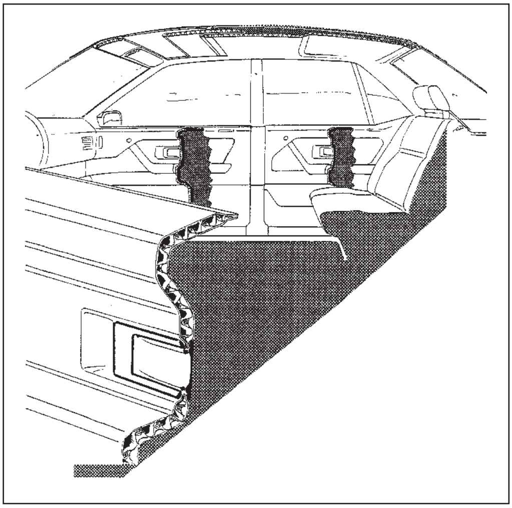

Fig. 6: Bonded fabric as internal car trim (by TexTec).

sewing multi-axial, non-shrink composite fabrics made of various textile materials (Fig. 12). Reinforcement is often achieved by means of textile refinement methods.

Most technical textiles are subjected to the textile refinement stage (TRS) during the fabrication process. Exceptions are for example tyre cord, cigarette filters, dyke reinforcement mats, ships' tackle, brake and clutch linings and similar items. Some technical textiles are not subjected to the complete, classical refine-

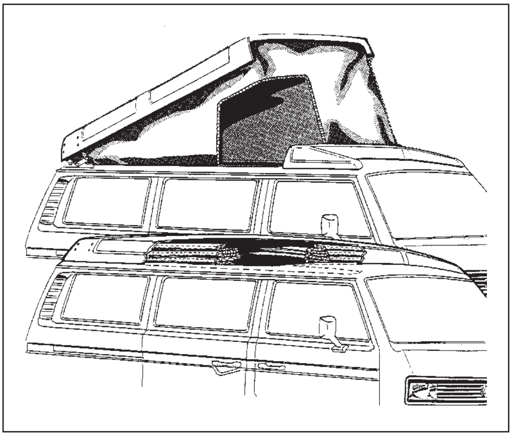

Fig. 7: Rising roof (open and closed) with extensible fabric sheathing, coated for improved insulation (by TexTec).

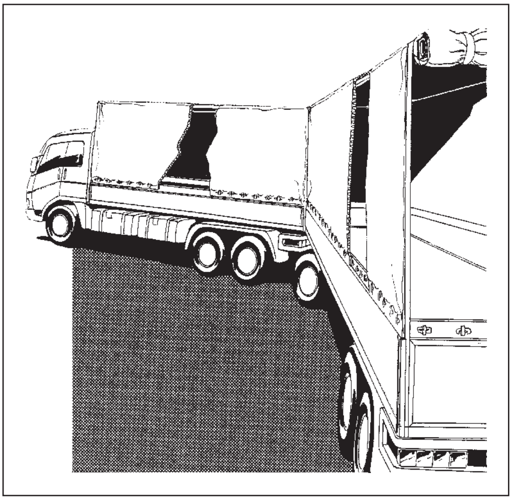

Fig. 8: Transport tarpaulins, used to insulate lorry cargo space against the weather (by TexTec).

Fig. 9: Pipe structure (Drainage) (Multiple Fabric Co. Ltd.).

ment process, i.e. pretreatment, dyeing or printing and finishing but are subjected to specific refinement processes, e.g. coating, glueing, cationisation, softening, roughening, etc.

Calculations made by the German Textile Processing Industry (TVI) Association come to the conclusion that the German textile processing industry treated approximately 126 000 tons of technical textiles in the form of fluff, yarn or made-up fabric in 1992, i.e. almost 19% of the total production of the textile processing industry in that year. This quantity can be broken down into the industry's main sectors (Fig. 13). Textiles for technical purposes sometimes play very differing roles in the individual refinement fields.

The proportion of fluff represents 41% and is thus the highest. Fabric refinement represents 15% and fabric printing only 4% (Fig. 14). The fluff as raw material is subjected to numerous refinement stages before being processed as technical textiles in the subsequent production path. These include materials for car seat coverings, fitted carpeting for car interiors and boots,

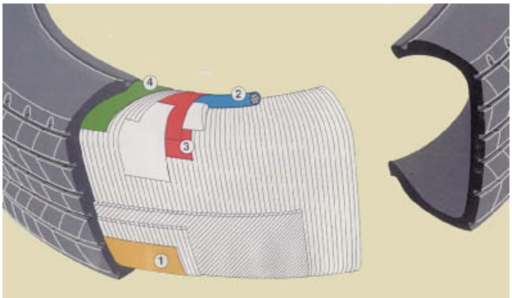

Fig. 10: Tyre structure (by Milliken).
1 = shoulder protection; 2 = closing ring; 3 = flipper;
4 = side protection.

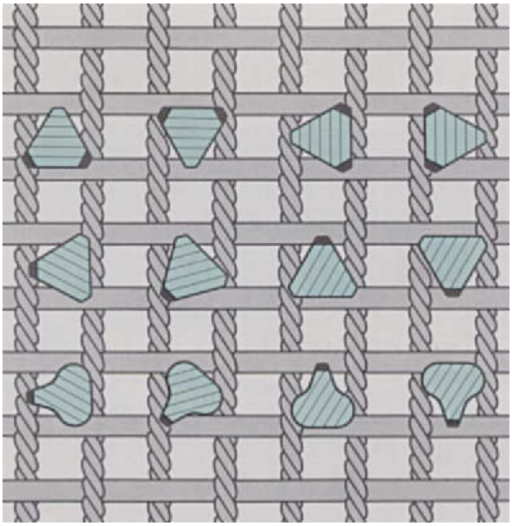

Fig. 11: Needling of a fabric (Groz-Beckert).

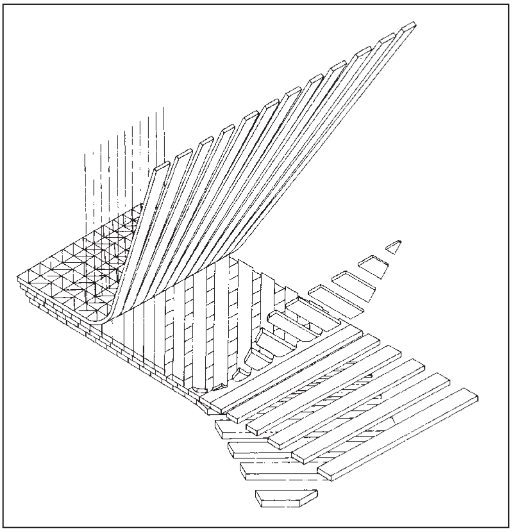

Fig. 12: Multiaxial textile construction.

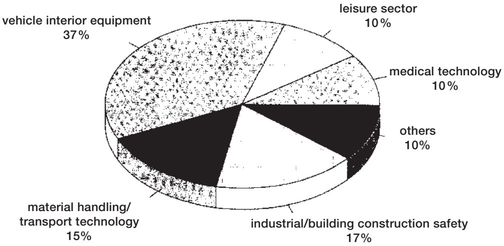

Fig. 13: Breakdown into portions of the total technical textiles tonnage in textile finishing for 1992, split into fields of application (estimate).

	loose stock	yarn	knitted fabric	fabric printing	woven fabrics	others
technical textiles tonnes ☐	10.86	13.11	17.72	3.1	45.99	34.61
sector total tonnes	26.49	119.16	77.03	77.64	306.6	49.45

Fig. 14: Breakdown into portions of technical textiles in the textile finishing categories for 1992.

belts, cotton-wool, fleeces and felts for various uses, e.g. as insulation material. Fluff industrial textiles are usually dyed and then processed into made-up fabrics. During the finishing process they are again subjected to textile refinement. The main materials to be bleached are cotton wool for medicinal and cosmetic use.

The most important substrates are polyester, polyacryl nitrile and polyamides. Fluff refinement has been considerably reduced in the fitted carpet area of the automobile sector due to the increase of spin jet dyeing of chemical fibres. Textiles for technical purposes represent 11% of yarn refinement activities. More than half of this quantity is destined for the automobile sector. Here dyed products are predominant and polyester, followed by polyamides, are the most used raw materials. As in the case of fluff, in the field of yarn refinement

Fig. 15: Foam fine-coating of a blackout curtain.

Fig. 16: Heavy-coating a transport tarpaulin with polyvinylchloride.

spin jet dyed articles have managed to attract parts of the market in the automobile sector. In the fabric refinement area technical textiles represent a considerable proportion at 15%. This is also true for the range of articles. The refinement sector is well represented in vehicle construction (fabrics for seat covers, roof linings and fitted carpeting for cars, air-bags, convertible roof covers, etc.), in the industry sector (base fabrics for conveyor belts, sanding and polishing discs, tarpaulins, computer adhesive tapes, filter materials, container construction), in medical technology (dressings, bandages and plaster materials, blood filters etc.), in safety technology (fabrics for certain types of protective clothing, life-rafts), in environmental protection, in the building sector (fabrics for façade cladding and roof construction, stall mats, tennis flooring, etc.) and others (e.g. fabrics for Velcro-fastenings), black-out curtains, parachutes, hot-air balloons, surfboard sails, ironing board covers). These fabrics are frequently coated (Figs. 15–18).

Dyed products represent a considerable proportion of the total, particularly in the case of fitted carpets for cars, but also for other industrial uses; car seat coverings have usually been dyed during the stages prior to fabric refinement and are only subjected to a finishing process as a fabric. Bleached products are predominant in the medical sector; an example of bleached products is gauze. In general the proportion of dyed products used as technical textiles is increasing. The most important types of raw material are polyester, viscose and cotton.

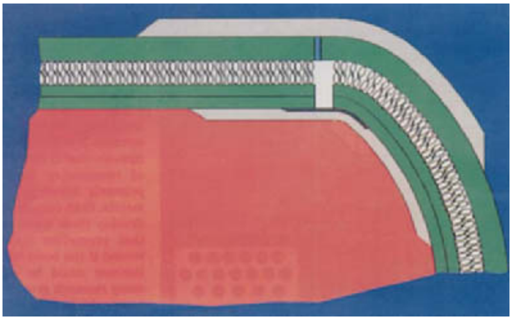

Fig. 17: Setting a 3D structure using double-sided coating (green) to form a tank-cell (red) (coating polymer: phenol-formaldehyde resin).

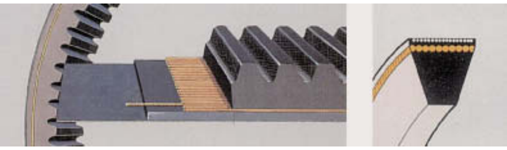

Fig. 18: Setting a 3D structure by coating it with rubber which is vulcanized into hard rubber.

The highest proportion of technical textiles refinement is represented by the refinement of mesh materials. Automobile construction with seat coverings and panelling elements plays a predominant role here. Due to economic trends in this user group the significance of technical mesh materials has increased over the last few years. This was intensified by the trend away from woven materials to mesh materials. However, there is also a range of other technical mesh materials, often special fabrics such as linings for loudspeakers, velvet for glasses cases, shoe linings etc. Dyestuff and equipment more or less balance one another. The most important raw material by far, is polyester.

The strengths of printed fabric lie in fashion articles for clothing, house and home textiles. The market segment for technical use is small at 4%. Car seat covers, tents, flags and sausage skins should be mentioned here.

Belt refinement covers a wide range of technical articles, e.g. safety belts, belts for lifting goods and window blind belts. Concealed and coated mesh materials, which are listed under other materials (these articles have often previously been subjected to another refinement stage), have numerous uses. The further refinement of these techniques has led to new applications in addition to established uses such as vehicle and container construction, safety technology and other markets. Technical textiles have a considerable significance in textile refinement. This market segment is very little affected by variations of fashion or structural changes as are clothing and house and home textiles. It is, however, very much dependent on the economy as a whole.

Technical textile sampling (taking of samples) is to be carried out in accordance with DIN 53 803. It must be representative for populations and be done in accordance with the statistical law of chance occurrence (random testing). → Statistical analysis.

Technique follow-up assessment Attempts to ensure socially and environmentally friendly choice of techniques. Technique follow-up evaluations and assessments are not at present subject to any generally valid definition. Guideline 3780 (Technique Assessment: Terms and Basic Concepts) produced by the German engineering association, Verein deutscher Ingenieure (VDI), has provided a current viable definition. According to this guideline, technique assessment consists (including technique sequence evaluation) of:

- analysis of the status of a technique and its development potential,
- evaluation of technical and non-technical consequences,
- assessment of the consequences on the basis of aims and values,
- definition of appropriate measures in terms of action and redesign.

Even on the basis of this definition, classification of projects in terms of technique follow-up assessment presents considerable difficulties, as plans and projects generally only investigate partial aspects of an overall technique follow-up assessment.

Technological progress Technological progress is expansion of technical knowledge by means of → Research and development. Technical research consists in the use of new technologies in industry, and brings about a macroeconomic increase in productivity which should include quality improvement.

Technology cards Specially developed clocking-on card (for thyristor technology) containing programmable tasks for machines and systems according to the type of process.

Tecum fibre → Palm fibres (Brazil), white and solid, similar to flax, sometimes coarser, high moisture absorbency without feeling damp, used particularly for upholstery material.

Tedeco mercerizing process Technique developed by the Norwegian Textile Institute and the Institute for Industrial Research in Oslo for treating fabrics in liquid ammonia. The technique is derived from the → Prograde process. The fabric is passed through liquid ammonia at –33/35°C causing an immediate reaction to occur. Reaction time is 10 seconds maximum. The fabric is then stretched and fed over heated drums where the ammonia evaporates and is recycled, except for a residue of 3%. The remaining 3% can be removed by steaming. The resulting ammonia steam mixture is incinerated.

TEFO Swedish documentation authority. → Technical and professional organizations.

TEGEWA German association of textile and leather aids and staining and washing raw material industry (Verband der Textilhilfsmittel-, Lederhilfsmittel-, Gerbstoff- und Waschrohstoff-Industrie e.V.). → Technical and professional organizations.

Telescope effect Microscopically detectable stretch marks in the form of local bottle-neck-shaped tapering (restriction effect) of zones most subjected to stretching when processing cold-stretchable high polymers (polyamide, polyester).

Telescopic dyeing spindle is used when dyeing cross bobbins or muffs which are compressed axially before dyeing. This process offers a time-saving factor compared with traditional methods. It consists of a perforated tube with appropriate base thread for screwing into material carrier. The charging spindle consisting of longitudinal struts can be screwed into the perforated tube in a telescopic manner (pressure spring fastening, as required, in extended position). A closing cap with several stable tenons is used for automatic locking. – Manuf. Tigges.

Telescopic dye vat loader → Telescopic packing cylinder.

Telescopic packing cylinder Infinitely adjustable telescopic central tube which can be lowered, using a crane, to 40% of the overall height of the packing cylinder before being re-lifted (after dyeing/bleaching). Compared with the conventional type design with its dome-like upper end (= unused packing volume), the telescopic packing cylinder encompasses 20–30% more material. A sprung ring acts as a seal between the interior of the apparatus and the packing cylinder lid (completely flat, adjustable). Economical solution for processing small quantities (including regulatable liquor condition) of fluff, coils, muffs, rope yarn, spinning cable. – Manuf.: Jasper.

Telescopic sleeves Telescopic sleeves which expand and retract into each other and can be easily compressed. They are often used instead of perforated sleeves for dye spools in order to achieve a better dye penetration.

Telomer → Telomerization.

Telomerization (Gk.) So-called specific → Polymerization uses compounds (so-called “telomer”) resulting in end groups, which are determined in advance, and renders possible a controllable, stage-by-stage increase of polymerization by adduction 1 : 1, 1 : 2, 1 : 3, 1 : x up to several thousand. Telomerization results in a wide range of synthetic waxes, plasticising agents, lubrication oils, textile aids, plastics, synthetic fibres, etc.

Temperature (Fr.: température = degree of temperature). There is only one temperature used to indicate the physical state of heat of a body or of the air. According to international agreement, this temperature is indicated by the name → Kelvin and the symbol K, the “degree” symbol being left out. According to this system, temperature is defined as a basic dimension of the SI system using Kelvin as its basic unit. The basic unit of 1 Kelvin is one 273rd part of the → Triple point of water, i.e. of the temperature scale which begins with 0 K (0 K = absolute zero point, 273 K = freezing point, 373 K = boiling point). Temperature units of other basic scales are determined arbitrarily. The so-called empirical temperature is based on the expansion of a fluid volume and the displacement effected thereby of a fluid filament. The conventional units are degrees Celsius (°C) [not valid in the SI-system; degrees Fahrenheit (°F), degrees Rankine (°R), obsolete; degrees Reaumur (°R)]. 1 degree Fahrenheit is equivalent to 1 degree Rankine, and likewise 1 degree Celsius to 1 Kelvin. When the temperature is quoted in degrees Celsius, this refers to the Celsius temperature scale where the freezing point of water (zero point) is ±0°C and the boiling point is +100°C. Kelvin units are equivalent to degrees Celsius with Celsius units being used here in a specialised sense. Temperature differences (temperature ranges) thereby have identical numerical values, no matter whether read in K or °C, for 1°C is equivalent to one K as a temperature differential anywhere on the temperature scale. In this sense, therefore, 1°C = 1 K since, throughout the temperature scale a temperature range of, for example, 15°C is identical to the temperature range of 15 K. What should be remembered is that the "Kelvin" is to be understood as a dimension and not as a scale, whereas Celsius remains a scale:

373.15 K = 100°C
273.15 K = 0°C
0 K = –273.15°C

Temperature characteristics of textile fibres are shown in (°C) in the Table.

	A	B	C	D
wool	110	80	130*	300
cotton	100	75	*	160
polyester	140	120	235	255
m-aramide	250	200	300	400

*Tab.: Temperature characteristics of textile fibres (ºC). A = hot air temperatures after 2500 h, causing a 50% reduction in the tear strength of the fibres; B = hot air temperatures after 10 000 h, causing a 50% reduction in the tear strength of the fibres; C = softening or decomposition temperature; D = melting or carbonisation temperature. * = according to moisture content.*

Temperature control of dyeing machines In practice, temperature regulation circuits are often planned according to the form of the programme or information carrier, i.e. circular plates, plug board, punched tape, plastic partition cards, cut cards, magnetic cards, computers. The Fig. depicts variations in such control systems for a temperature time-control on dyeing apparatus.

Temperature indicator colours Temperature-indicating salts (of e.g. copper, cobalt, nickel, chrome, molybdenum, uranium) which change their colour at certain temperatures and retain it after subsequent temperature reduction. Several colour transformations per salt are possible. Temperature indicator colours are used as a paint coating or as pencils for temperature measurement, which are used according to colour transformation range to monitor dangerous levels of heat on, for example, pipelines, radiators, electrical appliances and movable machine parts such as drums, brakes, couplings.

Temperature measurement Totally accurate temperature measurement is difficult. Usually only a mean temperature is measurable between the product, the wall temperature and the energy carrying medium (water, air, heat bearing oil). The exact temperature is not measured accurately even when it is taken in contact with the material to be measured. The temperature sensor is in a permanent state of temperature exchange with its environment and the following points should therefore be noted:

– Heat exchange between the material to be examined and the temperature sensor must be encouraged;
– Loss or addition of heat from or to the temperature sensor must be prevented as far as possible.

It is obvious that a measurement or sensor installation location should generally be chosen which has the highest constant speed of measurement and is as near as possible to the heat consumer. Depending on the system or machine, measurement locations should be as follows:

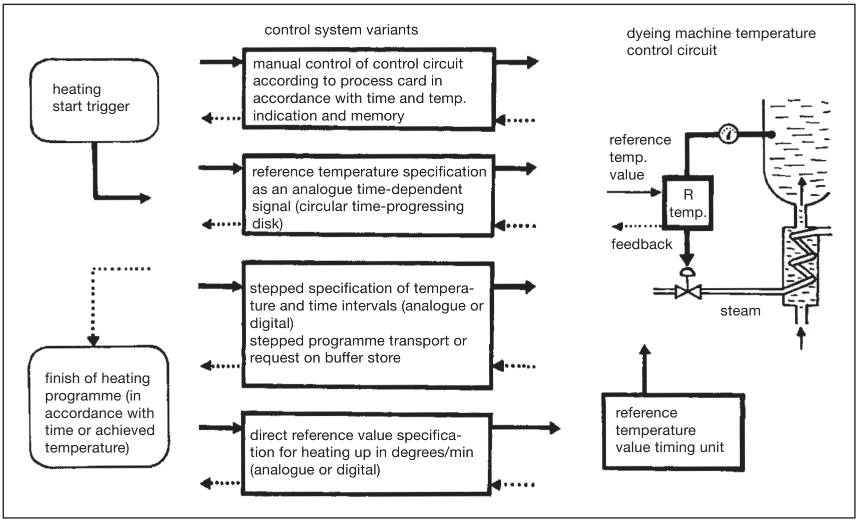

Fig.: Control system variants on dyeing machines for controlling steam supply (Rüttiger).

- For systems heated by means of fluids: at the heating agent influx or outflux;
- For systems with steam heating: pressure measurement at the heating agent influx, temperature measurement at heating agent outflux;
- On the product itself in machines or systems without circulation;
- At the product discharge point in machines or systems with circulation;
- At the mixed product discharge point.

Resistance thermometers are used as sensors in technology (Fig. 1). They can be manufactured with a high degree of accuracy but have the principal disadvantage compared with platinum sensors that they age, i.e. their values change slightly after a few years. For technical use (e.g. temperature regulation), constant voltage is applied to the resistance thermometer and the current is then measured. The process is generally too time-consuming for temperature measurement.

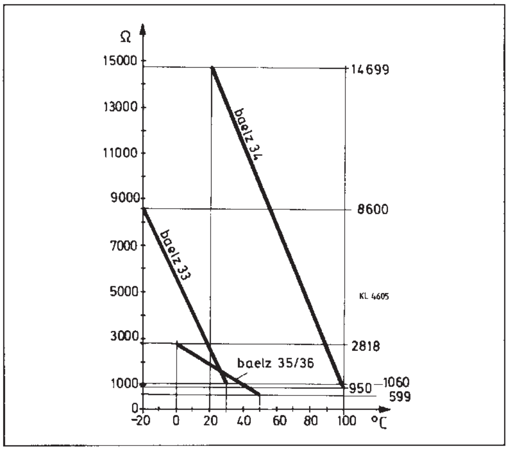

Fig. 1: Resistance thermometer resistance values (Baelz).

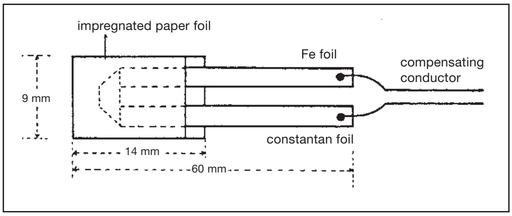

Fig. 2: Surface thermoelement diagram.

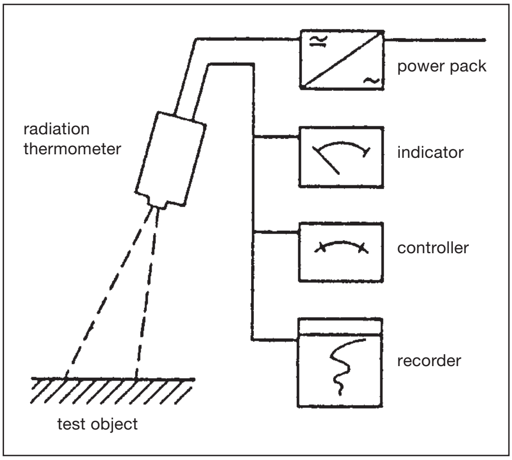

Fig. 3: Infra-red radiation thermometer, diagram (Heimann).

Thermoelements (Fig. 2) are used particularly for high temperatures. The measureing element is a thermometer consisting of two strips made of different metals or metal alloys soldered or welded to each other at one end of the measurement point. If the measurement point is subject to a temperature different from that at the free end of the thermocouple, a voltage or thermo electric voltage results at these free ends. The value of the thermo electric voltage depends on the temperature differential between the temperature at the measurement point and that at the free end, as well as on the material combination of the thermocouple. Thermo elements are less strictly linear than resistance thermometers, so that the measurement converter requires more time to achieve a comparable level of accuracy than the platinum measurement circuit.

If the correct materials are not used, measurement errors occur at clamping points and on the cable. Radiation thermometers function without contact (Fig. 3).

Normally temperature measurement with contact thermometers takes place on calenders, for example, when using radiation sensors. In the case of all heated and rotating cylinders, the most important component in order to achieve good, reproducible accuracy is the choice of the measuring device. In addition to radiation sensors, which are expensive, the following measuring methods can be used (Fig. 4):

- For slowly rotating cylinders: a thermo element sensor which glides directly along the roller surface;
- For fast rotating cylinders: a thermo element which is kept at a distance of 0.5 mm from the rollers;
- A normal resistance thermometer is adequate for use in heating with hot water or heat carrier oil;
- For steam heating: measurement with a resistance thermometer in a loop in the condensate outlet gives reliable results.

Dip sensors for measuring the temperature of baths are usually resistance thermometers.

Temperature sensor TDS 95 (Fig. 5) is used for non-

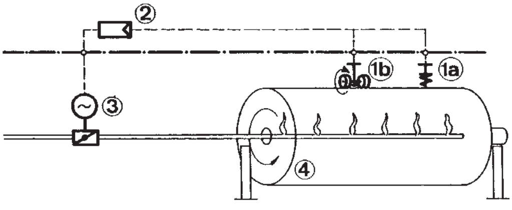

Fig. 4: Thermoelements acting as sensors in a gas heating closed loop control (according to Baelz).
1a = sliding thermocouple sensor; 1b = thermocouple sensor kept 0.5 mm away by revolving castors; 2 = control unit wih deviation indicator and actual indicator; 3 = motor-driven actuator for motor propulsion on control shutter;
4 = cylinder.

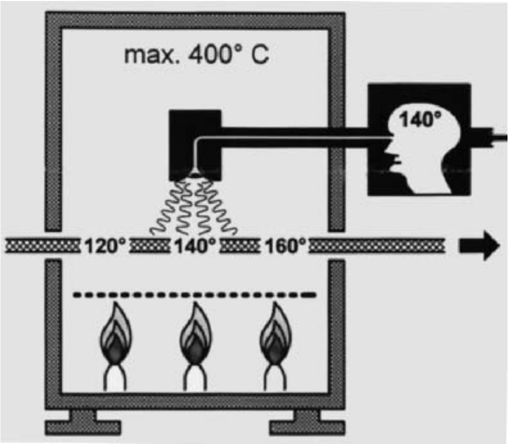

Fig. 5: Temperature sensor TDS 95 (according to Pleva).

contact measurement of the surface temperature of materials. The special design of the TDS sensor allows it to be used inside a heat-treatment machine (e.g. drier) up to temperatures of 400°C. The robust, rugged design of the sensor is a first requirement for use in production machines. The measuring principle is based on exchange of thermal radiation between the material to be measured and the sensitive surface of the TDS 95. It is located behind a radiation-permeable window in the TDS 95. Rapid changes in temperature are detected. The temperature sensor is calibrated for materials characterized by approx. the same properties as a black body (emission factor $\varepsilon \approx 0.9$). Such materials include textiles, paper and plastics for instance (according to Pleva).

Temporary hardness → Water hardness salts.

Tenacity → Viscosity.

Tendering dye Characteristic of certain vat dyes of damaging cellulose by catalysis during the dyeing process (→ Vat dyes and fibre damage). Damage only occurs if dyeing is carried out on open apparatus under strong light or if the dye oxidizes frequently due to lack of sodium dithionite making it necessary to reduce it again.

Tensile elasticity The most important type of → Elasticity which is measured after pre-tensioning under gradually increasing load (stress-strain behaviour). Evaluation of the figures to attain, for example:

1. Elastic elongation: Retraction of the test specimen when the load is removed as % of the initial length.
2. Degree of elasticity: Ratio of elastic elongation to overall elongation, as %.
3. Modulus of elasticity (E-modulus): Ratio of tensile stress to the elongation unit. Measure of the resistance of a fabric to changes in form.

Tensile force (tensile load). The force in the direction of traction acting on the test sample at any one time during a simple → Tensile strength test: the maximum measured tensile force on rupture of the test sample is known as the maximum tensile force; in relation to fineness = tensile strength; in relation to the initial cross-section = tensile stress.

Tensile strength (strength, rupture strength, limit strength, tear strength). Resistance of a material to tensile load; the tensile strength is the → Tensile force (maximum tensile force) in relation to fineness. In the SI system of units the tensile strength corresponds to the measured tensile load in newtons divided by fibre fineness in tex. If the centi-newton is chosen instead of the newton, the results are the same (with a 2% margin of error) as for the old measure of breaking length:

$$1\,\frac{\mathrm{cN}}{\mathrm{tex}} \approx 1\,\frac{\mathrm{p}}{\mathrm{tex}} = 1\ \mathrm{Rkm}$$

Tensile strength loss Measurement for loss of → Tensile strength in textile goods as a result of treatment expressed in %. Tensile strength loss can be caused by mechanical or chemical factors, e.g. as an evaluation of the impact of the washing process on fabrics (→ Laundry quality control) the tensile strength loss should not exceed 30% after 50 washing processes.

Tensile strength test (elongation test). The simple tensile strength test is used to establish the relationship between tensile force and length modification of a sample until it ruptures. Forces are only measured in one direction (fibre axis). The material to be tested is stretched between two clips in a tensile strength-testing unit at a defined pre-tensioning load, the stretching length being the distance between the two clips. One clip moves at a defined speed while the other remains fixed (deformation speed) until the sample tears (maximum tensile force). The resulting tensile force elongation curve is characteristic for a certain fibre material and for the particular yarn construction (→ Stress-strain behaviour).

Variations in yarn twist result in varying tensile strengths. This is because with increasing yarn twist the individual fibres are pressed more closely to each other causing friction between the fibre surfaces to increase. The friction exceeds the cohesion of the individual fibres relatively frequently and, as a result, the fabric is not forcefully reduced to its component parts but the individual fibres are destroyed at a certain point when the yarn ruptures, leaving the overall fabric intact directly next to the point of rupture.

Tensile strength testing During the course of textile manufacture, e.g. during yarn and fabric manufacture and during use, textile fibres are frequently exposed to stress at high stretching speed. Sudden and short term stress only occur for example during the weaving process (weft insertion, shed formation, beating up), during sewing and embroidery or when cutting tow. High acceleration at the deflection points also has to be taken into consideration during winding of the yarns. On modern high performance weaving apparatus, accelerations of up to 12 000 m/s^2 and during sewing at 6000 stitches/min. as much as 60 000 m/s^2 occur during weft insertion. The forces occurring during such short-lived stress often approach the limits of maximum tensile force.

The connections between tensile stress and subsequent relaxation, either under retardation (modification of the length at constant tension) or relaxation conditions (modification of the tension at constant length) are usually considered for low deformation speeds: the experiment of tensile strength testing of textile materials is generally carried out in accordance with DIN 53 835. This testing procedure with the deformation speed e = 0.83% does not, however, provide details of the characteristics of the materials during fabrication processes in which deformation speeds of up to 200%/s such as during weft insertion and up to 8000%/s such as during sewing occur. Experiments are therefore required in which the material is stressed under relatively high deformation speeds (according to Bossmann, Beier and Schollmeyer).

Tensile stress In a → Tensile strength test the quotient from the → Tensile force and the initial cross-section.

Tension control A textile finishing machine should keep the tensile stress on the fabric constant.

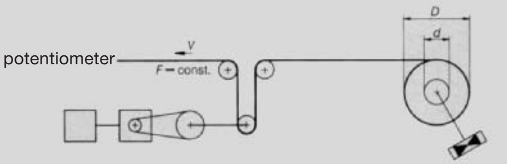

Fig.: Tension control (Siemens).

It is advisable to use a magnetic-particle brake as well as control equipment with a compensator potentiometer. The control equipment gives the brake the information on whether or not to brake according to actual/target comparison of the position of the compensator roll. The tensioning roller pair (not shown in the Fig.) always transports at the same speed.

Tensioning rollers When processing textile webs, it may be necessary to keep the web tension constant within the working or processing length (Fig. 1). For slow-running machines with low web tensions it is adequate to install a magnetic-particle brake on the second pair of tensioning rollers.

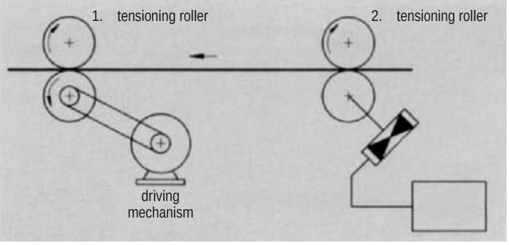

Fig. 1: Two pairs of tensioning rollers, with those at the rear being controlled by a magnetic-particle brake.

The necessary torque is adjusted in a potentiometer on the control equipment. The brake works with a constant slip. With this arrangement the total energy loss is converted into heat. If processing of the material takes place with fluctuating tension, a vertically-moving dancing roller should be installed in front of the second pair of tensioning rollers (Fig. 2).

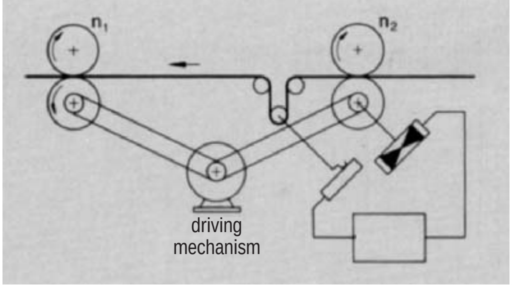

Fig. 2: Controlling the cloth tension between pairs of tensioning rollers by means of a dancing roller.

Coupled with the dancing roller, electrical supply to the magnetic-particle coupling is adjusted by means of potentiometer or inductive switching.

Tensions in fabrics These are metastable states expressed in the form of folds, waves, bulges and bands as well as in the form of slackness. If a fabric with tension from spinning (from differences in twist and number) and especially from weaving (from width controllers, warp beam let off) is able to relax whilst energy is released, weft and warp shift in relation to each other (deformation). A prerequisite for the successful relaxation of fabric tension is therefore the introduction of energy to overcome the fibre-to-fibre frictional forces as well as the ability of the fibres to slide as a result of the effect of water. In woollen fabric, the tensions are fixed by a range of hydrogen bonds. Soaking in water as a speed-determining function is a pre-condition to enable water to reach those groups of hydrogen bonds under tension in the wool fibre stem to bring about relaxation at the exact location where the tensions are. The hydrogen bonds split, the polymer chains slide over each other until a tension-free state is achieved, and hydrogen bonds are recreated in the relaxed state when water is removed during drying. In this sense, the degree of relaxation of a woollen fabric during washing of an individual article is important in terms of design factors.

Tenter frame for dry fabric Tensioning frame in the form of → Expanding device for fabrics and → Straightening machine.

Tent fabric The thermal regulation processes of a tent are similar to those of the skin which are influenced by clothing materials. The climatic zone between skin and textile is a micro-climate in the case of the clothing model which is larger in the case of the tent. This reduces the problems of condensation formation. The larger climatic zone allows a greater humidity absorption capacity and a suitable ventilation construction promotes evaporation.

The temperature difference between the interior and the exterior of the tent is normally less extreme, so that humidity on the tent fabric does not cool down so rapidly and does not condense if the textile has an adequate buffer effect. Differing temperatures during day and night do, however, cause a humid atmosphere in the tent in which the humidity which has formed cannot escape as air exchange is not sufficient. A humid climate of this nature promotes the formation of mould, so that the use of materials which allow humidity to pass through is beneficial, not only for comfort but also for tent stability.

During the day the temperature within the tent adapts to the temperature on the outside. At night the external temperature cools down much faster, however, resulting in a difference of temperature. During the cooling down process, the water absorption capacity of the interior climate decreases, and humidity condenses. This condensation is still present in the morning and only evaporates in the course of the day. This effect is increased with the effect of transpiration in the case of tents inhabited at night. Tent fabrics which allow humidity to pass through are designed to provide a remedy, by transporting humidity through the substrate to the outside with low ventilation before it condenses. In this way, inside temperatures can be maintained for a longer period than with strong ventilation otherwise needed to dispose of humidity.

Under certain climatic conditions the advantages of tent materials which allow humidity to pass through are limited. There must be a sufficient humidity pressure difference between the inside and the outside climate which means that their use in humid tropical climates is not beneficial. Under these conditions, condensation formation in the tent is also comparatively negligible as the outside temperatures do not cool down significantly, and therefore there is no marked temperature variation. Their use can also be beneficial under extreme conditions; humidity transportation mechanisms through the substrate are imaginable, for example, where temperatures fall strongly at night, as in the desert. Permeability of the fabric would also have a beneficial effect in extremely cold climates where the tent was being inhabited.

