Preferably a 3 or 4 section hot air oven (with individual temperature control) with tenter frame should be used. Hot air impingement from both sides is recommended but it is essential to have well functioning baffles in the system so that the air flow can be correctly adjusted. High temperature should be avoided in the initial stages of drying to prevent "mud-cracking". This can also occur if the cup weight has been allowed to climb to a higher level than recommended. The foam should be dried for approx. $1^1/2$ to 2 minutes at a temperature between 110°C and 135°C. The exact time and temperature requirements will vary depending on the efficiency of the oven and the density and thickness of the foam coating. Drying time and temperature are also dependant on the weave of the fabric, an open weave requiring less time and lower temperatures than a close weave. The foam can be tested for degree of drying by using the "thumb test". If the foam is not dry enough, there is only a surface skin and a slippery wetness will be felt. If the foam bounces back the foam has been over-dried (premature curing). The fault can be corrected by either speeding up or slowing down the drier and/or adjusting the temperature.

Most available steel/hard rubber (or paper or cotton) roll calenders can be used for crushing but crushing pressure should preferably be at least 250 N/cm.

The foam can be crushed cold under certain conditions but it is advisable to use a heated calender (50°C or more) to avoid poor crushing and, therefore, loss in abrasion and wash and dry clean resistance. To obtain clear coatings and strong laminates with the Primax 210/Primax 310 emulsions, the foam must be crushed at 150°C minimum.

In addition to waterproof and blackout coatings, a number of speciality crushed foam applications have been successfully developed based on the Primax emulsions mentioned above. Among those are coatings to seal-off porous substrates, conductive coatings for wallcoverings, simulated leather, textile laminations etc.

There are several types of foaming equipment on the market and details on these machines are available from the manufacturers. Most technical foaming devices employ a Mono pump to deliver the compounded emulsion to the mixing head where air is supplied to generate foam. In order to assure adequate and consistent foam generation, the delivery line from the compounded feed tank to the Mono pump should be as short and unrestricted as possible, and a head of at least 30 cm over the pump inlet should be maintained. In addition, care should be taken to avoid air entrapment while compounding and shipping the acrylic latex as the presence of excess air can dramatically reduce pumping rates and cause delivery to be erratic. Pump packings should be carefully maintained to assure that air is not sucked into the pump on the inlet side.

Crushed foam coating A coating process with acrylic foam which, after application, is dried on the underlay, broken between rollers and then hardened.

Crushed patent leather Polyurethane coated → Synthetic leather on a woven, warp knitted or nonwoven substrate, crinkled and calender embossed and lacquered. Can be washed, but cannot always be dry cleaned. Preferred on a polyester, polyamide or polyacrylonitrile base (blends). Use: clothing purposes, upholstery covers, motor car upholstery, decor textiles, wall coverings, covering fabrics and imitation leather.

Terms: antique velvet, crash velour, crushed velour, grained velvet etc.

Crushed styles Fabrics in which irregular folds and creases are set. They are stuffed in rope form into nets, and laid in boiling water, or steamed in a tumbler.

Crush-effect machine For producing crushed crease effects in continuous fabric throughput. A pair of draw rollers conveys the fabric free-running in rope form to the pressing unit, the material is pressed into a perforated stuffer tube where the desired crush structure is obtained, and subsequently steam set over an adequate dwell time. The top roller can be slewed; lateral material feed. The setting tube is a perforated stainless steel tube clad in an insulated stainless steel jacket with steam and condensate connections. Setting temperature thermostatically adjustable between 70 and 150 °C. Crease formation dimensions and setting permanence depend on the intensity of the pressing process, the steam temperature and the dwell time. The draw roller pair feeds in free-running mode only on the operating stroke. Roller speed internally controllable, automatically following machine speed.

Crystall gum,

I. → Dextrines.

II. → Industrial gums.

Crystallinity The level of the crystalline content. Has a considereable effect on the characteristics of fibres and polymer application effects. In the latter case e.g. provides a measure of dry-cleaning fastness of heat-sealable polymers: the more crystalline a polyethlylene type (e.g. high-density polyethylene), the greater its resistance to penetration by solvents, the less crystalline it is (e.g. low-density polyethylene), the lower its resistance.

Crystallites (micelles). Crystal-like, elementary bodies of crystalline construction, i.e. uniform spatial arrangement of a very small cell structural component. So-called chain grate construction for example (pleated sheet structure). In the fibre fine structure, these types of crystallite are well ordered areas of a crystalline structure. They are identified by X-ray observation. To some extent, the densely packed molecule chains overlap from one crystallite to the next (elastic bonding) giving rise to loosened, so-called non-crystalline (amorphous) areas between individual crystallites. The single-phase model (crystallites with faults) is the opposite of the dual phase model with crystalline and non-crystalline areas (“fringe micelles”).

Crystalloid Crystal-forming substance, e.g. sodium chloride, sodium sulphate, copper(II) sulphate, sugar. Antonym → Colloid.

Crystalloidal solution Mainly solutions of low molecular substances in water, like sodium sulphate, sodium carbonate, magnesium sulphate, urea (as softeners and weighting and hygroscopic agents) for example, on the other hand, scarcely or not at all in a form already precondensed with formaldehyde = transition to the → Colloidal solution already.

Crystals (Lat., Gk.). More or less uniformly constructed bodies which occur by the crystallisation during cooling of saturated salt solutions (sodium crystals). There are 32 crystal symmetry classes with 230 space groups. Classification in six crystal systems in accordance with the type and number of symmetry axes and axis intersection:

I. Cubic (regular or isometric): 3 identical vertical axes, as for example in sodium chloride or potassium aluminium sulphate.

II. Hexagonal: 3 axes, two of them equally at a 120° angle, and one vertical to them; also included here is the so-called trigonal system, as in quartz or tourmaline for example.

III. Tetragonal: 3 axes as in I., vertical to each other; 2 identical, the 3rd of a different dimension.

IV. Rhombic: 3 dissimilar axes vertical to each other, as in magnesium sulphate or zinc sulphate for example.

V. Monoclinal: 2 axes of different dimensions at right angles, and one intersecting at an oblique angle, as in sodium tetraborate or sodium carbonate for example.

VI. Triclinal: 3 dissimilar axes at oblique angles to each other, as in copper(II) sulphate for example.

There are also multi-form crystal shapes, so-called dual, triple and quadruple combinations etc.

CS, abbrev. for: Commercial Standard (USA).

Cs, chemical symbol for caesium.

CSIRO, abbrev. for: Commonwealth Scientific and Industrial Research Organization, East Melbourne, Australia; → Technical and professional organizations.

CSN, abbrev. for: Ceskoslovenskych Norem (Czechoslovakian Foreign Standard).

CT,

I. → Triacetate fibres, → Standard abbrev. for textile fibres, according to DIN 60 001 up to 1988, from 1991 → CTA.

II. abbrev. for: Commission Technique = technical committee.

CTA, → Triacetate fibres, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

Ct Product, c = concentration in mg/m^3, t = reaction time in min. It is relevant to particularly volatile toxicants which are local irritants when inhaled (e.g. phosgene) where, instead of the dose, information on the effective concentration and duration of exposure (ct) apply. For specific degrees of poisoning, the ct product is constant over a fairly broad concentration range, i.e. at low concentration and with a long reaction time, there is the same effect as at high concentration for a short time.

CTNSS, abbrev. for: Centre for Thai National Standard Specifications, Bangkok, Thailand; → Technical and professional organizations.

CTTN, abbrev. for: Centre Technique de la Teinture et du Nettoyage (French Technical Centre for Dyeing and Drycleaning); → Technical and professional organizations.

CU → Cupro fibres, → Standard abbrev. for textile fibres according to the → EDP fibre identification code; → CUP.

Cu, chemical symbol for copper.

Cubex Wash test machine especially for determining the felting shrinkage of wool fabrics. Temporarily proposed by the IWS as a standard washing machine.

Cudbear, Archil → Natural dyes.

Cuite silk degummed natural silk.

Cumulative effect (Lat.: cumulatio = accumulation). Aggregation, concentration, increased effectiveness, e.g. by different products next to each other in the chemical finishing cycle or by different waste residues next to each other in effluent. "Cumulative effect" is the term employed here.

CUP → Cupro fibres, → Textile fibre symbols according to DIN 60 001 T4/08.91.

Cupra A collective term of the IVC for filaments and textile fibres (cupra fibres) produced by the cuprammonium process in use until mid 1956. Since then (in accordance with the CIRFS ruling) the term "Cupra" may only be used throughout the world, other than in Germany, for customs, statistical purposes and the like, whereas in Germany, the term → "Cupro" is now used.

Cuprammonium → Cuprammonium hydroxide.

Cuprammonium fluidity It is well-known that purified natural cellulose dissolves in cuprammonium hydroxide solution to give a solution that is viscous even at low concentrations. Cellulose that has been partially hydrolyzed or oxidized dissolves to give less viscous (more fluid) solutions at the same concentration; → Damage factor (S).

Cuprammonium hydroxide (cuoxam, Schweizer's reagent), $[Cu(NH_3)_4](OH)_2 \cdot 3H_2O$. Dark blue solution. Production: add a saturated solution of copper(II) sulphate ($\cdot 5H_2O$) in distilled water to 25% ammonia; thoroughly rinse the precipitate with distilled water, and dry. The resultant powder is durable for a long period, and is dissolved for use with 25% ammonia. Use: for the chemical identification of cellulose fibres and silk, and also for the quantitative determination of the degree of polymerisation (DP) of cellulose fibres.

Cuprammonium silk → Cupro fibres.

Cupric, Copper (II) compounds.

Cupric acetate (acetic copper, neutral copper acetate, copper acetate), $Cu(CH_2COO)_2 \cdot H_2O$. Molecular weight 199.67; density 1.88. Easily soluble bluish green crystals. Use: resisting agent for indigo resist products; oxygen carrier with aniline black.

Cupric chloride (hydrochloric copper), $CuCl_2 \cdot 2H_2O$, molecular weight 170.52. Greenish crystals, easily soluble (colour green, blue diluted). Use: highly effective oxygen carrier for aniline oxidation black.

Cupric ethylene diamine (ethylene diamine copper), $Cu(NH_2{-}CH_2{-}CH_2{-}NH_2)_2(OH)_2$. Solution of copper hydroxide (0.5 mol) in ethylene diamine (1 mol). Use: solvent for cellulose (and silk), like cuprammonia, but, in contrast, superior due to greater swelling and solvent capacity (much more rapid and intensive), cellulose solution not so sensitive to light and oxygen.

Cupric sulphate (blue vitriol, bluestone, blue jack, sulphuric copper), $CuSO_4 \cdot 5H_2O$; molecular weight 249.6; density 2.3. As blue crystals containing water of crystallisation (only these are correctly described as "blue jack") and as a white salt free of water of crystallisation. Soluble in water; also soluble in glycerine, but not in alcohol; aqueous solution strongly acid. Use: as an oxygen carrier; for fastness after-treatment of dyed fabrics, antiseptic agent (finishes), only in the presence of rust-resistant steels); for oxycellulose identification etc.

Cupro The term "cupro" has now come into widespread use throughout the world to denote any regenerated cellulose fibre produced by the cuprammonium process.

Cupro fibres A class of → Cellulosic fibres, regenerated, produced by the cuprammonium process from raw materials containing cellulose (predominantly cotton linters, also wood pulp). Principle: mechanical pre-cleaning of the linters, chemical treatment with sodium hydroxide solution (kier boiling), bleaching, expressing to approx. 70% water content, dissolving in ammoniacal copper oxide (cuoxammon cellulose), filtering, deaerating, spinning through multihole spinnerets (as a single filament bundle) into a weak ammoniacal coagulation bath, i.e. the so-called draw spinning process, followed by removal of the copper, washing, softening by adding lubricants, drying, then winding on to bobbins or sectional beams. Chemical properties as for viscose filaments. Due to the higher degree of swelling, cupro fibres possess a greater affinity for dyestuffs than viscose. In contrast to viscose (surface structure with dogbone cross-section), cupro fibres have a circular cross-section and a scale-like torn filament surface structure, which therefore gives a more matt, silk-like lustre. Because of the copper content of the spinning mill effluent, cupro fibres are ecologically problematic.

Cuprous,

I. Chemical: copper (I) compounds.

II. Name for → Cupro fibres.

Cuprous ion dyeing method (cuprous ion process, copper (I) ions dyeing process). A now obsolete method for dyeing acrylic materials. It is a dyebath premordanting dyeing process, in which cuprous ions bind acid wool dyes to the polyacrylonitrile molecule. As mordants, copper salts give the strongest effect on polyacrylonitrile fibres whereby cuprous ions co-ordinate with the nitrile groups and thus produce positively charged sites in the fibre on which adsorption of dye anions can take place.

Curie (Ci) A unit for the measurement of radioactivity. One Curie of any radioactive substance is the matter from which $3.70 \cdot 10^{10}$ atoms decay radioactively per second. The Curie is an extremely large unit. Clothing contaminated with radiation is measured in millicuries (microcuries) = $^{1}/_{1000}$ Curie. From 1965 to the end of 1977 abbreviation Ci. Since 1978, the SI unit is given per second, i.e. the activity of a radioactive nuclide with $3.700 \cdot 10^{10}$ disintegrations/s.

$$Ci = 3.700 \cdot 10^{10} s^{-1}$$

The “new Curie” (Ci) is a useful unit of activity for counting tube measurements and is applicable to all radioactive substances. Now replaced by the becquerel (Bq), $1\ Bq = 2.7 \cdot 10^{-11}$ Ci.

Curing characteristics Temperature and time function of a chemical product (e.g. reagent) which distinguishes the course of the cross-linking process up to the max. cross-linking effect. Particularly important with permanent press processes operating with a number of reagents of different condensation characteristics.

Curing conditions Cross-linking conditions in the → Cross-linking of permanent finishing agents.

Curing curve The graphic representation of the achievable dry crease angle (→ Crease recovery angle) relative to the cross-linking temperature with constant cross-linking times for a specific permanent finish agent.

Curing machine Used for the continuous heat treatment of textiles, particularly for curing (cross-linking) permanent finish agents (→ Dry cross-linking process). Designed on the hot flue principle, with driven rollers, generally stepless speed control, for temperature measuring and regulating systems, various infra-red radiators being located upstream for quicker fabric heating.

Curing machine, festoon type Condensing machine with a large fabric content and tension-free fabric guiding for (benzine-free) pigment printed knitted fabrics. Festoon system with special insulation-covered carrier rods rotating during fabric run.

Curing process Usual term in resin finishing for the dry cross-linking process (→ Cross-linking).

Curl → Snarl.

Current (market) value → Service life of textile plant and equipment.

Current strength, electrical The base measure of the → SI system of units with its basic unit of ampere (abbreviation: A). Defined as the ratio of the current Q flowing through a conductor and the time, t, it takes to do so:

$$I = \frac{Q}{t}$$

Curtain coating process Low add-on application technique for woven and knitted goods based on the Texo-Roll machine, and which avoids the use of the pad mangle.

Curtain materials →: Window curtaining fabrics; Furnishing fabrics; Net curtain fabrics.

Curved blade applicator (CBA). A low pick-up application system. Liquor is applied over the entire width of a stationary curved blade and forms a fine film which is stripped off by the fabric. Unused liquor at the edges is recirculated for reuse. – Manuf.: West Point/USA.

Curved expander rollers The name describes the curved form of these → Expander rollers (Fig. 1). A rubber hose runs on the curved axis, and is held at regular intervals by several ball bearings (Fig. 2). The expansion effect results from the varying distances which the goods have to travel.

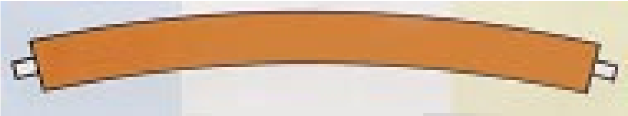

Fig. 1: Curved expander roller (Wittler).

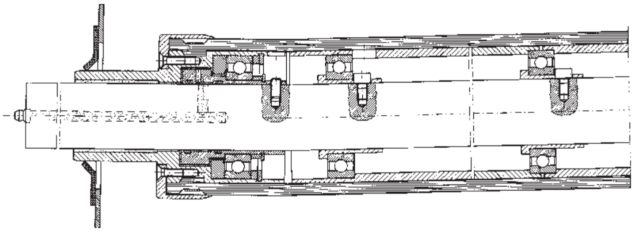

Fig. 2: Rubber hose held by ball bearings of the curved expander roller (Wittler).

Cut (Na Cut). An American yarn numbering system used for woollen yarn measurement. 1 Cut = 1 hank at 300 yards/lb.

$$1\ \text{Cut} = 0.605\ \text{Nm} = \frac{1\,653.5}{x} \cdot \text{tex.}$$

Cut fabric Of tubular knits or → Fents, made up using patterns and sewn together to form garments.

Cut film in screen making When producing hand-painted → Colour separation designs, smooth surfaced patterns may be produced through screens.

Transparent film is used which has a similarly transparent laminate coating and the pattern is traced with a knife on the laminated side. The laminated layer is then removed, without damaging the base film, wherever the pattern should be absent when printing.

Cuticle (Lat. cuticula = skin). In general use a biological term meaning the epidermis or superficial skin. In a textile context the term cuticle is used for the thin surface membrane of the cotton fibre and especially of hair and wool fibres. In the latter case the term is not quite correct as the surface of hair and wool is not a self-enclosed membrane but a series of overlapping keratinized scales enclosing the actual fibre stem, the → Cortex. The literature includes other terms such as epicuticle, endocuticle and exocuticle (components of the cuticle), epidermis and epidermal cells, epithermis and epithermal cells, epithelium, surface membrane etc. The term scale membrane is also sometimes used, referring to the scales of which it is formed. The internationally accepted terms are cuticle or cuticle cells.

Cutin,

I. (Suterin). A component (3.5–4%) in the primary wall of cotton. It is apparently still awaiting elucidation and cannot yet be defined more precisely.

II. (Cutin). A working description in research for a substance enveloping the → Cuticle of the wool hair which apparently consists of chemically highly resistant → Keratin of high density. The terms epicuticle, exocuticle and endocuticle are used as alternatives.

Cutis (Lat. = skin). A rarely used term for → Cuticle in radial fibre structure. In wool structure, it is identical to the scale cell layer beneath which lies the subcutis (intermediate membrane).

Cut length → Staple length.

Cut of garments, style, shape, design, cut, e.g. the cut of a suit.

Cut of spiral shearing cylinder → Shearing machine.

Cut-pile carpets → Tufted carpets, the pile of which consists of loops which have been cut open; in contrast to → Loop pile carpets.

Cut-pile plush A knitted plush fabric produced by cutting the loops of → Circular-knit pile fabrics. The production of this article involves high finishing costs (up to 40% of the final material cost). The following example represents a typical processing route: Slitting of tubular knitgoods – presteaming – pre-cropping – washing – hydro-extraction – drying – heat-setting – dyeing – tumbler drying – cropping – stentering. The total weight loss in pre-cropping and final cropping is 20–25%.

Cut selvedge suction remover For removing selvedge and centre strips by suction; can be used on all reroll cutting, transverse cutting, laminating and coating machines, extruders, stenters, printing machines etc.

Cutting in textile finishing The different types of cut in use are shown in Fig. 1.

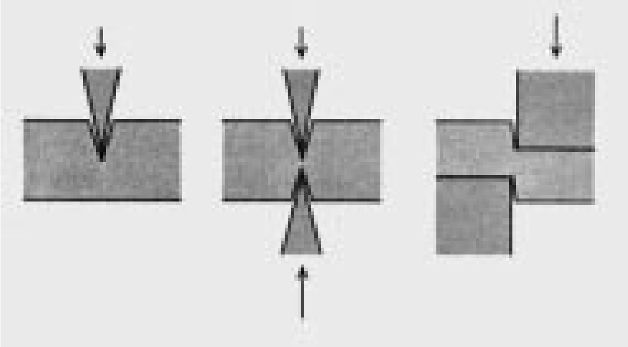

Fig. 1: Diagrammatic section of the different types of cut: cutting – biting in – shearing.

The cutting of fabrics often does not take place as an individual process, but usually directly on exit from a production machine. Conventional procedures include cold cutting with rotating blades or hot cutting with rotating cutting blades for thermoplastic fabrics. Cutting with circular rotating blades is used for the cutting of cloth edges or the length-wise splitting of fabric lengths, two different cutting principles are applied, a) rotary blade cutting and b) rotary blade shearing (Fig. 2).

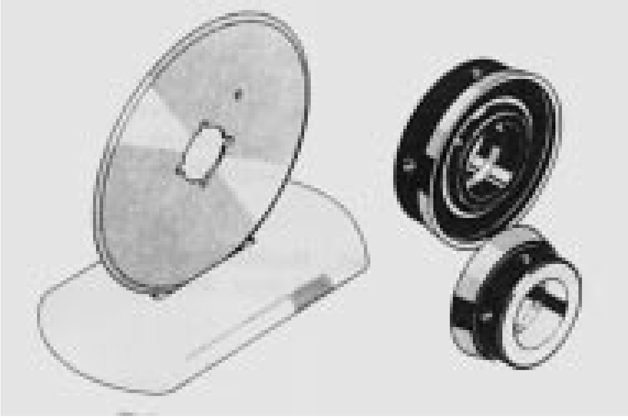

Fig. 2: Principles of rotary blade cutting (left) and rotary blade shearing (right).

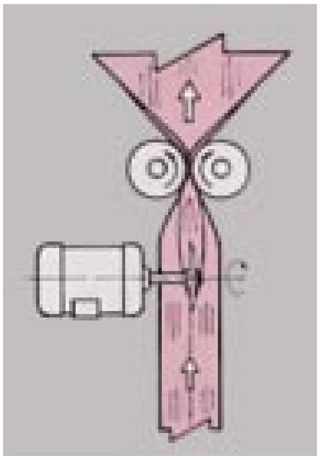

Fig. 3: Tubular fabric slitting machine (Fong's).

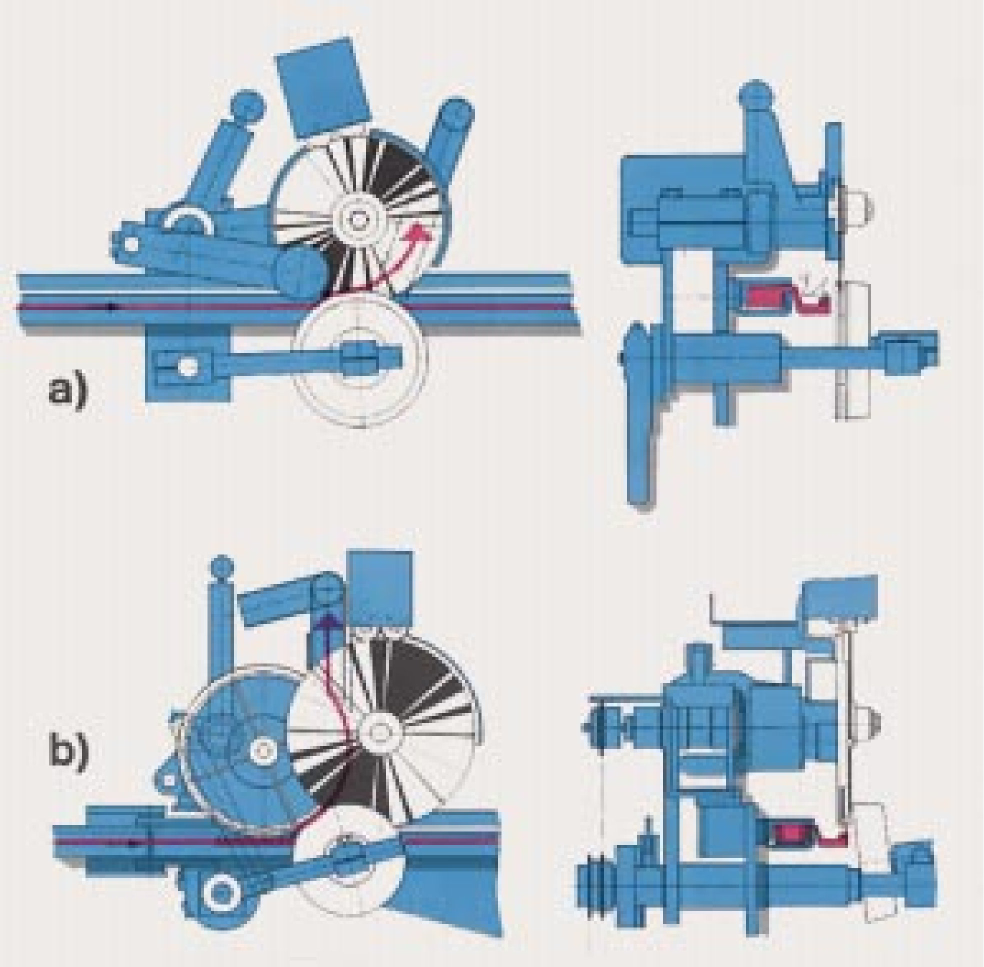

Fig. 4: Selvedge cutting machine with automatic extraction of the cuttings (Krantz).
a) Type LS 11 for cutting close to the warp; b) Type LS 8 for cutting above the warp, reduced clippings.

The rotary cut is only suitable for relatively thin material. A disc blade is used that penetrates only slightly a groove in the cutting table. The disc blade is fixed directly on to a drive shaft. It is sharpened by means of a grinding device during operation. The cutting speed of the blade is unimportant, but should nevertheless be sufficiently in excess of the cloth speed.

In the case of rotary blade shearing two slightly overlapping rotary blades work together, pressing slightly against one another. This method is suitable for cutting thick, thin and relatively hard material, especially for edge cutting and central cutting up to approx. 2 mm material thickness. The cutting speed is approx. 5% higher than the cloth speed. The blade assembly for edge trimmers takes two forms, the disc blade/lower blade for thin material, and the plate upper/lower blade for thicker and stiffer material. Both cutting principles, modified as appropriate, are used for selvedge and central cutting and tubular fabric slitting (Fig. 3). Complete cutting units (cutting machines) use the cutting equipment described, e.g. for the cutting/waste extraction on exit from the machine (Fig. 4) (rotary blade cutting, max. 200 m/min.), for the cutting of foam-bonded fabric lengths and also felt lengths (rotary blade shearing, max. 60 m/min.) and for the cutting of tubular knitted fabrics (rotary blade cutting, max. 60 m/min.); the latter with e.g. photo-electronic split detector and tubular piece guide (→ Tubular fabric slitting machines).

Cutting of textile fabrics A survey of the possible methods of generating heat reveals four principal groups:

– mechanical heat generation,
– numerous methods of generating heat by electricity,
– chemical generation of heat,
– heating by means of radiation.

These methods of generating heat are used for cutting and joining. More important is the question of "active energy" at the actual cutting or joining point. By active energy is meant that which leads directly, i.e. with no change in appearance, to an alteration in energy or a change in the material in the active element, that is the microscopic area surrounding the cutting and joining point. If all types of energy are examined and regarded as possible types of active energy (see fig.), then the thermal processes can be arranged systematically. A great many types of active energy are required; some of the most important for textile processing and the garment industry are listed.

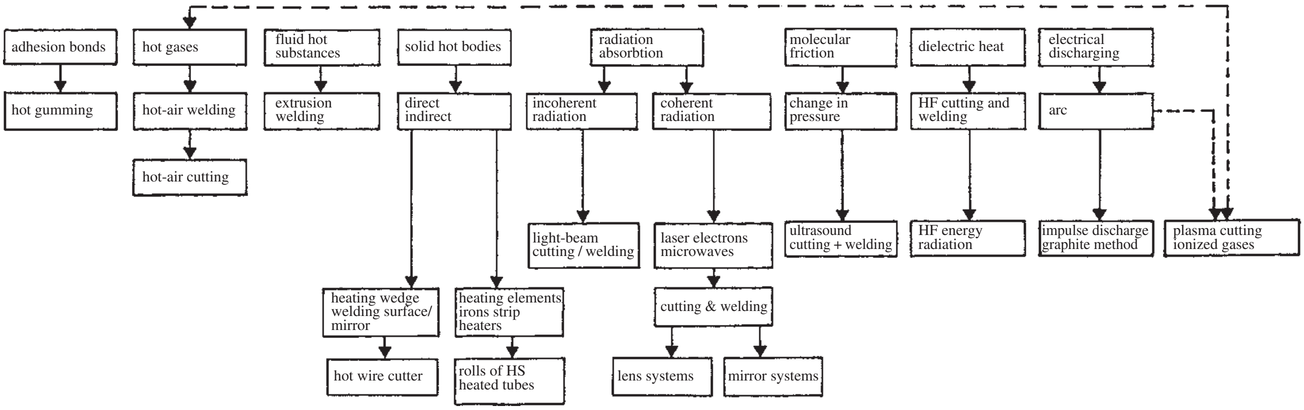

Fig.: Survey of well-known active energies for thermal cutting and joining (welding) (according to Bäckmann).

Cutting	Trend
– Hot cutting with bars	+++
– Hot wire cutting	– –
– Roll hot cutting	+++
– Light-beam cutting	–
– Laser cutting	++
– Electron-beam cutting	– –
– Plasma cutting	–
– Energy beam (HF cutting)	– –
– Ultrasound cutting	+++
– Electroerosion	–
– Hot-air or hot-gas cutting	+

Thermal cutting processes are increasing in importance. Thermal cutting such as hot cutting or ultrasound cutting, thermal pressing such as hot pressing or high-frequency pressing, thermal cutting by laser, light beam or hot air and plasma must be examined (source: Bäckmann).

Cutting oils Facilitates the work of cutting tools by conducting away the heat generated during (metal) cutting processes. Cutting oils are (non-)emulsifiable mineral oil blends.

Cuttle down Generally refers to the cooling down of woollen piece goods by laying up in piles.

Cutts sizing system A minimum application process based on the nip-padding principle. The warp is no longer immersed in the sizing bath. Instead, the sizing agent to be used is applied at higher concentration by means of an engraved roller.

Cuvettes Square, standard glass vessels comprising a centrepiece with plane-parallel window plates fused on, or also as disposable plastic cuvettes, used particularly in liquid colorimetry and spectrophotometry.

CV, → Viscose fibre, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

CY, → Modal fibre, → Standard abbrev. for textile fibres, according to DIN 60 001 up to 1988, from 1991 → CMD.

Cyanine dyes → Polymethine dyes.

Cyanoethylation of celluloses Applies particularly to cotton and involves treatment with → Acrylonitrile. Main reactions:

$$\text{Cell–OH} + CH_2{=}CH{-}C{\equiv}N \rightarrow \text{CellOCH}_2\text{CH}_2\text{CN}$$

The reaction is dependent on the following factors:

- Concentration of alkali, max. substitution is 15% NaOH;
- Moisture content of the fabric (50–80%);
- Reaction temperature;
- Reaction time;
- Concentration of acrylonitrile.

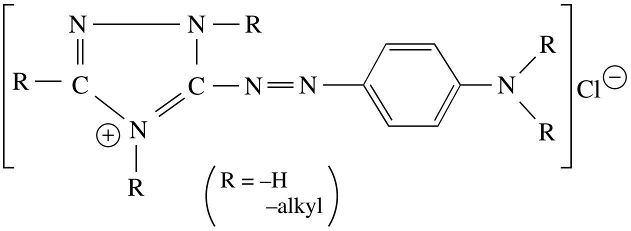
Various processes such as single-bath, two-bath and impregnation processes are known. Properties of cyanoethylated cotton: with an increasing degree of substitution there is a decrease in density and breaking strength; a gradual increase in the elongation at break, the dry abrasion resistance and the resistance to acids. It is highly resistant to rotting and oxidizing agents, saponification in the presence of alkalis, and is not resistant to washing at the boil in alkaline wash liquors. It can be dyed with direct, acid, cationic, vat, sulphur and naphthol dyes. Coloration with disperse dyes in heat transfer printing is possible. The required degree of substitution is at least 0.1.

Cyanurtriamide → Melamine.

Cybernetic Relating to → Cybernetics. In contrast to single track/linear-causal thinking in insulated individual factors (e.g. egocentric profit optimisation) cybernetic thinking is holistically oriented (e.g. sociocentric efficiency optimisation). Cybernetic control circuit: principle of maintaining a specified set value. Taken account of by controller and controlled system by constant adaptation of the control unit also faults (during implementation). When the control unit is adapted to constantly changing conditions, the control unit makes an adjustment and at the moment when information feedback is coupled with the control position in such a way that specific changes in effect ensue "automatically", it is referred to as back-coupling and also as self-regulation and automation.

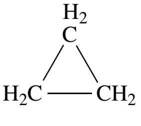
Cybernetics (Gk.: kybernetik = steersman's art). Theory of the behaviour and organisation of target oriented systems. Mechanically imitable path of energy flow (frequently interpreted as information/communication flow), comparative control and regulatory processes, as science of the structure, relations and behaviour of dynamic systems which make automation possible. These systems can organise themselves by internal structural change in the event of significant environmental change, for which reason they are called adaptive systems. They include for example machine systems (electronic computer systems, electronic data processing) and social systems (economics, administration and management functions).

Cyclammonium dyes Cationic dyestuffs of the type:

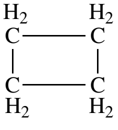


Cyclic (Lat.: *cyclus*; Gk.: *kuklos* = circle, ring). Recurring or revolving in regular cycles, circulating, ring-shaped. → Cyclic compounds.

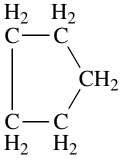
Cyclic compounds Organic compounds whose structure is characterized by one or more closed rings. Single ring compounds may contain ring structures based on 3, 4, 5 and 6 atoms, e.g.:



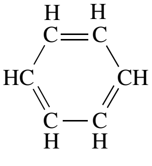
Trimethen
Cyclopropan



Tetramethen
Cyclobutan



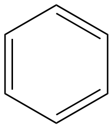
Pentamethen
Cyclopentan

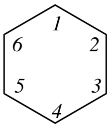


Benzol

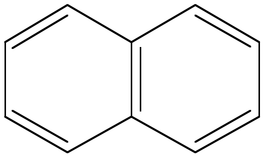
Cyclic compounds can be subdivided into homocyclic compounds, in which the ring is composed only of carbon atoms, e.g. benzene, and → Heterocyclic compounds, in which the ring is composed of atoms of more than one kind, e.g. pyridine. Higher ring compounds are derived from benzene and are described more fully under → Cyclic hydrocarbons.

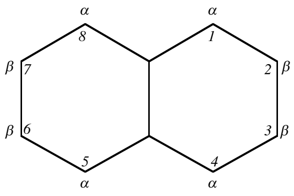
Cyclic hydrocarbons Comprehensive group of aromatic hydrocarbons which form ring systems, and the best known representative of which is → Benzene. → Naphthalene follows with 2 condensed benzene nuclei or benzene rings, whilst → Anthracene consists of 3 condensed benzene nuclei. For identifying complicated systems, the benzene formula is thought of as numbered consecutively, and derivatives are represented in the 1.2 position as ortho-compounds, in the 1.3 position as meta-compounds, and, in the 1.4 position, as para-compounds. The benzene formula is generally written simply as a six-membered ring:



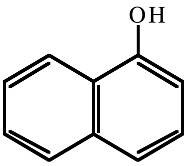


Corresponding also to the naphthalene form simplified:

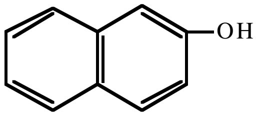




Complicated derivatives are consecutively numbered, and, if necessary, represented by α or β, because isomers can have different characteristics, e.g. α-naphthols and β-naphthols, of which only the latter have affinity for cellulose:

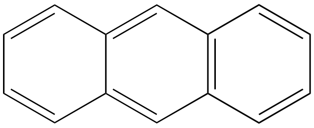


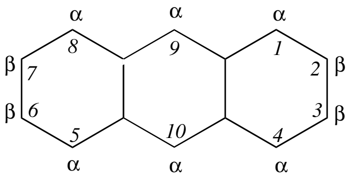
α–naphthol



β–naphthol

A similar procedure is also used with all other ring systems, e.g. with the anthracene formula:



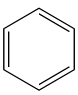


Cyclic hydrocarbon classification into:

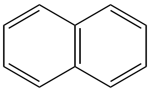
I. (Iso)cyclic or aromatic hydrocarbons with ring members only of carbon atoms, benzene type. Aromatic hydrocarbons (isocyclic, cyclic) have predominantly the common characteristic of easy alkylating and sulphonating ability, from which follow almost incalculable possibilities of building up different types of substitution products. The lower members (benzene and its homologues) are not only outstanding solvents, but the higher members serve also as an extremely important basic substance for many dyestuffs, textile auxiliary products and other products.

Classification as:

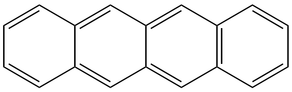
a) single and multinuclear condensed ring systems, consisting of 1–5 benzene rings:



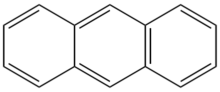
C_6H_6
benzene



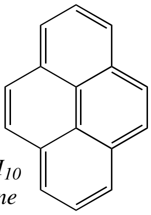
$C_{10}H_8$
naphthalene



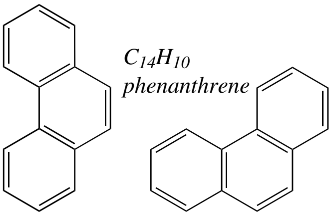
$C_{18}H_{12}$
tetracene



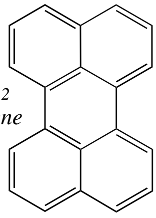
$C_{14}H_{10}$
anthracene



$C_{16}H_{10}$
pyrene

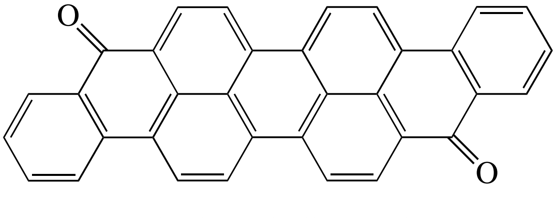


$C_{14}H_{10}$
phenanthrene



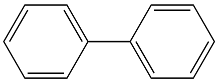
$C_{20}H_{12}$
perylene

There are however still bigger important ring systems with up to 30 C atoms, which form the basis of a series of indanthrene dyes for example:

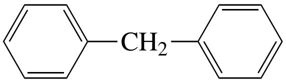


indanthrene brilliant violet 3 B

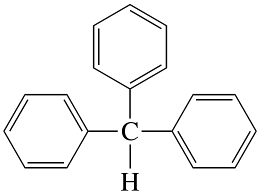
b) Multinuclear uncondensed rings also play a part as a basic substance for numerous important dyes, like for example:



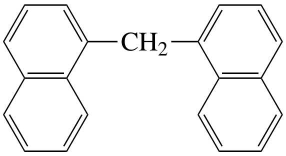
$C_{12}H_{10}$
diphenyl



$(C_6H_5)_2CH_2$
diphenyl methane



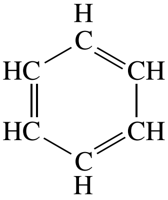
$(C_6H_5)_3CH$
triphenyl methane



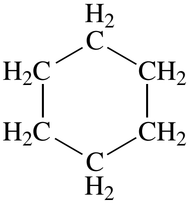
$(C_{10}H_7)_2CH_2$
dinaphthyl methane

II. Alicyclic, cycloaliphatic or hydroaromatic hydrocarbons with, in contrast to I., a higher number of hydrogen atoms, → Cyclohexane type.

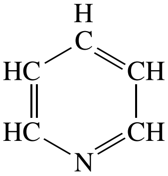
III. Heterocyclic compounds with foreign atoms in the ring system, → Pyridine type. Strictly speaking, this group is no longer included among the hydrocarbons.



benzene
(iso)cyclic



cyclohexane
alicyclic
hydroaromatic



pyridine
heterocyclic

Cyclic polyphosphates → Metaphosphates.

Cyclic sulphonates So-called nuclear sulphonates of aromatic compounds like benzene, napthalene and toluene sulphonate. → Alkyl benzenes.

Cyclo-aliphatic (alicycyclic). Cyclic carbon compounds which do not possess an aromatic ring with its system of conjugated double bonds. They are cyclic compounds with aliphatic characteristics, e.g. cyclopropane and cyclohexane. →: Aliphatic compounds; Alicyclic hydrocarbons.

Cycloalkanes Cyclic → Alkanes. Saturated hydrocarbons also referred to as naphthenes; → Alicyclic hydrocarbons.

Cycloclatrate Technical realisation of the removal of non-exhausted dye molecules from segregated streams could take the following form at the dyeing machine: phase 1 involves the selective filtering out of residual dyes, while regeneration takes place in the side vessel of the machine (see Fig.) in phase 2.

Cyclodextrins Used as textile auxiliaries obtainable from the bacterial degradation of starches. They form inclusion compounds with a wide variety of organic substances, whereby the physico-chemical properties of the included molecules are changed, e.g. in-

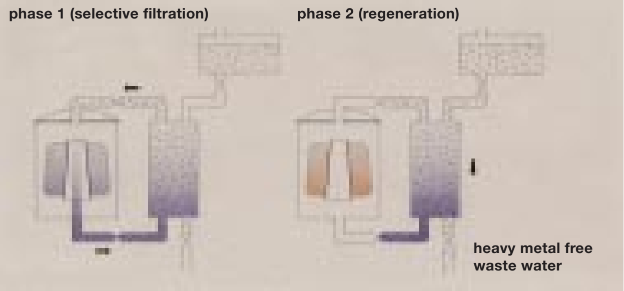


Fig.: Jasper's ideas (according to Schollmeyer) for the selective adsorption of dyes from used dye liquors with regeneration.

creased light stability of sensitive compounds, improved water solubility of sparingly-soluble compounds, reduction in the vapour pressure of highly volatile substances. Cyclodextrins are non-toxic and readily biodegradable. In comparison with other textile auxiliaries, their use brings about a clear reduction in the pollutant load of effluents and improved effluent clarification. → Cycloclatrate.

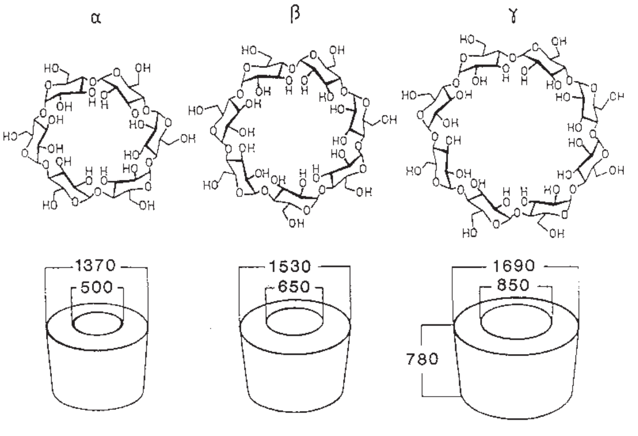

Fig.: Chemical structure and hollow space dimensions (in pm) of cyclodextrines (Buschmann).

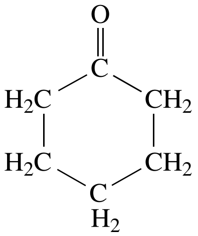
Cyclodextrins (see Fig.) are fixed on the fabric by the condensation reactions of cross-linking agents with the hydroxyl groups of cotton and those of the cyclodextrin structure. This makes it possible to include aromatics (e.g. perfume oils) in the fixed cyclodextrin molecules, so that they are able to volatilize over a fairly long period of time from the textile fabric at low concentration. It is also possible to bind unpleasant substances which are e.g. contained in perspiration, and thus reduce their vapour pressure. The ability of cyclodextrins to bind nonpolar substances prevents the redeposition of oily soils already located in areas close to the surface of such a finished fibre, thereby also achieving better soil removal during washing.

Cyclohexane (hexamethylene, hexahydrobenzene, hexanaphthene), $(CH_2)_6$; → Alicyclic hydrocarbons.

Cyclohexanol (hexahydrophenol). Chemically correct term for → Hexalin.

Cyclohexanol acetate (cyclohexanyl acetate). Solvent for nitrocellulose, cellulose ether, bitumens, metallic soaps, basic dyes, blown oils, crude rubber, many natural and synthetic resins and gums, lacquers, waxes.

Cyclohexanone (pimelic ketone, ketohexamethylene), $C_6H_{10}O$. Water-white to pale yellow liquid with acetone and peppermint-like odour. Immiscible with water, soluble in alcohol and ether. Solvent for nitrocellulose, celluloid, acetate cellulose, cellulose ether, chlorinated rubber, vinyl compounds, fats, oils, resins and cationic dyes. Also used in fat solubilizing soaps.



Cyclohexanyl acetate → Cyclohexanol acetate.

Cyclone An installation for dust extraction, e.g. from raising, emerizing, shearing, singeing and other machines which generate dust. The air to be extracted is pumped into large vertical funnels with the aid of powerful fans where it circulates downwards in the form of a vortex (Fig. 1). The dust is separated from the dust-laden air by centrifugal forces and friction on the walls of the funnel and spins slowly to the mouth of the cyclone at the bottom from where it is collected in bags for subsequent disposal (Fig. 2).

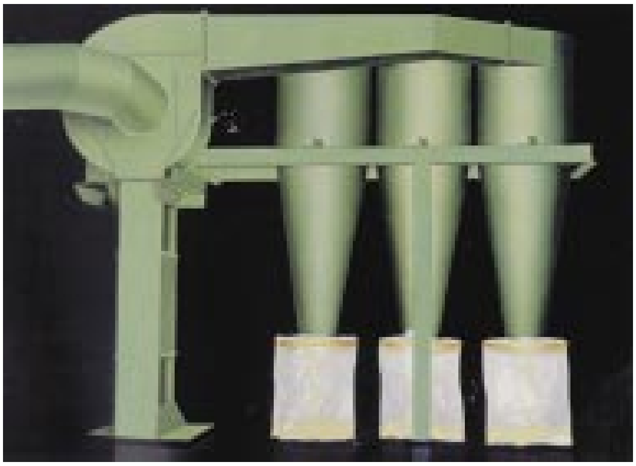


Fig. 1: Cyclone unit (LTG).

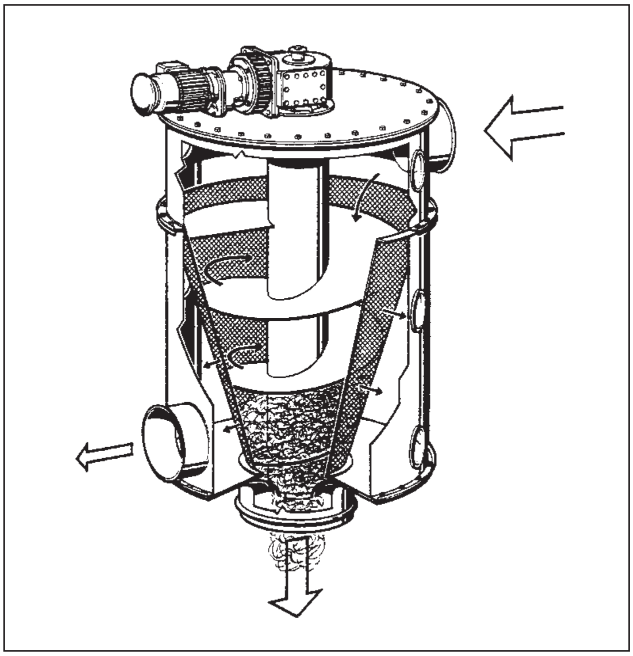

Fig. 2: Fibre compactor model FKA (LTG).

Cycloparaffins Cyclic → Paraffins, alicyclic hydrocarbons.

Cylinder dryer Cross-wound package dryer, in which the packages to be dried are exposed to different drying conditions creeled in segments of a cylinder or lying on perforated bottoms.

Cylinder drying machines In order to increase drying efficiency and improve heat utilization, cylinder drying machines are available in enclosed versions (Fig. 1) with additional ventilation. As a rule, the steam formed during the drying of textile materials on vertical or horizontal stacks of cylinders (Figs. 2 and 3) is ex-

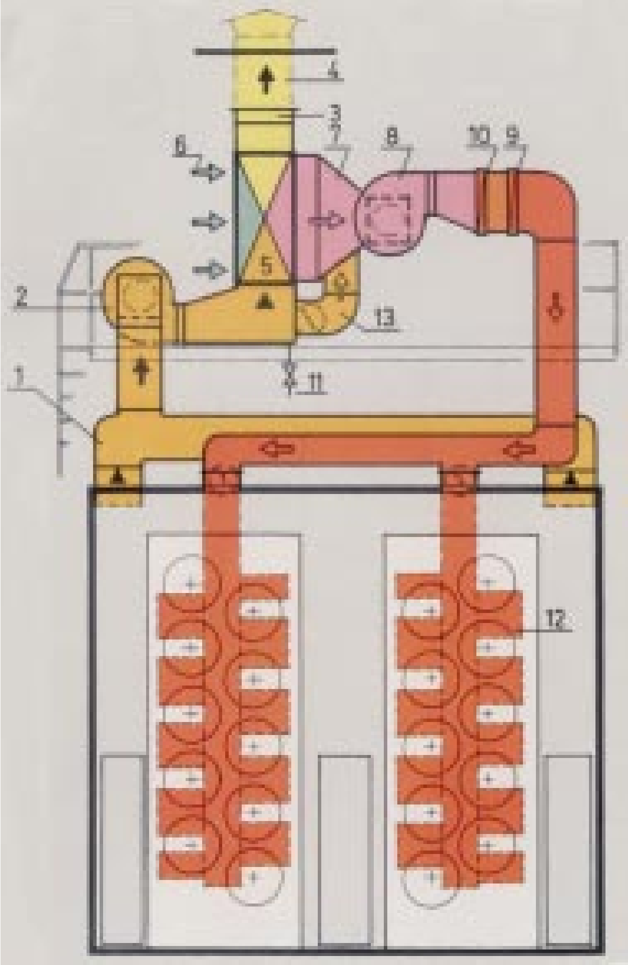

Fig. 1: Schematic diagram of a heat recovery plant for a cylinder drier (Monforts).
1 = exhaust air; 2 = exhaust fan; 3 = exhaust air after heat extraction; 4 = exhaust air vented to atmosphere; 5 = air/air heat exchanger; 6 = incoming fresh air; 7 = incoming heated air; 8 = incoming air fan; 9 + 10 = heating elements; 11 = condensate discharge; 12 = air distribution; 13 = circulating air addition.

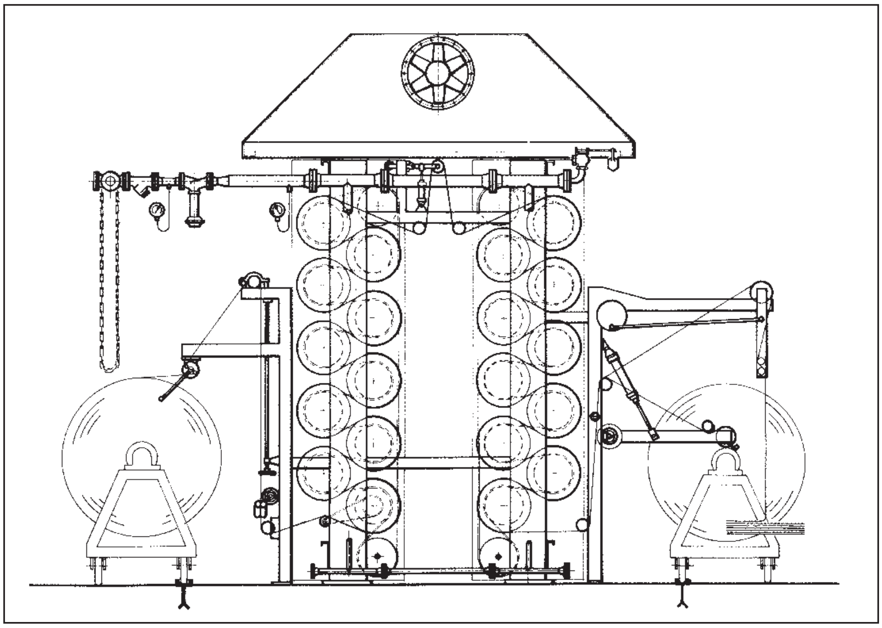

Fig. 2: Vertical cylinder drier with steam exhaust hood.

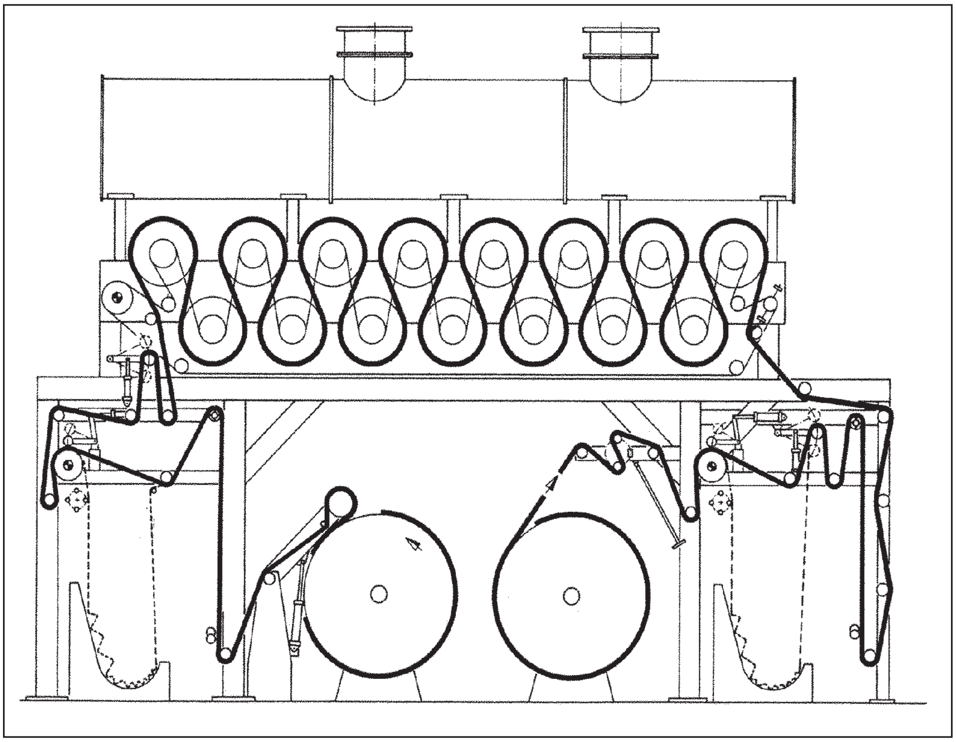

Fig. 3: Horizontal cylinder drier with steam exhaust hood (Wumag).

tracted via a steam exhaust hood above the cylinders. The adhesion of textile auxiliaries, finishes, etc. to cylinder surfaces when drying textile materials can be prevented by applying a surface coating of polytetrafluoroethylene (Teflon) to the first few cylinders. During contact transfer, heat is transferred by contact between the textile material and the heated cylinder surfaces through thermal conduction. The material may be dried by cylinder contact on one or both sides (Fig. 4).

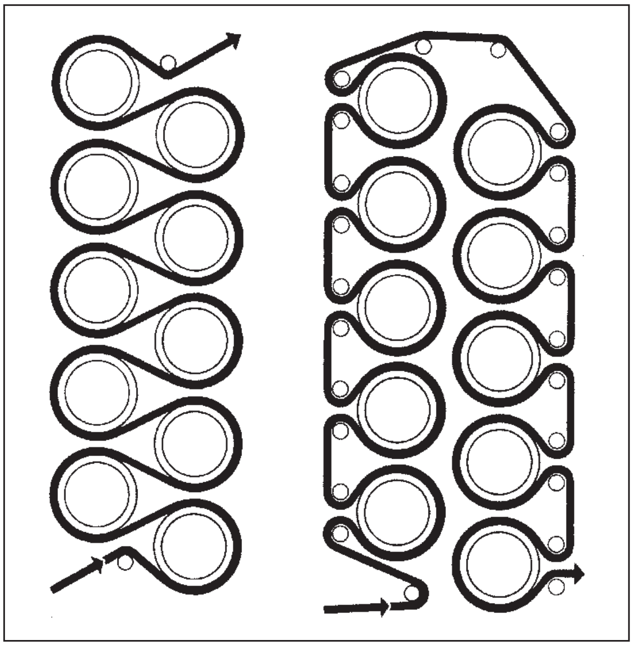

Fig. 4: Drying of material with contact between both sides (left) or one side (right) and the drying cylinders (Monforts).

Fig. 5 shows a closed loop control system for a steam-heated cylinder drier where it is desired to dry lightweight fabrics followed by heavy fabrics. As a control parameter, the moisture content of the material is determined by means of a sensor roller. The steam pressure for heating the cylinders is regulated by means of a central control valve in the centralized steam supply line to all cylinders.

a) Control function for material where the moisture content is too high: for material having too high a moisture content all the cylinders are in operation and the machine is run with maximum possible steam pressure at a manually preselected transport speed. If these heating conditions are still insufficient to dry the material to the desired residual moisture content, the transport speed is reduced by the control system until the set target value for moisture content is achieved.

b) Control function for material where the moisture content is too low: if the actual moisture content value of the dried material is too dry, the steam pressure is reduced first of all at the manually preselected temperature rate to a minimum value consistent with the safe discharge of condensate from the cylinders which must not be exceeded. If this measure is insufficient, and depending on the degree of variation from the target value, the steam supply to individual cylinders is shut off by the diaphragm valves 4–9, beginning with number 9.

Cylinder drying of textiles Contact drying by passing sheets of yarn, tapes and woven fabrics in open-width over heated stainless steel cans or cylin-

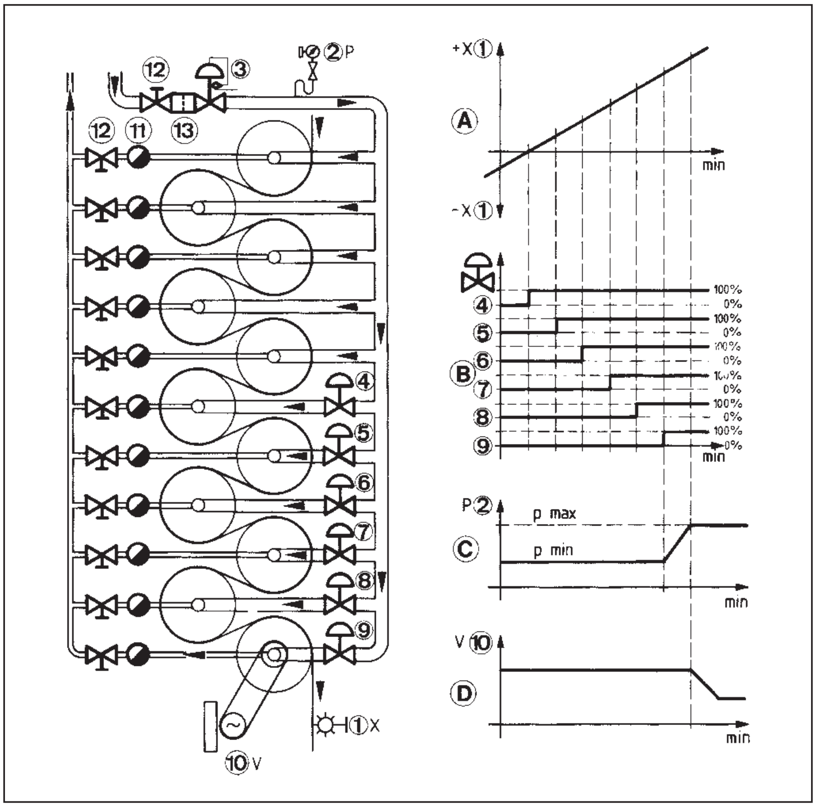

Fig. 5: Closed loop control system for the steam heating of a cylinder drier (Baelz). 1 = sensor roller to determine the moisture content of the material; 2 = steam pressure sensor; 3 = pneumatic control valve with i/p converter; 4-9 = two-way diaphragm steam valve with air control three-way valve; 10 = continuously-controllable drive to all cylinders; 11 = steam trap; 12 = manual valve; 13 = dirt trap; A = moisture content variation curve of the material; B = phase diagram of cylinder valves 4–9; C = steam pressure of cylinders for heating; D = curve of transport speed.

ders. The cylinders are driven by toothed wheels so that the textile material is subjected to lengthwise tension during drying. Cylinder driers with just a few cylinders up to 30 are available. Flat fabrics are threaded through the drier with alternate contact on the face and reverse sides from one cylinder to the next. Structured or figured fabrics, on the other hand, are dried with contact on one side only; i.e. only the flat reverse side is in contact with the cylinders. For improved heat utilization, the stacks of cylinders are enclosed, and air circulation is used for rapid drying. Only → Sieve-drum driers are suitable for elastic knitgoods whilst in the pretreatment of woven cotton fabrics (see Fig.), the material is dried at an undefined width on cylinder driers at the end of a continuous process. This is possible since cotton fabrics are subsequently dyed wet-on-dry before drying to specified width is carried out on the stenter in final finishing. → Drying systems.