A breathable tent fabric should be structured in such a way that a hydrophilic layer on the inside absorbs humidity quickly. It can then be diffused in the material and transported to the outside. On the other hand it must also have adequate waterproofing with a hydrophobic outer layer to preclude the risk of becoming saturated. As one-sided coating is generally used, the interior side consists of a textile carrier which must be stable against hydrolysis, mildew, moulds, micro-organisms, etc. as well as having the necessary strength. Polyester fabrics are often used, the properties of which can be modified by specific fabric pre-treatment. Coating properties depend on the product used and can be improved if necessary by using additives. In addition to the properties already mentioned, the outer layer must have features such as light stability, light fastness, pigmentation capacity, soiling-resistance, etc. The requirement profile for the entire system also includes sewability, add-on specifications and requirements for handle, drape and optical properties.

Teratogen (Gk.). Substances which are harmful to the health causing deformation (→ Poisons). In addition to teratogen potential effective pharmaceuticals, this includes, for example, radiation protection substances, certain dyestuffs, solvents, insecticides, etc.

Terephthalic acid $C_6H_4(COOH)_2$. This p-dicarbonic acid is an important raw material for synthesis of polyester fibres. Production, for example through oxidation of p-xylol (petroleum and crude oil fraction) or through toluol (coal tar distillate). The name terephthalic acid is derived from turpentine (Latin: telbinthina, originally for terephthalic acid fabrication) and phthalic acid.

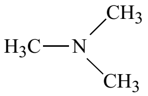
Terephthalic acid dimethylester → Dimethylterephthalate.

Terminal Outside, located at the end. Term used for example for the location of typical groups in the elongated (chain) molecules of textile auxiliaries. Term denoting the opposite: → Internal.

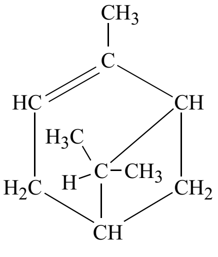
Termoman Test doll which was originally developed by the US airforce (→ Copper man), which withstands intensive heat and registers textile burning characteristics as well as effects on the human being. The termoman is 1.85 m tall and is equipped with 122 sensors distributed over the entire body registering each temperature increase. With the doll it is possible to ascertain how long it takes before a person feels pain and on which parts of the body second and third degree burns occur with time.

Terms of delivery (committee for) → RAL.

Ternary Triple, consisting of three substances; e.g. a product fabricated from three different elements (ammonium chloride: NH_4Cl) or triple substitution by alcyl groups, e.g. trimethylamine:

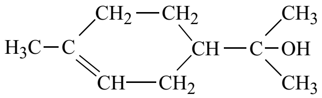


Terpenes Terpene hydrocarbons (terpenes), a group of cycloaliphatic and hydro-aromatic hydrocarbons with the general formula $(C_5H_8)_n$, which form important solvents of the type →: Turpentine oils; Pine oil; Hydrated terpene and depanols, and are derived primarily from α-pines $C_{10}H_{16}$.



Used in components for solvent soaps or emulsions for boiling cotton, for linseed oil sizing agents, antifoam agents, for dissolving rubber, polyacryl acid esters and artificial resins (for print thickeners), for stain removing purposes, etc.

Terpineol (α-terpineol). $C_{10}H_{17}OH$.



Component part of → Pine oil. Density 0.92. Boiling point 219°C. Thick oil, colourless or yellowish, lilac-like smell. Not soluble in water. Easily soluble in alcohol, ether, benzol, chloroform, etc. Possesses hydrotropic properties. Dissolves → Linoxyn, among other substances. Used as component of textile auxiliaries containing solvents (linseed oil de-sizing); foam prevention agents (printing pastes), etc.; lightening agents for microscopy.

Terpolyamides Melting adhesive for bonding textiles and for melting lining materials. Consists of polyamides with various chemical structures. Terpolyamides for textile bonding must be colourless and have melting temperatures of approx. 100°C, so that they can be utilized in presses with LP steam (118–120°C). They have to withstand the effect of soapsuds at 60°C and chemical cleaning with tri- and tetrachloroethene.

Terpolymer → Polymerization products with three basic structural element types.

Terry cloth identification,

I. Frotté:

- woven on standard weaving machine,
- looped fabric surface,
- effect may be produced by using frotté,
- loops cannot be pulled out.

II. Terry fabric:

- woven on terry weaving machine,
- loops formed by the pile warp,
- loop thread can be pulled out in the warp direction.

Terry fabric Looped fabric made of cotton or cotton viscose mixture; fabricated on terry fabric weaving frames (Dobby or Jacquard loom) with a so-called pile wire and 2 warp systems. A tightly-tensioned base warp forms the base fabric together with the weft. The loosely-tensioned pile warp is pulled by the pile wire after only every 3rd or 4th end (depending on the desired loop length). Milled terry: a particularly soft and fluffy structure is achieved using a roller process. Warp terry: the loops are formed with the aid of a pile bar and bound into the base fabric using a locating rail before removing the pile bar. Terrry velours: dense terry fabrics with loops which have been cut open or sheared on one side giving them a velvet-like appearance. Used for hand and bath towels, dressing gowns and the like.

Tertiary alcohols → Alcohols.

Tertiary salts Neutral salts of three basic acids in which three H-atoms are replaced by metal, e.g. tri sodium phosphate Na_3PO_4 derived from phosphoric acid H_3PO_4. →: Primary salts; Secondary salts.

Test batch → Batch.

Test fabrics for soiling tests Artificially soiled fabrics of cotton, polyester/cotton, wool, synthetics; soil consisting of tetrachloroethene or hydrocarbon solvents.

Testing and evaluation costs Costs of routine tests and control of → Quality (→: Quality costs; Quality assurance). Similar problems occur as in the case of → Defect prevention costs. Checks are integrated into the production method more and more frequently or allocated to fabrication departments.

Testing costs → Testing and evaluation costs.

Testing for chromium → Chrom test for dyeings.

Test specimen (test sample, test unit), → Sample unit for testing purposes. → Fastness test specimen.

Tetra (Gk. = four),

I. Prefix meaning "four times, quadruple".

II. Abbrev. for → Carbon tetrachloride.

Tetracene $C_{18}H_{12}$ → Cyclic hydrocarbons.

Tetrachloroethylene (perchloroethylene, per) C_2Cl_4. Colourless fluid, clear as water, neutral, evaporates rapidly, characteristic smell, anaesthetizing, nonflammable. Stabilized, non-decomposed tetrachloroethylene corrodes metals at temperatures up to 140°C even if water is not present. Distillation takes place inter alia by injecting steam up to 0.5 bar (thereby lowering the boiling point to approx. 100°C). Dissolves all fats and oils including resin, pitch, asphalt, tar, wax, paraffin and perfume stains (particularly well, compared with other similar solvents). Tetrachloroethene is of great significance in chemical cleaning processes.

	Water	Tetrachloroethylene
Density [g/ml]	1.00	1.62
Boiling point [°C]	100	121
Surface tension [mN/m]	72.7	32.3
Dielectric constant (DIN 58 483)	80	2.4
Specific heat [kJ/kg K]	4.2	0.9
Heat of vaporisation [kJ/kg]	2257	210

Tab.: Comparison of textile washing agent water (washing) and tetrachloroethylene (dry cleaning).

Advantages of tetrachloroethylene compared with water for cleaning outer clothing:

- textile compatibility: no fibre swelling, no shrinkage, causes no deterioration of shape.
- high density: stable for use in highly-mechanized processes, good dirt removal properties.
- low surface tension: rapid moistening, rapid dirt penetration.
- grease dissolving: cleaning without temperature increase.
- rapid evaporation: rapid, energy-saving drying.
- low evaporation heat: bath regeneration by means of distillation, waste concentration in residue, well-directed disposal.

As far as the care of outer clothing is concerned, → Dry-cleaning has advantages with regard to maintaining the value of the textiles and to cleaning performance, lower time requirement, lower energy requirement and lower material consumption, since the solvent used is always recovered and the residue is disposed of efficiently. The use of tetrachloroethylene does, however, involve certain risks. Its environmental behaviour is determined to a large extent by the following typical characteristics:

- decomposition as a result of hydrolysis and/or ultraviolet radiation;
- release of chlorine radicals;
- formation of salt acids in the hydrosphere;
- its half-life in the atmosphere is 2–4 weeks;
- tetrachloroethylene is highly mobile; it is distributed over long distances by air currents;
- almost all greasy surfaces (e.g. tree foliage and needles) form depositories for tetrachloroethylene where it accumulates;
- forms layers under ground water;
- penetration of walls and brickwork;
- reacts to highly poisonous phosgene (carbonyl chloride) in an open flame.

General toxicology: acute toxicity is low, i.e. relatively high one-off doses have to be consumed before symptoms of poisoning occur, such as slowing down of central nervous system, damage to liver and kidney and finally lung oedema. The fatal one-off dose for a human is approx. 0.5–5 g/kg body weight. The substance has a moderately irritating effect on eyes, nose and respiratory system. It has a drying effect on the skin and can cause skin ailments. Tetrachloroethylene is easily assimilated via skin and the digestive system. When it is breathed into the lungs, it is mostly exhaled again without being assimilated. Records of observation of people exposed to the substance over a long period of time at their workplace show frequent toxicological damage to the liver resulting from a past high dosage range. As is also known from the workplace as well as from investigations carried out on volunteers, concentrations of around 100 ppm can cause a series of central nervous system vegetative phenomena, such as inability to think, dizziness, tiredness, sickness, etc.

Standard mutagenic tests provide no evidence of a mutagen effect of tetrachloroethylene; there are no indications of toxicological effects on reproduction. Tetrachloroethylene has been tested in a number of long-term trials for a possible carcinogenic potential. Inhalation studies on rats and mice submitted by the National Cancer Institute in 1986 are of particular significance. According to these studies liver carcinomes were observed in male and female mice and mononuclear leukaems in male and female rats as well as a somewhat increased frequency of kidney tumours in the male rats. The carcinogenic effect is attributed to certain metabolic by-products (Fig. 1).

Since the metabolic assimilation of tetrachloroethylene in humans is frequently less than in the case of

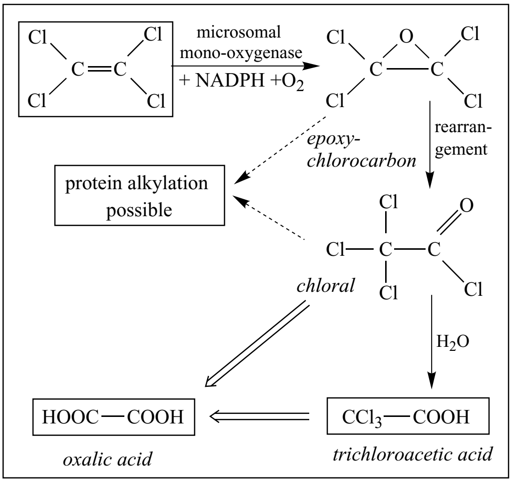


Fig. 1: Metabolism of tetrachloroethylene. Urine metabolites detected are trichloroacetic acid and (in the rat) oxalic acid. MFO = microsomal mono-oxygenase ("mixed functional oxidase").

rats and mice, the results observed in the animal tests cannot be assumed to be applicable to humans. Epidemological studies have not to date provided any scientific proof of a carcinogenic effect on humans. The theoretically attributable possibility of tumour origination does, however, remain. The substance is therefore categorized by the World Health Organisation's (WHO) International Agency for Research on Cancer as well as by the TLV Commission, as one strongly suspected of carcinogenic effect.

Tetrachloroethylene contamination of the consumer can take place

- when visiting a chemical cleaning facility,
- from chemically-cleaned clothing,
- by living adjacent to a chemical cleaning facility,
- by contamination of foodstuffs which have been stored in the immediate vicinity of a chemical cleaning facility.

When visiting a well-managed chemical cleaning facility (for generally only a few minutes) no impairment of health is to be expected. This also applies to chemically cleaned materials supplied by well-managed cleaning facilities. However, there have been a number of incidents in conjunction with textiles cleaned in coin-operated cleaning facilities. This invariably involved voluminous textiles such as cushions and soft toys and/or the drum was overloaded and the aeration times were not observed, or material, which was unsuitable for cleaning in this type of coin-operated chemical unit, was not adequately freed of solvent in the aeration period. The revised German legislation (2nd BImSchV – Bundes-Immissionsschutzverordnung – German Federal Immission Protection Regulation) prescribes that self-operated machines may only be used in the presence of trained personnel.

Incorrect use of chemical cleaning facilities is known to have caused instances of high indoor contamination in appartments in the same building as the facility, as well as to contamination of food which was sold in the cleaning facility itself or in its immediate vicinity. Particularly during the years 1986–1988, tetrachloroethylene values were found in living areas (flats, consulting rooms, offices), some of which approached the range of the TLV scale. Article 1 of the relevant German Federal Immission Protection Law (BImSchG – Bundes-Immissionsschutzgesetz) provides the possibility of intervention.

A biological workplace tolerance value (BAT-value) of 1 mg/l tetrachloroethylene is applied to workplaces. This BAT-value in the blood of exposed employees is defined according to the TLV list in such a way that the corresponding blood test may not be taken until at least 15 hours after the end of the last tetrachloroethylene exposure in the workplace. Only then can the measurement be seen as a reliable warning of the threat of damage to the central nervous system due to increased contamination of the body during the period of exposure. The value is not usually exceeded when the TLV value is constantly observed, but can be reached or exceeded in individual cases. In the case of permanent tetrachloroethylene contamination, e.g. when living in the vicinity of a chemical cleaning facility, these exactly defined framework conditions cannot be complied with; the analysis value gathered cannot be evaluated as the environmental reference points are missing. Evidence of tetrachloroethylene in the blood indicates that contamination has taken place. However, only an investigation of the air in the room can provide exact information on the extent of the exposure.

Foodstuffs which are stored or sold within the emission range of chemical cleaning facilities can be significantly contaminated by tetrachloroethylene. High content values were established in tests on foodstuffs from apartments situated above chemical cleaning facilities as well as in tests on foodstuffs from the grocery trade. Foodstuffs with a high fat content always proved to have the highest contamination levels. The tetrachloroethylene content of foodstuffs is influenced by factors such as

- ventilation in the foodstuff outlet and in the cleaning facility,
- duration of storage of the foodstuffs within the emission range
- type of packaging.

Basic contamination is generally under 10 µg/kg. In accordance with a regulation which came into effect on 10.10.1990, foodstuffs exceeding a content of 0.1 mg/kg can no longer be sold. This regulation of solvent upper limits also specifies that foodstuffs whose tetrachloroethylene, trichloroethene and trichloromethane content exceeds 0.2 mg/kg together are no longer saleable. The second regulation passed in October 1990 on the implementation of the relevant German Federal Immission Protection Law (BImSchG – Bundes-Immissionsschutzgesetz) contains rules requiring the recommended orientation value of 0.1 mg/m^3 in living areas in the vicinity of chemical cleaning facilities can be met within a transition period of 2 years.

In addition to tetrachloroethylene,1,1,1-trichloroethane, 1,1,2,2-tetrachloro-1,2-difluoroethane (R112), 1,1,2-trichloro-1,2,2-trifluoroethane (R113) and trichlorofluoromethane (R 11) have been used in chemical cleaning facilities. Due to their physical and chemical characteristics, these can also diffuse into adjacent rooms and accumulate in foodstuffs containing fat. Because of their damaging effect on the ozone layer, their use was prohibited by the revised second German Federal Immission Protection Regulation (BImSchV – Bundes-Immissionsschutzverordnung) which came into effect on 1.1.1993.

The use of tetrachloroethylene is therefore problematic. As a result the legislature has put into place effective application guidelines. Thus a chemical cleaning facility may only be operated when staff are present who have proven specialist knowledge and have passed the appropriate examination. In addition, guidelines have been prescribed for the installation of chemical cleaning facilities which are intended to ensure that tetrachloroethylene can no longer escape from the facility. The core points of the guidelines are:

- no open use of tetrachloroethylene;
- max. 2 g/m^3 drum volume at the end of the drying period depending on the type of cleaning apparatus;
- max. 0.1 mg/m^3 enclosed air in the vicinity of chemical cleaning facilities;
- diffusion barriers on the facility walls to prevent tetrachloroethylene from escaping into the vicinity;
- regulated ventilation and air-release to outside of facility.

The detail is as follows:

- Article 4, para. 1: the max. mass concentration of tetrachloroethylene in the drying air at the exit from the drum area with rotating drum and closed loading door and a temperature 35°C must not exceed 2 g/m^3 (Fig. 2). An air exchange rate of at least 2 m^3 up to a maximum of 5 m^3/kg load weight and hour in the measurement phase.
- Article 4, para. 1, sentence 2: It must be ensured that the loading door remains locked until levels are below the above-mentioned mass concentration. This must be guaranteed by a permanent measurement monitoring system.
- Article 4, para. 2: With open machines the exhaust fumes must be conducted to an extraction unit.

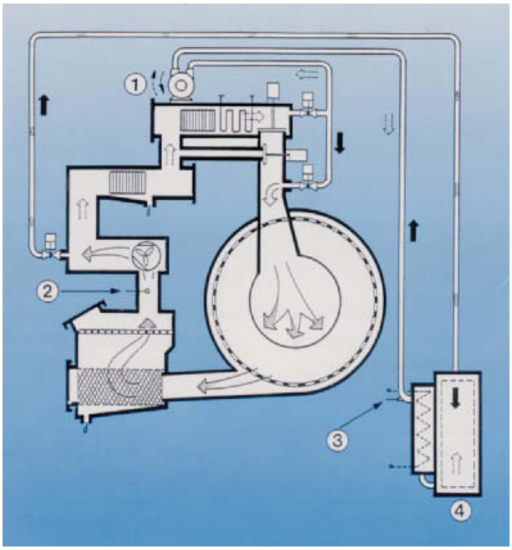

Fig. 2: MULTIMATIC multisolver air exchange system in dry-cleaning machines.
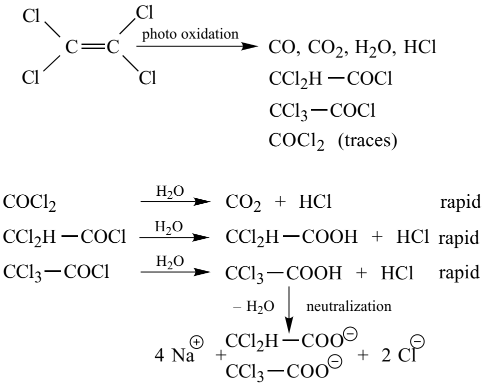
1 = air-exchange fan; 2 = ppm measuring position/drum exit; 3 = ppm measuring position/activated carbon exit; 4 = multisolver (adsorption/regeneration).

- Article 4, para. 3: Only filters which can be re-cycled may be used in chemical cleaning machines for cleaning the liquid solvent.
- Article 12, para. 2: The operator of the facility (textile cleaner) is obliged to inspect the machine to determine whether it meets the legal requirements for a facility as defined in Article 26 German Federal Immission Protection Law (BImSchG – Bundes-Immissionsschutzgesetz) between 3 months and 6 months after commissioning of the facility.
- Article 12, para. 3: The operator of the facility (textile cleaner) is obliged to determine conformity with the appropriate requirements in accordance with the second German Federal Immission Protection Regulation (BImSchV – Bundes-Immissionsschutzverordnung) once in each calendar year after notification of opening of a facility in accordance with Article 26 of the BImSchG.
- Article 13, para. 1: Filling of the system with solvent or aids may only be carried out using a closed device.
- Article 13, para. 1: The removal of used solvent may only be carried out using a closed device.
- Article 13, para. 2: Residues containing volatile halogenous hydrocarbons may only be removed from systems using a closed device.
- Article 12, para. 7: No re-occurring measurements are necessary if proof of conformity with the requirements is provided by means of continuous

monitoring using a measurement recording system. (according to Hasenclever and Rosskamp).

Tetrachloroethylene in the atmosphere It seems that the substance is subject to decomposition by photo-oxidation in the atmosphere:



In addition to CO, CO_2, H_2O and HCl, relatively stable chloro-organic decomposition products (di- and trichloroacetylchlorides) and traces of → Phosgene are formed which hydrolyze very rapidly. Chloro-acetic acids are neutralised by alkaline components in the lower atmospheric layers and their anions eliminate themselves, for example by means of biological decomposition in sea water (oxidation).

Tetrachloroethylene recovery for distillation residues Economy dictates the distilling out of distillation residues, i.e. extracting and recovering tetrachloroethylene residues quantitatively to the greatest possible extent. This becomes more difficult towards the end of the distillation process, as the residue in the distillation receptacle loses solvents and becomes increasingly thick. Three methods are used in practice:

I. direct steam distillation;

II. addition of water without direct steam;

III. addition of water and direct steam.

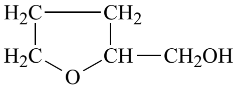
Process III is known to be the most economical method, particularly in the case of residues of heterogeneous composition, since 10 min of distillation by this method cuts down by half the tetrachloroethylene losses which otherwise occur with processes I and II.

Tetrachloroethylene retention in hydrophobic fibres Whilst small quantities of tetrachloroethylene remain in treated textiles during → Dry-cleaning (working method under/around 50°C, i.e. below the glass transformation point of approx. 60°C), finishing processes in the tetrachloroethylene boiling point range (120°C) lead to very stubborn tetrachloroethylene residues under drying conditions. The glass transformation point possibly plays a role and is quoted for the polyester/tetrachloroethylene system at up to <40°C. In hydrophobic polyester yarn, tetrachloroethylene absorbtion of max. 9.8% by weight is reached at a treatment temperature of 0–120°C in 1 h. Outlet tests (polyester, texture and mesh goods) contained approx. 4.5–5% by weight before drying. By drying in dry heat at 22°C and 50°C the remaining tetrachloroethylene content remained almost unchanged even after 1 hour at approx. 4 % by weight. Not until over 80°C is there a noticeable increase of the desorption speed and a sharp decrease of the residue values to approx. 2% by weight. At 120°C the residue contained falls to less than 1% after only 10 minutes. A further change in the drying conditions has demonstrated that, with wet steam as the drying medium, tetrachloroethylene can be eliminated completely. It is important not to use too dry steam, which works as an inhibiting medium on the tetrachloroethylene. The hydrophobic wool fibre in the scale layer binds up to 3% by weight tetrachloroethylene.

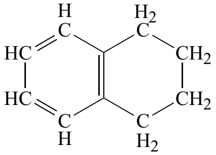
Tetrachloroethylene water pollution Tetrachloroethylene (like all → Chlorinated hydrocarbons) is not biochemically decomposable or is biochemically difficult to decompose and is a substance which is harmful to water. Evidence and quantitative determination takes place either by gas chromatography (more expensive in terms of apparatus but higher specific separation sharpness) or spectro photometrically (interference from other chloride hydrocarbons). The presence of the slightest concentration of unimaginably small quantities can be detected by means of measurement methods which have become more sensitive. German, and in particular European legislation in respect of ground water quality, utilizes extremely low concentrations as guideline values for max. permitted pollution of potential drinking water. Suspected ground contamination with tetrachloroethylene therefore results in costly removal and decontamination of affected ground. In addition to the call for chlorine-free chemical processes, it is the expensive consequences of water contamination which above all point towards eventual discontinuation of chemical cleaning with tetrachloroethylene, while the argument concerning its carcinogenic potential has less weight because of its slight probability.

Tetrafluoroethylene fibre → Polytetrafluoroethylene fibres.

Tetrahydrofurfuryl alcohol (THFA). Hydration product of → Furfural. Density 1.064, boiling point 177°C. Pleasant smelling liquid, clear, slightly tinted, mixable with water. Good solvent for nitrate cellulose, chloro caoutchouc, styrol resin, vinyl acetate, schellac, waxes, resins, etc., as well as for all widely-used dyestuffs; also has a cleaning and degreasing effect.

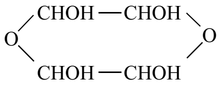


Tetrahydronaphthalene (tetralin). $C_{10}H_{12}$. Molecular weight 136. Density 0.976. Boiling point 200–209°C. Colourless liquid with characteristic smell. Insoluble in water. Easily soluble in turpentine oil, petroleum, benzole, chloro-hydrocarbons, ether, amyl alcohol. Good solvent for grease, oil, wax, pitch, asphalt, lacquer, varnish, linoxin, rubber. Tetrahydronaphthaline, particularly in fine emulsified form, forms temporary peroxides which have a mild bleaching effect before they decompose. This is used for kier boiling of cotton. Used as a component of grease dissolving soaps, stain removing agents, etc.



Tetrahydropyrimidone resins Reactant types which, as with for example → Dimethylol-propyleneurea, have a low nitrogen content and are similar in structure to dimethyloltriazine.

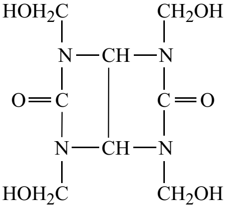
Tetrahydroxydioxane Hydrated form of → Glyoxal in aqueous solution, which contracts when dried in the presence of acid to glyoxal.



Tetralin → Tetrahydronaphthalene.

Tetramer Consists of four → Monomer.

Tetramethylol acetylenediurea Tetramethylol glykoluril, suitable for use as → Resin finishing agents for dry, damp, and, in particular, for wet moistening processes, does not impair light fastness but is not chlorine-fast.



Tetramethylol-2,4-diamino-6-3,3,3-trisbromo-1-propyl-1,3,5-triazine (TM-DABT). Phosphor-free flame-retarding agent for cotton with washing permanence. Application of dimethylformamide/water mixture without additional auxiliary aids, binding agents or catalysts. Condensation at 140°C. Optimum flame-retarding effects at 11–13%. On polyester/cotton 50 : 50 application takes place together with colloidal antimonic trioxide.

Tetraoxymethene (tetroxane, tetraoxane). Tetrameric, cyclic formaldehyde which is used in high finishing as a moistening agent (→ Polyoxymethyenes). Application of tetra- and/or pentaoxymethene in the form of solvents or dispersions and moistening in the presence of acid catalysts at temperatures of at least 100°C.

Tetrapod test Utilisation test for textile floor coverings. Walking with rubber heels is simulated using a specific four-footed (tetrapod) device in a rotating drum which is lined with the floor covering to be tested. This English test specifically measures the change in appearance of floor coverings, particularly in bedroom and living areas. Marks are awarded on a scale of 1–5. The tetrapod test is known to have good simulation properties in terms of colour changes, surface characteristics, patterns, design errors (fibre hardness, pilling), etc.

Tetrapropylene benzene sulphonate (TBS). $NaSO_3C_6H_4C_{12}H_{25}$, → Alkyl benzenes sulphonate with branched alkyl chain. Washing raw material which is biologically difficult to decompose. In Germany, alkyl benzine sulphonates with straight alkyl chain is substituted.

Tetroses → Sugar.

Tex system Used to define the length-related mass (→ Linear density of fibres and yarns) of textile fibres, bi-products, yarns, threads and related products. 1 tex is the degree of fineness at which a fibre or yarn of 1 km length weighs 1 g: 1 tex = 1 g/km. Multiples and fractions thereof are kilotex (ktex), decitex (dtex), centitex (ctex), millitex (mtex). The fineness of fibres is usually quoted in dtex, yarns and threads in tex, and cables, tapes, etc. in ktex.

Textile (Lat.: textilis = woven, knitted). In the widest sense fabric made of spinnable fibre (materials). Textile processes include spinning, weaving, knitting and all processes derived from or based on these processes. The semi-finished products and products resulting from these processes are known as → Textile product or → Textiles.

Textile auxiliaries (assistants, agents processing aids), considered as belonging to → Textile chemicals. Textile auxiliaries on the one hand make it possible to or have a positive effect on the execution of a textile process, and on the other hand have a positive effect on quality, efficiency by helping to reduce or eliminate faults and damages. Textile auxiliaries are thus found in all types of textile processes from fibre production, oprocessing, finishing and make-up of finished goods to subsequent textile care in washing, dry cleaning and soil removal.

The term “textile auxiliaries” is a historically-based generic concept for chemical products which are used in the manufacture of textile fibres, yarns and fabrics and in the finishing of textiles. The term includes products which remain on the textile end-product as well as auxiliaries which are applied to the material temporarily and facilitate or improve certain stages of the finishing process and are no longer contained in the end product.

Products included under the generic term “textile auxiliaries” include:

I. Auxiliaries and finishing agents for fibres and yarns:
- additives for spinning solution,
- additives for spinning lubricants,
- additives for spinning baths,
- preparation agents (frequently used as a generic term),
- spinning lubricants,
- spool oils (coning, winding and twisting oils),
- yarn humectants and stabilising agents.

II. Pretreatment agents:
- fibre protection agents for pretreatment,
- boiling auxiliaries,
- bleaching auxiliaries,
- mercerizing and causticizing auxiliaries,
- carbonizing auxiliaries,
- size and size additives,
- desizing agents,
- hydrophilic auxiliaries.

III. Textile auxiliaries for dyeing and printing:
- dye solvent and hydrotropic agents,
- dispersing agents and protective colloids,
- dyehouse wetting and de-aerarting agents,
- levelling agents,
- dye accelerators (carriers),
- anti-crease agents,
- dye protective agents, boiling protective agents,
- padding assisitants (anti-migration agents, anti-frosting auxiliaries, products for increasing liquor take-up),
- fixation accelerators for continuous dyeing and printing,
- after treatments for improving fastness,
- binders for pigment dyeing and printing,
- print thickening agents,
- emulsifying agents for solvent printing,
- print thickener removal agents,
- print shop and fabric edge gums,
- oxidizing agents,
- reducing agents,
- etching and etching assisiting auxiliaries,
- reserving agents,
- staining agents,
- brightening and clearing agents,
- fibre protection agents for dyeing,
- pH-regulators, acid and alkaline release agents.

IV. Finishing agents:
- optical brighteners (white toners),
- agents for improving crease and shrinking properties,
- additives for low crease and shrinkage finishing,
- catalysts for low crease and shrinkage finishing,
- handle modifying agents (weighting, filling, stiffening and softening agents),
- anti-static agents,
- repellent agents (hydrophobic agents, oleophobic agents, agents for soil-repellent finishing),
- agents to assist soil release,
- milling auxiliaries,
- antifelting agents,
- lubricants,
- lustre finishing agents,
- matt finishing agents,
- anti-slip, -ladder and -snag agents,
- flame-retardant agents,
- anti-microbial agents (finishing and storage preservative agents),
- rot proofing agents,
- agents and additives for fibre and yarn binding,
- coating agents and relevant additives,
- concealing agents and corresponding additives.

V. Auxiliaries which can be used for applications throughout the textile industry:
- wetting agents,
- defoaming (foam inhibiting agents),
- scouring, dispersing and emulsifying agents,
- stain removing agents,
- complexing agents,
- stabilizers (except bleach and preparation stabilizers).

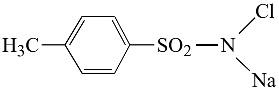
Textile auxiliaries association → TEGEWA.

Textile auxiliaries – ionic activity Also known as ionic charge. When textile auxiliary electrolytes dissociate in aqueous solution, the ionic charged residue (alphatic hydrocarbon) carries either a negative charge (cationic) or positive charge (anionic). In both cases the character is determined by the solubilising (hydrophilic) group attached to the water insoluble (hydrophobic) fatty residue, the former being correspondingly ionically active and strongly solvated thus bringing about dispersion in water. Usually such a group is adequate to overcome the hydrophobic properties of a hydrocarbon of 10–20 C atoms.

Textile auxiliaries with fibre and dye affinity (wool) The wool fibre reacts electro-positively in an acid dye bath, therefore it is a cation. Acid stable anionic products have the effect of producing a fibre affinity. They are rapidly absorbed by wool (weight increase 5–10%) and thereby force slower dye anions to exhaust more slowly. However, if the levelling product is cationic, it quickly accumulates on the electro-negative dye particles. Its reaction demonstrates a dye affinity.

This takes place in a similar fashion with non-ionic products during neutral dyeing. Enlarged dye/auxiliary agglomerations occur (molecular weight increased up to 1000-fold and more) which reduce the rate of exhaustion. The addition of anion-active products naturally has the effect of cancelling deceleration.

Textile auxiliaries with oxidative action E.g. the important toluene sulpho chloramide:



Organic chlorinated products of this type are hardness and alkali stable, by exposure to higher temperatures slowly release their chlor-containing part to allow a controllable oxidative bleaching action. Application: starch decomposition products for sizes and finishes, desizing and alkali boiling, alkali boil additives with bleaching effects, pre-bleaching, coloureds bleaching, oxidation, development of fast dyeings, chlorination of wool. More important are chlor-isocyanate compounds, e.g. for bleaching effects in household detergents, disinfectants for textile laundries and anti-felting finishing of wool. Valuable in combination with fatty alcohol derivatives, with active oxygen content and stabilisers; give slow, temperature controlled release of effect. Application: Desizing and pre-scouring, pre-bleach, combination bleach (single bath de-chlorinating after wash), oxidative development of fast dyeings (aftersoaping), etc. Based on the majority of inorganic oxygen donating products (sodium perborate, sodium percarbonate) are a wide range of starch decomposition agents as combinations with fat, waxes, glues, for sizes and finishes. Sodium perborate is the most important bleaching agent for laundries.

Textile auxiliaries with soaplike properties Various emulsifiers, e.g. saponified castor-oil anhydration products for fats and oils for lubrication and softening, etc. or saponified castor-oil polymerization products in the form of low-stability hydrocarbon emulsifiers. Fatty acid amides derived from disubstituted ethenamines forming a foam even in very acid liquors, as excellent emulsifiers, etc. In the wider sense, also foaming and washing textile aids of more or less synthetic character, e.g. →: Fatty alcohol sulphates; Fatty acid condensation products and → WAS.

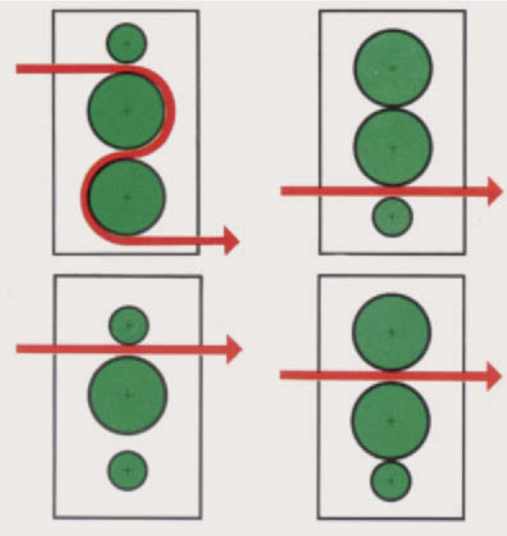


Fig. 1: Various take-in possibilities in textile calenders.

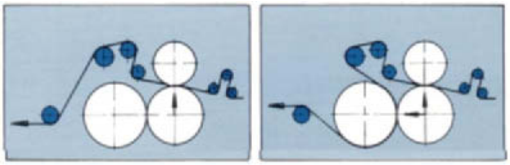

Fig. 2: Kleinewefers KTM L-Calender.

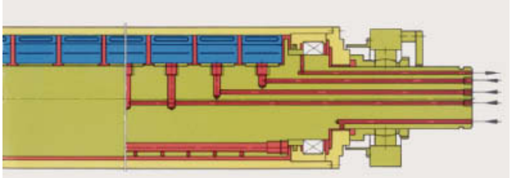

Fig. 3: Multi-zone, thermo hydrein roller (Kleinewefers KTM).

Textile calenders Arrangements of smooth rollers which rotate on each other in such a way that fabrics are compressed under the influence of heat once or several times (Fig. 1). L-shaped arrangement of the rollers has proved advantageous in order not to overload the rollers under the huge pressures (Fig. 2). In order to compensate for the natural unevenness in pressure over the width of the material the roller is divided into multi-zone pressure stamp-pads which are operated with oil (Figs. 3–6). Unusual systems are used to achieve special effects (Fig. 7). Thus, for example, the combination of two calenders with special properties on certain home textiles is necessary (in bed linen, particularly for lining and damask qualities). “Nipco-Star” is the Pre-calender for stabilizing the material so that it does not stretch. The subsequent chasing calender is a roller device which transports the fabric through the calender in spiral form. The material lies in 7 layers in the roller nip. With the chasing calender the material is lead to the calender from the interior over a bar. The material travels outward in a spiral form so that with the last

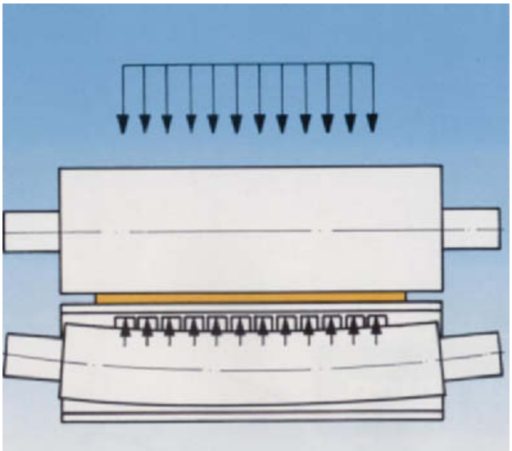

Fig. 4: Attaining the ideal slot load flow through use of a thermo hydrein roller with a compression zone (Kleinewefers KTM).

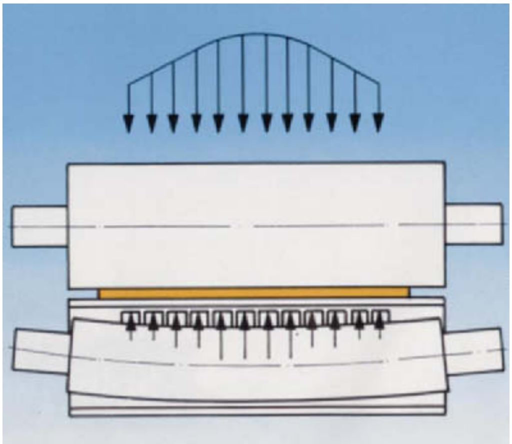

Fig. 5: Any slot load arrangements can be set when using multi-zone print settings over the width of the roller (Kleinewefers KTM).

Fig. 6: Subdivision of the contact surface of a Kleinewefers KTM calender roller.

outer strip the material leaves the roller nip before being rolled up. The material density is increased when it passes through the chasing calender. Density and at the same time air permeability are the aims which are achieved in the chasing calender. The yarns remain round and voluminous due to the multi-layer threading system in the machine and the roller nip. → Calender.

Textile care This encompasses the maintenance of efficiency of textiles including amongst other things → Textile cleaning.

Textile care labelling → Care labelling for textiles.

Textile chemicals All chemicals (including → Textile auxiliaries), which are used in → Textile finishing and should be biodegradable. Depending on the type of application, the following are differentiated:

I. Textile chemicals which only come into contact with the fibre temporarily, such as during wetting, scouring, mercerising, carbonising, bleaching, dyeing, printing, etc. Such products should offer optimum effect, not have any negative impact on the textile material (wool sensitivity to OH^-, cellulose to H^+, etc.), be easily removable from the material (particularly important in the case of lubricants) and not form any difficult to remove residues (e.g. line soaps).

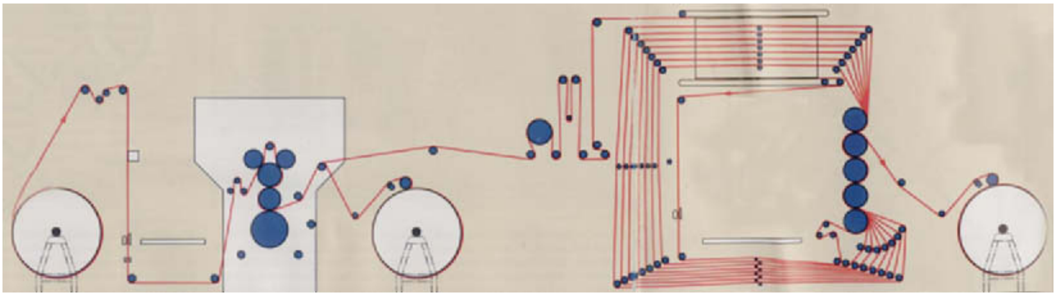

Fig. 7: Nipco-Star and Nipco-Chasing calenders combination (Kleinewefers KTM).

II. Textile chemicals which remain on the material including all types of finishing. In addition to optimum effect and non-impairment of the fibre material, products in this group also need to demonstrate certain fastnesses, as is for example possible when proofing against creasing and moths, and to a certain extent also in the case of dressings which must withstand washing and chemical cleaning using synthetics and in the case of crease resist finishing.

Textile chemicals, concentration determination Physical and chemical determination and quality control methods (mainly for electrolytes and ionic compounds):

I. → Potentiometric measurements: at the forefront is pH-measurement using a glass electrode. Sodium-sensitive measurement chains are used often in combination with pH-electrodes (for sodium salts and mixtures of these with acids, such as used in dyehouse processes). Antimony oxide alloy electrodes are used for surfactant control. Electrodes of the second type are used to determine, for example, chlorides (→ pCl) or sulphides and hydrogen sulphide (silver/silver sulphide-electrode), for example in the exhaust air of a viscose spinning plant by absorption into a solution and potentiometric determination.

II. → Redoxpotential measurement: determination of concentration changes in oxidation-reduction systems, for example in bleach baths.

III. → Conductometric measurement: suitable for use with acid, alkali and salts. Also suitable for monitoring rinsing water.

IV. Amperometric measurements are seldom used.

V. → Photometric measurements: Particularly for low concentrations and traces of substances. Also suitable for non-electrolyte. Operation monitoring methods for non-electrolyte or non-ionic compounds are still in their early stages.

Textile cleaning Generic term for chemical cleaning and washing treatments.

Textile dyehouse (dyeing company). Industrially-operated → Dyehouse for loose material, tow, cops, warps, hanks, piece goods, garments, etc. Either for own requirements (vertical operation) or on commission to other companies (spinner, knitter, weaver, trader).

Textile dyeing A general term for textile coloration which includes all dyeing processes, methods, etc. The dyeing of textiles is a finishing process in which, depending on the type of fibre, suitable dyes and machines appropriate for the form of textile material are used. The dyeing process can normally be sub-divided into the following stages:

1. pretreatment.
2. preparation of the material (work scheduling) and dye solutions (colour kitchen).
3. dyeing operation in the dyeing machine.
4. washing-off and rinsing + aftertreatment if necessary.
5. drying.

In dyeing by the exhaust process, a dye exhausts from a dilute solution (dye liquor) and concentrates on the fibre. Such a process cannot proceed on its own; certain forces must be involved which bring about the exhaustion of dye on to the fibre. In general, a distinction has to be made between continuous and batchwise (discontinuous) dyeing processes. The former includes the pad dyeing process in which the addition of dyes and chemicals is calculated in g/l whereas in the latter (i.e. exhaust process), the addition of dyes and chemicals is calculated in % on the weight of material. In order to carry out a dyeing, a dye liquor is required which, apart from water and the necessary dyes, also contains chemicals and auxiliaries. The quantity of dye liquor required is determined by the quantity of material to be dyed. The ratio of these two values is called the liquor ratio, e.g. 20 : 1, which means that 20 l of liquor is needed in order to dye 1 kg of material. For a batchwise dyeing machine, the loading and unloading times involve machine downtime and are referred to as “set-up” times.

Dye molecules contain a component which is responsible for the sensation of colour (the chromophore), certain substituents (auxochromes) and sometimes reactive groups. Dyestuffs are characterized by the following properties:

- chemical structure
- dyeing behaviour
- general colour fastness properties
- commercial form
- dissolving requirements
- principle of dyeing
- suitability for specific fibres.

Nowadays, dyes are mainly synthetic organic compounds which are capable of colouring textile fibres by suitable methods of application. Natural organic and inorganic colorants also exist which are no longer of much commercial importance. The synthetic organic dyes are classified in accordance with their chemical structure or according to their dyeing properties. Both soluble and insoluble dyes are used in practice. Direct and acid dyes are examples of dyes which are soluble in water. Disperse dyes, on the other hand, are almost insoluble in water and, because of their better solubility in polyester fibres, they dissolve preferentially in that fibre during the dyeing process. Before dyeing with vat dyes, they must first be made water-soluble by a process known as vatting (chemical reduction) in which form they have an affinity for cellulosic fibres; at the end of the dyeing process, the vatted dye is converted back again to the insoluble form on the fibre by re-oxidation to give a very fast dyeing.

The quality of a dyeing on a textile substrate is evaluated by its colour fastness in addition to its levelness and by how closely the colour matches that of the standard sample. As far as the colour fastness is concerned, a distinction is made between the colour fastness to processing treatments and the colour fastness of the dyed textile in use (serviceability fastness). Colour fastness to processing includes, e.g. the colour fastness to milling, carbonizing and cross-dyeing, etc., as well as the wet fastness. Examples of serviceability fastness include the colour fastness to light, washing, perspiration, rubbing, water, etc. Colour fastness is assessed by comparison against standard fastness scales. The standard blue scale, which covers 1–8 steps (where 1 = the worst and 8 = the best fastness), is used for the assessment of light fastness. For all other colour fastness assessments the standard grey scales are used (one to assess colour change and another to assess the degree of staining on to adjacent textile material). Both these grey scales cover 1–5 steps (where 5 is the best).

An understanding of dyeing terminology and its implications is essential for the textile dyer. The following characteristics of each dye are usually given in the respective dye maker's pattern cards:

- build-up properties
- rate of exhaustion
- migration properties
- behaviour on different types of fibre or the covering of irregularities
- combinability
- suitability for aftertreatments
- ability to reserve other fibres
- ecological aspects.

Textile dyes → Dyestuffs for commercial reasons are not identified according to their structure, rather by their comparison to established dyestuffs types.

Up to October 1990 the Colour Index lists, for example, 439 red acid dyestuffs, 369 blue disperse dyestuffs and 179 yellow reactive dyestuffs. Some of the generic names recorded in the index no longer show products, as the dyes are technically out-of-date or only of secondary importance. These figures are, however, intended to give an idea of the variety of dyes that can be used to dye textiles and which can be categorized analytically (see Tab.) (according to Sewekow).

Textile eczema Contact eczema caused by textiles and finishing chemicals, localised on parts of the body where there is particularly close contact between the skin and clothing. The distribution of textile eczema outbreaks is therefore characteristic and can be diagnosed clinically. → Skin diseases.

Textile fibre materials → Fibres.

Textile fibres → Fibres.

Textile fibre symbols These are used to simplify correspondence and texts for the sometimes complicated terms denoting chemical fibres. They are intended to be an internationally understandable communication aid between trade, production, research and teaching. In addition to the two most commonly used systems the → EDP Code and the DIN symbols, there has existed since April 1989 a recommendation from BISFA. The DIN symbols have a scientific classification basis and have been more extensively applied in favour of other systems during decades of use. They are used by technicians in the fibre and chemical industries. An international directive on abbreviations resulted in the issuing of DIN 60 001 in October 1988, revised in the modification of August 1991. The result was an adjustment to a unified method of spelling in capitals according to international nomenclature [e.g. CO for cotton instead of the German Bw for Baumwolle = cotton] and similarly for the synthetic fibres with the BISFA system. The EDP Code of → Gesamttextil was designed for data transfer systems. It works according to phonetic values and is consequently limited to using 2 letters. It is used by textile salesmen and is included in the European

dye class	yellow	orange	red	violet	blue	green	brown	black	total
acid	127	81	183	45	146	50	204	86	922
cationic	57	23	47	25	77	4	11	3	247
direct	72	33	79	24	113	27	52	55	455
disperse	104	68	168	44	160	3	12	11	570
chrome	18	10	18	9	18	11	19	21	124
pigment	111	41	146	22	38	26	18	18	420

vat	16	16	21	13	41	19	30	31	192
									3 644

Tab.: Number of C.I. generic names covered by commercial products (October 1990 status).

Textile Labelling Regulations as an appendix but not an integral part. To resolve the problems of the use of 2 separate systems by sales and technical users in Western Europe, BISFA issued a binding unitary system for its members in April 1989. This system follows the scheme of ISO 1043 and is incorporated in DIN 7728 and has been used for many years in the Plastics Industry. In addition to these 3 systems, there is also the Eastern European TGL system from the former GDR. This lexicon has not used abbreviation symbols in the text to avoid this confusion.

Textile finished goods In accordance with DIN 60 000 these are "products utilising textile fibre materials, semi-finished or finished products by tailoring, designing and/or other work processes which are passed on to the processor, the trade or the end consumer in a state suitable for sale".

Textile finishing This facilitates production of attractive ready-to-sell textiles intended to fulfill requirements for specific use. This includes all processes which help to maintain the value or increase the value of the textile material.

Textile finishing encompasses:

- dyeing,
- printing,
- resin finishing,
- finishing,
- dressing,
- coating.

Related areas: technical preparation for spinning and weaving, spin dyeing and spin matting of fibres, incorporation of ultra-violet stabilisers, heat stabilisers, antioxidants as well as garment dyeing, dry cleaning and spotting agents.

Generic terms corresponding to the German "Textilveredlung" (textile finishing) do not exist in all languages; other languages tend to differentiate in accordance with the above list.

Textile finishing is used at all textile processing stages to impart the necessary processing and utilisation properties to textile products. The requirement profile for improving the properties of the textile raw material depends on the area in which the finished product will be used. The work processes associated with textile finishing increase the quality in that they result in saleable and attractive products in the technical textile range or with fashion appeal in the form of articles of clothing or home textiles. Textile finishing therefore makes textile raw material usable by creating properties with a useful effect. But they are also effective in facilitating all the aspects of textiles which express an aesthetic appeal by dyeing, forming and other effects. Durability of the desired finishing results in the subsequent processing stages or during consumption of the product (use and care) is demonstrated by fastness of finishing effects. In the case of representation properties, optical and detail values are tested and placed in correlation to subjective assessments, whereas, when finished products are used for technical purposes, objective values of fibre substance testing as a material represent a criterion of the quality of the finishing process. As the utilisation properties of technical textiles are subject to constantly increasing demands and fashion requirements are exposed to constant modifications of marketability, the textile finishing industry has to be very adaptable and must react dynamically to new textile products or take the initiative with regard to textile design itself. The legislature also makes considerable demands on textile finishing from the point of view of environmental protection measures.

Textile finishing machinery Textile finishing makes use of the basic technological principles of physics and chemistry, in particular physical chemistry. The design of finishing machinery takes into consideration the often complex properties of the fibres used. As a textile product in varying presentations the fibre can only be subjected to a sensible physical and/or chemical change if the necessary energy forms and finishing products are transported into the fibre in a suitable medium in the textile finishing machine. Diffusion and convection processes in the heterogenous system are typical processes in the medium. If the finishing

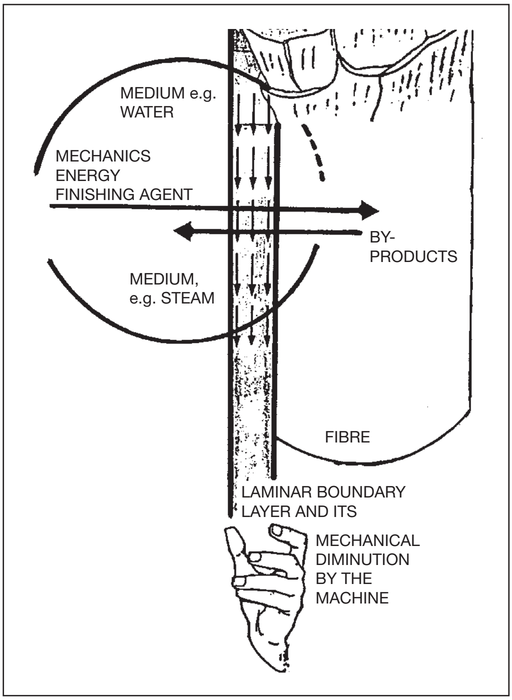

Fig.: Fibre/medium interaction in the textile finishing machine.

process is no longer diffusion-controlled by suitable permeation processes in the liquor exchange zone, the time spent in the rest zone is composed of the processes which make the procedure reaction-controlled. Typical parameters which are frequently dealt with empirically are time, temperature, pressure and humidity which often interact with each other in complex fashion (Fig.). Liquor exhange zone and rest zone are frequently not clearly separated in the machine.

The limitations of the textile finishing machine are to be found where the properties of natural or synthetic fibres and of the products manufactured from them are overstretched. Textile finishing always attempts to improve or to eliminate typical negative (undesired) fibre properties. In addition, textile finishing initiates completely new and positive (desired) fibre properties (e.g. Easy care finishing). Finishing effects are, however, usually only achievable by tolerating undesired side effects. If these side effects exceed subjectively determined and objectively measurable tolerances, the term “damage” is used (e.g. excessively high fibre strength losses) or the overall result is seen as a reason for complaint (e.g. colour deviation). The costs of machine time to achieve uniform finishing effects are usually considerable. The investment necessary to achieve certain effects or to reduce undesired side effects to tolerable levels is expressed in the costs. The finishing costs only make up a small proportion of approx. 10% of the final finished product when it is placed on the market. The costs of energy and environmental protection are, however, assuming increasing proportions in the cost structure for textile finishing.

Together with wage costs, the requirements for air protection and effluent cleaning as well as those of the workplace make textile finishing a capital-intensive industry. For this reason, textile finishing in the last instance requires a high standard of ecological conscience, since it uses large quantities of chemical products which are not always wholly absorbed by the fibre and therefore, under certain conditions, have a potential impact on clothing physiology or the environment around the plant location but are frequently transported away as surplus by-products, possibly in the finishing medium, before being prepared for recycling or disposal. Environmental protection measures are, therefore, a prime consideration when designing textile finishing machinery.

Textile finishing processes Development factors which impact heavily on textile finishing are the requirements of the consumer (e.g. ease of care), those of the legislature (e.g. environmental friendliness, safety), those dictated by scarce resouces (water, energy) and new fibres or fibre mixtures. A more economic design of apparatus which facilitates batch processing would appear to be more important than further investment in the development of continuous processes. This is particularly true of the dyehouse in which overflow apparatus is offered. The significance of continuous finishing lines will increase with the growing printing industry. This will be accentuated as more progress is made towards continuous wet processing of fabrics such as knitted fabrics which have previously not been accessible to such processes.

The following developments of process technology are conceivable in textile finishing:

- monitoring and control of work processes across all areas by process computer (process data registration);
- shortening of work processes (e.g. dyeing);
- reduction of reaction temperatures;
- recovery of auxiliaries and energy;
- high-temperature steaming;
- increase of passage or turnaround speeds (e.g. continuous systems to 300–500 m/min);
- reduction of liquor ratios during dyeing to 1 : 3;
- more formaldehyde-free finishing;
- uniform, substrate-independent dyes and auxiliaries which have no adverse effect on the environment;
- dyes and auxiliaries with a one hundred percent fixing effect;
- products which dye and finish simultaneously;
- use of electrical power as a finishing agent;
- complete recovery of products which are not one hundred percent fixed;
- self-destructing and self-disposing finishing agents.

Textile floor coverings Generic term used in the carpet trade for fitted carpet, carpeting, runners, rugs, bed surrounds, bath mats in a wide range of fibre materials (natural and synthetic). The most important requirements: low electrostatic build-up, measurement accuracy/form stability, good sound-proofing capacity, high resistance to wear (durability), good repeat capacity, adequate light, rubbing and shampoo fastness. The most important finishing processes: anti-static, anti-soil, anti-microbial finishing, flame-retardant finishing, metal fibre incorporation, fibre types with “anti-static building”, anti-static aftertreatment, 3-effect anti-soil-anti-static hygiene-active finishing.

Textile foam Especially fine-pored and soft → Foam which is characterised by tear and tensile strength as well as greater extensibility. After laminating they are extensively used for upholstery covers.

Textile glass According to DIN 61 850, generic term for → Glass fibres and products made of glass fibre.

Textile institutions → Technical and professional organizations.

Textile iodine solution Used to detect starch based sizes and for testing for true starch sizes. Presence of starch results in blue colour. Details: → Iodine potassium iodide solution.

Textile labelling Details of the raw material composition of textile products.

I. Between processing stages as a rationalisation measure.

II. For the consumer as a protective measure when purchasing textiles in accordance with → Textile labelling regulations

Textile labelling regulations (Ger.: TKG – Textilkennzeichnungsgesetz). Based on a consumer protection control over trade and industry requiring the labelling of all items sold with regard to the composition of the textile raw material. It specifies the labelling according to the percentage composition of the principal fibres present and any other required or specified detail. The proportion of the main fibres must always be listed. The remaining fibres have to be listed in the order of the quantities used without quoting the percentage, if none of the fibres makes up 85% of the total weight. If two types of fibre in a mixture make up less than 10% of the mixture, they can be listed together under "other fibres". If a single fibre makes up at least 85% of the total weight, the remaining fibres do not have to be named. The consumer should always find clear and unambiguous details of raw material content on every textile item, including clothing, suits, linens, carpets and furniture coverings. The lining material of a piece of clothing must be listed separately. → Care labelling of textiles.

Textile leather → Artificial leather.

Textile lubricants Oily liquid, paste or solid products which are applied to textile materials to be processed by carding in cotton and wool spinning plants in order to bring the fibre to the necessary state before carding or spinning. Lubricants help in the opening and blending of fibres and impart smoothness and suppleness to the fibre structure, and on the other hand they provide better cohesion of the fibre during spinning and elongation due to their cohesive qualities. Textile lubricants can also have wetting, scour-active or milling promoting properties depending on the purpose of their use. Textile lubricant groups:

I. Fatty acids and emulsifying mixtures: olein can be washed out easily but requires alkaline milling and scouring processes. Emulsified oleins facilitate preparation of lubrication emulsion and, with an appropriate choice of emulsifier, can make washing out easier if the quantity of sodium carbonate used is less than that necessary for total saponification. Triglycerides (olive oil), which are only used for worsteds, require a special washing technique with specific washing agents as they cannot be saponified with sodium carbonate.

II. Composite lubricants (compounded mineral oils) are mixtures of mineral oil with (usually more) olein.

III. Mineral oils have good spin-technical properties but require a washing procedure which is thoroughly controlled and carried out using specific washing agents.

IV. Emulsion lubricants are so-called self-emulsifiers on mineral oil basis with emulsifier.

V. Scouring and milling lubricants (spin washing agents) are compound products made of olein, mineral oil with emulsifiers and wash-active additives which promote the milling process (olein activators). Certain aliphatic alkyl phosphates, amino compounds, further anion-active and in particular non-ionogenic scouring agents have a similar effect.

VI. Various lubricants such as neutral silicon dioxide dispersions which, although they can be washed out, impart greater yarn strength (particularly of smooth fibres) by increasing fibre to fibre friction.

Textile magnifier → Piece glass.

Textile markers,

I. Textile markers in the form of paste in tubes for marking raw materials with 4 different writing heads (for different types of material), resistant to all finishing stages.

II. (markers, fabric markers, signal markers) are used for → Marking of grey fabrics in wet and/or dry processing (fabrics, number strips, garment bags, laundry). Suited to each process type (finishing, dry cleaning, laundering) with appropriate fastness and yet capable of being easily removed (e.g. with soap). Colours usually white, yellow, red and black. Textile marker types: Liquid as inks, semi-liquid in tubes or pens, solid as pencils.

Textile meter Kretschmer commented on the importance of permeability in textiles with textile finish-

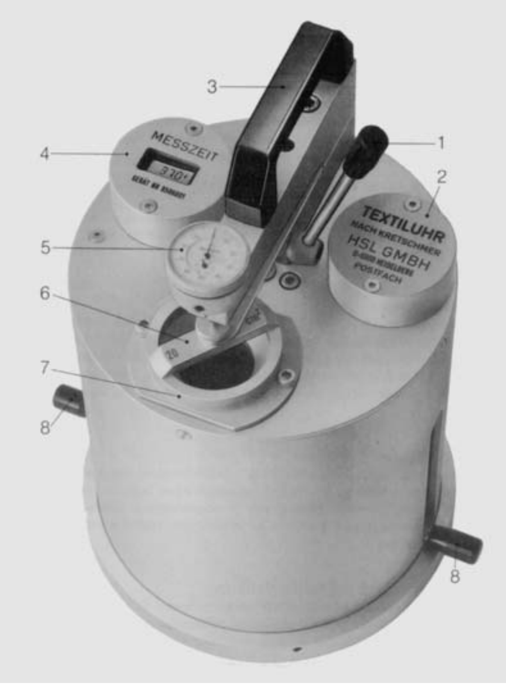

Fig.: Textile meter (Kretschmer) called "Textiluhr".

ing liquors. The textile meter measures the air permeability of dry fabrics. During the permeability measurement a weighted bellows is lowered thereby sucking air with defined differential pressure through the sample (Fig.). Before the measurement the bellows is (magnetically) fixed in the upper position. The sample is clamped into place between the sample pressure ring (6) and the support (7) with the aid of the operating lever (1). The measurement process is started by swinging the operating lever forward. The timed measurement is automatically switched on and off by the lowered bellows. The measurement process is completed by reading the measurement time indicator (4) and the thickness measurement indicator (5). The bellows is repeatedly led back to and fixed in the upper position by the two lifting jacks (8). The measurement time indication is automatically erased by the fixing process. The textile is ready for measurement again. With its rechargeable battery in (2), the textile meter can be used anywhere. The convenient handle (3), the low weight of 4.5 kg, the diameter of 20 cm and the overall height of 32 cm make the meter easy to use in laboratory and factory.

Cross wound packages can also be installed and their air permeability measured, if the other side of the tube is sealed.

Textile microtomy → Microtome.

Textile parasites Small insects, particularly small nocturnal lepidoptera such as moths as well as beetles from the Middle East such as fur and carpet beetles, which either feed on substances containing keratin (wool, animal hairs, feathers used in bed linen, down, fur) or live on the organic substances of cellulosic fibres such as silverfish and the golden spider beetle. Finishing agents to prevent carpet parasites are mainly used for preventing moth attack (via poisons which obstruct digestion); contact poisons are prohibited in the Federal Republic of Germany. Rooms and bookcases infested by parasites are sometimes treated using respiratory poisons (gas releasing substances such as camphor, naphthalene, paradichlorbenzene, moth balls) however, this kind of treatment can prove problematic even when using commercial parasite control agents and it is vital that instructions for use of these agents should be strictly observed; → Mothproofing. Destruction by insect infestation can be proven microscopically by identification of typical arc-shaped traces thereby enabling this type of damage to be differentiated from damage caused by small rodents. → Microbial damage to textiles.

Textile perfumes → Fragrant finishes.

Textile printing → Printing.

Textile product According to the textile designation law, goods or articles consisting of at least 80% weight → Textile raw materials.

Textile raw materials consist of fibres and hair which can be spun or processed to create textile fabrics. These also include fibres made of rubber, glass, metal, paper and asbestos. → Fibres.

Textile Research Institute American textile research institute; → Technical and professional organizations.

Textile scanner Typical → Scanners have larger formats of 112 x 100 or 112 x 247 cm. Different to colour scanners (for smaller formats), used for paper printing in that the recording of individual colours can be differentiated, digitalized and processed onto magnetic discs, making it possible to work on patterns on a desktop with an electronic pencil (digitizer). Images can be transferred directly onto film in “instant mode”. The following linked stages (with programmable options) can be carried out:

- colour separation into, for example, 15 colours with brightness control;
- recording onto a magnetic disc prior to further processing;
- alternatively in “instant mode” onto film with colour bleed-in and mixed colour separation, scanning (for three and four colour printing);
- zoom control (10–400%);
- automatic film alignmemnt (straightening of the gradation curve in film densities of the recording);
- colour area determination (information on the area of separate colour usage).

Textile serviceability This concerns human ideas regarding clothing and home textiles in areas such as ease of care, construction, raw materials, finishing, component parts, fabrication technology, special properties (→ Service life of textiles).

Textiles These are understood to include half- and fully-finished fabrics made from spinnable → Fibres. They are therefore structures which consist of textile fibres in their smallest components and are further processed by means of textile processes (spinning, weaving, knitting, etc.). Textiles are frequently influenced more by their structure than by the type of fibre.

At the outset of human history the first materials used as clothing textiles were leaves, furs and skins. These materials are two-dimensionally structured and have the disadvantage of limited availability and difficult handling. The textile industry and fibre technology, which originated several thousand years later, were based on the discovery that two-dimensional systems (textiles) can be fabricated from simple one-dimensional elements (fibres). Adequate quantities of fibre materials were available. These consisted exclusively of natural fibres, either from animals (wool, hair, silk) or from plants (cotton, flax, hemp, etc.) which differed in their chemical composition as well as in terms of their mechanical properties. These were spun into yarns and textiles and woven or knitted. All the handicraft stages, such as isolation of fibres from their natural sources, cleaning, spinning and production of the fabrics were based on empirical development without exact knowledge of the chemical composition of the raw materials. The technical revolution of textile production began at the outset of civilisation and continued into the 20th century in the form of technical innovations such as the steam engine which formed the basis of industry. Chemistry established itself in the textile industry at the end of the 19th century with processes such as mercerising of cotton or moth-prevention treatment of wool. If the discovery and introduction of spinning machines is recorded as the first technical revolution in the fabrication of textiles, then this innovation represents the transition from manufacture by hand to factory or industrial mass production of textiles (1750–1830). The discovery of worsted made of fine wool fibre (approx. 1870) represented the second technical revolution, since this made possible the manufacture of highly-fashionable articles in addition to simple woollen goods. From this point onwards, textile developments in mass consumption were strongly influenced by fashion. The third technical revolution (approx. 1960) can be seen as the introduction of Sulzer weaving machines. From then on, textile fabrication went through an enormous rationalisation process and developed from a wage-intensive to a capital-intensive industry. The fibre industry was dependent on the development of the textile industry. Since exclusively natural fibres were used as textile raw materials until the middle of the 19th century, scarcity of resources dictated the search for other raw materials.

This phase of research into fibres and textiles began with a chance discovery by Christian Friedrich Schoenbein, chemistry professor in Basle, in 1846. He noticed that cotton could be converted into a plastic substance by means of a mixture of potassium nitrate (“saltpetre”) and sulphuric acid. This was pressed into fine filaments by Hilaire de Chardonnet in 1884. At this time efforts were concentrated on the manufacture of regenerated fibres. Organic chemistry, which was already well-developed, succeeded in separating more and more natural products such as cellulose, proteins, or chitin by denaturing, thereby making them accessible to fibre production. New processes had to be found for each separated material in order to convert it into fibre form. When such a process had been found, it was possible to return to the time-proven technologies for production of textiles such as spinning, weaving and knitted goods fabrication. The range of products which could be fabricated from these new fibres ranged from fashionable clothing to transportation belts for the industry. These materials were not, however, “real” synthetic fibres, since they were based on natural materials.

In the nineteen twenties polymer research gradually began to develop with the work of Staudinger. The path to synthetic fibres with direct polymerisation of monomers had been found. This development was the beginning of the era of synthetic fibre technology and fibre research with its rapidly growing possibilities of producing new textile goods. The following criteria were evaluation standards for synthetic fibres:

- good spinnability from melt or solution,
- resistance to the usual organic solvents,
- high melting point,
- high tensile strength,
- good stretchability.

The first commercially successful polymer category were polyamides which came onto the market under the name nylon (PA 6.6). They were developed simultaneously by W.H. Carothers (DuPont) and P. Schlack (I.G. Farben). These were soon followed by polyester, polyacrylonitrile, polyvinyl and a little later polyolefine and polyurethane.

The existence of many fibres of differing chemical compostion accelerated the search for their molecular structure. Of particular interest was the dependence of the mechanical properties on the structure. By the sixties so much well-founded knowledge about the relationships between the structure and the characteristic properties had been accumulated that a start could be made with the “tailoring” of fibres. First the desired properties were formulated, then the suitable polymer was synthesised by Pfropf- or copolymerisation or by spinning two components. Systematic use of this concept of “macromolecular engineering” resulted in a range of special fibres whose properties (high elasticity, high strength, heat resistance, water repellency) were not comparable with those of natural or regenerated fibres. These “high chem”- fibres also initiated the development of modern high-speed spinning, weaving and knitting machines. The era of → Technical textiles began. New possibilities for use beyond classical textiles are represented by the increase of duro- and thermoplasts in the automotive, aviation and space travel industries. Other applications exist in medicine and the development of better optical fibres for data transmission.

Textile standards The responsible authority is the Specialist Standards Committee of the Textile and Textile Machinery Industry in the DNA (Deutscher Normenausschuß – German Standards Committee). Area of activity: establishment of standards for the entire textile industry, textile machinery constructors and the clothing industry which are issued by the DNA as DIN-standards. In the area of textile testing methods they work closely with the specialist standard committee for “Materials Testing”. → Industrial standards.

Textile testing Textile testing covers three main areas:

1. Product development: assessment of composition, structure, and characteristics (behaviour under various wear conditions) of behaviour during

- processing,
- use,
- recycling/disposal.

2. Production control, i.e.
- quality control,
- meeting specified values and tolerances (production-related).

3. Product declaration: quality definition, i.e.
- setting up of requirement profile (application-related),
- determination of the quality features and assessment of the product.

Test, evaluate and respond are the main activities of the material tester. Tab. 1 shows the close relationship of these three activities. The task of the material tester shows which decision will have to be made on the basis of the tests. The requirement catalogue and the quality profile must therefore initially be derived from the expectations of a product. The appropriate evaluation criterion must then be established which indicates which characteristic or properties must be tested.

test	→ assess	→ decide	
properties	← standard	expectations	
react	↑	↓	
↓	quality profile	← set of requirements	
observation of data			
material behaviour (spec. features or general)	observe product in the overall system		
in a set situation (consider test conditions)	user-product relationship in: – technical – economical – sociological – ecological		} context

Tab. 1: Link-up of the material checker's basic activities.

Material testing is permanently exposed to the tensions between analysis and synthesis. Measurement techniques should record significant individual characteristics. The situation in which measurement takes place is usually determined on the basis of test conditions in order to ensure reproduceability. The specific data recorded must subsequently be integrated into the overall system during the evaluation and decision-making process. The necessity for an integral system of evaluation with different frames of reference is becoming increasingly greater, particularly in the area of quality evaluation with growing awareness of the close relationship of technology, economy, society and the environment.

The Fig. demonstrates that technology, the market and the environment place demands on consumer goods during their entire life cycle. The suitability demanded in the individual stages must be tested again and again. In other words material testing accompanies a product from its conception to its disposal.

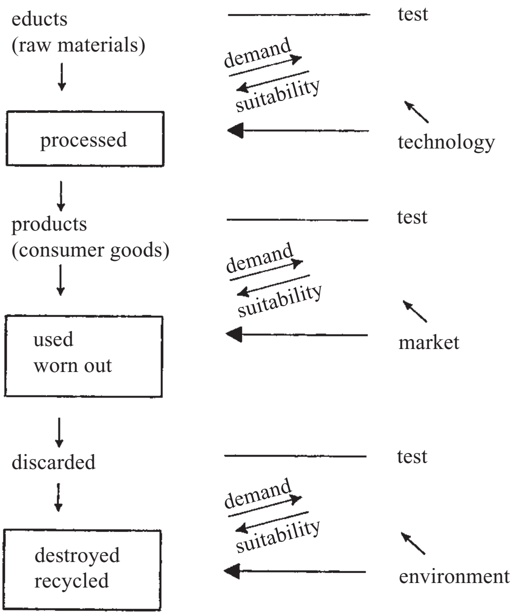

Fig.: Consumer goods requirements.

The quality characteristics of textile materials are often subject to considerable fluctuations since textiles are not an ideal standardised body. These fluctuations of the quality characteristics during fabrication or production can always be attributed to five basic factors. These are

1. material,
2. machine,
3. method,
4. human,
5. environment.

These factors determine the quality fluctuations either individually or in varying combinations. Not every fluctuation constitutes a defect, however, but only those which no longer fulfil the minimum requirements of the customer for the product. It is the responsibility of → Quality assurance to investigate to what extent the causes of such defects should be eliminated. To this end it is important to recognize whether or not the defects in question are of an accidental or systematic nature.

Accidental defects are unavoidable during all processes and are the result of various influences during fabrication compounded in different ways, therefore occurring completely unpredictably and possibly disappearing again after a certain time. The actual cause of an accidental defect is therefore difficult or impossible to determine. On the other hand systematic defects occur when certain factors have a disturbing influence on the production process. The causes of these factors can be eliminated if a thorough investigation is carried out. The causes of accidental and systematic defects can also be attributed to the above-listed five basic factors.

1. Material: a) accidental: e.g. fluctuations in the fabric or fibre material, fluctuations in size composition, etc.; b) systematic: e.g. false or improper pretreatment, use of an unsuitable material, etc.
2. Machine: a) accidental: e.g. fluctuations of energy, humidity, speed, etc.; b) systematic: e.g. damaged machine parts, worn machine parts, use of unsuitable machines, etc.
3. Method: a) accidental: e.g. varying speeds, not sufficiently precise observance of regulations, etc. b) systematic: e.g. choice of unsuitable process, false interpretation of regulations, missing or unclear regulations, wrong adjustment of machinery, etc.
4. Human: a) accidental: e.g. fluctuations in performance capacity, fluctuations in attitude to work, etc.; b) systematic: e.g. individual way of working, lack of training, etc.
5. Environment: a) accidental: unavoidable climatic fluctuations, etc.: b) systematic: e.g. avoidable climatic fluctuations, inadequate lighting, etc.

Textile testing is intended to determine a specific property, if necessary to derive other parameters from it and to relate this to the properties of the product during the following processing stage and during use. This task can only be carried out if largely objective, scientifically-based testing processes are used which are repeatable under identical uniform conditions thereby guaranteeing clear results. This is why the norming of testing processes is of national and international importance.

The quality characteristics of interest for textile finishing and the associated testing processes are listed below (*no compulsory norms exist).