Contact drying, like convective drying, proceeds in three drying stages. The heat transfer coefficient α_{contact} is defined by taking the processes of heat conduction from the heated (mainly with saturated steam) rotating contact surfaces (cylinders) into consideration. Heat and mass transport proceed simultaneously and the different kinds of heat and mass transfer (radiation, convection) influence the drying. The water vapour which forms on the contact side flows resp. diffuses through the material being dried and evaporates from its free surface into the boundary layer which forms above it. This can be extremely stable and makes removal of the

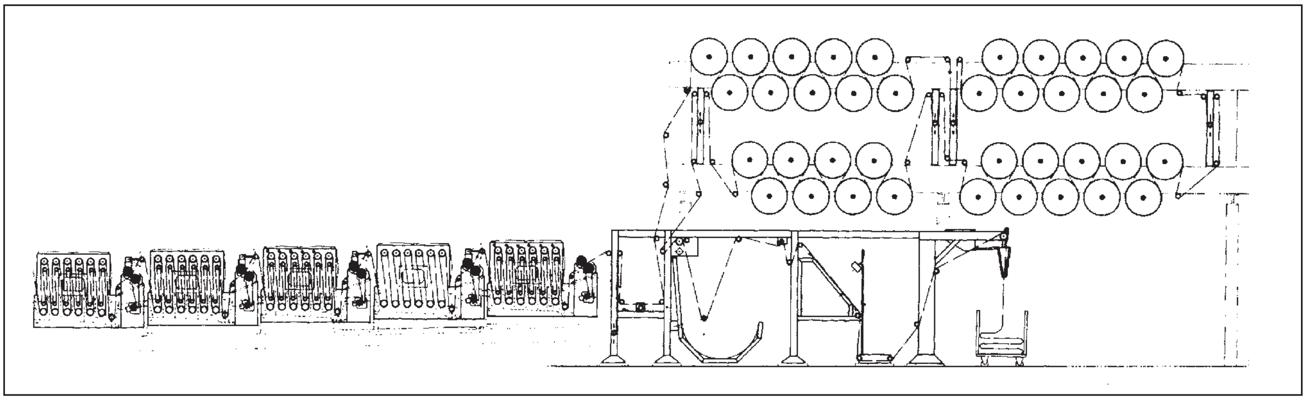

Fig.: Cylinder drying unit at the end of a pretreatment range for the intermediate drying of cotton fabrics.

built-up steam more difficult. Consequently, methods which have been introduced to break down the boundary layer, e.g. by additional forced convection (supplementary ventilation with fresh air) lead to a significant improvement in the performance of cylinder driers (up to 20%).

Another factor can reduce the transferable thermal output in cylinder driers at least in the first stage of drying. If the material being dried meets an excessively high flow resistance to the steam forming between the contact surface and the material, a steam space is created between the contact surface and the material (Leidenfrost phenomenon) which can drastically reduce heat transfer and result in considerable losses of evaporative capacity (1 : 3 to 1 : 4). Good control of the material tension, especially between the individual cylinders, helps to eliminate or reduce these undesired effects.

A third phenomenon, (often not fully appreciated in practice) should also be mentioned here which can occur at high production speeds and lead to a fall-off in cylinder drier performance. As a rule, cylinder driers are heated with saturated steam. The resultant condensate collects in the rotating hollow cylinders from where it is discharged via siphon pipes and steam traps. Normally, the heat transmission coefficients of the saturated steam condensing inside the cylinders are higher by orders of magnitude than those on the outside of the material. However, at high rotational speeds, a so-called ring of condensate can form, i.e. the condensate sump which originally collects at the bottom of the cylinders ascends at high rotational speeds due to viscous forces and inner friction, combined with the influence of centrifugal forces, and a circulating ring of condensate several millimetres thick which presents a high resistance to heat transfer is suddenly formed.

If the negative factors of influence mentioned above are eliminated, drying performance in the first stage of drying can be readily predicted from the following equation:

$$GD = \frac{Q}{r} = \alpha_{contact} \cdot \frac{F\,(T_{temperature\ of\ the\ heating\ surface} - T_{textile\ material})}{r}$$

The order of magnitude of the heat transfer coefficient $\alpha_{contact}$ is approx. 1257 kJ/m^{2}h°C under sufficiently high fabric tension. With saturated steam heating, the temperature of the heating surface ($T_{heatsurf}$) can be obtained from the vapour pressure curve. For the temperature of the material (T_{mat}), the assumption that evaporation takes place at the boil is more or less correct.

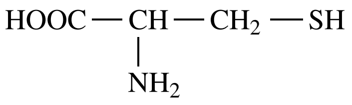
The total heat quantity balance is extremely favourable for (e.g. steam heated) contact driers. It is sufficient, in fact, to provide the process heat (Q_{Pr}) alone. Besides the heat loss (which, however, can be relatively high when the effective drying surfaces of the cylinders in the drier are not fully utilized, e.g. when drying narrow fabrics), as well as condensate losses (through evaporation), only a low proportion of energy is required to drive the machine (source: Pabst).

Cylinder fulling machine (milling stock, bumper). Used for the dry removal of hydrocellulose after → Carbonizing. Similar in design to the → Rotary milling machine.

Cylinder roller milling machines The most popular method of → Milling involves treatment in a rotary milling machine, in which woollen piece goods are processed in rope form and drawn through the machine between two rollers, where considerable pressure may be exerted by the top roller. The material then passes into a trough or spout (stuffing channel) where it is compacted.

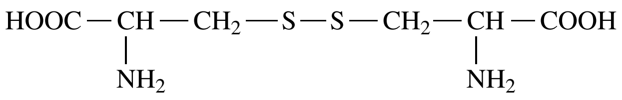
Cylindrical package, cheese A → Yarn package in which the surface of the wound yarn runs parallel to the axis of its supporting package centre or tube (only suitable for cross-wound packages). With single-end conical cylindrical yarn packages, one end of the package is built up conically.

Cysteine A sulphur-containing amino acid, constituent of many proteins where it forms disulphide bonds crosslinking the protein chain. Present in wool up to 0,5%. With oxidizing agents 2 mols of cysteine can combine to form 1 mol of → Cystine.



$$HOOC - \underset{\displaystyle NH_2}{\underset{|}{CH}} - CH_2 - SH$$

Cystine A sulphur-containing (double) amino acid (diaminodicarboxylic acid):



$$HOOC - \underset{\displaystyle NH_2}{\underset{|}{CH}} - CH_2 - S - S - CH_2 - \underset{\displaystyle NH_2}{\underset{|}{CH}} - COOH$$

It is formed in proteins by oxidation of the sulphydryl groups of two cysteine residues to form a disulphide bridge crosslinking the protein chain. It is a substantial constituent of wool keratin (12%) and animal horn, etc. (Burning test gives a typical odour of burnt horn). On reduction it forms 2 mols of → Cysteine.

Cystine bridges (disulphide, sulphur, –S–S– bridges). They form a substantial part of the side chains in wool keratin which is crosslinked by sulphur-sulphur bonds. These bonds are broken down resp. degraded by the action of alkalis, hydrolysis (boiling water), oxidation and reduction. →: Sulphitolysis; Thioglycolic acid.

Cystine oxides Oxidation processes on wool and animal hair fibres are always accompanied by cystine oxidation. The cleavage of cystine bonds involves a loss of tensile strength, however, and is therefore gen-

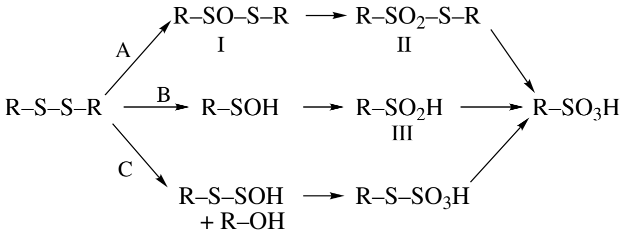


Fig.: Reaction diagram of disulphide oxidation.

erally undesirable. The extent of this oxidative damage is determined by increased solubility in alkali or by cysteic acid analysis. However, these methods are not conclusive, as they do not determine the actual degree of oxidation of sulphur in the oxidised keratin.

Even the free amino acid cystine can form compounds in which the sulphur occupies an intermediate oxidation stage between the disulphide and the sulphonic acid.

The reaction (see Fig.) can either proceed along route A, whereby the disulphide bond remains intact during the first two oxidation stages, or along routes B or C, which means a rupture of the disulphide bonds already at the initial oxidation stage. Under certain conditions, the intermediate stages II as well as I and III of the cystine have been isolated.

Oxides of the non-ionic peptide model are more stable than those of the "free" cystine. The monoxide has an unexpectedly high stability over a wide pH range. This is consistent with the observation that aminothiolsulphinates are hydrolysed considerably more quickly than their aryl and alkyl equivalents. For disulphides in general, it can therefore be deduced that dissociative hydrolysis of their partially oxidised products only takes place to any significant extent if adjacent amino groups are present. As this is only the case with peptides and proteins when amino side chains of neighbouring amino acids are present, relatively stable cystine oxides can exist there.

Cystine sulphur Sulphur bonds of the → Cystine (in wool keratin), which in part is extremely labile under the action of alkali and is converted into hydrogen sulphide, while the other part does not decrease any further even after fairly long treatment with a mild alkali. The "residual sulphur" remaining in the wool is then no longer present as cystine, but exists as → Lanthionine (easily isolated).

Cytoplasm → Protoplasm.

D

D, symbol for:

I. → Debye.

II. → Dielectric constant.

III. → Diffusion coefficient.

IV. deuterium.

d,

I. unit prefix for → Deci- (one tenth), factor 10^{-1}.

II. abbrev. for dextrorotatory (→ Optical activity).

DA, abbrev. for dye accessible. The term is used e.g. in connection with the bilateral structure of the cortex cell layer in wool (paracortex/orthocortex).

da, symbol for deca- (prefix indicating 10, as in decametre), factor 10^1.

Dabbing Faults in silk fabrics with a brushed face (white or mealy marks) are rendered invisible by dabbing with a felt pad lightly impregnated with paraffin oil. Also on → Dabbing machines.

Dabbing machines These are used for → Dabbing. Paraffin oil is applied either continuously using rotating felt discs or intermittently using oiled felt rollers which are traversed by a cam mechanism across the cloth. The cloth advances once an area has been treated.

Dabbing print Surface printing in the form of a stamp for printing industrial textiles using pigment printing, e.g. trademarks on drive belts and carpet backing. If necessary, the substrate to be printed should be pre-treated with primers (adhesion agents) or by corona treatment in order to overcome the polymer incompatibility between the substrate and the pigment printing binder.

Daghestan rugs Provenance: Republic of Daghestan. The country extends into the eastern part of the Caucasus up to the shores of the Caspian Sea. The principle centre for rug making is the town of Derbent. Technical details: Warp and weft in wool. The warp thread, which is often quite thick and brown in colour, can easily be seen on the back of the rug. The medium deep pile is of good quality but lustreless wool. The field is completely divided into fairly narrow diagonal bands (5–10 cm wide) of different alternating colours. The most frequently used colours are blue in various shades, yellow, white, and a faded green. These bands are closely decorated with small squares of different colours. At opposite corners of each square is a hooked motif. The decoration of these bands is completed by stylized roses or eight-pointed stars scattered in haphazard fashion. The ground colours are red and blue. The Turkish knot is used with a density of approx. 150 000 knots per m^2.

Damage factor (S) is used to assess the effects of chemical treatments on cellulosic textile goods. It is calculated from the average → Degree of polymerization (DP) before and after the treatment. Celluloses with different degrees of polymerization can be compared. Chemical damage does reduce the degree of polymerization, even though it cannot be detected from a loss of tensile strength. The reduction is not a direct measure of the damage, as the same damage to celluloses with different degrees of polymerization produces different reductions. The damaging effect of any treatment on celluloses with different degrees of polymerization can be compared through the damage factor, S, which is calculated with the following formula:

$$S = \log\left(\frac{2\,000}{\text{Final-DP}} - \frac{2\,000}{\text{Orig.-DP}} + 1\right) \cdot 3{,}3219$$

Orig. DP = average degree of polymerization of the material being tested before the damaging treatment;
Final DP = average degree of polymerization after the damaging treatment.

A value of the damage factor of DP = 2000 serves as the reference for the damage factor. A graph of the DP values against time for a constant damaging treatment is hyperbolic, (i.e. the same treatment produces a much bigger drop in DP with high mol. wt. cellulose than with low mol. wt.). The damage factor can be read off much more quickly and simply as a nomogram. The test is carried out as follows: the sample is shredded and dissolved in a suitable solvent, e.g. cuprammonium. The time it takes for a definite volume of this solution of the fibre sample and cuoxam to flow through a capillary tube is measured with a suspended level viscometer (see Fig.). The greater the damage, the faster the solution flows through the capillary.

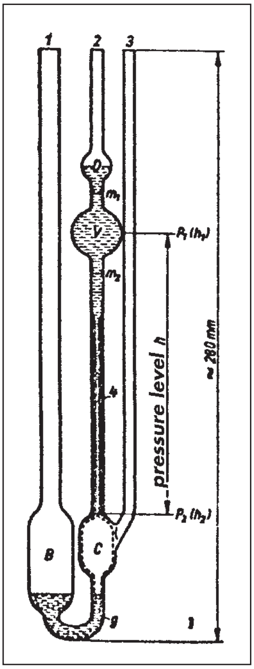

Fig.: Flow viscometer (Ubbelohde) for measuring the average degree of polymerization.

Damage factors in bleaching:
S = 0–0.4 → good process,
S = 0.4–0.7 → the process is still acceptable,
S > 0.7 → the process is not acceptable.

The damage factor should not exceed a maximum value of 1.0 in laundering, if the results are to comply with current regulations.

Damage to fibres → Fibre damage tests.

Damask A compact, figured fabric which takes its name from the city of Damascus from where the original Chinese-made fabrics were introduced into Europe. It is woven with medium to fine count yarns of cotton (often mercerized), linen, linen/cotton union, silk, regenerated cellulose or wool. Both the ground as well as the figured effects are in satin weave (patterns also in twill). Irrespective of its colour (usually a plain shade), damask owes its effect to the contrasting lustre of adjacent areas of warp and weft satin (usually 5 resp. 8-shaft) which reflect light differently. Stripe or check patterned damask is produced by dobby constructions and large patterns by jacquard techniques. It is necessary to distinguish between single and double (true) damask as follows:

1. Single damask: patterning by dobby or jacquard weaving; the borders and outlines of the pattern are smooth and rounded, with each individual thread having its own particular weave and interlacing. The floats of warp and weft threads are of unequal length; the ground is in satin weave whilst the patterning can be produced with various weaves.
2. Double (or true) damask: dobby or jacquard patterning woven on special looms; stepwise rounding of the pattern edges and, depending on whether the steps involve 2, 3 or 4 threads, the effect is referred to as a 2, 3 or 4-thread satin construction; the floats of warp and weft threads are always of the same length; only warp and weft satin weaves are used as a rule, i.e. no other weave constructions.

Depending on their field of use, damask fabrics include the following main types:

- Bed damask: consists always of 100% cotton. In addition to the numerous figured patterns, this damask quality was also referred to particularly as stripe damask in former times and is known today as stripe satin. Various types of stripe patterning are used for bed damask fabrics. Some stripe satin is produced nowadays with coloured yarns, e.g. for coloured satin or “irisette”. Used for bed and duvet covers.
- Table damask: this quality is often made of linen or linen/cotton union; a 5-shaft satin weave is frequently employed as well as 8-shaft for finer qualities; the dobby check pattern damask is typical here as well as some smaller patterns; usually white (for lunchtime and dinner table settings) or soft pastel shades (for coffee or tea table settings); these fabrics often have cross borders as well as the usual side borders thus forming a kind of rectangular frame; as in the case of bed damask, table damask is sold by the metre or in measured lengths.
- Hand towel damask: this is only mentioned here to convey some idea of the versatile applications of damask fabrics. Made from cotton, linen and linen/cotton union. Sold by the metre or measured pieces.
- Quilt damask: used for the face side of eiderdowns and quilts, mainly jacquard patterns woven with viscose or synthetic fibres which are therefore very smooth, so that pure cotton fabric is mostly used for the inner material. Because of the delustring possibilities with man-made fibres, advantage can be taken of special patterning effects here, e.g. with a bright synthetic fibre in the warp and a dull (delustred) type in the weft to achieve particularly attractive light-contrast and lustre effects. This latter variant is frequently used for coffee table damasks. Quilt damasks have lost much of their former importance due to the fact that, nowadays, they have been largely replaced by coloured continental quilts and duvets.
- Upholstery damask: also known under the name lampas. Made from silk, wool and synthetic fibres; in general, these are heavy and richly patterned for use as upholstery fabrics, furnishings and wall coverings. In most cases, these fabrics are woven with several warp and weft systems and various weave constructions as well as broché patterning. Lampa-

sette is an example of such a fabric but with a more simplified weave construction.

Damask effects in printing → Pigment printing.

Damassé,

I. A general term for silk fabrics woven on a jacquard loom (also viscose) used for festive clothing, furnishings, linings and quilt covers. Compared to true → Damask, damassé has floating threads of different length in the pattern areas.

II. A descriptive term for rich woven designs similar to damask, with contrasting lustre in the ground and pattern.

Dammar resin (cat's eye resin). A tree-derived resin of irregular form, often teardrop-shaped, pale yellow, transparent, sprinkled with white and frequently containing turbid patches. It is brittle and breaks down to a white powder on chewing. The resin has a mildly aromatic odour and is somewhat harder than colophony. At 70–90°C it becomes plastic; at 100°C it is thick, and at 150–180°C it is highly liquid and glass clear (not milky or turbid). Adulteration: especially with colophony. Dammar resin is soluble in chloroform, turpentine, chlorinated hydrocarbons. Used for oil sizing applied from a solvent or emulsion with non-drying oils, fats, waxes and solid or liquid fatty acids. When sizing is carried out correctly, viscose yarn is not brittle and not subject to dusting. Desizing: soap with the possible addition of a fat solubilizer.

Damp centrifuged Designation for textile goods which are only hydroextracted/spun dry briefly, which are damp, but no longer dripping wet.

Damping,

I. Dynamic parameter: the extent of reduction of amplitude of oscillation in an oscillatory system, due to energy dissipation, e.g. friction and viscosity in mechanical systems and resistance (ohmic losses) in electrical systems.

II. Static parameter: the ratio of input power to output power. Damping distortions as a result of the dependency of damping on the frequency.

Damping of textiles,

1. The application of moisture to yarns (yarn packages) by means of a) spray nozzles, with water containing additions of hygroscopic agents; or b) application of a vacuum and subsequent suction of moist vapour through the material (Figs. 1 and 2).
2. The application of moisture to piece goods by means of spray nozzles or brush rollers partially immersed in a water bath. Wool and wool-blend fabrics are moistened in a fine mist of water which is sucked through perforated drums (air suction damping). The application of steam on steaming tables is also sufficient in many cases.

The damping of fabrics in the Hygrocor damping machine (Fig. 3) takes place around the circumference of a perforated damping drum (1). This is covered with a

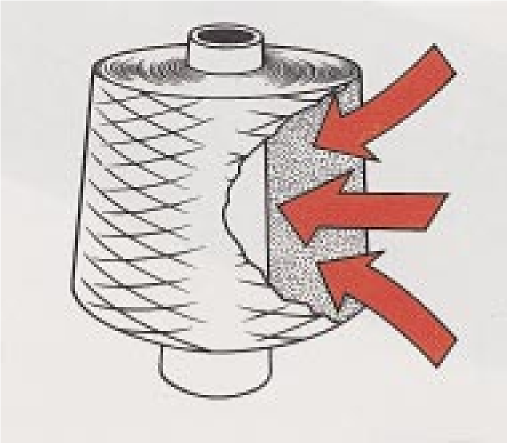

Fig. 1: Due to the extremely deep vacuum in the Welker damping process (over 95%), the steam penetrates to the core of the yarn package.

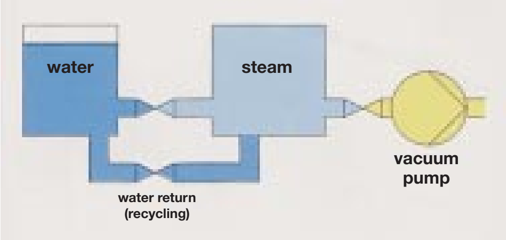

Fig. 2: Simplified processing diagram of vacuum damping.

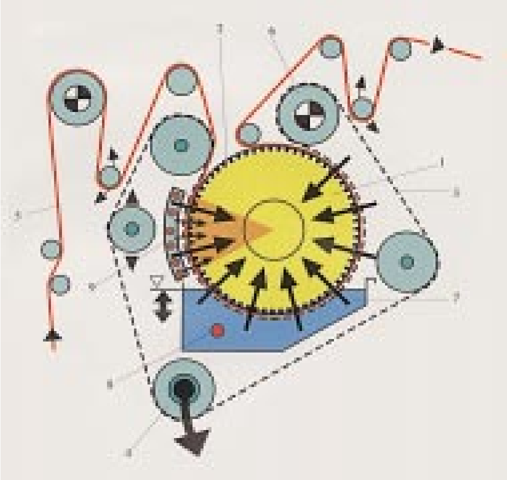

Fig. 3: Menschner Hygrocor intensive damping machine for woven wool fabrics. 1 + 2 = perforated cage; 3 = nonwoven fabric; 4 = tensioning roller; 5 = fabric; 6 = drive; 7 = water; 9 = steam shoe.

non-marking lapping (2). The drum is driven by an endless blanket, permeable to the damping medium (3) which, by means of an adjustable tensioning device (4), presses the fabric radially around the circumference of the drum thereby ensuring intimate contact between the drum and fabric (5). The blanket is driven by the drive rollers (6). As clearly illustrated in Fig. 3, the drum, together with the fabric and blanket, is partially immersed at the bottom of its passage in a trough (7) filled with liquid for damping in which a heating element (8) is installed. The liquor level in the trough as well as the heating temperature can be regulated. A continual damping of the lapping and blanket, and therefore the fabric, is achieved by rotation of the drum, whereby the blanket (3) is moistened from outside and the lapping from inside the drum (wicking system). Steam impinges on the tensioned blanket (3) from a steam box (9) which is drawn through the lapping, blanket and fabric into the drum under partial vacuum. A good contact with moisture is already produced by the steam and the fabric under pressure which is further reinforced by subsequent suction of hot water through the material.

Another well-established damping technique for piece goods is the Weko-Rotor-Damping-System which ensures a contact-free uniform application of moisture. The moisture is applied by means of special spraying discs called rotors. These rotors spin at high speed and are fed with the damping liquid from a separate unit. Centrifugal force causes two very flat fans of spray to form which are then thrown on to the moving web of material. The rotors are installed side by side in a rotor carrier and the number of rotors required depends on the width of the textile material. Typical applications of the Weko rotor damping system include: 1) damping before sanforizing; 2) damping before calendering; 3) reduction of the residual shrinkage in tubular fabrics made of cellulosic fibres; 4) improvement of dye fixation (colour yields) in certain printed fabrics prior to steaming (e.g. reactive dyes printed on viscose, etc.).

Dancer roll → Compensator roll.

DänP Obsolete abbrev. for Danish Patent. Now → DK.

Dark-dyeing polyamide → Differential dyeing polyamide fibres.

Darning (Mending) Correction of defects in wool fabrics carried out manually using needles and thread in the weave itself, either directly, where threads are missing (holes) or, where there are incorrect threads, after these have been removed. Generally carried out after burling on loom-state (grey) or scoured cloth. (→ Invisible mending).

DAS, abbrev. for Deutsche Auslege-Schrift (German Patent Specification), preliminary stage (→ Patent law).

Data logging Data from process measured variables or the signals representing these are taken and subsequently recorded in a storage medium, e.g. in order to process data (→ Process data logging). A distinction is made between absolute data logging, where every item of data can be reproduced, and incremental data logging, where determination of changes in past data takes place. In addition, a distinction is made between analog data logging, where the signals received are recorded by appropriate conversion as a graph on recording strips, and digital data logging, where it occurs using standard steps which can be defined digitally and are stored on optical disk.

Data processing systems Now almost entirely electronic data processing (EDP) systems for the collection, storage and analysis of data and information. The former Hollerith machines and manual punched card systems were also examples of simple data processing systems.

Day-glow colours The intense luminosity of the so-called day-glow paints and dyes is based on their property of reflecting both the light component of a specific colour of sunlight and the ultraviolet which has been changed into the same colour visibly for the eye, whereby the normal luminosity of the colour is increased. Such day-glow colours give → Fluorescent dyes whose shade is to a large extent the same in daylight and UV light, thus e.g. for wool or silk, optimum 0.5% fluorescein (yellow-yellow), on silk, cellulose, acetate optimum 0.5% Rhodamin 6G extra (pink-orange-red) or B extra (bluish red). With these and similar dyes, organic glasses are used as colour carriers and then generally sold as day-glow colours in finely powdered form. Use (textiles): decorative fabrics, swimwear, sunshades, flags and bunting, etc. provided that the light fastness requirements of the dyed products are not too high.

Daylight colour Appearance of a colour in daylight. → Colour matching.

Daylight lamps For constant lighting conditions in colour matching cabinets. W.C. Heraeus Original Hanau developed the Variolux in addition to the D 65 daylight lamp. The Variolux had four types of light for colour matching which is suitable for testing metamerism, where the sample is viewed under two different sources of light. Fluorescence phenomena can be tested with the UV component. A range of equipment is available in the form of test analysis lamps for tests in the short and long-wave UV range. → Colour matching.

DB, abbrev. for Deutsches Bundespatent (German Federal Patent).

dB, abbrev. for decibel; → Sound level.

DBGM, abbrev. for Deutsches Bundes-Gebrauchsmuster (German Federal Registered Design), formerly DRGM.

DC multi-motor drives for textile finishing machines These involve optimum arrangements of motors with power supplies from voltage-regulating transformers and downstream silicon-controlled rectifiers (with additional correction via synchronization field voltages) or with individual thyristor supplies for progressive drives, designed to subject the fabric to minimum tension. Further alternatives are also available:

I. Controller for the synchronization of several drives supplied by voltage-regulating transformers: an oscillation-free synchronization can be achieved by this means which is not influenced by variations caused by the fabric. This system makes it possible to run machines designed for different speeds in continuous synchronized operation as an integrated production line. The continuous control provides problem-free operation up to a max. speed range of 1 : 10.

II. Synchronization field voltage regulators for multi-motor drives: the field voltage to the individual motors is controlled in order to achieve synchronization of the fabric passage. Compensators or dancer rollers are coupled with the synchronization field voltage regulator for this purpose.

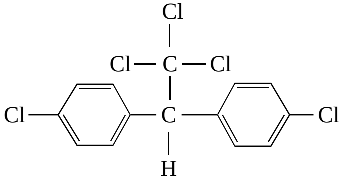
III. Digital difference measuring system for mercerizing plants. Consists of a motor with a pulse generator for the precise adjustment of fabric shrinkage or extension. Variable multipliers are used to balance out differences in fabric synchronization with motor speeds. Individual values are called up via measuring switches and displayed digitally in % with the measuring-indicator unit.

IV. → Technology cards (machine-programmable punched cards for thyristor technology).

DD → Differential dyeing.

D.D. American abbrev. on textile care labels for drip drying (hang only). Applies to garments made from self-smoothing fabrics.

DDT, abbrev. for: dichlorodiphenyltrichloroethane; a synthetic insecticide remarkable for high toxicity to insects at low rates of application. Formerly used as a contact insecticide in moth proofing formulations. DDT is the best known of a number of chlorine-containing pesticides used extensively in agriculture in the 1940s and 50s. The compound is stable, accumulates in the soil, and concentrates in fatty tissue, reaching dangerous levels in carnivores high in the food chain. Because of its high toxicity, DDT has been banned in Europe and many other countries; it can, however, still be found in imported materials.



Deacetylation of acetate In practice, this means the same as → Saponification.

Dead cotton Cotton fibres which have died before maturity, unlike → Immature cotton they do not contain any protoplasm. The fibres are collapsed flat, have broad, more solid and more brittle ends and thin, transparent cell walls. On the whole, they are very brittle and have low elasticity. They have a lower dye affinity than mature cotton, so pale areas occur in dyeing. These can be compensated however, by sodium hydroxide treatment, which also increases strength. → Cotton maturity index.

Dead time Dynamic parameter of transfer elements in automation systems; the time between turning on an input signal in a system at rest before the output signal begins to alter distinctly (for humans: reaction time).

Dead times in dyeing The length of time in which dyes have not yet been absorbed, or have been completely absorbed before reaching final fixation conditions, is referred to as dead time. In batch dyeing processes, these should either be completely avoided or be accomplished quickly. The Fig. shows a temperature-controlled method.

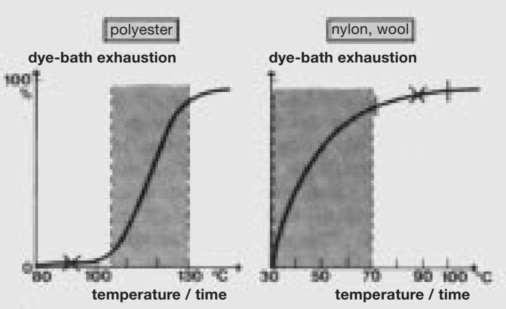


Fig.: Dead times (x) before the critical temperature range is reached in polyester dyeing (left) or after passing through the critical temperature range in nylon or wool dyeing.

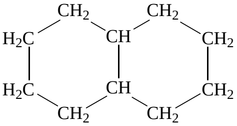
Above or below the dye absorption zone (critical temperature range), rapid heating can be carried out without endangering levelness. The necessary absorption zones, (temperature, pH or salt level zones) of the dyes and fibres should be obtained or determined from recommended dyeing procedures. With high levelness and reproducibility specifications, controlled absorption techniques are used, with absorption and/or fixation being controlled in such a way that dyeing is virtually level from the very beginning and generally more economic. In contrast to this are the migration processes, which require dyestuffs with good migration characteristics to be used, as the greater initial unlevelness must be compensated by migration. In this case the unfavourable dyeing conditions (lower liquor throughput, slower passage of the cloth) can be more economic, as it would be time consuming to achieve virtually level dyeing under these conditions. However, migration processes often cannot be avoided, e.g. with fibre and temperature differences in the machine or with dyes having rapid absorption (e.g. vat dyes). By using controlled absorption, insufficient attention is often paid amongst other things to the following: it is only necessary to control the absorption approximately to avoid absorption which is essentially too fast (lack of levelness) or that which is essentially too slow (time consuming). This is possible by rule of thumb (derived from → Dyeing theory) to control temperature, pH or levels of salt or even with the aid of absorption control instrumentation. Despite this, there is no direct relationship between dye absorption rate and levelness of different shades as the dye absorption rate is always only one of several factors which govern levelness.

Dead wool An inferior wool quality that is insufficiently protected by wool fat (suint) with reduced softness, elasticity and strength. It is not identical with → Fallen wool.

Debye A unit of molecular dipole moment equal to 1 x 10^{-18} electrostatic unit. Named after Peter J.W. Debye (1884–1966). → Dipoles.

deca- (Gk.: *deka* = ten). Unit prefix denoting ten times = 10^1; e.g. 1 daN = 10 N.

Decahydronaphthalene (decalin), $C_{10}H_{18}$.



Colourless, water-clear, liquid with a faint odour (naphthalene-like). Miscible with most organic solvents. It is a solvent for fats, oils, resins, pitch, wax, etc. Uses: component of fat solubilizing soaps, spotting agent (turpentine substitute).

Decalcification of water Softening of water; → Water-softening process.

Decalin → Decahydronaphthalene.

Decationization The removal of cations from water using a hydrogen-ion exchanger. First step in complete desalination. → Ion-exchange processes.

Decatized A German quality label which guarantees a lustre fast to water drops and ironing (→ Decatizing); fabrics bearing this label must be dimensionally stable but should nevertheless permit styling during garment manufacture.

Decatizing (decating). A finishing process mainly used to improve the characteristics of wool and wool-blend piece goods with regard to appearance, shape, handle, lustre and smoothness, thereby producing a fabric in the desired finished state. Decatizing is accomplished by steaming under pressure, i.e. by subjecting the well-packed or firmly wound fabric to a steam treatment. Since this treatment is usually carried out as the final operation after the rotary press, the pressed state of the fabric is retained by the decatizing treatment. The purpose of decatizing is therefore to improve handle by the action of moisture, to moderate and set the lustre imparted by pressing or calendering (lustre effects resistant to steam pressing), to achieve a finish fast to water spotting and to set the fabric in length and width. This process is carried out immediately before final inspection and making-up and is primarily applied to wool fabrics as well as some fabrics composed of man-made fibres. Whilst the → Wet decatizing (wet setting) process carried out in the early stages of finishing is preferably carried out with hot water, final decatizing is a dry setting process which is the reason why the term steam decatizing is often used and, depending on the steam quality, wet steam or dry steam decatizing. Decatizing includes open decatizing as well as kier vacuum decatizing (Figs. 1–5).

Decatizing, fastness to Resistance of the dye to the effect of steam when → Decatizing wool goods. Wind a sample sandwiched between molleton cotton cloth brushed on both sides around a perforated decatizing cylinder through which dry saturated steam is blown for 15 min.; a) light decatizing factor: steam pressure 147 kPa, temperature 110ºC; b) intense decatizing factor: steam pressure 245 kPa, temperature 127ºC. Dry specimen in warm air (< 60ºC). Simultaneously test dyed reference fabric. When assessing the dyed reference fabric using the grey scale, light decatizing should result in yellowing to grade 4, and intense decatizing yellowing to grade 3, which is more yellow.

Dechema, abbrev. for: Deutsche Gesellschaft für Chemisches Apparatewesen (German Society for Chemical Instrumentation). A technical scientific society concerned with the promotion of chemical instrumentation and equipment. → Technical and professional organizations.

Dechlorinate, to → Antichlor.

deci- (Lat.: *decimus* = tenth). Unit prefix denoting one tenth = 10^{-1}; e.g. 1 decitex = 0,1 tex.

Decibel (dB). One tenth of a bel. A unit for comparing levels of power, often used to express sound intensities. → Sound level.

Decolorization of waste water The indirect release of dye water, from textile mills, for example, often presents the operators of municipal sewage works with insoluble problems. Usually, it is only in exceptional cases that sufficient decolorization can be achieved using mechanical/biological processes and indeed, from time to time, the dye substances impair the biological process. The wavelength (λ) of the dye is measured and reveals whether, for example, it is blue (436 nm), green (525 nm) or red (656 nm) which is present. Thus, in waste waters, the dye is described via the transmittance colour index ((TCI) as described in DIN 5033, Part 1). The whole visible spectrum, from violet to dark red, lies between λ = 390 nm and λ = 760 nm. The colour intensity is given by the absorbance E. The absorbance is the logarithm of the reciprocal of the transmittance T.

$$E(\lambda) = \log \frac{1}{T}$$

In Appendix 38 of “Allgemeinen Rahmen-Verwaltungsvorschrift über Mindestanforderungen an das Einleiten von Abwasser in Gewässer [General Framework Administrative Regulation Covering the Minimum Requirements Concerning the Discharge of Waste Water into Waterways] 25.05.1990, the coloration of waste water is restricted. Thus, for a 2-hour mixed sample, the spectroscopic absorption must not exceed the following values (the absorbance is generally related to a layer thickness of 1 cm). The transmittance colour index listed here is evaluated by eye using a 1 meter long plain cylinder (layer thickness 1 m) according to Streichfuß:

7 m^{-1} at 436 nm
5 m^{-1} at 525 nm
3 m^{-1} at 620 nm

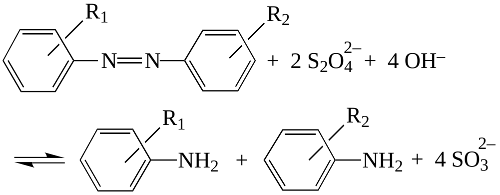
Selective discharge constraints are also confronting the textile industry with new demands in regard to exceeding specified tolerance limits. Because the dyeing process involves establishing a distribution equilibrium between dye exhaustion in the fibre and dye in the liquor, there will always be a certain amount of dye remaining in the liquor – bath exhaustion lies between 85% and 95% depending on the dye. Effluents from textile printing works are particularly damaging to the environment because of their colour and the high levels of organic contaminants which they contain. Their disposal is very problematic and they usually cannot be discharged to municipal sewage works as certain components pass through the biological purification steps unchanged or may even impair them. Even in conventional effluent treatment plants, the dye content is not reduced sufficiently.

There are various processes in waste-water treatment which can reduce the colour to a certain degree. Hydrolysates, produced during dyeing processes using reactive dyes, are hardly degraded at all by biological methods and, for this reason, they must be removed from the effluent using suitable procedures. Their removal is usually accomplished by means of precipitating agents and flocculants although inorganic reagents, such as iron and aluminium salts, are not suitable for their separation, making it necessary to use organic flocculants instead. But this creates new ecological problems as a certain amount of the flocculant remains in the effluent and is itself difficult to degrade biologically. Precipitation produces sludge which must be classified as hazardous waste and this has a detrimental effect on the costs of the process. Furthermore, this sludge contains little dye but a comparatively large amount of water.

The following may be considered for decolorizing effluent:

1. Adsorption (e.g. activated carbon).
2. Oxidation (e.g. ozone).
3. Biological purification.
4. Precipitation/flocculation (iron or aluminium salts).
5. Reduction.

Reductive cleavage of azo dyes (and therefore decolorization) to amines using $Na_2S_2O_4$ is well known in preparative organic chemistry. This takes place according to the following equation:



The standard potential for the system $S_2O_4^{2-}/2\ SO_3^{2-}$ is –1.12 V in alkaline solution and –0.082 V in acid solution ($HS_2O_4^-/H_2SO_3$). From this, it is clear that reductive decolorization must be carried out in an alkaline medium. Electrochemical treatment of effluents can also lead to a reduction in coloration. Using iron electrodes produces iron hydroxide in the solution which precipitates out together with the heavy metals contained in the liquor. Organic substances such as dyes can also be removed in this way. However, this method

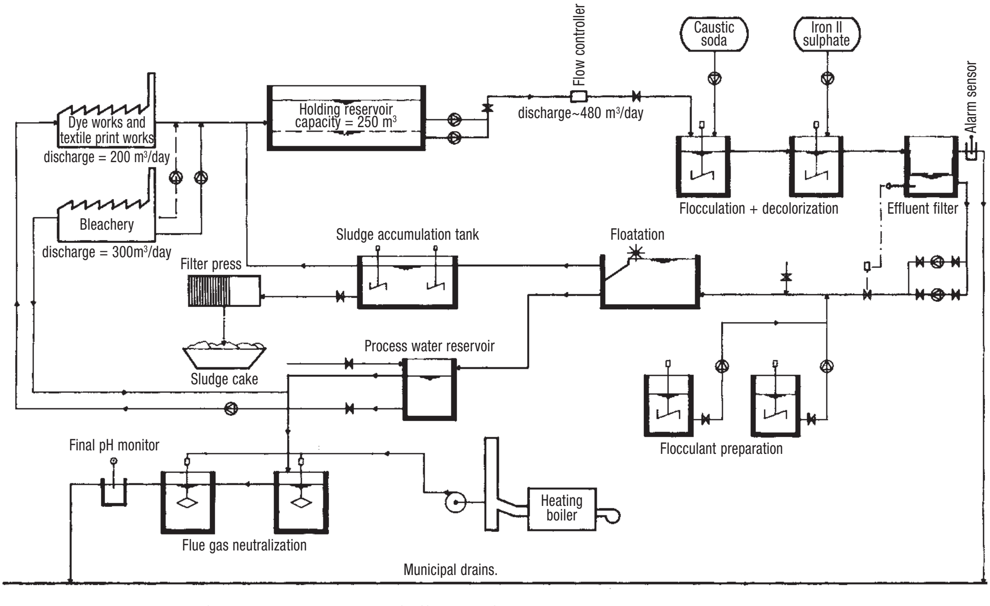


Fig. 1: Treatment plant for the decolorization of effluents (flow diagram).

produces a dye-containing iron-hydroxide sludge which has to be disposed of as hazardous waste. Oxidative cleavage using hydrogen peroxide also produces sludge because iron salts have to be added as activators.

Decolorization by flocculation and floatation can be achieved as follows (Fig. 1): all coloured effluents from the printing works, including those from the floor drains, are collected in a 250 l holding reservoir. Many of the components in the effluents neutralise each other in this pool and the waste water is continually fed throughout the day to an effluent treatment plant and then on to the municipal sewage works. The pH of the effluent is reduced to 10.5 in a 4 l initial neutralisation step using caustic soda and in a second 4 l container, 20% Iron II sulphate solution is added to produce flocs and decolour the effluent. The pH drops to around 9.2 as a result and the flocculation process is complete after a short reaction time. The flocculated effluent is pumped into the floatation plant where the iron hydroxide flocs are made to float by adding more flocculant and injecting air, as the air inflates the flocs. The macro flocs produced separate out on the surface and can then be skimmed off as a sludge.

One possible method for removing dyes from aqueous solutions which has received little attention up until now, consists of forming low solubility dye-inclusion compounds using a macrocyclic complexing agent.

This type of selective decolorization can be achieved by creating occlusion compounds of specific dyes in cyclodextrins. A corresponding process for decolorizing dye-works water has been suggested by Jasper (Figs. 2 and 3): in Phase 1, the extracted dye feed liquor is pumped through a filter cake with cyclodextrins and the individual dyes occluded. Regeneration is carried out during Phase 2 using salt solution, thus producing altogether a colourless effluent.

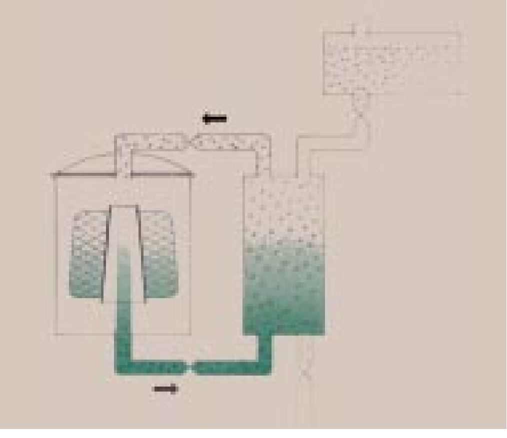

Fig. 2: Phase 1: selective filtering out of dyes in the effluent with cyclodextrins (source: Jasper).

Fig. 3: Phase 1: regeneration (source: Jasper).

Decolorizing carbon → Activated carbon.

Decomposition When sizing or finishing, using standing dye baths etc. and as a result of multiple foreign substances on mainly natural and man-made fibres, numerous degradation phenomena may occur. A distinction is made between → Decay and → Fermentation.

Decontamination A term generally used for the removal of radioactive components. In a wider sense, the elimination of toxic, microbial or radioactive pollutants.

Deconvolution index According to Calvert and Clibbens, this is the criterion for assessing mercerization. It is determined by counting out approximately 800 fibres (0.1–0.2 mm long) under a microscope. The percentage number of fibres with no twist corresponds to the deconvolution index. Assessment: 9–15 = unmercerized cotton, 60–70 = mercerised cotton (for piece goods, 25–40, usually fewer in the weft direction than in the warp direction).

Deep-dyeing polyamide → Differential dyeing polyamide fibres.

Deep Dye process (colourbox process). This unit was developed by Deep Dye Processes, USA, for the printing of tufted carpets. The printing element consists of a plastic block, with which all the colours in a design are applied simultaneously. The individual colours of the pattern are separated by ridges, so that the pattern figures form practically flat “colour troughs”. The print paste is fed into the troughs from below through special feeding channels. During the printing operation, the blocks are pressed mechanically against the material from below, so that the print paste is applied to the carpet pile. This printing process is no longer in use.

Defect According to § 459 BGB, an object displays a defect if it “contains faults which negate or reduce its value or fitness for normal use or use as laid out in the contract”. → Faults in textiles which only “result in an insignificant reduction in value or fitness for purpose" are not classed as grounds for a defect. In the area of textiles, performance defects include incompleteness or deviation from the contract covering properties which have been guaranteed and "permanent defects". A distinction is made between the following (although it is not always possible to make a clear distinction):

1. Visible defects: immediately recognisable according to the state of the art and without costly preliminary examination, possibly preventable by specialist assessment.
2. Latent defects: only avoidable at considerable test expense.
3. Hidden defects.

Defect costs (→ Quality costs), are costs which arise when production or processing does not meet up to specified quality requirements. In contrast to → Defect prevention costs and quality control costs, defect costs may vary substantially from month to month; thus regular evaluation is justified, especially as this facilitates recording/evaluation, e.g. by frequently occurring causes of defects.

Defect elimination during dyeing is the avoidance and removal of factors which cause defects during the dyeing process by the selection of specifically compatible fibre material, auxiliaries, dyestuffs, dyestuff combinations, mechanical settings and process types.

Defective colour vision In Germany, 8% of the male and 0.4% of the female population have defective colour vision. Of these, 60% suffer from → Anomalous colour vision and 30% suffer from → Colour blindness.

Defect prevention costs (→ Quality costs) are the costs of preventive quality assurance for the purposes of defect prevention. Defect prevention costs may arise in practically any cost centre in the form of salaries and similar cost types. Apart from the cost centres directly concerned (quality planning, quality job preparation) these are not readily definable.

Defect rate Ratio of faulty goods to the total number of goods (percentage seconds).

Defects in grey goods For the finisher of textile fabrics, grey goods are the products obtained directly from the respective production machines (e.g. machines for weaving, knitting, warp-knitting, production of nonwovens, etc.) without having been given any aftertreatment. For the dyer of textile fibres (loose stock, tops) or yarns, the material from the corresponding preceding stage of processing represent grey goods. Defects in grey goods are those defects present in a visible or latent form in the goods before they have been given a finishing treatment and which are unacceptable for quality reasons. They may be subdivided into the following groups:

I. Localised defects:

- Defects present in grey goods which are visible to a greater or lesser extent and which cannot be caused in finishing.
- Defects present in grey goods which, from their appearance, could also be caused in finishing.
- Latent defects in grey goods which only become visible during finishing, or give rise to problems in the finishing process.
- Defects in grey goods which can, perhaps, be eliminated during the course of finishing.

II. Variations from agreed standards:

- Grey goods which have been finished according to tried-and-tested recipes as agreed between customer and finisher, but which subsequently no longer give reproducible results.

The possible causes of defects in grey goods should be listed separately according to the process stage, and not by the type of fabric. By classifying the defects according to their source, the process stage (or stages) where most of the defects originate can be clearly identified. Once this has been done, an attempt should be made to eliminate the most costly defects first of all. This type of defect classification system, however, calls for a detailed knowledge of all the various process stages involved in the manufacturing process.

The textile finishing plant receives its grey fabric for finishing from the preliminary manufacturing stages of spinning and weaving. The following process stages stand out as possible sources of defects here:

1. Raw material
1a. Dyeing of the raw material
2. Spinning
3. Winding and twisting
3a. Yarn dyeing
4. Warping and sizing
5. Fabric production
5a. Dyeing the textile fabric

The classification scheme for defects in grey goods may be demonstrated by reference to defects in woven textile fabrics:

Defect type	Source of defect
I. Defects present in grey goods which are visible to a greater or lesser extent and which cannot be caused in finishing:	
– Constructional defects in the yarn (incorrect twist, coarse yarns, irregular yarn, slubs, neppiness, fluffiness, interlacing faults, knots, weft snags, differences in texturing)	1, 2, 3
– Impurities in the yarn (fibre fly, dirt, waste material, husk and leaf residues in cotton, burr residues in wool)	2
– Damaged threads (broken ends, broken picks, chafe	5

Defect type	Source of defect
marks, shuttle smashes, interlacing faults)	
– Constructional defects in the fabric (floats, mispicks, weaving bars, wrong check pattern, double picks, weft defects; Drawing-in defects: reed marks, reed stripes, cracks; Machine defects: stop marks, start-up marks, loose shuttle picks, sloughed-off weft, standing places, taut picks, reed marks, reed stripes, double ends, kinky weft, floating weft, slack threads, shuttle pressure marks, uneven weft density, lashing-in, loom-stained fabric)	5
– Tension differences in the thread systems (tight threads, bright picks, shed changes, baggy fabric)	1, 2, 3, 4, 5
– Impurities in the fabric (fibre fly, soiled yarns)	5
– Damaged fabric caused by improper procedures to eliminate defects (scratch marks, cleaning marks, ripples, pick-out marks)	5
II. Defects present in grey goods which, from their appearance, could also be caused in finishing:	
– Damages in the fabric (holes, tears, damaged selvedges, abrasion marks, cloth expander stripes)	5 + 5a
– Deformations in the fabric (folds, wrinkles, pressed-in folds, creases, moiré)	5 + 5a
– Stains in the fabric (water stains and rings, oil, rust and dirt stains)	5 + 5a
III. Latent defects in grey goods which only become visible during finishing, or give rise to problems in the finishing process:	
– Falsely declared goods and inadvertently mixed up fabric qualities	1, 2, 3, 4, 5
– Constructional defects in the yarn (abnormal fibres, non-uniform filament count)	1, 2
– Impurities which are neutral in colour (fibre fly, foreign fibres, invisible oil stains, small iron particles, uneven size add-on, inadequate fastness properties, non-removable spin finishes)	2, 3, 5
– Structural differences (chemical damage, differences in shrinkage, absorbency and dye uptake)	1, 1a, 2, 3 3a, 4, 5
IV. Defects in grey goods which can, perhaps, be eliminated during the course of finishing:	
– Faulty selvedges (pulled-in, folded, curled, wavy, slack edges)	5
– Distorted goods (skewed weft, bowed weft)	5
– Variations in width	5
– Impurities (dirt, oil, rust, chalk, size residues)	1, 2, 3, 4, 5
– Inadequate fastness properties	2a, 3a
V. Grey goods which have been finished according to tried-and-tested recipes as agreed between customer and finisher, but which subsequently no longer give reproducible results:	
– New production batch (man-made fibres) or different source (natural fibres)	1
– Differences in texturing	1
– Differences in structure	1, 3
– Variations in yarn construction	1, 2, 3

(source: Berndt and Heidemann).

Defects, invisible marking of, using → UV fluorescent dyes or UV marking pens.

Deferred curing (post curing) → Permanent-press process.

Defixation Defixing in the sense of neutralising the effect of fixation. In this way, it is possible, for example, to observe the progressive defixation of a finished textile (e.g. having a non-shrink finish) after repeated washing as a result of the gradually increasing shrinkage.

Deflecting bar,

I. Deflection device inserted at a 45° angle to the passage of the cloth, causing the cloth path to undergo a 90° turn (e.g. in conventional → Spiral steamer). With a cylinder having a double deflecting bar, a double reversal of 2 x 90° occurs (enabling cloth to enter and exit at an adjacent position). In the form of a heatable hollow body, a deflecting bar enables a steam cushion to form which reduces friction, particularly when steaming damp goods (e.g. in two-stage printing with vat dyes).

II. Piece guide in drying lofts, hotflues or steamers which draw the processed goods out of the side of the machine from the centre.

Deflecting roller Smoothing roller to deflect the run of cloth in another direction (Fig.) or onto another level.

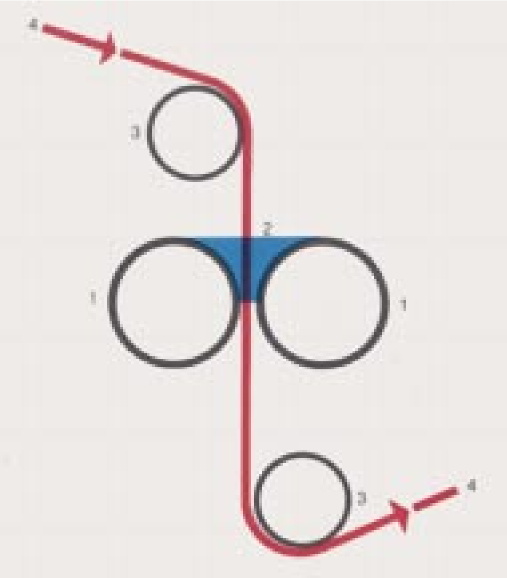

Fig.: Action of deflecting rollers in a padding machine. 1 = horizontal pad; 2 = impregnating liquor; 3 = deflecting or guide roller; 4 = goods.

Defoamers (defoaming agents, foam suppressants). → Antifoams. Products designed to prevent the formation of foam or considerably reduce foam stability in processing liquors, print pastes, etc. The main requirement for an effective defoamer is that the agent should be insoluble in the foaming system in order that, at low concentrations, it can be retained at the phase interface. The entry coefficient must be positive and the agent should form quasi-gaseous boundary layers. These requirements are fulfilled e.g. by the following products: straight or branched-chain and alicyclic alcohols (with 5–18 carbon atoms in the molecule hydrophobe such as isooctanol), pine oil (chief constituent terpineol), insoluble alkyl esters of phosphoric acid (such as tributyl phosphate) as well as lower alcohols. A distinction is made between “defoamers” which are intended to destroy already-existing foam, and „antifoams“ which are designed to prevent the formation of foam.

Deformation damage Defects in textile materials caused by mechanical energy, e.g. impacts in weaving due to shuttle malfunction, etc. The cross-sections of the affected threads/fibres are changed or deformed (detectable microscopically) which then have variable lustre, or they suffer surface damage.

Deformation-free rolls (deformation-free bowls). Used in calenders, padders and squeezing units to ensure an absolutely uniform distribution of pressure across the entire width of the nip.

Deformation of squeeze rollers Rollers are a major component of calenders or padding machines which are used in the textile industry for mangling and pressing goods. These rollers, which should act uniformly across the entire width are elastic bodies which deform slightly under strain. Deformations pose a major problem in use as well as for the technical designer, as they exert direct influence on the quality of the product. The normal design of rollers basically takes into consideration the flexing deformation, as this is the most important, though by no means the only type of deformation. In addition to flexing deformation, shear and contact deformation, as well as the less commonly cited radial deformation are important factors.

The deformation can be “reversed” (Fig. 1a) by exerting pressure on the journals outside the roller covering. This is known as roll-bending. Positioning two rollers so that they intersect slightly (Fig. 1b) also corrects the roller gap in the desired direction.

Both these measures are functions of the 2nd order, while deformation corresponds to the 4th order. Therefore theoretically, congruence between the curves of the corrective measure and the deflection cannot be achieved. A profile in the form of an “ox-yoke” (Fig. 1b, bottom) is formed. With rubberised rollers, rubber helps to solve the problem, as with its elastic deformation, it evens out the negligible differences which are of the order of hundredths. Whilst roll-bending is used in textile squeezing apparatus, oblique adjustment is not suitable here as it would lead to crease formation along the length of cloth.

Another means of correction is the extension to a triple roller system by adding an auxiliary roller (Fig. 1c). With this type of system it is possible to use a roller with a relatively small diameter and consequently a narrow nip, which results in a highly specific surface pressure and consequently a high squeeze action. With this type of system, it is preferable for the central, small roller to be bare metal and to cover the large outer rollers. The fabric is generally fed through the lower opening so that the liquor only takes the shorter route over the large roller. In addition to the triple roller system, a quadruple roller system with two squeeze rollers and two auxiliary rollers is conceivable; for this, the rubber covering must be of suitable type and at least one of the small rollers must be rubber coated.

In order to even out the deformation in a roller system, one or both rollers can be lapped with cloth. However, this correction only applies to one specific load. Different load conditions require different lapping.

One possibility is to lap the core of the roller (Fig. 2a). The most common method is without doubt lap-

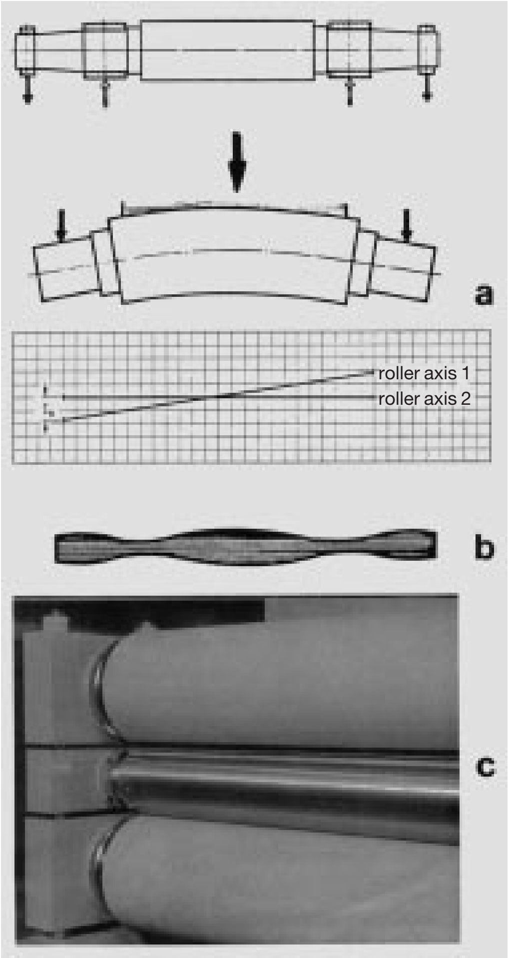

Fig. 1: Correction of deflection of roller – corrective measures in the system:
a) Roll bending; b) Intersection of rolls, below: "yoke";
c) Supporting roller, triple roller system.

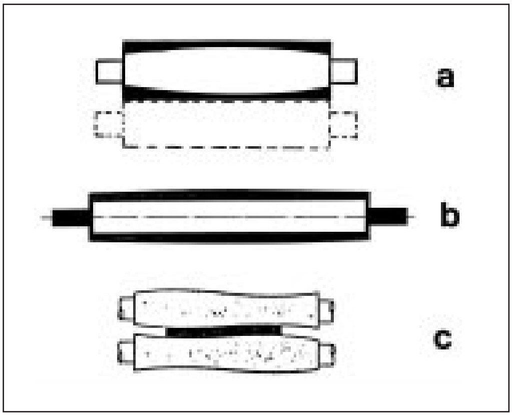

Fig. 2: Correction of deflection of rollers – corrective measures on the roller.
a) Lapping of the core; b) Lapping of the rubber cover;
c) S-lapping, CVC = Continuously Variable Crown.

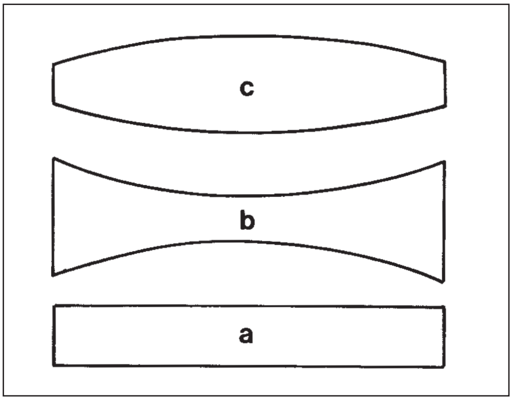

Fig. 3: Lapping of rollers - nip profiles.
a) Correct gap, correct lapping; b) Too little lapping; c) Too much lapping.

ping the rubber covering (Fig. 2b). If the hard roller of a hard/soft combination is lapped, this has the advantage over a lapped soft rubber roller that less damage will occur as a result of wear or edge contraction.

In the event of lapping being incorrectly applied, as shown in Fig. 3b where there is insufficient lapping, or in Fig. 3c where there is too much, then the necessary correction can be calculated using the following formula:

$$b = \frac{(B_M^2 - B_E^2) \cdot (D_o - D_u)}{2 \cdot D_o \cdot D_u}$$

and for rollers with the same diameter:

$$b = \frac{B_M^2 - B_E^2}{D}$$

Nip = width of pressure zone,
B_M = width of nip in the centre,
B_E = width of nip at the end of the roller (measured 50 mm from the [stress-bearing] end of the cover),
D_O = diameter of the upper roller,
D_U = diameter of the lower roller,
b = correction of lapping in mm for the pair of rollers (in relation to the diameter).

Deformation of squeeze rollers

Whilst both these methods were introduced a long time ago, the use of rubber lapping is predominant for cost considerations alone, but this is also easier to produce than core lapping. The third method (Fig. 2c) was only introduced in the past few years, however. With this method, upper and lower rollers are provided with a ground-in section of S-shape which is identical for both rollers. The rollers are simply arranged at 180° to each other, so that when axially displaced in relation to each other, their shapes form a symmetrical contour in the roller gap. The differences in diameter are slight, corresponding to the deflection to be corrected of a few tenths and do not affect the run of the cloth. In 1987 CVC rollers (Continuously Variable Crown) were introduced in Monforts' Matex Color padding machine.

Rollers with central supports are a cost-effective solution for roller deflection problems and are therefore often found in practice, especially with rollers for machines which are not very wide, such as those used in textile finishing. Combinations with normal rollers and solid-cored rollers, whether or not they are lapped, are standard in squeezing apparatus and padding machines, where more costly designs are not used.

Rollers or roller combinations of this kind are often given company-related names: e.g. Stabil rollers (Babcock), Elastoroll rollers (Kleinewefers KTM), Unipad (Brugmann), or Variflex-S-padding machine (Babcock). A similar solution is the Wakoflex roller in which the contact surface of the central support is narrow in order to assist adaptation to the deflection curve of the counter roller.