I. Incoming check of raw materials:

– Weft thread count (raw) Stitch density (rows)	DIN 53 853, 53 883
– Warp threads count (raw) Stitch density (stitch wale)	DIN 53 853, 53 883
– Width of raw materials	DIN 53 851, 53 881
– Length of raw materials	DIN 53 851, 53 881
– Weight of raw materials (piece weight)	DIN 53 854, 53 884
– Yarn contraction	DIN 53 852
– Strength and elongation	DIN 53 857, 53 858, 53 861
– Pile height	*
– Chemical properties	IWTO 2-66, 3-66, 4-66, 11-66, 15-66
– Solubility of sizing and preparation	*
– Shrinking test (raw)	DIN 53 892, 53 894
– Visible yarn and weave defects	*

II. Preparation of raw materials

III. Dry pretreatment

IV. Wet pretreatment:

– Liquor condition (concentration, pH, quantity, temperature)	DIN 19 260
– Squeezing effect	*
– Liquor absorption, residual humidity	DIN 53 923, 53 800
– Residual content of sizing and preparation	DIN 54 285 IWTO 10-66
– Modification and damage	*
– Degree of desired properties (e.g. wettability)	IWTO 2-66, 3-66, 4-66, 11-66, 15-66
– Drying	*

V. Dyeing:

– Raw material weight	DIN 53 854, 53 884
– Raw material humidity	DIN 53 800
– Dyestuff weight (recipe)	*
– Time-dependent changes in liquor condition	*
– Dye (sampling)	DIN 6169
– Number of additions	*
– Drying	*
– Uniformity of dyestuffs	*
– Colour fastness	DIN 54 000–54 065
– Modification and damage	*

VI. Printing:

– Dye weight (recipe)	*
– Dyestuff (sampling)	*
– Defects	*

VII. Print aftertreatment:

– Temperature	*
– Time	*
– Steam pressure	*
– Liquor condition	*
– Drying	*
– Modification and damage	*

VIII. Wet finishing:

1. Milling	*
– Milling width	DIN 53 851, 53 881
– Milling length	DIN 53 851, 53 881
– Milling weight	DIN 53 854, 53 884
– Milling liquor (quantity, pH, concentration, temperature)	*
2. Scouring	*
3. Wet decatizing, boiling and corresponding processes	*
– Temperature, time, pressure	*
– Concentration, pH	DIN 19 260
– Fabric width	DIN 53 851, 53 881
4. Impregnation and finishing	*
5. Carbonization	*
– Acid concentration of bath	*

– Duration of acidifying	*
– Acid content of wool before oven	DIN 54 280, IWTO 3-66
– Water content of wool before oven	*
– Temperature in chambers	*
– Liquor condition of neutralization bath	*
– pH of aqueous extract from carbonized wool	DIN 54 276, IWTO 3-66
– Acid content of carbonized wool	DIN 54 280, IWTO 3-66
– Alkali solubility of carbonized wool	DIN 54 281, IWTO 4-66
– Purity	e.g. payment system
6. Raising and combing	*
– Raised effect/combed effect	*
– Air permeability	DIN 53 887
– Shearing height	*
– Number of passages	*
IX. Dry finish	
1. Mechanical shrinking	*
– Temperature, humidity, duration	*
– Width of fabric	DIN 53 851
– Residual shrinkage	DIN 53 894
2. Shearing	*
– Shearing height	*
– Pilling test	*
3. Drying	*
– pH	DIN 54 275, IWTO 2-66
– Temperature, humidity	*
– Residual moisture content	DIN 53 800
– Weft distortion	*
4. Setting, condensation	*
– Temperature	*
– Moisture content of goods	DIN 53 800
– Air humidity	*
– Degree of desired properties	IWTO 2-66, 3-66, 4-66, 11-66, 15-66
– Modification and damage	*
5. Pressing, decatizing	*
– Incoming goods moisture content	DIN 53 800
– Temperature, pressure, duration	*
– Thickness of goods	DIN 53 885
X. Final inspection:	
– Finished width and length	DIN 53 851, 53 881
– Finished weight	DIN 53 854, 53 884
– Colour (sampling)	DIN 6169
– Handle, effects	*
– Strength, elongation	DIN 53 857–53 859, 61 200
– Weft thread count	DIN 53 853
– Residual shrinkage	DIN 53 892, 53 894
– Colour fastness	DIN 54 000–54 065
– Bending strength	*
– Bursting strength	DIN 53 861
– Abrasion testing	DIN 53 863
– Crease recovery angle	DIN 53 890, 53 891
– Other required properties	*
– Defects	*

Material testing provides different types of statement. These are:

– attributive	(nominal)	without values
	(ordinal)	with values
– metric		by measurement
– graphic		function, frequencies, integration.

Evaluation of such information is generally carried out with the aid of mathematical statistics, i.e. the distribution of features resulting from sampling can be analysed by the usual characteristics such as average, standard deviation and manner of distribution, whilst the conclusions from sampling are investigated in terms of their more general relevance or a hypothesis is tested with the aid of test and estimation methods with regard to the probability of its occurrence. As well as considering what constitutes reasonable risk, exact testing and monitoring plans can be set up in this way as the basis of all types of statistical quality control.

Classification of defects, which is important for quality control, can also be made on the basis of the quality profile into the following categories:

- supercritical defects (e.g. risk to life and health),
- critical defects (unusable),
- main defects (greatly impaired usefulness),
- additional defects (slightly impaired usefulness).

The furnishing of a testing laboratory with testing apparatus and calculators is complex. When the testing equipment is suitably standardised then Industry Standards can be applied to using comaptible computerised systems. For reasons such as testing frequency and economy not every → Laboratory will use computer-integrated systems. In many cases tests still have to be carried out using traditional methods, i.e. measured values are simply read from testing equipment. To control the work of the laboratory these individual values must be recorded appropriately and evaluated by a suitable system. The use of mobile data units (MDU) allows the measured value to be input at the place of measurement. The measurement values are stored in the MDU and passed on to the computer after measurement is completed. This can take place via a direct coupling by means of a plug in connector or via the telephone by means of an acoustic muff.

The use of mobile data technology makes it possible to apply computer technology to conventional quality assurance methods such as the use of control chart techniques. The purpose of control charts is to establish nat-

	process control	goods labelling	performance testing
reference point	production	product	application
requested	standard values tolerances	composition properties	– behaviour under wear and tear – use – destruction
testing methods	simple rapid	analysis standard method	– situation simulation – model and parameters
accuracy	tolerances adapted	often very high	risk adapted
sampling	frequent, considerable ↓ production control	once, typical ↓ – customer information – comparability – safety	once ↓ forecast on use and life-span

Tab. 2: Material testing tasks.

ural or accidental occurrences of a process and using this as a basis to establish limits above which systematic deviations are indicated. Using control charts the process can be monitored in such a way that fabrication can be interrupted immediately at the appropriate time. Software systems allow all measurement data occurring in the laboratory and during the fabrication process to be recorded, statistically evaluated and the appropriate test reports printed out. The measurement values are then archived on hard disk or diskette and are therefore available as long-term statistics.

As quality documentation can be said to be the passport of a product it is important that the data documented for a quality product is clear and generally intelligible. There is further scope for the introduction of norming in this area. Both norming and textile testing need to pay attention to the definition of quality-relevant properties. The testing processes and conditions can then be developed from these definitions. It must be the aim of normed testing processes to differentiate the products on the market in a logical manner and to carry out testing under conditions which do not only allow good reproduceability of the results but also demonstrate a clear relationship to practice.

The material tester is expected to make statements on the suitability, nature or general quality of a product (Tab. 2). On the other hand he should also compare and evaluate products, raw materials and semi-finished products as well as establishing defects and contamination and clarifying their causes. Defect investigation always plays an important part in material testing. In many cases it could be defined as a rare occurrence in terms of probability which originates as the result of the coincidence of a number of unfavourable factors. Clarification of the cause of damage involves studying the interaction of these negative factors and possibly reproducing the damage by simulating the case.

Product comparison is an important component of quality assessment. The results of such tests naturally have considerable economic consequences. This is why all product comparisons require careful planning. It is therefore not surprising that there is extensive literature on this matter although it is not possible to establish exact regulations of a prescriptive nature. In fact only the principles on which such comparative tests should be carried out can be set out. Comparative tests should enable the consumer to make a reasonable choice from the products available on the market. First of all it is important that a study of the market ensures that a representative selection is made. The quality features to be tested should be based on the end-purpose but should also take into account factors such as safety, operating costs, environmental damage and use of energy. As a price comparison is usually included, packaging, customer information and service should feature as well (according to Fink and Dressler).

Textile wallcoverings Wall coverings and textile wallpapers of polyamide, polyproylene, polyacrylnitrile, wool and glass fibres. Main requirements: simple application, good form stability, ease of care, good light and wear fastness, good sound-proofing properties.

Textile wallpapers Composite wallpaper produced by laminating paper and textiles as threads, woven- or raschel knitted fabrics. Polymer dispersions are usually used as adhesives, seldom from solvents, more often from polymer powder by dot coating.

Textile waste recycling → Recycling.

Textile wastes According to the waste catalogue specified by waste removal legislation, this includes specific natural and man-made fibre waste materials (textile industry), material/fabric remnants (textile clothing industry), used clothing/rags (used materials trade), cleaning wool/cleaning cloths (used commercially), filtration cloths (filtration processes, exhaust air cleaning), polishing wool/felt (polishing), sludge from textile dyeing plants, textile finishing, wool washing facilities and laundry sludge.

Textile waste water In many cases the pollutants which occur during textile finishing are eliminated in biological waste water treatment works. The following list shows the core substances contained in textile waste water including important categories:

I. Relatively easily biodegradable:

- natural fibres and accompanying substances,
- sizes on the basis of starch (quantity problem),
- scour and rinsing agents with predominantly linear alkyl chains,
- acetic and formic acids,
- neutral salts in not too high a concentration.

II. Biologically difficult to eliminate:

- scour and rinsing agents with aromatic rings, long alkylene oxide chains or branched alkyl chains,
- synthetic polymers (some dressing agents, as well as sizes on the the basis of polyvinyl alcohol and polyacrylate),
- fibre preparations on a mineral oil basis, silicons,
- complexing agents, emulsifiers and softeners,
- some dyes and optical brightening agents.

III. Toxic to the biological treatment stage:

- mineral acids and alkaline lyes,
- active chlorine, chlorine dioxide,
- inorganic (sulphite-like) reducing agents,
- chlorinated organic solvents, e.g. as carriers,
- phenols and diphenyl derivatives in high concentrations,
- formaldehyde (toxic in first phase, then biodegradable),
- various other organic compounds or solvents,
- heavy metal compounds such as chrome-VI, mercury.

This list demonstrates that category allocation and therefore a targeted approach to waste water problems is only possible if, in addition to the brand designation of the products, the safety data sheets contain adequate details of composition and ecological properties. Without this information, vital preventive → Water protection measures are not feasible (choice of the right products, economical use, optimization of finishing processes) and waste water cleaning will have no chance of success. (according to Schefer).

Textile whiteness scale (textile whiteness standard, cotton whiteness standard), derived from the → Ciba-Geigy white standard. Division into 18 sections (each comprising 10 units) on a scale from 70 to 240. The lowest section of 70 is applied to max. bleached, non-brightened cotton and the highest level of 240 to intense white effects achieved with optical brighteners. → Whiteness scale.

Textometer Device for measuring moisture content of textiles which determines the residual moisture using the principle of conductivity. There are various versions of the device: easily transportable battery unit, universal device for monitoring processes as well as a version with electronic regulation for monitoring and automatic control of sizing machines, fabric driers and the like.

Texture Natural arrangement (structure) of crystallites in fibres, etc. Orientation phenomena exist in higher structural units (→ Micelles) and in → Macromolecules, such as occur in crystalline substances after plastic distortion and re-crystallisation. In contrast, there are also non-orientated regions when the crystalline micelles in the molecular structure do not show orientation effects. (Fig.). Relaxed, orientated polymers crystallize easier than polymers under stress.

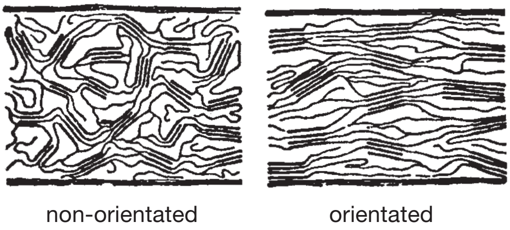

Fig.: Non-orientated and orientated network of cristalline and amorphous zones in polymers.

Where symmetry exists around an axis, this is known as → Fibre texture. Growth textures are the result of natural organization processes during growth which are familiar in the case of a number of natural fibres. Texture determination is carried out by means of X-ray interferences which directly reflect texture by intensity distribution. → Structural models for man-made fibres.

Textured fabric Fashionable fabrics for underwear, clothing and outerwear with raised or depressed waffle-like pattern effects (lace-like tied warp and weft threads).

Textured yarns (texture yarns, structured yarns). Generic term for yarns of mainly synthetic fibre filaments whose external structure is modified during or after yarn manufacture by means of mechnical, physical or chemical methods in order to create additional properties such as: increase in volume, more or less increased elastic twist, increased moisture regain, greater air content and therefore greater insulating capacity, gloss reduction, improved texture, avoid pilling. Chemical fibre filaments are usually used as fibre material (in addition to acetate, tri-acetate, cupro, viscose, mainly polyamide 6/6.6, polyester, polyacrylonitrile, modacryl). Special yarns made of natural fibre (e.g. → Slack mercerization of cotton) are less significant.

The extensive range of textured yarns makes it necessary to divide them simply into the following textured yarn types in accordance with their main properties of appearance and manufacture:

I. Stretch-yarns: highly elastic, stretchable to approx. 5-fold length, usually made of thermoplast threads with relatively low bulk (→ Helenca principle), preferable not doubled but in Z or S form. Produced mainly by means of real or false twist process, Klingen process. (→: Core spun yarns; Elastomeric fibres).

II. Crimped yarns: in addition to strong mechanical or chemically-created crimp, these are characterised by moderate elasticity and moderate to strong volume. Production particularly according to stuffer-box process, gear-wheel crimping process. (Bi-component yarn; in the case of bi-component thread material bulking is also by means of subsequent hot-air treatment in tumbler or in specialised dry-cleaning machine).

III. Bulked yarns: are characterised by high volume and therefore good covering power, combined with relatively low additional elasticity. Produced mainly by air jet technique.

IV. Types on the borderline of basic types I.-III, for example highly-elastic volume-yarns, elasticity-regulated (so-called modified) stretch yarns, high-volume crimped yarns and the like (e.g. →: Torque; Non-torque yarns).

BISFA definition of textured yarns:

- Dual-component yarn: textured yarn containing filaments which consist of two components (dual-component fibres).
- False twist bulked yarn: texture yarns treated with false twist process producing high crimp elasticity or crimp contraction.
- False twist yarn (set yarn): yarn treated with false twist process where a heat fixing process is carried out in a state of intermediate tension between complete relaxation and complete uncrimping.
- Yarns with variously shrinking filaments: textured yarn made of two groups of filaments with differing shrinking properties.
- Knit/de-knit yarn which is de-knitted after knitting.
- Torque-yarn: yarn with a strong looping tendency.

Texturing This term isused to include all process stages downstream of the actual texturing process. In the filament yarn sector these include:

- Intermingling: normally accomplished by air-jet techniques,
- Assembling: combination of multiple yarns with zero twist,
- Coning (winding): transferring the yarn onto a suitable carrier.

Texturizing The treatment of smooth filament yarns by permanently modifying the orientation of the molecular structure giving it more textile character. The changes to texturized yarns are: improved softness, volume and covering power, increased thermal insulation effects and an end-use required increase in elasticity. Thermoplastic filament yarns are particularly suitable for texturizing, i.e. yarns which are deformable under the influence of heat. These are mainly polyamide and polyester yarns. The most important texturizing processes are (Fig. 1):

- Twist-texturizing (including false twist): A filament yarn which has been twisted under the influence of heat is straightened again.
- Air jet texturizing: Yarn is crimped in a turbulent current of air (gas or steam).
- Knit/de-knit texturizing: Yarn is knitted, subjected to heat treatment and then de-knitted.
- Stuffer box-texturizing: Yarn is crimped by means of compression.
- Asymmetrical heat-texturizing: Contraction of the filaments on one side only is induced by asymmetrical heat treatment.
- Edge-texturizing: Yarn is pulled over an edge at an acute angle.
- Gear wheel-texturizing: Yarn is crimped between two sprockets.

Processes have been developed for the most commonly used twist-texturizing with which the texturizing procedure is combined with stretching.

Thermoplastic filament yarns are usually smooth when they have been spun and less well adapted to requirements than natural fibre yarns. The textile qualities of such yarns are improved significantly by texturizing procedures. Texturizing often increases the volume of the filament yarn by modifying the geometrical form of the filaments resulting in a certain elasticity in some cases which represents an advantage for the yarn. In the lower decitex range up to 300 dtex (frequently clothing fabrics, underwear and curtains) the false twist texturizing process is the predominant texturizing technique. This is mainly due to the economical nature of the technique but also to the elastic properties of the resulting yarn.

The false twist texturizing process (Fig. 2) is based on twisting the filament to a high-twist density and fixing this twist into the molecular structure of the filaments by heating and subsequent cooling in this twisted form. The yarn is then completely straightened. As the filaments and therefore their molecules have had a migrated spiral-form configuration, back-winding the filaments does not re-align the molecules. The filaments

	False twist	Edge crimping process	Knit/Deknit process	Stuffer box process	Air jet process
Working plan					
Properties	Highly elastic (HE) yarn, good extensibility and large bulk volume, as stabilised (set) yarn, lofty with less elongation	Helical crimp, elastic yarn low with increased bulk volume	Wavy crimp, elongation, yarn produces a loftiness crepe effect	Zig-zag to wavy crimp, low elasticity, increased	Inelastic yarn, increased loftiness due to capillary thread loop formation, fancy yarns
Crimp structure					

Fig. 1: Comparison of the most current texturizing processes.

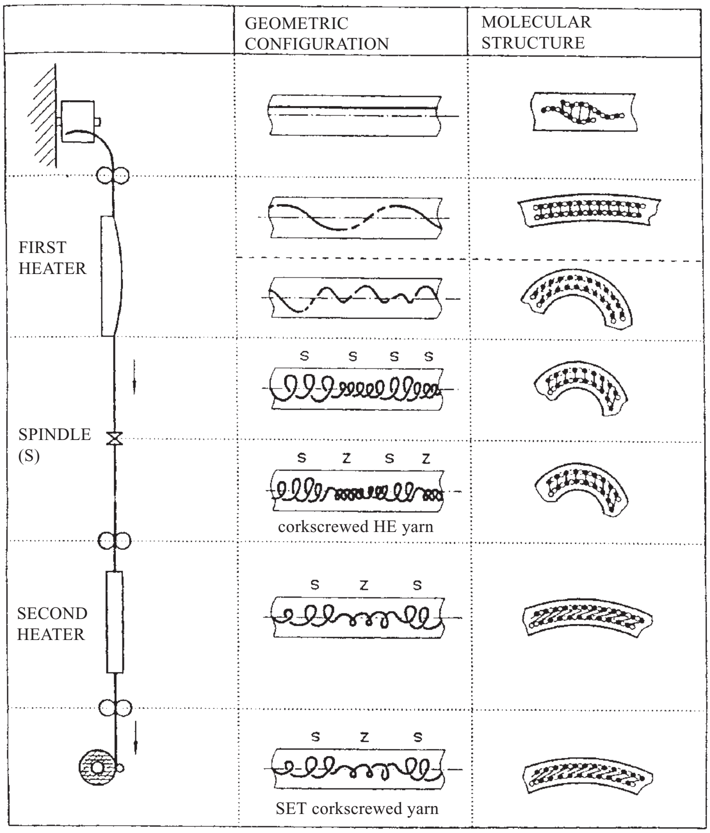

Fig. 2: Schematic illustration of the false twist texturizing process with the geometric and molecular structure of an individually texturized filament in different processing stages (according to Akzo).

have a tendency to move to the minimal energy level, i.e. to a spiral-form configuration. If they are not forced to open completely, the yarn assumes a voluminous structure. The volume of the yarns depends on the tension at which they are treated. This limited elasticity of the yarns coincides with the elastic properties and represents an advantage for certain applications such as for tights and elastic fabrics.

During its long period of development the false twist texturizing process underwent a spectacular transformation from a long multi-stage process to magnetic false twist texturizing at moderate speed and on to friction false twist texturizing at high speed. Most friction false twist texturizing processes now use a POY Feed pack (polyester, polyamide and polypropylene), stretch and texturize simultaneously at speeds of 800 m/min and, in some applications, at speeds of up to 1200 /min. The actual texturizing operation is completed after passing the false twist spindle. At this stage of processing the texturized yarn is voluminous and elastic. The process is, therefore, often known as HE (High Elasticity) or HB (High Bulk). As the molecules are aligned in a migrated, spiral-form structure, the outer filaments create a torque. This torque in the molecules creates a looping effect in the yarn which becomes visible when both ends of the yarn (or of a single filament) are fixed and the tension is reduced by placing the two ends together. The yarn or the filament will then assume its minimal energy level by creating a loop.

The looping effect of HE yarn is also considerable. This looping effect (Fig. 3) sometimes results in problems in the subsequent processing stages of textile production. Particularly in the case of applications for which high elasticity and volume are not important, volume and elasticity and therefore the looping tendency of the yarn are reduced by a subsequent setting operation. The HE yarn is fed with over-feed through a second heater in order to reduce elasticity and to increase the size of the diameter of the spirals which were fed into the first heater. This results in reduction of the volume, the elasticity and the looping tendency of the texturized yarn.

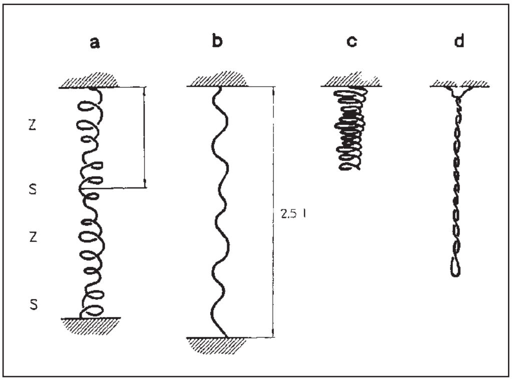

Fig. 3: Model of a single texturized filament (a), stretched filament and formation of internal torque (b), texturized filament free on one side: theoretically balanced out, minimal energy level (c), curled-up texturized filament: balanced out and with minimal energy level (d).

The individual filament of a texturized yarn can be regarded as a fine spring with variable diameters along its length. The yarn is produced in such a way that both ends are fixed. As a filament is a flexible element, the torsion is compensated by reversal of the spiral direction. When such as filament is pulled apart it assumes the form shown in Fig. 3b. Strong torsion also occurs in the filament. If an end of this filament is free it rotates and contracts until all the torsion has been compensated. If both ends are placed together without letting one end rotate freely, the torsion is compensated by a loop.

Texturizing oils In order to ensure a sufficiently low friction coefficient when processing textured yarns on knitting machines, texturizing oils are applied to the threads either on the texturizing machine before spinning or during unwinding on the precision-wound package machine. Thread speed and thread tension fluctuations caused by different upper and lower yarn package diameters on the precision-wound package machine result in correspondingly differering texturizing oil absorption by the thread on the lick-roller which can lead to uneven distribution of texturizing oil within the yarn package body (local differences up to approx. 1 : 3). This variation in texturizing oil distribution within the yarn package is already present after winding has been completed and therefore cannot have originated as a result of texturizing oil migration. As no noteworthy changes in texturizing oil distribution are to be found after long storage periods, it can be concluded that migration does not take place at all but that local accumulation of texturizing oil in packages is caused by corresponding thread speeds and tension conditions. On the other hand cylindrical direct winders and texturizing machines, in which only periodical thread speed and tension differences occur, show even texturizing oil distribution.

TGL Technical standards, quality regulations and delivery conditions (Technische Normen, Gütevorschriften and Lieferbedingungen) of the former German Democratic Republic.

Th Element symbol for thorium (90).

Thermachrome process (thermacrome process). Transfer print process for transfering paper prints in up to 4 colours onto synthetic fibre textile piece goods. The paper is printed with thermoplastic pigment print pastes which are transferred onto the textile material on passing a heated calender. This process is limited to the printing of labels and emblems.

Thermal (Gk.: thermos). Concerning heat.

Thermal analysis Thermal analysis uses sensors to monitor changes in polymers during thermal treatment. Differential Scanning Calorimetry (DSC) is one of the processes used in thermal analysis. With this process conversion temperatures and heats can be determined in a relatively simple way. The principle of the DSC process is that two pieces of test material are heated together. A temperature regulator ensures that both pieces of test material always have the same temperature (iso-thermal trial management). When the test material reaches a conversion point either more or less heat must be added to it than to its counterpart depending on the type of conversion. This is registered by a recorder which records ΔQ as a function of time (see Fig.). Thus an exothermic peak appears in the case of crystallisation processes and an endothermic peak in the case of melting processes. Glass conversions require a modification of c_p; this is shown in the thermogram as a displacement of the base line. (The base line corresponds ΔQ = 0. It should ideally be horizontal.) As the heat capacity also changes during the melting and crystallization process, a displacement of the base line also occurs here.

Determination of the thermo-dynamic dimensions of polymers encompasses:

1. Glass point: As the temperature is recorded as a function of heating rate, it follows from the equation:

$$\frac{dQ}{dt} = c_p \frac{dT}{dt}$$

that displacement of the base line in the thermogram corresponds to Δc_p; therefore Δc_p can be determined simply from the thermogram.

2. Melting of the crystals: as polymers do not have a sharply-defined melting point the melting range is quoted in their case. The melting enthalpy can be determined in accordance with the following equation:

$$\Delta H_u = \frac{K \cdot R \cdot A}{m \cdot S}$$

ΔH_u = conversion enthalpy
K = equipment constant
R = sensitivity
A = peak surface
m = contents
S = paper speed

Another thermal analysis process is Differential Thermal Analysis (DTA) which functions adiabatic (ΔQ = 0). This process records against temperature the temperature differential which occurs upon conversion between the two pieces of test material. The evaluation process is rather more complicated than in the case of the DSC method.

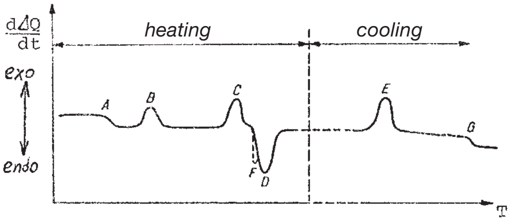

Fig.: Thermal effects of physical transformation of high polymers (in diagram form).
A = glass transformation; B = cold crystallization; C = premelt crystallization; D = melting; E = crystallization; F = disorientation of crystalline zones; G = glass transformation upon cooling.

Thermal balance → Heat balance.

Thermal conductivity coefficient → Heat conductivity.

Thermal conductivity coefficient of textile fibres Whereas heat conductivity in liquids and gases is a diffusion phenomenon, in the case of solid substances it is based on interaction with neighbouring oscillating molecules and the forces involved (→ Absorption). Thermal conductivity varies enormously according to the type of substance, metals having the highest, and gases the lowest, as only relatively few molecules are available for energy transporation within the unit of space. This is why textile materials which have a high air content are characterised by low thermal conductivity. The technical thermal conductivity (λ) indicates the quantity of heat which flows through two opposite surfaces of a cube of 1m edge length per hour when the temperature difference between both surfaces is 1°C (→ Heat retention).

Thermal conductivity in W/m · °C:

glass	1.000
polyethylene	0.337
polypropylene	0.221–0.302
polyamide	0.209–0.290
m-Aramid	0.128
viscose (filament)	0.071
viscose (spun fibre)	0.063
asbestos	0.058
cotton	0.058
triacetate	0.058
acetate	0.050
polyester	0.046–0.081
wool, silk	0.046
air	0.025

Thermal disinfection Disinfection by means of direct heat ; 5 min at 30°C in the pre-wash phase, 10–20 min at 85–90°C followed by clear-wash cycle. → Disinfection washing of textile.

Thermal imaging camera,

I. The measurement procedure of the thermal imaging camera is based on the principle of heat radiation detection. The infrared radiation given off by bodies and media is detected with an HgCdTe-photo-semiconductor and the digitalized infrared images are recorded with a video recorder or represented in colour or grey shades on a monitor. Thermal imaging cameras are used anywhere where heat radiation can indicate a defect or inadequate processing. A thermal imaging camera can, therefore, just as well ascertain a burst pipe in a wall or a badly-insulated window as it can a heat leak in a stenter frame, permitting heating costs to be reduced in each case.

II. The measurement system of the thermal imaging camera is based on the infrared radiation of an object being recorded by means of an infrared optical system and suitable semi-conductor sensors (mercury-cadmium-tellerium) in the context of time and position. By comparison with an internal reference source in the camera absolute temperature measurements are possible allowing direct analysis of dynamic and static thermal patterns. As the camera records a representation of the temperature distribution of the entire surface, this process is also known as thermography. The representation is made in false colours, i.e. a certain colour is attributed to each temperature which can be observed on a monitor in an image-like representation. With the aid of infrared optical system selector the resolution capacity of the system can be varied from microscopic applications to the recording of entire landscapes. For technical measurement with the thermal imaging camera the measurement data is transferred to comprehensive infrared image processing computer software (CATS Computer Aided Thermography Software). In addition to false colour representation, dynamic point measurements and temperature profile representations are also possible.

This feature makes a thermal imaging camera with a computer-aided evaluation unit very well suited to registering the entire thermal pattern of a length of textile in the exit area and to recording temperature profiles or cooling down properties at designated points.

Conclusions can be drawn from such analyses regarding the influence of the cooling down conditions on the properties of the textile (Schollmeyer).

Thermal post-combustion (TPC) Combustion of substances contained in exhaust air takes place in accordance with the following reaction:

$$C_n \cdot H_m \cdot O_x + \left(n + \frac{m}{4} - \frac{x}{2}\right) \cdot O_2 = n\,CO_2 + \frac{m}{2} H_2O$$

If air is the source of oxygen, nitrogen oxides $(NO)_x$ result from the nitrogen in the air. As the concentration of the harmful substances in the exhaust air is far below ignition point, automatic combustion of the harmful substances in the exhaust air is not possible. In order to ensure that the above-shown reaction occurs, it is necessary to increase the temperature level of the exhaust air (usually between 700°C and 800°C) and to keep it at this temperature level until the reaction is complete.

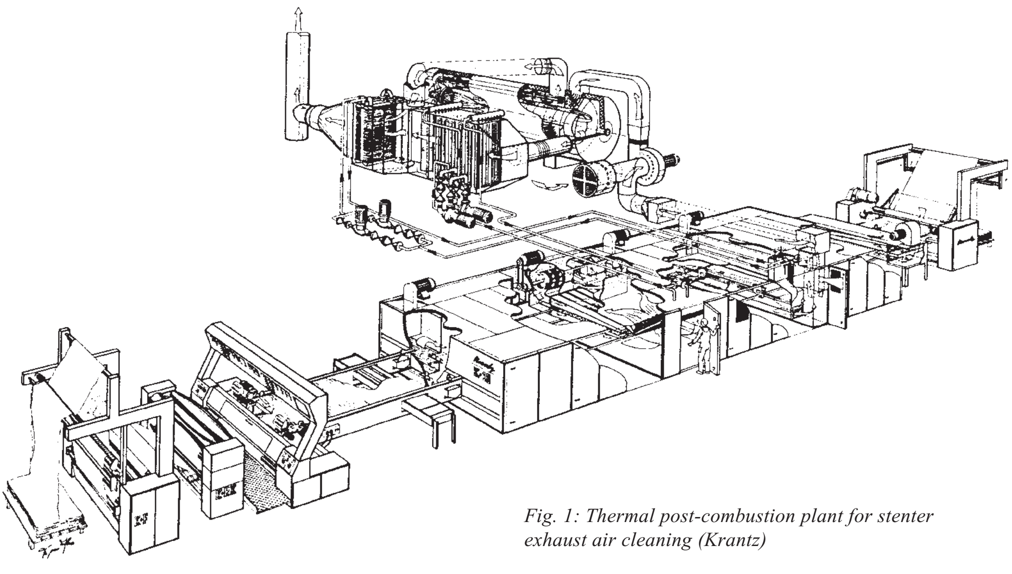

Fig. 1: Thermal post-combustion plant for stenter exhaust air cleaning (Krantz)

Additional fuel is, therefore, necessary to achieve higher temperatures (Fig. 1).

The production of CO_2 is problematic in terms of global warming. There are limitations to possible energy recovery when using heat exchangers. For example it is practically impossible to construct heat exchangers with a thermal efficiency of more than 70%. If, for example, a flow of exhaust air is to be combusted in a TPC at 750°C, pre-heating of the exhaust air to more than 550°C is not achievable using a recuperative heat exchanger. In order to maintain the desired 750°C it is, therefore, necessary to add energy to the process in the combustion chamber until the exhaust air flow is increased from 550°C to 750°C. The cleaned exhaust air then leaves the TPC at a temperature of approx. 230°C higher than the input temperature.

The reaction temperature of TPC can be reduced with special catalysts. Pure oxygen can be used instead of air in order to eliminate $(NO)_x$ production and to achieve higher combustion temperatures.

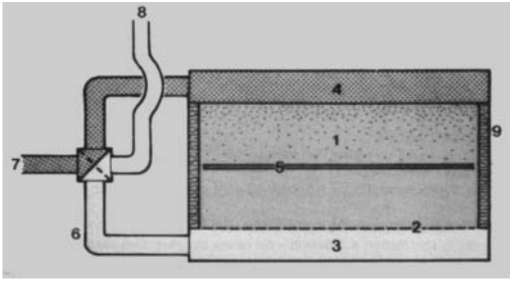

Fig. 2: Principle of the Combu-Changer (Kraftanlagen Heidelberg AG).

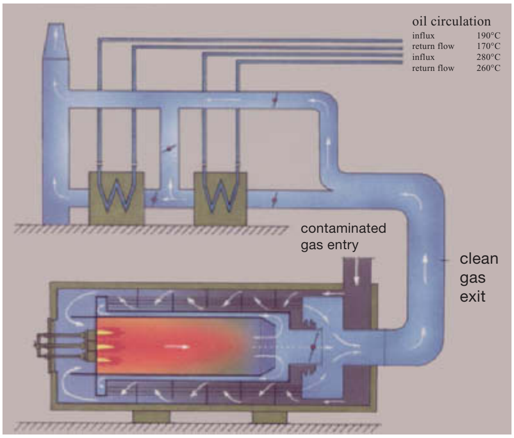

Fig. 3: Recovery of heat energy from the waste gases cleansed by post-combustion.

The Combu-Changer principle (Fig. 2) uses a different method of eliminating $(NO)_x$ production. The Combu-Changer consists of a layer of shingle which is heated electrically in the centre. When it is put into operation the shingle bed is heated electrically over a period of several days without admitting air. The exhaust air to be cleaned is then conducted to the shingle bed from one side. The exhaust air is heated to approx. 1000°C as it passes the shingle bed. This temperature is far above the reaction temperature of the harmful substances which is between 700–750°C. The advantage of this process is that there is no open flame so that nitrogen oxides and carbon monoxides practically do not occur. The volume of the shingle bed is chosen so that the temperature difference between the shingle bed and the air is never greater than 20°C. The exhaust air is heated in the first layer of shingle as it passes through and reaches the necessary temperature for converting hydrocarbons into CO_2 and H_2O in the centre of the shingle bed. Then the cleaned exhaust releases its heat to the second layer of shingle which it now passes through before being conducted to the outside. In order to prevent displacement of the temperature profile and therefore reduction of the max. shingle bed temperature the flow direction of the air through the shingle bed is changed every 90 seconds. When the combustion reaction takes place exothermically, the electrical heating energy can be switched off after a certain time since the process is running of its own accord. Pollution of the exhaust with 0.7–0.8 g/m^3 is adequate to compensate for the consumed temperature difference of 20°C depending on the heat value of the harmful substances. When using TPC it is always advisable to recover the surplus heat from the cleaned exhaust (Fig. 3).

Thermal resistance Capacity of textiles to retain the heat of a covered body.

Thermal shock Heat treatment at 200°C:

I. Thermo-stabilization of synthetic fibres within 1 second.

II. Rapid fixing of dyes (particularly of reactive dyes) during printing and continuous dyeing within 20–60 seconds.

Thermal stability →: Thermal stability of dyes; Thermal stability of fibres.

Thermal stability of dyes Thermal stability when subjected to contact heat (ironing, fixing, drying), hot air (fixing, drying) and steam (steaming, decatizing, pleating).

Thermal stability of fibres The impact of dry heat can bring about changes to fibre properties, the extent of which depends on the specific thermal stability of the fibre (heat stability) as well as the duration and temperature of treatment. As not only recognizable changes in chem. and technological properties, such as yellowing and greying, can be effected, it is advisable to check for other non-visible signs of temperature impact. This applies particularly to synthetic fibres (→: Softening range; Melting point).

Thermal value Specific thermal value based on the relationship between mass, volume, molar thermal value and the fabric quantity. Particularly important when comparing energy source data. Indication in Joule/unit (J/kg, J/m^3, J/mol).

Thermal value of fuels Thermal value indications are generally made as “lower thermal value” H_u. The “upper thermal value” (combustion value H_o) is of lesser practical value as the condensation heat of the steam produced on combustion of fuels containing hydrogen is included which is practically not useable. When calculating the thermal value of different fuels it is important to take care that they are based on either thermal or combustion value (Tab.).

	thermal value H_u	combustion value H_o
solid fuels [kJ/kg]:		
– hard coal (Ruhr)	35 000–35 400	36 000–36 250
– anthracite (Ruhr)	35 275	36 000
– coking duff	33 100	33 225
– coalite	32 700	33 300
– brown coal	26 000–26 800	27 450–28 300
– brown coal briquettes (Rhineland)	25 775	26 800
– wood (firewood)	18 850	20 100
liquid fuels [kJ/kg]:		
– benzene	43 500	46 925
– paraffin	43 350	46 500
– heating fuel oil EL	42 750	45 675
– heating fuel oil S	40 650–41 000	43 150–43 575
gaseous fuels (liquid gases) [kJ/m^3]:		
– n-butane	123 725	133 650
– propane	93 000	100 775
– propane	46 400	50 275
– n-butane	45 775	49 450
– natural gas (NAM)	31 850	35 200

Tab.: Thermal value and combustion value of various fuels.