In the covering of rollers with rubber, three points must be considered for rollers of this type:

- During production of the cover, especially during vulcanizing, the seat of the core and sleeve should be protected from dirt and moisture. In practical use in finishing plant this is achieved by fixing rubber caps.
- During production of the cover (this is not absolutely necessary during grinding) the free ends of the rubber covering must be supported at the core.
- If the rubber covering needs to be renewed, it is important to ensure that the thickness of the roller sleeve is not reduced, otherwise the flexing line will no longer correspond to the calculations.

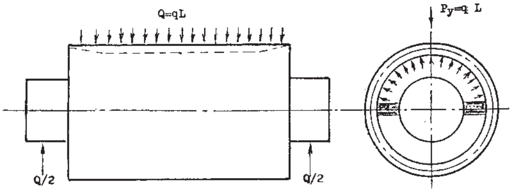

Fig. 4: Sectional view of Küsters' "swimming roll". Arrows: hydraulic pressure in the upper half of the chamber.

Amongst the roller systems in which the roller tube is hydraulically supported (or shaped), Küsters' "swimming roll" or "S-roll" is the oldest and most widely used system throughout the world (Fig. 4).

1. The principle of Küsters' "swimming roll" is that the inner pressure in the upper half of the roller evens out the squeeze pressure applied, i.e.

$$10\ qL = p_b \cdot 2\ rL,\ \text{oder}\ p_b = 5\,\frac{q}{r}$$

q = the linear equalizing pressure (N/cm),
p_b = the equalizing pressure (bar)
L = the inner width of the hydraulic chamber (cm),
r = the inner radius of the hydraulic chamber (cm).

   The eye is not able to perceive any bending moment which affects the normal levels of the centre lines of the rollers. The cylindrical cross-section (Fig. 4, right) shows that the squeeze pressure is concentrated above, whereas the hydraulic pressure extends across the entire upper semicircle. Consequently radial deformation in the upper cylindrical section occurs. This radial deformation is reduced at both ends, as the roller barrel is loaded above the bearings. For this reason, the operating pressure, p, should be slightly higher than the compensating pressure p_b.

2. The Kleinewefers KTM Vari-Flex roller has two roller traversing devices, one acting on the axial shaft, the other acting on the roller barrel by means of pneumatic pressure, so that the flexing resulting from pressure control can be regulated (Fig. 5). This compensation effect is highly effective with low tolerance of the bending on the squeeze roller. However, this design uses two loads which act in opposing

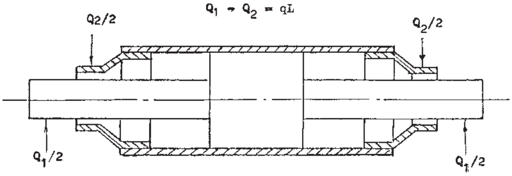

Fig. 5: Diagram of Kleinewefers KTM Vari-Flex roller.

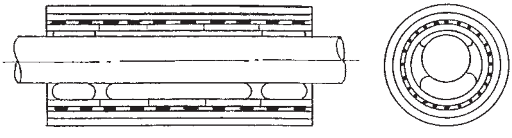

Fig. 6: Side and end views of Kleinewefers KTM Bicoflex roller.

directions. This is a result of the bearings wearing excessively and from high energy consumption.

3. The Kleinewefers KTM Bicoflex roller is equipped with a pneumatic bag which controls the squeeze pressure (in place of the hydraulic pressure of Küsters' "swimming roll", so that no oil seal in the chamber is required. Nor are any external loading devices required (Fig. 6). As the pressure of the rubber bag is kept below 6 bar, the compensation effect is also restricted. This effect can be increased by reducing the roller hardness. Copper and aluminium alloys could be used, copper being preferred to aluminium due to its better anti-friction behaviour, as it can be easily provided with an anti-friction coating.
4. The Kleinewefers KTM Nipco roller is a roller made from the plastics material Racolan, and does not have any kind of rigid roller barrel shell. The roller barrel is not connected to the stationary spigot. The piston mounted on the spigot is used to even out the squeeze pressure. The squeeze pressure is only dependent on the piston loading.

(Source: 1. Wang, 2. Zeppernick).

Deformation of textiles Creases arise when folding or wrinkling textiles as a result of:

1. Alteration of the geometry of the yarn and/or fabric in the peak of the fold (Fig. 1).

   The points of cohesion between the warp and weft when flat are indicated (Fig. 1). On bending, the warp and weft threads push against each other to a certain extent. Whether or not this happens depends on the cohesive force between the yarns and their mobility. Where the cohesive force is strong, these displacements only occur under high deformation forces, and are then partly irreversible or require a high degree of smoothing force in order to remove them (pressing, mangling). If these types of high forces are at work, without it being possible to displace the shifted threads, smoothing is achieved in flat plate screening. This can be seen in the form of visual phenomena which are observed at the site of the original creases (crows feet etc.).

   If the cohesive forces are low, then these creases can be removed using low forces. Low cohesive forces are present in smooth yarns (e.g. filament yarns made from man-made fibres), in textiles of mobile structure (e.g. knits). However these articles have disadvantages in terms of lower shape retention properties or clothing comfort disadvantages (early nylon shirts). High mobility of the yarns also occurs in floating state in the washing liquor, less so when wet. Auxiliaries which reduce non-slip properties (fabric conditioners, crease inhibitors) make it simpler to remove wrinkles caused by displacement of the yarn. Creases are caused in this way with all types of textiles.
2. However, creases are also caused by deformation of fibres in the peak of the fold (Fig. 2). If the fabric is not able to accept the deformation by changing the geometry of the fabric (and this is almost always the case to a certain extent), then the fibres themselves become deformed.

   If a fibre is deformed, internal compression forces and external tensile forces arise in the peak of the fold (Fig. 2). If these forces are so low that they still remain in the elastic region of the stress-strain diagram, then the fibre spontaneously returns to its original form when the load is removed. However, this only applies if the load time is sufficiently short. Fibres are visco-elastic materials: this means that they fatigue under tensile stress or deformation stress; retroactive force diminishes slowly. The fibre then no longer returns completely to the original form (source: Krüßmann, Hloch, Vogel, Ertl and Schultes).

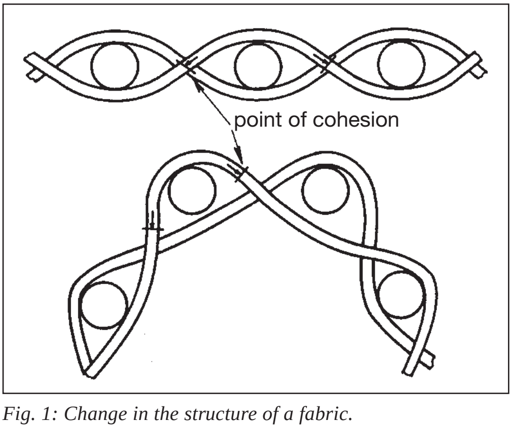

Fig. 1: Change in the structure of a fabric.

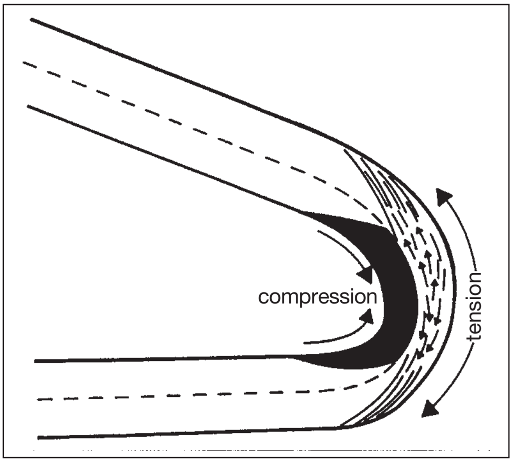

Fig. 2: Deformation of fibres.

Degradation,

I. The stepwise breakdown of high molecular weight compounds to simpler compounds of low molecular weight. Examples: the degradation of cellulose by mineral acids to hydrocellulose; the degradation of starch by diastases to simple soluble sugars; the degradation of proteins by proteases (protein digesters) to amino acids; the degradation of high polymers by ultrasound; the → Biodegradation of surfactants in waste water treatment. Various possibilities for the degradation of wool by acid or alkali during finishing processes exist (this degradation is shown in Fig. 1 as undesirable side reactions).

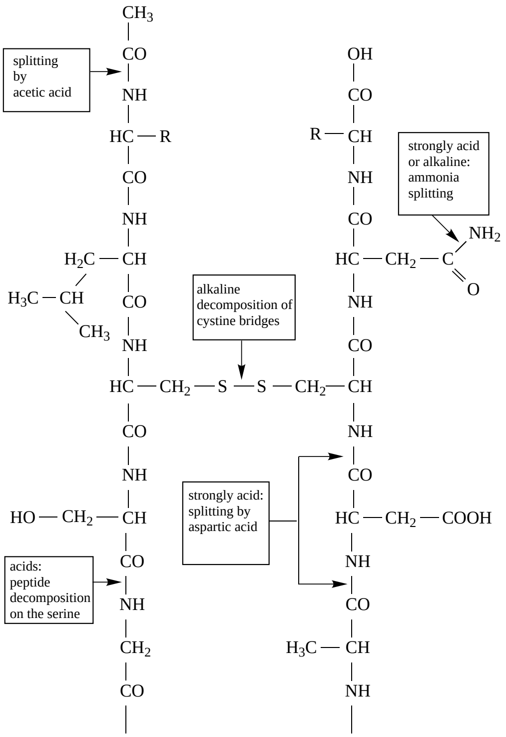

Fig. 1: Decomposition of wool protein by acid or alkali (schematic).

An example of degradation as the desirable main reaction of a textile finishing process is the enzymatic degradation of starch (Figs. 2 and 3): β-amylase “chops off” monomeric glucose from the non-reducing chain ends whilst α-amylase attacks within the polymer chains producing dextrins, i.e. chain scission fractions (R = reducing end at a C atom).

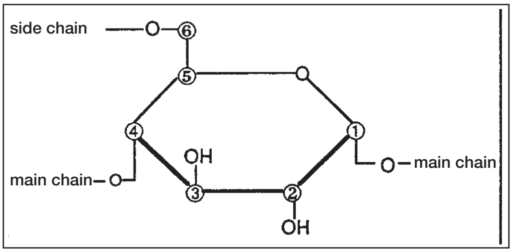

Fig. 2: Starch molecule structure.

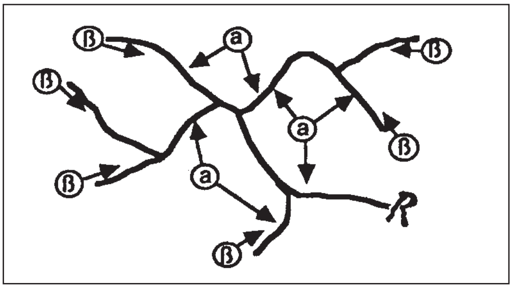

Fig. 3: Enzymatic decomposition of starch with α and β amylase.

II. → Depolymerization.

Dégradé An ombré effect with alternating light/dark zones, where the shade gradually changes in contrast to the uninterrupted dark/light/dark sequence (→ Ombré). Such effects can be achieved by interlacing suitably dyed yarns or alternatively by liquor feed pipes which have holes of varying diameter. These enable dye liquor and water to flow into the trough of the padding machine and create a variable dyestuff concentration in the trough.

Degree of coverage → Print coverage.

Degree of polymerization Average number of → Monomers contained in a → Polymer. As the degree of polymerization always fluctuates to a greater or lesser degree, the so-called → Average degree of polymerization (DP) is often quoted; e.g. for cotton: 2000, i.e. the structure of a cellulose chain consists of on average 2000 chain linked glucose ring molecules.

Degree of transparency → Transparency.

Degree of water hardness → Water hardening salts.

Degumming Boiling of silk to remove natural substances on the fibre. Silk is the fibre extruded by silk worms when they spin their cocoons. It is fine and strong and possesses a natural sheen. Raw silk fibre, however, is not homogeneous, and consists of:

- 70–80% fibroin (the silk fibre itself)
- 19–28% sericin (silk gum, consisting of three layers)
- 0.5–1% fatty substances
- 0.5–1% mineral components

The degumming process is the first and fundamental finishing process for yarns and fabrics made from natural silk and it has a crucial effect on the aesthetic and utility properties of these textiles. The principle is to remove all possible substances, such as sericin, fats, waxes, pigments and mineral salts from the silk fibres. A whole range of parameters of the fibre and its production, such as strength, softness, handle, crease resistance, sheen, smoothness and dyeability depend on this process being carried out correctly. Fibroin and sericin have the same chemical composition. An important difference is found in their reaction to alkali solutions. Fibroin is sensitive to alkalis whereas sericin is soluble in alkalis.

The standard method used for removing sericin consists of → Scouring the silk in a bath containing soap and sodium carbonate. In so doing, the two outer layers of sericin are easily removed through the treatment with hot alkali. The molecular groups of the inner sericin layer, which are intimately bound with the fibroin during silk secretion, are difficult to remove. The choice of correct treatment time, therefore, is a critical factor in the conventional degumming process as excessive degumming can easily cause damage to the fibroin.

Qualitative analyses used for the verification of degumming:

a) Neocarmine W (Merk): stains degummed silk golden-yellow and the gum red.
b) Sirius Red F3B 200% (Bayer): only stains the gum red. The degummed silk remains colourless.
c) Dissolving in Cuoxam: fibroin is soluble but sericin is not.

Silk is degummed using soap in mildly alkaline baths in which the sericin dissolves away. During this process, the pH must not go above 9–10. At higher pH levels, the degumming process is faster but there is the risk of alkali damage to the fibroin. Soft water must be used when degumming with soap to avoid lime-soap deposits which later cause unevenness when the silk is dyed and printed. It is best to use Marseilles soap (olive oil soap). The process is always carried out batchwise in the vat or on a star frame at 98°C in two baths in succession. Before the actual degumming process takes place, if the gum is adhering strongly, the silk pieces are soaked folded in bookform in the vat for 3–4 hours. This swells the gum and the acid components are then neutralised in the soap solution.

Procedure:

I. Steeping vat: 1–2 ml/l concentrated ammonia + 1 g/l nonionic surfactant.

II. Degumming bath (1.5–2 h at 98°C): 8–10 g/l Marseilles soap + 1–3 g/l complexing agent (according to the residual hardness of the plant water) + 1–2 g/l nonionic surfactant.

III. Repeat bath (1.5–2 h at 98°C): 4–5 g/l Marseilles soap + 1–3 g/l complexing agent + 1–2 g/l nonionic surfactant.

If necessary, the pH of the degumming liquors is adjusted to 9–10. When degumming in the vat, the silk pieces in book form are rolled or cuttled with sticks inserted. The degumming bath is brought to the boil and the steam switched off before putting the material in, as the liquor must not be boiling briskly or the silk will float. Even and gentle degumming is achieved by carefully moving the sticks backwards and forwards ("interspersion"). After 20–30 minutes, the sticks are thrown out onto grids and the bath brought to the boil again and the process repeated. After 1.5–2 h, most of the gum (80–85%) is dissolved. To remove the rest of the gum, the fabric pieces are placed in a second, light, repeat bath. There, the silk is treated under the same conditions for another 1.5–2 h. The repeat bath is replenished by adding more soap and then used again as the initial degumming bath. Rinsing is also carried out in a vat of hot soft water. A final rinse is carried out in cold water and acetic acid is used to bring the pH down. Attempts have been made at rationalising the degumming process of silk in book form in the soap vat by installing heating coils in the base as a source of indirect heat and monitoring the temperature electronically. After loading, the vat is covered with foil and the temperature held precisely at 98°C, thus avoiding any risk of the liquor boiling briskly. Because the heating is applied indirectly to the base of the vat, the liquor simmers gently obviating the need for interspersion using sticks.

Dehydration Removal of water. The splitting-off of water from chemical compounds (opposite effect → Hydration). Dehydration is an intramolecular reaction, i.e. the elimination of hydrogen and oxygen in the ratio of 2 : 1 from the same molecule during the course of reaction with the formation of water. Thus, during e.g. the combustion of cellulose, the formation of carbon dioxide, carbon monoxide and water vapour takes first place. The dry distillation of cellulose results in a liquid degradation product in the form of a water-containing tar distillate.

Deionization → Ion-exchanger.

DEK, abbrev. for: Deutsche Echtheitskommission (German Fastness Committee); → Technical and professional organizations.

Delamination The breakdown of lamination in textiles, e.g. as a fabric defect after drycleaning or washing.

Delayed curing (post curing). → Permanent-press process.

Delay factor, washing machine The distance covered by a fixed (imaginary) point on the circumference of the drum when the drum revolves (duration of the drum cycle = effective washing time). Calculation in m delay factor of the goods = 0.4 · m/s circumferen-

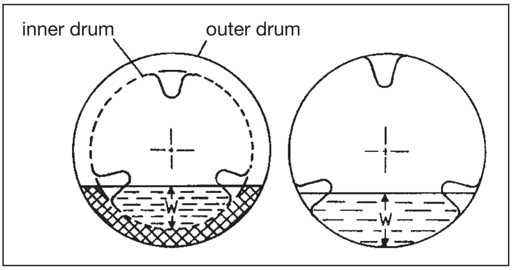

Fig.: Cylinder washing machine with double drum (left) or with single drum (source: Hloch). W = working liquor.

tial velocity · s drum revolution + m height of fall · 1/s number of revolutions · s drum revolution (see Fig.).

The liquor in domestic washing machines is referred to as the working liquor. This is calculated from the difference between the total liquor and the liquor in the inoperative space:

$$V_{\text{work}} = V_{\text{total}} - V_{\text{inoperative space}}$$

One of the factors determining the detergency efficiency is the working liquor. For this reason, attempts are made to construct single or double drum machines with the smallest possible volume between the inner and outer drum.

Delicate articles, in contrast to non-boil → Coloureds, these are delicate articles of wool, silk, viscose (filament and staple fibre) and synthetics (sorted for washing into dark and light colours), which are best washed lukewarm with → Mild washing agents (or possibly weak acetic acid) or high-quality soap. Such items include e.g. fine lingerie (including delicate tops, nightwear, socks), knitwear, needlework, delicate curtains, soft furnishings and drapes, lace, embroidery etc., and all colour sensitive or otherwise delicate items, especially those for which dry cleaning is not suitable.

Delphin rope processing range Brückner's continuous rope processing plant employs an unusual fabric run: i.e. the fabric rope runs into the first fabric chamber via the feed unit. From here, it slides over a Teflon lining to the back side of the machine. From there, the fabric is immediately transferred into the neighbouring chamber by the transport roller and slides in the opposite direction to the front of the machine again. This passage is continued throughout the remaining chambers of the machine. There is a considerable difference here compared to other well-known machines where the fabric passes spirally through the treatment chamber; this involves long distances before immersion in the following bath takes place, which has a negative effect on the lengthwise extension of the fabric. With the Delphin machine on the other hand, the distances are extremely short and the fabric is transported gently with the aid of large diameter transport rollers. The counterflow system is not only used from chamber to chamber (as in conventional machines) but also within each individual chamber itself. This leads to an improvement in the washing effect.

The diagrams shown in Figs. 1 and 2 illustrate the essential elements of fabric transport and liquor flow with a cross-section of a chamber. This shows the fabric passage in the first chamber. The fabric slides over the Teflon-lined bottom and is lifted from the bath by the transport roller. A forced displacement of the fabric by a pair of rollers and intensive spraying is given before and after each transport roller which ensures good fold transfer.

The large diameter of the transport rollers also allows the machine to be operated without squeezing

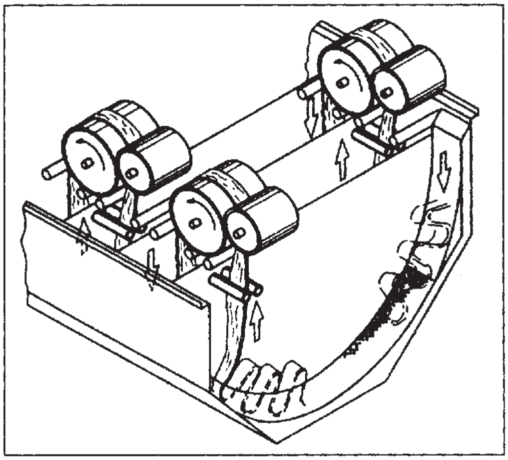

Fig. 1: Perspective diagram of Brückner's "Delphin" rope washing machine.

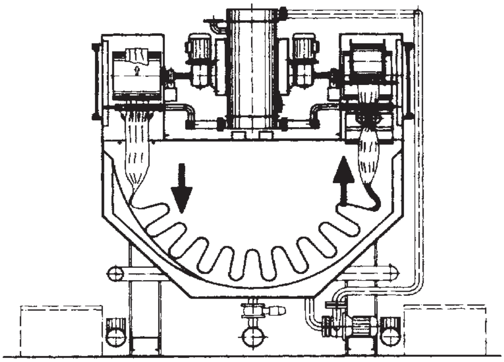

Fig. 2: Section through a fabric chamber of the Delphin plant (Brückner).

rollers, although this is only possible up to certain speed limits within the 40–60 m/min range (depending on the rollers and the chemicals used). The max. production speed is 80–120 m/min with squeezing rollers applied. The transport rollers are driven separately and, together with the stepless fabric loading control ensures precise synchronization of the machine. Switching between light and heavy articles in quick succession is possible due to the individual drives. If e.g. a fabric runs into chamber 1 with double the weight of the fabric already in the machine at that time, the feed is adjusted to half speed for the same hourly production performance. However, the final section of the machine continues to run at double the speed. Main fields of application include prescouring, prebleaching before dyeing, bleaching, washing after mercerizing or causticizing, washing off after dyeing and printing.

Delustring Causing delustring effects required by fashion on woven fabrics and knitwear made from manmade fibres, particularly from regenerated cellulose. A distinction is made between dope delustring and post-delustring.

I. Dope delustring is achieved by adding white pigments, in particular titanium dioxide, from water-insoluble fatty compounds or by the formation of blowholes during the spinning process. The effect is wash-fast and fast to cross-dyeing, but is covered by dyeing with full shades (unattractive greasy shine). With some direct dyes, the light fastness when damp is considerably reduced when titanium dioxide is used. Lustrous acetate fibres can be delustred in boiling soap liquors before dyeing. The effect can be accentuated by adding phenol, pine oil, fenchyl alcohol etc. Triacetate woven or knitted fabrics can be delustred by impregnation with urea, drying and heating to 165°C (Courtaulds method).

II. Post-delustring has lost a great deal of significance in favour of dope delustring. Delustring lustrous synthetic fibres is based on the formation of an optical dull layer on the fibre by pigment deposits. The pigment can be applied as such to the fibre or formed on the fibre itself. If delustring is carried out before dyeing, it must be fast to cross-dyeing; if it is carried out after dyeing, then only light to medium shades are suitable as a whitish layer appears when dark hues are used.

III. A certain reduction of lustre can also be achieved by embossing with a suitable pattern.

Delustring agent These are used to reduce the shine on textiles, predominantly those made from viscose and synthetic fibres. One-bath delustring agents can be divided into three groups:

I. Pigment dispersions: extremely fine pigment suspensions in association with softening agents, e.g. fats. Titanium dioxide, zinc sulphide, aluminium oxide and barium sulphate are predominantly used as pigments. They are generally cation-active and therefore high affinity absorbent products.

II. Hydrolyzable salts: commercial products based on zirconium oxychloride or stannates.

III. Synthetic resins: Non-pigmented products whose effect is based on the fact that finely dispersed synthetic resin particles are deposited on the fibre during condensation following coagulation. This produces wash-fast finishes. The following values result as percentages of delustred fabric after incineration (in a platinum or quartz crucible):

Viscose with barium sulphate	2.02%
Viscose with titanium dioxide	3.4–4.75%
Cupro with titanium dioxide	2.05%
Viscose with tin phosphate	10.3%

Delustring in spinning → Delustring.

Demulsifier A substance which is capable of breaking an emulsion. It functions by changing the state of electrical charges and the surface tension of emulsified sulphonic acids, etc. Opposite → Emulsifier.

Denatured A product that has been made undrinkable, e.g. alcohol (→ Ethanol, denatured) or sodium chloride for exemption of tax and reduced price for industrial purposes.

Denatured alcohol (methylated spirits, industrial methylated spirits = IMS). Alcohol (ethanol) which has been made unfit for human consumption by law with the addition of nauseating or toxic substances, e.g. methanol, pyridine, etc. For household use, it is often coloured with a violet dye.

In Germany, the product consists of 95% alcohol by volume (ethanol, denatured alcohol). As a fuel, 1 kg denatured alcohol produces approx. 31 425 kJ (= 7500 kcal.).

Denep, to → Knops.

Denier A weight-per-unit-length measure of any linear material. Officially, it is the number of unit weights of 0,05 g per 450 m length. This is numerically equal to the weight in g of 9000 m of the material. Denier is a direct numbering system in which the lower numbers represent the finer sizes and the higher numbers the coarser sizes. In the U.S., the denier system is used for numbering filament yarns (except glass), manufactured staple fibre (but not spun yarns), and tow. In most countries outside the U.S., the denier system has been replaced by the tex system. → Linear density of fibres and yarns.

Denim A firm 2/1 or 3/1 cotton twill-weave fabric (workwear twill) with a dyed blue warp and raw white weft. The warp is sometimes dyed during sizing (→ Blue jeans, etc.). Denim represents a further development of “Serge de Nîmes”, a coarse cotton fabric produced during the last century in Provence. After reaching North America, the Bavarian immigrant Levi Strauss realized as early as 1873 that an urgent need could be satisfied with this material. At the time of the California Gold Rush tough, hard-wearing trousers were needed by the hard working gold prospectors.

Denim finishing

Strauss designed a pair of trousers from denim material provided with ample pockets. He achieved rapid success and was soon able to build a factory in San Francisco for their production. These trousers were given the name „jeans“ which was supposedly derived from Gênes = Genoa, since Genoese sailors had already been accustomed to wearing working clothes made from denim material some time previously.

Denim finishing, includes e.g. chemical shrink-resistance, Sanforizing, liquid ammonia treatment and permanent press process. Stone-washed finish refers to indigo-dyed denim with a faded appearance. This is achieved by using stones when washing the articles, so that the dye is washed out partially and unevenly. This effect can also be achieved in the dyehouse by a form of aftertreatment following dyeing (e.g. by enzymes = biowash); it is fashion-dependent and today may also be produced commercially at a subsequent stage. The warp preparation, dyeing and sizing procedures are of great significance in the manufacture of denim. Dyeing with indigo requires a combination of practical experience and precise knowledge of the physical and chemical background. The various dyeing and sizing methods, recipes and concentrations, the reaction and oxidation times not only influence the associated weaving process, but also determine to a substantial extent the appearance, characteristics and quality of the denim. There is a fundamental distinction between the classic indigo rope dyeing method (Fig. 1) and the slasher, sheet dyeing or double sheet dyeing method (Fig. 2), in which the dyeing and sizing processes are carried out in a single cycle or separately. Another variation is the loop dyeing process.

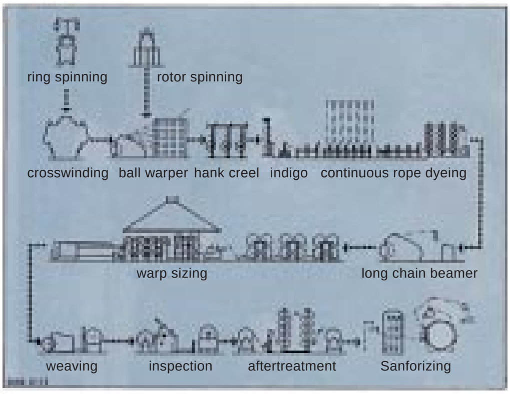

Fig. 1: Rope dyeing method for indigo.

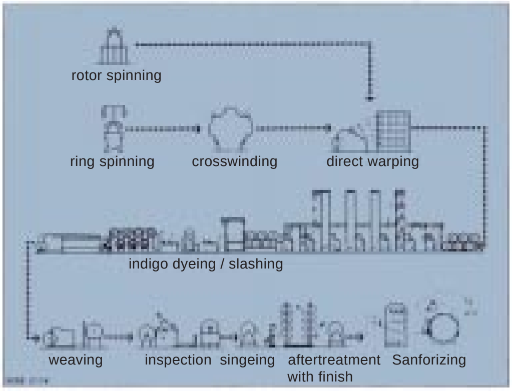

Fig. 2: Slasher or sheet dyeing method for indigo.

I. Rope dyeing method: 350–400 warp threads are combined by the ball warper to form a rope of 10 000–15 000 m in length. 12–36 ropes at a time are conducted through the continuous dyeing plant, dried on cylinders after dyeing, and deposited in cans. The ropes are converted into warps on the long chain beamer. These are introduced to the sizing machine, sized, and assembled to form the weaver's warp with the required number of ends.

II. Slasher or sheet dyeing method: Instead of ropes, warps are fed to the continuous dyeing/sizing machine. The warps are dyed, oxidized, dried, sized and after drying again, assembled to form the warp.

III. Double-sheet dyeing: A further development of the sheet dyeing method, the dyeing and sizing processes are here carried out separately. Double the number of warps are fed to the dyeing machine. The dyed, oxidized and dried warps are wound into two batches according to the total warp thread count, and these feed the sizing machine. Production rates are thus practically doubled.

IV. Loop dyeing method: All the methods described above involve passing the ropes or warps through several successive dye baths until the required depth of colour is achieved. In contrast, the loop dyeing method involves passing the warp threads repeatedly through the same bath until they have attained the required depth of colour.

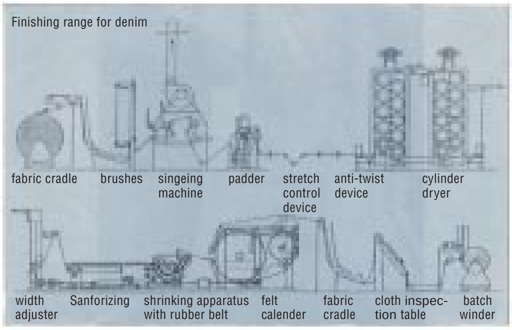

Fig. 3: Finishing range for denim.

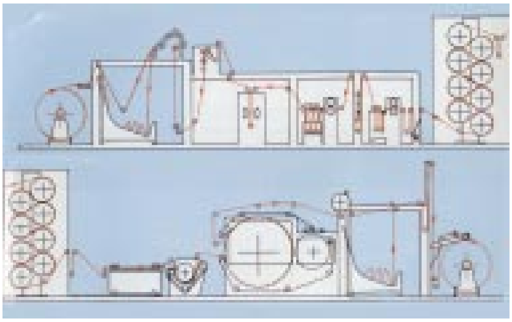

Fig. 4: Cibi finishing range for denim, consisting of feeder with fabric cradle, singeing machine, dust extraction, impregnation troughs, width stabilization unit, weft straightener, cylinder dryer, stenter, shrinking unit with rubber belt, felt calender, cooling roller, fabric cradle at outlet end, large batch winder, various stock reservoirs, shrinkage value display, moisture meter for monitoring optimum cloth shrinkage.

The finishing and Sanforizing of denim ususally takes the form of a continuous (in-line) method, but depending on the plant and machinery may be carried out in several stages (Figs. 3 and 4).

The finshing process is made up of the following stages:

- Brushing (on one or both sides),
- Singeing (on one or both sides),
- Desizing (where necessary),
- Padding (1–2 padding mangles),
- Stretching to the desired cloth width (where necessary), Stretch Meter (compensator),
- Weft skew correction (Anti-Twister) 6–16% excluding 3/1 and 2/1 twill, to prevent twisting of the fabric,
- Drying (12–24 cylinders) to a residual moisture content of 15–20%,
- Stentering (clip or clamp stenter),
- Sanforizing (moistening, shrinking, calendering) with a shrinkage of 11–15% to a residual shrinkage value of 2–2.5%.

(source Kessels).

Denitrifying bacteria Anaerobic bacteria which use cellulose as an oxygen carrier and therefore have a destructive action on cellulose. → Microbial damage to textiles.

Densimeter A → Hydrometer which provides a direct reading of the density of a liquid.

Densitometer An instrument for measuring the optical transmission or reflection of a material.

Density, mass per unit volume, specific gravity:

$$\text{density} = \frac{\text{mass}}{\text{volume}}$$

Relative density is the ratio of a given mass of a substance to the mass of an equivalent volume of water at the same temperature. The basis is the maximum density of the water, i.e. 1 ml water at +4°C = 1 g = relative density 1. It is determined by means of a hydrometer, hydrostatic balance or pycnometer.

The derived SI unit is kilograms per cubic metre (abbreviated to kg/m3).

$$\text{density } 1 = 1\,\frac{\text{kg}}{\text{m}^3}$$

All other ratios of a statutory mass unit and a statutory volume unit may be used for the representation of density, e.g.:

$$1\,\frac{\text{kg}}{\text{dm}^3} \quad \text{or} \quad 1\,\frac{\text{g}}{\text{cm}^3}$$

As the law relating to units of measurement equates the terms for mass and weight, relative density replaces the term specific gravity.

Density balance by de Vries and Weijland, used for the determination of the relative density of e.g. textile fibres. The fibre sample is weighed, attached to a quartz fibre 220 mm in length and 0.4 mm thick, and immersed in a fluid with a density lower than that of the fibre. The downward deflection of the quartz fibre caused by the weight of the fibre is read off microscopically and used to determine the fibre relative density. Reproducibility up to ± 0.002 g/cm^3 (given a fibre sample of approx. 0.5 mg).

Density determination of fibres From the definition of the concept of density it is clear that in order to determine the relative density of fibres two physical parameters must be measured at a constant temperature, mass and volume. Whilst the mass of a fibre may be determined without problem by weighing, the precise determination of the volume of a fibre is dependent on the existence of a defined impermeable periphery. If a solid body has simple, geometrically regular surfaces, the volume can be calculated. If a body has an irregular surface configuration, as is the case with fibres, the volume may be determined by submersion in a wetting fluid or introduction into a known volume of gas and measuring the volume of the gas or fluid displaced. Determination in this way is relatively simple, provided the prerequisite of a defined, impermeable periphery is satisfied.

In the case of fibres this condition is generally not fulfilled. Microscopic or submicroscopic cracks and/or pores of varying shape, location and permeability are often a typical feature of fibres. Thus the volume of a fibre is to a certain extent ambiguous, and from the outset only relative results can be expected from determination by means of fluid or gaseous media. This factor raises the question of whether fibres should be considered "porous bodies". Porosity is typically a macroscopic concept which loses its meaning when applied to intermolecular space. The term packing density is more appropriate. When considering the mass of fibres, account must also be taken of the fact that the solid body of a fibre often does not comprise a single substance, but is to all practical purposes a "hybrid", consisting of the substance of the fibre itself and attendant materials; water and air as atmospherically determined attendant materials are particularly significant in a textile context. The idea of fibre density expressed as a ratio of fibre volume and fibre mass therefore requires a precise explanation, both in terms of the concept itself and of the various means of experimental determination.

When determining density we should really speak of apparent density, giving the conditions (method, medium) which were obtained during the measurement. The apparent density is just as meaningful as the absolute density, as it is relative density which is used to establish structural changes. When studying the structure of cellulose, the following should be required of the immersion fluids:

- The molecules of the immersion fluid must be sufficiently small to be able to penetrate the microcapillary system of the cellulose.
- The fluid must be chemically inert in relation to the material being tested.
- It must not cause the test sample to swell or dissolve.
- It must not form an adsorption layer on the surface of the test sample.
- It must not promote moisture exchange between the test sample and the medium.
- It must not cause decomposition.
- It must show a low surface tension in the fluid/test sample system.
- Should a second medium be added to produce a gradient it must preserve the layered structure and must not cause selective diffusion.

In addition to the importance of temperature, especially when using inhibiting fluids, the time factor is fundamental and must be taken into account when considering the results of the measurements. Fibre density is also dependent on the method of determination and the medium used. Therefore, if unequivocal concepts are to be obtained, account must also be taken of both influencing factors when establishing the concept. The best-known density measurement methods are:

- Pycnometer (density bottle) method,
- Hydrostatic balance method,
- Buoyancy method,
- Suspension flotation method with concentration variation,
- Suspension flotation method with gradient column,
- Electromagnetic float method,
- Gasometric method,
- Radiographic method.

The individual measuring techniques often differ substantially from one another, as do the densities thereby determined. The density values determined by different methods and using different media may therefore only be compared with one another in relative but not absolute terms. Further influences include preparation of the test sample, measuring time, evaluation etc.

Density gradient, linear gradation of density per unit of length within a fluid, with varying densities obtained by the combination of selected fluids. The reference fluids are combined so that the composition of the mixture constantly alters during the mixing process. The constantly changing mixture passes into a graduated glass column. The gradient column thus obtained shows a density gradient reading downwards of, say, 1–0.0001 g/cm^3 per mm column height. In order to determine the density of e.g. a fibre sample, it is introduced to the gradient column whereupon it sinks to the level corresponding to its density. The gradient column is marked beforehand by calibrated glass spheres. The statistical error of the calibrated density gradient, given a statistical significance of 90% , is less than 1%.

Density gradient method, a method for determining the density of e.g. textile fibres using a → Density gradient. Reproducibility: $\pm 2–0.7 \cdot 10^{-4}$ g/cm^3.

Deodorant A substance used to remove or mask an unpleasant odour. Products suitable for use as deodorants include, inter alia, oxidizing agents (products containing chlorine or peroxide), adsorbents, fragrant finishes, chlorophyllin, etc. →: Fragrant finishes; Antiperspirants.

Deodorization refers to the bonding of odourous substances by sealing in the odour-emitting molecules (clathrate), a process which has not yet been fully explained. Odour molecules are bound according to their structure and thus rendered indectectable to the senses. There is a quantitative interrelationship between the odour-emitting substance and the deodorant. Zinc soaps are an example of a group of deodorants.

Deodorizing treatment A procedure for removing substances responsible for generating undesirable odours from textiles.

Deodorizing Making a material odourless by → Odour suppression, masking, destruction (oxidizing agents) or adsorption (adsorbents). In solvent processes (drycleaning, solvent finishing, solvent sizing) deodorizing is carried out at the end of the process, after drying, by subjecting the goods to a current of fresh air in order to ventilate them and make them odourless.

De-oiling

I. → Washing wool fabric.

II. → Desizing (of linseed-oil-based sizes).

Dephlegmator A precondenser (e.g. activated carbon) on the surface of which the material to be adsorbed (e.g. solvent) accumulates.

Depolarization at metal surfaces The process of rust formation. Principle:

1. Iron ions and free atomic hydrogen are initially formed through the action of chemically pure water (e.g. rain water); this produces a complete, unbroken (hydrogen) iron-protective film on the metal surface (polarization).
2. Molecular hydrogen (gas bubbles) are formed in the presence of free, aggressive, carbonic acid. If water containing dissolved atmospheric oxygen is present, reaction takes place between oxygen and hydrogen resulting in the back-formation of water, partial dissociation, formation of new hydrogen ions, and corrosion (rusting).

Depolymerization The opposite of → Polymerization, i.e. the breakdown of polymers into their monomers, dimers, etc.

Depreciation →: Amortisation; Service life of textile plant and equipment.

Depth gauges Mechanical or optical devices which are used e.g. to check the engraving depth when manufacturing printing rollers.

Depth of shade is regarded as the criterion for dyestuff concentration on dyed material, enabling fastness evaluations to be carried out. → Saturation.

Dermatitis → Skin diseases.

Desalination (demineralization) → Ion-exchange process.

Design Generally pattern, model, design, but also in the sense of an illustration, figure. In the textile industry, design is often regarded in the sense of an optical effect, in particular an aesthetic effect of the surface of the textile fabrics.

Every textile fabric has a specific structure, but this cannot be automatically described as design. Important characteristics arise from this structure, which in the simplest case is distributed evenly across the entire fabric. The following are characteristic of the structure:

- Fibres and/or threads with their specific properties.
- The way in which the cohesive assembly of fibres and/or threads is formed.

The interlacings for the most important textile materials are unique structural features for a particular type of thread. The fundamental structures are typical of woven and knitted goods. This principle is also true of other textile fabrics. The basic structures, i.e. the basic weaves, are non-patterned. Altering or changing the fibres and/or threads and the sequence of their interlacing gives rise to other structures, generally with different properties, or other visual effects. These can be added to by further ornamentation, i.e. colour, material or 3-dimensional effects both during fabric production and in subsequent processes (in particular during finishing). This results in patterned textile fabrics.

On the other hand, however, a relatively large number of textile fabrics cannot be described as plain despite their regular appearance. The borders between plain and patterned are fluid. The following conclusions can be drawn from this:

1. The characteristic structure of a textile material, plain weave in the case of fabrics, appears non-patterned when only one fibre or type of thread is used.
2. All variations of the conditions described above under 1 may be regarded as patterned textile fabrics.
3. In the processes which follow fabric production, the non-patterned effect is only retained if the basic structure or the surface remains unmodified.

The following definitions can therefore be made:

- Design is the result of variation being introduced into a fabric in terms of material, colour or structure, or a decoration.
- Patterning is on the one hand the intricate technological means of producing a design and on the other the appearance of a design as a whole.
- Pattern is the individual feature and/or element of a design.

(contributed by Martin, Loler and Mühlmann).

Design digitalization The production of stored design information on data storage systems through scanning. For textile printing applications, the production of colour separation films with the extremely precise utilization of digitalized design information as follows:

- by means of a laser beam directly on to film, e.g. the Scitex Response 200 System;
- by direct engraving on to a printing roller, e.g. with the Helio-Klischograph;
- by direct engraving with a laser beam on to a roller with a plastic skin, e.g. with the Crossfield Laser Engraving System 700;
- by printing without a printing roller or printing element by using a laser beam for ink-jet printing, e.g. the Chromotronic or Millitron process for carpet printing.

Designing Product development and textile designing, e.g. of woven and knitted fabrics. In the production of, e.g. plain-dyed or yarn-dyed woven and knitted fabrics, as well as prints, successful sales of a collection can only be ensured if it meets the requirements of the market and is attractive. The task of producing a collection is the responsibility of the designer and consists of a) a creative element and b) his/her efforts to bring about the realization of creative ideas. Finally, the designer has to follow up „his/her“ product not only during sampling, but also in production throughout the entire season and, possibly, also through garment making to the final consumer. This wide-ranging task must be accompanied by

- increased creative possibilities,
- reduced sampling costs,

- reduction in reaction times in meeting customer demands and trends,
- linking of production methods to CIM concepts in weaving, dyeing (colour measurement) and printing.

This very diverse work can only be accomplished within the time scale of “quick response” with the aid of data processing and CAD systems. Creativity must be supported by possibilities for integrating the design computer into the total information flow of the company. In a CIM concept, product development is of outstanding importance. There are several reasons of decisive significance for this:

1. Considerable master data relating to the article arises during the construction process which is required in the further course of production and organization.
2. A construction which conforms to the production requirements improves the manufacturing possibilities and reduces production costs.
3. Important end-product costs are already determined during construction (yarns, colours, machine types, finishes).

Because of the above reasons, it is important that a CAD system is installed not as an isolated solution for the designer only, but should also be capable of generating production data and production control information. Moreover, quality control results as well as actual production data from previously manufactured products should also be available.

CAD/CAM systems are now available for virtually all types of textile product, with systems for knitting, dobby and jacquard weaving, as well as textile printing being particularly prominent. For dobby weaving applications, two different types of system are currently available:

1. Systems in which the output is in the form of a paper printout and which also incorporate extensive CAM functions, e.g. High-Tex, CIS/Barco (Design 3), IAM (Tweed), Sophis.
2. Systems which are connected to a “semi-mechanical” sample weaving machine whereby the output is in the form of a short length of grey fabric, e.g. Texel-Texy.

Designing techniques in textile printing When printing, a distinction is made between the types of design shown in Fig. 1.

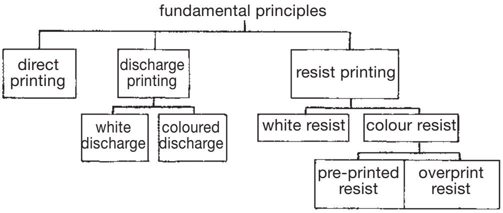

Fig. 1: Classification of printing techniques.

I. In direct printing the dye is applied to the textile surface in accordance with the pattern and dried and fixed as required by its chemical and physical properties (Fig. 2).

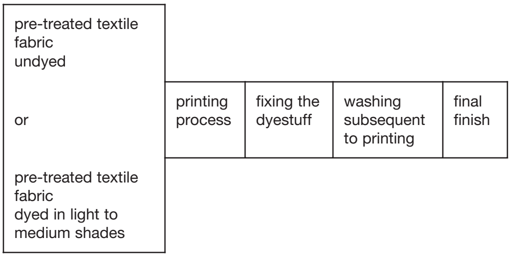

Fig. 2: Direct printing sequence.

II. If an already present dye is locally destroyed by the application of print paste during subsequent fixation, this is referred to as discharge printing (white discharge) (Fig. 3). If a coloured pattern is to be produced on a coloured base, chemicals which break down the base and discharge-resistant dyestuffs are added to the print paste (coloured discharge) (Fig. 4).

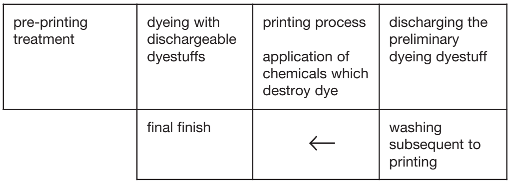

Fig. 3: White discharge printing sequence.

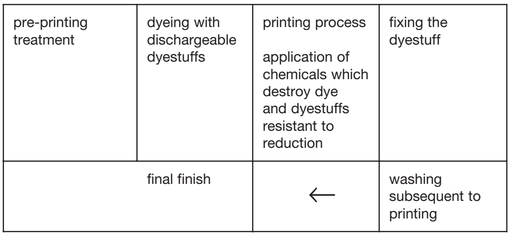

Fig. 4: Colour discharge printing sequence.

III. The resist print is characterized in that suitable thickening agents are printed on an undyed textile material according to the pattern. These prevent penetration or fixation of the dyestuff on subsequent dyeing. Such white resists (Fig. 5) can be achieved either by purely mechanical means or by using agents which have a chemical effect. Using the mechanical resisting

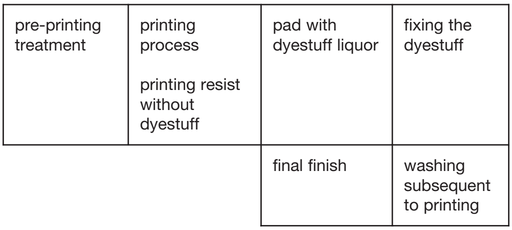

Fig. 5: White resist.

agent, the dyestuff is denied access to the fibre during dyeing, e.g. by using wax. A chemical resist agent prevents the fixation of the dyestuff by a chemical reaction. This is referred to as pre-printed resist, whereas the term overprint resist is used when a previously applied dyestuff component is prevented from subsequent dyestuff formation with a second component by direct printing using predominantly chemical means.

If a dyestuff is applied at the same time as the print paste so the resist printed areas later appear coloured, this is referred to as colour resist (Fig. 6).

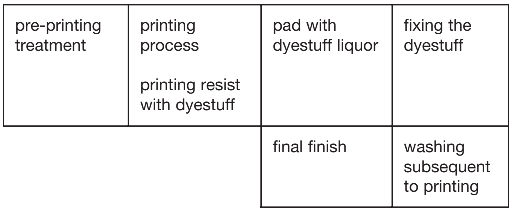

Fig. 6: Colour resist.

Design transfer to printing screens The aim is to close the fine pores of the gauze fabric to the area which is not to be printed using an agent which is impermeable to dye paste, and which cannot be dissolved by dye paste. On the other hand, the areas where printing is to take place should remain open and permeable to dye paste. Various methods are used for this operation. The simplest method in terms of the agents required is manual design transfer. The most widely used method is design transfer by means of photochemical processes, but also with laser technology.

Desize/bleach, single-bath A so-called combination process whereby the oxidising agents used for bleaching will also degrade starch and polyvinyl alcohol under certain circumstances. It is dependent on the type of size used.

Desizing Intended to remove size and finish constituents to ensure even bleaching, level dyeing and soft handle. The process is geared towards the type of size present. These can be as follows:

1. Sizing agents based on natural substances:
   - Starches and starch derivatives: native starch, degradation and chemically modified starch products,
   - Cellulose derivatives: carboxymethylcellulose (CMC), methylcellulose and oxyethylcellulose,
   - Protein-based sizes: glue, gelatine.
2. Fully synthetic sizes:
   - Polyacrylates,
   - Modified polyesters,
   - Polyvinyl alcohols,
   - Styrol/maleic acid copolymers.

The cost of the chemicals and the process used for desizing depends on the type of size. For this reason, the person responsible for desizing will aim for a desizing process that is technically simple and environmentally friendly with regard to effluent. While production speeds are continuously increasing in the textile mill, correspondingly increased demands are being made on the fabric and, therefore, the sizing agents. As a result, significantly more size (up to 30%) is applied. Because of the high water content, heavier size deposits require adjustments to be made to the evaporative capacity. In most cases, this adjustment is not achieved by lengthening the drying zone but by increasing the temperature of the drying cylinders. The formerly gentle drying conditions have now developed into high-speed drying at 150–160°C. In the meantime, sizing has been optimised in such a way that the simple rule of thumb “the more the better” is no longer valid with regard to the efficacy of size in the weaving process.

The different desizing processes are as follows:

- Thermal desizing of starches on glass-fibre fabrics (corona discharge),
- Enzymatic desizing of starches on cotton fabrics,
- Oxidative desizing using peroxymonosulphuric acid or sodium bromite,
- Desizing of water-soluble sizes using a washing procedure.

I. The corona discharge of starches on glass fabrics (0.8–1.2% binder and 1% size in the form of starch derivative and polyvinyl alcohol) is carried out in a stationary bath with the fabric wound on perforated beams in order to avoid breaking the glass fibres. The beams stay in an oven for 72 h at 365°C before they are unwound. The glass fabric is then fed through an IR tower ager at 450°C to burn off residual size.

II. The classical desizing process consists of removing the starch from cotton fabrics using enzymes. This desizing process simply involves liquefying the film of size on the product. The size kitchen of a warping plant has equipment for dissolving the conventionally powder-form size products. The amounts incorporated may be selected so that the desired sizing objective can be achieved, compatible with temperature, viscosity, operating speed and liquor uptake. For the desizing process, the situation appears to be significantly less favourable. The concentration of size on the product is predetermined and, in most cases, the amount of desizing liquor which would produce ideal liquidity cannot be absorbed by material which has invariably been overdried on the singeing machine.

The causes of desizing problems are as follows:

Group 1 (problems arising from pre-treatment):

- Over-drying the sized warp,
- High content of fats with poor emulsion properties or waxes subsequently applied to the warp,
- High content of finishing auxiliaries released from the synthetic component during sizing of polyester/cotton products,
- High copper content from the size-hydrolization plant and size trough,
- High content of preservatives.

Group 2 (problems arising from the process itself):

- Liquor uptake too low, because the impregnation box is too small or too little surfactant has been added.
- The swelling time (dwell time) is too short.
- Enzyme-toxic surfactant has been used.
- The wash power is too small for removing the hydrolized size.

Unlike other types of size, starch can be easily identified. A drop of brown iodine solution will colour a fabric violet-blue which has been sized with starch. The depth of coloration corresponds to the amount of starch on the fabric. A violet scale (TEGEWA) calibrated from 1–9 serves as a reference. When carrying out the comparison test, the ranking is used to evaluate the degree of desizing. Non-damaging treatment of material and environment calls for the use of enzymes which decompose the starch without attacking the cellulose. In this method, diastases are used including pancreas and malt extracts. Enzymes may be defined as organic, soluble bio-catalysts, formed by living organisms and quite specific in their action on a particular substrate. A small quantity of enzyme is able to decompose a large quantity of substrate. In chemical terms, an enzyme may be defined as a molecular protein complex with a very specific number of amino acids. It reacts to all chemically active substances (including water) and requires precisely determined conditions to produce the optimum effect.

Strict control of pH, temperature, water hardness, electrolyte addition and choice of surfactant are vital for effective desizing. Otherwise, desizing cannot be guaranteed and problems can arise, especially during dyeing and printing.

The possible consequences of inadequate desizing are as follows:

- Irregular dyeing,
- The presence of (undesirable) reserve sites in the dyed or printed materials,
- Weaker colour depth,
- Increased tendency towards moiré phenomena,
- Increased tendency to crease because of the harder handle,
- Reduced absorbency,
- Lower whiteness.

In general, insufficient desizing impairs all subsequent finishing processes. The reasons for poor results may be as follows: unsuitable choice of enzyme, reduced enzyme activity due to incorrect storage or unfavourable working conditions, outdated or crystallised sizes and insufficient wetting giving rise to insufficient uptake of liquor etc. In practice, the combination singeing/sizing pad-batch system is used most often. Approximately 2000–5000 m textile fabric passes through a desizing bath at 70°C containing amylase directly after singeing. After squeezing, the fabric is batched, wrapped in plastic film and held for 4–6 h at room temperature. After this, the fabric is washed out. For successful desizing, the washing stage is as critical as the desizing process itself, as all size residues must be loosened from the fibre and removed. For this reason, it is advisable to heat the wash liquor to 95°C, to use counter-current washing machines and to squeeze out the fabric several times. At the end of the washing process, the iodine test should give a yellow coloration. Apart from these, there are other desizing processes which are used in practice, such as continuous processes using J-Box and pad-steam equipment, the Enzyme shock process or batch processes using jiggers, winch vats, jet machines and autoclaves.

III. The oxidative desizing methods are relatively unimportant and when using them, damage to fibre can never be completely avoided. The power of oxidizing agents to break down starch has always given occasion to use this method for desizing. Perborate or sodium toluenesulphochloramine have been tried as additives to the kier liquor. Later, sodium or potassium persulphate have been recommended as oxidizing agents and have been used to some degree (Fig.). In both cases, intensive alkaline after-treatment is necessary to achieve complete desizing.

IV. When water-soluble sizing films, such as polyacrylates, polyvinyl alcohol or sulphonated polyesters, are to be removed from the fibre, then the swelling and dissolving processes overlap. This form of desizing does not follow simple first-order kinetics as one would

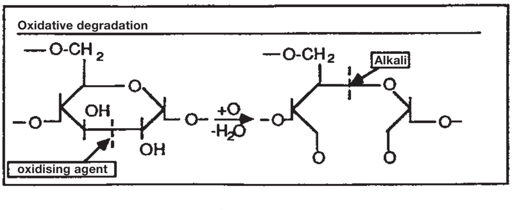

Fig.: Oxidative desizing of starch.

expect. Apart from the delay during the swelling phase, it is more the case that two first-order partial-processes take place concurrently: a) release of the enveloping size-film mantle from the yarn surface and b) leaching out of the size from the core of the yarn as the rate-determining step (as accessibility to the textile matrix is so low). Raised temperatures and turbulent flow increase accessibility by improving the extraction of domains of higher viscosity out of the fibre assembly.

Desizing agent Desizing agents are used for → Desizing and removing water-insoluble printing thickeners from printed fabric. The different desizing agents are distinguished as follows:

I. Those for starch-based sizes, in the form of starch-splitting → Diastases (bacterial, malt and pancreas amylases).

II. Those for protein-based sizes, in the form of proteolytic enzymes (→ Proteases).

III. Those for oil-based sizes, in the form of surface-active substances in combination with solvents (fat-dissolving soaps) or oxidising agents.

Desizing auxiliary Products which accelerate the desizing process and removal of printing thickeners (when there are starch-containing products present). Suitable surface-active substances, such as wetting agents or detergents, can also be used in conjunction with enzyme products.

Desmo- (desmos = bond, band), relating to bonding.

Desmolases A small sub-group of → Enzymes which are capable of rupturing C–C- or C–H-bonds generally preceded by or accompanied by simultaneous oxidation.

Desmotrope This term applies to tautomers which can be separated from each other.

Desorption The process of removing an adsorbed material from the solid on which it is adsorbed. The opposite of → Sorption.

Detection limit This is the smallest quantity of a substance by weight which is still capable of giving an identification reaction (analysis). Expressed in mg or µg.

Detergency The cleansing power of surface-active compounds (surfactants) or detergents in developing a washing or cleansing effect often associated with the emulsification of fatty soils and the prevention of soil redeposition. →: Washing; Washing efficiency.

Detergency efficiency Problems of cost reduction, water resources and effluent treatment and disposal force finishers to study wash processes in depth and to learn as much as possible about performance when buying new machines. Detergency efficiency is a measure of the extent to which chemicals and foreign substances can be removed from the goods in a specific situation. However, this parameter is not representative of the overall efficiency of a machine.

$$\mathrm{WWGRD} = \frac{C_A - C_E}{C_A} \cdot 100\ \%$$

WWGRD = detergency efficiency,
C_A = initial load of foreign matter on the textile,
C_E = final or residual load on the textile after laundering.

With a given washing plant the detergency efficiency of solvent scouring is dependent on the following factors:

- Type of fabric circulation,
- Type of liquor circulation,
- Temperature,
- Dwell time,
- Liquor supply,
- Type of bath separation,
- Flow conditions.

When discussing the washing process in terms of detergency efficiency several influencing variables should be considered:

- The equilibrium of the wash, i.e. the limit value in a bath or liquor exchange,
- The rate of adjusting the equilibrium of the wash in a closed system,
- The rate of adjusting a stationary process in an open system,
- The combination of individual washing elements.

Every textile and liquor system reaches equilibrium after an infinite length of time, in which the concentration of the contaminant in the textile and liquor no longer changes. This condition can also be achieved after a shorter period of time under practical conditions. Equilibrium should be aimed for as close to the beginning of the wash as possible in order to achieve uniform treatment.

Calculation of the equilibrium concentration is possible using the mass conservation law:

$$m_{S0} + m_{F0} = m_{S\infty} + m_{F\infty}$$

m_{S0} = mass of the substrate at time moment zero,
m_{F0} = mass of the liquor as make-up water at time moment zero,
$m_{S\infty}$ = mass of the substrate after adjusting the equilibrium,
$m_{F\infty}$ = mass of the liquor after adjusting the equilibrium

When introducing make-up water, $m_{F0} = 0$ and with $m = V \cdot c$, this equation follows:

$$V_S \cdot c_{S0} = V_S \cdot c_{S\infty} + V_F c_{F\infty}$$

V_S = substrate volume,
c_{S0} = concentration of contaminant contained in the substrate at time moment zero,

$c_{S\infty}$ = concentration of contaminant contained in the substrate after adjusting the equilibrium,
V_F = liquor volume,
$c_{F\infty}$ = concentration of contaminant in the liquor after adjusting the equilibrium.

In equilibrium, $c_{F\infty} = c_{S\infty}$ and therefore

$$c_{S\infty} = c_{S0} \frac{V_S}{V_F + V_S}$$

If the volume ratio from the liquor and the substrate is introduced using

$$F \equiv \frac{V_F}{V_S}$$

then

$$c_{S\infty} = c_{S0} \frac{1}{1 + F}$$

and the detergency efficiency is

$$WWGRD = 1 - \frac{c_{S\infty}}{c_{S0}} = 1 - \frac{1}{1 + F}$$

If the substrate has a particular retentivity for the contaminant, this is often described using the Nernstsch distribution isotherm

$$\frac{c_{S\infty}}{c_{F\infty}} = k > 1$$

The mass flow of the substance to be scoured out via the interface between substrate and liquor is proportional to the magnitude of this interface A_s and to the difference in concentration of the substance to be scoured out between substrate and liquor.

The proportionality factor is known as the mass transfer coefficient β. The diffusion coefficient D of the substance to be scoured out in the liquor, the viscosity η in the liquor and the thickness δ of the flow interface are contained in the thickness factor β:

$$\beta \equiv \frac{D}{\eta \cdot \delta}$$

The mass transfer is therefore dependent on temperature and flow. It is assumed that the diffusion rate in the substrate is high compared to the rate of mass transfer. This is the case with contaminants e.g. on the surface of the substrate. Consequently, when calculating the concentrations in the substrate c_s, only those masses of the substance to be scoured out which have correspondingly high mobility are to be taken into consideration (source: Heidemann and Dugal).

Detergency power Detergency power is calculated using the formula:

$$\% \, WK = \frac{\%WG_{gew.} - \%WG_{ung.}}{\%WG_{unb.} - \%WG_{ung.}} \cdot 100$$

gew. = laundered,
ung. = unlaundered,
WK = detergency power,
WG = white content, laundered, unlaundered or unsoiled.

This is based on the term “one hundred percent detergency power”, which corresponds to the → White content of the textile before soiling.

Detergent and Cleaning Agent Law The German Detergent and Cleaning Agent Law (Waschmittelgesetz) is concerned with the environmental compatibility of detergents and cleaning agents and was originally a reaction to the → Eutrophication of rivers and lakes by phosphates from household detergents. This law was promulgated on 20.08.1975 and published in the Federal Law Gazette No. 100 of 23.08.1975, page 2255 et seq. The law came into force on 01.09.1975.

According to official objectives, this law was intended to further develop the provisions of the former Detergent Law (1961) and conform to the relevant EC guidelines. In addition, it also provides a legal framework to take action against the pollution of water courses by detergents and cleaning agents through comprehensive legally-enforceable measures. The scope given in § 2 is more extensive than the range of application of the former Detergent Law and also covers detergents and cleaning agents used in the industrial sector. § 3 provides the statutory orders relating to biodegradability requirements for surface-active and other organic substances. § 4 provides the statutory authority to fix the maximum permissible quantities of phosphates. Provisions for legal hearings concerning affected parties are embodied in § 6. Specific directions for package labelling are contained in § 7 and the statutory obligations of manufacturers to notify the Federal Department of the Environment of their generic product formulations are given in § 9. →: Water Resources Law; Washing agent additives.

Detergent base materials To manufacture detergents, cleaning agents and rinsing agents for industrial, commercial and domestic use. Detergent base materials are not textile auxiliaries. Product basis: surface-active substances (→ WAS) or preparations resulting from these.

Detergent booster An additive to improve the performance of → Detergents. Usually based on fatty acid (mono) ethanolamides R–CO–HN–C_2H_4OH. These products improve foam stability (foam control) and detergency properties, and also protect the skin. → Heavy duty detergent booster

Detergents The meaning of this term has changed during the course of time and even today a clear definition has still not proved possible. As defined during the 1960s (German Detergents Law of 1962, Regulations on Detergent Degradability 1962, European Convention 1968) detergents were primarily understood to be surfactants, i.e. synthetic surface-active substances. After the so-called 1973 European Community Guidelines, a more comprehensive definition was further extended to include additional components as well (such as additives, diluents, extenders and other secondary constituents). The still further extended Washing Agents Law of 1975 also defined products containing no surfactants as washing and cleaning agents. For the purposes of this law, washing and cleaning agents are understood to be products which, in mixtures with surface-active substances, as well as phosphates, perborates or their substitutes, as well as supplementary additives, have a cleaning action together with water, or which are formulated for cleaning purposes and which can enter a water course after use.

Detergents Law (Germany) → Water Resources Law.

Detinning of weighted silk Pretreatment with a liquor containing 1–1.5% hydrochloric acid or salts of oxalic acid. Processes with a preliminary step using mineral acid produce the greatest possible activity while allowing significant savings to be made in concentration in the detinning bath.

Deuteranomalous So-called “green deficiency”; → Anomalous colour vision.

Deutsche Forschungsgemeinschaft e.V. (DFG), an organisation which supports research in Germany. Provides financial assistance for technical, scientific or research projects etc. Work includes the provision of a senate commission for the control of substances hazardous to health (dangerous substances) in the workplace. → Technical and professional organizations.

Deutsche Industrie-Norm → DIN.

Deutscher Färberkalender (FärKal). International finishers’ yearbook, Deutscher Fachverlag, Frankfurt (formerly Lorch-Verlag, Frankfurt). An annual technical publication containing articles of topical interest for the dyeing and finishing industry, published since 1875.

Deutscher Normenausschuß (DNA), in mid-1975 the name was changed to “Deutsches Institut für Normung”, → DIN.

Deutscher Textilreinigungs-Verband (DTV) → Technical and professional organizations.

Deutsches Institut für Normung → DIN.

Deutsches Teppich-Forschungsinstitut (TFI) → Technical and professional organizations.

Deutsches Textilforschungszentrum Nord-West (DTNW) → Technical and professional organizations.

Deutsches Wollforschungsinstitut (DFI) → Technical and professional organizations.

Developer (coupling components for diazo dyes) are usually phenols, naphthols and amines which couple with previously diazotised dyes. This process leads to an increase in the size of the molecule and this significantly improves the wet fastness properties of the dye. There are numerous developers available, some of which are very diversely constituted, depending on the existing diazo dye, intended colour tone and desired fastness. Their solubility can be extremely variable and their range of application in each case is very limited.

Developing dyestuff All dyes consisting of a pair of components such as → Naphthols in dyeing and printing. → Dyestuffs for coupling are seldom used.

Deviation In statistics, deviation is the difference between an observed value in a series of such values and their arithmetic mean. It is also the difference between an observation and a fixed (target) value.

Devoré style → Burn out style.

Dew point The dew point is defined as the temperature at which water vapour present in the air saturates the air and begins to condense, i.e. dew begins to form. The relative humidity of air with a constant water vapour content increases on cooling and dew (condensed water) forms as the temperature falls below the saturation line. A particular temperature (the dew point) can thus be assigned to this point at which the saturation line is crossed. In other words, the dew point is the temperature at which an initially unsaturated mixture of air and water vapour has to be cooled in order to reach saturation.

Dextran ($C_6H_{10}O_5$). A storage polysaccharide polymer synthesized by bacteria (Leuconostoc mesenteroides resp. Leuconostoc dextranicum) consisting of macromolecules with chain-like structures made of glucose residues joined by α-1,6 linkages with an average molecular weight of 100 000–200 000. Fibres can be spun from hardened dextran (60% aqueous solution with acetone or alcohol acidified with hydrochloric acid) or it can be used as a lacquer on paper or fabric with the addition of glycol as a plasticizer and ammonium chloride. Clinical dextran is used as a blood plasma substitute.

Dextrin Heat-treated starch used as a size ingredient for finishing and printing purposes. Colour varies according to the degree of heat applied.

Dextrines Degradation products of starch, yellowish to white friable granules or powders (crystal gum, British gum, roasted starch, burnt farina). They are further broken down (liquefied) to maltose or glucose by the action of diastases. In finishing they produce a starch-like crispy handle. They have a sweetish and slightly harsh taste. Water solubility: cold (depending on quality) extremely variable (25–98%); most are soluble in hot water. Iodine reaction: blue-violet to red-violet, red-brown to colourless (depending on extent of degradation). Stiffening power approx. 5–6 times lower than starch. Adhesive power considerably greater than starch. Uses: important finishing agent (stiffening, non-dulling, non-chalking, cheaper substitute for gum arabic), textile printing thickeners.

Dextrins Intermediate products obtained in the transformation of → Starch with the following properties: a) external characteristics: progressively low viscosity; b) iodine reaction: blue-violet, red-violet, red, reddish brown (achromatic); c) solubility: cold water soluble; d) Sizing mechanism: hardens, strongly conglutinated dextrin films (size, proofing) are transparent and decrease rapidly in strength and elasticity with progressive decomposition.

Dextrorotatory → Optical activity.

Dextrose → Glucose.

DFE, abbrev. for: directional frictional effect. The term is used in connection with the wool fibre and means that the friction in the tip-root direction is greater than vice versa. It contributes largely to the → Felting propensity of wool.

DFG, abbrev. for: Deutsche Forschungsgemeinschaft; → Technical and professional organizations.

D-form, an abbreviation used in chemistry to describe that form of a compound which is dextrorotatory in polarized light (opposite = laevorotatory → L-form). → Optical activity.

DGN, abbrev. for: Dirección General de Normas (General Office for Standards, including textiles); → Technical and professional organizations.

DGQ, abbrev. for: Deutsche Gesellschaft für Qualität (German Association for Quality, with textile division), Frankfurt, Germany. Until the end of 1972 known as ASQ. It collaborates, as the DGQ technical group on textiles with the → Gesamttextil organization in Germany. → Technical and professional organizations.

dH Obsolete abbrev. for: German Hardness Degree for water. → Water hardness units.

di-, prefix meaning two, twice, double, e.g. disodium phosphate (Na_2HPO_4).

Diagonal register in roller printing Achieved by altering the horizontal position of the printing roller. This is accomplished by a device which raises or lowers the bearing on one side. This means that the roller can be positioned slightly diagonal to the passage of the cloth. The type of repeat is seldom used as it results in increased wear of the bearing shell.

Diagonals Textile fabrics characterized by (often fairly wide) stripes running in a diagonal direction. The term refers only to the pattern effect and not to any particular fabric quality. Mainly described as broad twill or stitched twill fabrics.

Dialog system A unit in electronic data processing systems which permits a two-way information exchange between an operator and a computer based on question and answer interplay.

Dialysis → Osmotic pressure.

Diamine → Hydrazine.

Diamines Diamino compounds, i.e. containing two –NH2 groups as represented in numerous → Direct dyes. → Amino group.

Diaminocarboxylic acids → Amino acids.

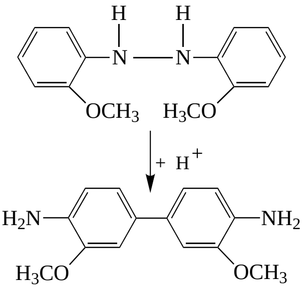
Diammonium phosphate (DAP) → Ammonium phosphates.

Diamond finish → Embossing.

Diamond point graver Engraving tool used in pantograph engraving to scratch the engraved design into the varnish coated surface of a copper printing roller.

Diamond-wound package → Crosswound package.

Dianisidine base MW 244,24. Obtained by the rearrangement of benzidine:



Dianisidine blue A vivid blue shade produced on cotton fabrics prepared with beta-naphthol, especially for blue/red styles. Unsatisfactory colour fastness to light and acids.

Diaphragm porous dividing wall which a) is water and ion permeable; b) impedes diffusion from one side to the other (clarification); c) renders impossible a mechanical combination of the liquids separated by the diaphragm. An example of a diaphragm is a plate of Portland cement with occlusion of sodium chloride solids (which dissolve away in water giving the necessary porosity). Application: for osmosis (diluting or increasing concentration), dialysis (principle: the separation of colloids and crystalloids), electrolysis. Diaphragm process principle: the separation of the anode and cathode areas, e.g. of sodium chloride solution, to produce caustic soda and chlorine (production of sodium hypochlorite).

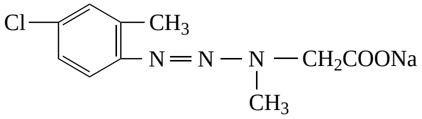
Diastases (Gr.: *diastasis* = a separation). Available for practical use as technical (impure, diluted) enzyme products, i.e. starch-degrading products of three types →: Bacterial diastases, Malt diastases and Pancreatic diastases. As active degradation constituent they contain a more or less temperature-sensitive enzyme (→ Amylases) which converts insoluble carbohydrates (starch) via dextrines into soluble sugars (maltose, glucose). Malt diastase has a strong liquefying and saccharifying action. Bacterial diastase hydrolyzes the glucoside bonds in starch and has a strong liquefying and weak saccharifying action. Pancreatic diastases have a strong saccharifying action. The degradation of starch by diastases is always accompanied by various stages of degradation at the same time proceeding via dextrine to maltose resp. glucose.

Diatomaceous earth → Kieselguhr.

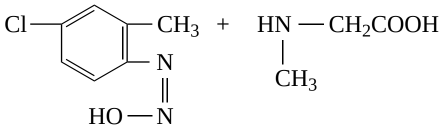
diazo-, an atomic grouping of the type –N=N– in → Aryl compounds

diazoamino- The atom grouping: –N=N–NH–. → Diazoamino compounds.

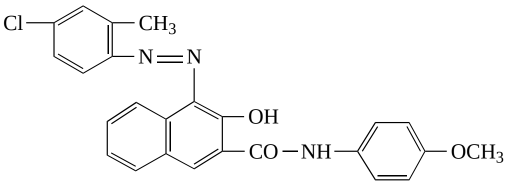
Diazoamino compounds participate e.g. as important components in dye synthesis. For example, a mixture consisting of equivalent amounts of a naphthol and a diazoamino compound with a stabilizer is allowed to react. At this stage, the stabilized diazoamino compound is not yet able to couple with the naphthol present.



Coupling only occurs after an acid treatment (acid steam). This breaks down the stabilizer with the formation of a diazonium compounds which is capable of coupling:



Coupling now takes place with the naphthol to give an insoluble azo dye:



Diazo compounds are characterized by the presence of the azo group (–N=N–). Isomeric diazo compounds are represented by the mostly unstable syndiazo compounds and the stable antidiazo compounds (both in the cis-form). They are subdivided into two structurally different types:

1. Diazonium compounds: Ar–N≡N–X.
2. Diazotates resp. diazohydrates: Ar–N=N–X.

Diazo fast salts → Fast colour salts.

Diazonium compounds Diazotized bases having a salt-like character (from hydrochloric, sulphuric or nitric acids) with the formula $(Ar–N^+≡N)X^–$, where Ar represents an aryl group and X a negatively charged ion (e.g. $Cl^–$). Diazonium compounds dissolve in water like ammonium compounds with a neutral or alkaline reaction. They are formed, e.g. as unstable intermediate compounds by diazotization of an amino group in a direct dye:

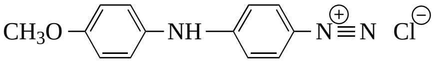
$$R-NH_2\cdot HCl + HNO_2 \longrightarrow R-\overset{\oplus}{N}\equiv N-\overset{\ominus}{Cl}$$

$$\left[R-\overset{\oplus}{N}\equiv N\right] + Cl^{\ominus}$$

The dye-diazonium compound formed in this way is then coupled with a developer, as a result of which a henceforth stable azo group is formed as a new bridge in an enlarged dye molecule:

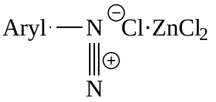
$$R-N=N-C_{10}H_6-OH.$$

Similar diazonium compounds are formed by Fast Colour Salts, e.g. the well-known Variamin Blue Salt B (Fast Blue Salt NBL):



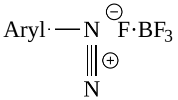
Whilst this product, because of its low solubility in aqueous salt solutions may, by way of exception, be readily isolated as the dry salt form, the majority of other diazonium compounds are more difficult to separate and readily decompose in the dry state.

Diazonium compounds in stabilized form are complex → Diazonium compounds. Thus, the extremely stable tetrachlorozincates of diazonium salts are produced with the following typical formula:



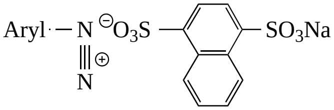
$$Aryl-\underset{\overset{|||\oplus}{N}}{N}\overset{\ominus}{Cl}\cdot ZnCl_2$$

or the very stable tetrafluoroborates can be produced with the typical formula:



$$\text{Aryl}-\overset{\ominus}{\underset{\underset{\text{N}}{|||\oplus}}{\text{N}}}\ \text{F}\cdot\text{BF}_3$$

Another approach is the introduction of naphthalene disulphonate:



Fast Colour Salts produced by the above means are so stable that no stabilizer addition to solutions prepared for practical use is necessary. They mostly contain suitable standardizing agents in the form of, e.g. acidic salts (sulphates of aluminium, sodium, magnesium and zinc, or sodium chloride) etc., so that the commercial forms often have only a 20% content of stabilized diazonium compounds. Uses: Fast Colour Salts and coupling components for substantive dyes.

Diazo reaction for wool damage (according to Pauly-Binz, Eppendahl). A well-known macroscopic and, particularly, microscopic rapid test for the detection of mechanical, bacteriological and chemical damage to wool. It is based on the red resp. orange staining produced by a soda-alkaline diazo solution with the amino acids tyrosine, tryptophan and histidine which are only encountered beneath the scale layer. Ice-cooled diazobenzene sulphonic acid (decomposes readily; must always be freshly prepared) readily stains even healthy wool quite markedly at elevated temperatures. A test solution with longer keeping properties (to be used with care) has been developed by Reumuth and Köhler. An even more trouble-free method is that of Eppendahl using Fast Yellow Salt GC which is dissolved in cold water and conc. sodium carbonate solution added until a weakly alkaline reaction is obtained; the pre-wetted wool specimen is immediately added, treated for a few minutes, then rinsed in cold water. Evaluation: undamaged wool = beige (turning red at the cut edges); damaged wool is stained red to a greater or lesser degree depending on the type of damage; alkali damage = orange.

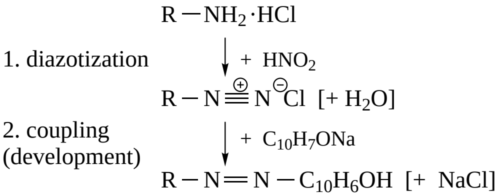
Diazo single bath chrome dyeing process, a combined dyeing process for wool-cotton mixtures with diazotizable direct and single bath chrome wool dyes. The process is complicated and very time-consuming due to the various operations; it is only employed relatively infrequently.

Diazo solution An aqueous solution of a diazonium salt (capable of forming an azo linkage).

Diazotizable dyes Includes direct dyes for cellulosic fibres containing one or several diazotizable amino groups. Limited shade gamut. Good wet colour fastness but only poor to moderate light fastness. Used for cheap washable articles, corduroy, hosiery, umbrella fabrics. Principle: → Diazotization. Analogous to diazotizable disperse dyes for acetate, triacetate, polyester; mostly deep shades.

Diazotization and development of dyeings Aftertreatment for dyeings produced with diazotizable direct dyes (development, coupling). The treatment involves the following stages after dyeing: a) rinse thoroughly; b) depending on depth of shade diazotize cold (15–20 min) with 1,5–2,5% sodium nitrite and 5–7,5% hydrochloric acid (20°Bé) or 3–5,5% sulphuric acid (6°Bé); c) rinse (if possible, continue treatment immediately, avoid long standing, protect from alkali, light and, especially, direct sunlight, avoid local drying out to prevent the formation of stains; d) develop cold over 20–30 min with 0,3–1,75% developer; e) rinse; f) soap (to improve colour fastness to washing).

During diazotization, the nitrogen atom resulting from the formation of nitrous acid (HNO_2) combines with the nitrogen atom contained in the amino groups (NH_2) of the diazo dye to form a new compound which forms a new dye with higher fastness properties on the fibre after coupling or developing with a dye developer. Principle (direct dye-hydrochloride):



$$\begin{array}{ll} & R-NH_2\cdot HCl \\ \text{1. diazotization} & \quad\downarrow +\ HNO_2 \\ & R-\overset{\oplus}{N}\equiv N\,\overset{\ominus}{Cl}\ \ [+\ H_2O] \\ \text{2. coupling (development)} & \quad\downarrow +\ C_{10}H_7ONa \\ & R-N=N-C_{10}H_6OH\ \ [+\ NaCl] \end{array}$$

Completely diazotized dyeings on the fibre. Diazotizable acetate dyes on polyamide are treated as follows after dyeing: a) rinse thoroughly; b) diazotize cold; c) short rinse; d) develop with β-oxynaphthoic acid at 70°C; e) soap. Diazotizable disperse dyes and a coupling component are applied to polyester in a single bath, followed by rinsing, diazotizing hot at 70–80°C and soaping.

Dibasic Term used to describe acids with two active acid hydrogen atoms which can be ionized and replaced by metals, e.g. sulphuric acid H_2SO_4 (sodium sulphate Na_2SO_4), phosphorous acid H_3PO_3 (sodium hydrophosphate Na_2HPO_3).

Dibutyl phthalate (DBP) (phthalic acid dibutyl ester), $C_6H_4(COOC_4H_9)_2$. Density 1,045–1,055, b.p.

205–210°C, flashpoint 160–170°C. Miscible with common organic solvents; insoluble in water. Compatible with most binders (except acetate cellulose) and resins with very good stabilty to light and resistance to frost. It is the most used plasticizer for nitrocellulose lacquers, resins, chlorinated rubber, polyvinyl chloride, etc.

Dicarboxylic acids Carboxylic acids containing two COOH groups, such as:

oxalic acid	HOOC–COOH
adipic acid	$HOOC–(CH_2)_4–COOH$
sebacic acid	$HOOC–(CH_2)_8–COOH$
terephthalic acid	$HOOC–C_6H_4–COOH$

The last mentioned is an important raw material for the manufacture of polycondensation fibres (polyester).

Dichlorobenzenes ($C_6H_4Cl_2$). The most important are:

a) Ortho-dichlorobenzene (1,2-dichlorobenzene), colourless liquid, density 1,328, b.p. 179°C; highly toxic (all contact with the skin must be avoided).

b) Para-dichlorobenzene (1,4-dichlorobenzene), white crystals, volatile (sublimes readily) with a penetrating odour, density 1,458, b.p. 173°C, insoluble in water, soluble in ether and benzene. Toxic by ingestion, irritant to eyes. Uses: formerly used as a moth repellent by spreading the crystals between the material or by dispersing the vapour in closed rooms from above (vapour is heavier than air), using approx. 100 g per 1 m^3 of enclosed space.

Dichlorodiethyl sulphide (2,2´-dichlorodiethyl sulphide, mustard gas). Can be formed e.g. as a result of contact between thio(di)ethylene glycol and hot hydrochloric acid. Colourless oily liquid with a faint garlic or mustard-like odour. It a powerful vesicant and poison, and can penetrate clothing and leather, etc., where it is absorbed by the skin causing the cells to blister and die.

Dichlorodifluoromethane (difluorodichloromethane, fluorocarbon-12). → Chlorofluorocarbons.

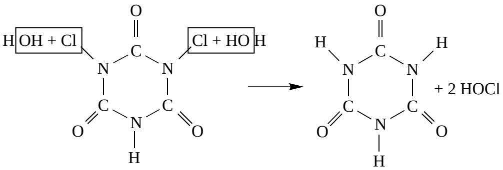
Dichlorodiphenyltrichloroethane → DDT.

Dichloroethylene (1,2-dichloroethylene, dichloroethene, acetylene dichloride, dichloracetylene). $C_2H_2Cl_2$ or CHCl=CHCl. Colourless, low-boiling liquid, similar to chloroform, low flammability (flashpoint +11°C). Slightly soluble in water up to 0,1%. Miscible with practically all organic solvents. Does not corrode metals even in water under the influence of heat). It must not be mixed with solutions diluted with alcohol or water due to the formation of acetylene chlorides which are subject to spontaneous combustion. Dichloroethylene is an excellent solvent and spotting agent (substitute for chloroform and ether). It is a solvent for fats, oils, varnish, waxes, resins, rubber, lacquers, oil colours, tar, etc. Often used in mixtures with 25% carbon tetrachloride. Also used in combinations as a non-toxic respiratory poison in moth repellents. Symmetric dichloroethylene referred to here must not be confused with asymmetric dichloroethylene ($CH_2=CCl_2$), which is used in the production of polymerization products.

Dichlorohydrin (1,3-dichloro-2-propanol). → Chlorohydrins are toxic compounds. Formerly used as a resin finishing agent.

Dichloroisocyanurates → Dichloroisocyanuric acid salts.

Dichloroisocyanuric acid (→ Chloroisocyanuric acids). DCCA solutions and DCCA processes are used as antifelting finishes for wool. Besides dichloroisocyanuric acid, the salts (dichloroisocyanurates) are also used. The special importance of products based on these chemicals is based on the formation of hypochlorous acid (HOCl) through hydrolytic breakdown:



Aqueous solutions of dichloroisocyanuric acid lie within the range of pH 6–7 (stable for several days).

Dichloroisocyanuric acid salts The sodium and potassium salts of → Dichloroisocyanuric acid have an intense bleaching action on secondary acetate, triacetate, cotton and polyester between pH 3–11. To some extent, a simultaneous crosslinking action has been established in the case of cotton.

Dichloromethane (methylene chloride, methylene dichloride), CH_2Cl_2. Colourless liquid, slightly soluble in water (1:40), readily soluble in alcohol and ether. Nonflammable. Vapours are narcotic. Dichloromethane is a good solvent for fats, oils, resins, rubber, chlorinated rubber, cellulose acetate, cellulose ethers, polyvinyl chloride, polystyrenes. It is used in the manufacture of lacquers and adhesives as well as the production of cellulose triacetate fibres. It is also used as a spotting agent and for solvent extraction in the determination of residual fat content, etc.

Dichlorotetrafluorethane (fluorocarbon 114) → Chlorofluorocarbons.

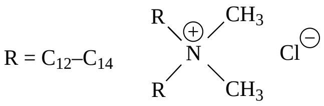
Dichroism, the characteristic of birefringent crystals to appear as different colours when viewed from two different directions. Thus for example the absorption maximum of a dye may extend on the one hand to infrared and on the other to ultraviolet. The dichroism of applied dyestuffs indicates the orientation of the absorption of the longitudinal axis of the dye molecules parallel to the fibre axis, as is the case (according to Morton) with direct dyes on wool and disperse dyes on polyamide, but not on acetate, as longitudinal orientation of disperse dye absorption is not possible here.

Conversely (according to Evans) dichroism showing the orientation of the fibre structure again occurs in the case of direct dyes on deacetylized acetate. As demonstrated by Morey and Morton, the dichroitic behaviour is more prevalent in disperse dyes of elongated, symmetrical shape, although the dyeing conditions also have an effect (fibre swelling, degree of dispersion of dyestuff, dye/fibre bonding, liquor composition etc.). Under certain conditions, dye molecules are primarily bonded to micelle surfaces, and secondarily in the amorphous region. Generally, in the above cases, a stronger dichroitic effect is obtained from dyeing with an aqueous alcohol solution than from dyeing with an aqueous dyebath.

Dichromatic Having, or consisting of, only two colours.

Dichromatism → Colour blindness.

Dicoconutalkyldimethylammonium chloride,



Reviving agent, which, because of its short-chain dicoconutalkyl residue fatty substituent, is used to ease manufacture.

Dicyandiamide is formed by dimerization from cyanamide $N{\equiv}C{-}NH_2$ and is used in the manufacture of → Melamine. Colourless, easily water-soluble, melting point 209°C, stable up to approx. 80°C in neutral and acidic solution. Stable to a certain extent in neutral and alkaline solution. Strong alkalis cause transformation to urea (is then hydrolysed). Possesses hydrotropic qualities (removes e.g. cloudiness or flocculent precipitation in aqueous solutions of surface-active substances). Dicyandiamide-formaldehyde and urea-dicyandiamide-formaldehyde synthetic resin (precondensate) are used as crease-resist finishes. Dicyandiamide is used e.g. under thermosol conditions as a substitute for urea in the fixation of reactive dyes. It has greater thermal stability in comparison with urea, along with other process technology advantages. Its solubility in cold water is low (22 g/l), but good in hot water. At higher concentrations crystallization is impeded by the dye, so that the pad liquors may be augmented up to 35 g/l. In the presence of dicyandiamide certain reactive dyes react with wool without the need for alkali; the slightly alkaline character of these compounds has the effect of promoting reaction, which has led to the development of the thermosol/thermofixation dyeing process for the continuous dyeing of polyester/cotton blends (AT process).

Dielectric Electrical non-conductor (insulator) which receives an "induced dipole moment" by displacement polarization when subjected to friction, pressure or tension or when it is in the vicinity of dipole molecules. Examples of dielectrics are: amber, ebonite, quartz and electrostatically charged textiles. A well-known "dielectric crystal" is piezoelectric quartz which when subjected to pressure or tensile force, responds by changing polarity, i.e. it produces piezoelectricity. It is used conversely for producing ultrasound (electrostriction). Non-polar liquids may also be polarised but, in this case, polarizability decreases with increasing temperature, as the thermal molecular movement makes dipole orientation more difficult. The dielectric constant, one of a number of material constants for the dielectric, also decreases; its value is always greater than 1 (1 = vacuum, the absolute non-conductor) and, in the case of most solid materials, lies between 2 and 5 or at most 25. For ceramic materials, this value can be as much as 100.

Dielectric constant (D) → Dielectric.

Dielectric drying → High frequency drying.

Dielectric heating In drying and heating processes, the thermal energy required is usually applied to the surface of the material from where it reaches the interior through heat conduction. For materials having a low thermal conductivity in particular, this results in long drying times and non-uniform temperature and moisture distributions. In the case of dielectric drying or heating with radio waves (RF-drying and heating), the material represents part of a "lossy" capacitor. Thermal energy is generated directly in the interior of the material by the displacement of electrical charges in an alternating electrical field. If a body composed of electrically non-conducting, or poorly conducting, material is exposed to the action of an alternating electrical field, then that body will be heated up (Fig. 1). The material occupying the space between the electrodes (e.g. the plates of a capacitor) is described as the dielectric. The electrical power absorbed by the treated material generates heat within that material.

The power P which is converted into heat in the dielectric of a capacitor for RF treatment is given by:

$$P = 2\,\pi\,F\,\varepsilon_0\varepsilon_r\,\tan\delta\,E^2\,\Lambda\,h\ [W]$$

F = operating frequency [Hz]
ε_0 = electrical field constant
= $8.85 \cdot 10^{-12}$ [As/Vm],
ε_r = relative dielectric constant,
$\tan\delta$ = loss factor,
E = electrical field strength [V/m]

$$= \frac{\text{voltage}}{\text{plate separation distance}}$$

Λ = surface area of capacitor plate [m^2],
h = capacitor plate gap [m].

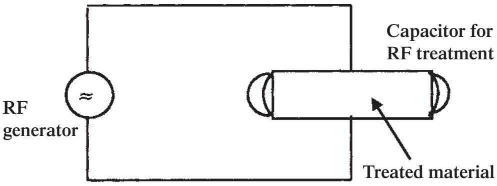


Fig. 1: Principle of dielectric heating.

By introducing a material with a sufficiently high loss factor $\varepsilon_r \cdot \tan\delta$ into an alternating electrical field with a high frequency and high field strength, it will be heated rapidly. The required field strengths are obtained by applying high voltages to the electrodes. The power achieved is limited by the permissible field strength E. As long as the system works without an air gap and no locally limited field concentrations arise, this is dependent on the electrical breakdown strength of the material. In practice, however, the permissible field strength is lower as a rule, due to the occurrence of field concentrations, entrapment of air in the material, and the process-dependent necessity for an air gap between the electrodes and the material. Moreover, high energy densities are not always desirable, since they can damage the material. In virtually all drying and heating investigations, it has been found that, as a rule, the material being treated sets the upper limit for the energy density.

The heat is generated in the body of the material itself. If the material is homogeneous, a uniform generation of heat takes place, so that the temperature is the same throughout the material. Since direct contact with the electrodes is not necessary, the possibility exists for the heating to be carried out in special atmospheres. As a rule, the required frequencies are so high that electronic generators (vacuum tube oscillators) must be used. The frequency range lies between 3–50 MHz. Since dielectric heating equipment must not create any stray interference radiation, appropriate shielding precautions must be adopted. The standard frequencies are:

13.560 MHz ± 0.06%
27.120 MHz ± 0.60%
40.680 MHz ± 0.05%

The most commonly used frequency in high-frequency ovens is 27.120 MHz, which also has the widest tolerance limits.

In the microwave oven (Fig. 2), microwaves are radiated within the metallic cladding of the oven interior and a more or less uniform microwave field is created by reflection from the walls of the oven. Microwave generators (magnetrons) are usually of low power (a few kW), which is why provision must be made for a large number of magnetrons to achieve a high power output. A high-frequency (RF) installation consists essentially of an electrode system and a generator. By this means, generator power outputs of a few hundred kilowatts can be realized. The price : performance ratio of installations with high power outputs (from approx. 60 kW) is therefore much more favourable. With suitable electrode design, the electric field can be controlled in a way that is most appropriate for the actual application. The lower frequency, compared to microwaves, permits a high degree of penetration so that even those materials having a large volume can be uniformly irradiated with energy. The efficiency for part loads is better with RF installations than microwave equipment since the transfer of power is “demand-oriented” in the former case, i.e. the power to be transmitted by the electrode is determined by the material itself. There is also a considerable difference in the shielding precautions required between the two systems. Due to the large wavelength of the high frequency used, relatively short decoupling zones are sufficient for large free incoming and outgoing cross-sections. The execution of comparable free cross-sections is not possible for microwave installations.

In HF (RF) installations, the electric power from the mains supply is conducted to a high voltage transform-

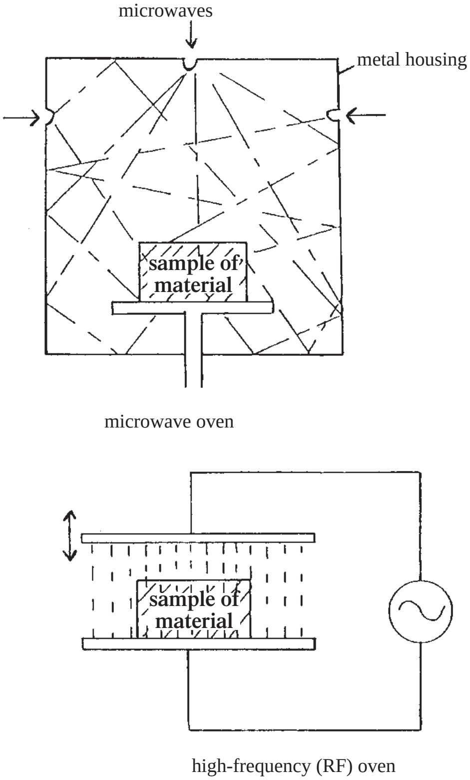

Fig. 2: Principle of microwave and high-frequency technology (source: Böhnke).

er via an electrical regulator (thyristor regulator). The task of the regulator is to limit the grid current of the transmitter tube under no load conditions, to start up the high voltage transformer via a “ramp” and ensure a quick disconnection in the event of an overload or high voltage flashovers. The high voltage transformer converts the mains voltage to a voltage of approx. 10 kV. This “3-phase high voltage” is rectified by means of a 3-way rectifier after which the voltage is approx. 14 kV.

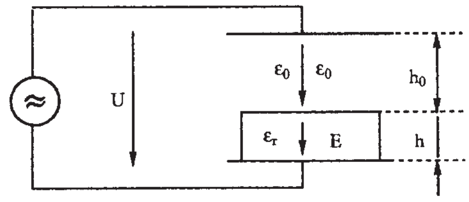
By means of an oscillator and downstream oscillation circuits and HF filters, the DC voltage is converted into a high-frequency AC voltage. This HF voltage is then supplied to an electrode system. The power transferred to the material can be measured directly in the intermediate DC circuit since no idle power is transferred there. Approx. 10% no-load power as well as the heat losses of the generator must also be taken into account here.

In principle, electrodes of various designs are possible. When deciding on the configuration of an electrode layout, attention has to be given to the following points:

- it must be capable of achieving the required or permissible energy density,
- the energy density should be distributed as uniformly as possible in the material,
- it must be capable of transferring the full power of the HF generator used,
- some possibility to adjust or regulate the power output should be provided,
- local field strength concentrations as well as the associated risks of overheating and flashover must be prevented as far as possible.

Among the many possible systems, the 4 most commonly used in practice have been selected here:

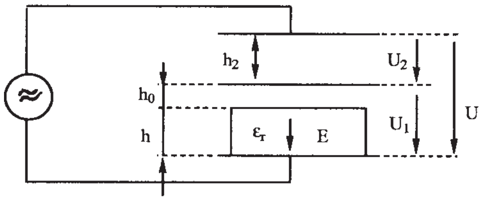
1. Parallel-plate electrodes:
   a) Direct coupling, without intermediate electrode (Fig. 3).
   When drying individual objects which are narrower than the width of the electrode, energy density concentrations occur, which results in non-uniform heating and rates of drying. Layer thickness up to approx. 500 mm.



$$E = \frac{U}{h + \varepsilon_r h_0} = \frac{\varepsilon_0}{\varepsilon_r}$$

Fig. 3: Direct coupling without intermediate electrode with parallel plate electrodes in an RF drier (source: Böhnke).

   b) Capacitive coupling into an intermediate electrode (Fig. 4).



$$E = \frac{U_1}{h + \varepsilon_r h_0} \qquad U_1 = \frac{U}{\frac{h_2}{h \cdot h_0} \cdot \varepsilon_r + 1}$$

Fig. 4: Capacitive coupling with parallel plate electrodes in an RF drier (source: Böhnke)

   This involves a series connection of 2 capacities. Consequently, no voltage division takes place. E_1 is the dielectric index of the air gap h_0 + material h combined. The advantage of this arrangement is that h_0 can be made very small, so that the field distribution in the material is very uniform. Layer thicknesses up to approx. 200 mm.

2. Stray field electrode (Fig. 5).

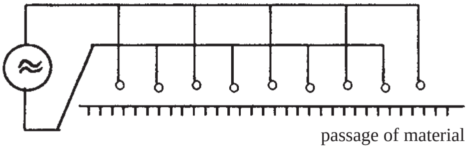


Fig. 5: Stray field electrodes in an RF drier (source: Böhnke).

The power which is converted into heat is dependent almost exclusively on the field components in the direction of movement. Its value depends on the distance x_W. Layer thickness ≤ 1 mm. Plot: $K = F(x_W)$. x_W = distance between material and electrodes.

3. Z-Z field (Fig. 6).

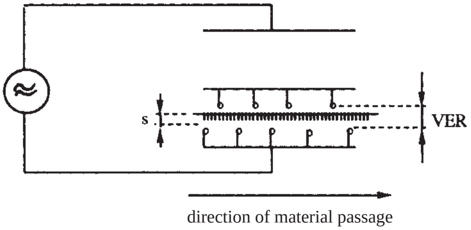

Fig. 6: Z-Z field electrodes in an RF drier (source: Böhnke).

Capacitive coupling into an intermediate electrode; the field is generated between the upper and lower rods. Layer thickness up to approx. 100 mm. Plot: the power is dependent on the distance from the vertical rod. u = a constant (source: Böhnke).

Dienes (diolefins). Unsaturated aliphatic hydrocarbons (olefins) with 2 conjugated double bonds (diene) of the → Butadiene and → Isoprene type. The position of the double bond in the molecule is designated by the respective number of the C atom at which the double bond begins, e.g.:

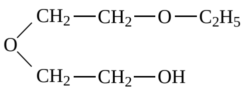
1 2 3 4
$CH_2{=}CH{-}CH{=}CH_2$ 1,3-butadiene or butadiene (1,3)

Compounds of this type have a particularly high reactivity and are readily polymerized (polyenes) to give technically important end-products such as, e.g. synthetic rubbers.

Diethylene glycol (DEG, diglycol, dihydroxydiethyl ether), $CH_2OHCH_2OCH_2CH_2OH$. Density 1,121, b.p. 245°C. Colourless, practically odourless, viscous liquid; extremely hygroscopic. Soluble in water, alcohol, acetone, chloroform. Solvent for oils, resins, nitrocellulose, etc. Uses: substitute for glycerol in finishes, stabilizer for emulsions, auxiliary in discharges on acetate fabrics, solvent for vat leuco ester dyes, improves the homogeneity of Marseilles soap, increases the solubility of benzine soaps in special boiling point spirits, etc.

Diethylene glycol esters These are encountered especially as → Synthetic waxes under various trade names.

Diethylene glycol ethers The most important are diethylene glycol diethyl ether (diethyl “Carbitol”) and diethylene glycol dibutyl ether (dibutyl “Carbitol”):



They are excellent solvents for cationic dyes as well as vat leuco ester dyes; pasting auxiliaries for vat dyes, print pastes, etc. Good solvents for fats, oils, waxes, synthetic resins, etc., b.p. 180–200°C.

Diethylenetriaminepentaacetic acid (DTPA), $(HOOC{-}CH_2)_2N{-}C_2H_4{-}N(CH_2{-}COOH){-}C_2H_4{-}N(CH_2{-}COOH)_2$. White crystalline solid. The sodium salt is readily soluble in water. Chelating agent used for complexing iron, alkaline earth metals, etc. in water softening. Additive in washing agents and detergents.

Differential dyeing Differential dyeing technology for synthetic fibre mixtures composed of normal and/or chemically modified polyacrylonitrile, polyester or polyamide fibres. Single bath piece dyeing is employed to produce solid shades, similar shades but in different depths, as well as multicolour and contrast effects. Advantages include the avoidance of stockholding of dyed yarn, easier adaptation to changes in fashion and more rapid delivery of finished orders. Applications: predominantly in the carpet sector (tufted carpets), and also for woven and knitted fabrics (shirts, blouses, hosiery, beachwear, nightwear, sweaters).

Differential dyeing fibres in carpet printing In carpet printing the possibility exists to produce multicolour effects (analogous to dyeing) by employing polyamide fibres with different dye affinities. As a rule, Low and Deep dyeing fibres are used for tone-in-tone effects or Deep dyeing and Basic types for contrast effects. Differential effects are, however, more difficult to control in printing since the dyes are applied from a thickened paste in this case. For this reason, fibres with only slight differences in amino end-groups give very little colour differentiation or none at all, and dyes must be carefully selected with regard to their resist properties. In addition, a precipitation inhibitor must be used in order to avoid the possibility of precipitation when acid and cationic dyes are present in the same print paste.

Differential dyeing polyamide fibres The following types are available:

a) Dyeable with anionic dyes:	
R – Regular type	normal dyeing
D – Deep type	dyes more deeply than regular polyamide
L – Low type	very low dye uptake
b) Dyeable with cationic dyes:	
B – Basic type	dyeable with cationic (basic) dyes.

Polyamide types with different affinities for anionic dyes are used for the production of tone-in-tone dyeings or (including the Basic type) for the production of multicolour effects in single bath dyeing. The technology is based on the different number of amino end-groups in fibre types dyeable with acid dyes, whilst in fibre types dyeable with cationic dyes the amino end-groups are saturated and no longer capable of protonization. By combining different fibre types and dyestuffs, tone-in-tone and contrast effects may be obtained. Fields of application: floorcoverings, textile fabrics.

Differential reading, a display which indicates by how much the actual value differs from the specified set-point value.

Differential Thermal Analysis (DTA), is used for the analysis of:

1. Glass-transition temperature of polymers.
2. Burning processes of fibres.
3. Synthetic fibres which have been pre-treated in various different ways.

Differential Thermal Analysis

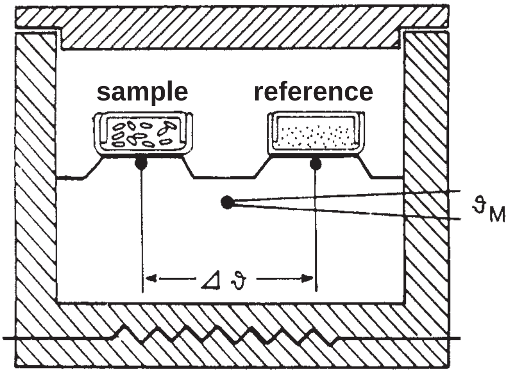


Fig. 1: DTA measurement principle (source: Berndt).

I. Principle (Fig. 1): Two measuring chambers, each provided with a thermal element, are placed in a metal furnace (approx. 1 cm x 1 cm x 1 cm). Measurement Chamber I contains an inert reference substance such as pre-heat-treated (burnt-out) sand. Measurement Chamber II contains the film obtained from a dispersion (approx. 1 g) fused compactly into the measurement chamber by heating it for a short time to determine the approximate glass-transition temperature for the polymer. Both chambers are cooled externally using liquid nitrogen to a temperature at least 50°C below the temperature at which glass transition is expected. When the cooling process has been completed, heat is applied steadily (3–5°C/min. – time required: approx. 1 hour). Plots of the temperature difference between the two measurement chambers and the temperature inside Measurement Chamber II are recorded. Two curves are produced from which the temperature of the glass-transition point is determined (Fig. 2). When the temperature curves have been determined for the two measurement cells, in the ideal case, these will appear as two typical plots. The temperature rise of the inert material will be constant throughout the measurement period. The temperature curve for the polymer, on the other hand, will reach a plateau, giving the temperature at which the polymer heat demand is greater because of an increase in specific heat caused by the greater mobility of the molecules. The increase in temperature is delayed. The temperature at which the heat demand is greater is the glass-transition temperature (glass-transition point) (Fig. 3).

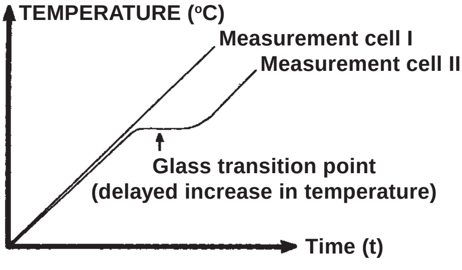

Fig. 2: DTA: Time/Temperature curve.

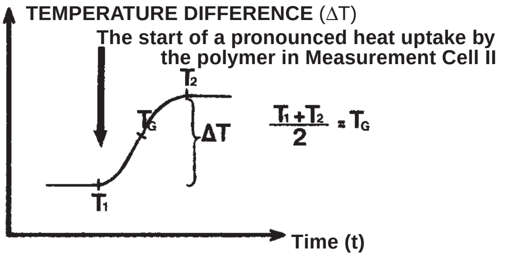

Fig. 3: DTA: Determination of glass temperature.

From T_1, the temperature difference between the two measurement cells increases until T_2, due to the increased heat demand caused by the polymer becoming more mobile. From this, we have:

$$\frac{T_1 + T_2}{2} = T_G$$

Temperature differences between T_1 and T_2 of 8–10°C suggest a uniform homopolymer. Temperature differences > 10°C indicate increased chemical impurities or copolymers.

Fig. 4 shows the curves of different pre-treated polymer-fibre materials. The arrows on the endothermic

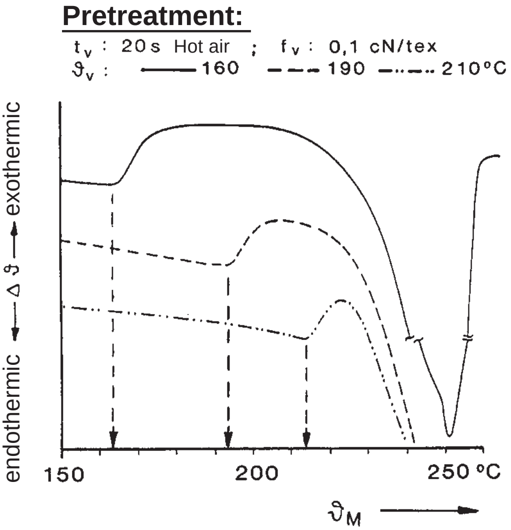

Fig. 4: DTA diagram of a heat-set polyester fibre (Arrows: effective temperatures of pre-treatment) source: Berndt.

shoulders of the curves indicate the temperature at which the partial fusion of the crystallites, formed during fixing (or during cooling) in the non-crystalline areas, takes place. This is defined as the effective temperature of thermal pre-treatment. The main fusion peak at approx. 255°C represents the endothermic fusion of the crystalline areas. Crystallisation of polyesters in the non-crystalline areas (and therefore the effective temperature) increases linearly with the pre-treatment temperature (around 7 K per time decade with increasing periods of delay and in swelling media between 35 K and 60 K). The effective temperature decreases with increasing heat-setting tension. The crystallite-size distribution increases with increased cooling rate.

II. Volatile thermal breakdown products are produced during the different phases of decomposition throughout the burning process of fibres. The burning process can be analysed using DTA to reveal the following phases: a) pyrolysis, b) carbonisation and c) combustion. Pyrolysis precedes ignition and ignition precedes the thermal combustion process. Pyrolysis refers to the thermal decomposition or dry distillation of a substance. In inert atmospheres, this type of decomposition is predominantly endothermic. Because of the exclusion of oxidation reactions, it is possible to obtain reproducible, discrete determinations of the temperature and time-dependent de-polymerisation behaviour of high polymers, thus yielding important information about the course of pyrolysis in air. Distinct exothermic decomposition reactions which take place during pyrolysis may also occur in atmospheres such as those which contain oxygen. Temperature and time-dependent data in relation to the type and quantity of gases which are produced are particularly important when examining the combustion processes. These have a significant effect on ignition and combustion behaviour and therefore on the possible toxic effects.

As far as the course of pyrolysis is concerned, washed cotton can be regarded as pure cellulose. In inert atmospheres, the endothermic maxima of depolymerization are found at 125°C and 375°C (Fig. 5). In the case of cotton, within a temperature range of about 280°C–360°C and under conditions of air exclusion, the easily combustible decomposition products, hydrogen, methanol, methane, ethanol, ethylene, furfural, low molecular weight organic acids , low molecular weight aldehydes and ketones as well as phenolic compounds and levoglucosan are produced in addition to carbon monoxide, carbon dioxide and water. In oxygen atmospheres, the depolymerization of cotton starts at around 200°C. Exothermic decomposition reactions clearly start at 275°C and rapid carbonization takes place above 350°C. At temperatures a little above the carbonization temperature, the cotton can easily ignite. The exothermic course of the depolymerization of polyacrylonitrile suggests a smaller heat capacity in comparison to other thermoplastics. This, together with the relatively high heat of combustion of polyacrylonitrile (approx. 30 kJ/g) may possibly explain why combustion is comparatively easy.

III. In transfer printing, DTA provides heat-effect prognoses for dispersed dyes, i.e. it clarifies the relationship between the behaviour of the dye at increased temperatures and the transfer properties, thus providing information for the selection of dyes for transfer printing.

Diffusion Molecular movement of a substance due to its natural intrinsic mobility, i.e. without the participation of external forces. A substance in solution will migrate at constant temperature from zones of higher to lower concentration until a concentration equilibrium is established within the entire system. Diffusion is thus a general characteristic of the dilution tendency of a solution which is accelerated by elevation of temperature.

Diffusion coefficient A proportionality factor which gives the number of moles of a dissolved substance diffusing through a cross-sectional area of 1 cm^2 per unit time for a given temperature and solvent when the concentration gradient is –1 (Fig.):

$$D = \frac{\text{Depth of penetration}^2\ (\text{cm}^2)}{\text{Time (s)}}$$

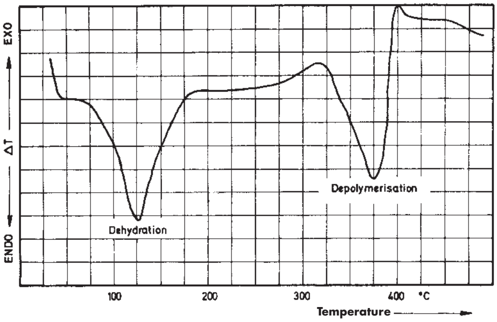

Fig. 5: Thermogram of the pyrolysis of cotton in an inert atmosphere (DTA).

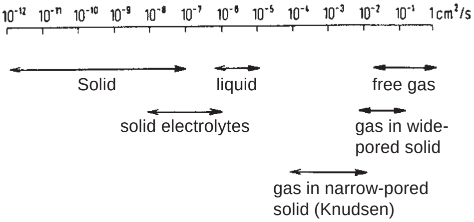

Fig.: Orders of magnitude of real diffusion coefficients (D_{real}) (source: Rys).

In a concentrated solution, the diffusion coefficient is dependent on the concentration. Basically, it is much smaller in solids than it is in solutions and gases and in solids it is more strongly dependent on temperature. From an exact scientific point of view, it is only constant where dilution is significant. Depending on the case, the differences in the packing density of the fibre molecules presupposes an average value composed of the component values over the whole fibre cross section. In the case of acid dyes, for example, the diffusion coefficient is much smaller than it is for dispersion dyes depending on the constitution. Generally speaking, the diffusion coefficient decreases more or less strongly as the number of atoms in the dye molecule increases. The value decreases according to the following sequence: dispersion dyes, acid levelling dyes, milling dyes and metal complex dyes. With regard to the receptivity of dyes against fibre-molecule packing densities, the relationship is exactly the reverse. The diffusion coefficient is well suited to characterising the properties of dyes by number values for assessing the dyeing behaviour of the dyes, because these values characterise the diffusion of the dye in the fibres. In combination dyeing using dispersion dyes, differences in the dye penetration come about when the ratio of diffusion coefficients for the dyes used exceeds 1 : 1.3. The result is unevenness in tone or faded dyeing. Similar diffusion coefficients for the component dyes, on the other hand, guarantee even extraction of all dyes from the bath. After the fibre surface has been fully covered, further dye pick-up takes place in relation to the coefficients of the components. Before this, it takes place in relation to the affinities. When the fibre surface is covered with dye, further dye pick-up only takes place in proportion to the way in which dye diffuses from the outer areas into the interior of the fibre. This happens more quickly for dyes with large diffusion coefficients than it does for those with small diffusion coefficients. Where dye affinity is low, dye penetration is good for dyes with large diffusion coefficients and poor for dyes with small diffusion coefficients. High-affinity dyes with large diffusion coefficients penetrate evenly and well and those with small diffusion coefficients penetrate unevenly and badly. The ability of the dye to even out differences in concentration inside the fibre, therefore, depends on the diffusion coefficient of the dye and this property depends on the dye. (→ Levelling capacity of dyes).

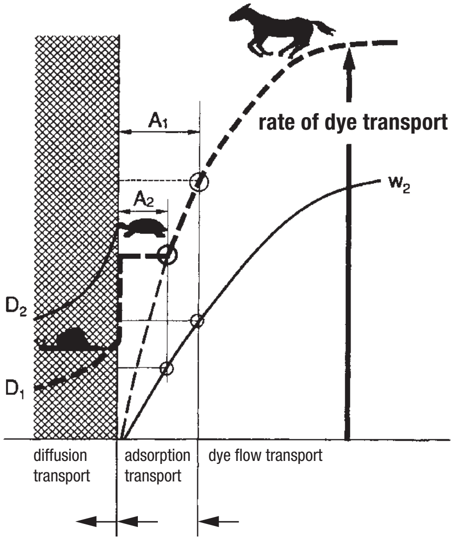
During washing, dye is first released from the surface. More dye follows in relation to the way in which the dye diffuses from the interior of the fibre to the fibre surface. The loss of dye from the surface during washing increases with the size of the diffusion coefficient. Small diffusion coefficients are required for good wash fastness. In general, the diffusion coefficient increases with temperature.

Diffusion constants Various laboratory methods are available for determining the rate of diffusion of dyes in textiles of a certain configuration during dyeing. Two procedures have been found to be worthwhile:

1. 130 circular fabric platforms are placed in a cylinder and subjected to flow under defined conditions to simulate a beam-dyeing section of approximately 8000 m of cloth. The coloration of the 1st and 130th platform is compared colorimetrically.
2. A defined, yarn cross-wound bobbin is dyed for twenty minutes at setting temperature and the maximum and minimum dye concentrations in the winding compared to obtain the Ku_{20} value (contributed by Hoechst).

Diffusion mechanisms in dyeing Dyeing processes are very dynamic as they involve the transport of diverse products from the dyeing medium into the fibres. Because dyeing processes seldom reach a genuine state of thermodynamic equilibrium, analysis of the "end product" usually only gives a transient picture of the distribution of dye between the medium and the fibre after a certain dyeing time, long before the state of equilibrium would be reached.

Three transport zones which depend on three different transport carriers and transport effects have been defined (Fig. 1):



dye flow transport primarily determined by the dyeing **machine** resp. the **liquor circulation pump**,

adsorption transport primarily determined by the chemistry of the **dye and auxiliaries**

diffusion transport primarily determined by the chemistry of the **substrate** and the **dye**.

Fig. 1: Schematic presentation of the dye transport mechanism and the spheres of influence in a random fibre mass subjected to through flow (source: Kretschmer, simplified for purpose of illustration).

1. The zone of transport due to flow, which is mainly determined by the machine or flow pump.
2. The zone of transport due to absorption, which is mainly dependent on the chemistry of the dye and the ancillary agents on the liquid side.
3. The zone of transport due to diffusion, which is mainly dependent on the chemistry of the dye and the substrate.

The combined effects of the three transport zones in the random fibre mass is expressed quantitatively in Fig. 1, starting with a simple example dye which is easy to understand. The insight gained from the dye example, which involves the transport of dye to the surface of the fibre mass, also applies, of course, to the transport of substances away from the surface of the random fibre mass during other processes such as washing.

If the dye is delivered at a sufficiently high rate through the laminar boundary layer on the surface of the fibre, then it will get into the fibre by a process of absorption and slow diffusion. As the dyeing time progresses, it is only when the flow towards the fibre is strong that deterioration of flow in the immediate vicinity of the fibre surface will be avoided. The knowledge that a dye accesses the fibre via a transition interface is the key to understanding the dye interactions in the area of dye kinetics. That is to say, if a dye exists on its own, then the rate of diffusion of the dye into the fibre interior is controlled by its concentration at the fibre surface. If the dye is present in combination with another, then not all of the surface is available to this dye for bonding. The dye kinetics and resulting concentration profile are determined by the rates of the following component processes: diffusion, adsorption and immobilisation. In the case of reactive dyes, for example, the process of immobilisation is a chemical reaction. Adsorption of the dye molecules on the fibre surface is characterised by a decrease in the number of degrees of freedom in thermal molecular movement. Within the flow, a dye molecule has at least six degrees of freedom. In the adsorbed state, on the other hand, only slight translation movements are possible. Rotation appears to be inconceivable. It is very probable that even the number of degrees of freedom associated with oscillation is reduced.

There are many reports on the relationship between the fibre titre and dyeability. When considering the effect of the titre, we start from the external geometry of the fibre, i.e. the size of the surface through which the dye penetrates to the fibre interior. The specific surface of the fibre appears in the simplified Crank solution to Fick's second law of diffusion:

$$\frac{(c_F)_t}{(c_F)_\infty} = 2\frac{F}{V}\sqrt{\frac{Dt}{\pi}} = \frac{4}{r}\sqrt{\frac{Dt}{\pi}}$$

Strictly speaking, this only applies to fibres with a circular cross section and fully homogeneous structure. Porous fibres cannot be clearly described by their external dimensions or radii. F and V are not exactly accessible. However, it is possible to replace the specific surface in relation to volume F/V by the value F' which relates to mass:

$$F' = \frac{F}{m} = \frac{F}{V \cdot \rho}$$

thus yielding the following equation:

$$\frac{(c_F)_t}{(c_F)_\infty} = 2\ F'\rho\sqrt{\frac{Dt}{\pi}}$$

The mass-specific surface area F' can be calculated from the fibre titre in tex and the cross-sectional area in cm^2 taken from the microscope picture:

$$F' = \frac{20\sqrt{Q}\cdot\pi}{\text{tex}\cdot f}$$

$(c_F)_t$ = Dye concentration in the fibres at time t
$(c_F)_\infty$ = Dye concentration in the fibres after equilibrium has been established
F = Area in cm^2
F' = Mass-specific surface area in cm^2/g
V = Volume in cm^3
D = Average apparent diffusion coefficient in cm^2/min
ρ = Fibre density in g/cm^3
t = Dyeing time in minutes
r = Fibre radius in cm
Q = Cross-sectional area in microscopic picture in cm^2
f = Enlargement ratio

This equation gives a linear relationship between the mass-specific surface area of the fibre and the dye pick-up. The dyeing speed, therefore, increases with increasing fibre fineness. If ring dyeing is not the aim, the even distribution of the dye over the fibre cross section among other things may be regarded as a measurement standard for successful dyeing. After adsorption onto the fibre surface, the dye must migrate into the interior through the fibre mass or through existing channels and distribute itself there in the optimum manner. At the same time, the diffusion medium has a vital influence on the rate of diffusion. This becomes evident in the variable order of magnitude of the true diffusion coefficient D_0. The diffusion coefficient is significantly greater in the gas phase than in liquid or solid phases. The main driving force behind diffusion is the difference in concentrations. The diffusion coefficient is also dependent on temperature. If the concentration in a stationary system remains constant, the number of dye molecules diffusing through a membrane (Fig. 2) is constant and Fick's first law of diffusion applies:

$$\frac{\Delta n}{\Delta t} = - D \cdot F \frac{c_1 - c_2}{\Delta x}$$

The minus sign on the right of the equation indicates that the particles flow from the high concentration to the low concentration. If the (thin) layer is replaced by a uniform porous plate of greater thickness, there will be a concentration distribution in the stationary case.

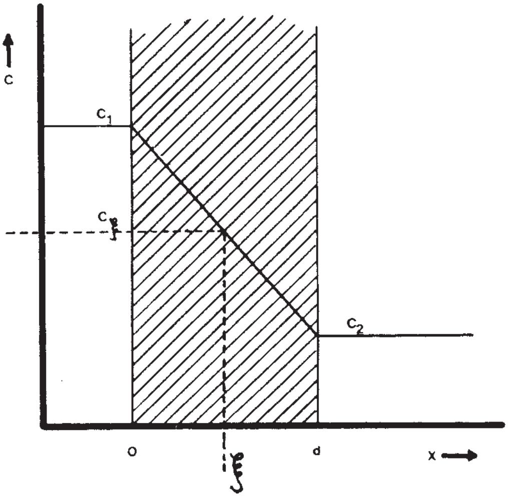


Fig. 2: Diffusion through a porous plate: the concentration c_x at at x is $c_\xi = c_1 - \frac{\xi}{d} \cdot (c_1 - c_2)$.

So-called "non-stationary diffusion" is what is found in practice and characterises the variation in flow according to the periodic assembling of diffusing dye molecules at a particular location on the fibre. In this case, Fick's second law of diffusion applies to the porous plate just described. The left side of the equation describes the change in concentration at any one location in relation to time:

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2}$$

If interactions are taking place between the diffusing dye molecules and the medium, then the following equation applies:

$$D_{exp} = D_0 \cdot e^{(-E_a/RT)}$$

D_{exp} = experimental diffusion coefficient
D_0 = true diffusion coefficient

E_a is a kind of activation energy and remains constant within a range of temperatures for the same diffusion mechanism. In the case of the so-called Free-Volume or Mobile-Segment model, the diffusion coefficient is quite different to that for the so-called Pore model (Fig. 3).

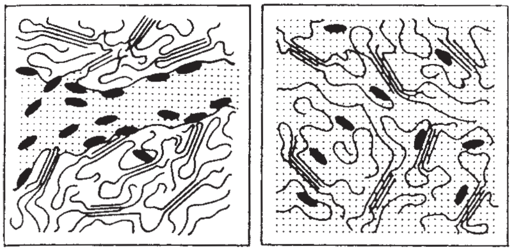

Fig. 3: A comparison between the Pore model (left) and the Free-Volume model (right) (source Hori and Meyer et al.).