In the case of liquid fuels it is advisable to note whether quotations indicate the thermal value in J/kg or J/l (approx. 10% lower thermal value).

Thermo-balance The so-called thermogravimetric method is used mainly for determining water and moisture on the basis of the weight loss of a specimen which has been dried using heat. The specimen to be investigated is placed on the thermo-balance and dried using infrared heat. Penetration of the material by heat radiation causes the moisture to evaporate rapidly and this process can be monitored with the aid of the balance. When the evaporation process is complete, the moisture content of the specimen can be established. Specimens can, of course, be examined for substances other than water content. Other substances which evaporate easily can be determined gravimetrically. Using high steam pressure it is possible, for example, for material to be examined for substances adhering to it which have been left after finishing processes.

Thermobonding Increasingly stringent demands on the quality of non-woven products and the requirement for more and more rapid production speeds make optimum production lines a necessity. Fleece strengthening using calenders, known as thermobonding for the sake of brevity, is one of the processes principally applied for economic production of quality fleeces. This process is becoming more and more widespread. It is based on the two physical elements of temperature and pressure. It is important that both elements can be adjusted in optimum fashion as this ensures the best possible quality of the final product which can be characterised by

- strength in lengthwise and transverse directions,
- elasticity in lengthwise and transverse directions,
- handle
- appearance.

Pressure and temperature cannot be chosen at random. Also too low a pressure cannot be compensated by high temperature or vice versa. Optimum pressure and temperature depend on the fibre material used, production speed, diameter of the rollers (Fig. 1) and also on the engraving. It is only possible to ascertain the optimum combination of pressure and temperature by means of intensive experimentation and on the basis of extensive experience. Heat transfer from the thermo-oil to the roller improves at higher oil speed. This achieves efficient heat transfer. It is also important for the oil flow to be distributed absolutely evenly over the width of the roller in order to reach the same temperature. This requirement is met by so-called peripheral-bore rollers which are equipped with several oil boreholes around the circumference of the roller. The oil makes it possible

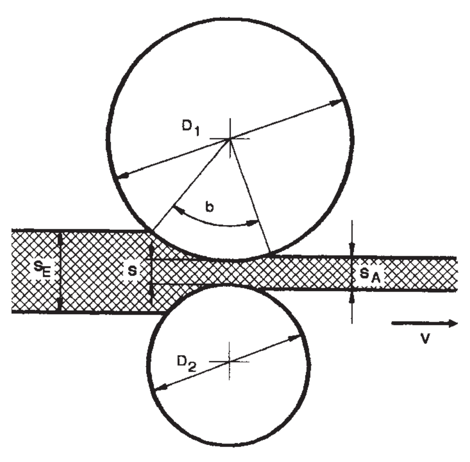

Fig. 1: Contact with heavy nonwovens.
s = roller press slot; s_E = thickness of nonwoven upon entry; s_A = thermobonding thickness.

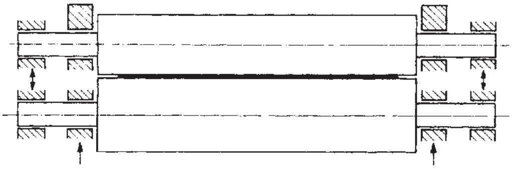

Fig. 2: Flex compensation through roll bending.

to achieve an even temperature which can be adjusted rapidly. It is important to install a bending compensation system (Fig. 2) in which no temperature differences occur by means of heat losses, for example to an appropriate support roller which cannot be heated to such a high temperature. Each roller is bent as far as possible by the pressure in the gap. If this effect is not compensated, a lower gap pressure results in the centre of the roller than at the outside edges. Several principles are used in technology to compensate for this effect:

- roller lapping,
- axis distortion,
- hollow roller charged with interior pressure,
- roll bending,
- hydraulic elements inside a hollow roller.

The lapping of a roller is certainly the simplest and most effective procedure but is only suitable for a certain line pressure. In the case of axis distortion, the roller axis is crossed by means of lateral displacement of the main bearings resulting in an increase in the size of the gap at the extremities. In the case of the hollow roller with interior pressure, partial compensation of the bending line occurs. Bending of a roller due to constant gap pressure and compensation with a hollow roller cannot be expressed by the identical function. This means that compensation can only be achieved to a limited extent. The so-called W or M profile occurs as a result of overlaying of the two curves. In the case of roll bending, (Fig. 2) bending compensation is achieved by means of an overlayed bending moment positioned from the outside. Compensation is, therefore, purely mechanical.

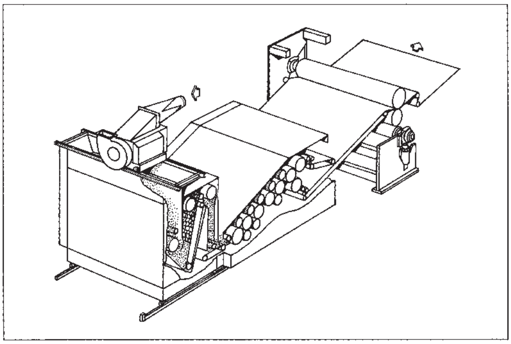

Fig. 3: Diagram showing the course of the thermobonding nonwoven device by the Hergeth-Hollingsworth system.

Efficient thermobonding systems include fibre mixing, fine opening, card (preferably random fleece card), thermobonding calenders and a winding device. Fig. 3 shows the Hergeth-Hollingsworth system with a processing width of 3.5 m and a max. production speed of 150 m/min for fleece layers of approx. 20 g/m^2. The process makes extreme demands on fibre preparation.

Thermochrome pencils A range of different pencils for temperature measurement in the range of 65–670°C. Each one has a specific temperature-dependent colour-turning point whose colour pattern is recorded on the pencil. When applied, for example, to steam conduits, calender rollers and irons, a coating is formed which can be removed quickly by wiping it off. Colour transformation within approx. 1–2 seconds corresponds to the testing temperature whilst delayed colour transformation indicates a lower temperature.

Thermochromism Often significant, reversible change of colour shade brought about by an increase of temperature which, in the case of certain dyes, is of adequate duration to represent a problem, for example during drying, thermo-fixing, steaming and ironing. In the narrower sense thermochromism is the result of the occurrence of long-wave chromatic bands in the visible spectral range. The cause is assumed to be a temperature-dependent → Trans-cis-isomerism of dyes, facilitated by an increasingly polar molecule structure. It is present in the azo-naphthol types due to a temperature-dependent displacement of azo-hydrazone tautomerism. Thermochromism is taken into account, for example, when testing ironing fastness in accordance with DIN 54 022, when a colour shade is assessed after heat application and after a certain recovery phase.

Thermocolour markers (temperature measuring pencil). Usually metal salts of complicated structure whose colour change at certain temperatures is based on oxidation or separation of water, carbonic acid and ammonia. Temperature measuring dyestuffs are also used as measures of heat radiation.

Thermocouple, thermoelement Principle of a bimetallic strip which, by heating its connecting solder or welding points, creates a measurable thermocurrent, the voltage of which increases with increasing temperature. With a copper and constantan thermoelement (which is used for temperature measurement and regulation up to temperatures of 350°C), a temperature change of, for example, 20°C corresponds to a voltage change of a millivolt. Used for example in → Pyrometer or → Total radiation pyrometer.

For determining the temperature on or in a textile test piece, miniature jacket thermoelements are used with the thermopair combination nickel-chrome, nickel-aluminium (NiCr-NiA1). The diameters of the jacket

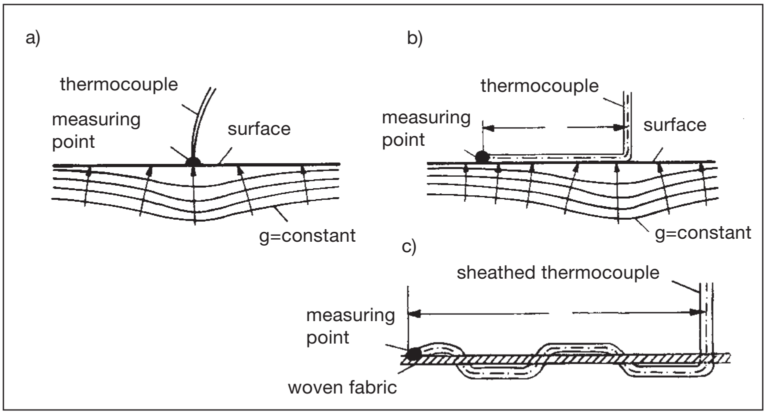

Fig.: Mounting a thermocouple (thermo-element) on textile fabrics (DTNW).

thermoelements are 0.25 mm, 0.5 mm and 1.0 mm (according to DIN specifications). The connection between measurement test price and temperature sensor has to be adapted to suit the measurement in question. In order to ensure optimum heat transfer between the test piece and the temperature sensor (this applies in particular to bodies with a high specific surface), the sensor is pressed onto the test piece so as to promote heat conductivity. The Fig. shows the impact of the supporting length of the thermoelement on the temperature field. This impact lessens with decreasing diameter of the thermoelement and increasing supporting surface.

Due to bending tensions the tip of the thermoelement, i.e. the actual measuring point, is pressed firmly onto the fabric and, in the case of thicker fabrics, penetrates the yarn composition. The thermoelements are connected to a measurement converter with zero point and measurement range adjustment. This measurement converter provides an analogue output signal of 0–1 V which is directly proportional to the temperature. The measurement signal is registered on a multi-channel recorder together with the measurement signal of the radiation pyrometer (partially in accordance with Schollmeyer et al.).

Thermocracking Dyestuff constitution based phenomenon caused by certain reactive dyes by which the wet-fastness values of a dyed or printed material are significantly impaired after thermal treatment. Thermocracking is caused by splitting the ether or ester binding of the dye to the cellulose fibre and is most in evidence in ester-bound dyes.

Thermodynamics Thermodynamics is an important principle of natural science as it describes the equilibrium of a system. Thermodynamic concepts therefore occupy an important place in ecology as well. A knowledge of thermodynamics is particularly necessary in order to answer the question of whether and in which direction a system can develop and what its stable final condition will be (see Fig.).

Whether it is a gas (ideal or real), liquid or solid, a thermodynamic system can be described by means of condition equations and condition functions which depend only on the initial and final condition. Condition functions (thermodynamic potentials) include inner energy U, enthalpy H, free energy F, free enthalpy G and entropy S. The system can be regarded macroscopically. This involves describing the named system by means of macroscopically-measurable system characteristics and their connections. This is known as phenomenological thermodynamics, which is the oldest branch of thermodynamics. The system can also be regarded microscopically. This involves attributing the macroscopic system characteristics to the interaction of the system components (atoms, molecules). The statistical methods of classical and quantum mechanics are used to describe phenomena. Thus, for example, the kinetic gas theory explains the origin of gas pressure and makes possible a deeper understanding of the concept of temperature. Or, with the aid of statistics, thermodynamic potentials can be derived from which all condition dimensions and material properties (e.g. specific heat capacity) result.

A thermodynamic system can be in a state of interaction with its environment. If no exchange of energy and mass takes place across the system boundaries, the system is closed. If only energy ΔW (e.g. mechanical, magnetic, electrical energy) is exchanged, this is known as an adiabatic system. With closed systems an exchange of energy ΔW and heat ΔQ takes place and with open systems an exchange of mass takes place as well.

The primary basic law of thermodynamics, that of energy conservation, states: energy can neither be created nor destroyed. In an isolated system, in which neither energy nor material exchange with the environment takes place, the overall energy content is constant. The energy occurs in various forms which can be transformed into each other. Energy forms are, for instance,

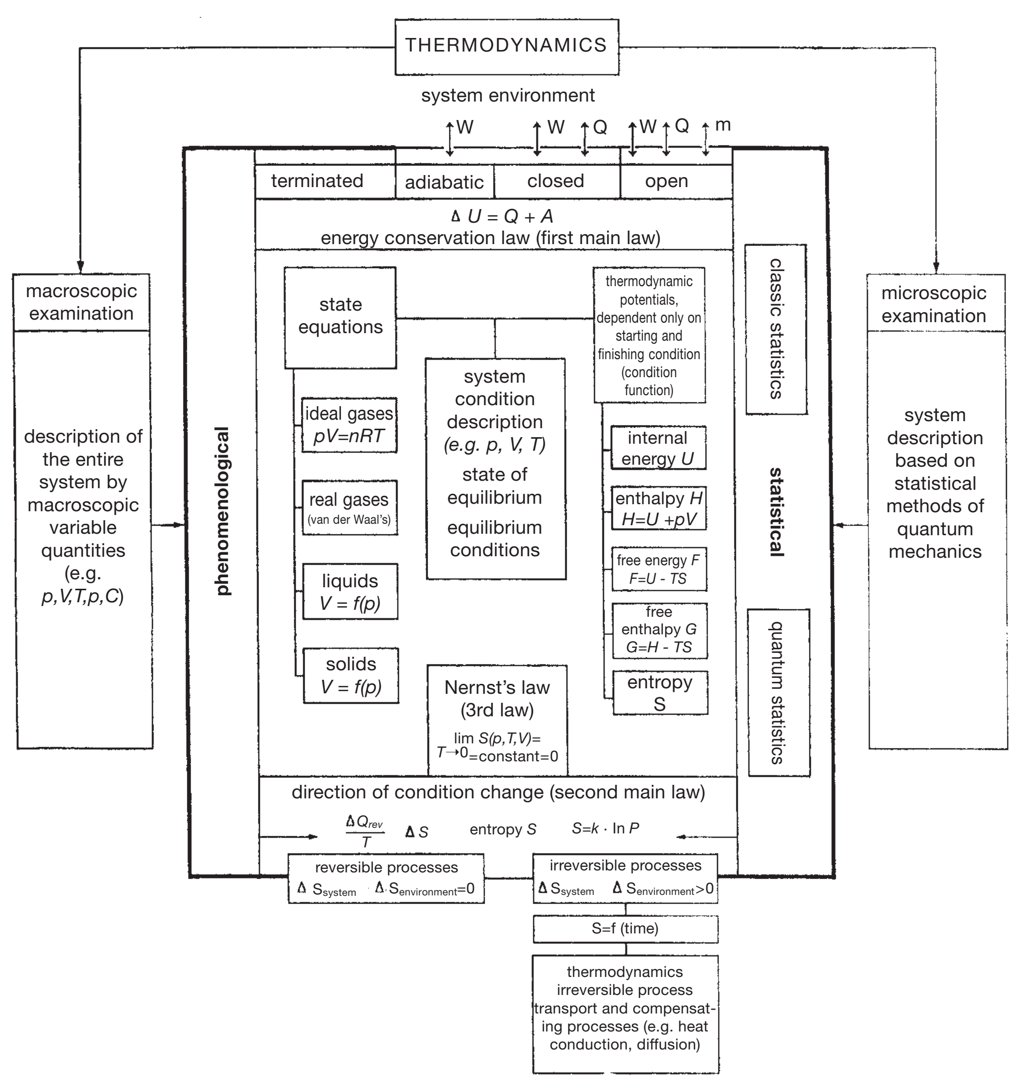

Fig.: Thermodynamics.

mechanical energy (kinetic and potential), electrical energy, light, chemically-stored energy, work or heat. According to the primary basic principle (and the mass conservation principle) the world's resources can never run out. If enough energy was expended, all substances could be recovered from waste materials. There are, however, limitations to energy transformations in physical or chemical processes.

The second basic law of thermodynamics describes the direction in which a certain energy transformation takes place of its own accord. With each energy transformation part of the energy is transformed into a (theoretically and practically) no longer usable energy form. What changes during energy transformation, therefore, is the further usability of the energy. As opposed to the substance cycles in an ecological system, there can be no energy cycles, as according to the second basic law energy recycling is impossible. With the concept of entropy, the second basic law states how the direction of condition changes. The entropy change is zero in the case of reversible processes; in the case of irreversible processes it is positive, i.e. the heat is not completely transformable into other energy forms. Among the irreversible processes of thermodynamics, transportation and compensation processes are of particular practical significance. Entropy S can also be interpreted microscopically as a probability function (logarithm of condition probability ln P multiplied by the Boltzmann-constant k). Condition changes will take place in the direction of max. probability (max. entropy). The third basic law (Nernst) shows that entropy becomes constant when the temperature approaches the absolute zero point. This constant is equated to zero. It also follows from the third basic law that the absolute zero point (T = 0) cannot be reached. As a result of the influence of technology and civilisation, ecological systems can be so far removed from a state of balance that they react to small interferences in an unpredictable way. The further a system is removed from a state of balance, the more rapidly the processes take place and the more entropy is created per time unit (according to Hering, Martin and Stohrer as well as Kummert and Stumm).

Thermofixation and thermosol process (TT-process). One-stage continuous process for dyeing fabrics made of polyester/cotton mixture using disperse and reactive dyes in which the reactive dyes are only bound to the cellulose in the presence of polar substances which facilitate their diffusion into the fibre interior. It is preferable to use dicyandiamide rather than urea for this process as it permits fixing of the reactive dye without alkali. If urea is used the process takes place as follows: Pad with dye, urea, alkali (sodium hydrocarbonate) and with further additives depending on the dye, → Thermosol fixation and Washing off.

Thermofixation of disperse dyes on polyester Mechanism of solid solution of the dye in the substrate in which hydrotropic substances in the print paste actively promote the endothermal process. At the high fixation temperature they also form a fluid paste which dissolves the dye particles and facilitates transportation to the surface.

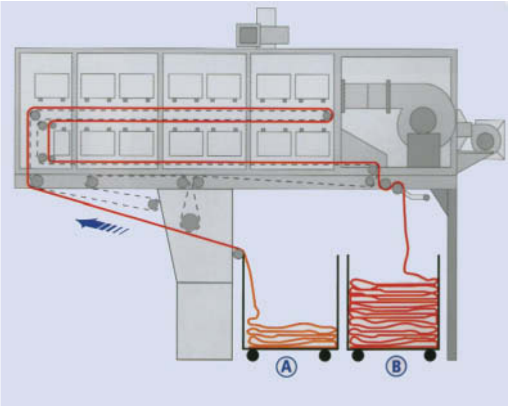

Fig.: Heat setting/thermofixing.

The above advantage offers the possibility of a normal drying and a heat setting or thermofixing of dyestuff if needed. The above is carried out independently from the next printing cycle. As shown in the Fig. during the a.m. process the cloth from A goes through the drier and is collected at B (Viero).

Thermoflush Procedure for shortening the rinsing process for reactive dyeing by means of intermediate steaming several times, thereby reducing water consumption.

Thermofusion Procedure whereby dry fleeces are completely bonded just by means of heating and subsequent cooling, e.g. → Spot-bonded nonwovens. The bonding of nonwovens of bi-components and other fibres or fibres mixtures is carried out using thermofusion systems, in every case using only hot air without steam or binders.

Thermograph (temperature recorder). A recording thermometer which functions on the principle of the bimetal thermometer. The movements of the bimetal strip are transferred to a recording lever which records temperature flucutations on a registration drum. The thermograph is used for uninterrupted recording of the temperature in drying systems and air-conditioned rooms.

Thermogravimetric analysis (TGA). Procedure for investigating flameproof textiles. The weight reduction of a test piece is determined at increasing temperature (until decomposition).

Thermohydrograph Device for uninterrupted recording of temperature and air humidity.

Thermolabels Self-adhesive thermopapers, coated with plastic, printed for 37.8–260°C and for five temperature ranges in 8 different arrangements (reaction speed: 2–5 seconds).

Thermomechanical analysis (TMA). In many finishing operations fibres are subjected to one or more thermal treatments. During these treatments, not only the finishing chemicals are fixed but massive structural changes can take place in the fibres as well as changes in the mechanical properties of the fibres. TMA attempts to simulate these processes. Fibres are measured for strength and elasticity in a controlled heating chamber (Fig. 1). This type of simulation is important to ascertain the influence of fabric tension on their heat setting effect (Fig. 2) (according to Berndt).

Thermometer Thermometers are divided into:

I. Glass thermometers with liquid filling: a) mercury column surrounded by a vacuum (measuring up to 100°C), also available as rod and angle thermometers (for drying rooms, boilers, heating system pipes) and as tele-thermometers (for calenders, drying systems, washing machines); b) as listed under a) but, instead of vacuum, high-melting glass with nitrogen, hydrogen or carbon dioxide under pressure (prevents mercury evaporation, measuring up to 750°C; c) particularly for

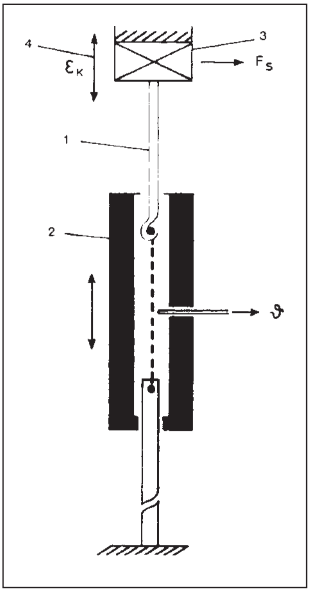

Fig. 1: Thermomechanical analysis diagram of a unit for shrinkage force measurement (Berndt).
1 = clamping unit with measuring sensor; 2 = heater unit with thermocouple for recording room temperature; 3 = force transducer for recording shrinkage force F_s; 4 = possibility of applying specific shrinkage methods ε_k.

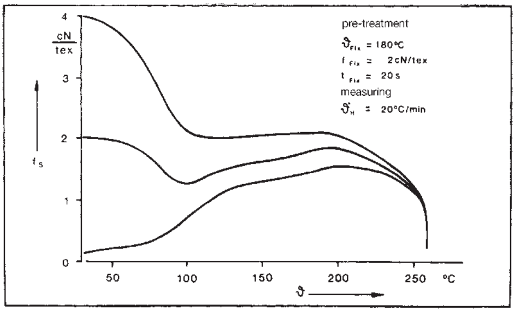

Fig. 2: Thermomechanical analysis of PES filament yarn shrinkage force measurement. Effect of pre-tensioning at the start of measurement on shrinkage force behaviour (Berndt). f_s *= count-related shrinkage force;* J *= measuring temperature;* J_H *= rate of heating;* J_{Fix} *= setting temperature;* f_{Fix} *= count-related setting tension;* t_{Fix} *= setting duration.*

wide measuring ranges by means of other fluids such as, for example, toluol (–90°C to +100°C), ethanol (–110°C up to +40°C) and pentane (–200°C up to +20°C).

II. Spring thermometers: a) indicator thermometer with metal spring as temperature meter and face (also available as tele-thermometer); b) tensions thermometer with liquid filling and tubular conduit in the heat sensor, indicating and registering with tele-conduit or contact device (controls relay and signals), frequently used in, for example, dyehouse, boiler plants.

III. On thermo-electrical principle: a) thermo-elements; pyrometers; b) so-called surface thermometers (for drying cylinders and other heated rollers, also available as tele-thermometers).

IV. Resistance thermometers: Measurement of electrical resistance of a platinum wire located in the submerge tube (increasing resistance with increasing temperature), direct temperature indication up to 1000°C, both registering and tele-transmission, also for light mains connection.

V. Electronic surface thermometers: Heat-sensitive sensor with germanium semi-conductor, the resistance value of which changes almost instantaneously with temperature, impacting on the anode flow of an electron tube and visible on the indication instrument within 2–3 seconds of operating the switch. Various portable models with measuring ranges of –10°C to +210°C, battery-operated.

Thermometer papers Paper strips or rolls with heat-sensitive covering (also self-adhesive) in series of varying heat degree gradations (37.8–254°C). At a certain temperature each strip changes its colour from white to black instantaneously and constantly at a quoted reaction speed of ±1% of the standard value.

Thermomigration Desorption in the form of migration of dyes, particularly of disperse dyes on polyester under the influence of dry heat and in the presence of surfactants.

For thermal post-treatments, e.g. for drying, post-fixing and finishing of dyed polyester fibres, disperse dyes can migrate to the fibre surface and accumulate on it. Thermomigrated disperse dyes are no longer fixed and can, therefore, drastically reduce the fastness of previously perfect dyes. The change in fastness depends not only on the quantity of thermomigrated dyes but also on their affinity for white accompanying fabric under fastness-testing conditions. If standard accompanying fabrics are treated with dye additives under test conditions, it will be found that even small amounts of additive result in staining, rating 2–3 on the grey scale. If these dye quanitites are related to dyeings in 1/1 standard type depth, it becomes evident that a non-fixed proportion of 1% of the total dye applied can reduce wet fastness by 2 scale points. These results are of particular significance for selection of dye. It is not sufficient to select dyes which have low migration properties during thermal treatment on the basis of a one-off test and which are not absorbed or only slightly absorbed by white accompanying fabric during fastness testing.

As small quanities of non-fixed or low-fastness dyes can reduce fastness by several scale points, it is necessary to ensure that the selected dyes are regularly (on delivery-to-delivery basis) free of less fast auxiliary components or shading dyes.

Disperse dyes for polyester fibres generally demonstrate low solubility in water which only increases within limits at higher temperatures. Absorption rate, affinity to the fibre and diffusion rate are also important. A measure of the affinity of a dye is the distribution co-efficient between fibre and dye-bath

$$\text{Distribution coefficient (K)} = \frac{\text{Dye concentration in the fibre } (C_F)}{\text{Dye concentration in the dye-bath } (C_B)}$$

The disperse dye dispersed in water is in equilibrium with the part that is dissolved in water and this again is in equilibrium with the part which is absorbed by the fibre surface, which in turn is in equilibrium with the part which is dissolved in the fibre and has dispersed in the fibre interior.

Generally the following procedure can be assumed for levelling:

a) diffusion of the dye at the fibre surface;
b) desorption at the fibre surface;
c) solution of the dye particles in water and migration to the surface layer fibre/water;
d) renewed adsorption at the fibre surface;
e) diffusion into the fibre interior.

The slowest step is stage b), i.e. the desorption rate could be a measure of migration. The levlling capacity regularly decreases independently of the dye constitution with increasing distribution coefficient (C_F/C_B). Dyes level most readily with a distribution coefficient of less than 700. However, these dyes are not adequate in terms of exhaustion rate and sublimation fastness. Dyes with a higher distribution coefficient must be applied at increased temperature or in the presence of carriers. Dye dispersion in the dyebath is in equilibrium with a saturated solution of the dye. At a dyeing temperature of 120–130°C, the dispersed dye can disperse more intensively into the aqueous phase. If this dye is not totally exhausted during the dyeing process, the solution can tend to crystallize when cooling down. The dye crystals can settle on the fibre with low rub fastness results. A significant increase in particle size (risk of recrystallization) can occur with many disperse dyes due to an excess levelling agent in the dyebath. It would, therefore, appear to be more advisable to dye at 130°C in the presence of carriers or other auxiliaries which can diffuse into the polyester fibres.

The disperse dye is present in the polyester fibre in “solution” (mono-molecular) form. If the polyester fibre is offered a competitor in terms of solubility capacity for disperse dyes, then the disperse dye follows the Henry’s distribution law and migrates to where there is higher solubility. It is well-known that the mobility of disperse dyes within the polyester fibre improves as the temperature increases.

The causes of thermo-migration can be summarised by the following points:

- heat treatment: drying and themofixing,
- preparation treatment: softeners, anti-static agents,
- finishing: finishing agents,
- coning: spool oils,
- residues of preparation treatment, dyeing auxiliaries.

The following reactions can easily occur under the influence of thermal treatment during migration of disperse dyes from dyed polyester substrate to a finishing agent. However, the extent to which these reactions occur depends on the chemical constitution of the dye, the type of finishing agent as well as treatment time and temperature. Depending on time and/or temperature, these reactions impact on desorption of the dye from dyed substrate to finishing agent:

1. Current distribution of dye between surface active substances and surface layer of the substrate: The first stage of migration consists of migration of the dye from the surface layer of the dyed substrate into the finishing agent. This movement is dependent on the area through which dye migration takes place, the diffusion coefficient of the dye in finishing and modification of chemical potential, which is the driving force for migration of the dye at any one time.

2. Diffusion of the dye from fibre interior to the surface: in order to replace the dye which migrates from the suface layer of the substrate into the finishing agent during reaction, migration of dye from the interior of the substrate to the surface layer takes place. This dye migration is dependent on the diffusion area within the fibre, the diffusion coefficient inside the fibre and the local gradient of chemical potential. As this local concentration gap of the dye in the substrate is a consequence of extraction of dye molecules by the finishing agent, the extent of the concentration gradient is proportional to current dye migration which takes place during the first step. During this phase the compact inner structure of the substrate constitutes greater diffusion resistance for the dye compared with the resistance of dye molecules during diffusion into the finishing agent. Under these conditions, migration within the fibre is the rate-determining step which determines the further extent of thermomigration as a result.

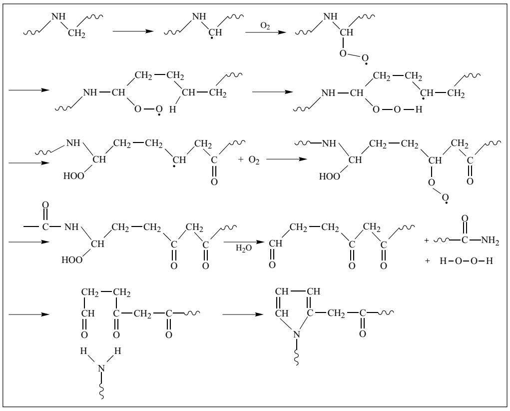
3. Diffusion of the finishing agent into the fibre: depending on the nature of the finishing agent and the time and temperature of the thermal treatment, the finishing agent can in some cases penetrate the substrate. In this case the dye content of the finishing agent decreases at the fibre surface for two reasons; firstly because the dye-containing finishing agent disperses into the substrate and secondly because the quantity of finishing agent available for extraction of the dye from the substrate is now reduced as a result of diffusion of the finishing agent into the substrate. During this phase distribution of the dye between the substrate and the finishing agent at the surface is determined by which of

the two reactions is predominant, diffusion of the finishing agent into the substrate or extraction of the dye from the substrate by the finishing agent.

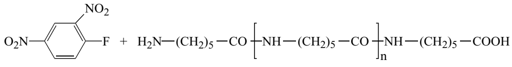
4. Formation of a phase substrate/dye/finishing agent: as a result of diffusion of the finishing agent into the fibre substance, a change in the morphology and fine structure of the fibre takes place. This can lead to an increase of the free volume in the fibre. Under these conditions the dye molecules in the fibre have greater mobility enabling them to diffuse from the fibre into the finishing agent at the fibre surface.

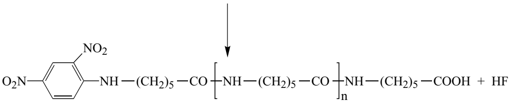
The extent to which some or all of the above mentioned reactions take place depends on the chemical constitution of the dye, the type of finishing agent and the conditions of thermal treatment (according to von der Eltz and Sheth).

Thermo-oxidative degradation of polyamide The most significant damage to aliphatic polyamides in terms of practical application is based on their heat sensitivity, particularly in the presence of oxygen. During the course of technical manufacture, processing and finishing, heat has an impact on the polymer. Macroscopically the impact of heat causes impairment of the mechanical-technological properties, a significant yellowing and a changed absorption capacity for dyes. At present assumptions can only be made as to the nature of the chemical processes which cause these changes. One of these assumptions, which explains a number of chemical changes to polymer, is illustrated below.

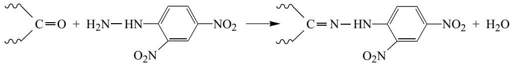


Where this mechanism is valid, a reduction of amino end groups and formation of carbonyl and pyrrol groups should be provable in thermo-oxidized polyamide. A photometric determination method for the amino groups is available which is based on conversion with 1-fluoride-2.4 dinitrobenzene:

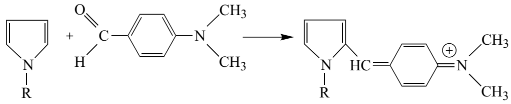




The carbonyl groups can be determined in similar chemical fashion using 2.4-dinitrophenyldydrazine:



Pyrrols can be determined photometrically after conversion with p-dimethylaminobenzaldehyde to a methine dye.



Thermo-physiological comfort Objectively thermo-physiological comfort is a state in which humans are not subjected to heat stress in terms of significant deviation from normal values for body temperature and in terms of other physiological parameters such as circulation or pulse frequency. Subjectively this includes the absence of unpleasant feelings resulting from temperature or humidity in the micro-climate between skin and clothing or from the presence of perspiration. The body has several involuntary means of maintaining or regaining thermo-physiological balance, e.g. shivering or perspiring in order to create or dispense with heat.

Fibre material, fabric structure and the cut of clothing can also have an impact on thermo-physiological comfort, since they influence the extent to which heat and humidity are transported away from the body. The heat insulation provided by textiles such as clothing or bed linen can support the body by altering the involuntary control range or inducing lower or higher environment temperatures. However, the limits which textiles place on heat disposal via perspiration (evaporation) can impair the control range to an undesirable extent thus limiting the body's capacity to adapt easily to changes induced by temperature or activity. → Clothing physiology.

Thermoplastic composites Filament-reinforced → Composites with duroplastic matrix are not only used in the aerospace industry but also compete with metals in all other sectors of industry. The cycle times during component manufacture are, however, too long for medium and large production series. Shorter cycle times can be realized with thermoplastic composites.

Thermoplastic composites

Composites with thermoplastic matrix can be divided into three sections (Fig. 1):

- glass-matting-reinforced thermoplastics (GMT) of long-fibre-reinforced polypropylene offer acceptable mechanical properties at a low price and are used in the automobile industry.
- endless-fibre-reinforced high-temperature resistant (HT) matrices, such as polyester for example, are used under the name “Advanced Composites”. They are mainly used in the aerospace industry.
- composites made of technical plastics allow mechanical properties to be achieved which utilise the strength potential of the fibres used. Good fibre/matrix adhesion is a prerequisite for this. PA12 is a technical plastic which is suitable as a matrix for these composites.

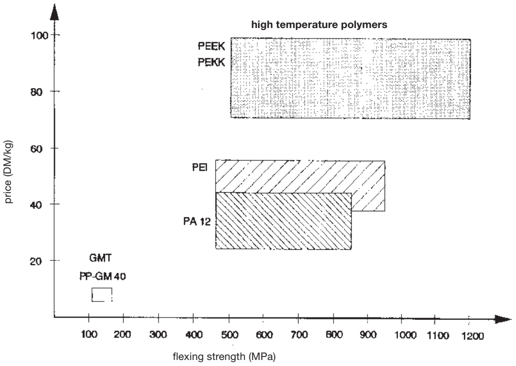


Fig. 1: Thermoplastic composites (glass fibre reinforced).

The fabrication of laminates or components with duroplastic or thermoplastic matrices requires different processes. In the case of duroplastic matrices, the properties and the quality of the finished component is influenced by monitoring the crosslinking reaction of the matrix. The crosslinking reaction is monitored throughout the entire fabrication process including storage and transportation right through to final hardening in the autoclave. In the case of composites with thermoplastic matrices, monitoring of the chemical process is not the decisive factor but the rheological properties of the matrix. Depending on the polymer, thermoplastics have a viscosity between 500 and 5000 Pa · s at their processing temperature, whereas duroplasts have less than 100 Pa · s. Due to the high viscosity of thermoplastic matrices, the impregnation process is particularly significant. Impregnation can be carried out in accordance with various processes:

- melting impregnation,
- solution impregnation,
- film laying process (film stacking),
- powder impregnation,
- hybrid yarn and hybrid weaving technique.

Not all processes can be used with each polymer. The melting viscosity of the polymer influences the selection of the optimum impregnation method. Thermoplastic polymers with a viscosity of less than 1000 Pa · s are suitable for most impregnation processes. Polymers with higher viscosity are dissolved in a solvent and the reinforcement fibres and/or a fabric are impregnated with the solution. Not all polymers can be dissolved simply, however. Disposal of the solvent after impregnation can pose an additional problem.

Film laying techniques and powder impregnation have proved particularly economical for the fabrication of thermoplastic composites. Both processes can be applied using PA12 as matrix. Due to the availability of PA12-powder, powder impregnation with this polymer is of particular interest. There are three processes for powder impregnation. In one process thermoplastic powder is enclosed with the reinforcement fibres by a foil of the same polymer or of a polymer with a low melting point. The resulting product can be used for component fabrication using the winding process or for manufacturing fabrics. Another process uses polymer powder in an aqueous solution for impregnating the fibre. The water is removed from the Prepregs during laminate manufacture. In the third process polymer powder is scattered onto the reinforcement fibres and then heated to a temperature above the melting temperature of the polymer.