It is mainly the rate of diffusion and not, as is often maintained, the affinity of a dye which is the decisive factor in regard to the rate of leaching. The affinity is only one of many parameters which influence the rate of diffusion. The phase during which the dye can diffuse freely (until it is stopped by reacting with the fibre or by the textile drying out), and the rate of diffusion have a significant effect on the levelness of dyeing, on the efficiency of the fixation phase and on fastness to certain agencies.

If cellulose fibres are dyed using reactive dyes, then in this particular case and under certain conditions, chemical reactions take place between the end groups or side chains and the reactive dye. Providing the reaction conditions are favourable for reactive dyeing, the affinity of the non-reactive reactive dye (in weakly acid media) is manifestly increased by the addition of sodium carbonate. In addition to the diffusion and setting processes, the most important processes which must be taken into consideration here are the competition reactions (substrate – water), competition adsorptions (reactive and hydrolysed dye), changes in the charge density of the substrate (which, among other things, is determined by the setting process) and the effect of established association and tautomeric equilibria on the setting rate and the selectivity of competition reactions (source: Gerber). →: Kinetics in heterogeneous systems; Kinetics in homogeneous systems; Weisz pore model.

Difluorochloropyrimidine (bis-FCP). Water soluble bifunctional crosslinking agent containing sulphonic acid groups based on difluoropyrimidine. Used on wool.

Digest (Lat.: *digerere* = to divide, separate). Process of digestion, e.g. the action of an enzymatic solution on a solid material (protein-stained textile) in a vessel (digester) at elevated temperature.

Digester Water, oil or salt bath for heating suspended containers (slub dye beakers) for laboratory-scale experiments.

Digital (Lat.: digitus = finger). Using figures or numbers; e.g. data and information represented by numbers.

Digital control A control system in which the signals along the control loop are in → Digital form and the control deviations are also processed digitally. Direct digital control = DDC.

Digital measurement technology Electrical measurement technology in which instrument pointer movements are translated into numbers. Control technology in which control values are resolved by individual steps.

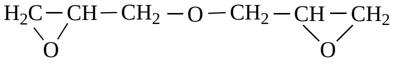
Digital output unit Functional unit of an input and output system of a process computer. It fulfils the task of transmitting control commands in digitally coded form or binary signals to a technical process.

Digital printing → Ink-jet-printing.

Digital readout Measurement values or signals are converted directly into numbers and transmitted.

Digitizer Electronic pen for design processing in electronic equipment for the production of colour separations.

Diglycidyl ether (DGE, di(2,3-epoxypropyl) ether). Colourless liquid with a strong, irritating odour. Used *inter alia* as a resin finishing agent (→ Epoxides).



Diglycol → Diethylene glycol.

Dihydroxydiethylsulphone → Bis(β-hydroxyethyl) sulphone.

Diisocyanates Organic compounds with 2 isocyanic acid groups $(–N=C=O)_2$. They have a wide textile importance as reaction products of diisocyanates with, e.g. glycols for the production of polyurethanes used in fibre manufacture, etc. Also used with ethylene glycol and adipic acid in coating, in reaction with diamines to give polyureas, with ethylene imines for water-repellent and swelling-resistant finishes, and with diphenylmethane for the production of adhesive binders and lacquers. Diisocyanates also react with alginic acid and can be used to produce alginate filaments with increased resistance to alkalis and soap.

Dilatancy A system is said to be dilatant if its rate of increase of strain decreases with increased shear. Dilatancy is usually associated with suspensions, especially those containing high concentrations of suspended matter often of colloidal dimensions. → Rheopexy induced by rapidly changing mechanical shear forces.

Diluent Diluting agent added to adjust commercial dyestuffs or textile auxiliaries.

Dimensa mercerizing range This plant is a combination of the classic chain mercerizing machine and a modern chainless mercerizing machine (see Fig.). This mercerizing plant was introduced to the market by Benninger in 1987 and enables a two-stage mercerizing treatment to be carried out (i.e. stage 1: hot mercerization for better penetration; stage 2: cooling to increase the exothermic swelling effect). The stabilizing zone incorporates a stenter passage.

Dimensional change Dimensional change is the change in length of a test specimen in the lengthwise and/or widthwise direction (→ Dimensional stability). The distance measured between two marks made on the test specimen before and after it has been subjected to a particular treatment is used as a measure of the change in length induced by that treatment. Dimensional change is expressed as the ratio (in percentage) of the change in length induced by the treatment compared to the original (untreated) length and is given a negative prefix when the distance between the measurement marks is shorter (due to shrinkage) and a positive prefix when it is longer (due to extension). In principle,

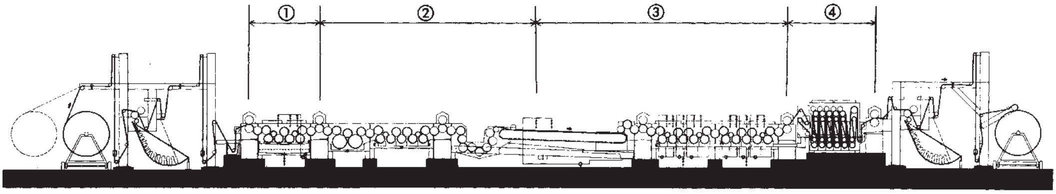


Fig.: "Dimensa" fabric path diagram (Benninger). 1 = impregnating zone; 2 = cooling and dwell zone; 3 = stabilising zone (in the form of a stenter); 4 = neutralising and washing zone.

shrinkage and contraction signify a negative dimensional change in manufactured textile products. The total shrinkage potential of a textile fabric involves several shrinkage mechanisms:

1. Residual shrinkage: this is generally understood to be the dimensional change which takes place in textile fabrics after the first wash. With a low washing machine load, i.e. in the largely relaxed state, tensions introduced during the manufacturing processes are released and the knitted loops (in the case of knitgoods) are able to assume their energetically more favourable round form. Depending on the direction of distortion, a knitted fabric can therefore become shorter or longer in the width or length direction. A change in shape without any change in the size of the surface area is described as affinitive deformation. Due to swelling of the cotton fibre, the yarns become more compact which increases the shrinkage of the textile. The result is an opening up of the yarn systems.
2. Progressive shrinkage (consolidation shrinkage): This phenomenon occurs gradually (successively) after several washing or drycleaning treatments. Progressive shrinkage is not attributable to fibre shrinkage but, rather, to the crimped fibres interlocking and slipping against each other. Progressive shrinkage ends as soon as the adjacent thread systems are able to support each other.
3. Tumbler shrinkage occurs when a fabric has not had sufficient opportunity for the inherent tensions to be released during washing. Moreover, when a cotton garment is dried to an absolutely dry state, the yarns become shorter, i.e. overdrying in a tumbler can cause a microscopic bending of the fibre. This kind of shrinkage has the same effect on the shape of a garment as shrinkage in washing and is particularly striking in heavy materials. With excess moisture of 30% and more, the cotton fibre is fully swollen. During extraction of this moisture the diameter of the fibre decreases which causes an increase in the free space surrounding the fibre. Through the mechanics of tumbler drying, and the possible addition of a lubricant (softener), the frictional forces between the fibres and yarns are further reduced and, as a consequence, the knitted loop structure becomes more compact.
4. Affinitive deformation of a geometrical figure exists then if an affinity axis of the figure remains unchanged in length, and all perpendiculars to this axis change by the same factor. In affinitive deformation, knitgoods usually exhibit two affinity axes where one axis is affected by contraction and the other by extension. Affinitive deformation and shrinkage represent the sum total of dimensional change in knitgoods. The affinitive deformation of knitgoods is attributable to a return of the distorted loop structure to the energetically more favourable form, i.e. into the largely rounded form of a knitted loop with bending tensions in balance with the circumference of the knitted loops.

Dimensionally stabilizing processes are intended to ensure minimum residual shrinkage in woven and knitted fabrics both during use as well as in washing. Such processes include: form retention finishes (wool); permanent-press treatments (cellulose); sanforizing (cotton); heat setting (synthetic fibres).

Dimensional stability This concerns the stability of a textile in terms of its dimensions and shape and is of particular importance for apparel fabrics. Steam pressing, either with direct steam or with a wet cloth and a hot iron, is the method employed to give a garment its required shape and final appearance. During this process, however, the material can shrink and problems relating to shape, size integrity, crimp and waviness may arise as well as some loss of appearance. It is for this reason that an upper limit of dimensional change during pressing is generally demanded by garment manufacturers. The procedures used to determine dimensional change in textile fabrics are typically based on in-house or national standard test methods in which steam is used.

The shrinkage value obtained on steam pressing a textile fabric is, however, not a single phenomenon. When a fabric is steamed on or in a press, a dimensional change occurs due to the release of relaxation shrinkage. At the same time, the fabric also shrinks to a certain extent depending on its properties of extensibility and contraction in the damp state. The dimensional change of a fabric in pressing is therefore the result of a combination of two properties which, together, are responsible for the dimensional stability characteristics of that particular fabric. These two properties are defined as follows:

1. Relaxation shrinkage is the irreversible dimensional change caused by the release of tensions in the fabric.
2. The extensibility in the damp state (hygral expansion) is the reversible dimensional change which occurs when the material absorbs or desorbs moisture.

In a test using a closed ironing press, it has been demonstrated empirically that the following relationship exists between shrinkage in pressing and the relaxation shrinkage (RS) and hygral expansion (HE):

$$\text{Shrinkage in pressing} = 0.3\ (\text{HE} + \text{RS}).$$

This relationship also demonstrates that for any material, a given shrinkage in the closed press can be due to a large number of combinations of damp shrinkage and relaxation shrinkage values. Furthermore, it is generally known that a great variation in the temperature and moisture content of the fabric exists depending on the pressing conditions.

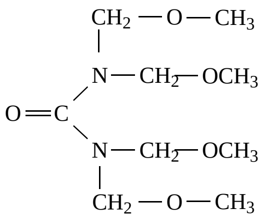
Dimensional stability-carpet test, a supplementary test for the dimensional change of carpet tiles and needlefelts to determine their suitability for use in humid environments. A customary accelerated test is used which involves 2 h dry heat at 60°C followed by a 2 h wetting treatment, drying at 60°C for 24 h and final connditioning for 48 h in a standard test atmosphere at 20°C/65% relative humidity. For special cases, more elaborate testing in climatic chambers is employed. The results are expressed as the percentage change in relation to the initial measurement made before the test.

Dimensional stability requirements for textile goods According to a draft proposal of the RAL (Reichausschuß für Lieferbedingungen, or the German Committee for Terms of Delivery and Quality Protection), easy-care or non-iron textiles should, in principle, not undergo a dimensional change in excess of –2% after 5 drycleaning cycles. After 5 wash cycles, however, the required limits are somewhat more discriminating: i.e. for shirts/blouses, –2% for woven and –4% for knitted fabrics. For the outerwear sector as well as for home textiles the required limits are –3% for woven and –5% to –6% for knitted fabrics. Control tests for machine washing are carried out in a standard reference washing machine according to DIN 53 920, drycleaning according to DIN 54 303 and dimensional change according to DIN 53 892, Part 1.

Dimensions are measurements, e.g. of the size of machinery, apparatus or plant in particular directions such as length, width, height or diameter and are useful in ascertaining the spatial requirements, e.g. floor space, etc., needed to accomodate such equipment.

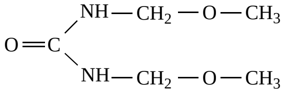
Dimer A compound formed by the polymerization of 2 molecules of a → Monomer.

Dimethoxymethyl-4,5-dimethoxyimidazolidone,



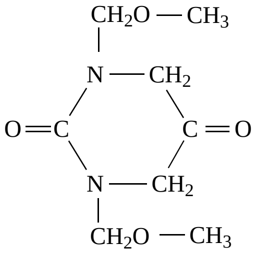
A resin finishing agent used *inter alia* for low-formaldehyde finishes.

Dimethoxymethylurea,



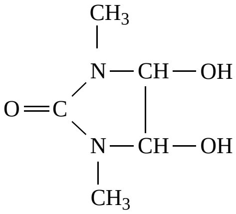
Resin finishing agent with better storage life than the free methylol compound. Finishes are less stiff but otherwise similar to → Dimethylolurea.

Dimethoxymethyluron,



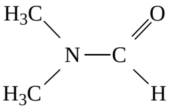
N,N´-bis(methoxymethyl)uron. It is produced from urea, formaldehyde and methanol. Because of their good stability, methoxymethyl compounds are used as reactant resins. Chlorine retention is dependent the purity. Co-application with buffered → Methoxymethylmelamine.

Dimethyl-4,5-dihydroxyethyleneurea (N,N´-dimethyl-4,5-dihydroxyethyleneurea),



Formaldehyde-free resin finishing agent for → Formaldehyde-free finishes.

Dimethyl formamide (DMF), $HCON(CH_3)_2$, colourless, mobile, liquid. Density 0,952, b.p. 153°C. Solvent for high polymers, natural and synthetic resins. Also used as a selective solvent.



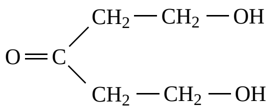
Reagent for some man-made fibres:

- Cold soluble: acetate, certain modacrylic copolymers, polyvinylidene dicyanide, polyvinyl chloride.
- Soluble at the boil: some polyacrylonitrile and modacrylic copolymers, copolyamides, polyacrylonitrile, polyamide 6 and 11, polyester, polyurethane, polyvinylidene chloride, triacetate.
- Insoluble, no change: polyamide 6.6, fluorofibres.
- Insoluble, changed (swells, agglomerates or disinte-

grates): polyethylene, polypropylene, polyvinyl chloride.

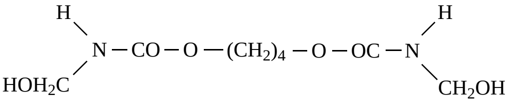
Dimethyl glycol phthalate, $C_6H_4(COOCH_2CH_2OCH_3)_2$, plasticizer (gelatinizing) for cellulose esters. Resistant to benzine and oils, very good stability to light and ageing, slightly sensitive to water. Density 1,160, b.p. 228–238°C, flashpoint +174°C.

Dimethylolacetone Acetone-formaldehyde. Reactant resin with no chlorine retention.



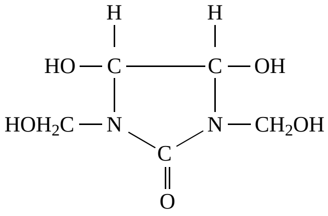
Dimethylolalkane diols Nitrogen-free reactant resins with the general formula: $HO–CH_2–O–(CH_2)_n–O–CH_2OH$, → O-methylol compounds.

Dimethylolbutane-diol-diurethane,



Resin finishing agent for self-crosslinking, non-chlorine-resistant finishes on cellulose with good wet crease recovery but only moderate dry crease recovery. Full handle.

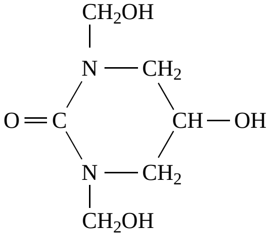
Dimethyloldihydroxyethyleneurea (DMDHEU), dimethylolglyoxalmonourein or N,N´-dimethylol-4,5-dihydroxy-2-imidazolidone. Produced mainly by reaction of urea, glyoxal and formaldehyde.



DMDHEU is the most important reactant resin. Universal application by dry, wet and moist cure methods. It is important for permanent-press and post-cure processes especially on coloured fabrics. Does not impair the light fastness of textiles dyed with substantive or reactive dyes. Very stable to hydrolysis, slight chlorine retention. The finished effects are fast to boiling wash treatments. Detection is possible by chromatographic analysis of the hydrolysate from textile fabrics.

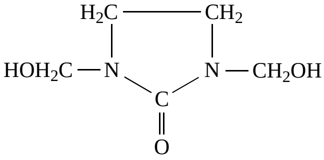
Dimethylol-4,5-dihydroxy-2-imidazolidone → Dimethyloldihydroxyethyleneurea (DMDHEU).

Dimethylol-5-dihydroxypropyleneurea (N,N´-dimethylol-5-hydroxy-hexahydro-2-pyrimidone),



Produced mainly by reaction of urea, 1,3-diamino-2-propanol and formaldehyde. Important reactant resin. The finishing effects are roughly similar to those obtained with the unsubstituted → Dimethylolpropyleneurea (DMPU) but more reactive and somewhat more stable to hydrolysis.

Dimethylolethyleneurea (DMEU), N,N´-dimethylol-2-imidazolidone,



DMEU is produced mostly by the reaction of urea, ethylene diamine and formaldehyde. It is a → Reactive resin of high reactivity. It finds particular application in dry crosslinking processes, and is also suitable for shock curing. Used for the production of finished effects on white and coloured goods which are fast to boiling wash treatments. Disadvantages: DMEU can impair the light fastness of textiles dyed with substantive or reactive dyes. DMEU finishes have inadequate fastness to chlorine (chlorine retention). For this reason, various co-applications with buffered → Methoxymethylmelamine are often employed.

Dimethylolethyltriazone → Dimethyloltriazone.

Dimethylolglyoxalmonourein → Dimethyloldihydroxyethyleneurea (DMDHEU).

Dimethylolhexahydro-2-pyrimidone → Dimethylolpropyleneurea (DMPU).

Dimethylolhexahydrotriazone → Dimethyloltriazone.

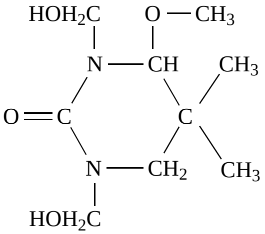
Dimethylolhydroxyethylenecarbamate → Dimethylol(mono)carbamate.

Dimethylolhydroxyethyltriazone → Dimethyloltriazone.

Dimethylol-5-hydroxy-hexahydro-2-pyrimidone → Dimethylol-5-dihydroxypropyleneurea.

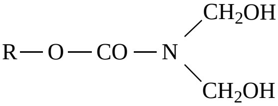
Dimethylol-2-imidazoline → Dimethylolethyleneurea (DMEU).

Dimethylol-4-methoxy-5,5-dimethylpropyleneurea N,N´-dimethylol-4-methoxy-5,5-dimethylhexahydro-2-pyrimidone.



Dimethylolmethoxyethylenecarbamate → Dimethylol(mono)carbamate.

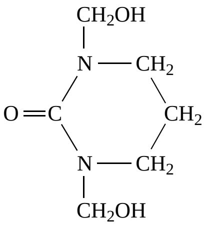
Dimethylolmonocarbamate (DMC),



R = alkyl residue
hydroxyalkyl residue
alkoxyalkyl residue

For application as resin finishing agents the toxicologically harmless dimethylol compounds of hydroxy and alkoxyalkylcarbamates are preferred. Strong curing conditions are required. DMC is particularly suitable for the production of resin finishes on polyester/cotton blends. The finishes are resistant to chlorine and hydrolysis and are fast to washing at the boil. The hydroxy and alkoxyalkylcarbamates do not impair the light fastness of dyeings. A disadvantage is the high content of free formaldehyde.

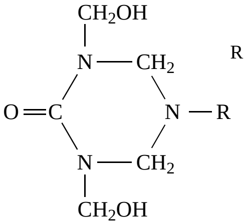
Dimethylolpropyleneurea (DMPU), N,N´-dimethylolhexahydro-2-pyrimidone.



DMPU is produced mainly by reaction of urea, propylene diamine and formaldehyde. It is an important reactant resin for finishes with very good resistance to chlorine and fastness to washing at the boil, especially on white goods. Disadvantages: impairs the light fastness of textiles dyed with reactive or substantive dyes, DMPU finishes are sensitive to hydrolysis.

Dimethyloltriazone Dimethylolhexahydrotriazone. Also known as a triazone resin.

It is produced inter alia by reaction of urea, formaldehyde and a primary amine. Important reactant resins (dimethylolethyltriazone, dimethylolhydroxyethyltriazone). Finishes produced with dimethyloltriazones have low chlorine retention and tend to have a fishy odour which makes an afterwash usually necessary.

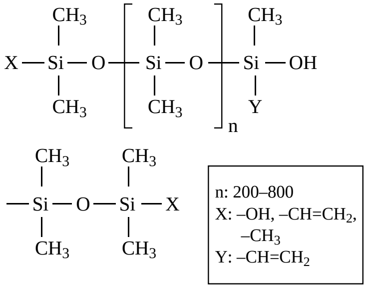


R = alkyl residue
alkylol residue

Reactant resin with good resistance to chlorine and hydrolysis. Does not impair the light fastness of dyed or printed fabrics. Particularly suitable for resin finishes on cotton. On polyester/cotton blends the finishes have a firm handle.

Dimethylolurea (DMU). Condensation product of urea and formaldehyde. A preferred resin finishing agent, available commercially in powder or paste form, very reactive. It is used to produce finishes with good crease resistance, non-shrink properties and high elastic resilience, especially on viscose. The finishes have only moderate fastness to washing at the boil and are not chlorine resistant. DMU has limited storage life.

Dimethylpolysiloxanes with reactive groups Linear dimethylpolysiloxanes containing various end groups, possibly with additional isolated reactive side groups:



n: 200–800
X: –OH, –CH=CH$_2$,
–CH$_3$
Y: –CH=CH$_2$

As silicone crosslinking agents, polymers are obtained which are capable of producing finishes on textiles with high resistance to solvents, temperature, washing, good extensibility, high tensile strength and resistance to rubbing as well as a soft and elastic handle. Uses: for coatings, as silicone elastomers for finishes on wovens and knits produced from fully synthetic fibres and synthetic fibre/cotton blends. Also used for low-shrink finishes on wool.

Dimethyl sulphoxide (DMSO, methyl sulphoxide), $(CH_3)_2SO$. Colourless, odourless, hygroscopic liquid. Density 1,1, flashpoint 95°C; soluble in water, alcohol, benzene, acetone, chloroform. Extremely powerful aprotic solvent. Solvent for hydrocarbons and numerous man-made fibres (cold = acetate, triacetate. modified polyacrylonitrile and some modacrylic fibres). Also used for the preservation of cells at low temperatures, e.g. hemicellulose. → Methylsulphinyl carbanions.

Dimethyl terephthalate (DMT, terephthalic acid dimethyl ester), $C_6H_4(COOCH_3)_2$. Starting material for the manufacture of polyester fibres (polyethylene glycol terephthalate) by condensation with glycol.

DIN DIN is an acronym for the Deutsches Institut für Normung e.V. (German Standards Institution) which succeeded the former DNA (Deutscher Normenausschuß, i.e. German Standards Committee) in 1975. As a member organization of ISO and CEN, the DIN is the official German institute with responsibility for standardization work. Purpose: to establish and publish standards through the combined efforts of all those involved as well as to represent standardization in Germany and abroad.

Organs: General Assembly, Presidium, President, Director General with Secretariats. The technical standards committees (Fachnormenausschüsse, FNA) and working committees (Arbeitsausschüsse, A) with their own departments are each responsible for a large technical field with special working groups for subfields if required. Independent working committees are maintained directly by DIN.

A prerequisite for use of the DIN mark is that manufactured products bearing this mark must meet the appropriate DIN standard and satisfy other authorized requirements of use. All the standards published by DIN carry the DIN mark together with the number group for particular fields of technology, e.g. textile standards are mainly grouped within the 60 000 series. The latest date of issue is decisive for the validity of a particular standard edition. The DIN “Normblatt-Verzeichnis” (index of standards) provides an overview of all published DIN standards (Beuth-Vertrieb). New and revised standards are reported monthly in the “DIN Mitteilungen, Zentralorgan der Deutschen Normung” (official gazette of the central organ for German standardization). Published DIN standards are sold exclusively by Beuth-Verlag GmbH, Burggrafenstraße 6, 10787 Berlin, Germany. → Technical and professional organizations.

DIN colour chart A system of colour filters (hues) which may be used for the determination of colours under standard illuminant C in terms of their appearance and characteristics (hue, chroma and lightness). Used for the systematic arrangement of colour collections (colour atlases), for the determination of colour tolerances, the evaluation of redyeings, and price calculations.

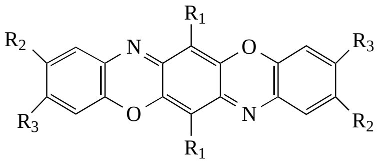
Dinitrile fibres → Polyvinylidene dinitrile fibres.

Diolefins → Dienes.

Diols (dihydric alcohols) → Alcohols containing two hydroxyl groups per molecule.

Dioxan (1,4-diethylene dioxide), $C_4H_8O_2$. A colourless, oily, neutral liquid with a faint and not unpleasant odour. Very toxic (suspected carcinogen). Miscible with water and virtually all organic solvents for printing thickeners. Solvent for cellulose acetate, nitrocellulose, cellulose ethers, chlorinated rubber, resins (mostly acrylate and methacrylate polymers), oils, fats, waxes.

Dioxazines,



Compounds with this general structure form the basis of a small, but not unimportant, group of metal-free violet pigment colorants.

Dioxins Dioxin is the commonly accepted, though chemically imprecise, name for the compound 2,3,7,8-tetrachlorodibenzo-p-dioxin, TCDD (see Fig.) which is the most well-known example of 75 chemically related chlorinated dioxins that differ greatly in their toxicity. They are generally considered together with the dibenzofurans, a further group of 135 substances

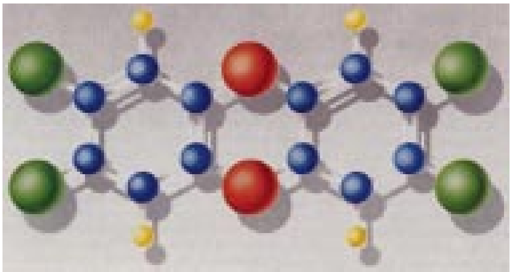


Fig.: Dioxin (TCDD).

which are actually closely related to the dioxins by reason of their chemical structure. All 210 substances have one thing in common, i.e. they are based on a skeletal structure composed of carbon, hydrogen, oxygen and chlorine atoms.

Chemists first became alarmed about these substances during the 1950s. After accidents in two German chemical factories where certain chlorinated hydrocarbons were manufactured, the same sickness symptoms were found in more than 200 workers, i.e. chloracne, besides headaches, indigestion and, in some cases, pain in the muscles and joints. The cause was first identified in 1956 as being due to 2,3,7,8-TCDD which was formed as a contaminant during production of the defoliant 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). The explosive nature of this problem was, however, still not recognized at that time and it was considered sufficient to introduce additional safety measures in chemical factories producing such substances. At the end of the 1960s, extensive research on dioxins began, triggered by American use of the defoliant „agent orange“ during the Vietnam war. One of the components of this herbicide is 2,4,5-T. Public awareness of the problem was aroused following a parliamentary hearing in the USA in 1970 on the subject “effects of 2,4,5-T on humans and the environment”. For the first time, people became aware of the possible dangers to health and the environment posed by TCDD. Shortly afterwards the defoliation program in Vietnam ended. Since the 1980s, the manufacture of substances such as 2,4,5-T and others, which can be obtained in the production of TCDD, is no longer allowed in Germany and many other countries.

Dip/extract method To dye hank yarns and cheeses with reactive dyes by the cold pad-batch method. Cheeses are impregnated with the dye bath on a centrifuge. Interest is restricted to → Space dyeing.

Diphenyl (biphenyl, phenyl benzene), $C_{12}H_{10}$, or $(C_6H_5)_2$, cyclic hydrocarbon containing two benzene rings. Starting material for the manufacture of benzidine.

Diphenylacetamidine (N,N´-diphenylacetamidine). Gas fume fading inhibitor to improve the colour fastness of disperse dyes to burnt gas fumes. It is fibre-substantive and can be applied to acetate fibres simultaneously during dyeing. It exhibits optimum substantivity at 65°C.

Diphenylamine (DPA), $(C_6H_5)_2NH$. A weak base, colourless crystals, virtually insoluble in water, readily soluble in alcohol, ether or conc. sulphuric acid. Uses: redox indicator.

$$\begin{array}{c}\text{diphenylamine}\\\text{(colourless)}\end{array} \xrightleftharpoons[\text{reduction}]{\text{oxidation}} \begin{array}{c}\text{diphenyl benzedine}\\\text{violet}\\\text{(deep blue)}\end{array}$$

For this purpose it is either dissolved at 0,2–1,0 g in 100 ml conc. sulphuric acid, or made up as a 0,2% solution of diphenylamine-p-sulphonic acid (or the sodium salt) which gives an even sharper colour change. It is also used for the detection of oxidizing agents and nitrate fibres (→ Diphenylamine sulphuric acid) as well as the detection of polyacrylonitrile (→ Diphenylamine copper sulphate test).

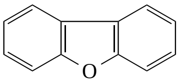
Diphenylamine copper sulphate test Confirmatory test for polyacrylonitrile and polyacrylonitrile copolymer fibres and analogous finishes. Procedure: A few grains of → Diphenylamine are dissolved in 1–2 ml conc. sulphuric acid followed by the addition of a few drops of copper sulphate solution and the test specimen. Positive reaction: the production of an immediate intense dark blue colour (also valid for finishes on fabrics etc., provided they are not too darkly coloured) which during fibre tests disappears after some time and then turns brown.

Diphenylamine sulphuric acid,

I. Specific reaction for nitrate fibres: the fibre specimen is placed in a solution consisting of → Diphenylamine in conc. sulphuric acid (1% solution). After a few seconds an intense blue colour develops, then a deep blue solution. On acetate a yellow, and on cupro or viscose, a weak brown coloration is obtained. With all other fibres the colour remains unchanged.

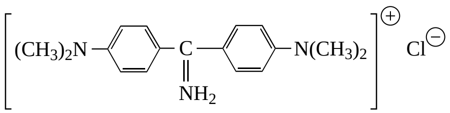
II. Sensitive confirmatory test for oxidizing agents (nitrates, chromates, nitric and nitrous acids, etc.) with which a blue colour is produced. Qualitative test in water: a little diphenylamine dissolved in some conc. sulphuric acid is added to 1 ml of the water to be tested plus 3 ml conc. sulphuric acid. Positive reaction: immediate deep blue colour.

Diphenylene oxide (dibenzofuran). Starting material for the production of carriers, mp 80°C, b.p. 287°C.



Diphenylmethane (benzyl benzene), $(C_6H_5)_2CH_2$, cyclic hydrocarbon composed of two benzene rings linked by a methane residue. Uses: organic synthesis, dyes, etc.

Diphenylmethane dyes A few basic dyes which are now of little practical interest belong to this group, e.g. auramine (C.I. Basic Yellow 2):



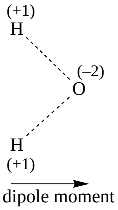
Diphenylthiocarbazone (dithizone), $C_{13}H_{12}N_4S$. A blue-black solid. Prepared from phenylhydrazine and CS2. Dissolves with a green colour in alcohol, chloroform and carbon tetrachloride. Decomposes at 100°C. Gives a characteristic coloration with heavy metals (Ag, Cu, Hg, Pb, Zn, etc.). Used as a specific confirmatory (colorimetric) test for metals.

Diphosphates → Pyrophosphates.

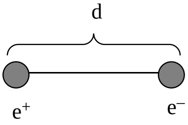
Dipole forces (orientation forces) → Secondary valency forces.

Dipole moment → Dipoles.

Dipoles These are best described by using water as an example. Water shows quasi-ionic character because of its weakly charged negative oxygen atom and two weakly charged positive hydrogen atoms. The result is a molecule with positive and negative "ends" or two permanent opposite poles forming the dipole. This is true for all polar molecules in which the centres of the two electrical charges do not coincide.



The deviation from symmetrical charge distribution, or "Dipole moment", has been chosen as a comparative measure of the degree of polarization of molecules.



The product of charge, e, times the distance, d, = μ, giving the dipole moment unit, $\mu = 1 \times 10^{-18}$, also called 1 Debye or 1 D, after Debye who discovered the dipole phenomenon. Using this value, which is known for many individual bonds, it is possible to estimate dipole moments (see Table where the valency angle and corresponding force parallelograms are taken into account in each case).

It is known that the dipole moment of a disperse dye has a significant effect on its dyeing properties. This is especially pertinent in regard to the suitability of strongly polar dye molecules for spreading the polymer chains and thus acting as carriers. The dissolving power of substances also commonly relies on the interactions between two individual molecules with distinct dipole moments (while non-polar liquids are good solvents for non-polar substances). In this connection, complexes with double dipole moments caused by partial polymerization, for example, are increasingly important because of their increased tendency to form hydrogen bonds.

Tab.: Dipole moments of different compounds in Debyes.

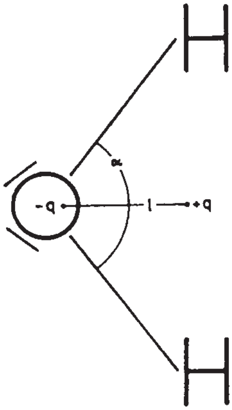

Fig.: Dipole in water molecule.
α = valency angle;
q = negative and positive centres of charge;
l = spatial distance.

Water is an insulator with a total charge of zero. The valency angle, formed by the bonds between the oxygen and the two hydrogen atoms, has been determined experimentally as 104° 27'. The centres of positive and negative charge are spatially separated (see Fig.). This permanent electrical dipole moment gives rise to microwave absorption as a result of dielectric losses. The valency angle α depends on the configuration of the whole molecular environment of the water molecule. As this angle changes, so does the spatial separation, l, of the centres of charge and, therefore, the permanent dipole moment. The more strongly bound the water molecule, the smaller the dipole moment and, therefore, the microwave absorption. In wet textile fabrics, the water has several bonding states with different proportions side by side, for example, the bonds between the OH groups of cellulose and neighbouring water molecules or the physical adsorption forces in the boundary layer between water and synthetic fibres.

Dipping vat Used very rarely nowadays and only for indigo, preferably for fabrics printed with reserving agents. Fabrics are hung up on hooks in a dipping frame so that they can be immersed in a vat and be held there. After the dipping frame is removed, air oxidation takes place and the goods are then immersed in the vat once again (one pass). Full-shade indigo requires several passes.

DIP process The abbrev. “DIP” stands for diazotization in the paste (→ Naphthols in direct printing). It represents a variation of base printing: for preference liquid bases are stirred into a thickener together with sodium nitrite. A second thickener contains a medium strength acid, e.g. phosphoric acid. By gradually mixing the two stock thickeners together, the fast colour base is diazotized without the otherwise usual addition of ice (for cooling). Due to metered addition, no nitrous gases are released by this method. The print paste with the diazotized fast colour base must not be neutralized, and is immediately ready for printing.

Dip treating The process of passing fibre, cord, or fabric through an adhesive bath, followed by drying and heat-treating of the adhesive-coated fibre to obtain better adhesion.

Direct coating The application directly on to the web of moderate and high viscosity polymers, both in the form of solutions, concentrated dispersions and in fused, thermoplastic state. This mainly applies to coating processes, as used in the manufacture of textile/plastics composites. Following this process, material can be added indirectly using another web (textile, foam or film). The Fig. shows a plant by Brückner for the direct coating of carpet backing.

The doctor blade (squeegee) process is also a direct-coating process. The polymer-based coating agent is applied directly to the coating base and adjusted to the required thickness over the entire width of the cloth by means of a doctor blade. The air knife (squeegee), knife-on-blanket and knife-on-roll processes are adjusted according to how the material is mechanically applied to the base at the doctor blade.

Unlike the direct coating process, indirect coating processes, such as roller-application methods, involve the indirect application of the product. The film of coating material is first applied to the roller and then transferred to the textile web.

Direct discharge of waste water The direct discharge of waste water into a main outfall (e.g. a stream) without prior treatment in a municipal waste water treatment plant.

Direct dyes Also known as direct cotton, substantive, benzidine or salt dyes. Group classification for dyes which exhaust substantively on cellulosic fibres, cotton, viscose, cupro and high wet modulus fibres, especially in the presence of salt. They are mainly sulphonated disazo or polyazo dyes. The sulphonic acid groups are responsible for good solubility in water. The high light fastness types already contain a complex-bound metal atom in the molecule. The colour fastness of various direct dyes can be improved by aftertreatment with metal salts (→ Aftercoppering dyes). Specially selected direct dyes are available for streaky-dyeing viscose qualities. Direct dyes represent the main class of dyes for cellulosic fibres in terms of usage: they are simple to apply, economical, have generally good levelling properties, a wide shade gamut and a wide range of colour fastness. Special types can be diazotized and developed on the fibre (→ Diazotizable dyes) for better wet fastness or may be coupled with readily soluble diazo compounds. Direct dyeings on cellulosic fibres exhibit considerable differences in colour fastness to light which ranges between 1 and 7–8. Different direct dyes can therefore be used for articles which are only required to have low light fastness as

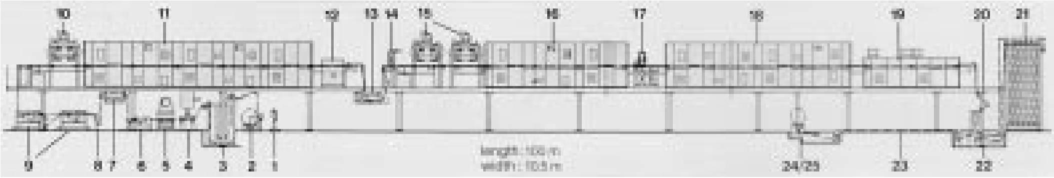

Fig.: The largest known plant for coating the back of tufted carpet with a primary coat for tuft anchorage and a finishing coat of latex foam (source Brückner).
1 = Sew end-to-end∞ 2 = Unwind∞ 3 = Accumulator∞ 4 = Brush/Suction extract; 5 = Steam; 6 = Straighten; 7 = Control; 8 = Tension; 9 = Lick applicator; 10 = Dry on; 11 = Pre-gel; 12 = Cool; 13 = Singe back; 14 = Coat; 15 = Dry on; 16 = Pre-vulcanize; 17 = Emboss; 18 = Vulcanize; 19 = Cool; 20 = Trim edge; 21 = Accumulator; 22 = Control; 23 = Monitor; 24 = Wind; 25 = Cut across.

well as goods with high light fastness. In general, direct dyes have poor wet fastness properties and dyeings must be aftertreated to improve their serviceability.

Direct dyes, dyeing mechanism As distinct from the concept of → Substantivity, frequently quoted in the field of cotton dyeing, the affinity of a dyestuff is determined as a measure of the distribution between fibre and dye bath under standardized dyeing conditions in equilibrium, and represents the difference between the dye affinity to water (hydrophilicity) and to cellulose.

According to Vickerstaff and others, the cause of the affinity of a dye molecule to cellulose is to be sought in the formation of hydrogen bonds between cellulosic hydroxyl groups and proton donors of the dye substituents such as e.g. amino groups (Figs. 1–3). According to Ciba-Geigy, the affinity of direct dyes to cotton cellulose results from hydrogen bond-like linkages of the cellulosic hydroxyl groups (as proton donors) with the de-localizable π electron system of the dye (as proton acceptor). All substances with substantial affinity to cellulose nevertheless have a large planar chromophore (Fig. 4) with a large number of conjugated double bonds. Any interruption of this planarity of the chromophore, i.e. any reduction in the extension of the de-localizable π electron system, reduces affinity. Besides such “Yoshida” forces, other interactions also play a part, such as van der Waals forces and hydrophobic interactions; thus the introduction of an increasing number of water-solubilizing (hydrophilic) sulpho groups into the chromophore of a direct dye causes a significant decrease in the affinity of the dye to cellulose fibres.

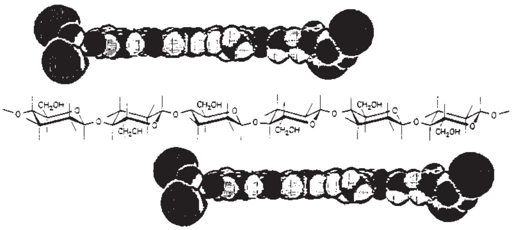

Fig. 1: Schematic representation of co-planar dye adsorption on cellulose (source: Flath).

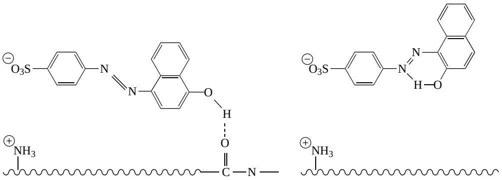

Fig. 2: Inter- and intra-molecular hydrogen bonds in the sorption of Napthalin Orange I (left) and Napthalin Orange II (right) in wool.

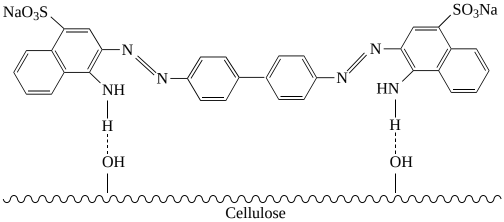

Fig. 3: Model of hydrogen bond formation between substantive dye and cellulose fibre (source: Vickerstaff).

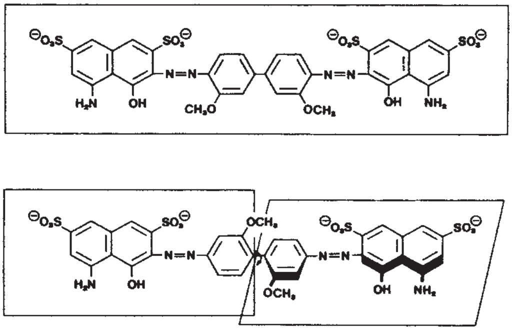

Fig. 4: Importance of the planarity of the dye molecule for the affinity to cellulose. Top: high affinity (direct dye); below: low affinity (acid dye).

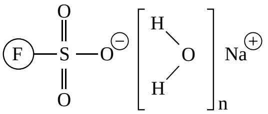
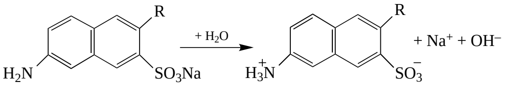
In pure water, cellulose carries negative charges, which with the negative charges of the sulpho groups cause electrostatic repulsion (electrostatic barrier or “Donnan potential”). Through the addition of electrolytes, such as e.g. sodium sulphate, to the dye bath, this electrostatic repulsion is suppressed, which causes a better interplay of the “Yoshida” forces and of the van der Waals interactions, and thus greater affinity. Higher concentrations of salt (which in low-affinity reactive dyestuffs is still 40–70 g/l sodium sulphate) cause an aggregation of the dye molecules in the solution (in effect, a salting-out action); however, these associates degrade with increasing dyeing temperature, so that the dyes diffuse in a monomolecular manner as dye ions into the fibre pores. In the fibre, the solubility of the direct dyes could be reduced through coagulation of several molecules. The dye aggregates in the solution could thus serve as a reserve supply from which, as a result of the association equilibrium, the individual dye ions are constantly supplied after they have been taken up by the fibre.

For the addition of salt, from the point of view of the process technology, there are basically two options: before or after adding the dye. The fixation yield of reactive dyes increases with increasing concentrations of salt; above 50 g/l, the influence of salt concentration in the dye bath declines, however. The trend towards shorter liquor ratios provides the option of reducing the salt content. The salt-saving potential is greater, the lighter the dyeing. Working with low amounts of salt aids the solubility of the dye; so one can use sodium chloride (corrosive to metal!) in place of sodium sulphate, without increasing the dye particle size or precipitation taking place. Besides this empirically obtained information, it still seems sensible to define the type of salt dosing (as a sol or solid) in terms of time, so that one can follow the influence of the salt on the state of the dye molecules in the dye bath and in the fibre kinetically.

Dyes with anionic groups have to be of substantially planar structure if they are to aggregate in the liquor; bulky molecule parts impede aggregation. The less the solubilising sulpho groups with their hydrate shells are mutually repellent, the better the dyestuff molecules are able to aggregate. The addition of salt to anionic dye solutions causes not only a suppression of dissociation, but also leads to the formation of ion pairs (hydratised counterions united via water molecules):



This “kinetic entity”, which is stable for a certain time, is electrically neutral. The same applies to zwitterions in the case of dyestuffs with the same number of amino groups and sulpho groups at a certain pH:



Levelling agents which have an affinity to dyestuffs, and which interact both with the polar groups, displacing water, as well as with the hydrophobic groups of the dye molecule, in each case incorporate a dye molecule into a micelle, and thus reduce the dye aggregation in the solution. The dye aggregation in solutions can be demonstrated photometrically. The interaction of the π-electron systems of aggregated dye molecules causes a splitting open of the excited π-states into two adsorption maxima in the transmission spectrum of a dyestuff solution with a higher and a lower energy. During the transition from the excited to the “normal” state of the aggregated molecules, short-wave radiation is emitted.

Although previously the view was held that anionic, planar dyes adhere in cellulose because they form aggregates there, it was later shown through transmission measurement – with transparent cellophane films dyed with Indanthren Dark Blue BOA – that anionic dyes bond to cellulose in a mono-molecular manner. It must be emphasized above all here that the dye which has been taken up in a mono-molecular manner is 200 times more concentrated in the film than in the liquor, where it is present as dimer. More recent work too assumes the mono-molecular adsorption of direct dyes in cellulose; postulating that the pores of cotton are only of such a size that the inward diffusion of dye monomers (at best with hydrate shell) is solely possible, but not that of dimers.

The salt content at the start of dyeing should be kept low, in order – with high dyestuff concentration – to control dyeing in such a way that initial dye monomers are “dissolved” out of dye aggregates with poor diffusion properties, due to the aggregate ↔ monomer balance, as these tend to form ion pairs with suppressed dissociation when salt is present. These ion pairs have affinity to cellulose, because their solubility in water is lower than their “solubility” (adsorption) in cellulose. With increasing temperature, more monomers emerge from the aggregate. The addition of salt also increases the tendency towards aggregation, but necessitates further addition of salt as dyestuff concentration declines during the dyeing process, to displace the equilibrium.

The substantivity of a cotton dyeing with direct dyes also increases depending on typical dyeing parameters, as follows:

- when the pH of the dyebath decreases,
- when the dye concentration in the dyebath decreases,
- when the dyeing temperature decreases,
- when the liquor ratio decreases.

That the hydroxyl groups of cellulose are somehow responsible for dye bonding is apparent from, amongst other things, the fact that when these groups are esterified, the dye-fibre affinity ceases to exist.

Direct dyes, dyeing methods,

I. Batch method: With batch dyeing, the dyeing method to be selected in each case depends on the type of dyeing equipment (loading system, winch vat, jig, paddle or jet), the nature of the material to be dyed, as well as the solubility and the affinity of the dye. Before the actual dyeing process, the material is pre-treated with a wetting agent. The dye is mixed into a paste with some warm water, and is then diluted with more water, boiled up, filtered, and then added to the dyebath. Whilst the bath, with the fabric, heats up to the optimum temperature (usually 80–90°C), the electrolyte is added, gradually if necessary. Dyeing takes 30–60 minutes. After the dyebath has been run off, the dyed material is briefly rinsed with cold water and, in general, subjected to after-treatment. The dyeing process is divided into 3 phases: a) uptake (adsorption) through substantivity; b) penetration of the dye into the fibre (diffusion); c) bonding to the fibre (immobilisation) through van der Waals interactions. Assurance of level take-up through progessive addition of salt, temperature control, sufficiently long dyeing time, and use of levelling agents.

II. High-temperature dyeing method: With suitable dyes, one can work in a closed system at temperatures over 100°C (up to approx. 130°). Due to the rapid diffusion rate, particularly level dyeings are achieved with short dyeing times, even with fabric with difficult dye penetration. After the high-temperature phase, the dyebath is cooled down to 80–90°C, with dye pick-up continuing, and the result is the same depth of colour as in the normal dyeing method at 80–90°C.

III. Continuous and semi-continuous method: With these so-called pad methods, the dyeing material, mostly in the form of woven fabric, is first of all steeped in a concentrated dye solution, passed full-width through a trough filled with the dye solution, and subsequently the excess liquor is removed between the rubber rollers. With high fabric speed, temperatures as low as possible (30–40°C for light shades, 60–80°C for medium to dark shades), and with the minimum amount of pad liquor, the situation can be avoided where the dye already picks up substantively in the padding process. Distinction may be made between the following methods:

1. Pad-jig method: Pad, salt bath develop on jig or winch vat.
2. Pad-roll method: Pad, heat up in an IR zone, roll up and rotate in a dwell chamber for a considerable time under fixation temperature/moisture conditions.
3. Pad-salt method: Pad, pass through salt solution at boil in continuous piece-dyeing machine (light shades only; for darker shades an intermediate steam process is necessary).
4. Pad-steam method: Pad, continuous steam, optional final salt bath.
5. HT-steam method: Pad, HT-steam.

IV. After-treatment: The wetfastness properties of direct dyeings are not adequate for the demands of everyday use, particularly in medium and deep shades. However, by means of suitable after-treatments, products can be obtained having good water and perspiration resistance, and which are washable at 40°C. Distinction may be made between the following:

1. After-treatment with cationic compounds: With anionic direct dye applied to the fibre, cationic after-treatment agents of relatively high molecular weight form water-insoluble salt-like compounds with good wetfastness properties. Possibly simultaneous shade alteration or reduction of the light fastness.
2. Metal complex formation: Some azo dyes can form 1 : 1 copper complexes. If such dyes are after-treated with aqueous metallic salt solutions (e.g. copper sulphate), then considerable improvements in lightfastness and, to some extent, also in wet fastness, are obtained since molecule enlargements reduce solubility and diffusion speed is considerably reduced. After-metallizing to improve wet fastness by means of copper sulphate/acetic acid, potassium dichromate/copper sulphate/acetic acid, potassium dichromate/copper sulphate. Metallizing can cause severe shade changes.
3. Diazotization and coupling.

Direct engraving process In contrast to the classical method of → Engraved printing rollers from individual colour separations produced by the engraving designer, in direct engraving the actual engraving is carried out directly from the multicoloured design by means of optoelectronic scanning.

Direction-dependent coefficient of friction → DFE, friction.

Directive for use of dangerous substances → Legislation on environmental protection.

Direct printing The most frequently employed method of textile printing in which print pastes are applied to white or dyed fabrics without destroying the ground colour, e.g. as in → Resist printing and → Discharge printing.

Direct steam as a liquor heating medium → Steam as a liquor heating medium.

Dis → Bis.

Dischargeability of dyes Dischargeability is mainly dependent on the chemical constitution of the dye. The presence of an azo group is the most important requirement. This is why, in principle, azo derivatives are used as dischargeable dyes since they can be destroyed by cleavage of the azo groups.

Dischargeable dyes are to be found in various dye classes:

- disperse dyes,
- vat dyes,
- cationic dyes,
- pigment colorants,
- direct dyes,
- acid dyes,
- metal-complex dyes,
- reactive dyes,
- naphthol dyes.

In the dye maker’s pattern cards, the dischargeability of each dye is rated on a scale from 1–5 (1 = virtually undischargeable, 5 = easily dischargeable). Many azo types are not readily dischargeable because the cleavage products formed during the discharge process have an affinity for the fibre. Moreover, small amounts of impurities or side products in the original dye can also impair dischargeability. Since these contaminants often only give rise to problems above a certain concentration of use, dischargeability is frequently concentration-dependent. Moreover, the same dye (i.e. with the same CI number) from different manufacturers can also exhibit different dischargeability properties. Colourless cleavage products can likewise have a negative influence on the discharge effect which usually becomes apparent only during storage of the discharge printed fabrics. Some white discharges are subject to yellowing due to the action of light or oxidation. Dyes which react typically in this manner, e.g. CI Acid Blue 116, are referred to as "reversionary" dyes. The state of fixation of a dye also has a considerable influence on its dischargeability. For this reason, dyes which adhere to the surface of the fibre after padding or printing are easier to discharge than those which have already been fixed on the fibre in a dyeing process. The nature of the fibre itself also plays an important role in dischargeability. Since the common reducing agents are all hydrophilic and, in some cases, readily water-soluble, it is obvious that water-soluble dyes on hydrophilic fibres (e.g. wool or cotton, are more easily discharged than hydrophobic dyes on hydrophobic fibres (e.g. disperse dyes on polyester fibres). Furthermore, the type and concentration of reducing agent and auxiliaries, as well as the drying and steaming conditions are of decisive importance here.

In the production of coloured discharges, a new dye (illuminating dye) is applied to the discharged areas of the design at the same time. This new dye is added to the liquor or print paste containing the reducing agent and must therefore be resistant to reducing agents. Discharge-resistant or coloured discharge dyes are mainly anthraquinonoid, phthalocyanine, triphenylmethane, methine or oxazine types. Whilst numerous discharge-resistant dyes were recommended by various dye makers in the past, the number of suitable dyes has been reduced to a minimum today because of their generally poor colour fastness properties. It is therefore almost impossible to cover all the desired shades for coloured discharges with one dye class due to the relatively limited selection now available. For this reason, up to 4 different dye classes can be combined alongside each other to produce one coloured discharge design. Acid and direct dyes are the most widely used among the following types:

- cationic dyes,
- pigment colorants,
- vat dyes,
- acid dyes,
- direct dyes,
- mordant dyes.

Although only azo groups are dischargeable with reducing agents, an alkaline discharge can also be used to bring about cleavage between the former vinylsulphone group and the –OH groups of cellulose in dyeings produced with vinylsulphone (VS) reactive dyes (see Fig.).

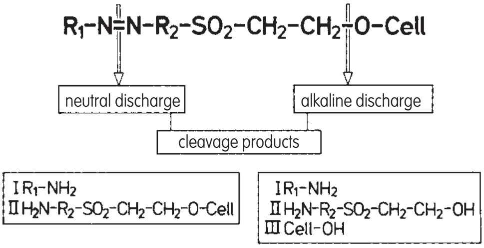


Fig.: Dischargeability of vinylsulphone ground dyeings (source: Hoechst).

Polyester fabrics are only dischargeable if the ground shade produced by continuous dyeing has not yet been fixed in the thermosol process. A classic discharge print on lightweight polyester fabric is produced as follows:

1. Dyeing: exhaust dyeing in conventional jet or beam dyeing machines.
2. Wash off: short rinse (a reductive afterclear is not necessary at this stage).
3. Drying: stenter dry at low temperatures to remove creases only.
4. Printing.
5. Fixation: HT steaming at 175–185°C, 6–8 mins.
6. Wash off: cold water rinse; hot alkaline reductive afterclear, followed by hot and cold rinses.
7. Drying.

Dischargeable grounds Dyeings made with dyes suitable for the production of white or coloured discharges. Direct, reactive and naphthol dyes are mainly used on cellulosic fibres; acid, metal-complex, disperse and cationic dyes are used on the appropriate synthetic fibres. An essential prerequisite is good dischargeability of the ground dyeing. Since there is a direct relationship between dischargeability and depth of shade, dye selection must be made by reference to recommendations given in the dye pattern card relative to the 1/1 standard depth. There is often no single dischargeable dye capable of producing the desired shade so that combinations of different dyes resp. dye classes have to be used. In many cases preliminary trials are essential in order to determine to what extent the inclusion of small proportions of a difficult to discharge dye may impair the discharge effect, or to establish the higher proportions of a readily dischargeable dye necessary to achieve a satisfactory discharge effect. The dischargeable ground dyeing is, in any case, dyed in the same manner as a normal dyeing.

Discharge print halo → Halo in discharge printing.

Discharge printing A style of printing in which predyed or prepadded fabric is printed with a paste containing chemicals capable of destroying the ground colour to produce white effects (white discharges) in the printed areas, or coloured effects (coloured discharges) with the addition of a discharge-resistant dye (see Fig.). The discharge print paste consists of a thickened discharging agent which may contain further additives, e.g. white pigments, discharge-resistant dyes if required, and other necessary chemicals, auxiliaries, etc. Well-bleached material is a prerequisite for white discharges. As dischargeable grounds, either normal plain dyed fabric or, more frequently, prepadded grounds are employed. Discharging agents consist mainly of reducing agents based on sulphinic acid derivatives and tin salts. The advantages of discharge printing, i.e. flexibility and great variety of design possibilities are offset by the more complicated and costly production process which generally involves the following stages: dyeing, intermediate drying, application of discharge print pastes, intermediate drying, steaming (reaction medium), washing-off and drying. The development of alternative processes is of great interest from the ecological point of view since, on the one hand, the classical discharge printing process is associated with a high energy consumption and a high water consumption on the other hand, in order to remove the thickener which is often difficult to wash out in the print afterwash stage. Moreover, the waste water is contaminated with *inter alia* sulphur-containing reducing agents and large quantities of high molecular weight thickeners which results in a drastic increase in the COD values (→: Acetate, Triacetate, Polyester, Polyacrylonitrile, Polyamide, Silk, Wool in discharge printing; Cationic, Mordant, Direct, Vat, Vat leuco ester, Naphthol and Reactive dyes in discharge printing).

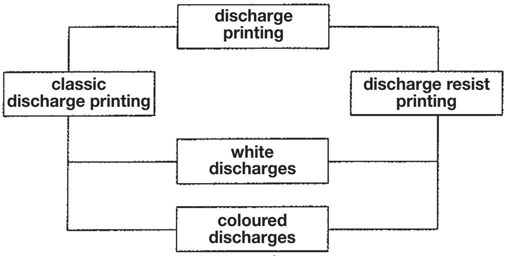

Fig.: Basic concepts of discharge printing (BASF).

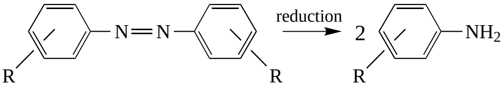
Depending on the class of dye to be discharged, 3 different types of chemical reaction are employed:

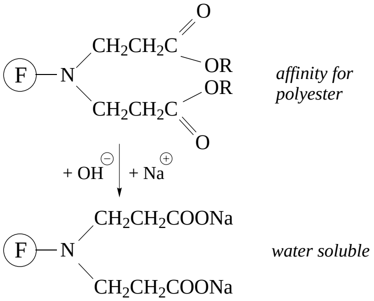
1. Cleavage of azo groups by reduction:



2. Alkaline cleavage of ether linkages in vinylsulphone reactive dyeings:

$$\text{Cell}-O-CH_2CH_2SO_2-\text{Ⓕ} \xrightarrow{OH^{\ominus}} \text{Cell}-OH + HOCH_2CH_2SO_2-\text{Ⓕ}$$

3. Alkaline cleavage of ester groups in disperse dyes (before thermosol treatment):



Discharge printing assistants These include products capable of making otherwise difficult to discharge dyeings (e.g. vat dyes) dischargeable, and which assist the discharging action and fixation of the coloured discharge illuminating dyes. In the main, these are products based on quaternary ammonium compounds. Hydrotropic auxiliaries accelerate or make possible the discharge process during dye fixation and also dissolve cleavage products thereby facilitating their removal in subsequent afterwashing. Hydrotropic auxiliaries also ensure the presence of a certain quantity of water on the fabric during steaming thereby increasing the efficiency of the reducing agent. Urea, which is the most frequently used hydrotropic auxiliary, performs the following functions:

- increases dye solubility in the discharge print paste or pad liquor,
- accelerates dye fixation during steaming,
- improves dye colour yield,
- prevents the fibre drying out during steaming.

Wetting agents are also employed in discharge print pastes or pad liquors to reduce the surface tension between water and air so that the aqueous medium can penetrate air-filled capillary spaces in the fibres more easily. White effects produced by white discharges can also be improved by additions of zinc oxide and titanium dioxide (often as mixtures of both), as well as fluorescent brightening agents, to the discharge print paste. Thiodiglycol is also used as a dye solvent and hydrotropic agent, whilst glycerol is used as a hygroscopic agent and solvent.

Discharge print pastes → Discharge printing.

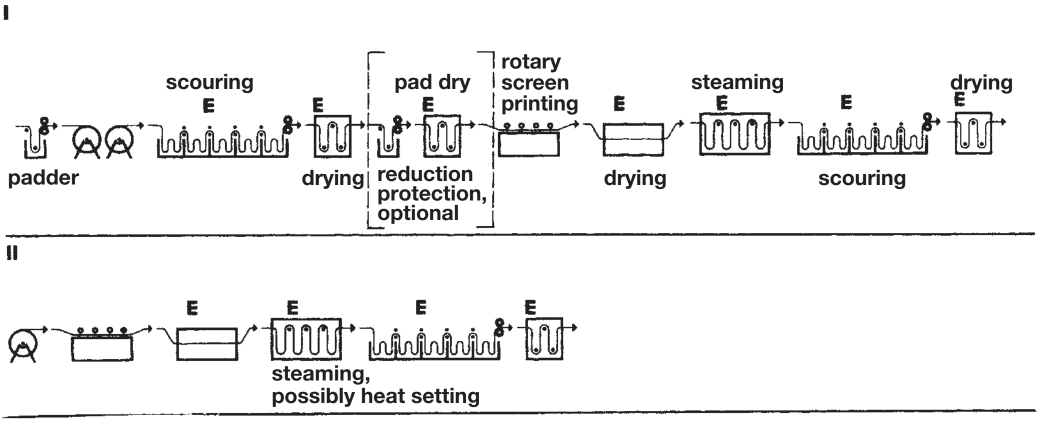


Fig. 1: 2 possibilities of discharge resist printing on cellulose fibres with indication of high energy cost processing stages. I = cold batching with reactive dyes, then coloured discharge with vat dyes or pigments as decorative dyes; II = wet on wet process, reactive under reactive or pigment reactive dye.