The scatter process can also be replaced by a spinning disc which controls the spraying of the fibres. Not every polymer is suitable for powder coating. Polymers which occur as powder with the appropriate grain size during the manufacturing process are the most economical for the impregnation process as they eliminate the necessity for additional grinding. Otherwise the matrix costs can increase by more than 50% and the process can become uneconomical. Variations of the third process for fabric impregnation use PA12. Glass, carbon and aramid fabrics are covered with PA12-powder on both sides. Impregnation of the fabric then takes place under infrared radiation, heating the polymer to 200°C

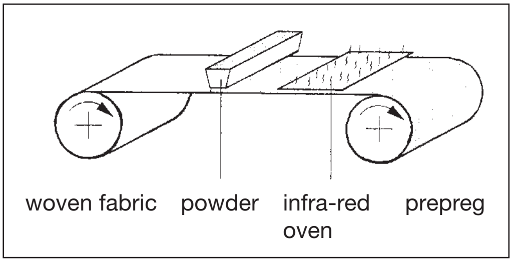

Fig. 2: The powder impregnation process.

(Fig. 2). The low melting viscosity of PA12 facilitates good penetration of the fibre bundles and good impregnation of the fabric. However, this does not yet constitute total coverage of all the fibres. When manufacturing laminates or components with more than two Prepreg layers, further consolidation in a stationary press or a double band press is necessary at approx. 250°C.

Thermoplastic composites of PA12-Prepregs are pressed at temperatures of 250°C and low pressures of 5–10 bar to form laminates and/or components. This can take place in heated or cold presses with preceding infrared treatment. These techniques were first used for the fabrication of sports equipment. Shoe soles with PA12-composite are layed up in cats before overspraying. The suitability of thermoplastic composites in conjunction with PA12 is currently under investigation in the automobile industry. Its good processing properties, low water absorption and its high energy absorption are of particular significance for the automobile industry. Composite bands with uni-directional glass or aramid fibre and PA12 as matrix are used for reinforcing pressure containers (Baron).

Thermoplastic fibres Fibres which demonstrate a → Softening range and are therefore thermoplastic. This property is also utilized during → Heat setting, → Thermoplastics.

Thermoplastic resins Glass-like, hard solids that are thermoplastic are used in textile finishing for improving texture, draping properties, stiffness, durability, scrub-fastness and dimensional stability. → Thermoplastics.

Thermoplastics (plastomers). Substances which are transformed reversibly into a plastic and therefore formable state when heated to a certain temperature (specific softening temperature). This does not involve any chemical change and the substance returns to its original hard or elastic state when it cools down. Thermoplastics can change from one state to the other as frequently as required.

Thermoplast print blanket adhesives Adhesives which are effective from a certain temperature and which are used in film printing where they are heated to the necessary temperature by means of heated rollers. Thermoplast adhesives, vulcanized in rubberized continuous printing blankets, allow the preheated fabric to be printed without glueing and washing using the preheated printing sheet to position the pattern for printing.

The temperature is adjusted and regulated by means of a thermostat. The fabric is transported over a convex plate allowing it to be bonded smoothly to the blanket (Fig.). Conventional types of glue can be applied to the thermoplast layer. After passing through the printing zone, the fabric can easily be pulled away from the printing cloth, even when cold. It is possible to print 200 000 to 1 million metres but it may be necessary to replace the thermoplast earlier depending on the printing process.

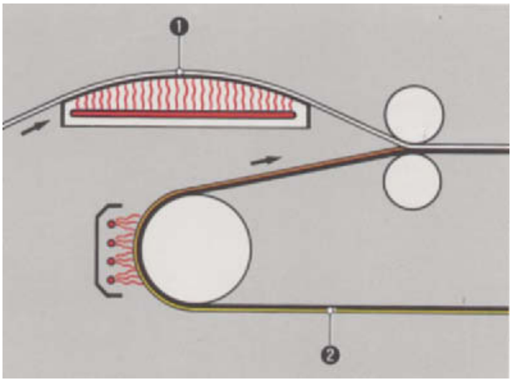

Fig.: Attaching the printing background to the rubber blanket containing the thermoplast backing cloth adhesives (Stork).
1 = fabric; 2 = thermoplast.

Thermosetting process → Heat setting.

Thermosol dyeing processes Important continuous process for dyeing polyester and polyester/cellulose fibre mixtures with disperse dyes, which is used mainly for fabrics and knitted materials. First dye, thickening agent or migration inhibitor and possibly a hydrotropic agent (urea, thiourea) and an acidifier are padded. Then initial pre-drying is achieved by means of an infrared heater (prevention of dye migration) before drying completely by means of jet drier, tension frame or cylinder drier (Fig. 1). Diffusion of the dye from the surface to the fibre interior takes place during subsequent → Thermosol fixation in the vapour phase. The thermosol fixation process is also suitable for triacetate fibres. It is only suitable for polyacrylnitrile fibre when certain cationic dyes are used.

During thermosol fixation, disperse dyes are set on polyester fibre at a temperature of 200–225°C which is applied for 30–60 seconds. The setting speed, the degree of setting and the penetration of dye into the fibre depend above all on the following factors (Fig. 2):

- chem. constitution and finish of the dyes,
- dye combination,
- concentration of the dyes and fibre surface,
- type of polyester fibre,
- ratio of polyester/cellulose fibre,
- fabric structure,
- auxiliary additives in the pad bath,
- temperature of the fabric and thermosol fixation time.

The fibre material is specified before dyeing; dyes, auxiliaries, thermosol fixation temperature and time can be selected. The temperature of the fabric and the ther-

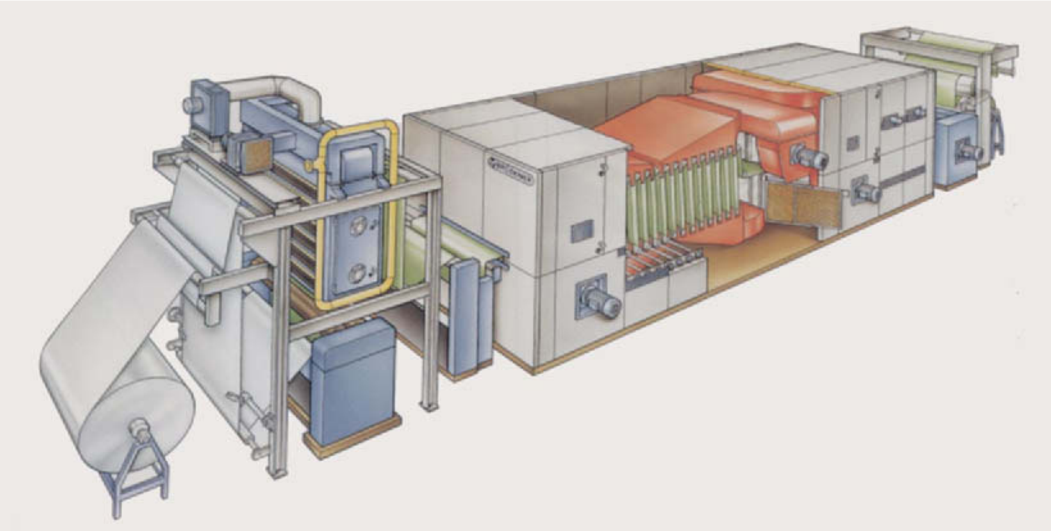

Fig. 1: Thermosol dyeing plant (Brückner).

mosol fixation time are not necessarily dictated by the temperature of the heat medium and the time spent in or on this medium. They are dependent on the heating speed which in its turn depends on the fabric structure, residual moisture and type of heat transfer. Fluctuations in the temperature of the fabric and the thermosol fixation time cannot be completely eliminated at reasonable expense under operating conditions. Therefore, disperse dyes are preselected which result in level dyeings over a temperature range which is as wide as possible. Temperature dependency of dye fixation is documented by so-called thermosol curves on which either the degree of fixing or the dye strength are recorded against the temperature. The degree of fixing indicates the quantity of fixed dye in relation to the padded dye quantity. The relative dye strength corresponds to the visual or colour measurement determined dye strength in relation to the max. achieved dye strength. Both dimensions are usually quoted as a percentage.

Migration during intermediate drying continues to cause problems in practice. The migration of dyes is not only the cause of two-sidedness and listing; strongly migrating dyes also lead to a non-uniform appearance, double colour effects (dichroism) and colour

Fig. 2: Thermosol dyeing process classification (according to Schollmeyer).

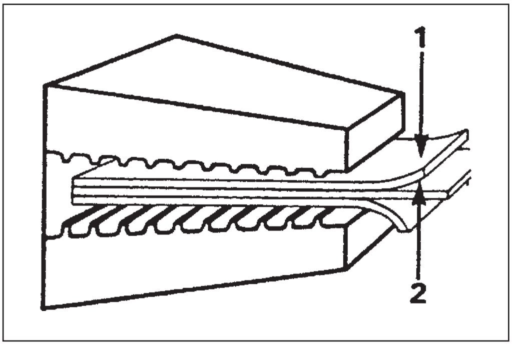

Fig. 3: Migration during intermediate drying – effect of the dispergator system on the migration code using the example of Foron marine blue S-2GL (Sandoz).
Fabric: PES/CO 65/35 merc.; padding liquor: 32 g/l Foron marine blue S-2GL, 20 g/l Sanapol AM liquid (Sandoz); dry/thermosol: 2 m, 150 ºC/min, 215ºC reductive cleaned, PES skeleton. 1 = fabric upper surface; 2 = fabric lower surface

deviations in the sewing sample. Thermosol dyeing on a polyester mix fabric can have a worse appearance than an exhaust dyeing due to inadequate dye penetration. Optimum machining prerequisites, drying conditions, the migration inhibitors used and also disperse dyes with a minimum tendency to migrate can have a positive impact on the appearance of a thermosol-dyed product. The migration capacity of a thermosol dye mixture can be simulated in a laboratory test (Fig. 3) (Richter and Somm).

Thermosol fixation Treatment during the → Thermosol dyeing processes which causes diffusion of dye into the fibre interior by means of hot air, superheated steam, contact or radiation heat. Of these, hot air fixation is the most significant. It is important that the material should be subjected to a constant temperature over its entire width during the thermosol fixation process since temperature fluctuations lead to colour differences. The specific optimum temperature and the duration of the process depends on the dye. In the case of temperatures which are too high there is a danger that the the dye already present in the fibre will re-sublime. If temperature stability is not ensured, dyes which are not very responsive to temperature differences must be selected. To achieve maximum dye utilisation the material should contain a certain amount of humidity. This should not, however, be too high as this could lead to dye agglomeration (flecks). Thermosol fixation during the thermosol dyeing process results in form stabilisation (thermosetting) as well as in dye fixation.

Thermosol pad-steam process Two-stage dyeing process for continuous dyeing of polyester/cotton mix fabrics with reactive and disperse dyes:

1. Padding with both dye groups (without alkali), drying, → Thermosol fixation.
2. Cold padding with alkali and steaming (fixation of reactive dyes).

Thermosol plants Combined plants designed for → Thermosol fixation which meet the following basic requirements: temperature accuracy and constancy over the entire material width and high production capacity, for which efficient measuring and recording units are a prerequisite. Dye uniformity in thermosol plants depends to a large extent on air circulation (Fig.) in the hot flues.

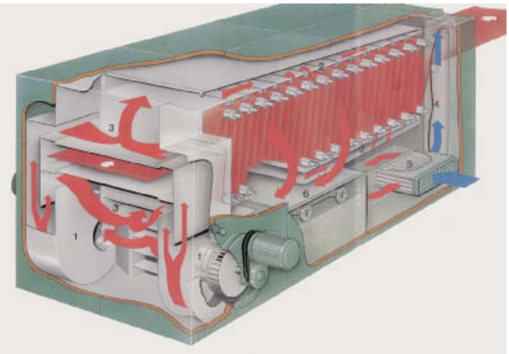

Fig.: Monforts Thermex system for thermosol fixation or hot air fixation of dyes.
1 = fans; 2 = distributor boxes; 3 = hot air; 4 = exhaust air; 5 = heat exchanger; 6 = sieve.

Thermosol single-bath processes These include:

I. Thermosol cold batch process,
II. Thermofix-thermosol process with urea,
III. Thermofix-thermosol process without urea,
IV. Thermosol-pad-steam process,
V. Thermofix-thermosol-pad-steam process,
VI. Thermosol-alkali-shock process,
VII. Thermofix-thermosol-alkali-shock process (one-shot process).

Thermosol stiffening Fabric stiffness and stiff texture brought about by → Thermosol fixation particularly of knitted fabrics in textured yarns which can be removed by subsequent wet treatments or on the mechanical breaking machine.

Thermosol two-bath processes These are divided into

I. Thermosol-exhaust process.
II. Thermosol-cold batch process.
III. Thermosol-thermofixation process.
IV. Thermosol pad-steam process without intermediate drying.
V. Thermosol pad-steam process with intermediate drying.

lation of contact thermometers. Heat sensors with, for example, a highly heat-sensitive fluid or, made of bimetal strips and used as impulse transmitters, transmit each contraction or expansion directly to an electrically operated steam inlet valve by making or breaking platinum contacts and opening the steam valve via a mercury relay after the set temperature has been reached. Various design principles (usually using compressed air, oil, or water). Varied use, for working liquor and processing machines of all types, drying aggregates, heating and cooling systems, boiler operation, hot water storage (contact switching of engines, ventilators, etc.), air temperature regulation, etc.

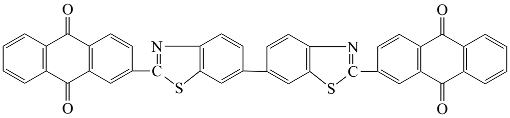
Thermoweave process Yarn or filament fibre used for producing carpet yarns by the bonding process are rolled and deep-frozen. This roll is sliced and the slices are bonded onto an underlay material.

Therm-Set process → Permanent-press process for cotton and polyester/cotton. The textiles are impregnated and dried with DHDMEU and a weak resin finishing catalyst (glycolic acid) before crosslinking and after-curing with a 1% magnesium chloride hexahydrate catalyst solution to fix pleats and creases in a pressing process.

Thiazine dyes A group of cationic, acid, mordant and sulphur dyes which are derived from phenthiazine (→ Heterocyclic compounds).

Thiazole → Heterocyclic compounds.

Thiazole dyes Dyes named after their principal structure (one or more thiazole, 5 atom rings) in various dye classes including cationic, direct, acid, sulphur and vat dyestuffs.



Thickener boiler Have lost their relevance as cold water soluble → Thickeners are more widely used. The most common thickener boilers are the double-wall boiler and the Votator with which the thickening boiling process can be carried out continuously and with pressure at over 100°C.

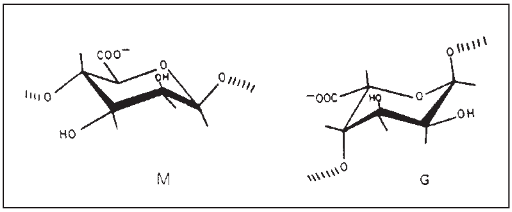


Fig. 1: Components of the alginates manuronate (left) and guluronate (right).

Thickener gel theory Thickening is made with polymer having a structural viscosity swollen to form a gel. As Flory demonstrated in his seminal work on crosslinking between 1941 and 1944, gelling occurs in a system when two crosslinking components per molecule used (monomer or polymer) are present. Below a critical total (α_c) only linear and branching molecules of finite size are present. Above (α_c) the system consists of an infinitely extending network encompassing the entire solution and a large number of finite branching clusters. When the topology formed during the reaction remains stable, homogenous, permanent, i.e. chemically-linked gels are referred to. In the case of reversible gels, however, the linkages are redissolved and can be reformed. Thus polymer chains can, for example, be linked to each other by means of hydrogen bonds, electrostatic interaction or dipole forces but also by “hydrophobic” interaction. These secondary valency bonds can be split temporarily by supplying energy (heat, mechanics). Alginates are composed of different (1–4) connected sequences of α-L-Guluronate and ß-D-Manuronate (Fig. 1), both homopolymer blocks and alternating sequences of monomer units.

Gelling occurs when monovalent ions (in particular Ca^{2+}) are exchanged. Gelling takes places with blocks of at least 20 guluronic acid units. However, blocks of manuronates play only a small part in the gelling process. The alternating sequences show no tendency towards association and therefore act as a solvent within the network. Rees proposed what he called the “egg box” model as the mechanism of Ca^{2+}-induced gelling of alginates (Fig. 2). Biaxial association of the guluronate results in a heavily-folded chain formation which contains “holes” the diameter of which corresponds to the ion radius of Ca^{2+}. O-atoms are located at a suitable

Thickener boiler Have lost their relevance as cold water soluble → Thickeners are more widely used. The most common thickener boilers are the double-wall boiler and the Votator with which the thickening boiling process can be carried out continuously and with pressure at over 100°C.

Thickener gel theory Thickening is made with polymer having a structural viscosity swollen to form a gel. As Flory demonstrated in his seminal work on crosslinking between 1941 and 1944, gelling occurs in a system when two crosslinking components per molecule used (monomer or polymer) are present. Below a critical total (α_c) only linear and branching molecules of finite size are present. Above (α_c) the system consists of an infinitely extending network encompassing the entire solution and a large number of finite branching clusters. When the topology formed during the reaction remains stable, homogenous, permanent, i.e. chemically-linked gels are referred to. In the case of reversible gels, however, the linkages are redissolved and can be reformed. Thus polymer chains can, for example, be linked to each other by means of hydrogen bonds, electrostatic interaction or dipole forces but also by "hydrophobic" interaction. These secondary valency bonds can be split temporarily by supplying energy (heat, mechanics). Alginates are composed of different (1–4) connected sequences of α-L-Guluronate and ß-D-Manuronate (Fig. 1), both homopolymer blocks and alternating sequences of monomer units.

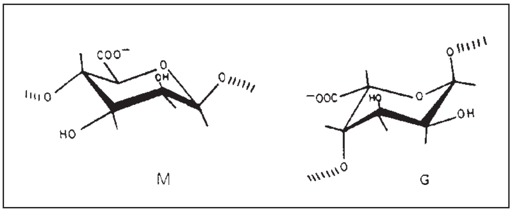

Fig. 1: Components of the alginates manuronate (left) and guluronate (right).

Gelling occurs when monovalent ions (in particular Ca^{2+}) are exchanged. Gelling takes places with blocks of at least 20 guluronic acid units. However, blocks of manuronates play only a small part in the gelling process. The alternating sequences show no tendency towards association and therefore act as a solvent within the network. Rees proposed what he called the "egg box" model as the mechanism of Ca^{2+}-induced gelling of alginates (Fig. 2). Biaxial association of the guluronate results in a heavily-folded chain formation which contains "holes" the diameter of which corresponds to the ion radius of Ca^{2+}. O-atoms are located at a suitable

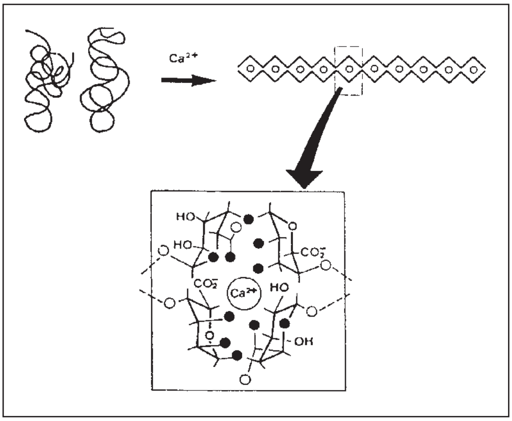

Fig. 2: The "eggbox"-model of non-reversible alginate gelation.

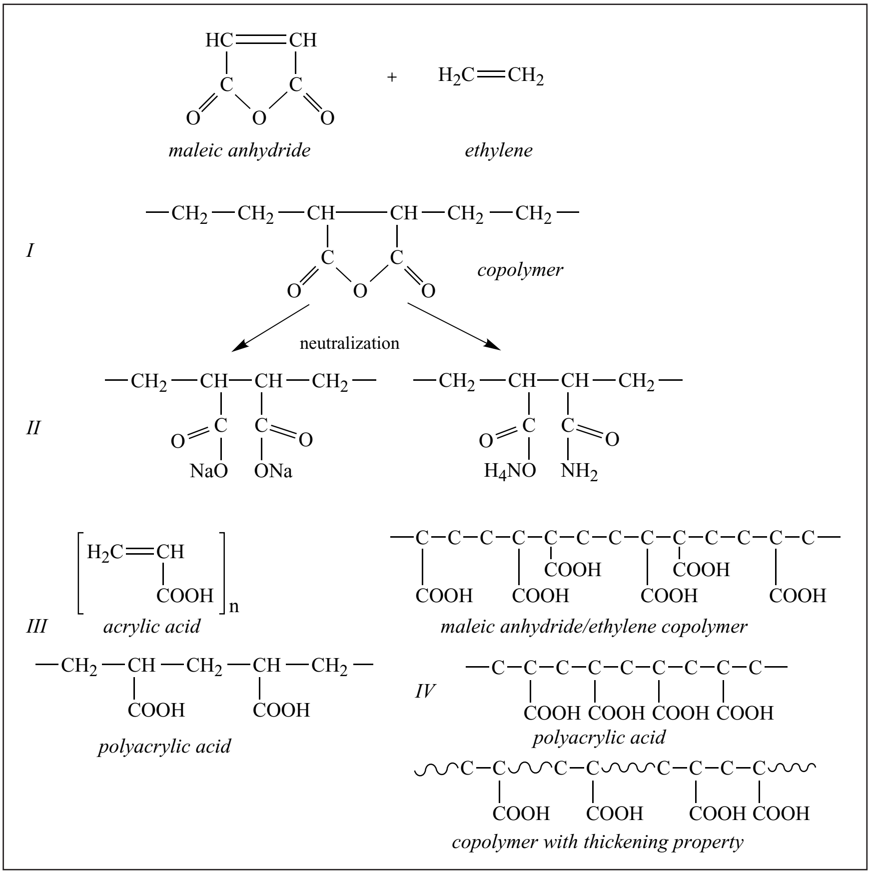

Fig. 3: Increase in the copolymer properties and fitness as a thickening agent due to the correct hydrophile carboxyl groups and hydrophobe components ratio (Zickzack).

location within these holes so that a deposit of Ca^{2+} in these holes stabilises the folded formation by means of complexing. Two polymer chains are linked to each other in parallel fashion by means of such – Ca^{2+}-chelate bridges. At higher Ca^{2+}-concentrations, several such double strings can form an association. The Ca-bridges between them are, however, considerably weaker and can be suppressed by high concentrations of single-value ions.

The manuronate blocks and the alternating sequences are not responsible for the formation of chelates and therefore prevent complete crystallisation of the alginates. Thickeners do, however, demonstrate similarity with liquid-crystallite surfactant solutions. The polymer chains have two different structural elements. Sequences which are capable of association and others which are unable to form an association. When they cool down those sequences capable of association form the linking points between the chains. The interspersed units prevent complete crystallisation of the polymers.

Association of the chains differs in strength depending on the degree of substitution and the thermodynamic conditions of the solution (ion strength, solvent activity). Gelling occurs when each polymer chain in the agent is associated with two others. Reversible gelling can be seen as a special case of polymer association (up to crystallisation). Quasi copolymer structure is a prerequisite. Thus, for example, copolymers of ethane and maleic acid anhydride represent synthetic thickeners; hydrophilic, carboxylic groups in the form of lateral chains (after neutralisation as carboxylate groups) alternate with hydrophobic areas (Fig. 3).

Such thickeners are structurally viscous in their flow characteristics and have a flow limit. Below this flow limit the viscosity is infinitely great and above it extremely low, causing printing pastes to flow through the screen mesh during the printing process. After the printing process, i.e. when the shear force is no longer present, the paste immediately adopts its original viscosity and remains still on the textile in exemplary fashion. This rheological property is demonstrated by benzine (white spirits) emulsions for example, which were the basis of pigment printing's success in the fif-

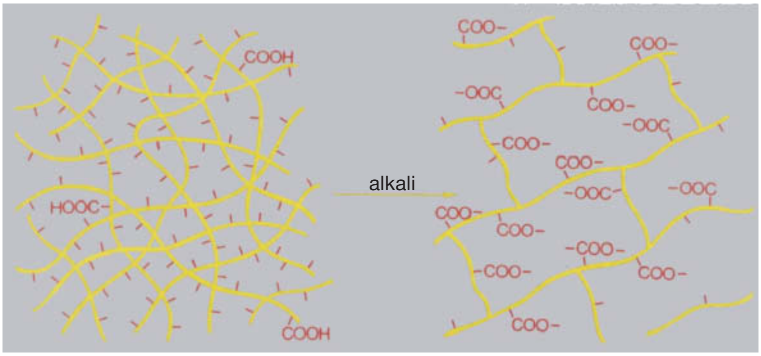

Fig. 4: Transition of polyacrylic acid copolymer in a colloidal solution into highly uniform, swollen, disperged polyacrylate gel, but with reversible gelation through the action of external energy (structural viscosity) (by Bayer).

ties. The use of benzine is, however, accompanied by a series of problems: flammability, odour, air and waste water contamination as well as the high price. For this reason benzine emulsions were replaced by synthetic thickeners as these have almost the same rheological properties as emulsion thickeners.

The substances in synthetic thickeners are "packets" of long molecule chains. The "packets" are achieved by weak crosslinking of macro-molecules which are produced by polymerisation and copolymerisation of suitable oleofinic monomers (e.g. acrylic acid, maleic acid anhydride). They are polyanionic bodies which only become effective as thickeners in the dissociated state. As the acids only dissociate very slightly even in water, they are transferred to the corresponding ammonium salt. The initially tangled packet of polyacid is now capable of expanding. It surrounds itself with a solvent shell. The bonding energy of the hydrosphere on the "balloons" is so slight that even slight stirring disturbs the structure of the system reversibly. The molecules align themselves parallel to the shear direction at an increasing speed difference (elongation and orientation) which renders the flow limit considerably more pronounced. This alignment of the molecules allows them to glide past each other more easily, which is expressed in decreased inner friction and viscosity (viscosity loss). After shearing and completion of the printing process the elongated molecules spontaneously take on their original tangled state as a result of the Brownian movement. Deformed drops become round again. The original resting viscosity has been assumed again (Fig. 4).

Synthetic thickeners act as a catalyst in pigment printing pastes and replace the otherwise necessary acidifier in benzine emulsions. In similar fashion to the acidifier (ammonium salts of low volatile inorganic acids), the ammonia evaporates on drying after the printing process, rendering the system acid via the polymer-bound carboxylic groups. The hydrophobic areas result, for example, from the monomers styrene, butadiene and acrylic acid ester in the copolymer. Copolymers of acrylic and maleic acid anhydride are statistically dissolved colloidally in the form of tangles in the water and gelling occurs, i.e. swelling and dispersion, if alkali is added (Fig. 4).

The quasi liquid-crystallite structure in the reversibly swollen gel can be imagined like a fringed micelle (Fig. 5) (with the crosslinking points in the gel similar to the crystallites shown by Hermann in 1930). As only like blocks can "crystallise", the length and distribution of the hydrophilic and hydrophobic blocks determine the thickness and length growth of the liquid crystals. The polymer chains can run through several "crystalline" areas causing a net-like structure to occur. A factor which influences gelling is the amount and the nature of the free dilution enthalpy relative to the free melting enthalpy of the crystallites.

For the thermodynamic interaction between network and solvent in the gel Flory derived a relationship in the form of osmotic pressure in a grid model. In addition to the interactions between polymer/polymer, polymer/solvent and solvent/solvent, which are also present in solutions, a contribution from the entropy-

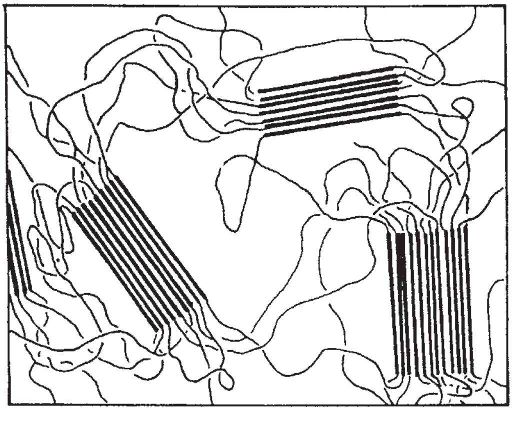

Fig. 5: Model of the fringed micelle network points in swollen gel.

name	Individual constituents	Solubility and viscosity behaviour in water	Gel formation
starch	glucose	swelling from approx. 60°C, viscosity behaviour variable, dependent on the amylose/ amylopectin ratio	gel formation at RT, destruction of gel structure in storage due to retrogradation
guar	mannose, galactose 2:1	soluble at RT, 1% solution: 3–4 Pa · s, electrolyte and pH resistant	no gel formation (only after the admixture of borate)
carob seed grain ether	mannose, galactose 4:1	soluble at 80 – 90°C 1% solution: 0.05–0.3 Pa · s electrolyte and pH resistant	no gel formation (only after the admixture of borate)
agar	galactose 3.6, anhydrogalactose approx. 1:1	soluble at 80–90°C, 1% solution: 0.005-0.01 Pa x s, electrolyte resistant	gel formation reversible, melting point: 80°C, gel temp. 30°C
gum arabic	arabinose, rhamnose, galactose, glucuronic acid 3.5:1.1 : 2.9:1.6	soluble at RT, 1% solution: 0.002–0.005 Pa · s, 20% solution: 0.03 Pa · s, electrolyte and pH dependent (max. pH 6-7)	no gel formation
gum tragacanth	arabinose, xylose, rhamnose, fucose, glucose, galactose, galacturonic acid	partially soluble at RT, 1% solution: 0.5–2 Pa · s: electrolyte and pH resistant	virtually gel-like consistency
carragheen (kappa, iota)	galactose 3.6, anhydrogalactose approx. 1:1 esterified with H_2SO_4	soluble at 50–60°C, 1% solution: 0.05–0.3 Pa · s, sensitive to electrolyte and pH	weak gel formation reinforced by K^+ ions + carob seed grain ether, reversible
lambda	galactose esterified with H_2SO_4		no gel formation
pectin	galacturonic acid (main constituent) galactose, arabinose, rhamnose (secondary constituent)	sodium salt, methylester soluble at RT, 1% solution: 0.005–0.1 Pa · s, sensitive to electrolyte and pH	highly esterified: gel formation with sugar + acids, irreversible, low esterification: gel formation with calcium salts, reversible
algin	mannuronic acid, guluronic acid 1:(0.5–1.9)	sodium salt, soluble at RT, 1% solution: 0.1–1.5 Pa · s sensitive to electrolyte and pH	gel formation with calcium salts, reversible
xanthane	glucose, mannose, glucuronic acid 2.8: 3.2 esterified with pyruvic acid + acetic acid	soluble at RT, 1% solution: 1.2 Pa · s, low dependency on electrolyte and temperature	no gel formation on its own, good gel formation with carob seed grain ether, reversible

Tab. 1: Survey of the properties of the most important polysaccharide-containing thickeners: natural products (according to Scherz).

elastic force of the network also has to be taken into consideration. It is a question of a swelling balance which can be displaced at any time by external influences such as, for example, mechanical squeegee force. Gelling is, therefore, reversible. The idea of quasi-crystallites is vivid if one remembers that the melting point as a thermodynamic property is characterised by the complete disappearance of the crystalline phase, i.e. the most stable crystal. The gelling point on the other hand is a purely topological property. The topology is not only determined by the long and large crystals but also by the large number of small associates whose melting point is lower and which only make a slight contribution to the melting point. The capacity to gel differs in the most frequently used thickeners, as shown in Tables 1 + 2.

This can be explained as follows: for pigment printing such high-solid thickeners are not commonly used as in direct printing. High-solid thickeners form “quasi-liquid crystals” depending on the concentration of dry substance in the thickener or exclusively tangle structure (Fig. 6). These super-structures depend to a large extent on the degree of polymerisation of the thickeners. The following therefore applies:

a) The concentration of possible bonding points is proportional to the polymer concentration.
b) The concentration of crosslinking points is proportional to the concentration of polymer molecules at the gelling point.
c) The binary association balance (free chains/crystallite) between crosslinking point and free bonding point is described by a van’t-Hoff’s Isochore.

Under these conditions the following parameters result for the link between polymer concentration c_p and “melting temperature” of the gel, $T_m{}^g$,

$$\ln (c_p) = \frac{\Delta H_m}{RT_m} + \text{const.}$$

ΔH_m being the dissociation energy of the crosslinking point. The connection between melting point of crystallite and gelling point is

$$\frac{1}{T_m{}^g - 1/T_m{}^k} = R \ln \frac{x}{\Delta H_u - 2\,\sigma_{ec}}$$

The end surface energy σ_{ec} is always smaller than the melting enthalpy ΔH_u. This means that the melting point $T_m{}^g$ of the gel with a fringed micelle gel is always below the melting point of the crystallite $T_m{}^k$. The gelling point is described by the probability of the presence of two branching points per polymer chain and according to Flory is dictated by

$$p_c = \frac{1}{f-1}$$

f = M(f–2) +2 is the functionality of the polymers with a degree of polymerisation of M. On the other hand the probability p_b exists of bonding between two monomer units according to statistical thermodynamics.

$$p_b = \frac{(1-\zeta)^{\frac{-E}{kT}}}{\zeta^{\frac{-W}{kT}} + (1-\zeta)^{\frac{-E}{kT}}}$$

E = bonding energy between monomer units;
ζ = weighting factor taking into account the semitropical difference between directed bonding to uncontrolled van-der-Waals interaction.

network dissolution structure	characteristic	rheological characterisation	printing result
	polymer concentration > $C_{crit.}$, no uncombined liquor, low thickener concentrations, “wide network dissolution,” high molecular weights	viscosity: high, shear sensitivity: high, covers a wide area of the speed gradient, viscosity at rest: immeasurable, elasticity: very high	colour application: high, contours: poor, reason: water extracted from the polymer network by the woven fabric capillary system
			
	polymer concentration > $C_{crit.}$, no uncombined liquor, higher thickener concentrations, “dense network dissolution”, low molecular weights	viscosity: average to high, shear sensitivity: marked, elasticity: high	colour application: good, contours: good

Fig. 6: Dependency of thickening property on polymer structure in the case of polyacrylic acid (according to Schulz).

If solvent is still present in the gelling system, bonding probability p_b has to be multiplied by probability a, a being the bonding probability that two adjacent grid places are occupied by a monomer segment. Thus a reduces the effective functionality of the polymers. Existing interaction between solvent/solvent and solvent/polymer is taken into account by factor a. By means of this interaction a is linked to the temperature. Thus the following condition results for the gelling point of a polymer/solvent mixture

$$p_b = a\, p_b(T)$$

i.e. there is a temperature $T_{max,}$ above which there can be no more gelling, no matter what the polymer concentration is, as a is always = 1. Low-solid thickeners also form super-structures in swollen gels but at considerably lower concentrations (Fig. 7) than high-solid thickeners. Low-solid thickeners are used as opposed to high-solid ones for emulsion thickeners. If they have a polyacrylic acid base, the structural viscosity proves to be very electrolyte-sensitive. In Fig. 8 the viscosity sinks considerably in the presence of a disperse dye with anionic dispersing agents, whereas the use of non-ionic dispersing agents has little influence on the course of the viscosity curve of the thickener.

Low-solid polyacrylic acid derivatives have become important in the area of thickeners for pigment printing for the following reasons: these ionised polyvalent chain polymers have polar or polarised groups incorporated in their molecule causing adhesion to the fibre and to the binder film by means of secondary valency forces. In addition to the adhesive effect, the thickening effect of this polyelectrolyte is significant in that it passes a maximum at a certain electrolyte concentration and can also have a thixotropic flow property. These products also have good emulsification properties. The acid groups in the molecule render the addition of an acidifier for condensation of the binder film superfluous. The concept of low-solid thickening originates from the time when pigment printing was applied using benzine as one phase and water as another in an emulsion. As heavy benzine and water evaporate when dried after printing, an emulsion is practically solid-free = free of

name	individual constituents	solubility and viscosity behaviour in water	gel formation
pregelatinised starch	glucose	swelling at RT, otherwise behaviour like natural starch	gel formation
thermally modified starch	glucose	soluble at RT, reduction in viscosity, increase in solution transparency	weak to no gel formation
acid modified starch 60°C	glucose	soluble from 60°C, reduced viscosity , in heat, low retrogradation,improved solution transparency	improved gelling ability
starch monophosphate	glucose esterified with H_3PO_4	soluble at RT, cold-swelling, clear solution, no retrogradation, good freezing and dew stability	no gel formation
di-starch phosphate	glucose with H_3PO_4 bridges	reduced swelling capacity, markedly improved viscosity stability at high temp., no retrogradation, good freezing and dew stability	gel formation reduced
starch acetate	glucose esterified with acetic acid	soluble at RT, clear solution, no retrogradation, little sensitivity to pH and electrolyte	no gel formation
methyl cellulose	glucose, methyl glucose	soluble at RT, falling out in the heat, 1% solution, ca.. 0.15 Pa · s	no gel formation at RT, reversible gel formation in heat
carboxymethyl cellulose	glucose, carboxy methyl glucose	soluble at RT, 1% solution: 0.05-1.2 Pa · s, sensitive to electrolyte and pH	gel formation with trivalent ions (e.g. Al)
propene glycol alginate	mannuronic acid, guluronic acid esterified with 1.2-propene glycol	soluble at RT, improved acid stability	gel formation with calcium: dependent on degree of esterification

dry substances, unless mixtures (wrongly known as “semi-emulsions”) to which small quantities of suitable, known thickeners (e.g. alginates, tragacanth, starch ethers) are added to a pure emulsion. This lack of solids in an emulsion provides a considerable improvement of handle as well as reducing effluent. There are also technical advantages from the printing point of view: as a result of the low surface tension, emulsion thickeners penetrate the fabric surface rapidly; a good push through is achieved and only small quantities of substance adhere to the screen. Emulsion thickeners are also not very sensitive to flushing of prints.

With the W/O system the emulsion frequently collapses as soon as it comes into contact with the fabric. The smaller the water droplets emulsified, the more this phenomenon can be counteracted. Pigment printing first utilised the advantage of solid-free, soft-handle thickener with the W/O system. As the greater inner phase consists of water, the solution and diffusion processes are often more productive. For environmental reasons the use of benzine is unfavourable as long as the emulsion is not used for low-benzine pigment printing by adding suitable wetting agents or hydrotropic compounds. With the type of emulsion used for benzine-free pigment printing one has to differentiate between an external, coherent phase, the dispersion medium (= dispersing agent) and the inner dispersion (= dispersed) phase. The degree of dispersion shows whether coarse dispersion, fine and colloidal-dispersions or high and molecular-dispersed ranges are present. Differentiation is also made between mono- and polydisperse systems depending on whether the particles are of identical or different size. By means of suitable emulsifiers, liquids which are actually not miscible are brought together to form a system which is as stable as possible using the necessary energy and the resulting significant increase of the inner phase (which in the thermodynamic sense does not exist in a stable state). With earlier benzine-based emulsions water and heavy benzine were used (boiling point 150–200°C, aromatic portion as low as possible, low Kauri-butanol values) and special emulsifiers with a hydrophilic/lipophilic-balanced polar structure. With HLB-values (hydrophilic/lipophilic balance) which are recorded in a norm system of 1–40, those emulsifiers which lead to water-in-oil emulsions (W/O) lie within the range of 3–6, i.e. in which the external phase is the oil (e.g. the heavy benzine) and the dispersed phase is the water. With emulsifiers with HLB-values of generally between 8 and 18, the system oil-in-water occurs (O/W) in which the phases are the other way round; the lower quantity of water is to be found in the external phase. Due to surface tension the liquid particles are normally present in the dispersed phase in symmetrically-ordered fashion in the form of small globules. Where a monodisperse system is densely packed with globules, the inner phase amounts to 74%. Due to the high volume proportion of the inner phase, emulsion pastes have a stiff consistency and high structural viscosity. Because of their globule structure emulsions also demonstrate a structure-viscous flow curve with a flow limit and typical plastic characteristics. The emulsifier builds an “interfacial film” around the globule-like particles of the dispersed phase. It can have monomolecular or multiple-molecular thickness and these molecules themselves are submerged into “their” adjacent liquids with their hydrophilic or lipophilic polar ends in brush or globule structure. The lateral surfaces of these rod-shaped emulsifier molecules can also either be interspersed with gaps or lie closely to one another causing an open or closed interfacial film to be formed (according to Wigger, ter Meer and Schlösser).

Thickener powder dissolving unit Dry, pourable thickener powder that is cold-soluble often has a tendency to form lumps when being mixed. Each powder particle therefore has to be wet-out immediately with water. With intensive stirring (Fig. 1) the preparation time (including swelling time) can be reduced considerably. In normal scattering processes preparation takes 60–90 min. with 6–12 h swelling time. A system (Fig. 2) for preparing thickener in the printing dye works produces thickener stock solutions.

Thickeners Usually water-soluble, swellable substances with colloidal character which are used in their thickened state as thickeners for printing with aqueous solutions of dyes, pigments and the like are

Individual thickeners and their properties:

1. Galactomannans: Galactomannans are polysaccharides which are predominantly constructed of the individual sugars mannose and galactose (Tab. 1). The mannose components form a chain of several hundred (1,4)-ß-D-mannopyranosyl-units which carry bonded α-D-galactopyranosyl units at varying distances (1,6) depending on the origin of the plant. Such galactomannans are mainly found in the endosperm of seeds from plants of the leguminosae species. These leguminous substances are in many cases able to supply themselves with nitrogen from the air via tuber bacteria. The galactomannan is incorporated plastically in the cells of the endosperm and can be released and produced by cell-destroying selective grinding.

Carubin, which is made of locust bean flour, had already been marketed in the twenties, and this was followed by guar (Tab. 2), fabricated from the guar seed, in 1953. It had been developed in the U.S.A. during the Second World War when the most important areas cultivating the locust bean tree around the Mediterranean were involved in the events of the war preventing access to locust bean sources.

Modification processes give locust bean meal a particular solubility in cold water, flexible thickening films, electrolyte-stability as well as better compatibility with dyes and chemicals.

Alkaline degradation and ethoxylation have the following effect:

- optimum cold-water solubility in a wide pH range (carboxymethylated products can be difficult to dissolve in the acid range),
- low salt content,
- optimum heavy metal salt stability.

Chemical treatments naturally also have an impact on environmental properties and the degradability of such thickeners (Tab. 3).

2. Starches:

a) Thermal decomposition of maize starch: this causes dextrin to be produced which is known as roasted starch or British gum. These are low-viscosity products which are used as colour-intensifying components. A further development is roasted swelling starch which is soluble in cold water.

b) Carboxymethylisation of maize starch: this process results in starch ethers which are all soluble in cold water. Starch ethers are predominantly used as colour-intensifying components in thickener combinations.

3. Celluloses: methyl-, carboxymethyl-, hydroxyethyl- and hydroxypropyl celluloses are used to a small extent in the printing industry. Depending on the degree of substitution the possibilities for use are varied including hot steam treatment and as an alginate substitute in reactive printing.

4. Alginates: fabricated predominantly from brown algae by precipitation and separation of the alginic acid with subsequent solution in caustic soda liquor or ammonia resulting in sodium and ammonium alginates.

5. Natural types of gum: all of these types must be subjected to a lengthy process of cleaning, hydrolysing and bleaching due to the high purity specification in textile printing. This method results in medium-to-low-viscosity thickeners with faster solution and good chemical stability.

a) Crystal rubber: a crystal-like gum-resin from cherry and almond trees from the Shiraz region of Iran. For this reason this is known as “Shiraz gum”.

b) Gum arabic: a dried, crystal-like plant juice from acacia arabica, also known as Senegal or Kordofan gum. This is no longer widely used in printing.

c) Tragacanth gum: a gum-related, dried plant juice of the astralagus type which is traded in plate or shell form. The colour is greyish white to reddish and usually indicates the degree of contamination. Tragacanth gum was a widely-used thickener in printing until the mid fifties.

6. Combination thickeners: in order to utilise the various properties of the different thickeners, two or three products are often used in combination. Whereas printers previously purchased the individual components separately, thickener manufacturers are increasingly asked to supply ready-mixed combinations. This is the most significant reason for the large number of printing thickeners to be found on the market. The reasons for using such combination products are numerous and range from increased colour yield and improved washing out capacity to cost reduction.

Important criteria when testing and assessing printing thickeners are:

- initial behaviour in water,
- viscosity and swelling rate,
- residues,
- push-through capability,
- pH,
- sieving capability,
- storage stability,

In addition to these criteria, print strike-offs are carried out on the textiles to be printed and assessed from the point of view of the following:

- colour yield,
- contour effects,

Basic galactomannan	Chemical change	Preferred field of application
Guarana Galactomannan 1.2	Unchanged	Carpet printing/dyeing Acid and metal complex dyes
	Depolymerised	Carpet printing/dyeing Acid and metal complex dyes Cotton/viscose Vat, substantive, fast salt dyes Polyester Disperse dyes Polyamide Acid and metal complex dyes Polyacrylic Cationic dyes
	Hydroxyethylated $-CH_2-CH_2-OH$	Carpet printing/dyeing Acid and metal complex dyes Cotton Africa print with fast salt Cotton/viscose Vat dyes Polyester Disperse dyes Polyamide Acid and metal complex dyes Polyacrylic Cationic dyes
	Hydroxypropylated $-CH_2-CHCH_3-OH$ Additionally depolymerised	Carpet printing/dyeing Acid and metal complex dyes Sizing
	Carboxymethylated $-CH_2-COO^-Na^+$	Carpet printing/dyeing Acid and metal complex dyes Cotton Vat/reactive dyes (conditional)
Carubin Galactomannan 1.4	Hydroxyethylated $-CH_2-CH_2-OH$	Carpet printing/dyeing Acid and metal complex dyes Cotton Africa print with fast salt Polyester Disperse dyes Polyamide Acid and metal complex dyes Polyacrylic Cationic dyes Wool/silk Acid and metal complex dyes
	Carboxylated $-CH_2-COO^-Na^+$	Cotton/viscose Vat dyes Wool/silk Acid dyes
Cassia Galactomannan 1.5	Hydroxypropylated $-CH_2-CHCH_3OH$ Additionally depolymerised	Sizing
	Carboxylated $-CH_2-COO^-Na^+$ Additionally depolymerised	Carpet printing/dyeing Acid and metal complex dyes Cotton/viscose Vat dyes Wool Acid dyes

Tab. 4: Fields of application of different thickening agents. +++ of importance; + of little importance; – of no importance.

- evenness of distribution,
- penetration,
- ease of washing out,
- handling properties.

One look at the range of textile materials made of natural and synthetic fibres and the variety of products available (from yarn to carpet and the finest taffeta fabric) makes it clear that it is not possible to print with only one type of thickener. Even if it is understandable for cost and environmental reasons that the printer aims to work with a thickener which is as low in solids and has as high a viscosity as possible, it is important to differentiate as the requirements for individual articles are different.

When selecting the print thickener the most important factors are:

- chemical compatibility with the dyes and chemicals to be used,
- the necessary high solids content (a high-viscosity locust bean flour is, for example, generally adequate for printing carpets whereas a polyamide umbrella silk definitely requires a low-viscosity thickener),
- machine facilities (dissolving systems and printing machinery),
- capacity of the thickener to be washed out and its ecological properties,
- costs of thickener taking into consideration the required quantity to be used.

Tab. 4 shows which natural substances are mainly used with different synthetic fibres.

Thickeners for pigment printing Emulsion thickeners are useful for pigment printing. The viscosity of emulsions plays a decisive role not only as far as subjective quality assessment is concerned. In addition thickeners must be dosed, applied and dispersed easily. In order to be able to adjust the required viscosities of emulsions, structurally different high-molecular or low-molecular additives are used according to their phase properties in aqueous medium usually in combination with surfactants, co-surfactants and electrolytes.

Most surfactant formulations are based on alkyl ether sulphates or alkyl sulphates mixed with betaines or amphoteric co-surfactants, the viscosity being adjusted by the addition of salt and/or fatty acid alkanol amides. When formulating emulsion thickeners surfactants are used which place particular demands on the effectiveness of a thickener. An additional factor is the possible formation of nitrosamine (NDELA) due to the unavoidable presence of free diethanolamine in the alkanol amides. It is therefore recommended to refrain from the use of secondary amines. At-

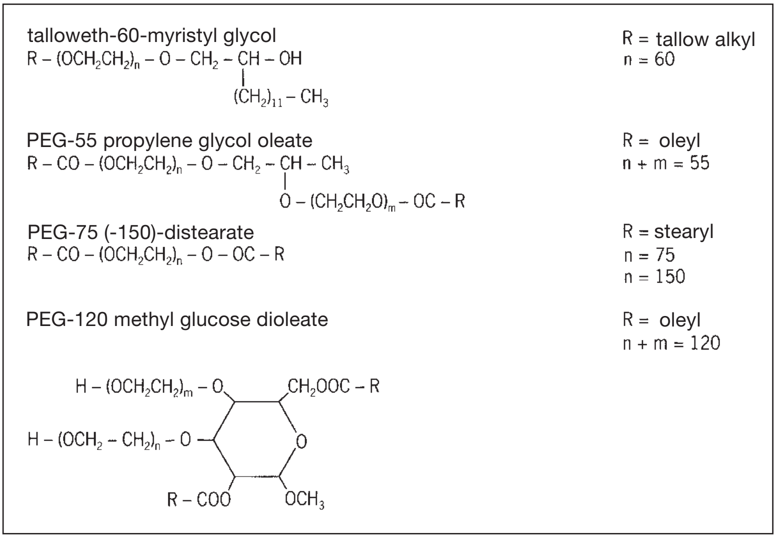

Fig. 1: Selected nitrogen-free thickeners (Henkel).

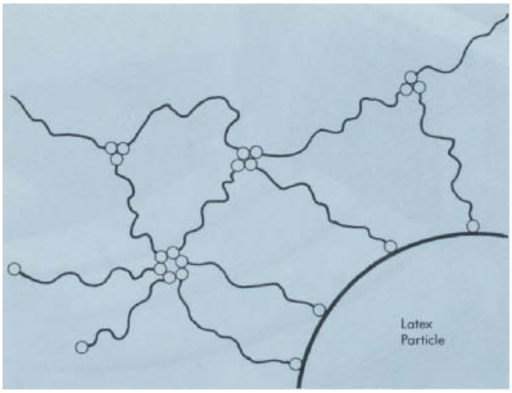

Fig. 2: Associative thickeners (Röhm).

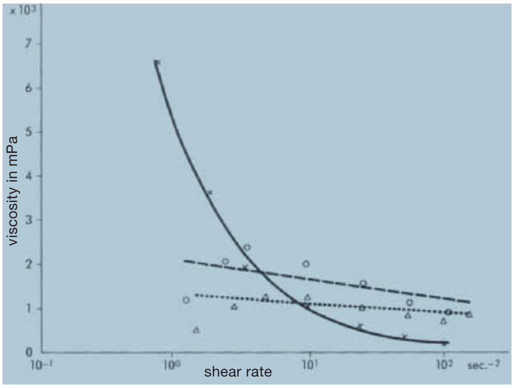

Fig. 3: Viscosity curves of alkyd resin lacquers and dispersion lacquers.
— x dispersion based on hydroxyethyl cellulose as the thickener; – – – O dispersion lacquer based on associative thickeners; - - - Δ alkyd resin lacquer.

tempts were made recently to develop new nitrogen-free additives to adjust viscosity (Fig. 1).

The viscosity-increasing effect of polymer thickeners in dilute aqueous surfactant solutions is due particularly to the construction of a three-dimensional hydratized network in the water phase into which the surfactant micelles are incorporated. Viscosity-promoting synergetic interaction between surfactant and polymers is an additional factor. In a similar fashion this mechanism is also relevant for synthetic co-polymers and chemically-modified natural polymers which can be used as thickeners. Associated thickeners on a polyacryl basis are alkali-soluble acryl polymers containing hydrophobic groups and behave in a similar fashion to a polymer emulsifier, i.e. the hydrophobic groups of the thickener molecules form an association creating a network and causing a viscosity increase. The dispersion and pigment particles are incorporated into the network formed by the thickener resulting in a stable dye paste with virtually Newton-like flow properties. The interaction between dispersion and the thickener also plays a significant role (Fig. 2). Appropriate structural viscosity naturally depends on the formulation of the thickener (Fig. 3).

Thickeners for printing reactive dyes Reactive dyes could not previously be used with locust bean meal thickeners on a galactomannan basis for printing as the dye reaction with highly-reactive galactomannan-OH-groups results in a stiff fabric handle. For this reason alginates are used exclusively which do not yield undesired reactions as they are polyuron acids. However, a guar-based thickener is fabricated by chemical modification of the galactomannan-OH-groups which can be used with reactive dyes without any effect on handle.

Thickness of textile fabrics DIN 53 855 Sheets 1 and 2 defines the following concepts (for textile with raw thickness of > 0.05 g/cm^3 ; with the exception of floor coverings):

I. Thickness a: Distance between upper and lower side of a textile fabric, measured as the distance of two plane parallel measuring plates of a certain size between which the textile fabric is located under a certain measured pressure. At a raw thickness of > 0.1 g/cn3 the size of the surface to be measured and the pressure on the textile fabric is defined.

II. Norm thickness a_x: thickness at a defined measured pressure and test area. It also serves as a reference dimension when calculating the raw density, the relative compressibility and dimensions derived from this.

III. Absolute compressibility Za_x: difference of norm thickness and thickness at 10 times greater measured pressure.

IV. Relative compressibility ZR_x: relationship of ZA_x to norm thickness or thickness as %.

Thin layer chromatography (TLC). A method for the separation of extremely small quantities of individual substances in mixtures by adsorption and partition chromatography. The procedure involves the use of glass slides which are coated with a thin, well-anchored sorbent layer (e.g. silica gels, aluminium oxide) so that development can proceed on a rising solvent front. Advantages in comparison with paper chromatography are:

- less time-consuming,
- as a rule, purely inorganic sorbent layers are employed,
- sharper separation effect and lower detection limit,
- extremely small quantity of test substance required,
- very simple procedure.

TLC utilizes the different distribution ratios of substances in the mobile (liquid) phase on the one hand, and in the stationary liquid phase adhering to a polar solid substrate on the other. Because of its simplicity, it is often used for preliminary checks on the purity of samples or to supplement other test methods. Procedure: a commercially prepared, coated glass or plastic plate is placed in a suitable eluent mixture in a closed container saturated with mobile solvent vapour. The eluent ascends by capillary forces and the substances applied on the start line at the bottom are eluted along with it. The different distribution coefficients of the substances lead to different migration rates which, in turn, result in separation. Mixtures of methanol, acetic ester, chloroform, distilled water, glacial acetic acid, heptane, etc. are used as eluents. When choosing the eluent, it is essential that the solubility of the substances being separated is taken into consideration. If the substances are too readily soluble, no separation takes place as they migrate along with the mobile solvent front. Too low a solubility, on the other hand, leads to the components not migrating from the point of application or the formation of blurred, indistinct peaks.

Thin shade Term used particularly when sampling dark colours to describe missing → Bloom or character.

Thio Gk.: thios = sulphur.

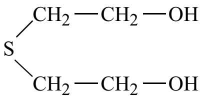
Thiocarbamide → Thiourea.

Thio compounds (Gk.: thios = sulphur). They are derived from oxygen compounds whose oxygen was substituted by usually divalent sulphur. Examples are sulphurous acid ($H_2S_2O_3$) and sodium thiosulphate ($Na_2S_2O_3$). Other thio compounds are, for example, thioethers (alkyl sulphides) of the type $H_5C_2–S–C_2H_5$ and thiophenols of the type (C_6H_5)SH.

Thiocyanates SCN-type compounds, e.g. thiocyanic acid HSCN and its salts, thiocyanates, such as → Potassium thiocyanate and KSCN. Thiocyanates are usually colourless and easily soluble; only lead thiocyanate is difficult to dissolve; copper, mercury and silver thiocyanates are not soluble. With iron(III)-chloride solution ($FeCl_3$), soluble thiocyanates result in a typical blood-red colour (iron detection).

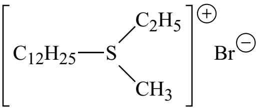
Thiocyanate/tin discharges A very aggressive discharge system → Tin salt discharges which are carried out under stringent conditions.

Thiodiethylene glycol (thiodiglycol).



Substance with a molecular weight of 122 and b.p. at 282°C which is used as a dye solvent and fixation accelerator for vat printing. Contact with hot hydrochloric acid results in the formation of mustard gas: $S(CH_2–CH_2–Cl)_2$.

Thioethers (alkyl sulphides, type: $R–S–R_1$) alkyl-substituted → Mercaptans and/or dialkyl derivatives of hydrogen sulphide such as dimethyl sulphide ($CH_3–S–CH_3$) or methylethyl sulphide ($CH_3–S–C_2H_5$). They are used as the basis of textile auxiliaries. Thus, for example, the thioether, dodecylmethylethyl sulphide, results in the corresponding cationic sulphonium compound.



Oxethylated thioethers on the other hand serve as the basis of non-ionic wetting agents and detergents ($C_{12}–H_{25}–S–(C_2H_4–O)_n–C_2H_4–OH$). Thioethers are usually water-soluble, in their pure form not unpleasant smelling liquids, which turn into sulphoxides ($R_2–SO$) and sulphones ($R_2–SO_2$) as a result of strong oxidation.

Thioglycolate number Test for evidence of damage to wool (particularly in the case of acid damage) in which the solubility of wool in alkaline thioglycolate solution is determined and quoted as a percentage. Untreated wool has a thioglycolate number of 15.9; after treatment with sodium carbonate: 0.00–6.8; with H_2O_2: 18.7–25.8, with H_2SO_4: 27.0–89.5. Determination of the thioglycolate number (based particularly on peptide splitting) is a valuable supplementation of alkali solubility determination (specifically on initiating cystine splitting).

Thioglycolates Salt of → Thioglycolic acid.

Thioglycolic acid (mercaptoacetic acid), $HS–CH_2–COOH$; unpleasant smelling, oily, colourless 80–85% liquid with a density of 1.325 and a boiling point of 104°C. It is miscible with water and boils easily (particularly in the presence of copper, iron and manganese). Thioglycolic acid is used, for example, for establishing the thiglycolate number; dehairing skins in tanning facilities, alkali stabilization of wool, removing rust and boiler scale, removing heavy metal contamination from water, providing evidence of iron and molybdenum by means of colourimetric determination, as an additive for artificial resins and synthetic rubber. The ammonium salt of thioglycolic acid, ammonium thioglycolate, is a strong reducing agent which is used widely for surface finish and permanent crease and pleat fixation in woollen articles as well as in the production of cold permanent wave effects. Basically the sulphur bonds of wool keratine are split reductively: $R–CH_2–S–S–CH_2–R \rightarrow R–CH_2–SH + HS–CH_2–R$. The wool fibre can therefore assume a new form which remains stable after washing and cleaning after the reducing effect has ceased.

Thioglycol test,

I. With Ferric(III)-chloride: a few drops of 5% solution in aqueous test extract (can also be carried out specifically on wool), adjust to alkaline using ammonia, red violet colour is a positive result.

II. With sodium nitroprusside: a few drops of 1% solution in aqueous test extract, adjust alkaline using dilute ammonia, red violet colour provides positive result.

-thiol Term used for organic compounds with the group R–SH of the type → Mercaptans which result, for example, during sulphitolysis of wool cysteine.

Thiol-catalysed disulphide exchange Self-cross linking reaction in wool during certain fixation processes (see Fig.). Both reducing agents (e.g. overheated steam) and bases produce wool-bound cystine ions out of cystine (in the case of reducing agents) or out of cysteine (in the case of the bases) which cause disulphide exchange during the further course of orientation (stretching). → Wool chemistry.

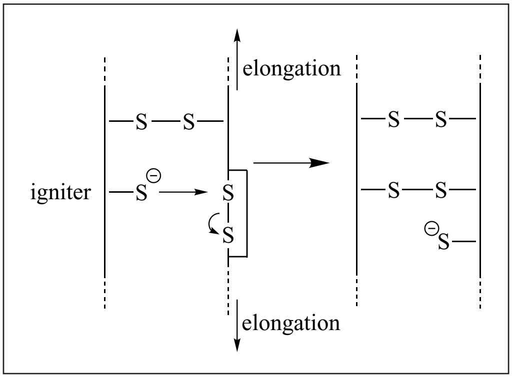


Fig.: Result of thiol-catalysed disulphide exchange in wool: additional crosslinking = stabilization.

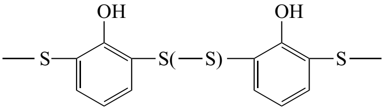
Thiols → Mercaptans.

Thionaphthene → Heterocyclic compounds.

Thionyl chloride An acid chloride of sulphorous acid: $SOC1_2$; colourless liquid which produces smoke when exposed to air, smells suffocating and is strongly light-refracting. It splits in water to HC1 and SO_2. Density 1.638; b.p. 78°C. Thionyl chloride is categorized as a “particularly dangerous substance” of high inhalation toxicity with less than 4 ppm/h. This value can only be seen as an average as the exact limit of inhalation duration cannot be determined. Thionyl chloride is used among other things for providing evidence of polyvinyl alcohol sizes; pass steam through of an aqueous fibre extract, after cooling add thionyl chloride until yellow coloration indicates total solution has taken place: change of colour to black-brown, then black precipitation as positive evidence for formation of characteristically coloured polyenes.

Thiophene → Heterocyclic compounds.

Thiophenols Phenol sulphur products which are used as reserving agents and tannin substitutes. Fat-free, aromatic products.



Thioplasts Rubber-elastic polycondensation products (elastomers) of dihalogen compounds with sodium polysulphide (Na_2S_4). The reaction products are precipitated as a coherent mass but contain many foul-smelling by-products which limit their technical usefulness. Like natural rubber, thioplasts are supplemented by filling materials, rolled and vulcanized. They decompose in acid and alkaline solutions but are characterized by high oil and petrol resistance. They can be hardened by means of oxidising agents which bring about a linking of the sulphur atoms. Equipment items made of thioplasts are used predominantly where high solvent resistance is required, for example in chem. apparatus construction, for boilers and pipe linings, cable coverings, fuel pipes and insulation materials. Thioplasts are used to a lesser extent as binding agents and protective coatings.

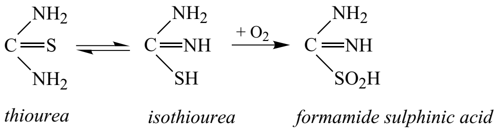
Thiosulphates Salts of thiosulphuric acid ($H_2S_2O_3$) which, with the exception of the salts of silver, barium and lead, are soluble in water.

Thio sulphuric acid → Sulphur oxyacids.

Thiourea (sulphonate urea, sulphonate carbamide, thio carbamide). $H_2N–CS–NH_2$; molecular weight 76, density 1.40. White rhombic prisms which are soluble in water (neutral reaction) and in hot alcohol. Thiourea salts are formed in conjunction with strong acids. Additional compounds result with heavy metal salts and many organic componds. Other chem. characteristics correspond approx. to those of → Urea. There is a close relationship to → Ammonium thiocyanate: $NH_4–SCN$.

Thiourea is used as a softening agent to increase the durability of heavy silk; for preventing over-oxidation when developing vat leuco ester dyes; as a vulcanization accelerator; as a padding auxiliary. Thiourea is used less and less frequently for printing polyamide with acid and substantive dyes. As a stable reducing agent in stripping and discharge effects on dyeings formamide sulphinic acid is used from the oxidation of isothiourea.

Condensation products with formaldehyde (→ Aminoplasts) are used for crease-free, swelling-resistant and low-shrinkage finishing. The development of cati-



onic thiourea derivatives is worth mentioning in this context.

Thixotropy Property of certain liquids to change their viscosity reversibly under mechanical strain and to convert from a thick gel-like consistency into a thin liquid solution state. Thixotropy is present in non-Newton liquids (→ Rheological behaviour of solutions). In thixotropic liquids viscosity decreases with increasing duration and intensity of mechanical strain under isothermal conditions in the form of a hysteresis. As opposed to structure-viscous and diluent flow characteristics, the viscosity does not increase when the strain is reduced but continues to decrease due to the increasing duration of strain. The viscosity does not reach its original value again until the liquid has recovered for a period after complete discontinuation of the strain. The reverse characteristics, sol-gel-sol conversion is know as → Rheopexy.

Thousand-point roller (kiss roller). Has fine point engraving and is used for → Kiss roll padding on the printing machine, i.e. for transferring a fine liquid film that may contain additional chemicals and dyestuffs. It is used for pre-moisturizing less absorbent fabrics, for dyeing one side of a fabric and for ludigol treatment, etc.

THPC Abbreviation for tetrakis-hydroxymethyl-phosphonium-chloride which is used for washing- and dry-cleaning-resistant → Flame-retardant finishing of cotton. Originally this finishing process was carried out using a nitrogen methylol compound, such as trimethylolmelamin, under dry crosslinking conditions. Nowadays the finishing process is usually carried out using THPC urea or substituted melamine products and subsequent gas- or aqueous NH_3 treatment. The advantages of this method are less significant losses of tear and friction resistance, although an impairment of texture has to be taken into account. Analytical determination of THPC is carried out by iodometric methods.

THPOH Abbreviation for tetrakis-hydroxymethyl-phosphonium-hydroxide which is used for flame-retardant finishing. THPOH is volatile at higher temperatures and the flame-retardant effect can therefore be partially reduced during machine stops in the finishing process.

THPOH-NH$_3$-Finish Permanent → Flame-retardant finishing for cotton and rayon staple fibre with → THPOH or → THP salts, such as, for example, → THPC.

THPS Abbrev. for tetrakis ammonium-hydroxymethylphosphonium sulphate which is used for → Flame-retardant finishes of cellulose and cellulose/polyester mixtures with a minimum proportion of 65% cellulose. The application process involves impregnation, which is carried out first, followed by drying, condensation and after-washing. The finish withstands 50 household washes. When used after the condensation process with the addition of finishing agents it results in a crisp, stiff handle.

THP salts Term used for tetrakis-hydroxymethyl-phosphonium compounds such as, for example, →: THPC; THPOH; THPS which are commercially available under different names.

THPX Abbreviation for → THP salts.

Thread According to DIN 60 900 thread is the term used to describe textile structures in linear form such as roving, simple yarns, ply-yarn, laces, etc., where the form and not the type of product is denoted.

Thread-by-thread (Fr.: fil à fil), fabric in plain weave 1/1 or twill 2/2 which is characterized by a special pattern achieved by alternate weaving of light and dark yarns in warp and weft directions. Fil-à-fil fabrics created in this manner are also known as → “Pepper and salt articles”, black and white and grey-white in point patterns. Thread-by-thread fabrics are used for manufacturing outer clothing.

Thread count Number of threads in warp or weft direction of a screen gauze per cm (= fabric-no.) or per inch (mesh number).

Thread lubrication → Yarn lubrication.

Thread-up Fabric path or thread-up in a → Steamer.

Three-bath process Term used in dry cleaning (solvent application). Cleaning, rinsing and finishing using 3 different liquors.

Threeply carpet (Scottish carpet). → Reversible carpet made of three interwoven fabric layers.

Three-quarter cloths Shorn soft and semi-dull brushed fabric (woollen cloth), belonging to the class of so-called fine cloths, in linen weave, not too heavy, i.e. below 400 g/m^2.

Three-roller yarn Generally cotton or viscose spun yarns (as opposed to two-roller yarns) from so-called three-roller spinning which works on the principle of the stretching process (3-cylinders as pre-spinning machine, also known as flyer, for stretching, twisting and parallel alignment of tow).

Three-stage carpet printing process When printing carpets it is normal to use 10–20 times the quantity of printing paste per surface unit which is used for printing textiles with a smooth surface. This is because particularly high-pile material absorbs dye in 3 dimensions whereas, in the the case of normal textiles, it is sufficient to dye the surface. The three-stage carpet printing process avoids these large quantities of printing paste (which a carpet printing machine has difficulty in processing technically) by applying only 30–50% of the total printing paste quantity necessary during the first stage which penetrates to approx. half the pile height (good print definition). Short heat treatment follows during the second stage (infrared, hot air or steam) to fix the dye in the pile tufts (preventing greying effect). During the third stage with the aid of a DD-unit a thin, chemical-free thickening solution is applied to achieve deeper penetration of the dye into the pile. The process achieves considerable savings in thickener and other chemicals as well as in effluent cleansing.

Three-stage drip-in dyeing process This is used for reactive dyes in exhaust dyeing processes. Especially recommended for jet dyeing machines. Constant temperature of 60°C. Addition of dye in two stages and of trisodium phosphate in three stages.

Threonine (monaminomonooxycarbonic acid). An amino acid contained in wool (6.76%) and silk (1.50%), → Amino acids.

Threshold effect Delayed precipitation of low solubility compounds that is shown by polyphosphates and also by complex phosphates in similar fashion. Polyphosphate ions are included in the network of low solubility precipitates that show interference in crystal growth. Phosphonic acids have the advantage over other complexing agents of high stability in cold and hot alkaline and also oxidizing liquors. Examples of the wide choice of phosphonic acids are listed in Fig. 1.

The property of preventing or delaying precipitation is known in technology as Stein-inhibition. This property is based on the "threshold effect". It indicates the effectiveness of a chemical compound in a substance or a physical process at under stoichiometric concentrations. This effect can be attributed to intermediate area phenomena which have an impact on crystal growth.

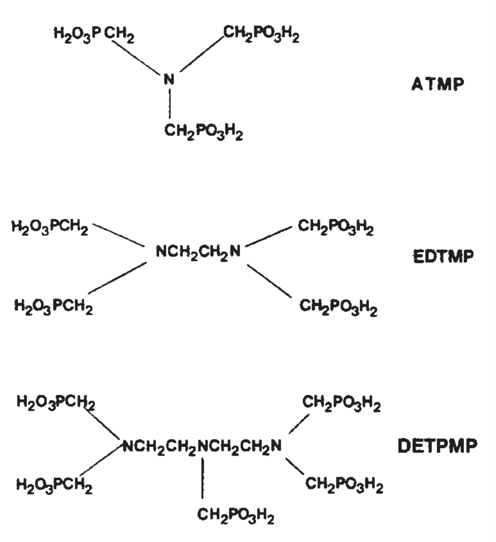


Fig. 1: Significant phosphonic acids.
ATMP = aminotrimethylenephosphonic acid;
EDTMP = ethylenediaminetetramethylenephosphonic acid;
DETPMP = diethylenetriaminepentamethylenephosphonic acid.

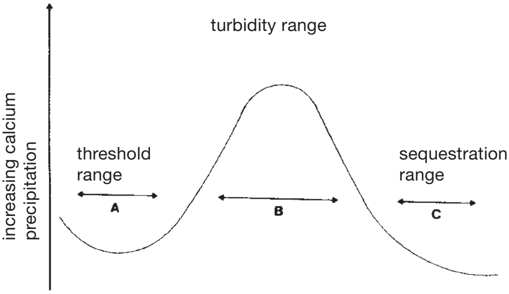

Fig. 2: Qualitative representation of the activity of threshold active substances.

The "threshold effect" was discovered at the end of the thirties with solutions of 1–10 ppm sodium hexametaphosphate, when it was established that precipitation of $CaCO_3$ from over-saturated solutions was delayed or inhibited (Fig. 2). In the sixties it was found that phosphonic acids also bring about a threshold effect. However, these have the decisive advantage over polyphosphates that they are hydrolytically stable and also have an effect over a wide pH range.

Threshold Limit Value (TLV). This value was created by the ACGIH (Am. Conference of Governmental Industrial Hygienists) → TLV values (used as an average concentration).

Threshold limit values for waste water The threshold limit values listed in Tables 1–4 (mg/l) are taken from the following regulations and drafts (in accordance with → DTNW, Krefeld):

A. 38. Administration Regulation of Waste Waters (Abwasser VwV – Abwasserverwaltungsvorschrift), Ministerial Publication No. 83, 6. December 1984.
B. Annex 38 Administration Regulation of Waste Waters (Abwasser VwV), Draft official representative, 26. July 1990.

D. Draft of the statutes of the town of Krefeld dated October 1989.

E. Waste water drainage statute of the town of Krefeld dated 22. December 1983.

F. Waste water regulation manual; draft dated October 1990.

Throttle valve Device for regulating flows of substances and media.

Throughflow drying → Water extraction throughflow method.

Throughput time includes production times as well as set-up and shut-down times. The “handling” and intermediate storage of fabric takes up a relatively high proportion of the throughput time. The repeated “reversal” of the fabric in particular, and the final unrolling of fabric from batch rolls, etc. necessitates repeated operations between all process steps which is time-consuming and also ties up capital in the stages of adding value. Moreover, transport operations are involved in plaiting down (“reversal”) of fabric and winding on to batch rolls. The throughput time is determined by the speed of the fabric through machines, resp. the treatment times and intermediate → Storage times between the individual processes. Intermediate storage times occupy a large proportion of the total throughput time. They can be reduced by appropriate work planning and order scheduling. Dependent factors may include:

- multiplicity of processes involved,
- non-standard batch sizes,
- different speeds of the various production machines,
- different machine efficiencies,
- transport problems (shortage of yarn carriers, fabric wagons, A-frames, etc.),
- several passages through one machine,
- changes to the order of batches in process,
- requests made at short notice by the sales department for changes to the production program,
- different aftertreatment requirements,
- sample batches and quality standards,
- unexpected major repairs,
- excessively long administrative procedures between receipt of order and the issuing of finishing instructions as well as in dispatching finished goods from the warehouse,
- failure to prepare the required dyes/chemicals in good time,
- inadequate or no daily planning of machine utilization,
- inadequate daily monitoring of work in progress with regard to meeting the required deadlines or maintaining production efficiencies.

Thrust reversal When tensioning frames come to a temporary halt measures have to be taken to prevent the stationary fabric from suffering hot air damage. Thrust reversal temporarily changes the direction of air flow whilst simultaneously reducing burner performance causing the jets to suck in air upon standstill (see Fig.).

Thumb test Subjective manual test for assessing the resistance to tear and elongation properties of textiles. The textile is stretched over the top of both thumbs until it tears. This represents a subjective assessment of quality and is difficult to reproduce.

Thyristor Used for feeding direct current multimotor drives which are used among other things for powering continuous finishing machinery.

Ti Element symbol for titanium (22).