Discharge resist printing In contrast to normal resist printing, fixation of the dye to be resisted is not only prevented but also simultaneously destroyed by the discharging agent (Figs. 1 and 2).

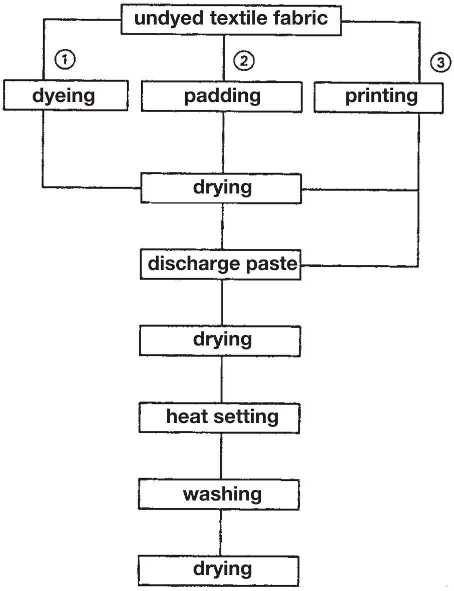

Fig. 2: Processing cycle in discharge and discharge resist printing.

Discharge resist printing on polyester Because of the difficulty of discharging polyester dyeings, the → Discharge resist printing technique is preferred. Either stannous chloride or sodium, calcium or zinc formaldehyde sulphoxylates are used to destroy the dyed grounds. An alternative is the use of alkali discharge resists without reducing agent.

The following method is used to produce discharge resists on polyester with stannous chloride:

1. Padding:

thickener (to prevent migration)	100 g/l
citric acid (adjustment to pH 5)	2 g/l
monosodium phosphate	10 g/l
dischargeable disperse dye (azo type)	x g/l

2. Drying:
   the drying temperature must not exceed 100°C
3. Printing:

thickener	500 g/l
urea	80 g/l
carrier (HT fixation accelerator)	10 g/l
stannous chloride	100–200 g/l
disperse dye for coloured effects (anthraquinone type)	x g/l

4. Drying.
5. Development:
   HT steaming or pressure steaming.
6. Afterwash:
   cold rinsing, followed by an alkaline reductive clear, hot and finally cold rinsing.
7. Drying.

Discharging agents in printing The application of a → Reducing agent is necessary for discharge printing. In practice, the formaldehyde sulphoxylates, thiourea dioxide (formamidine sulphinic acid) and, in certain cases, tin (II) chloride are the preferred reducing agents. The latter is unsuitable for wool since brown tin sulphate can be formed with the reduced cystine groups in the fibre resulting in unsightly effects. The most important reducing agents are:

– sodium formaldehyde sulphoxylate,
– zinc formaldehyde sulphoxylate,

– calcium formaldehyde sulphoxylate,
– thiourea dioxide.

The individual products are applied under different pH conditions. Tin (II) chloride is applied under strongly acidic, and zinc formaldehyde sulphoxylate under mildly acidic conditions. Thiourea is used under both mildly acidic as well as alkaline conditions. All other products are used in the weakly alkaline range. Discharging agents also differ in their solubility. Calcium formaldehyde sulphoxylate and thiourea dioxide are only sparingly soluble in water which also makes it possible for the former to be applied at higher concentrations without problem. All the other products have good to very good solubility in water.

Strongly alkaline sulphoxylate discharges are not particularly suitable for the production of discharge effects on alkali-sensitive fibres, e.g. wool, silk, acetate. Since thiourea dioxide is effective under neutral or mildly acidic conditions, it does not cause any damage to alkali-sensitive fibres. Choice of the optimum discharging agent for a particular application is based on the product which is capable of giving the best effects with appropriate additives under the given conditions of fibre type, dye class and processing technique. The selected product must not cause damage to the fibre nor influence the colour fastness of the dyes used. A prerequisite for the reaction is a sufficiently high reactivity of the discharging agent. This is characterized by the redox potential, i.e. the more negative the redox potential, the more reactive the discharging agent (dependent on temperature, pH and concentration).

Disinfectant cleaning → Sanitized chemical cleaning.

Disinfectants chemicals suitable for disinfecting, e.g. in particular oxidizing agents in the form of chlorine carriers (thermochemical disinfection of textiles), phenol derivatives, bactericidal finishes. It is probable that these agents mainly work by destroying the cytoplasm membrane of the bacteria.

Disinfectant washing agents, a product which combines detergents with → Disinfectant in the form of phenol derivatives or stabilized chlorine carriers. Typical disinfection system for thermochemical disinfection of textiles. Increasing interest in combining disinfectants with other agents to produce bactericidal, fungicidal, anti-tubercular bactericidal, antiviral etc. effects.

Disinfectant washing process →: Disinfection washing of textiles; Thermal disinfection.

Disinfection, destruction of microorganisms that cause disease (bacteria).

Disinfection in the laundry, is carried out in hospitals and similar institutions in pressure vessels using superheated steam and hot air, or in a washing machine using a disinfectant washing process.

Disinfection washing of textile Disinfection by adding disinfectant detergents at a time-dependent minimum temperature (40–60ºC, 10–15 min.) in the presence of a disinfectant. This is currently the predominant working method in hospital laundries. A list issued by the Federal Health Office taken from the federal law relating to the control of contagious diseases (§ 41) contains appropriate, i.e. officially tested, production and process procedures for the disinfection washing of textiles. Disinfectants often used are stabilised → Chlorine carriers, which can separate active chlorine and/or hypochlorite in washing liquors, although this does not necessarily have to occur. Risk of chlorine separation in the wash bath: → Active chlorine losses.

Disinfestation The destruction of harmful insects (clothes lice, bugs, moths, etc.) and their larvae or eggs.

Dislocation Term used to describe a change in position or place of dye during dyeing as in → Migration.

Disodium hydrogen phosphate Acid sodium pyrophosphate, $Na_2H_2P_2O_7$, fine powder, non-hygroscopic. Density 1,848. Solubility in water at 20°C up to 120/140 g/l. The solution has an acidic reaction at pH 4,2. Gives clear acidic solutions even in hard water. As a builder it improves the washing and foaming efficiency of detergents. Removes undesirable iron and manganese compounds in washing, dyeing, etc. (especially in iron dyeing vessels). Other uses include bleaching stabilizers and flame-retardant finishes. → Sodium phosphates.

Disodium phosphate Sodium phosphate, dibasic (DSP, sodium orthophosphate, secondary), Na_2HPO_4. Colourless translucent crystals or white powder with a saline taste. Soluble in water, very soluble in alcohol. Hygroscopic, converted to sodium pyrophosphate at 240°C. Textile applications include weighting of silk, dyeing and printing, flame-retardant finishes.

Disodium pyrophosphate → Disodium hydrogen phosphate.

Disodium salt → Triethylsulphateamine.

Dispersants Dispersing agents which are effective e.g. in aqueous treatment baths. Dispersants prevent the redeposition of largely insoluble substances (e.g. soil particles). They are mainly → Surface active compounds. Dispersants reduce the surface tension of water and accumulate on the fibre surface. They are used in virtually all wet processing and finishing treatments.

Disperse dyeing systems For dyeing polyester fibres, in practical terms only disperse dyes are suitable. Through their hydrophobic properties, these dyes are capable of penetrating into the similarly hydrophobic polyester fibre. This class of dyes has only extremely poor solubility in water; for this reason, conventional aqueous dye liquors, e.g. tensides, have to be added as levelling agents. Since it is only such dye that has been dissolved to a molecularly dispersed state which is capable of diffusing into the fibre, only poor levelness can be achieved without levelling agents.

The model of an aqueous disperse dye system is shown in the figure. Through the dispersant, stabilisation of the dispersion is achieved (prevention of crystallite enlargement etc.); by adding tenside, a reservoir for dispersed-molecule dye is created via the solubilisation of dye molecules into micelles. The actual dyeing process is initiated through the adsorption of the dispersed-molecule dyes on the fibre surface. A boundary layer forms on the fibre surface, through which the dye molecule must diffuse. The rate of the dye transfer through the boundary layer depends on the diffusion coefficient, the fibre surface, and the change in the chemical potential in this process. The same applies analogously for diffusion of dye in the interior of the fibre.

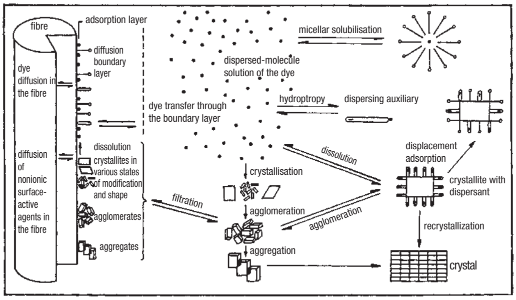

Fig.: Model of a disperse dyeing system (source: Schollmeyer).

Assuming that the transfer of the dye molecules through the solution itself is not the step which determines the speed, the diffusion of the dye into the fibre shows itself to be the slowest sub-process. In the polymer/water/disperse dye system, there must be a sufficiently large free volume present. For this reason, the mobility of the polymer chains determines the rate of the diffusion. To increase the diffusion rate, carriers are often added to the aqueous dyeing liquor. They act as plasticizers in a similar way to solvent molecules, i.e. they increase the free volume of the system. Both the solubility of the dye and the kinetics of the dyeing process are increased by higher temperatures. However, problems arise with the dispersion stability. Thus for example recrystallization processes become more likely, and above the cloud temperature characteristic of a particular tenside, an additional tenside phase forms besides the aqueous phase.

In order to achieve high bath exhaustion, the distribution of the dye between fibre and bath must be in favour of the fibre. In equilibrium, the distribution coefficient $K = c_F/c_L$, where c_F is the concentration of the dye in the fibre, and c_L is the concentration in the solution. Since the solubility of disperse dye in aqueous solution is very low, one thus obtains a suitable equilibrium. Other known dyeing systems have used organic solvents instead of water. This causes considerable acceleration of the dyeing process. As a solvent, predominantly tetrachloroethene has been used, in which dispersion dyes have good solubility. Moreover, its evaporation enthalpy is considerably lower than that of water, which is of economic significance for the drying process after dyeing. However, the bath exhaustion when using tetrachloroethene is unsatisfactory (source: Schollmeyer).

Disperse dye parameters for suitability in heat transfer printing These parameters are used to characterize disperse dyes under standard conditions for their suitability in heat transfer printing. The parameters for this purpose are →: Equilibrium yield; Standard time t_{70}.

Disperse dyes Dyes with extremely low solubility in water which, in a finely dispersed state, are used for dyeing polyester, acetate, triacetate, polyamide, polyacrylonitrile, modacrylic and polyvinyl chloride fibres. Both azo and anthraquinone disperse dyes can differ considerably in molecular weight (see Table).

Since the majority of synthetic fibres do not possess any ionic groups, they cannot be dyed by an ionic mechanism as is the case with e.g. acid, metal-complex or cationic dyes. These synthetic fibres can only be dyed with non-ionic dyes (= disperse dyes) which are practically insoluble in cold water due to the absence of any solubilizing groups in the molecule. Disperse dyes are applied in the form of fine aqueous → Dispersions (→ disperse dyeing systems). The size of the dispersed dye particles is in the region of approx. 0,5–1 µm. Because of their hydrophobic character, disperse dyes have an affinity for the likewise hydrophobic synthetic fibres. The dye particles are able to penetrate the fibre during dyeing in a molecularly dispersed state and are held in the fibre in this form. Disperse dyes are produced with various chemical structures. The two main classes are the azo and anthraquinone dyes. Azo disperse dyes contain relatively unstable azo linkages in the molecule so that the sensitivity to reduction of these dyes must be taken into consideration. Anthraquinone disperse dyes have more stable structures and a smaller molecular size which gives them greater mobility. The solubility of disperse dyes in cold water is very limited (only a few mg/l). Solubility rises rapidly with increasing temperature, however, and some dyes can achieve a solubility of 100 mg/l at dyeing temperature. As alternatives to the azo or anthraquinone disperse dyes, a small number of dyes with very different chemical structures exist which, in most cases, produce more brilliant shades.

Important parameters for disperse dyes are:

1. Sublimation fastness: a property specific to this class of dyes which is evaluated by the behaviour of

the dye on transition from the solid to the gaseous state. Sublimation problems can arise during dye fixation (thermosol process, steaming) or during thermal treatments of the dyed material.

2. Thermomigration: the fastness properties of a disperse dyeing can be impaired by certain finishes or preparations applied to the fibre. The effect of heat as well as prolonged storage of dyed goods can cause thermomigration.

The dyeing process between dye and synthetic fibre can be described as a process of solution whereby the dye dissolves in the fibre. The fibre therefore acts as a solid solvent for the dye (solid solution). However, in order for the dye to migrate more easily into the fibre interior it must be present in a monomolecular form; → Dispersing agents are employed in practice to assist this process.

Disperse dyes, diazo → Disperse dyes.

Disperse dyes, diazotizable Disperse dyes which can be diazotized and developed on the fibre. → Disperse dyes.

Disperse dyes, dyeing methods Synthetic fibres (especially polyester, which is the most important fibre for disperse dyes) are difficult to dye because of their high cohesion forces and high degree of orientation. For this reason, dyeing conditions must be selected which promote a loosening of the fibre structure in order to allow easier uptake of dye. The dyeing methods are subdivided into:

I. Exhaust methods: these involve exhaustion of the dispersed dye from the dyebath on to the fibre.

II. Continuous methods: in this case, the dye is applied to the fibre mechanically after which it diffuses into the fibre during a thermal treatment.

Continuous methods are subdivided into:

1. Thermosol process: the dye is applied to the fibre mechanically with water acting as a transport medium. The water is then removed by drying (approx. 1 min. at 200–220°C). The fibre becomes thermoplastic in this temperature range which facilitates diffusion of dye into the fibre.
2. Steam fixation: satisfactory results are not achieved by steaming in saturated steam at 100°C. Pressure steaming at 130°C gives relatively good fixation whilst superheated steam, which finds wide application in the fixation of printed disperse dyes, is only used on a small scale in continuous dyeing.

Examples of dyeing methods:

a) Dyeing at the boil: this dyeing method should be avoided whenever possible as it suffers from many disadvantages. In some cases, e.g. deep shades, very high carrier additions are used to obtain good results (problems of waste water and exhaust air pollution). The process also has disadvantages with regard to costs and the levelling of fibres which exhibit inherent differences in affinity compared to dyeing under HT conditions. Dyeing at the boil is carried out on atmospheric winch dyeing machines, atmospheric overflow machines or jets, and jig dyeing machines.

b) Dyeing under HT conditions (130°C): polyester piece goods are mostly dyed by this method. Suitable dyeing machines include: HT winches, HT jiggers, HT beam dyeing machines, jets and overflow machines. Additions of appropriate auxiliaries for the prevention of running creases as well as the dyeing of material that has already been heat-set are recommended measures.

c) Aftertreatment: After dyeing, the dyed fabric is subjected to an aftertreatment (in some cases a reductive clear aftertreatment is necessary) to improve colour fastness properties.

Exhaust dyeing with disperse dyes proceeds through the following stages: Stage A: movement of individual dye molecules at the molecular level due to thermal influences; Stage B: dye molecules are captured in the adsorption zone of the polyester fibre surface; Stage C: transport or migration of adsorbed dye molecules into the fibre interior. Stages A and C represent the bottlenecks of the dyeing process. Dye solubility plays a decisive role here and can be improved by chemical additions and rising temperature (see Fig.). Suitable chemicals for this purpose are, e.g. carriers.

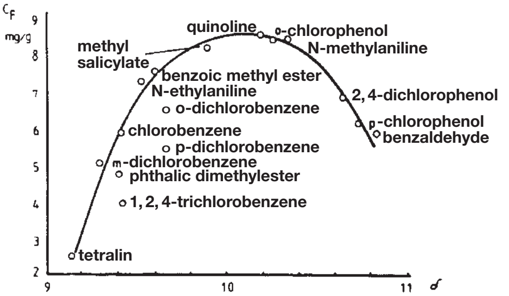

Fig: Disperse dye take-up (ordinate) relative to the solubility parameter (abscissa) of the added dye accelerator (Flath).

Disperse dye sensitivity Certain disperse dyes contain substituent groups in the molecule that are sensitive to hydrolysis. These substituents can be split off from the dye molecule by changes in pH of the dye liquor (Fig. 1). In general, marked deviations in the shade, exhaustion and fastness properties of the hydrolyzed dye in comparison with the original dye are observed.

Other disperse dyes can form metal-complex compounds with heavy metal ions, e.g. iron or copper ions, which again exhibit deviations in shade and dyeing properties. Calcium or magnesium ions can cause colour changes in the dyeings of numerous anthraquinone red dyes towards violet on drying.

Finally, changes can also occur in azo disperse dyes during dyeing due to substances with reducing properties. Under unfavourable conditions, azo disperse dyes can be broken down in the dyebath to yellow or colourless amines. Reducing agents responsible for such effects are size residues, cellulosic fibres, cysteine in wool, or certain dispersing agents (e.g. pyrocatechol groups in lignin sulphonates and sulphite-containing naphthalene sulphonic acid condensation products), see Fig. 2.

Sensitivity to pH, heavy metals, and reducing agents can seriously impair the reproducibility of HT-

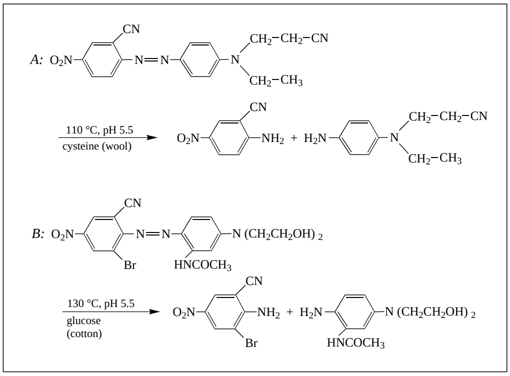

Fig. 2: Disperse dye reduction in the dyebath: the amines resulting from A and B do not dye polyester, or only dye it a weak yellowish shade.

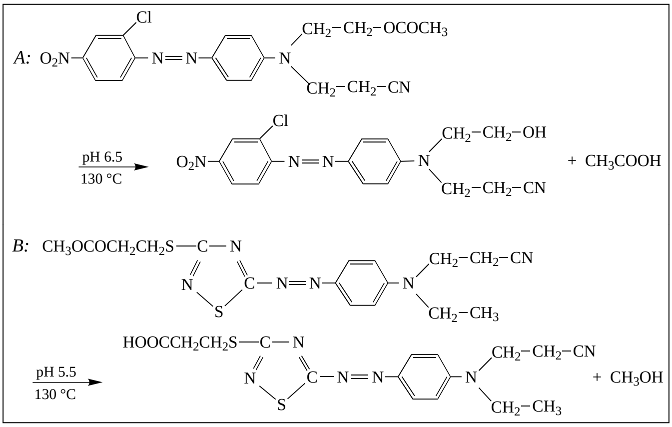

Fig. 1: Disperse dye hydrolysis in the dyebath.

B: The hydrolized dye dyes polyester only a little.

dyeings. In the optimization of HT-dyeing programs, therefore, highly sensitive disperse dyes should be avoided from the outset.

Disperse dyes in textile printing,

I. Printing on polyester: suitable thickeners include locust bean gum derivatives, guar derivatives and alginates or half-emulsions. Since a number of disperse dyes are sensitive to alkalis, the pH of the print pastes must be adjusted on the weakly acidic side by the addition of a non-volatile acid such as tartaric, citric, lactic or glycollic acid. The addition of a fixation accelerator is beneficial for the achievement of good colour yields if fixation of the prints is carried out by the thermosol or HT-steam process. In the case of half-emulsion thickeners, no addition of fixation accelerator is necessary. Print pastes are prepared by the stock paste method (strewing-in method) so that disperse dyes in powder or liquid form may be used as desired. After printing and drying, colour fixation can be achieved in 3 ways: a) by pressure steaming (20–30 min at 1,5–2,0 bar); b) by thermosol treatment (45–60 sec. at 190–200°C) or; c) by HT-steam (6–8 min at 160–180°C). Careful selection must be paid to dye selection (sublimation fastness) and thickener selection (hardening problems) when fixation is carried out by the thermosol and HT-steam methods. After fixation, the prints are first given a cold reduction clear treatment in a bath containing sodium dithionite, caustic soda and washing agent, which is repeated again at 60–70°C, followed by rinsing, neutralizing if necessary, and drying.

II. Printing on triacetate: print paste composition and choice of thickener as for polyester. However, unlike polyester printing, the print pastes must contain an addition of fixation accelerator, even in the case of half-emulsion thickeners if fixation is carried out with HT-steam.

After printing and drying, two methods can be used for colour fixation: a) by pressure steaming (20–30 min at 1,0–1,5 bar); b) by HT-steam (8 min at 180°C). After fixation, the prints are first given a cold reduction clear treatment in a bath containing sodium dithionite, caustic soda and washing agent, which is repeated again at 50–60°C, followed by rinsing, neutralizing if necessary and drying.

III. Printing on acetate: print paste composition and choice of thickener as for polyester. An addition of 50 g/kg urea can also be made to the print pastes. After printing and drying, colour fixation is achieved by steaming in the star steamer for 20–30 min at 0,2 bar, after which the prints are given a thorough cold rinse and dried.

IV. Printing on polyamide: seldom used due to inadequate colour fastness in most cases.

V. Printing on polyacrylonitrile: disperse dyes are generally only used for areas of large coverage where levelling problems may otherwise be encountered, or to obtain sharp outlines. They are also used for the production of light beige or olive shades which are difficult to obtain with good reproducibility if cationic dyes are used. Print pastes contain thickener, water, glycerol, tartaric acid and dyestuff. The prints are fixed by steaming in the star steamer for 20–30 min at 0,3–0,5 bar, after which they are rinsed, soaped or given a reduction clear treatment, rinsed and dried.

VI. Printing on polyester/cellulose blends: combinations of disperse and reactive dyes are used; the print pastes contain thickener (alginate or half-emulsion), urea, solubilizing agent, sodium bicarbonate and dyestuffs. Colour fixation is achieved either by a thermosol treatment (1 min at 200 C) or by HT-steam (8 min at 170°C), followed by afterwashing and drying.

VII. Printing on polyester/wool blends: combinations of disperse and acid or metal-complex dyes are used. The print pastes contain thickener, glycerol, water, acetic acid, carrier and dyestuffs. Colour fixation is achieved by steaming for 30 min at 1 bar, followed by thorough cold rinsing, soaping at 50–55°C, rinsing and drying.

Disperse dye solubility The solubility of disperse dyes in water is low at room temperature but there are two explanations for this in the case of azo dyes:

1. The azo group forms hydrogen bonds with water clusters (Fig.)
2. Entropy is achieved when parts of the water's iceberg structure are broken down; however, larger cluster areas can develop hydrophobic reactions with the benzene rings in the disperse dyes and dissolve them in this way. This effect is counteracted by the hydrophobic reactions between the dyes themselves (agglomeration), which can be reduced by adding urea, which is the reason why urea increases the solubility of dispersion dyes in water.

In order to understand how a → Disperse dyeing system model consisting of fibre, water and dye works in different states, with different emulsifying agents and level agents and with differing amounts of acetic acid for

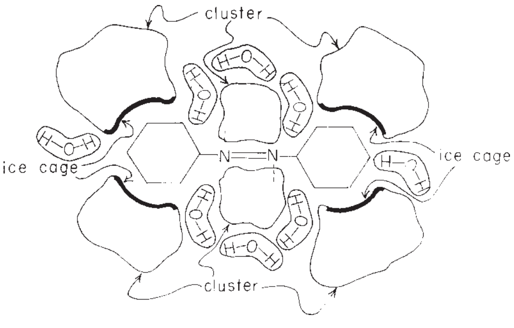

Fig.: Model representation of the solubility of dispersion dyes in water (contributed by Kimura).

adjusting the pH, it is important to provide evidence concerning the state of the disperse dye in the solution. In the dispersion phase the dye is added to the dye bath, which produces a low concentration dispersed molecule dye solution by means of a dissolving process. The stability of the crystallite is caused by adsorption of the dispersing agent, whereby the proportion of dispersed molecules is increased in the presence of anionic dispersing agents by the hydrotropic change effect. Levelling agents (usually non-ionogenic tensides) lead to increased dye solubility, which can be explained by the concept of micellar solubilisation: because of the differing solubility, dispersed molecule disperse dye is dissolved in the hydrophobic part of the micelle below the clouding temperature, whereas phase separation occurs above it. Displacement adsorption of the tensides on the crystal surface must also be taken into consideration, which usually reduces dispersion stability. Due to recrystallisation, either the larger crystallite will grow to the detriment of the smaller one, or crystal growth will occur in the oversaturated dispersed molecule master phase. Furthermore, agglomerates and aggregates occur, which can cake into a low-defect crystal.

Solubility is low, being between 2 and 100 mg/l at 130°C for pure dyes and increasing when dispersing agent is added. The dispersing agent molecules (condensation products or lignine sulphonates) are deposited on the dye particles because of π electron reactions, dispersion force and hydrophobic reactions. Anionic dispersing agents create a negative potential which leads to mutual repulsion of particles. Solvate coatings may be regarded as an effective stabilisation factor for non-ionogenic dispersing agents. The following mechanisms may become effective:

a) Increased osmotic pressure because of the local concentration increase occurring because of the convergence of two particles;
b) Volume limitation, i.e. the number of sorbed dispersing agent chain conformations is restricted because of reciprocal penetration of the solvate coatings.

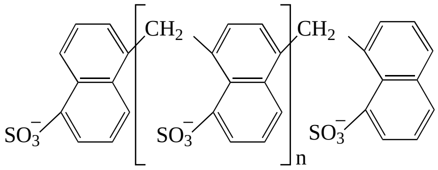
The dispersing agent molecules are approximately the same size as the dye molecules. If we assume that deposition does not just take place on the dye aggregates but (as shown by the increased solubility) also on the individual molecules, we can imagine how the intermolecular reactions work: the aromatic rings of dye and dispersing agent arrange themselves plane-parallel on top of each other, meaning that there is space for a dispersing agent molecule above and below the dye molecule, which is held by the strong π electron reactions and polar forces. It is understandable that dispersing agent molecules are displaced during sorption to the polymer, since the dispersing agent is more soluble in water.

Disperse phase The discontinuous phase of a → Dispersion.

Dispersing agents are products which promote the formation of a → Dispersion (→ Dispersants). Textile auxiliaries used as dispersing agents serve the purpose of bringing insoluble or virtually insoluble dyes into a form which makes them readily dispersible in water and keeping the dispersion stable throughout the entire application process. Dye dispersions can therefore be considered as examples of colloidal dispersions.

Typical dispersing agents include:

1. Lignin sulphonates (can have a reducing action).
2. Modified caseins (readily biodegradable, but expensive).
3. Formaldehyde-naphthalene sulphonic acid condensates (cresol is often co-condensed in such products which leads to the presence of phenol in waste waters).



Dispersing agents traditionally contain proportions of reducing agents as constituents which can have an adverse effect on disperse dyes that are sensitive to reduction.

Dispersing power The efficacy of a product's capacity to form a → dispersion.

Dispersion,

I. (suspension). A two-phase system where one phase consists of finely divided particles (often in the colloidal size range) distributed throughout a bulk substance, the particles being the → Disperse phase (internal phase) and the bulk substance the continuous phase (external phase or → Dispersion medium). In general, the finely divided distribution of a substance (e.g. dye) in an aqueous medium. → Dispersion, degree of.

II. Collective term for the variability characteristics of a feature. Measures are e.g. → Variance, → Standard deviation and range.

Dispersion colloids → Colloids.

Dispersion, degree of → Dispersivity.

Dispersion forces → Secondary valency forces.

Dispersion medium, continuous → Phase of a → Dispersion.

Dispersions for coating Considerable demands are made of the stability of the plastic dispersions used for coating the backs of carpets, which essentially relate to shear and storage stability (Fig. 1). A considerable amount of shearing force occurs when filler materials are mixed in, and also occurs beneath the doctor

Dispersions for coating

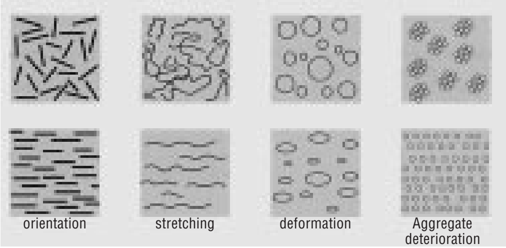


Fig. 1: Structural relationships in a dispersion in a quiescent state (top) and under shearing stress (bottom).

blade. The storage stability of plastic dispersions depends on the thickness of the particles. Sedimentation and creaming can occur after a long standing period. This does not indicate that a dispersion is unstable, provided that the particles can be redispersed. Electrolyte additives and lowering the pH considerably reduce the stability of the dispersion. Behaviour in the presence of fillers and pigments depends on their surface structure. A plastic dispersion can coagulate slowly or immediately by adsorbing the emulsifying agent on the surface of the fillers. Emulsifying agent migration ceases to occur if enough emulsifying agent is present. Dispersions often tend to coagulate when dry pigments or fillers are added. Help can be obtained by using appropriate polyphospates, ionogenic or non-ionogenic wetting agents or protective colloids. The pigment compatibility of plastics dispersions is improved by polymerising monomers with hydrophilic groups.

Perfect tuft anchorage is also dependent on the film-forming characteristics of the polymer dispersions when coating the backs of carpets. When dispersions are being processed the film formation temperature must be maintained, otherwise no film will form but a brittle, inconsistent layer. Too much humidity also prevents film formation when drying. Air bubbles, which can occur when the dispersions are applied, are undesirable. If they cannot escape during the drying phase they either cause large cavities in the surface or remain in the film as bubbles. The defective areas reduce both the mechanical strength and the extensibility of the material. Consistent pigment distribution is extremely important when processing dispersions, since it determines the evenness of the film coating and therefore affects the strength thereof.

The adhesive strength of the films differs on the various substrates. It can be improved (e.g. on leather, wood, textiles, paper) by using hydrophilic groups (–COOH; –C≡N; –COH; –CONH$_2$) incorporated by polymerization.

Surface tension is low in most dispersions because of the presence of emulsifying agent. However, if there are problems with the wetting capability of a substrate, the addition of more surface-active substances will reduce the surface tension even more. Unfortunately, dispersions with a high proportion of wetting agent tend to foam. In primary coating this would result in too little base coating being applied during slop padding, which means that the film would be extremely defective and the carpet yarn would not be correctly bedded in because of the increased viscosity.

Natural latex (Fig. 2) from the hevea rubber tree is a colloid system that has water as the liquid phase, which has organic and inorganic substances dissolved in it. The solid phase is rubber with a particle size of 0.5 µm. The rubber absorbs the anionic substances on the surface, which are in equal proportion to the positively loaded ions and represent an electrically neutral colloid system to the outside. The iso-electric range of this system lies at a pH of 4.8 to 5.1. For this reason, natural latex is preserved using ammonia in order to prevent coagulation. Protein in the latex acts as a natural stabiliser. Natural latex is concentrated by means of condensation, centrifuging, creaming or electrodecantation. During purification rubber approaches the element composition of $(C_5H_8)_n$, which represents cis-1.4 polyisoprene. Natural rubber has many applications.

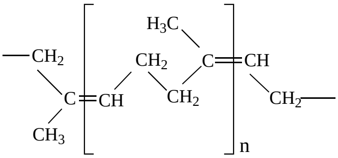

Fig. 2: Natural latex.

Most synthetic latices (Figs. 3–5) are manufactured using emulsion polymerisation. Their particle size is relatively constant for the individual products. Depending on the type, it varies between 0.03 and 2.0 µm. The application area of synthetic latices cannot be called universal. The product is often one which has been designed for a special purpose.

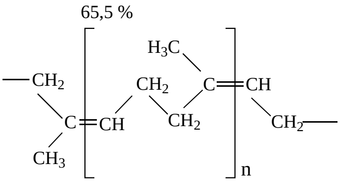

Fig. 3: Polyisoprene latex with fatty acid emulsifying agent. Solid content 65.5%. Application: oil-resistant submersible articles.

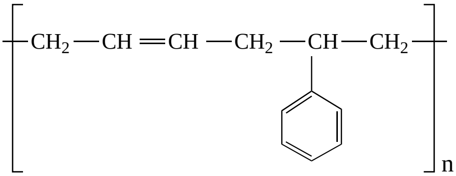

Fig. 4: Polybutadene styrol latex with fatty acid emulsifying agent, solid content 66–68%. Application: carpet foam application.

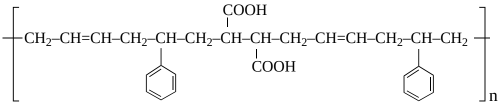

Fig. 5: Polybutadene styrol latex with fatty acid emulsifying agent, solid content 66–68%. Application: carpet foam application.

Dispersions in finishing The use of polymer "liquid plastics" offers considerable advantages. The production process using monomer building blocks leads to environmentally friendly products for which textile applications are found. Application areas are to be found in all areas of the textiles, non-wovens, carpet, wallpaper and textile glass fibre industries. Technical textiles in particular have attained growing importance from the point of view of textile finishing. These are woven materials, pile textiles, knit fabrics, non-woven fabrics, textile laminates, the use of which extends beyond the classic application areas of clothing, household, linen, furnishing fabrics, upholstery fabrics, carpets. The fundamental principle of the application of dispersions is: a) Apply dispersions to substrate (by dipping, kiss rolling, spraying, foaming, doctor coating, coating/spreading, bonding, laminating, printing; b) Drying/condensing. Dispersions can be used with other dispersions (latices), resins, pigment dyes, filling substances, water repellents, antistatic agents, foaming agents, thickeners, stabilisers, defoaming agents etc.

Textile use of dispersions:

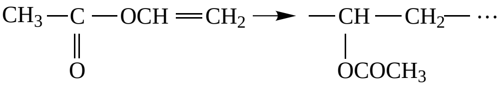
- Clothing: a) finishing of woven fabrics and knit fabrics, corduroy, velvet, Wildman plush, sports shoe uppers; b) modification of handle, proofing; as additive in resin finishing; c) non-woven: quilting in anoraks, coats, interlining materials, shoe inners, synthetic leather for clothing; d) coated textiles, rain wear.
- Hygiene, medicine, foodstuffs (non-wovens): quilting, tampons, nappies, incontinence pads, sanitary towels, milk filters, surgical products.
- Household, leisure, sport: a) modification of handle, proofing, down-proof finish; b) bed linen, table linen, curtains; c) non-wovens: cleaning cloths, table cloths, quilting in bedclothes; d) textile floor coverings: woven and tufted carpets (backings), needlefelts, sports mats, tennis mats, outdoor mattings; adhesive bonded structures; e) coated textiles: roller blinds, vertical blinds, table cloths, tent fabrics, sails, upholstery cover fabrics, flocked materials, textile wall coverings.
- Cars, aviation, railway: a) moulded textiles: carpets, needlefelts, bonded non-woven fabric waste; b) coated textiles: seat covers.
- Technical textiles: a) slick finish: glass fibre facing; b) non-wovens: non-woven filter fabrics, roof liners (polyester spun-bonded, glass fibres), soundproofing mats, non-woven coverings for cracked walls, polyester non-wovens, electrical insulations; c) finishing: glass fibre scrim interlinings, fishing nets, sailcloth; d) coated textiles: tarpaulins, canvas; e) laminates: non-woven/films etc.; f) geo-textiles.

Special finishes, such as e.g. antistatic, oil repellent, water repellent, gloss, play an important role in technical textiles too. They are also included in coloration (printing, dyeing). Dyeing auxiliaries are thus used. Frequently, an external textile finish and a textile handle are required. Since the method for producing technical textiles depends on special additives such as foamers, de-foamers, catalysts, stabilisers (additives), corresponding processing expertise is necessary. The quality control of technical textiles too is predominantly oriented on textile test methods.

For the sake of clarity, one can classify textile dispersions not only according to application areas, but one must also do so according to chemical composition and according to physical features or performance properties. Hoechst plastics dispersions, for example, are classified by chemical composition and glass transition temperature. At the same time, associated with this is an empirical classification of the dispersions according to their hydrophobic or hydrophilic actions. For orientation purposes evaluation is carried out after application and drying/condensation of the dispersions on viscose fibre non-woven fabric, with the capillary rise of water and the spread of a drop of water serving as a measure. A low capillary rise and a drop of water remaining for over 1 minute results in classification as "hydrophobic", whilst rapid wetting results in classification as "hydrophilic".

The glass transition temperature (T_G) is the temperature of the transition range of a polymer from hard glass state into the elastic state. A flexible film of a polymer dispersion becomes hard at the glass transition temperature, and breaks. T_G relates to a polymer or to the film of a dispersion, and not to the dispersion itself, which is a system of polymer, water and emulsifier/protective colloid; for example, films of pure polyvinyl acetate dispersions lie at T_G = 29°C/30°C; such a film breaks at room temperature; very soft films lie at T_G = < –0°C; in this range also are non-woven bonding agents for the impregnation process; contact adhesive laminating bonding agents lie at –30°C. In comparison with that: polyvinyl alcohol approx. 70°C, standard polyesters approx. 80°C, without fracture being observed in the stretched filament form. T_G is lowered by plasticizers; in the case of polyvinyl acetate from 29°C to –3°C with approx. 25% dibutyl phthalate, and to –21°C with 50%, in both cases related to the polyvinyl acetate content of the dispersion. Also through the co-polymerisation of vinyl acetate with maleic acid di-n-butyl ester or with butyl acrylate, dispersions are produced which form films with lower glass transition temperatures than those of the base-monomer vinyl acetate.

Textile dispersions are produced in water through polymerisation of monomers, polymerisable chemical compounds, such as e.g. vinyl acetate.



$$CH_3-\underset{\underset{O}{\|}}{C}-OCH=CH_2 \longrightarrow -\underset{\underset{OCOCH_3}{|}}{CH}-CH_2-\cdots$$

Without additions of emulsifiers or protective colloids, most monomers would dissolve in water only with difficulty. A polymerisation process can, however, take place; the polymer would be omitted and no viable dispersion would be produced. By adding selected emulsifiers or protective colloids, a viable dispersion can be produced. Thus the polymerisable substance is mixed by stirring with emulsifiers and/or protective colloids to form an emulsion, is dispersed and polymerised in emulsified form to fine solid particles or to aqueous solution. The type and amount of emulsifiers and protective colloids and the combination of various polymerisable substances mean that there is a wide variety of dispersions with different performance. Fine dispersion of the polymer particles, and the resultant high light scatter impart to the dispersion a milky-white appearance. Despite the emulsifiers and protective colloids, a dispersion remains an unstable structure. There is limited thermal stability anyway. Dispersions are not stable above 75°C. They coagulate by that point at the latest. Many dispersions are not compatible with salts, acids or lyes. Paraffin-based cationic water repellents often cause precipitation; albeit not in the case of certain non-ionic dispersions containing protective colloids. But the non-ionic character does not in every case mean stability to cationic products. Other stability factors such as emulsifier content and combination of emulsifiers play a part. Suitable protective colloids in textile dispersions include e.g. polyvinyl alcohol or cellulose ether.

An index less suitable for the systematic characterisation of polymer dispersions for the textile sector is the minimum film formation temperature (MFT). At a

Dispersion/ polymer of	Ionic character	Degree of dispersion	Film at room temperature	Glass transition temperature (T_G) °C	Min. film formation temperature, °C

* A film, also clear and transparent at room temperature, is produced after temperature treatment above 70°C.

Tab. 1: Characteristics of dispersions.
(Particle size: fine = 0.07–0.5 μm; medium = 0.07–5 μm; coarse = 0.5–5 μm, mostly 1–3 μm) (source: Fischer).

particular temperature, a polymer dispersion dries to a transparent or translucent continuous film. Below this temperature, a white membrane forms (white point). If for example a white point temperature of approx. 15°C is quoted for a dispersion, then this dispersion, if spread and allowed to dry on a glass plate at ≥ 16°C, will form a clear, continuous film. If drying on occurs at ≤ 15°C, on the other hand, a white inhomogeneous membrane forms. The softer the film of a dispersion is, the lower the white point temperature or the MFT. Through additions of plasticizers, solvents, as well as acetic acid etc., the MFT is lowered, thus e.g. in the case of a vinyl acetate/homopolymer dispersion from +15°C via 23% glycol acid butyl ester to +3°C. Dispersions containing protective colloids are medium or coarsely disperse, and those produced with tensides are mostly finely disperse. Particle size and particle distribution critically determine, together with the emulsifier system, the performance characteristics of a dispersion, such as e.g. the viscosity. Coarsely disperse dispersions sediment when diluted liquors are left to stand (source: Fischer).

In terms of their properties (Tab. 1), high-polymers are characterised by their primary components (monomers) and the type and course of the polyreactions. One characteristic is the degree of polymerisation, or the average degree of polymerisation (DP). In the case of high-polymers, the mean molecular weight is quoted as a rule for the sake of better comparability; generally it lies at 20 000–200 000. Also important for the properties of the high-polymers are reactivity and particle size, insofar as dispersions are involved. In the case of reactivity, as a rule one is dealing with one or more of the 5 reactive groups shown in Fig. 1.

These reactive groups enable high-polymers to react with the fibre, and/or to react on the fibre (with itself or with other compounds). The particle size is naturally only important in the case of dispersions (whether they are emulsions or suspensions) although, influenced by drying and other thermal processes, it is to a large extent responsible for the distribution of the high-polymer on the fibre surface. This distribution has a strong influence on the physical or physico-chemical binding forces, and thus on the permanence of the bond. The physical influence on the permanence is, as a rule, even more important than the influence which derives from the usually somewhat limited chemical reactivity.

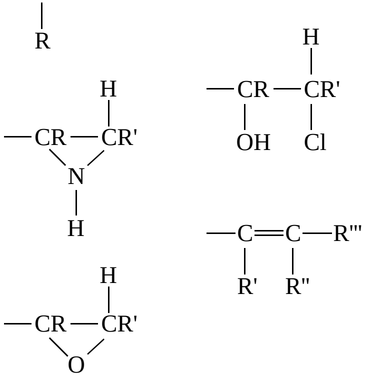

Fig. 1: Reactive groups in the case of additives.

The following polymers are important in resin finishing (source: Schlüter):

I. Polyacrylates: The versatility of acrylate chemistry is mainly provided by a broad spectrum of monomer primary products. Beyond that, the technical variation possibilities in the polymerisation have a decisive influence on the characteristics of high-polymers, their specific attributes in processing, and their quality on the textile goods. Film hardness or film softness show a clear dependence on the glass transition point of the respective homopolymer. The hydrophobic or hydrophilic character of the selected monomers is reflected, in equivalent amounts, in the high-polymer.

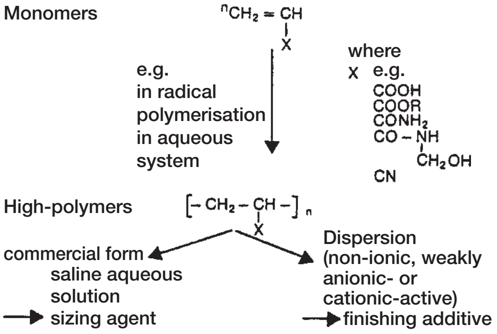

Fig. 2: Composition of polyacrylates.

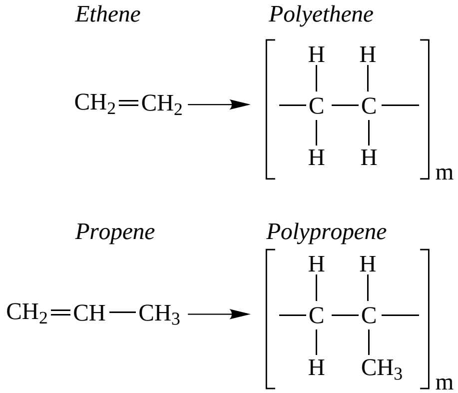
Fig. 2 shows the schematic sequence of the polymerisation process which, using monomers containing double bonds, produces polyacrylates. Here, the selection of monomers and control of the reaction are of vital importance to the “make-up” of the polyacrylate. Saline aqueous solution is chosen, for example, for use as sizing agent. When used as a resin finishing additive, for processing reasons (higher concentration, lower viscosity), dispersions are usually preferred. Of course dispersions can display sensitivity to shearing forces (hardness of the padding rollers, goods running speed). However, there are also auxiliaries which ensure perfect processing even under extreme operational conditions.

II. Polyolefins:

Polyolefins derived from (α) olefin

$C_n H_{2n} \longrightarrow [C_n H_{2n}]_m$



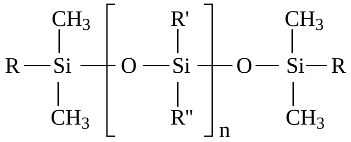
Polyolefins are obtained through the polymerisation of unsaturated hydrocarbons. To date, it has not yet been possible to achieve, with technically assured reproducibility, the manufacture of polypropene dispersions (neither primary nor secondary dispersions) with such qualities as would be suitable for the requirements of the textile industry. In the case of polyethene too, a distinction is made between primary and secondary dispersions (Tab. 2). Polyethene primary dispersions occur at high temperatures (> 200°C) and under high pressure (300 bar), in that ethene is caused to react in an aqueous solution containing catalysts and emulsifiers. The polymer results directly in emulsion form. In the case of polyethene secondary dispersions, one starts from a block polymer which has been rendered into a wax form through oxidation and hydration. The melted wax is stirred into a concentrated emulsifier solution, through which the secondary dispersion occurs.

	Primary disp.	Secondary dispersions	
Solids content [%]	40	35	25 - 40
Emulsifier content rel. to solids in %	7,5	25	25
Softening range [° C]	109 - 112	130 - 135	< 90
Mean molar weight	30 000	100 - 150 000	3500 - 4000
Preferred application area	Standard additive; sewability, bulk, good permanence	Speciality product for highest standards of sewability, handle, permanence	Economical products for good sewability and smoothness

Tab. 2: Properties of primary and secondary dispersions of polyethene.

An improvement in the sewing characteristics is apparent in all fibre types. Besides that, material containing cellulose fibre is noted as having fibre-protecting effects, e.g. improvement in the tearing resistance and abrasion resistance, shown to best advantage in easy-care polyethene products.

III. Polysiloxanes: For some considerable time now, silicon dispersions have been enjoying a special importance in the field of high-grade water-repellent finish. With siloxane chemistry, quite different opportunities are opening up (Fig. 3). It has revitalized and updated resin finishing of all types of woven fabrics and knit fabrics.



R = $-CH_3$, $-OH$

R' = $-CH_3$, $-H$, $-OH$

R'' = $-NH_2$, $-CH_3$, $-H$, $-OH$

Fig. 3: Diversity of polysiloxane structures.

The versatility is characterised by the diversity of the available options. Products with ethoxylated or oxpropylated substituents, which are water soluble, are suggested current options. Polysiloxanes have many functions:

- soft, lively handle,
- positive influence on the abrasion and tearing resistance,
- improvement in the crease recovery in woven fabrics,
- improvement in the bursting strength in knits,
- improvement in sewing properties,
- favourable behaviour in relation to dyeing and printing.

Polysiloxane dispersions are not without problems with respect to shear stability; however, this can be improved by technological measures.

IV. Polyurethanes: The well-known classic primary monomers are cross-linked in a polyaddition reaction. One thus produces polyether urethanes. If one first converts the diols with dicarboxylic acids (e.g. adipic acid), and allows these polyesters to react with isocyanates, then one produces polyester urethanes. There is

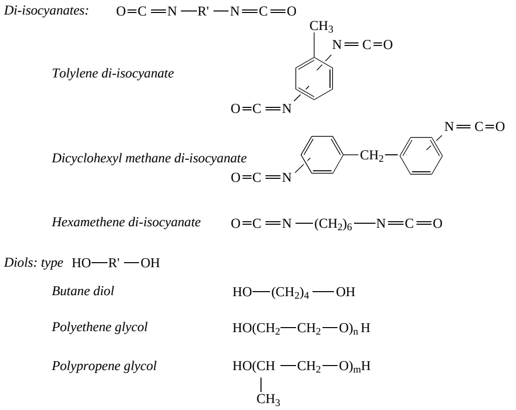


Fig. 4: Monomers for polyurethane formation.

a great variety of chemical variation options (Fig. 5): aromatic isocyanates yield cheap but light-sensitive products. Hydroaromatic or aliphatic isocyanates are more expensive, but provide a good and permanent whiteness. In simple reaction, diols yield soft, sometimes slightly tacky products. Polyalcohols lead, through spatial cross-linking, to permanent, usually somewhat harder films. Polyester types are susceptible to microbial attack, whilst polyether types are resistant to microbial attack. In resin finishing, the textile functions of polyurethanes are similar to those of the polyacrylates.

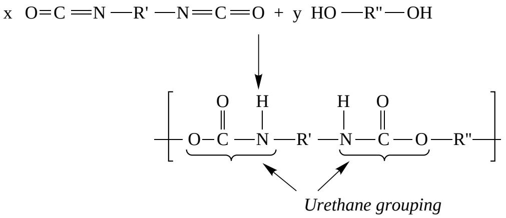

Fig. 5: Standard reaction of polyurethane formation.

Selected areas of process technology with high-polymers also include pigment dyeing, i.e. simultaneous pigment dyeing and proofing (Fig. 6). One advantage is not just the clear savings in terms of cost, but also the low effluent pollution. However, the process has limitations with regard to the depth of colour. The fastnesses depend on the quality of the high-polymer dye bonding agent and the ratio of pigment dye, bonding agent and cross-linking agent (n-methylol compound).

Dispersion stability of disperse dyes Generally applicable to the behaviour of dye dispersions in dyeing (of polyester) under dyeing conditions. Absolute dispersion stability in aqueous systems does not exist and, with regard to the dyeing mechanism, is not even desirable. However, in cases where dyeing problems arise (particularly in rapid dyeing processes and circulating liquor machines) due to filtering out, dye stains on the textile material or precipitations in dyeing vessels, the cause is often attributed to poor or inadequate

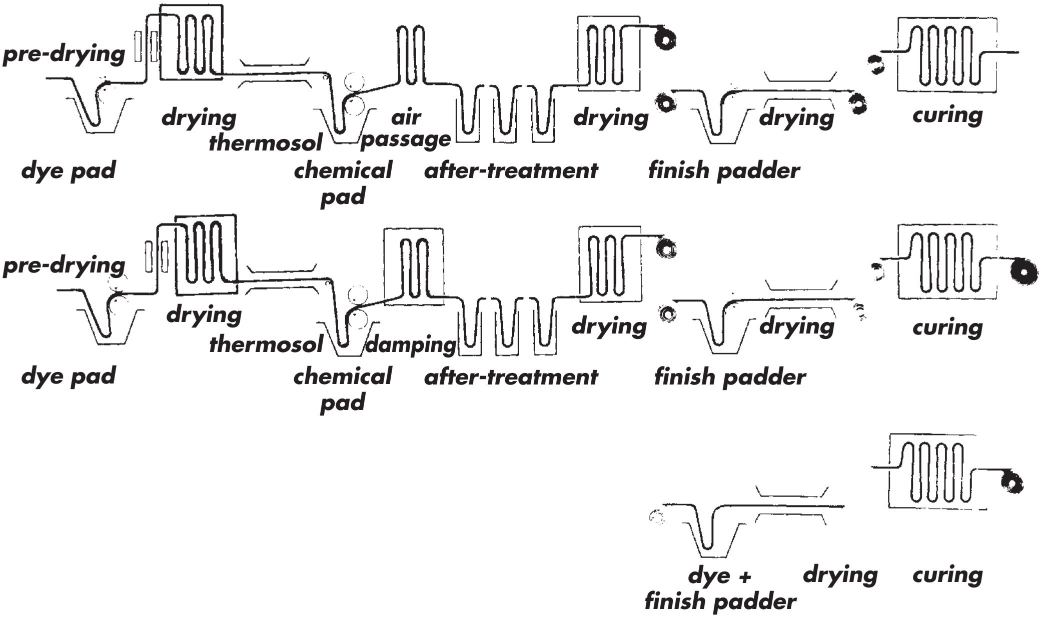

Fig. 6: Variants of simultaneous pigment dyeing and proofing.

dispersion stability. According to Ostwald's rule, dispersions are subject to continuous changes especially the tendency to change into coarser and more stable dispersions.

Dispersion instability can be due to a variety of causes: a) dyeing conditions (e.g. dispersing problems, effects of temperature); b) dyeing machinery (e.g. shear forces in pumps or jets, dye filtration problems in textile materials, liquor overheating in heat exchangers); c) liquor-dependent factors (e.g. dye concentration, non-removable preparations, carriers, levelling agents, electrolyte additions, pH variations).

Important criteria for dispersion stability: the temperature range from 60–80°C is often a critical one for disperse dyes. With additions of non-ionic products this temperature range should be passed through as quickly as possible, or the dye only added at temperatures > 80°C. Changes in the liquor flow rate can be directly related to dye levelling. For this reason, great attention should be paid to the liquor flow rate indicator/recorder during dyeing. In the case of an anomalous decrease in flow rate, an efficient levelling agent and extended final dyeing time is often beneficial.

Dispersive interaction → Adhesion.

Dispersivity (lat.: dispersio = spread), degree of dispersion of a (colloidal) substance in an aqueous solution. Dispersed phase: the dissolved or distributed substance (also known as adispersoid). Dispersion medium (also known as a dispersing agent or dispersant): the dispersant or solvent substance. Disperse system: combination of a dispersion medium and a disperse phase. The degree of dispersion can fluctuate considerably, depending on the particle size of the dispersed substance (see Table). The respective solution status is also evaluated according to the degree of dispersion: e.g. molecular solution, colloidal solution or macrodispersions (emulsions, suspensions).

In the individual disperse systems there are no strict particle size boundaries (grain or droplet sizes), but a continuous transition from macrodispersion to a colloidal solution to a dispersed molecular (crystalline) solution. It is similar to the size distribution of starch grains between approx. 0.2 and 10 nm, and differences of between 0.02 and 0.6 nm are not unusual, even in the submicron pigments in vat dyes. However, the maximum and minimum values can be shifted in one direction or the other using suitable means:

macrodispersion colloidal dispersion molecular dispersion

————> (Dispersion) ————> (Dissolution)
(Coagulation) <———— (Condensation) <————-

	→ Disperse systems Increase in degree of dispersal →			
	Macrodispersal		Colloidal dispersal	Highly dispersed
	Macroscopically disperse	Microscopically disperse	(fine dispersal)	(molecular dispersion)
Particle size µm	> 100	100–0.5	1–0.001	> 0.001
Number of atoms per particle	More than a billion		1000–100 000	1–1000
External signs	Mechanical division		Colloids	Molecularly dispersed (cristalloidal) solution
Particle nature	Most individual particles dissimilar			Molecules and ions have the same structure and same size in the same substances
Visibility	Some macroscopic, otherwise microscopic	Light microscope	Electron microscope	Hardly or not at all in the electron microscope
Filtering capability	Through filter paper (average pore diameter $5 \cdot 10^{-4}$ cm)		Only through parchment and organic membranes (these and ultrafilters with Ø-pore diameters of 10^{-5} to 10^{-6} cm)	Nor through parchment and organic membranes (e.g. sodium chloride solution)
Dialysis capability	no	no	no	diffuse and dialyse
Other means of detection			→ Increasing Brownian (colloidal) movement →	

Tab.: Distribution principle of dispersed systems according to average size of dispersed particles.

Important factors affecting the degree of dispersion are: particle size, molecule size, chemical constitution, concentration ratio, thermal influence, pH influence, influence of the addition of foreign materials (electrolyte, chemical reactions, physical processes etc.).

Displacement resist Displacement effect. A ground dye initially applied to a textile substrate is removed (displaced) by subsequent local application of chemicals, thickener and/or dye (or their combinations).

Display (VDU, monitor screen). Used in EDP and e.g. machine control/monitoring systems for the visual representation of information in the form of numbers, letters, symbols or other graphic elements (see Fig.).

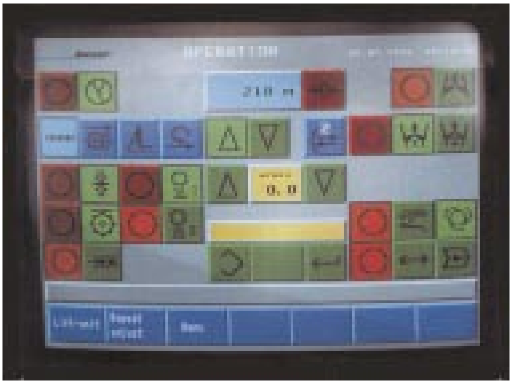

Fig.: Monitor screen display with direct touch basic control panels (masks) on a Buser rotary screen printing machine.

Disposable dye tubes (perforated). These are subdivided into rigid, axial-flexible and radial-flexible dye tubes. Radial-flexible disposable dye tubes are used in package dyeing for high shrinkage yarns (e.g. polyacrylonitrile, regenerated cellulose, polyester/cellulose blends, etc.). During dyeing, the tube remains soft and gives the yarn more room to shrink. In this way, hardness of the package centre (as a cause of unlevel dyeing and fibre damage on rigid plastic tubes) is avoided. When using soft paper tubes, the counter pressure of an interposed spring sleeve provides the necessary stability; their corresponding lengths must therefore match each other exactly. After drying, the spring sleeve is ejected, the yarn wound off, and the paper tube discarded.

In the dyeing of press-packed yarn packages, axial-flexible plastic disposable dye tubes are irreversibly deformed axially by up to 40% (see Fig.) in order to prevent leakages between the packages (without spacers) and achieve a uniform package density in the package column (almost like dyeing a yarn beam).

Fig.: Eisbär C disposable core before pressing (right) and after dyeing of the compressed core (left).

From the ecological standpoint the use of all types of disposable dye tubes raises the question of recycling. In the case of plastic tubes a possible solution would be to collect the deformed tubes after use, grind them into granulate form, and convert them into dye tubes again (injection moulding).

Disposable laundry Typical → Disposable textiles made of paper nonwovens. Used in hospitals (e.g. diapers, pads, drawsheets, bed linen). The use of such materials is questionable because of relatively high costs and problematic disposal/destruction.

Disposable textiles Articles of a more or less textile-like character intended for once-only or short-life usage such as → Disposable laundry (e.g. bed linen, table linen, hand towels, underwear, diapers); disposable garments (e.g. coloured or printed holiday and party garments); disposable workwear (e.g. hospital gowns, painters' overalls); disposable sanitary goods, etc. Short-term serviceability ranges from "disposal after use" to "multiwash/dryclean" goods. Disposables are made from tailored/shaped pieces (sewn, glued) of reinforced nonwovens (cellulose, textile fibres or fibrids). Binders used to achieve the necessary resistance to drycleaning, washing and wet treatments include, e.g. cellulose derivatives, plastics, reactant resins, etc. The competitiveness of such materials is subject to problems of price structure and especially environmental pollution (also procurement, pay-back and transport in the case of hospitals).

Dissimilation (Lat.: *dissimilis* = not alike). The breakdown and consumption of nutrients to provide energy and simple compounds for intermediary metabolism. It is the opposite of assimilation. Also a term used in waste water technology to describe the conversion of materials whereby energy is provided by the oxidation of organic compounds for the formation of new organic matter.

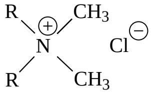
Dissociation (ionization). The electrolytic breakdown of acids, bases and salts on solution in water. This process involves the formation of ions, i.e. electrically charged particles: anions (–) and cations (+) from electrically neutral molecules. In practice, therefore, acidic reaction is due to electropositively charged cations (H^+ ions) and alkaline reaction is due to electronegatively charged anions (OH^- ions).

Dissociation, degree of Numerical expression for the state of dissociation (see Table). It corresponds to the respective (actual) strength of reaction (e.g. of acids, bases and salts). The degree of dissociation is of great practical importance since it is a term which denotes the strength and not the content of e.g. an acid. The degree of dissociation can be used to determine the equilibrium constant for dissociation, an important factor in ascertaining the extent of a chemical process.

hydrochloric acid	90 %	strong acids
nitric acid	90 %	
sulphuric acid	60 %	
oxalic acid	31 %	medium strength acids
phosphoric acid	12 %	
formic acid	5 %	
acetic acid	1,3 %	weak acids
carbonic acid	0,12 %	
boric acid	0,007 %	
salicylic acid, benzoic acid		

Tab.: Comparative examples of 0.1n acids with identical acid content at 18 °C (degree of association as a %).

Distearyldimethylammonium chloride (DSDMAC), $((C_{18}H_{17})_2(CH_3)_2N)Cl^-$; laundry softener,



R = (hydr.) stearic alkyl

Adsorption properties: better for natural fibres (cotton, wool) than synthetic fibres. Adsorption on synthetic fibres is increased in hard water. Uniform exhaustion is achieved in the neutral to mildly acidic range at an average liquor temperature of 30–40°C over at least 10 min. The optimum softening effect is obtained with 1–1,5 g/kg of material. The product is manufactured from fatty acids or fatty alcohols. As a classical laundry softener (paste form containing 75% active substance) it is used in a concentrated mixture with imidazolinium compounds or in combination with selected emulsifiers.