TI-air The Technical Instructions for the mainte-

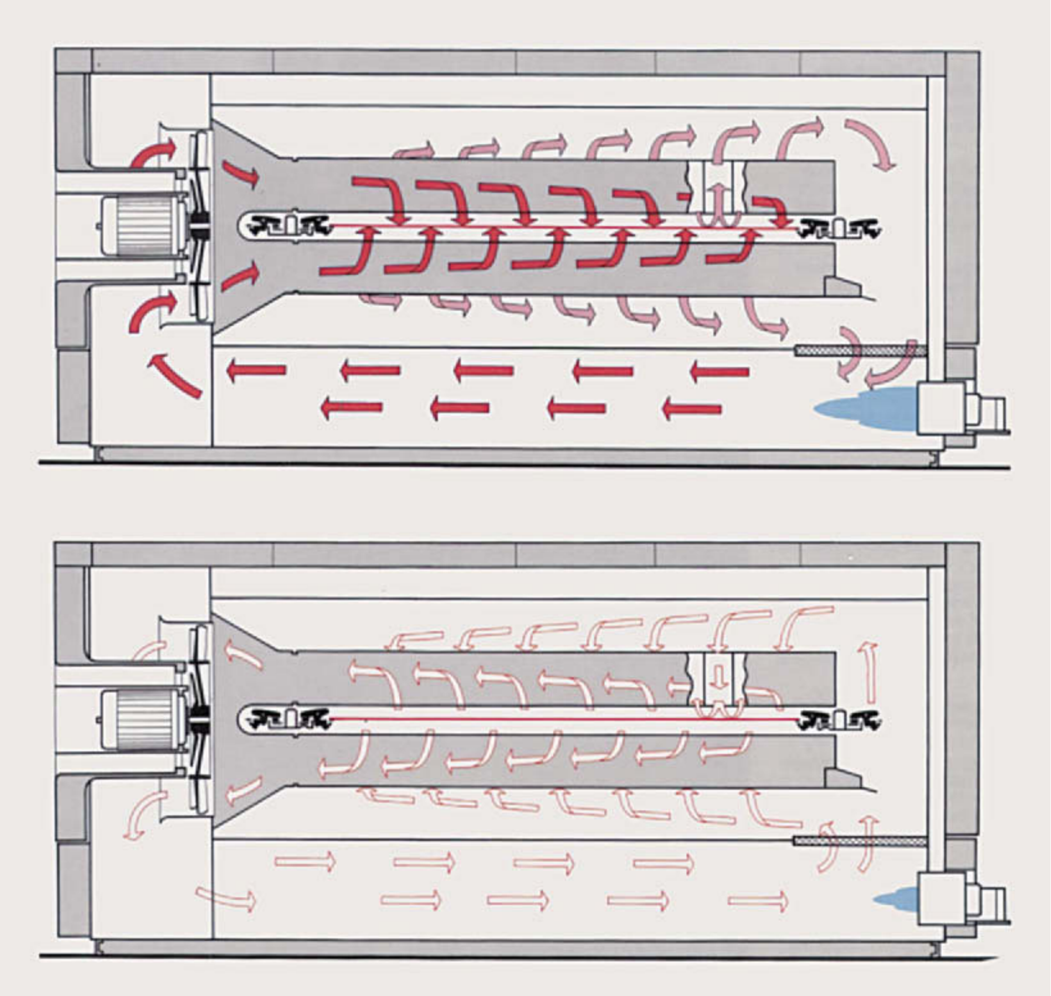

Fig.: Thrust reversal process in a Babcock stenter.

nance of clean air are general administrative regulations for the maintenance of clean air. Of significance for the textile finishing industry are the more stringent limits for volatile organic substances. The hourly rates have been reduced in Category I from 0.2 to 0.1 kg/h, in Category II from 3 to 2 kg/h and in Category III from 6 to 3 kg/h (Tab. 1). If these rates are exceeded, then the maximum concentrations for the corresponding category are applicable. The aim of the TI-air, is among other things, to protect the environs of a facility that emits toxic or offensive substances.

class	old		new		example
	mg/m^3	kg/h	mg/m^3	kg/h	
I	20	0.2	20	0.1	formaldehyde
II	150	3.0	100	2.0	tetrachloroethane, acetic acid
III	300	6.0	150	3.0	alcyl alcohols, paraffin hydrocarbons

Tab. 1: Classes of TI-air (as of 1993).

New regulations are coming into force concerning substances with an offensive odour. If neighbours feel that they are being unreasonably imposed upon by the presence of substances with an offensive odour, the facility is obliged to introduce measures to reduce emission.

The range of application of the TI-air.

– checking of applications from facilities requiring authorization (para. 6 BImSchG – Bundes-Immis-

sionsschutzgesetz – German Federal Immission Protection Law),
- checking of partial authorizations (paras. 8, 9 BImSchG),
- additional regulations (para. 17 BImSchG),
- regulations regarding the monitoring of the extent of air polluting emissions (para. 26 BImSchG).

In addition to the explanation of the range of application, the TI-air can be divided into two principal sections. The first of these is the section on “General Regulations” for keeping air clean and the second section on limitation and monitoring of emissions. As well as listing technical terms used and units used for measuring emissions, the General Regulations explain the range of odours and the processes of applying for authorization for a facility. The emission values for inorganic air content substances are also determined and listed in terms of concentrations and rates. Also listed are the measuring techniques used by the German engineering organization (Verein deutscher Ingenieure = VDI) needed to determine inorganic air impurities. In the second section, limits and methods of ascertaining emissions are defined. This section also contains the limits and categories for organic substances and for equipment for printing fibre material in strips or sheets as well as equipment for reticulated fibre soaking.

The annexe to the regulations concerning facilities requiring authorization contains a final list of those facilities that have to be licensed in accordance with standard or simplified procedures.

In the textile finishing industry the following facilities require a licence:
- rotary printing presses including appropriate drying units if they process more than 25 and less than 250 kg/h of organic solvents.
- dyeing equipment using dyeing accelerators including tension frames but excluding equipment operated under high pressure.
- equipment for bleaching thread or fabric using alkali, chlorine or chlorine compounds.
- equipment for coating or impregnating materials manufactured in strip form including appropriate drying units using from 25 to a max. of 250 kg/h of organic solvents.
- equipment for coating, impregnating or soaking materials with artificial resins in strip form, including drying aggregates (this includes tension frames).

Even if a facility does not fall under the licensing requirement, the plant is obliged to operate its equipment in such a way that neighbouring premises and the general public are protected from noxious and offensive air pollutants. The operator is obliged to take measures to prevent noxious air pollution from occurring. The TI-air uses the term offensive (offensive odour) as well as the term noxious. Both terms have implications for the emissions caused by textile finishing processes. Colour fixation and finishing/permanent finishing processes are particularly problematic. A proportion of the fibre preparations evaporates when untreated wool is dried. In particular, bobbin and spin oils are oxidized when subjected to high treatment temperatures to yield odour intensive aldehydes, the smell of which often gives cause for complaint. Depending on the finishing or per-

class	mass flow	mass concentration
I	0.5 g/h or more	0.1 mg/m^3
II	5 g/h or more	1 mg/m^3
III	25 g/h or more	5 mg/m^3

Tab. 2: TI-air: Threshold limit values for carcinogenic substances.

class	mass flow	mass concentration
I	1 g/h or more	0.2 g/m^3
II	5 g/h or more	1 mg/m^3
III	25 g/h or more	5 mg/m^3

Tab. 3: TI-air: Threshold limit values for inorganic substances in the form of dust.

class	mass flow	mass concentration
I	10 g/h or more	1 mg/m^3
II	50 g/h or more	5 mg/m^3
III	0.3 kg/h or more	30 mg/m^3
IV	5 kg/h or more	0.5 g/m^3

Tab. 4: TI-air: Threshold limit values for vapourous and gaseous organic substances.

class	mass flow	mass concentration
I	0.1 kg/h or more	20 mg/m^3
II	2 kg/h or more	0.1 g/m^3
III	3 kg/h or more	0.15 g/m^3

Tab. 5: TI-air: Threshold limit values for organic substances (e.g. steam distilled).

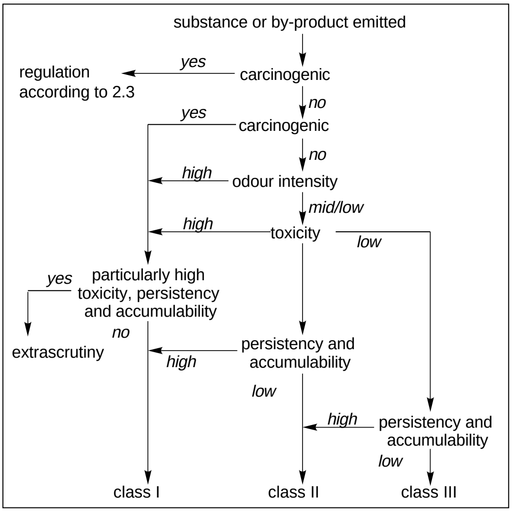

Fig: Assessment chart for the classification of substances according to TI-air (Umweltbundesamt – German Federal Environment Agency)

manent finishing process the resultant emission contains various substances of which formaldehyde can exceed the limit of 20 mg/m^3. Analysis of the emission is costly because of the difficulty of taking samples. It is therefore advisable to estimate the emission by means of an initial material analysis as a first step. The following measures for keeping emissions clean are the most important: selection of low emission techniques/products, optimisation of conditions of treatment and combustion emission from the boiler-house. Adsorbents and emission washers have a limited range of use (according to Richter and Schollmeyer et al.).

Limits for mass flow and mass concentration are determined in individual sections of the TI-air and the substances and groups of substances are divided into categories (Tabs. 2–5).

The order of magnitude of the permitted mass concentrations of noxious substances in accordance with TI-air can be illustrated by means of a practical example: An emission of 20 mg/m^3 means that at an emission volume of 12 000 m^3/h, 240 g of noxious substance may be transported in one hour. This means that on a strip of material of a width of 1.50 m treated at a speed of 50 m per minute only 50 mg = 0.05 g of noxious substances may be released per square metre. Irrespective of the mass concentration of the noxious substances (i.e. also in the case of less than 20 mg/m^3) the environment can be affected in an offensive way in the case of odour intensive properties. In this instance the TI-air specifies that “odour intensive emissions are generally to be fed into emission cleaning facilities or that equivalent measures are to be taken” (see Fig.). →: Emission problems; Environmental protection legislation.

Tibetan cashmere is derived from the Tibetan goat which lives in Tibet and is closely related to the cashmere goat. Tibetan cashmere is somewhat rougher and a little more glossy in appearance. Production, properties and utilization are similar to cashmere. → Animal hair fibres.

Tibet wool (Tybet). Term used for unmilled fabrics sorted as → Rags and used to produce → Reclaimed wool of quality category II.

TIC Abbreviation for “Total Inorganic Carbon”; value used in → Biological waste water treatment, quoted in mg/l waste water or in mg carbon/g substance.

Ticking Densely woven, generally striped patterned linen, cotton or half linen fabrics in twill weave. → Drill fabrics.

Tie (tying). This is carried out for patterning of:

– warp or weft threads (→: Ikat; Kasuri dyeing),
– fabrics (→: Bandhana; Plangi; Shibori technique).

Tying is carried out by binding with threads which prevents penetration of the dyes on subsequent dyeing. Machine tying of yarns has also been carried out for some time using wires which give reproducible patterning.

Tie-dyed batik →: Bandhana; Plangi; Shibori technique.

Tie-Dye-Pack Special folding technique which can be combined with → Tieing techniques and is used, for example, for dyeing with reactive dyes.

Tieing techniques Fabrics (and in many cases finished items of clothing, particularly T-shirts) are tied in a certain way along the lines of tie-dyed batik or tie-dyed technique prior to dyeing resulting in interesting patterns. Dependent on the type of → Tie, effects known as the “Mukeka Mutono Special“, the “Grill” or the “Tortoise” are given.

Tie molecule The physical structure of semi-crystalline polymers, of which polyethene terephthalate is one, can be described by means of a two-phase model of alternating crystalline and amorphous regions. The crystallites are rigid blocks upon first approach. The molecular arrangement in the amorphous regions is, therefore, of decisive significance for the mechanical properties of the yarn. The molecule folding at the edges of the crystallites and the length distribution of the connecting molecules (“tie-molecules”, Fig.) can be recorded by infrared-spectroscopy. If a yarn is stretched, molecule “a” in the elongated location can adapt by widening of the valency angle or chain bridge. Molecule “b” can bridge the enlarged distance between the crystallites by rotation from the gauche into the trans-conformation. Molecule “c” is so long that it can contain a considerable portion of the original tangling even in the lengthened form.

Infrared-spectroscopy can be used to determine the

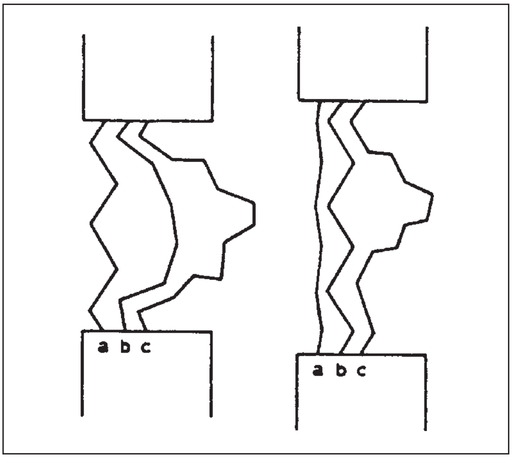

Fig.: Polyester tie molecule transitions in the amorphous ranges on elongation of the fibres (left = unstretched; right = stretched).

trans-gauche transitions, sections of folded molecules and molecular tensions were recorded quantitatively on the tie-molecules. With increasing winding-up speed of spun yarns, the crystalline character and the number of folds increases whilst the proportion of gauche conformations decreases. The increasing orientation of the amorphous molecules can also be recognised, as these untangle and adopt the trans-conformation. The best orientated amorphous trans-segments are incorporated in the growing crystallites (according to Zahn).

Tier drier Driers through which textiles are moved in several tiers (Figs. 1 and 2).

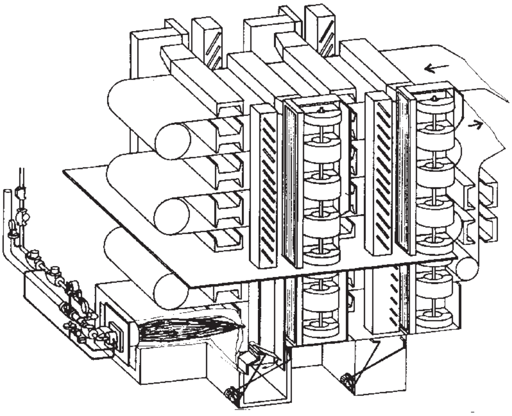

Fig. 1: Krantz's old style drying stenter in tiers (without housing).

Tie-up thread (tie-up yarn, tie-up) →: Hank; Skeins; Reel.

Tightness factor (TF) → Cover factor (CF).

Tight pick → Shiners.

Tight threads Warp or weft threads caused by too great a tension (usually due to the state of humidity during weaving so that these threads in the fabric shrink during drying) which can result in unevenness in fabrics which has to be eliminated by stitching or at least improved.

Tiles → Carpet tiles.

Tillandsia fibre,

I. (American moss, tree hair, Louisiana moss). This is produced from the jointed and branching stem of the

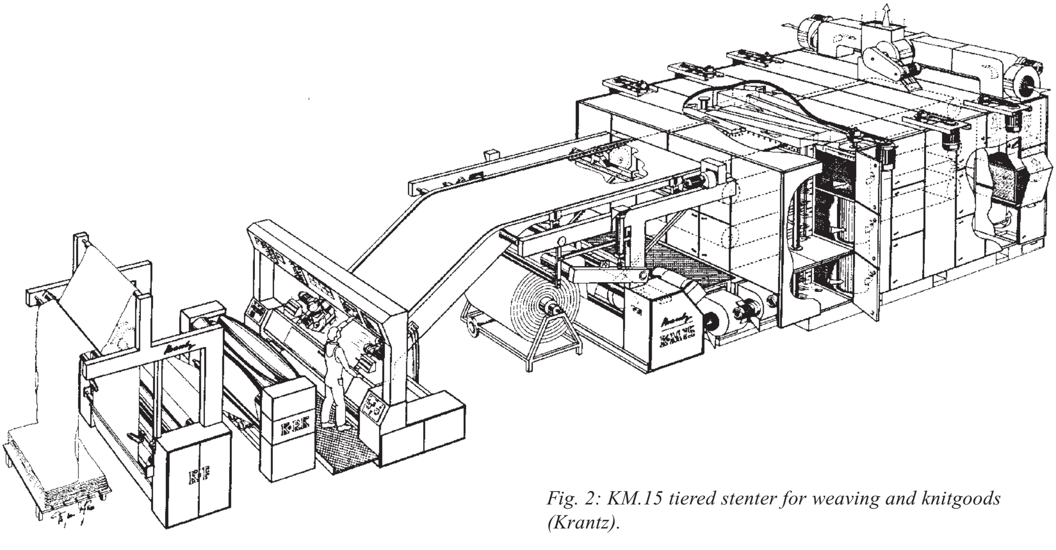

Fig. 2: KM.15 tiered stenter for weaving and knitgoods (Krantz).

rootless tendril creeper (tree parasite) whose three metre long stem hangs from branches in beard-like fashion. The unpeeled raw fibre is grey-greenish white; the peeled pure fibre is brownish black and is often dyed black artificially. The fibre bundles are separated using boiling sodium carbonate solution. Tillandsia fibre is characterised by great durability and strength and is often used as a substitute for horse hair and as upholstery material.

II. → Kenaf.

Time (concepts) of time used in the course of processing →: Operating time; Processing time; Working life; Idle machine time; Throughput time; Transportation time; Storage time; Machine time; Down time; Productive time; Forming time; Handling time factor. Work study terms →: Order processing time; Completion time; Basic time; Setting-up time; Allowance; Standard times; Unit time.

Time of half-dyeing Time in minutes which is required for 50% of the amount of a certain dye contained in the liquor to be absorbed by the fibre. Unsuitable as a basis for selection of combination dyes for cationic dyes on polyacrylnitrile. → Compatibility value is better suited.

Time step levelling test This is used to compare the effectiveness of different levelling agents for dyeing wool (Fig.). Recipe: 1% Supranol fast blue G (Bayer), 10% sodium sulphate anhyd., 3% acetic acid 60%, liquor-to-goods-ratio 1:50 in relation to the total weight of dyed wool. Method: fabric samples of equal size are placed in the dyebath when it reaches boiling temperature (0 min) and at 2, 4, 8, 16, 32 and 64 min. When testing without levelling agent the greater proportion of the dye is absorbed almost completely after a short period and there is no levelling between the fabric sample first treated and the one which was added later. When dyeing with levelling agents all test samples are dyed to almost the same intensity due to the levelling and suppressing capacities of the levelling agent.

Tin (Sn), atomic weight 118.8. Silver white → Metals, glossy, crystalline, very soft and elastic, rollable (leaf-tin, tin foil). Resistant to air and water. Melting point 228/232°C, can be pulverized at 200°C. Soluble in hydrochloric, sulphuric and nitric acids and alkalis. Compounds bivalent and trivalent, the latter being more stable. SnII compounds are strongly reducing. Tin(II)-hydroxide is important as a stain, tin-acetate as a discharge, tin-chloride as a tin salt stain. The latter is easily soluble. When the corresonding solutions are diluted with water strong hydrolysis takes place (decomposition). Alkalis, alkali carbonates and ammonia cause precipitation that is soluble in the alkali surplus. Sn(IV)-compounds have a low-oxidizing effect. Important: with alkalis, alkali carbonates and ammonia, tin-chloride (for staining and weighting) results in easily-soluble tin(IV)-hydrate as meta stannic acid, $Sn(OH)_4$ (salts: stannates). This is used for staining and weighting silk.

Tinge Term used in sample dyeing for “a trace more” dye.

Tin(IV) hydrate $Sn(OH)_4$ or $SnO(OH)_2$. Used as a mordant in alizarin printing inks.

Tin(II) hydroxide $Sn(OH)_2$, molecular weight 152. Used as a mordant in alizarin printing.

TI-noise The Technical Instructions for noise prevention apply to all facilities requiring authorization to operate in accordance with paragraph 4 of the German Federal Immission Protection Law (BImSchG – Bundes-Immissionsschutzgesetz), even if they are only authorized by means of the simplified procedure in accordance with paragraph 19 of the same legislation. The concept of “facility” is to be understood in a wide sense. A facility is understood to mean the overall complex of technical equipment necessary for operation of the plant including auxiliary appliances that have been

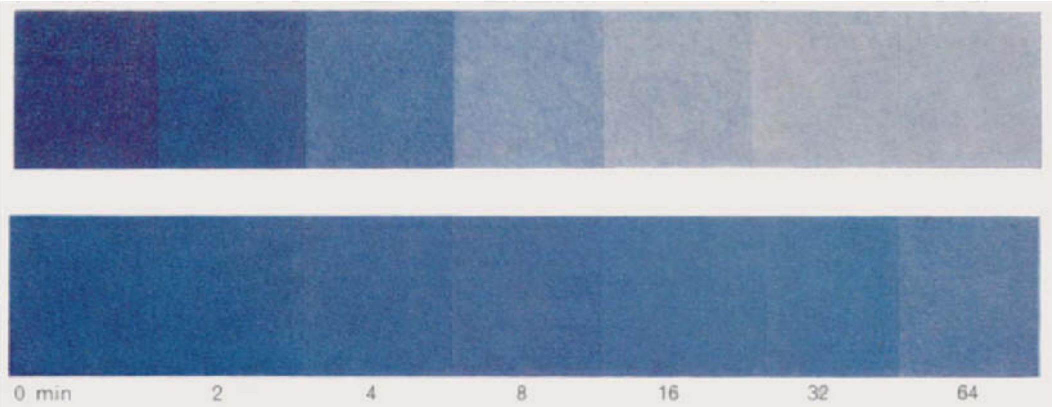

Fig.: Time step levelling test; top without and bottom with levelling agent.

set up and are operated in close geographical proximity, for technical, procedural or other reasons. Ownership conditions are not to be regarded as definitive on their own. Applications for authorization should prove that noise prevention measures in accordance with state-of-the-art noise abatement technology have been put in place and that it can be expected with a high degree of certainty that noise pollution guidelines will not be exceeded throughout the entire area influenced by the facility, including the area outside the boundaries of the facility premises excluding any noise originating from other sources.

Measures which can be considered to ensure that the noise abatement guidelines are observed include positioning the noise sources at an appropriate distance from the areas under protection by extending the facility premises or by a commitment guaranteeing that adjacent premises will not be used in a manner necessitating noise prevention measures.

Paragraph 5, item 2 of the German Federal Immission Protection Law (BImSchG – Bundes-Immissionsschutzgesetz) obliges the operator of facilities, requiring authorization to take preventative action against detrimental environmental impact of noise in particular by taking measures to limit noises which meet current standards. The legislation makes it unlawful not to implement state-of-the-art measures in accordance with current standards. →: Noise protection; Environmental protection regulations.

Tin-phosphate-silicate weighting Mineral silk weighting: → Weighting of silk.

Tin salt discharges → Reductive discharges with tin(II)-chloride. No longer generally used on cellulose fibres. Was used frequently prior to introduction of sulphoxylates. On acetate and triacetate → Acetate fibres in discharge printing.

Tin salt reaction is used for testing alkali-damaged wool. Method: hot treat sample for approx. 30 min in acetic tin salt solution (10% acetic acid + 5–10% stannic (II)-chloride) resulting in a light to dark brown colour depending on degree of damage. Reaction consists of slight sulphur discharge; formation of brown stannic sulphate.

Tin salts, organic E.g. → Tributyltin oxide. These have an important function as a → Preservative.

Tinsel → Paillette.

Tinsel-print Pigmentation process with tinsel pigments.

Tinsel threads Metal threads made of base metals; → Metallized yarns.

Tin sulpholeate (ammonium sulphoricinoleate, stannisulpholeate), used as a stain for alizarin colours and for softening of pink and red colour shades.

Tin(II) thiocyanate $Sn(CNS)_2$. Used as an additive in alizarin printing pastes.

Tinting dyes for bleached goods (blueing dyes). Blue, red and violet dyes for application during → Tinting of bleached goods. In small quantities tinting dyes achieve a significant increase of the white appearance both with optically-brightened material and with optically-brightened ground white. Dyes used for this purpose are as brilliant as possible in order to reduce the absorption range for as narrow a band as possible. On the other hand dull tinting dyes, such as mixtures of a brilliant dye with grey, reduce the brightness unnecessarily. Use: a) to increase degree of whiteness whilst to a large extent retaining the optical brightening shade; b) for modifying the optical brightening tint, usually whilst likewise increasing the degree of whiteness.

Tinting of bleached goods (blueing). Application of blue-violet tinting dyes to prevent yellow cast (blue defect) of a ground white to further increase the degree of whiteness. This makes reflectance in the green-yellow spectral range relatively lower then in the blue and red range, i.e. yellow-green light is absorbed more and no longer reflected thus reducing brightness, but darker as well, since compensation of yellow by blue violet produces neutral light grey (subtractive dye mixture). This is perceived visually but not as such due to the fact that a blue-violet shift is registered by the eye as an increase in the degree of whiteness. However, the proportion of grey produced is also increased with a more pronounced yellow cast before the shade converts from yellow to blue and the grey portion becomes obvious all the sooner. This is why poor ground white cannot be changed into attractive white by means of tinting but only into light grey. Stronger tinting leads to over-compensated yellow cast as blue cast. The rule of experience as far as tinting is concerned is that light can only be taken away by tinting, as opposed to fluorescent brightening where the blueing effect is not based on taking away yellow-green light but on adding blue light (additive radiation mixture), i.e. increase of brightness, → Fluorescent brightening agents. These parameters are still valid as they explain why further white effect increase is possible by means of tinting after optimum bleaching and its optical brightening effect. It is, however, only possible when brighteners and tinting dyes are harmonized as well as possible.

Tin weighting → Weighting.

Tip effects Tip effects on pile fabrics; vivid patterned woven fabrics or furs are produced by surface coloration of the extreme tips of the pile. → Emboss printing.

Tippy dyeing The tips of woollen fibres are exposed to light, weather and environmental influences during their growth. For this reason tips and root-ends dye differently (→ Skittery dyeing wool). The extent of the colour difference between tips and root-ends depends not only on the wool but also on the category of dye and the process used. The addition of cationic or non-ionic levelling agents only partially compensates for the colour difference. More hydrophobic dyes or hydrophobia-increasing auxiliaries result in more even dyeing whilst the easily-soluble, more highly sulphonated and more hydrophilic dyes colour the tips more intensively.

Tirtey Reasonably-priced and generally durable fabrics which consist in the warp of fine-threaded strong cotton or rayon staple fibre yarns but of carded yarn (often reclaimed wool with the addition of cellulosics) in the weft. Finished with either Melton or brushed effects.

Titanium White metal, at. wt. 48, melting point approx. 2250°C. Contact with air causes it to convert to titanium dioxide. Trivalent compounds are violet in solution and have a strong reducing effect whereas quadrovalent compounds are colourless. The most important compounds are: → Titanium dioxide (TiO_2) as a matting agent, titanium acid ($TiO_2 \cdot H_2O$) as a reagent to hydrogen peroxide, titanyl sulphate $TiOSO_4$ which dissolves easily in cold water and hydrolyses easily when heated.

Titanium dioxide Titanium(IV) oxide, TiO_2; molecular weight 70, density 3.8 (–4.2). The white powder is not soluble in water or dilute acids. It is used as a white pigment with a high covering capacity in paint coatings and as a matting agent for fibres and frosted glass. It is usually supplemented by calcium or barium sulphate. Thus, for example, Kronos-titanium dioxide contains 1–5% barium sulphate. Fixation takes place with fatty alcohol sulphonates (sulphonated oils, suet, wax) possibly with the addition of protective colloids (proteins, cellulose). It has a negative impact on certain substantive dyes in that it reduces the light fastness by 4–5 categories. Titanium dioxide is the most important pigment for synthetic fibre delustring but it is also used for printing damast; it absorbs ultra-violet rays.

Titanium potassium fluoride → Titanium potassium hexafluoride.

Titanium potassium hexafluoride K_2TiF_6. Molecular weight 240.09. White crystals, soluble in hot water. Used in IWS-flame-retardant finishing.

Titration is used for quantitative content determination of a solution to be tested by means of a normal solution of known content which flows into it (using a burette or a pipette), → Normal solutions. The end of the reaction (neutralisation, oxidation, reduction, precipitation) is shown by the colour change of an added indicator. The content calculation is made from the relationship between the utilized quantity of solution to be tested and the consumed normal solution.

Titration is a method which can be carried out rapidly, which supplies precise values in terms of weight analysis.

Titrimetry is subdivided as follows:

I. Alkaline and acid measurement: determination of alkalis and acids with normal acids or alkalis.

II. Oxidimetry: determination of reduction or oxidation with normal permanganate solution.

III. Iodometry: determination of reduction or oxidation with normal iodine and sodium thiosulphate solution.

IV. Precipitation analysis: reaction evaluation by means of mutual precipitate formation.

V. Complexometry.

VI. Electrometrical processes: a) Conductometry: recognition of the end point by determination of conductivity; b) Potentiometry: recognition by measurement of potential.

Titration curves of proteins The electrostatic interaction between protein and hydrogen ions and hydroxyl ions can be measured because the lateral chains, which project from the main chains, have varying pK depending on sequence. When the consumed acid or alkali quantities are calculated against the particular pH of the solution, in which the soluble or insoluble protein is located, the titration curve (Fig. 1) is attained. As shown in Fig. 2, acid reacts with wool below pH 4.7(cationic and acid dyes) and alkali above pH 4.7.

Wool does not provide such a steep titration curve as, for example, insulin and the definition of the isoionic point is problematic. In the wide range between pH 4 and pH 8 neither acid nor alkali are bound and the loading charge remains zero (isoelectric zone). This is a result of the insolubility of wool and the formation of an electrical double layer on the fibre surface. This makes it difficult for the hydrogen ions to penetrate. The addition of salt reduces the electrical double layer so that the wool behaves like a soluble protein and the curves for the acid and alkali absorption meet at the isoionic point.

Salts destroy the electrical double layer which builds up on the fibres. Peters and Speakman give an

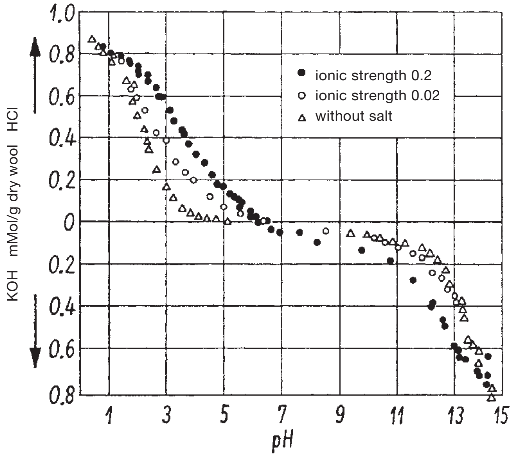

Fig. 1: Wool titration curves (according to Steinhardt and Harris).

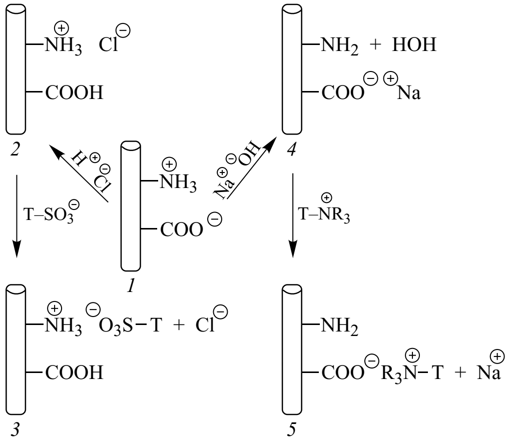

Fig. 2: Reaction of wool (1) with acid during the formation of the wool cation (2) or with alkali during the formation of the wool anion (4); (3) = acid dyed wool; (5) = alkaline wool transformed with cationic substances.

internal pH-curve for titration which corresponds to a soluble protein nitration and define an inner pH. On the basis of the Donnansch membrane balances the salt effect explains why the internal pH comes into line with the external pH when the salt concentration increases.

Titre,

I. Term denoting fineness of fibres and yarns. The valid SI-fineness is tex which indicates weight in grams per 1000 metres length, → Tex system. The older term of Denier (den) indicated the mass in grams in relation to 9000 metres length (1 tex = 9 den).

II. Decimal titre in gram per kilometre as gen. fineness term for fibres and yarns: Titre = thread mass/thread length.

III. In dimensional analysis the content of effective reagent in a solution used for titration (expressed in gram equivalent/l).

Titre of soap solution (turbidity point, cloud point). Any temperature at which coarsely dispersed, non-detergent particles occur in a colloidal soap solution. The turbidity point is a measure of the temperature-dependent application range of a soap and corresponds to the melting point of the fatty acid used in its manufacture. That is why soaps made of unsaturated oleic acid are used for low-temperature washing and cleaning processes (e.g. raw wool scouring), but not for wash-at-boil processes, where soaps made of palmitic and stearic acid (tallow and hard soap, soap flakes) are more useful. Soaps made with liquid fats are used at temperatures of approx. 40°C, soaps made with semi-solid fats at temperatures up to 60°C and soaps made with solid fats at 80–90°C and even higher temperatures.

Titre variations Variations in the → Titre of fibres:

I. As an intentional effect (→ TS).

II. Accidentally such as, for example, great titre variations in polyester threads of strongly striped tie fabric. The cause of these titre variations, which cannot be compensated in terms of colour, is partially blocked spinning nozzles.

Titrimetry → Titration.

TITUS (TITUS Textile Information). Abbreviation for “Textile Information Treatment Users Service”; international documentation system which is operated on the basis of international community work by the TITUS organisation and is based on the “Thesaurus of Textile Terms” developed by the MIT (Massachusetts Institute of Technology) in 1966 (Ger. further development: Internationale Thesaurus Textiler Begriffe, Düsseldorf; Verein Deutscher Ingenieure). Since 1971 the TITUS organization has been working with a linguistic analysis and translation system with the aid of data processing, which for the first time enables scientific texts to be translated automatically into German, English, French and Spanish using abstracts (short versions) of textile-specific publications. The foundation of the “Association of Textile Documentation and Information” (Verein textiler Dokumentation und Information e.V.) has created a widely based maintenance association which links the TITUS organization with associations of the user organisations as well as with information providers and information conveyors.

Documentation and information make an important contribution to technology transfer. In 1980 the → VDTI (Verein Deutscher Textilindustrien) was founded by the Textile Industry, the Textile Machinery Association (Fachgemeinschaft Textilmaschinen) in the → VDMA (Verband deutscher Maschinenbau- und Anlagenbau e.V.) as well as textile research institutes and specialist textile publishers. Its brief is to inform the textile industry and associated areas, i.e. the chemical fibre industry, textile machinery construction, the clothing industry as well as the laundry and chemical cleaning industry, about global literature of relevance to textiles and to document the publications.

To this end the VTDI promotes the development of a data bank which is accessible by remote data processing, as well as the production of printed services and the procurement and delivery of original literature. The association, which is promoted by its members, transferred the documentation activities to the Fachinformationszentrum Technik e.V. (“FIZ Technik”) (Specialist Technology Information Centre) in 1989. At the same time it declared its readiness to support “FIZ Technik” financially and to participate in the management of “FIZ Technik” to promote its interests. This measure represented an important step towards rationalising data base production and to making the data bank design more user-friendly.

The extended possibilities of "FIZ Technik" were used in 1990 to develop the TOGA data bank. This is based on the TITUS data bank system but has a greater range of expression for the abstracts at its disposal due to its free choice of words as well as improved search facilities.. The inclusion of additional sources makes a contribution towards a more complete information supply for the textile industry. Approx. 140 international trade magazines are evaluated as well as all leading specialist conferences. Interesting Ger. and European registered patents and exchange of papers with the Fr. co-operation partner and with other data bank providers supplement internal literature evaluations.

The rapidly increasing operation times of the TOGA-data bank have confirmed that the right measures were introduced. As well as the data bank offered by "FIZ-Technik" a further 70 data banks are provided for technology, economics, purchasing guides, standards and materials. Specific software known as "Sherlock" makes it possible for the uninitiated to carry out research in all of the "FIZ-Technik" data banks without prior knowledge.

The monthly magazine "FIZ-Technik Information Service for the Textile Industry, Textile Machinery Construction and the Clothing Industry" gives an overview of textile publications world-wide which have recently been included in the data bank. Many companies use the possibility of gaining a rapid overview of important publications in the field of fibres, spinning, yarn treatment, manufacture of textile fabrics, composite materials, finishing, confection, textile care, examination of polymers, textile testing, plant organisation or environmental protection before ordering the particular original literature required.

Retrospective research and selective permanent information (profiles) are interesting information services offered by "FIZ-Technik".

The range of services also includes the following:

- magnetic tape service,
- information on products and manufacturers,
- thesaurus (as search aid for research),
- list of evaluated magazines quoting publisher,
- advice, user training, provision of original literature.

As well as "FIZ-Technik", the Textile Research Institutes are also active as information distribution points, as requested by the Textile Industry Research Curatorium. The employees of "FIZ-Technik e.V." are available for information regarding the most suitable information service and for all specialist questions. "FIZ-Technik" also provides photocopies of original literature from around the world.

TIUC Abbreviation for "Textile Information Users Council Inc.", a loose association of textile companies for promotion of information and documentation, founded in 1961; → Technical and professional organizations.