Distillation, comprising the constituent processes of evaporation and condensation. The term fractional distillation is applied to the separation of liquid mixtures (fractions) on the basis of their different boiling points. Distillation as a process for the separation of substances is classified according to the delivery of the liquid mixture. Thus distinction is made between distillation carried out intermittently and continuous distillation. In the first case the mixture to be separated is collected and then evaporated as a whole. In the second case the liquid mixture is fed continuously in a controlled flow. The processes are further classified according to the flow pattern of the distillation liquid. If there is only one phase of motion, i.e. the vapour phase, it is known as simple distillation. If, on the other hand, part of the condensed vapour (the return flow) moves in the opposite direction to the rising vapour, this is known as counter-flow distillation or fractionation.

The separation procedure is based on Raoult's Law which when derived leads to the following essential basic value:

$$\frac{y}{1-y} = \alpha \frac{x}{1-x} \quad \text{with} \quad \frac{p_a}{p_B} = \alpha$$

α = ratio of vapour pressure of the pure constituents,
x = mol fraction of the liquid,
y = mol fraction of the vapour.

x and y apply to the more volatile constituents. α is designated relative volatility and where the Pictet-Trouton rule applies, i.e. ideal behaviour, may also be calculated from the absolute boiling point. The above relationship shows that separation by distillation only occurs when $\alpha > 1$. Only in this case may a difference in the composition of vapour phase and liquid be achieved. The concentration of the more volatile constituents of the vapour on the other hand increases as α increases, i.e. the greater the difference between the vapour pressure of the pure constituents. The equation only represents a single evaporation, however. If the difference in the volatility is insufficient, the process must be repeated, or fractionation selected as the method to be used.

Representation of the phase equilibrium: three diagrams are significant for the graphic illustration of the phase equilibrium between vapour and liquid: the diagrams for pressure, temperature (= boiling point diagram) and composition (= state of equilibrium diagram).

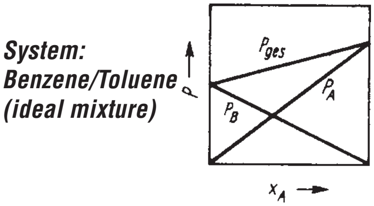


Fig. 1: Diagram of equilibrium in two-component mixtures. Dependency of pressure p on the composition of the system.

The pressure diagram (Fig. 1) shows the partial pressures p_1, p_2 and the total pressure dependent on the composition of the liquid (x_1 and x_2) and the vapour. Fig. 1 is intended to exemplify this. A characteristic feature of evaporation is that the two-phase region is exceeded (an increase in pressure would conversely lead to condensation). On the basis of Raoult's Law under isothermal conditions, linear curves are obtained when plotting p_1 against x_1 and p_2 against x_2. Further more, according to Dalton, the total pressure p is obtained from the sum of the partial pressures.

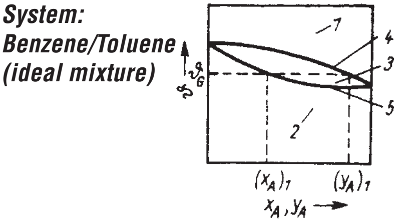

Fig. 2: Diagram of equilibrium. Dependency of boiling point on the composition of the system.
1 = vapour; 2 = liquid; 3 = saturated steam; 4 = dew point curve; 5 = boiling point curve.

In the temperature diagram the boiling point is plotted against the composition of the system under constant pressure (Fig. 2). This type of representation is important, as in practice constant pressure is generally employed. Two curves are obtained from the T-x-diagram, the boiling point curve and the dew point curve. The boiling point curve connects the temperature values at which the first liquid particles evaporate or starting from the vapour condition, the last vapour particles condense. Below this curve there is only liquid, above the dew point curve there is only vapour. In the boiling point region liquid and vapour exist in equilibrium. This area is known as the saturated steam region.

The composition diagram which represents the equilibrium curves shows the composition of the vapour phase dependent on the liquid under constant pressure conditions. The more volatile constituents of the vapour phase are plotted against the proportion of more volatile constituents of the liquid phase. The arc of the resultant curve is sharper, as the relative volatility increases (Fig. 3).

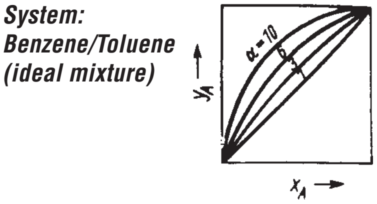

Fig. 3: Diagram of equilibrium in two-component mixes. Dependency of mole fraction of the more volatile constituent of the vapour y_A on the mole fraction of the more volatile constituent of the liquid x_A.

Types of mixture systems: mixtures exhibit ideal behaviour if the individual constituents in any proportion are soluble in one another and the interaction forces between different molecules are equal to those between ones of the same kind. Raoult's Law applies to ideal mixes, and in accordance with this law there is no heat of mixing. If a mix is characterized by real behaviour, the interactions therein are not equal, as there are deviations from Raoult's Law. These deviations may be of a positive kind. A further special case is represented by substances which have miscibility gaps. Azeotropic behaviour is distinguished by vaporization curves showing either a maximum or a minimum (the opposite phenomenon applies to their boiling behaviour). This is explained by the fact that above a certain temperature or a certain pressure, vapour and liquid have the same composition. The heat of mixing at the point where the total pressure reaches a maximum or minimum is equal to zero.

$$\frac{dp_{tot}}{dx} = 0$$

p_{tot} = total pressure

Azeotropic mixes cannot be separated by simple distillation or fractionation. It is therefore necessary to control the point of inflection in order to permit mixture reduction down to the point of disappearance. For this reason azeotropes may only be separated by means of a specific type of distillation, such as two-stage fractionation, heteroazeotropic fractionation, or fractionation with azeotrope converters such as azeotropic and extractive distillation. In the case of a positive azeotrope there are stronger interactions within the individual constituents than between the different constituents. In contrast to a fictive ideal solution, a non-linear vapour pressure curve is observed. The vapour pressure curve is at a maximum, the boiling point curve at a minmum. This phenomenon is the most common. It arises firstly if a liquid liable to association and forming a dipole is mixed with a liquid which destroys this association; secondly in the case of hydrocarbons with similar boiling points. In the case of negative azeotropes the interactions in the pure constituents are less than those between the different constituents. As against an assumed ideal solution this leads to a minimum in the vapour pressure curve and a maximum in the boiling point curve. This type is rarer and arises when both constituents have a certain affinity to one another.

If the volatility α = 1, the equation

$$\frac{p_a}{p_B} = \alpha$$

represents a straight-line equation, which runs through the coordinate origin and possesses the gradient 1. If α > 1, then curves are generated which have a greater arc as α increases. In the case of azeotropes these S-shaped curves intersect the linear curve, for which α = 1, and a separation by distillation is not possible. The course of the equilibrium curves of positive and negative azeotropes is shown in Figs. 4 + 5.

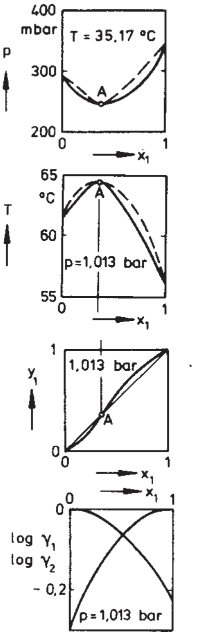

Fig. 4: Phase equilibrium diagram for the system of acetone (1)/chloroform (2) (negative deviation from Raoult's Law).

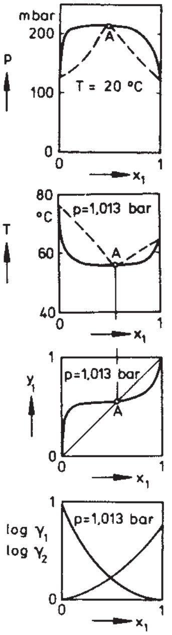

Fig. 5: Phase equilibrium diagram for the system of methanol (1)/carbon tetrachloride (2) (positive deviation from Raoult's Law).

The solubility is influenced by additives. This is used in the recovery of materials, e.g. the crystallization of organic substances from aqueous solutions. This problem also applies to the recovery of materials from textile processing effluent; to the recovery of surfactants from laundry effluent, and to the recovery of salts (Fig. 6) and dyestuffs from dyeing effluents. The solubility of the substances contained in the aqueous medium affects the separation obtained. This is also dependent on the volatility. It may be deduced that the

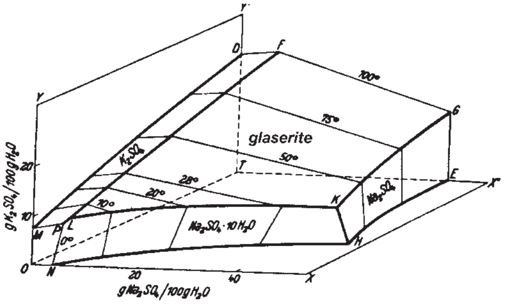

Fig. 6: Crystal composition of the mixed salt $Na_2SO_4 \cdot K_2SO_4 \cdot H_2O$ (perspective diagram). The isotherms for 0, 10, 20°C etc. have been plotted on the areas representing the equilibrium between saturated solution and the various crystal types.

greater the solubility and the boiling point, the greater the energy expenditure.

Distillation residues from dry cleaning plants (tetrachloroethylene sludge) must be classified as hazardous waste due to their high toxicity, regardless of the level of the residual solvent content. Even traces of solvents can cause considerable pollution to the ground water and drainage systems. Disposal may only be carried out at hazardous waste disposal sites or incineration plants, or alternatively the waste material should be handed in for solvent recycling at reclamation centres with suitable equipment; these will also undertake the disposal of any remaining residues.

Distribution coefficient (Partition coefficient). If a substance is introduced to a system of two immiscible solvents and the mixture is shaken vigorously, the substance will separate into the two phases. A distribution equilibrium occurs according to the law first formulated in 1891 by Nernst: the ratio of a soluble substance between two solvent phases is constant.

$$K = \frac{c_{\text{substance}} \text{ in phase 2}}{c_{\text{substance}} \text{ in phase 1}}$$

K = Nernst distribution coefficient.

On the surface of a solid body, the forces of attraction which the atoms or ions exert on one another, are not fully assimilated. External molecules which occur can therefore be added and bonded firmly to a greater or lesser extent. This interfacial concentration is described as adsorption, or chemisorption, when the bonding forces are chemical. The quantity of adsorbed substance (the adsorbate) per m^2 of the surface of the solid substance (the adsorbent) is defined as the interfacial concentration. As this is not known precisely, however, the quantity adsorbed is generally rounded up to 1 g of adsorbent and called “specific packing density” or “loading”. It is quoted in mol (or also in g) of adsorbate per g of adsorbent and depends on the temperature and, when a gas is adsorbed, on the pressure of the gas, or when a dissolved substance is adsorbed from a solution, on its concentration. A bivariant equilibrium thus occurs:

$$\text{Load} = f(p, T) \text{ or } f(c, T)$$

If a cationic surfactant for example is permitted to flow through a column under controlled flow conditions, with the column packed with cellulose, then one can deduce the surfactant mass adsorbed by the cellulose powder in relation to the initial concentration of the surfactant solution added c_0, and the concentration of the eluate. An adsorption process of this type is a reaction of the first order due to the distribution of the surfactant between cellulose and liquor, so both the equilibrium concentration c_∞ and thus the distribution isotherm as well as the material exchange constant β can be ascertained from such experiments (Fig. 1). A relevant adsorption isotherm is shown in Fig. 2.

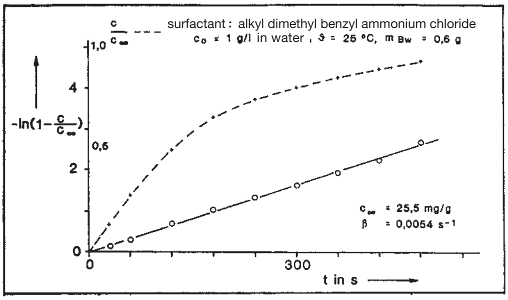

Fig. 1: Adsorption of the cationic surfactant alkyl dimethyl benzyl ammonium chloride on cotton (source: Schollmeyer).

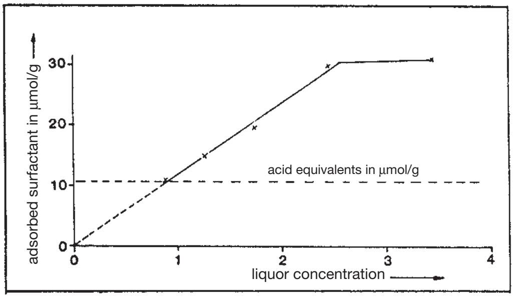

Fig. 2: Adsorption isotherm of DSDMAC (distearyl dimethyl ammonium chloride ammonium chloride) on cotton. Water, 25°C (source: Schollmeyer).

If the acid equivalents which can be compensated by cationic surfactants can be defined, it may be seen

- that more surfactant is adsorbed than appropriate for the acid groups present,
- that with a liquor concentration of up to 2.5 µmol/g (+ 1.5 g/l distearyl dimethyl ammonium chloride), there is a proportionality between the concentration on the fibre and in the liquor with a distribution coefficient of

$$k = \frac{c\infty}{c_{B\infty}}$$

From this distribution coefficient, it is possible to calculate the liquor exhaustion under the conditions of equilibrium when exhausting from a finite bath with the liquor ratio FV:

Next Page

$$BE = \frac{c_\infty}{c_{0T}}$$

c_{0T} is the initial concentration of the surfactant in the liquor in relation to the textile mass and is therefore dependent on the liquor ratio FV:

$$FV = \frac{\text{mass of textile goods}}{\text{liquor volume}}$$

In addition the mass equilibrium gives

$$c_{0T} = c_{BT\infty} + c_\infty$$

where $c_{BT\infty}$ is the equilibrium liquor concentration in relation to the textile goods.

$$c_{BT\infty} = \frac{c_{B\infty}}{FV}$$

With the distribution coefficient

$$k = \frac{c_\infty}{c_{B\infty}} \left(\frac{\text{liquor mass}}{\text{textile mass}} \right)$$

the bath exhaustion is therefore

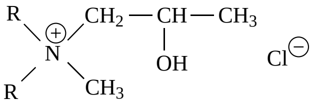
$$BE = \frac{k \cdot FV}{1 + k \cdot FV}$$

and amounts to only 50% with a distribution coefficient of k = 10 and a liquor ratio of 1 : 10. A systematic investigation into the influencing variables on the distribution coefficients is consequently of high practical relevance (source: Schollmeyer).

Disulphide bridges Crosslinkages between wool protein chains via two mutually bound sulphur atoms, W–S–S–W. → Cystine bridges.

Disulphonated acid dyes → Acid dyes.

Ditallow-alkyl-hydroxy-propyl-methyl ammonium chloride



$$\left[R_2\overset{\oplus}{N}(CH_3)-CH_2-\underset{OH}{CH}-CH_3 \right] Cl^{\ominus}$$

R = C_{16} or C_{18} (non-sat.)

Avivage substance (as ditalg imazolinium derivate with 70/75% active substance) for fabric softener. A similar effect can be obtained using coconutalkyl residue with shorter chains as fat substitutes (→ Dicoconutalkyldimethylammonium chloride).

Dithio compounds Compounds with 2 sulphur atoms in the molecule, e.g. dithionous acid (sulphinic acid) $H_2S_2O_4$, known in the form of its salts, e.g. sodium dithionite $Na_2S_2O_4$ (incorrectly described as sodium hydrosulphite).

Dithizone → Diphenylthiocarbazone.

Diversification (Lat.: *diversus* = turned in different directions) Sustained company adaptation to new markets through entry into markets not previously exploited by varying products, operations, etc., in order to spread risk, expand, exploit spare capacity, etc. In many cases these changes or extensions to the manufacturing program, although fundamentally new to the company, nevertheless often have some connection with former business activities. Diversification is a policy for long-term growth and the spreading of risks. There are 3 possible routes, i.e.:

1. In-house development of new products.
2. Acquisition of licences to manufacture/distribute products for which the company has had no former experience.
3. Amalgamation (merging) with other companies which offer alternative products/customer services.

Divided screens in screen printing Design interrupted several times across the width of the screen. Predominantly used when producing new collections (patterning) as several colours can be printed at the same time with one screen.

Divider Used in liquor compartments to decrease the liquor ratio, e.g. in padding machines incl. full-width treatment machines and cheese dyeing machines (Fig.).

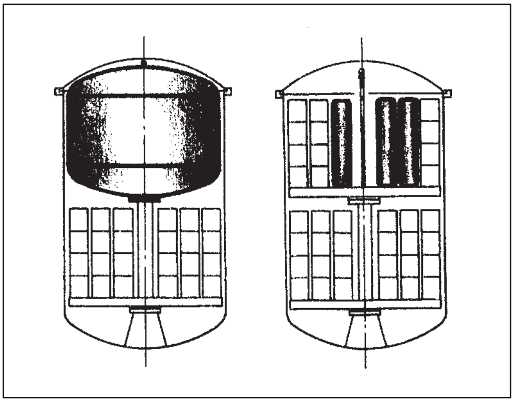


Fig.: Use of divider inserts to decrease the liquor ratio with circulating-liquor machines which are not fully loaded.

Previous Page

Divinylsulphone compounds are derived from divinylsulphone $CH_2=CH–SO_2–CH=CH_2$, mainly with masked vinylsulphone groups, e.g. $R–O–CH_2–CH_2–SO_2–CH_2–CH_2–O–R$, where R = e.g. $–SO_3Na$, $–CH_3$, –H; symmetrical and asymmetrical divinylsulphone compounds. Used as resin finishing agents, e.g. →: Bis (β-hydroxyethyl) sulphone; Disodium salt of tris-(β-sulphoethyl) sulphonium.

DK, abbrev. for: Danish Patent.

DMC → Dimethylol (mono) carbamate.

DMDHEU → Dimethyloldihydroxyethyleneurea.

DMEU → Dimethylolethyleneurea.

DMF → Dimethyl formamide.

DMI, abbrev. for: Deutscher Medizinischer Informationsdienst e.V. (German Medical Information Service). An independent nonprofit-making association for general health information, considerations of industrial and public medicine, promotion of industrial hygiene and protection against infection hazards in the workplace environment, and the control of readily combustible textiles. → Technical and professional organizations.

DMPU → Dimethylolpropyleneurea.

DMT,

I. → Dimethyl terephthalate.

II. → Dimethyloltriazinone.

DMU → Dimethylolurea.

DNP, abbrev. for: dinitrophenyl, e.g. DNP-formic acid.

DNS → Sodium sulphate.

DOB, (Ger.) abbrev. for: Damenoberbekleidung (women's outerwear).

Dobby mechanism, a shedding mechanism on looms or weaving machines (→ Weaving). The harness motion can be either negative or positive by means of a controlled lifting gear. In negative-dobby shedding, the shafts are raised by the dobby and lowered by some form of spring undermotion. In positive-dobby shedding, the dobby machine both raises and lowers the shafts. A distinction is made between single and double lift, as well as between closed and open shed dobby machines.

DOC, abbrev. for: dissolved organic carbon. → Summation parameter.

Doctor bars in roller printing These arise due to the doctor blade lying unevenly on the roller. This gives rise to oscillations which can be seen in the form of horizontal stripes on the goods and which are generally repeated 3–6 times. In order to rectify the fault, the doctor blade must be readjusted.

Doctor bed-plate Scraper device in flat screen printing where the fabric passes between a stationary padded table and the → Doctor blade positioned on this.

Doctor blade Stripping device in the form of a fixed blade which extends across the entire treatment width in steel, as a wedge-shaped, tapered vulcanite strip or as a roller squeegee (→ Squeegee systems in printing). It is used to form an angle of incidence on a moving substrate by means of an incline. When moving, this then enables a highly viscous paste (for printing or coating) to become fluid briefly as a result of its intrinsic viscosity due to the shear forces which arise,

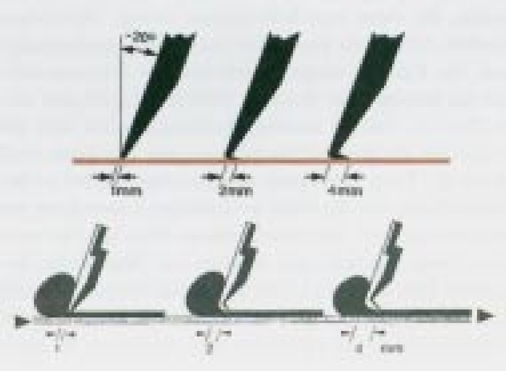

Fig. 1: Illustration of the bevel (in mm) in three different widths at the same angle of incidence, with and without paste in front of the doctor blade (doctor blade is stationary; fabric in motion).

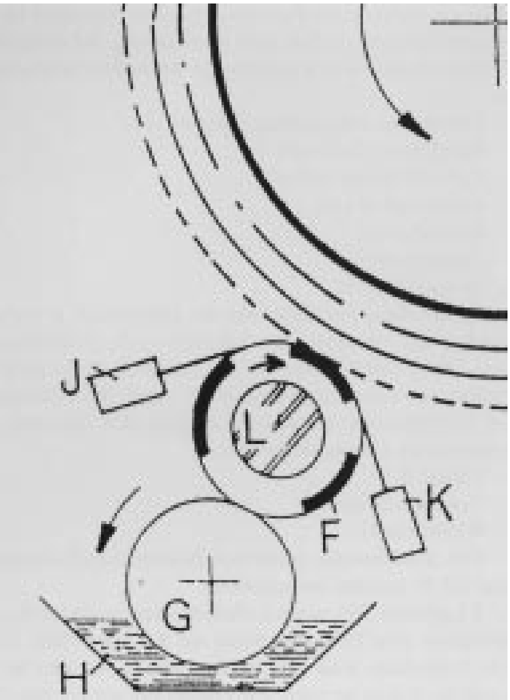

Fig. 2: Position of the doctor blade in classic roller printing. F = engraved zone in roller printing; G = dye paste feed roller; H = trough; J = tractive doctor blade; K = counter doctor blade applying pressure.

and this can therefore be applied. The passage of the paste under a rubber doctor blade is controlled by the angle of incidence and the bevel (Fig. 1). A doctor blade pushes the paste and a squeegee pulls the paste (Fig. 2). Double bladed doctors also move the printing paste back and forth (Fig. 3). Doctors and roller squeegees can be used in both flat screen and rotary printing (Fig. 4).

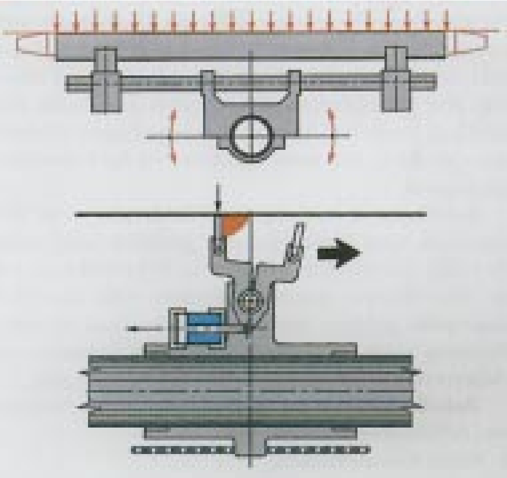

Fig. 3: Reggiani double bladed doctor for flat screen printing (doctors applied weftway on a stationary fabric).

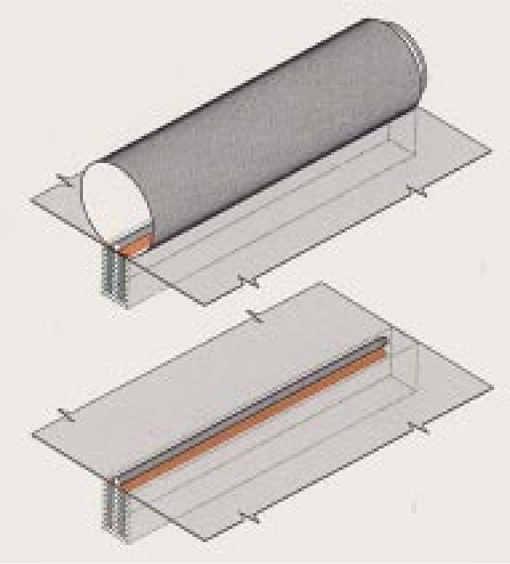

Fig. 4: Magnet roller squeegee technique in rotary printing (above) and flat screen printing (below).

Doctor blade grinding machine Precision machine to grind all types of doctor blades up to 300 cm in length. Operation with rotating continuous abrasive disc, with a universal rapid fixing device for every type of doctor blade, continuously adjustable for any angle in the swivelling range of 0–90°.

Doctor blade holder The doctor blade in roller printing consists of a doctor blade holder and a doctor blade plus possibly an auxiliary doctor. The doctor blade holder consists of a steel protector bar with axle bearings, two load-bearing arms, spigots for the thrust rods and a brass drip bar over which the squeegeed printing paste runs back to the trough. The protector bar and drip bar are bolted together and the doctor blade is clamped between the two.

Doctor blade sharpening in roller printing Three operations are carried out:

1. Filing (straightening).
2. Filing the “crown”.
3. Sharpening (grinding).

Filing takes place initially with a file of coarse cut and is intended to make the blade of the doctor even. In this procedure, the doctor blade is generally filed into a moderate concave curve, the slope of which measures approx. 3–5 mm from the end of the doctor blade to the centre with a blade length of approx. 100 cm. This shaping ensures that the doctor blade fits more evenly on the printing roller. The file is then held against the doctor blade at an angle of 20–45° depending on the slope of the covering in order to “file down” the “crown”. The crown is sharpened on the side of the blade which is opposite the roller surface. Finally sharpening or grinding of the blade imparts strength and smoothness. A special grade of grinding stone is used for this purpose. Two surfaces need to be ground. Then the entire blade area on the side facing the roller is sharpened and the stone is then placed in such a position that it acts on the upper quarter in particular. Next the crown is ground. During this process, the blade and the crown are ground alternately until the burr which has formed on the cutting edge during filing has worn away.

Doctor edge → Doctor blade sharpening in roller printing.

Doctor roller as opposed to the conventional blade used in rouleaux printing (stripping knife) and flatbed and rotary screen printing (doctor knife, roll doctor), which usually have a straight edge or surface, the doctor roller takes the form of a roller with surface engraving, fluting or helical grooving of varying depth. However, because of the contact pressure on the padding roller, only a minor quantity of the liquor that is originally taken out of the trough remains on this doctor roller. Other forms include the → Comb doctor → Squeegee blade system in printing.

Doctor roll padder Padder which has a → Doctor roller attached to its application roller for minimising the amount of liquor that is collected from the trough, after which the retained liquor is evenly distributed on the lick roller.

Doctor roll washing machine With automatic drive system for printing. This cleans soiled doctor blades without wasting water and prevents damage to the doctor blades. Water-efficient valve system adjustable to the number of doctor blades. Doctor blades are transported in the trolley into a lockable washing cabinet. Vertical brushes move over the exterior of the doctor blade, with simultaneous traversing water injection.

Doctor sharpening stone → Levantine squeegee oil stone.

Doctor streaks Incorrect stripes which become visible on roller printed fabrics as fine streaks following damage to the sharpness of the doctor blade.

Doctor traverse in roller printing The doctor blade moves back and forth with an eccentrically mounted doctor blade traverse device. The printing paste is stripped as thoroughly as possible on the smooth roller surface as the blade moves in one direction and as it moves in the other, the doctor blade is prevented from cutting into the engraved roller.

Dodecylbenzene sulphonates → Alkyl aryl sulphonates.

Doeskin Two different types:

1. A fine quality, close, compact, all-wool fabric of five or eight-shaft satin weave with a lightly napped dress-face finish. Used for suits, coats, uniforms.
2. Rayon twill or small satin with face nap. Used for suits, coats, sportswear.

Dog hair Once a valuable commercial ware (hat felt). Nowadays only of limited regional significance, e.g. for arts and crafts. Productive breeds include St Bernard, Newfoundland, chow-chow, poodle, spitz. Is spun alone or with wool.

Dolly A term used for various types of faller washing machines consisting of rectangular troughs in which the goods to be treated in a detergent solution are placed. Rotating beaters or fallers are lifted by cams and allowed to fall into the trough. At the same time, the trough moves backwards and forwards. The machine is also known as a tom-tom and is used by finishers of knitwear, hosiery and lace.

Domestic washing (household laundering) The washing of domestic household → Laundry. Over the last two decades there has been a dramatic change in domestic washing practices due largely to requirements for protecting the environment with regard to the conservation of resources and the minimisation of environmental pollution caused by waste waters. The liquor levels and washing temperatures in domestic washing machines have been significantly reduced and solutions for multiple water usage, especially in commercial laundries, are being adopted on an increasing scale. The standard test methods (e.g. colour fastness to washing) have not kept pace with these changes which, to a large extent, have been introduced as a result of legislation. As a consequence, considerable discrepancies exist in some cases between these test methods and the procedures now used in practice. The adoption of reduced wash temperatures is, on the face of it, an advantage but energy-saving wash programs can also subject textile materials to higher mechanical stresses since the wash times in these programs have been extended to the same duration as high temperature programs. Of particular significance are the changes in detergent formulations to include bleach activators in order to meet the trend of consumers to use low-temperature wash programs. As a result, dyeings on textiles which will only be washed at low temperatures must also possess adequate colour fastness to bleaching. The adoption of lower liquor levels in washing machines to reduce energy consumption is accompanied by a more intensive textile/textile contact. At the same time, the concentration of detergent is increased which leads to a greater interaction with dyeings and prints. This tendency has been further reinforced by the use of dosing systems. In exceptional cases, this can cause the stripping of prints due to the high surfactant concentration used as well as bleaching damage. This practice runs counter to current efforts aimed at reducing the quantities of detergents used in household laundering.

At present, environmentally-compatible washing is frustrated due, especially, to the problem of colour transfer (bleeding, staining) which prevents washing machines being used to their maximum capacity. Each part load involves higher specific consumption rates. The tendency for dyed or printed textiles not be washed off adequately after coloration and for consumers to be compelled to wash coloured articles separately must be regarded as particularly questionable in this context. Similar tendencies aimed at conserving resources are to be found in commercial laundries which likewise widen the discrepancies between the requirements to be met in practice and the test methods. The abandonment of chlorine as a bleaching and disinfecting agent, which has been largely realized in the meantime, and its substitution by peracetic acid which is less aggressive towards dyeings, is a definite advantage. The obligation stipulated in the appendix relating to “laundries” contained in the General Administrative Regulation for the reuse of wash and rinse liquors has given further scope to acidification as a means of achieving a satisfactory rinsing effect. The resultant concentration of the acetic or formic acid which takes place during drying must be taken into consideration in the selection of dyeings, finishes, sewing threads, etc. Colour fastness, as well as the problem of optical brighteners, also present difficulties here. As a result of the compulsory ban on the use of powerful sequestrants, the need for textile materials to be free of catalysts (inclusions or iron pigment in yarns, etc.) is of increasing importance (source: Krüßmann and Hloch).

Domestic washing practices The dictates of fashion determine the use of particular fibres, certain textile constructions which go beyond standard woven and knitted fabrics and, in addition to dyeings and prints with high colour fastness, even some colorations with poor wash fastness. Whilst dyeings and prints are expected to meet the requirements of, e.g. the Marks & Spencer "multifibre strip" wash test on the one hand, the detergents must still be capable of adapting to extreme fashion-related trends on the other. Based on the wash and care requirements of textile materials, the term "fast to domestic washing" needs to be defined. This is to be understood as the sum of the desired colour fastness requirements together with appropriate requirements concerning easy-care properties in relation to the washing operations in modern washing machines with modern detergents. From the standpoint of wash fastness, these requirements mean perfect wet fastness ratings after repeated wash cycles (at least 5 wash cycles) within a temperature range of 40–60°C with the main emphasis on 60°C. The chief requirements to be placed on the detergent system are, of course, selected on the basis of the particular textile material being washed (see Table).

Lower washing temperatures are preferred in order to save energy (Fig. 1). Most of the energy consumed in washing is used to heat the water. For this reason, washing is mainly carried out at 60°C nowadays whilst in former times washing at the boil was predominant. The energy consumption for heating and running a washing machine at 40°C, 60°C and 95°C is given in Fig. 2.

The good washing performance and the low energy and water consumption of the automatic drum-type washing machine will ensure its continued usage in the European market for many years to come. Where the

Type of fibre:			
Textile material	Desired detergent action	Achieved by	Particular requirements of the detergent system
wool	reduced mechanical washing action no felting	fine suds	foam-specific surfactant combination
silk	no colour bleeding	neutral to weakly acidic conditions	surfactant combination, pH control
PES/PAC/PA/PP	improvement of handle	softener in the wash bath	non-ionic and cationic surfactants
PES/PAC/PA/PP	antistatic preparation	cationic surfactants in the wash bath	non-ionic and cationic surfactants
Textile construction:			
down	no adhesion during drying	softener in the wash bath	non-ionic and cationic surfactants
fleece fillings	no drying stiffness after drying antistatic effect	softener in the wash bath	non-ionic and cationic surfactants
membrane textiles	retention of proofing	cationic surfactants in the wash bath or neutral wash liquor	non-ionic and cationic surfactants non-ionic surfactant combination
suede leather panels	no stiffening of the leather	cationic surfactants in the wash bath	non-ionic and cationic surfactants
Dyeings and prints:			
dyeings and prints with poor fastness to washing	no colour bleeding	absence of salts which promote dye staining ≃ pH 7	non-ionic surfactant combination / low electrolyte content
	no dye migration; dye stabilizing effect	dye-stabilizing additives	non-ionic and ionic surfactants
pastel dyeings	no change in colour	washing without optical brighteners	no optical brightener in the product
bleach-sensitive dyeings and prints	no change in colour due to bleaching agents	washing without bleaches	no bleaching agent in the product

Table: Particular requirements placed on special detergents on a textile-specific basis.

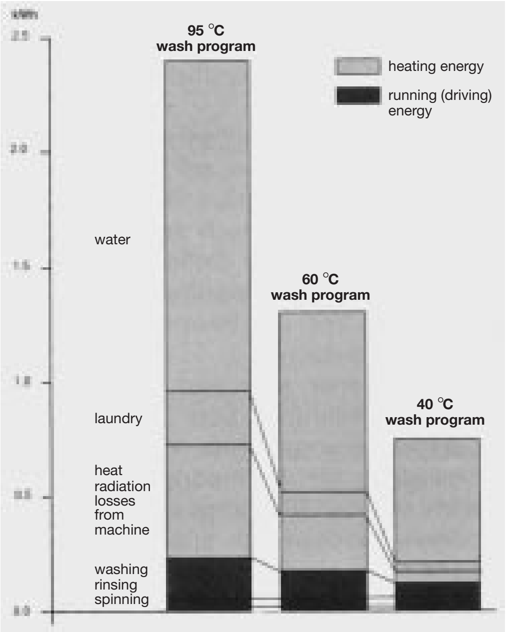

Fig. 1: Comparison of the kWh consumption of a washing machine (3–4 kg load) for washing energy and driving energy.

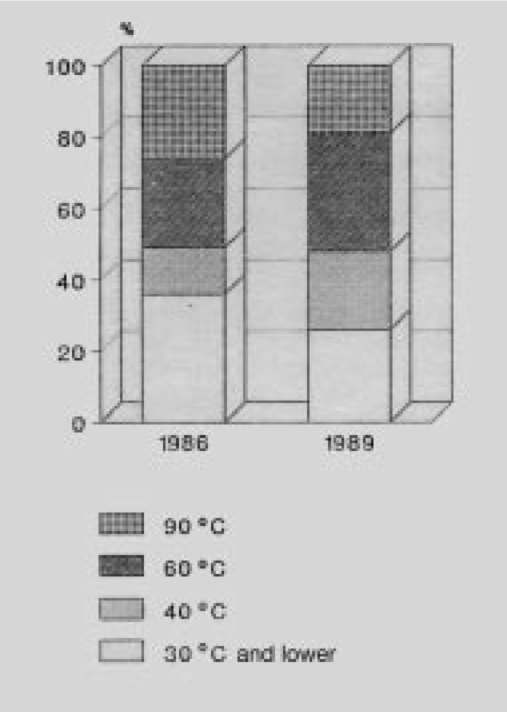

Fig. 2: Comparison of temperature selection in machine washing.

top-loading agitator type of machine is still in use, gradual replacement by the front-loader drum machine is to be expected. In recent years, new developments in washing machines have led to considerable savings in energy and water consumption. Formerly, the energy consumption of a washing machine with a nominal capacity of 4.5 kg was 3 kWh. Currently, the energy consumption for the same type of machine is below 2.1 kWh, i.e. almost 30% less. Water consumption has followed a similar trend: consumption has been reduced from the former 120 l to well below 100 l (usually 60–70 l) per wash cycle. Moreover, the utilization of detergents has also improved. Formerly, complaints of substantial detergent losses in the wash liquor sump were not uncommon. Losses of this kind have been overcome through technical modifications in the construction of the draining system, e.g. bypass conduits, “eco-locks” or spherical closures. Currently, the most up-to-date drum-type washing machines, which are gaining an ever-increasing share of the market, circulate extremely small volumes of water which results in the laundry being cleaned largely by “showering” with wash liquor.

Although the principle of the drum-type washing machine will not change, developments in this area will be concerned with the automatic dosing of detergents and the composition of the wash load. The success of liquid detergents has prompted the washing machine industry to develop automatic dosing systems for these products. A new development in this field is represented by the so-called “multi-component washing machine” in which the products required by the particular wash process are supplied by automatic dosing. Washing is carried out with liquid products which include a universal liquid detergent, a special detergent without optical brightener, a bleaching agent containing optical brightener and a concentrated fabric conditioner. As an alternative, a conventional powder detergent can be used with the usual drawer-type flushing dispenser. It remains to be seen whether such complicated and expensive machines will succeed in the market.

The increasing number of tumble driers, which is certainly expected to rise in future, raises questions as to the advantages of this type of drying for easy-care textiles. In principle, textiles made of synthetic fibres, or their blends with cellulosic fibres, may be dried quite successfully in such machines.

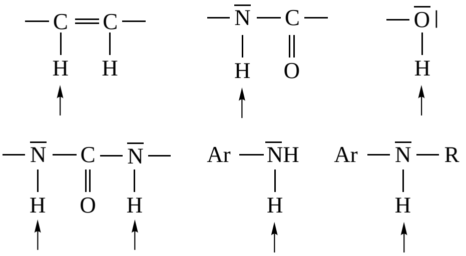
The undesirable build-up of electrostatic charges on synthetic fibres can be reduced or largely suppressed through the use of fabric conditioners (softeners) in the final rinse. The antistatic effects achieved by this means are dependent on the concentration of softener used. Cotton and resin-finished cotton textiles do not suffer from the build-up of electrostatic charges.

A fabric conditioning pad can also be used during drying in the tumble drier instead of a conventional fabric softener in the final rinse. These pads facilitate the transfer of softening and antistatic substances to the laundry during drying and an improvement in odour is also achieved. Moreover, textiles made of synthetic fibres which may have become creased due to inappropriate washing conditions, are smoothed out again in tumble drying. The influence of temperature on the thermoplastic fibres during constant movement of the laundry in the water vapour atmosphere of the drier is crucial in this respect (source: Robinson and Egger, Weber, Krings and Hoffmeister, as well as Brüschweiler, Felber and Schwuger).

Donegal A plain-weave tweed fabric made of wool and characterized by brightly-coloured randomly distributed slubs or flecks introduced at intervals into the weft yarn before spinning. The touches of colour are scattered throughout the cloth and show up usually against a light grey or natural coloured ground. Donegal is named after the county where it was first produced as a coarse woollen suiting in northwest Ireland. Originally, it was woven entirely by hand but today power looms are used for its manufacture. There are many imitations of Donegal on the market today, executed in a wide variety of qualities and weaves mostly consisting of relatively coarse, strong plain-weave all-wool fabrics with white or coloured slubs; very often the warp is lighter and more uniform than the weft which is darker and has more slubs.

Donnan membrane equilibrium The distribution of ions on each side of a membrane separating two portions of a solution of an electrolyte, e.g. NaCl in water. A polyelectrolyte, e.g. a protein, the molecules and ions of which cannot pass through the membrane is introduced on one side of the membrane. The distribution of NaCl on the two sides of the membrane will be unequal and a membrane potential is established.

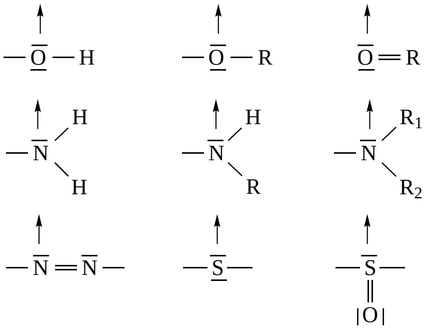
Donor (Lat.: *donare* = to give). A term used in chemistry when the supply of certain functional groups is necessary for the initiation of a reaction, i.e. an atom, ion, or molecule that provides a pair of electrons in forming a coordinate bond. Example: A proton donor is a compound which donates a proton for the initiation of a reaction (e.g. transesterification). In the case of hydrogen bonds, the water donor donates hydrogen ions, and is therefore known as a proton donor. Such functional groups include, e.g.:



In the same process, hydrogen ions are accepted by the hydrogen acceptor:

H_2-donor + acceptor → donor + H_2-acceptor.

Since, in the case of hydrogen bonds, the coordinate bond of hydrogen ions is formed by an electron pair from an atom of the functional groups, the hydrogen acceptor is also described as an electron donor. Examples:



Dosacid system A process developed by Ciba-Geigy for dyeing polyamide carpets in winch dyeing machines with liquor circulation. Principle: pH control during the course of dyeing by means of a metering system consisting of a sensor and a programmmable metering unit.

Dosimetry, method of studying colouring processes in molecular dye solutions, whereby a dye concentration that is constant over time is achieved using automatically-operating burettes, the replenishment from which over time provides the desired dye absorption curve. This makes it possible to perform a single dyeing test (without the need for analysis of the dyed material). Dosimetry is therefore regarded as a rational, fast and precise method (approx. 1% statistical error compared to conventional analysis). Principle: concentration loss in a dye bath caused by dye absorption causes a potential change in a colorimeter, which activates the automatic burette via a controller, i.e. injects concentrated dye solution into the dye bath until the original bath concentration is restored.

Dot coating Process to produce → Hot melt adhesive materials using dot/pattern type paste coating of the non-woven fabric base by printing silk screen printing screens in the rotary screen printing method. In the dot process polyamide dots, for example, are “printed” onto the length of fabric (Fig. 1) in a wet-on-wet process. This process is particularly suited to non-woven bonded or siliconized fabrics. The moisture is removed from the dot in the drying chamber; it is baked at the same time.

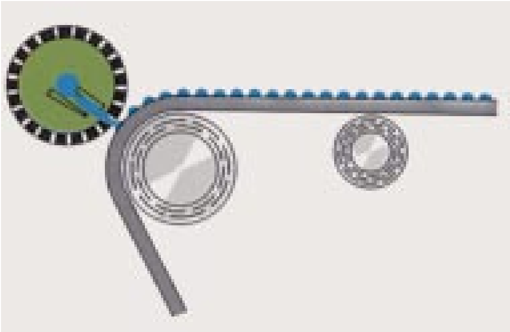


Fig. 1: Caratsch dot process.

Fig. 2 shows the principle for → Direct coating with separate laminating in the form of a diagram. The main part is the applicator head which is in the form of a “two lip” applicator. A closed system should be used for application from the melt. This is the only way to ensure uninterrupted deposition of material on the film screen and to prevent reticulation in the applicator

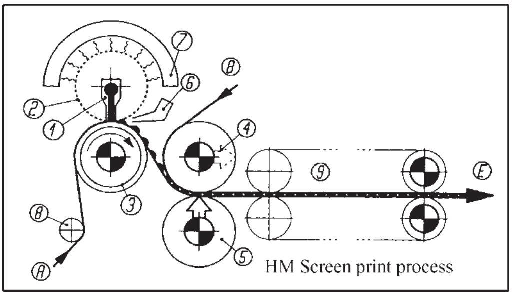

Fig. 2: Direct paste dot coating with separate lamination (Villars).
1 = applicator head; 2 = screen stencil; 3 = counter roller; 4 = laminating station; 5 = calendar roller; 6 = hot air jet; 7 = IR-emitter; 8 = guide roller; 9 = twin-belt laminating and cooling press; A = substrate 1; B = substrate 2; E = end point.

head. Equipment of this type is particularly suitable for applying low viscosity melts, preferably those with a viscosity of below 20 000 mPa/sec. Reactive single-component systems which reticulate at standard atmospheric humidity are able to be processed in the same way if the viscosity remains within the indicated range.

The “print” element is the critical factor in this process. This is known to be minimal in silk screen printing. Pressure-sensitive substrates are able to take advantage of this. Materials which are less pressure-sensitive can also coated directly from granulate using a heated engraved roller. In detail, the granulate comes from its reservoir into a melt unit or an extruder (Fig. 3). Filling the cup cleanly with the melt poses a problem. A special doctor blade system ensures a clearly defined pattern of deposition. The counter roller presses the textile fabric against the engraved roller and in doing so this removes the coating material from the cup of the engraved roller, as it adheres to the textile more readily than to the steel of the engraved roller. The web coated in this way then passes into the laminating station into which the second web is fed and lamination takes place between the transfer and calendar rollers.

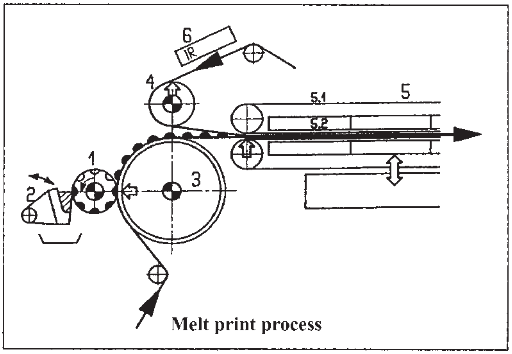

Fig. 3: Paste dot coating with engraved roller instead of a screen stencil (Villars).
1 = engraved roller; 2 = applicator head; 3 = counter roller/ transfer roller; 4 = laminating station; 5 = cooling zone; 5.1 = cooling belt; 5.2 = cooling plate; 6 = IR-emitter.

Double backing (double back). A → Secondary backing glued or laminated to the back of a carpet, usually to increase dimensional stability.

Double bonds →: Atomic bonds (unsaturated); Conjugated double bonds.

Double cloths Compound fabrics consisting of two component fabrics with two warp and two weft systems woven at the same time in a single operation. They are bound together by interchanging warp and weft threads between the face and back fabrics, or by using a special binder thread (e.g. ulster). The weave of the two fabrics can be different.They are produced in order to give the material greater weight or to achieve differently coloured face and back sides (e.g. double face or ulster fabrics).

Double crabbing jack Used to accelerate the crabbing process by winding the fabric from one crabbing jack to another.

Double cure process A two-stage → Permanent press process. Stage 1: pre-cure in the presence of swelling agents; Stage 2: post-cure after garment making.

Double drum machine Double drum machine concept for the washing, dyeing and drycleaning of ready-made garments with an inner and outer drum (see Fig.). The so-called “free liquor space” available for liquor uptake by the garments is held between both drums.

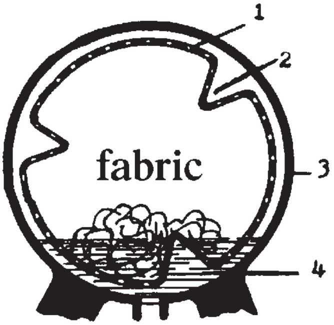

Fig.: Conception of a double drum machine for washing, dyeing or dry-cleaning finished fabric.
1 = perforated inner drum; 2 = driver rib; 3 = outer drum; 4 = liquor.

Double-faced carpet → Treeply carpet.

Double face fabrics In general, these are textile fabrics having two different sides, i.e. with a different colour, design (printed or otherwise) or material on each side.

Double mercerization Double mercerization of yarn (only applicable to high quality yarns). By double mercerization any variations in the mercerizing effect on the yarn which may occur in single mercerization are avoided. The process is nevertheless very expensive.

Double plush (double velvet, double plush carpets) Produced by the double velvet technique to obtain two completely identical fabrics in design and colour which are bound to each other by shared pile yarns. These pile yarns are finally separated in the weaving machine by a knife giving two identical plush, velvet or carpet materials.

Double shed In carpet weaving machines two sheds are formed from the pile and binder warps, i.e. an upper and a lower shed, through which the weft is inserted.

Double-sided transfer paper is a → Transfer printing paper which has been printed on both sides to enable the simultaneous transfer printing of two fabric webs by using the sandwich principle (fabric/paper/fabric).

Double spot coating A dot coating process in which each dot consists of a lower melting core and a higher melting outer shell. The advantage is that, in pressing, the adhesive is prevented from sinking into the fabric thereby achieving a stronger bond.

Double squeegee A squeegee system for wide printing widths in which the print paste is applied between two squeegee blades. Used in screen printing and screen printing machines.

Double stitch (double loop) Combination of stitch and loop.

Double weft carpets → Woven carpets where each row of tufts is tied up by 2 wefts.

Double worsted cloth Given this name because of the double-faced weave. A type of compound warp fabric consisting of two warp thread systems but only one weft thread system. The warp and the weft are usually fine twofold yarns in the case of worsted fabrics. Fine, dense fabrics, sometimes worsted, usually in muted shades with discreet weave, yarn and silk effects; with a deliberately smooth finish. Dyed in loose stock, yarn and piece. Used in classic suits and formal wear.

Doubling machines (folding machines) During the lengthwise passage of a fabric through such a machine it is folded in the centre to half its width and either batched on rolls (doubling and batching machine) or plaited down (doubling and plaiting machine) as desired.

Douppioni (doupion, dupion) Silk fabric with a characteristic irregular slubby texture. The effect is obtained by the use of irregular, raw, rough silk, reeled from double cocoons, in the weft. The double cocoons are the result of two cocoons having been spun by two silkworms too close together. Nowadays schappe silk slub ply yarns or raw tussah silk is often used in the weft. A schappe silk ply yarn is used in the warp.

Dowlas Originally a plain-weave coarse linen fabric. Now often used for a cotton fabric produced from coarse yarns and finished to imitate linen in handle and lustre.

Down the soft fine feathers that grow under the contour feathers of ducks, geese and other waterfowl to prevent loss of heat. The eider duck has been the principle source for textiles as a filling material. The German RAL-RG 094 specification distinguishes between the following qualities:

(1) pure down (also known as “feather-free original duck or goose down”) which is the softest quill-free plumage consisting of core down without any feather content, (2) down, similar to pure down, but with a permissible content of 10% small feathers by weight, (3) feathery down, like pure down, but with a permissible content of max. 50% small feathers by weight, and (4) half down, which consists of feathers with at least 50% down content and occupies approx. half the volume of pure down since the latter is considerably lighter than feathers. Uses: filling material for pillows, quilts, eiderdowns, etc. (approx. 30 geese produce 1 kg of down).

Down mixture 50%/50% small feather → Down.

Downproof batiste (maco downproof), a fine, tightly woven, fabric made from particularly fine and uniform long-staple cotton (maco). Combed yarns are mainly used. Special finish: feather and down proof. Qualities: grey fabric and dyed. Used for tickings.

Downproof fabric, a woven cotton fabric of approx. 120 g/m^2 made from very fine yarns (usually of maco cotton) and extremely tightly woven. It is used for pillows, quilts, etc. filled with down. Downproof fabric is very prone to creasing and the crease marks are highly visible after subsequent dyeing; it is also difficult to wash off because of the tightly woven construction. As a rule, it is only produced in plain weave and supplied in its natural colour for this reason. These fabrics are generally given a wax finish to make them downproof.

Down time, operationally dependent component of → Operating time.

DP, abbrev. for: → Degree of polymerization.

DPB, abbrev. for:

I. Deutsches Bundespatent (German Federal Patent), now → DB.

II. → Dibutyl phthalate.

Drafting zone, a section in many spinning machines which reduces the cross-section of a fibrous strand (sliver, slubbing or roving) by drawing in order to decrease the linear density and bring the fibres into parallel alignment at the same time.

Draining of steam chests This is carried out in such a way as to remove condensate from the heat exchanger as quickly as possible using a → Steam trap and condensate pipe.

Drape, serviceability parameter of woven and knitted textile fabrics.

Drawing (drawstretching) of synthetic fibres A process applied in the spinning of thermoplastic man-made fibres to achieve optimum performance characteristics. Drawing involves a post-stretching of the freshly spun filaments (by 400–1200% depending on the type of synthetic fibre). The process brings about a deformation of the polymer structure and, at the same time, an increased orientation of the chain molecules in the direction of the fibre's longitudinal axis (→ Texture). The long-chain molecules are pulled into alignment so that they become more closely packed alongside one another (chain packing) thereby forming crystalline regions (crystallites) which increase the fibre's tenacity through secondary valency forces (dye affinity is reduced in highly oriented fibres). The degree of "orientation" achieved can be determined by means of X-ray diffraction, infra-red spectroscopy, ultrasonic or double refraction measurements. The high strength of synthetic fibres is founded on the link between drawing and the degree of crystallization. →: Drawing variations in synthetic fibres; Melt-spinning process

The drawing of a non-oriented polyester fibre can proceed across the entire test sample if sufficient heat is provided. In cold drawing, however, orientation of the chain molecules occurs at a contraction point or flow zone which moves along the length of the test sample at a certain speed (known as neck formation). A schematic representation of the stress-strain curve and corresponding flow zone is given in the Fig. As can be seen from this stress-strain curve, a small, reversible, Hooke's deformation zone (3% extension) is followed by a plastic, irreversible, deformation zone after a minimum resp. flow stress σ_M is exceeded, at which point a flow zone creeps along the test sample. The minimum applied tension σ_M is constant here. The fibre is fully drawn after passing through this plastic deformation zone. Further extension leads to a reversible deformation of the fibre which can lead to rupture at very high extensions.

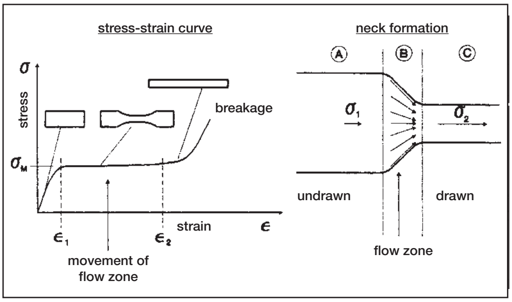

Fig.: Schematic representation of the stress-strain curve and the flow zone during the cold drawing of a synthetic filament fibre.

The important transformation of the amorphous polymer from the undrawn to the drawn, oriented, state occurs in the flow zone (see Fig.). The heat liberated in the flow zone is transferred to neighbouring molecules in the undrawn region which, through the combined effects of thermal mobility and external stress, easily overcomes the secondary valency forces and a parallel arrangement of the chain molecules results. The flow effects proceeding in region B are largely triggered by shear forces and are maintained. Because of the reduced cross-section in the drawn part of the fibre C, the external stresses summoned up here are greater than in the undrawn region A.

The energy balance of the work done in external deformation is essential for the observation of neck formation. A part of the work done is irreversibly dissipated as heat due to internal frictions. A further, reversible, part of the heat here is based on the decreased entropy of the material. The temperatures generated in this way are just sufficient to maintain adequate flowability in the moving flow zone. A further part of the mechanically performed deformation work is, on the other hand, not necessarily dissipated as heat, but is stored resp. frozen as increased internal energy in the drawn material. The material sustains internal stresses during the course of drawing. This part of the work done in deformation, and the resultant internal stress field, is the source of the shrinkage effects which occur in this material during thermal treatment. Moreover, these frozen, internal stress fields are considered to be the driving forces for shaping the structure.

In contrast to highly drawn fibres, in which the stress field is internally frozen and blocked by a network of crystallites, the stress field required for shaping the structure of undrawn fibres can be generated through subsequent external stretching (source: Schollmeyer).

Drawing in spinning → Melt-spinning process.

Drawing variations in synthetic fibres These are caused by differences in → Drawing (drawstretching) of synthetic fibres. They become manifest in fibre production as local differences in the radial structure of the filaments (telescopic effect). Such variations can give rise to difficulties in dyeing (it is particularly problematic with polyamide and other articles dyed in solid shades) since the more highly stretched finer sections of the filaments require more dye for a specific depth of shade. For the same volume, the surface area of a fibre inversely proportional to the radius (→ Microfibres). Corresponding changes in surface effects are predictable. Dyeing variations due to differences in drawing can occasionally be levelled out within certain limits (e.g. by appropriate dye selection, dyeing process and the use of specific levelling agents).

Draw out, to → Water extraction.

Draw roller, cloth handling roller driven by cogs; → Rollers.

Draw texturing → False twist yarn (textured).

DRE, directional (or differential) friction effect, German form of DFE.

DREF, false twisting method In this system a sliver, preferably produced by a drawframe, is drafted on a high draft drawing system. The drawn sliver is aerodynamically split on leaving the drawing system by being separated by force lateral to the roving axis. The slivers obtained in this way are combined by conventional means and twist is imparted by a twisting unit. A heavier feed sliver can be produced by drafting just one intermediate sliver instead of both. This practice further improves the economic viability of the false twisting method by reducing preparation costs and provides considerably better drawing from a technological point of view. The increased number of fibres in the cross-section of the sliver to be drawn and less twist compared to the conventional roving produced by the speed frame guarantees more even drafting in the high draft drawing system. The aerodynamic splitting of the drawn sliver which follows mechanical high draft drawing is less precise than in ring spinning. The in-phase combination of the two rovings whilst being twisted together immediately following the splitting process compensates any irregularities of fibre mass distribution in the two slivers. The character of the false twisting method is ultimately governed by the relatively easily controlled high drawing process, whereas splitting problems are of secondary significance.

Dried gypsum Calcium sulphate (anhydrous or with $^1/_2$ molecule crystal water), solidified when mixed with water (with heat generation), is able to hold large volumes of water. Produced by heating to 150–180°C = plaster of Paris for modelling and rendering purposes, for plaster casts, for fixing iron objects to stone walls (should harden in 10 min with one part water), or to over 1000°C = anhydrous flooring plaster (as accelerated setting agent, mortar admix). In the region 400–600°C "dead-burnt gypsum" is produced (only combines with water slowly).

Driers for textile materials A drier for textile materials has the following functions:

- Removal of the surface water (e.g. expression of water by pressure) (Fig. 1);
- Evaporation of the capillary water (Fig. 2);
- Achievement of an equilibrium moisture content with the chemically-sorbed water which is characteristic for the type of fibre being dried (conditioning) (Fig. 3).

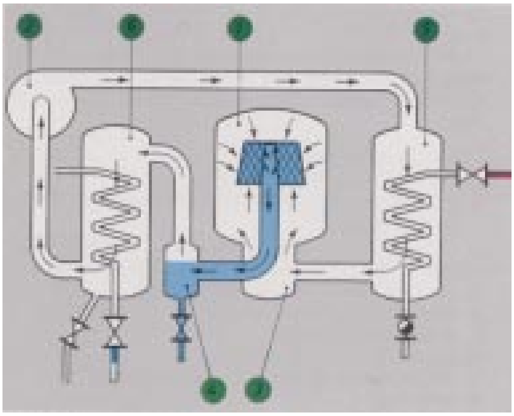

Fig. 1: Expression of surface water from a yarn package by pressure in the drier.

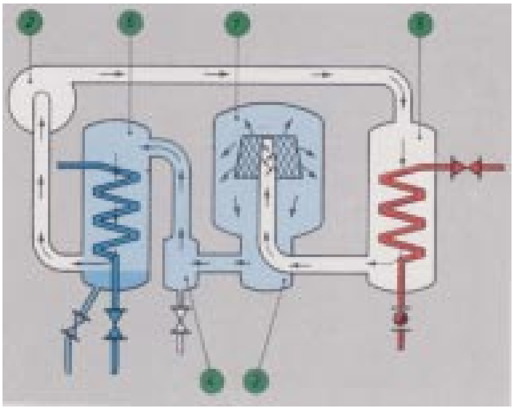

Fig. 2: Removal of capillary water in the drier.

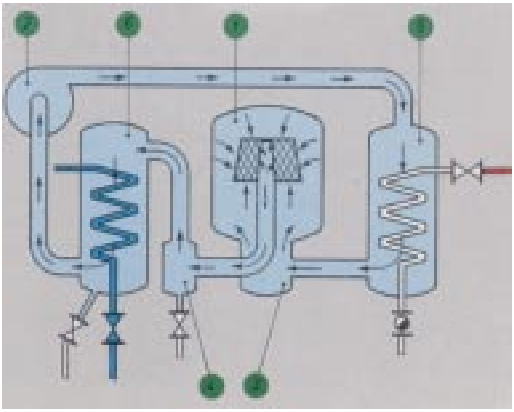

Fig. 3: Conditioning of chemically bound water in the drier.

Moreover, the drier must be designed specifically for the particular form of textile material being processed:

- Loose fibres (loose stock),
- Yarn in package or hank form,
- Woven or knitted fabrics (Fig. 4),
- Open-width or tubular fabric (Fig. 5),
- Made-up garments.

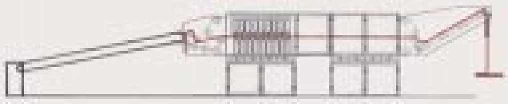

Fig. 4: Santex drier for knitted fabrics with feed zone.

Fig. 5: Henriksen drier for tubular knitgoods.
1 = fabric feed; 2 = reel; 3 = drying tube outlet; 4 = jet; 5 = jet compartment; 6 = fabric basket; 7 = fabric chamber with Teflon coating.

Finally, there are drying processes which represent part of a 2 or multi-stage treatment and must therefore take into account the preceding and subsequent stages:

- Drying after printing (Fig. 6),
- Drying and thermofixation (thermosol) treatment (Fig. 7),
- Drying after application of resin finishes,
- Drying with simultaneous relaxation of the tensions previously built up in the textile material.

Moreover, energy in a wide variety of forms can be supplied to the textile material, depending on the drying method, in order to achieve the evaporation of water:

- Contact heat (Fig. 8),
- Convective heat (Fig. 9),
- Electrical energy (high frequency energy),
- Chemical combustion energy.

Fig. 7 illustrates the drying zone of a conventional drying machine with infrared radiators and heat exchangers. In conventional drying processes, heat energy is supplied to the material as a drying medium from the outside. Steam, gas, oil and electricity are the energy carriers used. Evaporation is achieved through heat radiation and hot air currents. A pad liquor with 100% water requires large amounts of energy for evaporation.

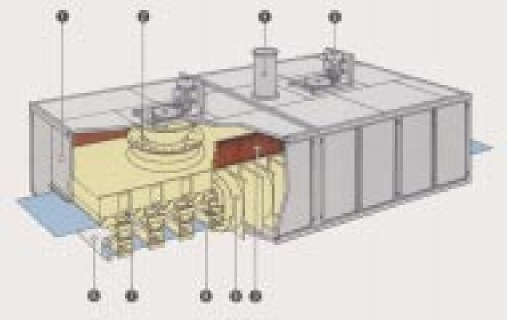

Fig. 6: Construction of a drier for printed fabrics (Stork).
1 = insulation; 2 = axial fan for air circulation; 3 = heater; 4 = exhaust fan; 5 = motor for air circulation; 6 = one or three passages; 7 = air nozzles; 8 = slit nozzles; 9 = air distribution system.

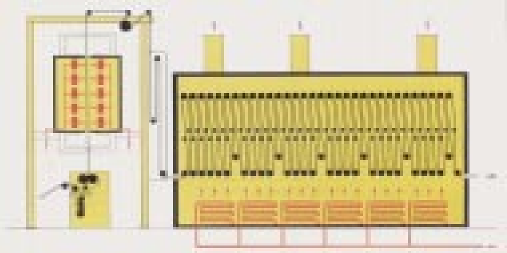

Fig. 7: Brückner pad-dry-thermosol unit with IR pre-drier and thermosol dye fixation chamber.

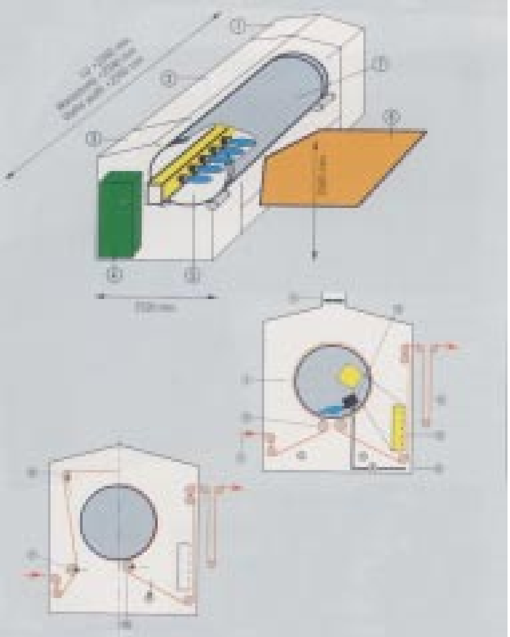

Fig. 8: AGI cylinder drier with gas heating.

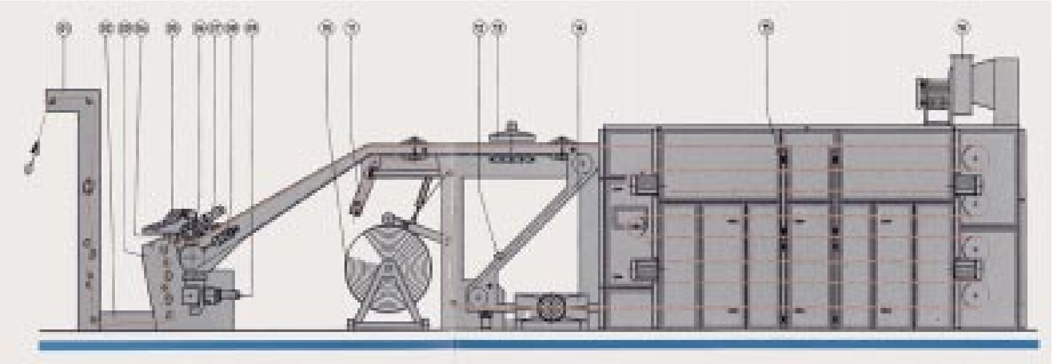

Fig. 9: Santalucia multi-layer stenter based on the convective drying principle.

Long fabric passages are necessary for the achievement of uniform temperatures on the fabric. The addition of expensive wetting agents and migration inhibitors are essential for uniform results.

Through-flow driers (e.g. sieve-drum driers) achieve a very good utilization of heat energy (Fig. 10).

If it is intended to bring the shrinkage which takes place through de-swelling of the fibres under control during drying, the textile fabric has to be dried in special machines. An important example of this type of drier is the → Stenters (Fig. 11).

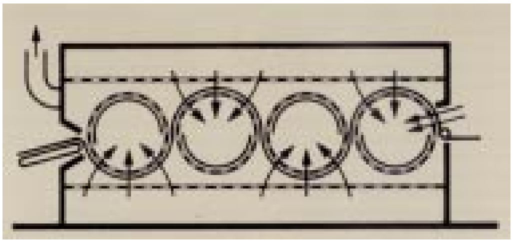

Fig. 10: Through-flow drier based on the sieve-drum principle (Fleissner).

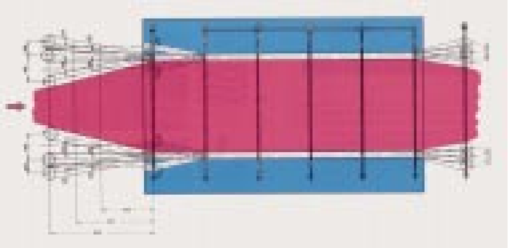

Fig. 11: View of fabric passage through the stenter with entry zone (left), drying tunnel and exit.

Driers, heat recovery systems → Exhaust air heat recovery.

Drill A general term for a strong, medium to heavy weight, densely woven fabric (linen, linen/cotton union and cotton) produced mainly in twill weave and occasionally satin weave (satin drill, mattress drill), also with herringbone stripe or check patterns, etc. Drills with a twill weave construction resemble denim except that the latter has a warp-faced right-hand twill and the former a warp-faced left-hand twill. Various terms are used according to the nature of the fibre used and the field of application (e.g. bed drill, table drill, trousering drill, sacking drill, cotton drill, etc.). It finds use in the grey, bleached, dyed or printed state for a variety of applications including workwear, pocketings, shoe linings, uniforms, bookbinding, coated fabrics, industrial fabrics, ticking, etc.

Drive belts →: Belt drives; Transmission belts.

Drives → Electric motors.

Drop printer Jet printing system for manufacturing sharp-edged prints (100 lines/inch). When leaving the end of the nozzle, the dye solution droplet is given a defined electrical charge (16 possible charge levels). Depending on the charge level, the droplet is either withdrawn, in which case no dye is applied, or electrostatically deposited over a width of 4 mm in a certain position (nozzles arranged at 4 mm intervals across the width of the material).

Drum cleaning machine, for batch dry cleaning of finished goods using tetrachloroethylene (perchloroethylene). Two parallel processes take place, cleaning and liquor recirculation (Figs. 1 and 2).

Drum drying machine →: Drying systems, Sieve-drum drier, Cylinder drying machines, Tumbler drier.

Drum dyeing machines consist of a perforated, reversible rotating drum, sometimes consisting of several compartments. Liquor ratio 1 : 8–1 : 10. Finished items, such as hosiery and fully-fashioned garments, and piece goods, such as uncut and cut plush fabrics,

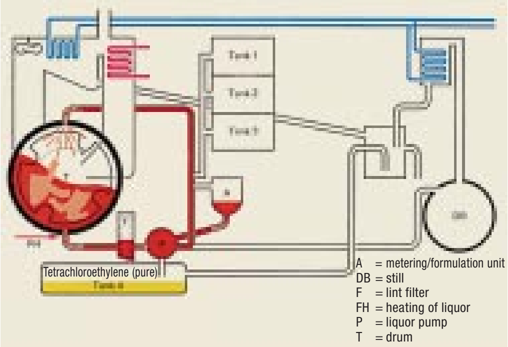

Fig. 1: Drum machine; basic diagram showing the liquor circulation during processing (for colour legend see Fig. 2).

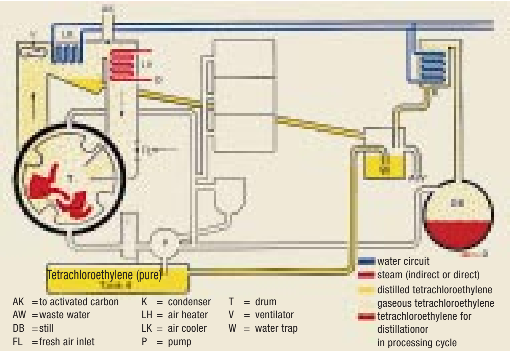

Fig. 2: Drum machine; basic diagram showing the liquor regeneration and drying of the goods.

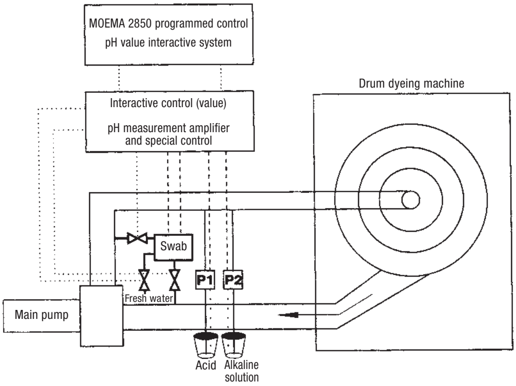

Fig.: Proposal for retrofitting of pH control equipment in a drum dyeing machine (Pardes Speciality Hosiery)

towelling and raised goods, can be dyed or finished. Drum dyeing machines are practically indispensable for the finishing of double plush goods. After tumbling or spongeing, and following shearing, the drum is loaded and the goods are washed, rinsed, spun, bleached, rinsed and spun again, dyed, rinsed, washed and hydroextracted. Processing times, e.g. for bleaching and dyeing, are often substantially shorter than those using other machinery, as the contact between liquor and goods is more intensive, and the direction of flow of the liquor is constantly changing as the rotation of the drum changes direction. A pH control system (see Fig.) is recommended for hosiery drum dyeing machines.

Drum partitions There are several different types of partition of inner drums, as shown in the Fig.:

O-partition = open, undivided circular drum;
D-partition = 2 sections, 2 inner chambers to the drum;
Y-partition = 3 sections, 3 inner chambers to the drum;
Star partition = 4 sections, 4 inner chambers to the drum;
Vertical partition = possible additional subdivision.

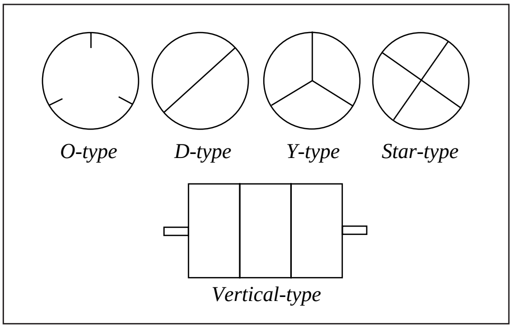

Fig.: Drum partition types.

Drum partitions and their effect on the washing mechanics are judged as follows: O-type: → Fall height across full drum diameter, items allowed to fall individually with good penetration, fast drum rotation = high fall frequency. D-type: items fall with “slippage brake”, tendency to bunch together with moderate penetration of inner sections, slower drum rotation = lower fall frequency. Y-type: fall height practically as low as half drum diameter, tendency to bunch together and fall outside liquor level. Slow drum rotation = low fall frequency.

Drum perforations, perforations in the surface of inner drums of → Drum washing machines, to allow the penetration of liquor.

I. Simple perforation (round holes) e.g. in the case of washer-driers.

II. Funnel-type holes, used in the majority of washing machine drums (= more efficient flow conditions, low mechanical loading).

III. Beaded holes (= more favourable flow conditions, high mechanical loading).

The perforation area usually represents 20–40% of the total area of the drum in washing machines. Sometimes additional perforations are found in the end or partitions of the drum (= additional penetration).

Drum pumps (barrel pumps) Purpose-built pumps for drawing liquids from drum containers, etc. Depending on chemical resistance requirements, constructed from polypropylene, aluminium, stainless steel, etc.

Drum washing machine In a high-speed washer (see Fig.) with special drum, the goods are advanced without conveyor belt, air cushion or pressure belt and the kinetic energy transformed into impact or compression forces. The washing and relaxing effects on fabrics and blends with wool content are therefore achieved with short processing times, thus eliminating the undesirable running creases which often result from wet finishing of textile substrates in rope form.

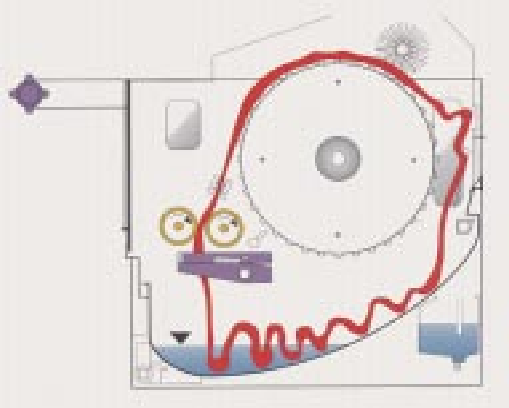

Fig.: Drum washing machine for wool cloth in rope form (Hemmer-Menschner).

Dry bonding → Bonding on textiles.

Dry chlorination, oxidative → Antifelting finish for wool with chlorine gas.

Dry clean, basic Cleaning and drying only in dry cleaning plants, i.e. without any special stain removal (spot removal) treatments.

Dry-cleaning Dry-cleaning involves 4 stages: 1) presorting of articles for dry-cleaning, 2) a basic dry clean in special machines with suitable solvents in combination with dry-cleaning detergents at a liquor ratio appropriate for the type of articles being cleaned, 3) stain removal with spotting agents and 4) finishing to shape by Hoffman pressing or ironing by hand.

Soil adheres to the surfaces of fibres to a varying extent. This attachment mechanism, referred to as adhesion, exists between a solid boundary layer and a second phase which is composed of individual particles (dust particles, gas molecules) or a continuous solid film. This adhesion may be due to electrostatic forces, van der Waal's forces, adsorption or an actual chemical bond. According to DIN 50 900, the energy of adhesion is defined as follows:

"The work expended in the isothermal and reversible separation of two phases carried out at their interface brings about an increase in the free energy of the system. This energy is described as the free energy of adhesion. It is equal to the sum of the free energy of wetting and the free surface energy (surface tension)."

The majority of surface contaminations are of an oily nature; they are therefore hydrophobic and consequently insoluble in water. Water is a polar compound; a water molecule is a dipole with a positive partial charge at the side of both H atoms and a negative partial charge at the side of the O atom due to the high electronegativity of the oxygen atoms and the geometry of the molecule (both H atoms are positioned at an angle of < 180° to each other). By contrast, a hydrocarbon molecule is non-polar since carbon is less electronegative and the chain-shaped molecule is completely enveloped by the hydrogen atoms.

The bond strength between a molecule in a contamination layer and the surface of the substrate is dependent on the potential energy of the particle. The dependence of this potential on the distance of the particle from the surface is shown in the Fig. Depending on the magnitude of the binding energy E_B, a distinction is made between the physisorption ($E_B < 40$ kJ/mol) and the chemisorption ($E_B > 40$ kJ/mol); as far as the bond strength is concerned, this latter represents the transition to an actual chemical bond. Whilst the bonding energy (resp. the amount of adsorption enthalpy) increases from the physisorbed through the chemisorbed

state to the reaction layer, the distance between the sorbed particles and the surface of the substrate decreases. The minimum of the potential energy shows that a sorbed particle on the substrate surface is in an energetically-favourable state. The desorption of contamination layers requires the introduction of energy which corresponds at least to the amount of the bonding or sorption enthalpy.

In a dry-cleaning machine, this energy is introduced by means of chemical engineering. The energy required is provided in the form of mechanical, thermal and chemical energy. A comparison of the amounts of energy has revealed that it is not possible to desorb the adsorbed contaminations in a dry-cleaning machine with mechanical energy alone. Moreover, in order to remove adsorbed contaminations with thermal energy alone, temperatures significantly higher than 100°C must be realized in the dry-cleaning bath. In this regard, an increase in the bath temperature, which is limited by the boiling point of the dry-cleaning solvent, can only serve to shift the physical characteristics and interfacial properties of the contaminations in a favourable direction. As a consequence, the kinetics of dry-cleaning are influenced in the sense of a process acceleration.

In a dry-cleaning machine, the energy necessary for the desorption of contaminations is provided in the form of chemical energy. This is achieved by the selection of a cleaning solvent with suitable physico-chemical properties. In the simplest case, this requires that the contaminations should be soluble in the selected solvent. The cleaning action of halogenated hydrocarbons and halogen-free non-aromatic hydrocarbons for fat-based and oily contaminations is based on this principle. The energy required for desorption is provided by the enthalpy of solution, i.e. the energy gained in dissolving the contamination.

The advantages of oil and fat-based soil removal with halogenated hydrocarbons together with those of cleaning with surfactants can be combined by using a hydrocarbon/water dispersion. Because of the cleaning mechanism, which is based essentially on the solubility of contaminations in both phases, similarly uncomplicated types of dry-cleaning plant to those used for cleaning with halogenated hydrocarbons have been realized. As an alternative to the use of halogenated hydrocarbons, cold dry-cleaning agents based on hydrocarbons are available. These products contain neither chlorine, fluorine nor aromatic compounds, but have comparable cleaning properties to the halogenated hydrocarbons. Product and safety data for a number of solvents are compared in the table accompanying this article.

The advantages of the halogenated hydrocarbon solvents are due to their very low flammability at low boiling points and high vapour pressures. Comparable halogen-free hydrocarbons with similar boiling points would be extremely flammable. For dry-cleaning purposes, only those solvents with flash points above + 55°C are acceptable. The low volatility of such solvents reveals itself in their relatively high boiling points and low vapour pressures. The flammability of non-halogenated hydrocarbons involves a higher outlay on adequate safety precautions for dry-cleaning plants. Under no circumstances must the flash point, or lower explosion limit, be exceeded. The solubility of non-halogenated hydrocarbons in water is extremely low and, for this reason, a water endangering classification has not yet been allocated to these solvents (source: Haase).

Dry-cleaning antifoams (→ Antifoams in dry-cleaning) prevent and destroy the build-up of foam in solvent distillation liquor by means of e.g. saturant containing silicon in combined action with residues of finishing agents and dry cleaning detergents, and prevent the contents of the distilling kettle from boiling over, which would otherwise often be inevitable. Usually flammable liquids.

Dry-cleaning detergent (dry-cleaning intensifier). These are used in → Dry-cleaning in normal organic solvents to considerably increase the cleaning action with maximum removal including water-soluble impurities. New concept introduced in 1953, replacing → Benzine soap in terms of composition, efficiency and economic viability.

Composed from synthetic active detergents with low salt content + dissolving agents (low molecular alcohols) + possibly activation additives (surface active agents, emulsifiers, organic phosphates etc.) + (water 5–20 %) + (organic solvent) + possibly special additives (anti-static agents, optical brighteners, bleach (hydrogen peroxide), disinfectants, fabric conditioners, proofing agents, leather oils, corrosion inhibitors etc.). Non-ionics are preferred as they can be used as dissolving agents for solvents in addition to their active detergent properties. Commercial forms as clear solution, water-in-oil emulsion, dispersion and also as powder.

Attributes: Increases the solvent conductibility (prevention of electrostatic charges on the fibre or redeposits of previously removed soil which promotes greying; intrinsic detergent action even without the addition of water (N.B. necessary for light, loose woollen goods); can be easily filtered, even when water has been added (no increase in the filtration pressure); repeatedly capable of absorbing water in the solvent liquor (high charged system) for enhanced removal of water-soluble impurities; promotes high water retention in the solvent; does not impair any subsequent wet or dry impregnation; inert to fibres, dyestuffs and finishes; promotes pleasant fabric handle; inert to metal parts of the machine and in closed circuit systems.

Dry-cleaning detergent concentration test → Methylene blue method.

Dry-cleaning effects The effects of appropriate dry cleaning extend beyond the cleaning effect itself, as they are also accompanied by extensive quality characteristics of various kinds which are altogether typical of the advantages to be gained from cleaning by means of a solvent treatment, e.g.:

- a clearer, cleaner, odour-free result is achieved;
- the colours, effects and printed designs are maintained and appear clearer and brighter;
- the finish effects are also maintained (provided they are not soluble in the dry cleaning solvent), restored and improved;
- the fibre properties are protected;
- the original made-up dimensions remain unchanged;
- parasites are destroyed;
- germs are completely destroyed through the use of special additives.

Dry-cleaning effluents According to scientific investigations, the presence of tetrachloroethylene (perchloroethylene) in quantities of less than 10 mg/kg in effluents does not impair aerobic degradation in biological waste water treatment plants. In 1975, the Hohenstein Institute was able to establish that the tetrachloroethylene content in water from water separators was usually below 200 ppm (= 200 mg/kg), i.e. only slightly above the natural solubility of tetrachloroethylene in water at 20°C which is 160 ppm. In order to assess possible effluent contamination by tetrachloroethylene, the quantity of effluent outflow must be taken into consideration: only 0.10–0.15% of the total water leaving the drycleaning machine flows from the water separator. Consequently, the concentration of tetrachloroethylene in the total water is reduced to below 0.5 mg/kg. Although the dilution ratio is, in fact, reduced to 1 : 30 by steam distillation, there is still no danger for the effluent at this phase of the operation. In order to take advantage of all possible precautionary measures, the effluent (together with other waste process water = dilution effect) can be diverted into a separating pond with an upper outlet for water and a possibility for draining off tetrachloroethylene at the bottom (with a bypass line in order to break-up any emulsions, if necessary, by high additions of salt and thus separate off the tetrachloroethylene); regular inspection and maintenance are necessary here. Effluents from collection sumps and extracts from stain removing tables contain, in addition to predominantly surface-active compounds (harmless in effluents), numerous chemicals and many different solvents which should not be discharged into the effluent. These wastes must be disposed of, together with distillation residues, as special sludge wastes.

Dry-cleaning fastness, determination of the capability of dyed textiles to withstand → Dry-cleaning. A bag of cotton twill containing 12 steel discs and the test sample is treated for 30 min in the appropriate machine at 30°C in 200 ml tetrachloroethylene (or other solvents) without added reagent, then spun and dried at max. 65°C. In commercial dry cleaning consideration is also given to the following fastnesses: →: Fastness to: Stain removing, Organic solvents, Water spotting, Ironing, etc.

Dry-cleaning machines, various models in long drum (industrial scale) or high drum (cabinet) design. Dry-cleaning machines consist of:

1. Cleaning system (perforated cylindrical cleaning drum with paddles, cleaning cycle (partially reversible), spin cycle, pump cycle via needle traps and filters, with solvent tank).
2. Drying system (air is drawn through the outer drum via heating/cooling radiators for the evaporation and recovery of the solvent contained in the hydroextracted dry-cleaning load).
3. Distillation system (distillation apparatus, condens-

er, water separator, distilled solvent tank) for the regeneration of the soiled solvent. Different designs for chlorinated hydrocarbons, fluorinated hydrocarbons and petroleum hydrocarbons. So-called cold units (cleaning and fresh air drying in separate systems, manual unloading-reloading) are used for petroleum hydrocarbons. So-called hot units are used for chlorinated hydrocarbon and fluorinated hydrocarbon solvents. In these, the goods for dry-cleaning are automatically passed through the entire working process including drying. Drying method: for chlorinated hydrocarbon machines, circulatory flow drying with partial fresh air drying. For fluorinated hydrocarbon machines only circulatory flow drying in closed machine systems due to the high volatility of the solvents. The operating cycle is always controlled by an automatic programme; duration: 20–30 min., cleaning incl. drying (hot units). Use of activated carbon devices to recover the solvent in the adsorption process serves a) to remove exhaust air which is free of solvents, (statutory directive for air pollution control) and to reduce solvent loss; b) particularly with fluorinated hydrocarbon installations to maintain a closed drying and recovery cycle, where work does not occur in a vacuum.

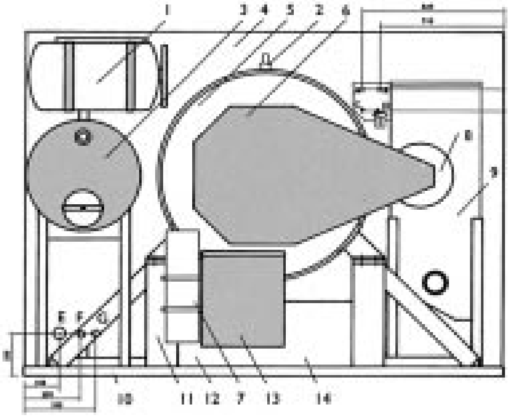

Fig. 2: Rear view of the HC-sol.
1 = rotating filter; 2 = door lock; 3 = distillation apparatus; 4 = front wall; 5 = drum; 6 = V-belt guard; 7 = collecting bin; 8 = drive motor; 9 = settling tank; 10 = collecting basin; 11 = machine stands; 12 = distilled solvent tank; 13 = needle trap; 14 = operating tank; A = compressed air; B + C = water supplies; D = maintenance unit; E = water run-off; F = condensate run-off; G = steam supply.

The use of petroleum fractions in new-style machines is experiencing a revival, e.g. MSG HC-sol with Shell hydrocarbons (Shellsol D60 S or T) or Exxon (Actrel Dryclean 56 or Isopar H). The principle problem when using pure hydrocarbons as textile drycleaning agents is their flammability and therefore the risk of explosion, which led people to switch to halogenated hydrocarbons at one point. The HC-sol machine (see Figs. 1 and 2) has the following three advantages in relation to this:

- Operating temperature is below the flash point (71°C);
- Operating mode at low pressure, i.e. pressure is less than 1 bar (e.g. 300 mbar) in the cylindrical cleaning drum during the drying process;
- Air-tight drum.

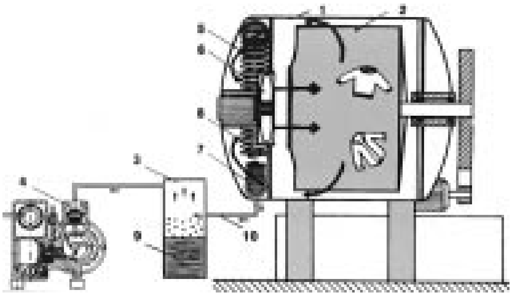

Fig. 1: Design of the HC-sol (MSG).
1 = outer drum; 2 = inner drum; 3 = collecting bin; 4 = vacuum pump; 5 = heating coil; 6 = exhaust fan; 7 = cooling coil; 8 = lint trap; 9 = solvent; 10 = condensate run-off.

After the loading door has been pneumatically sealed, the drum is evacuated. If a leak or defect prevents the necessary vacuum forming, this is indicated and the programme is interrupted. Filling the machine with solvent, cleaning, solvent discharge etc. takes place at temperatures well below the flash point. During the final stage of the hydroextraction, evacuation of the drum begins and the radiator is heated up. In the evacuated drum, the remaining air is now circulated and heated. The solvent expelled from the clothing condenses on the walls of the tank and on the cooling coil and is continually extracted. Drying can take place above the flash point without posing a risk in the evacuated drum. The vacuum also reduces the boiling temperature of the solvent by approx. 50°C, enabling gentle drying. The radiator is switched to cold water throughput for cooling, the ventilation cools down the goods being treated. The drum can be unloaded after airing.

Dry-cleaning – organisational procedure,

1. Receipt of goods and tagging with identification marks.
2. Textiles, leather and fur goods, as well as details concerning their resistance to dry cleaning are checked, and the appropriate treatment method is allocated.
3. Brushing.
4. Sorting according to type of material (quality, colour).

5. Preliminary treatment with spotting agents for stain removal.
6. Machine dry cleaning (basic treatment).
7. Appearance and shape of cleaned goods is restored by e.g. ironing, steaming.
8. Final inspection.
9. Collation of orders and preparation of bills/invoices.
10. Despatch.

Dry-cleaning problems Of the approximately 8000 dry-cleaning companies in the Federal Republic of Germany, in 1990, 1500 of those companies made up 80% of the turnover, while a further 4000 companies accounted for only 10% of the turnover. Of the 100 000 tonnes per annum of tetrachloroethylene used in Germany, only 15 000 tonnes per annum were used by the dry-cleaning companies for clothing. Tetrachloroethylene (perchloroethylene) may cause cancer in rats, however it is not the tetrachloroethylene, but the epoxide formation in the rat's metabolism which can be carcinogenic if the oxygen metabolism is exhausted. The question as to whether this metabolism is specific to rats and to what extent it may be applicable to humans still remains unanswered.

In laundries, alternatives to dry-cleaning in aqueous systems are being looked into. When clothing is used, foreign substances present in the environment inevitably come into contact with the textile. The longer the garment is used, the more the protective effect in particular is lost. The textiles are able to be permeated by those substances against which they are intended to provide protection. They become increasingly impermeable to water vapour, i.e. perspiration. Body temperature, well-being and performance become impaired. Cleaning processes ensure that such deposits are removed again. Cleaning processes involve aqueous treatment methods (laundering) or solvent treatment (dry-cleaning). This results in emissions. In laundering, this means predominantly pollution of the washing water as a result of the cleaning chemicals and soiling which has been removed; in dry-cleaning, these are solvent emissions in the air and accumulation of distillation sludge which needs to be disposed of as special category waste. Laundering and dry-cleaning are therefore being put increasingly under pressure from requirements by the laws and regulations governing environmental protection. Extra costs are also incurred in fulfilling these requirements. The main concern in laundering is the Water Resources Act (WHG) and the appendices based on § 7 for framework regulatory provisions, and for dry-cleaning, in addition to this regulation, the Federal Clean Air Act (BImSchV) and the 2nd ordinance relating to this (2nd BImSchV). Environmental liability and environmental penal law must also be taken into consideration. The polluter-pays principle in environmental law is significant here, i.e. the person causing damage to the environment must make good the damage regardless of blame. Procedures therefore have to be assessed as regards their potential to cause damage and any resulting charges.

Fundamental requirements of that cleaning process, which is in actual fact a recycling process for a textile which can be reused rather than scrapped, are that a garment is produced which is completely hygienic, free from harmful substances, clean and able to be completely used again. Cleaning technology is faced with a conflict of aims between the fulfilment of the environmental directives and the maximisation of cleaning results in order to be profitable. One factor which is a decisive element in achieving profitability is the retention of fibrous substances, as in addition to ensuring that there is sufficient removal of dirt, this also determines the life-span of the recyclable textile.

These cleaning processes are particularly significant if industrial or commercial processes are used where hazardous substances are involved. Penetrative hazardous substances can pose a risk to health. In order to avoid risks of this type to the workers, e.g. in the form of dermatitis and allergies, it is not only important to make a suitable choice of textile, but more importantly to remove these substances as far as possible, to avoid re-deposits on other textiles which are washed together and to achieve this under conditions which pose the minimum risk to the environment. An essential prerequisite for this in addition to optimising cleaning technology is an optimal adaptation of the textile to use in the trade concerned and the necessary care treatment. The correct care treatment is determined by the properties of the textile goods, such as fastness and cleanability, the nature and severity of the soiling compared with how successfully it can be removed, the requirements of the cleaned textile (flame resistance, permeability to water and dust) and in recent years increasingly by the nature and severity of the soiling with respect to environmental impact.

When deciding between laundering or dry-cleaning a garment, a whole range of issues need to be considered: the cleaning process is determined in the first instance by the properties of the textile (is wet treatment possible or not?), and secondly by the nature of the soiling (is the soil water or solvent soluble?). It is only possible to remove a large proportion of water-soluble soils sufficiently by laundering, whereas bitumen or similar highly viscous mineral oil products can only be sufficiently removed using a solvent treatment.

The Table gives a list of selected soils and whether they can be removed by cleaning or laundering. If a type of soil is poorly removed by one process, this is also true of any hazardous substances present in this type of soil. Although laundering chemicals contain substances which pollute effluent waste, they can later be safely removed by a communal clarification plant. Laundering can therefore be regarded as a polluting

process, but which does not affect the quality of the surface water or groundwater. It is therefore not usually necessary to treat the effluent or exhaust air, or if it is necessary, then only in ways which are simple to implement (pH, temperature). Mineral oils and fats in the form of restricted pollutants according to local authority regulations and “hazardous substances” according to § 7a come almost exclusively from soiling, with the exception of AOX compounds (chlorine compounds) which may also arise as a result of the technical procedures (chlorine bleaching).

Dry-cleaning with chlorinated solvents basically requires emissions to be minimised due to toxic properties which pollute the air and water. The high risk of endangering groundwater together with the high density and low water-solubility result in considerable risks in the event of an accident. In contrast to laundering, dry-cleaning chemicals and soil have to be extracted in concentrated form through the distillation sludge as special category waste and are not passed into municipal sewage. The 2nd BImSchV, which has already been referred to, or the amended version and the appendices to the “Dry-cleaning” and “Laundries” framework regulations specify the necessary work involved.

a) In the amendment to the 2nd BImSchV, a ban on tetrachloroethylene was originally envisaged for 2002. In the new edition of April 1990 this ban was withdrawn, but the limitations on levels of emissions in adjacent rooms of 0.1 mg/m^3 has been retained. It is of no importance here whether the source of the emission is the cleaning process itself or subsequent procedures (e.g. discharge from the textile).

b) “Hazardous substances” are to be minimised in accordance with § 7a WHG in line with the state of the art before introducing the effluent into the sewerage system. This state of the art is stipulated by standard limits and discharge pollution maxima in the appendices to the framework regulations.

Dry-cleaning processes These are subdivided according to the amount of dry-cleaning detergents applied:

I. Low-charged process: dry-cleaning detergent concentration 1–10 g/l liquor, rinsing bath necessary in exceptional circumstances.

II. Medium-charged process: dry-cleaning detergent concentration 10–20 g/l liquor, rinsing bath necessary for mercery and aftertreatments.

III. Super-charged process: dry-cleaning detergent concentration 20–40 g/l liquor, rinsing bath necessary.

Distinction is made according to the technical processes required:

- one-dip process,
- two-dip process,
- three-dip process,
- multiple dip process,

which generally need to be further subdivided into stage processes. A stage refers to a process phase in which the composition and/or circulation of the liquor is altered. The “no-dip process” is unique; this is carried out with a cylindrical cleaning drum which operates without dipping and continually applies filtered solvent to the goods before immediately draining this away (generally used for badly soiled, hard-wearing goods). Other processes include emulsifier processes, steam spray processes etc. which use a large proportion of free water which continues to be evaporated and discharged during the cleaning process via a blower (only for hard-wearing goods). These processes take approx. 20–30 min. in general for 1 to 2-dip processes.

New processes are developed by replacing halogenated hydrocarbons with those which are non-halogenated (→ Dry-cleaning solvents). In the cleaning process, the use of non-halogenated hydrocarbons creates more problems than tetrachloroethylene, for example. Due to the lower steam pressure, drying processes are more costly and due to the flammability of the products, each thermal treatment must take place in inert gas or in a vacuum for safety reasons. Regenerating the solvent in the dry-cleaning machine is more difficult with high boiling-point products, as pollutants from textiles and flammable substances such as ethanol from auxiliaries with boiling points below that of hydrocarbon solvents have to be separated in the same way as pollutants with boiling points higher than those of the solvents. With tetrachloroethylene, it can be assumed that, with the exception of water, the pollutants which have entered the solvent from the textiles and auxiliaries have a higher boiling point than the solvent itself and therefore it is possible to separate them off in a simple batch distillation as residue. Substances separated off by distillation must be disposed of as hazardous waste in the case of both tetrachloroethylene and hydrocarbon solvents. However, disposal by incineration of hazardous waste is simpler with halogen-free residues as it is possible to avoid flue gas being produced chemically.

Hydrocarbon machines dry the dry-cleaned textiles in a closed cycle, similar to tetrachloroethylene machines. Exhaust air drying systems are standard in some countries, although not in Germany. As the drying process is more difficult when using hydrocarbons (which have a high boiling point), the drying system needs to be designed differently from that of tetrachloroethylene machines in terms of heating capacity and air circulation. To achieve a drying time which is technically feasible, drying must take place at a temperature of above 60°C, as steam pressure is too low below this temperature. The drying temperature is therefore well above the flash point. In order to avoid the formation of explosive air/solvent mixes, work therefore takes place either in a vacuum or with nitrogen.

With a Transferon system, the interior of the machine is rinsed with nitrogen after loading. This comes from a separating plant which by means of an adsorption process produces nitrogen from air with a residual content of 2% O_2 which is used for making the system inert. The oxygen content in the machine is continually monitored. As an explosive mixture is no longer possible at an oxygen content of less than approx. 12% with hydrocarbon vapour with a lower flash point of approx. 0.6% and with an upper flash point of approx. 6%, the machine is operated at approx. 6%, i.e. half the limit value. The machine cleans after the air-nitrogen exchange in a cold state due to the nitrogen and automatically activates the drying process. The inert gas in the machine is heated by a steam-heated gas heater to approx. 90–95°C, passes through the drum with the textiles and takes the solvent vapour with it. This is condensed on the refrigerant vaporizer of a heat pump and removed from the cycle. The circulating gas then flows through the condenser, i.e. the warm side of the heat pump, and thus ensures effective heat exchange. The drying time is approx. 30–40 min.

Rewatex uses vacuum technology in its hydrocarbon machine. After loading the machine, the door is pneumatically sealed. Before the program begins, a leak test is performed (brief evacuation of the drum followed by reventilation). The following steps – filling with solution, cleaning, solvent run-off, pre-heating the heating radiator, hydroextraction, take place below the solvent's flash point. In the final stage of hydroextraction, evacuation of the drum begins, the heating radiator is heated up. When an absolute pressure of 500 mbar is reached, hydroextraction is interrupted, the drum is bled until the correct operating pressure is reached. During the drying process, the solvent expelled from the clothing condenses on the walls of the tank and the cooling coil and is continually extracted. The boiling temperature of the solvent is reduced by approx. 50°C as a result of the vacuum, and this enables a gentle drying to take place. For cooling, the heating radiator is switched to cold water throughput and a fan cools the goods down. The drum can be unloaded after airing.

Dry-cleaning regulations The fundamental legal points concerning operation of dry-cleaning equipment are protection of labour (e.g. Technical Regulations for Hazardous Substances, TRGS) and protection of the environment (e.g. the Federal Clean Air Act, BImSchG). Permission, licence, or authorization to operate hydrocarbon solvent dry-cleaning equipment is not necessary. The machines must meet the generally accepted engineering standards (a.a.R.d.T.), e.g. the regulations guiding protection of the environment and the regulations for the prevention of accidents in line with the employer's liability insurance association, DIN and other standards applicable in Germany. "Approved safety" labels are available, but are not compulsory. Authorization in accordance with the Federal Clean Air Act under the 4th BImSchG is only compulsory for emissions above 25 kg/h during the drying stage. According to the state of the art, limit values of the technical directive on air must be complied with. Appendix 40 of the regulatory provisions concerning effluent must be complied with due to the Fundamental Principles of the Laws Relating to Water Resources. For environmentally problematic substances such as hydrocarbons, only the generally accepted engineering standards are applicable. Hydrocarbon cleaning equipment should be placed in a collecting basin. The "Order governing Flammable Fluids" (VbF) is applicable to the reservoir function of the dry-cleaning equipment not to its operation. Basically, the numbers present in a plant are not storage containers in this sense and are therefore not subject to the regulations for public permits.

The situation for de-aromatized hydrocarbons (→ Dry-cleaning solvents) is detailed below.

I. Industrial health: according to TRGS 420, a so-called tolerance level is determined from the saturation concentration divided by the max. work place concentration (MAK = threshold limit value). For hydrocarbon compounds, working standard values (ARW) are given as a basis in accordance with TRGS 404. For de-aromatized hydrocarbons, this value is 350 ppm. De-aromatized hydrocarbons do not irritate the skin according to the OECD test procedure (4 h semi-occlusive). However, nitrosamines which have conclusively been classified as carcinogenic in tests on animals can form in an oxidizing atmosphere. A particularly oxidizing atmosphere arises in the atmospheric drying working area, for example.

II. Industrial safety: The primary danger when dealing with hydrocarbons is the risk of explosion and fire. As long as the working temperature is 10–15°C below the flash point, there is no risk of explosion from steeping baths. The same applies to spray applications with pressure of up to 2 bar at the nozzle exit with diameters > 2 mm (current safety level). Products with a flash

Tab.: Effluent parameters for solvents.

point of approx. 99°C and working temperatures of over 80–85°C which are watered down by more than 10% in the fluid phase are rendered sufficiently inert. When drying garments which have been cleaned and rinsed, it is compulsory and sufficient to comply with the regulations for the prevention of accidents (VGB 24) and the “Regulations concerning calculation of necessary ventilation for cabinet and continuous flow dryers”. Exhaust fans should be designed in accordance with VDMA 24 619.

III. Air emission: The quantity discharged into the atmosphere per unit of time is significant in the reduction of exhaust air. When comparing the evaporation losses from open baths, all substances with low vapour pressure must naturally separate off sufficiently. A comparison between hydrocarbons and chlorinated hydrocarbons at working temperature indicates lower emissions by a factor of 100.

IV. Effluent: Effluent parameters for solvents are given in the table. Compliance with appendix 40 of the framework regulatory provision governing the effluent when using de-aromatized hydrocarbons is unproblematic. These substances are subject to microbial decomposition, although this is not significant at operating temperatures above 45–50°C (water solubility of hydrocarbon compound 180–210°C with 20% aromatic compounds = 42 mg/l, with 0.1% aromatic compounds = 5 mg/l). The concentrated aqueous extract from hydrocarbon dry-cleaner agents is neither toxic to fish nor bacteria toxic, and the products have therefore been assigned 0 on the water pollutants toxicity scale (WGK). As isoparaffin is less biodegradable, it is classed as WGK 1; white spirits containing aromatic compounds come under WGK 2. When cleaning using hydrocarbons, it is advantageous not to use surfactants and dissolving agents especially oil separation in a gravitational separator in accordance with DIN 1999, which means that pre-dilution and separation plants at the end of the process (coalescence filters, flocculation plants, membrane filters etc.) are not generally necessary. Tried and tested three phase decanters (centrifuges) are suitable for recycling (longer serviceable life).

V. Waste management and recycling: Hydrocarbons obtained from mineral oils are waste oils according to § 5 a of the Refuse Disposal Act. They cannot therefore be disposed of as industrial refuse. The assignment to recyclings bowls depends to a large extent on whether the re-processor has suitable equipment and operating permits. Hydrocarbon dry-cleaning agents can be used in association with the “contaminated oils” as category 2 waste oil. As, in dry-cleaning, dispersed water contents of 10–12 % are generally sufficient to remove water-soluble stains and to achieve surface activity but also by making inert by steam it is possible to economically dispose of all the fluid in the cleaning bath (hydrocarbon solvent + water) without the need for any in-house effluent treatment/processing. With quantities below 500 kg/year, it is not necessary to provide regular proof on the waste disposal site in accordance with the "specimen regulatory provision for the implementation of §§ 11 and 12 of the "Waste Disposal Act" and the "Regulations for monitoring wastes and refuse" of 3.4.90. Hydrocarbons, including the "contaminated oils" or their distillation residues, can be physically recycled if they occur in a sufficiently large quantity in a carbon or oil residue hydrogenation plant as long as they are pumpable. Mineral oil products containing chlorinated paraffin in particular can be disposed of in this way. For thermal recycling, authorisation in accordance with the Federal Clean Air Act and separation treatment in the context of mineral oil excise duty is necessary (source: Hertlein).

Dry-cleaning solvents These are generally classified into two groups:

1. Flammable solvents: light petroleum distillates, white spirit, Stoddard solvent, and heavy petroleum spirit.
2. Non-flammable solvents: chlorinated hydrocarbons such as trichloroethylene, tetrachloroethylene (perchloroethylene), 1,1,1-trichloroethane and trichlorotrifluoroethanes (solvents R11 and R113).

The general properties of halogenated hydrocarbons have been responsible for their wide application in commercial dry cleaning. They offer the following advantages:

- non-flammable;
- superior cleaning power compared to petroleum distillates;
- better solvents for fats (animal, vegetable, mineral);
- good solvent action towards asphalt, resins, oil paints, paraffin, pitch, tar, waxes, etc.;
- no fibre damage (exception: polyvinyl chloride = PVC).

Their disadvantages are:

- various synthetic resins (e.g. in zip fasteners, buttons, finishes, etc.) are partially soluble;
- in the presence of aqueous moisture, they promote the corrosion of certain metals;
- trichloroethylene has a certain solvent action towards cationic (basic) dyes as well as some disperse dyes;
- they have properties which are injurious to health: suspected carcinogens.

In the draft of the German 2nd Federal Emissions Protection Law, which has been in force since 01.03.1991, the use of tetrachloroethylene for textile dry cleaning has been permitted without any time limit (→ Dry-cleaning problems) and the chlorofluorocarbons (e.g. R11, R113) were banned. On the other hand, the Federal Government has been directed by parliament to seek suitable alternatives in order to reduce as far as possible the usage of organohalogen compounds. As more acceptable substitutes, especially for cleaning delicate textiles which were formerly cleaned with chlorofluorocarbons (CFC's), higher boiling point hydrocarbons offer a possible alternative. Other possible products are currently not available for large-scale industrial use. In the search for alternative solvents, it must be assumed, in principle, that all organic products which have not been fully halogenated are flammable. An important criterion for the suitability of alternative solvents in dry cleaning is the possibility for hazard-free handling outside the machine. This provides a good indication as to whether the solvent is compatible for use by operatives employed in the dry cleaning industry under acceptable circumstances and that, in the case of flammable products, the flash point is so high that the product can be handled safely at ambient temperatures. Moreover, if the product leaks or spills into the environment, in the event of accidents, it should be less harmful than tetrachloroethylene which is highly persistent. Adequate protection against the risk of fire or explosion is provided if the flash point of the product lies above 55°C and it can therefore be classified under Class A3 for flammable liquids. This flash point requires that the product has a boiling point of approx. 180°C.

Dry crease recovery angle → Crease recovery angle; a measure of the tendency of a fabric to crease when dry.

Dry cross-linking → Cross-linking of cellulose in a de-swollen, i.e. dry, state with resin-finishing agents in the presence of resin-finishing catalysts at elevated temperatures (120–190°C) within a few minutes or seconds (→Resin finishing). Practical significance as dry cross-linking process with methylol compounds in the presence of acid-active catalysts, such as the classic curing process, the →: shock-cure process and the permanent press process. Alkaline dry crosslinking processes are rarely used. The most important is the classic curing process with co-application of latent acid catalysts such as ammonium salts (e.g. ammonium nitrate) or metal salts (e.g. zinc nitrate, magnesium chloride). Procedure: impregnate (pad), dry at 110–130°C (stenter), cure 140–160°C, 5–2 min in curing machine, where necessary wash off/apply softener. Finishes obtained: high dry crease recovery angle, good wet crease recovery angle, excellent shape retention and dimensional stability, reduction in tear and abrasion resistance commensurate with the dry crease recovery angle improvement.

Dry distillation → Fibre identification by dry distillation.

Dry finish,

I. Gen.: → Final finishing.

II. Specifically relates to a dry finish applied to garments following dry cleaning; it is used as a final finish for suits, wool garments, overcoats, skirts, which have become limp through wear and from the effects of dry cleaning, especially those items which have been finished with solvent-soluble finish (softener). Application of a dry finish has the effect of enabling garments to stay clean for longer.

III. Term used for the mechanical processing of textile fabrics (→ Dry finishing of fabrics), e.g. opening, brushing, decatizing, embossing, calendering, polishing, pressing, pleating, raising, shearing etc.

Dry finishing of fabrics The fundamental modification of handle and quality of fabrics is carried out using → Wet finishing procedures appropriate for each type of goods. The processes of dry finishing, on the other hand, have the task of further developing and refining the effects achieved by wet finishing. The appearance and handle of the finished goods can only be fully achieved by a combination of wet and dry finishing. Although the sequence of operations in dry finishing to achieve a finish ready for make-up is to some extent a standard one, involving the standard processes of shearing, pressing, shrinking, decatizing, at least in the case of high-volume smooth finish worsteds, which are compatible with continuous processing systems (Fig. 1). The stages in the dry finishing process or the sequence of operations require constant review, due to factors such as fashion trends. Dry finishing not only touches on the latter stages of the fabric finishing routine; specific surface finishing measures such as singeing, emerizing, brushing or raising for quality enhancement may also be applied to cloth in the dry state during pretreatment.

Apart from singeing, all visual effects forming part of the surface finishing of fabrics are achieved by mechanical action on the fibre. While the results of shearing and raising are mainly tactile, the characteristics achieved by lustre or glazed finishes (e.g. by Polrotor machine) or raising are largely of a visual nature. Whilst the skin provides sensory perception of the complexities of the handle of the fabric, the eye when examining a surface perceives a specific area by means of its two-dimensional matrix of light-sensitive elements. By irregular displacement of this area across the whole surface in rapid succession the optic nerve uses comparison to form an overall image of the evenness or unevenness of the textile surface of the cloth. The optic nerve is working in the same way as a very complex computer, which can take in certain physical characteristics at high speed and relay to the consciousness highly condensed data such as matt, lustrous, silky, sandy, granular, rough, level, unlevel, patchy, etc. as visual references. Such perceptions of the eye are augmented by the tactile aspects experienced through the skin (and possibly also acoustic perceptions of the ear), such as hard, soft, full, lean, limp, crisp, etc., to form impressions of the material which predominantly derive from surface finishing.

The fact that no unified sequence of operations is found in finishing machines or processes is linked with the fact that individual stages (dry and wet treatment) often overlap. The fabric, which itself is often used as the guide for the sequence of the treatment stages, can often pass through the same machine several times in different stages of its production (e.g. surface finishing in the form of wet and dry raising). The DIN 61 704 standard is suggested as a basis for sequential arrangement. In the case of appearance-related processes, which also include finishes such as wet brushing, the

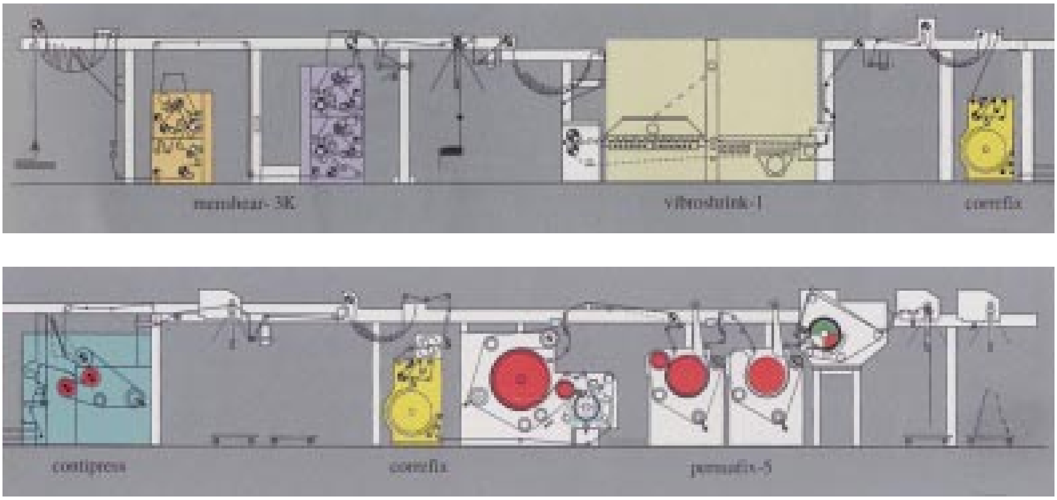

Fig. 1: Sequence of operations in a worsted smooth-finish range for wool fabrics (Menschner).

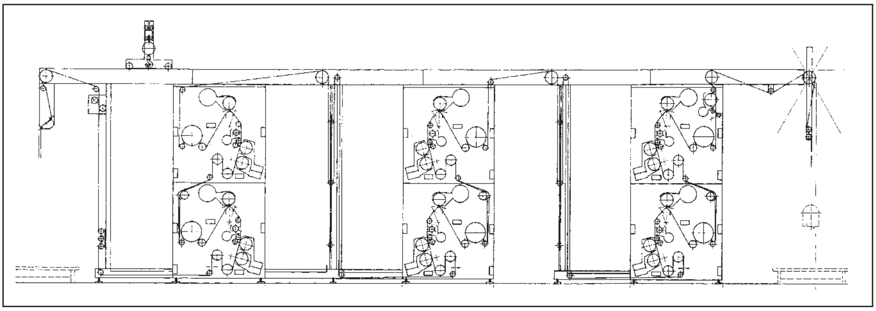

Fig. 2: Shearing machine by Sperotto-Rimar.

sequence suggested here could cause problems. Thus in the systematic arrangement of wool fabric finishing processes, the concept of surface finishing by mechanical means is only applied to the processing of dry goods (singeing, shearing, brushing, raising, emerizing, lustre finishing, raising), while wet raising and wet brushing are regarded as stabilizing processes, as drying is essential to this stabilizing process in order to achieve the texture retention (permanence) of the finish.

The sequence of operations for individual articles determines their passage through the dry finishing processes. The finishing manager coordinates and simplifies the flow of goods; this pre-planned flow should if possible not be interrupted, even if certain qualities are only required by parts of the production chain.

In this case it makes more sense simply to cancel (set to zero) the parameters relating to the processes which are not required, e.g. shrinkage without steam or low-pressure press. Any interruption requires stoppage and thus a reduction in efficiency. Interruptions also cause impairment of the finish, such as stop marks and similar. They also take up storage space and time and incur transport costs. Only an interrupted cycle through the whole range can ensure success. The machine line shown in Fig. 1 incorporates precautionary measures which ensure non-stop operation. Thus, for example, special fabric trucks and mobile cuttling units capable of setting down goods at several points contribute to uninterrupted operation. Stoppages are no longer required even for changing fabric rolls or trucks. Monitoring elements ensure the movement of the goods through all processing stations with the minimum of tension, and readjust the synchronization of travel.

As can be seen from Fig. 1 automatic weft straightening equipment (Correfix) is installed at various intervals, always before setting operations, e.g. before pressing, before permanent decatizing and/or before the final decatizing. Also of particular importance are the control and measuring stations, which monitor the moisture content of the goods. The fabric is dampened at certain points and a constant humidity is ensured through closed-loop control systems.

Machine lines such as this provide an additional advantage: the reject level in a continuous plant is re-

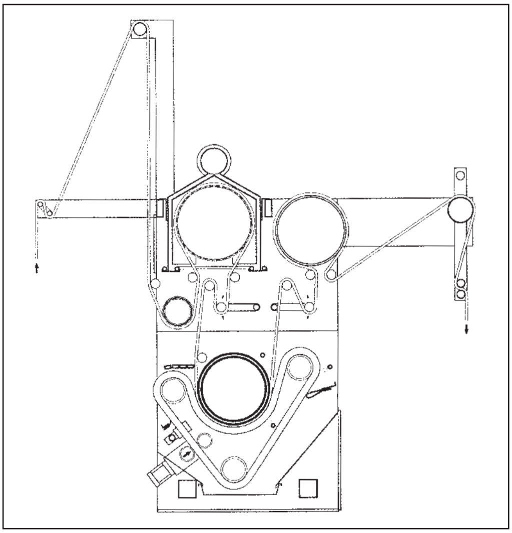

Fig. 3: Machine for the shrinking of fabrics (Sperotto-Rimar).

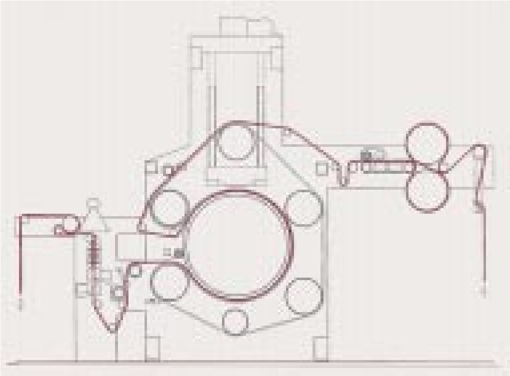

Fig. 4: Multiset decatizing plant by Sperotto-Rimar with finish similar to that achieved by batch decatizing.

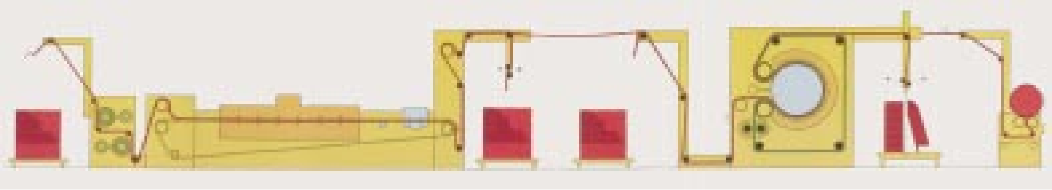

Fig. 5: Shrinking and continuous finish decatizing for wool fabrics (Sperotto-Rimar).

duced, as the functioning of a dry finishing range is more reproducible, whilst in a finishing plant with batch operation at all stages and which is subject to frequent human intervention, there are plenty of opportunities for faults to arise.

A classic dry finishing sequence for wool fabrics (continuous) could, for instance, be made up of the following processes:

- Shearing section (Fig. 2): for example, the back of the fabric is sheared once and the face twice to min. 0.1 mm shearing height.
- Pressing (Fig. 3), corresponding to the rotary press: sandwich systems are used here, in which the thickness of the fabric is reversibly established; subsequent batch decatizing stabilizes the thickness.
- Batch decatizing or equivalent continuous decatizing (Fig. 4) at 140°C using the parameters of moisture content and time.
- Shrinking on a perforated belt steam shrinking unit (with vibration) for relaxation of the fabric (Fig. 5).
- Finish decatizing (Fig. 5) for the removal of all finish characteristics not properly stabilized.

Dry heat fixation → Heat setting.

Dry heat setting and pleating fastness, resistance to dry heat, as is usually found with → Heat setting and dry pleating. → Sublimation fastness during heat treatment. The test sample is heated on both sides by contact heat for 30 s at 150°C, 180°C, 210°C or other temperatures, in a precision ironing press or Fixotest apparatus (Heraeus). Experience has shown that this test corresponds to hot-air treatment on a hot-air stenter at a temperature around 20°C higher. Unlike the DIN standards, the AATCC standards differentiate between the behaviour of dyed goods and prints under the effect of heat during finishing operations (In-Plant Test), AATCC 117-1974 and those during pressing (End-Use Test), AATCC 133-1973/74 in course of making-up or use. Three temperatures, 110, 150, 220°C are used for the End-Use Test. The temperatures for the In-Plant Test are in the region 163–218 ± 2°C.

Dry ice, carbon dioxide snow pressed into blocks (evaporation temperature –76°C), evaporates without melting, thus does not generate water when used. Cooling effect per kg double the strength of conventional ice (152 kcal).

Drying A process to free a textile material of moisture, thermal hydro-extraction. → Drying systems for textiles are based on, e.g. convection, contact heat, radiation, through-flow or combustion drying. In choosing the most suitable machine, consideration has to be given as to whether it will be used for the final drying stage only, or for the intermediate drying of material impregnated with dye liquors as well. The use of appropriate monitoring instrumentation and control systems is essential for the achievement of uniform drying and energy savings without overdrying and its negative effects on quality. More and more driers are now being provided with heat recovery systems for optimum economy.

Drying carriage in screen printing When working on a short printing table, using a drying carriage enables the printed pattern to be dried, avoids smearing of the underside of the stencil and produces sharper prints.

Drying chamber, (→ Hot air drying chamber, jet-drying chamber), drying chamber system in which the cloth is carried in a spiral path, print side upward, via guide rollers, used especially for the drying of printed piece goods. Operated by means of warm or hot air (60–110°C) or by means of jet drying.

Drying loft, hot-air chamber for printed fabrics. A distinction is made between airing lofts with drying temperatures of approx. 60–70°C and jet-heated drying chambers (see the following Fig.) which operate at higher temperatures (100–140°C) and which therefore enable shorter drying time.

Drying of textiles The aim here is to achieve preferential evaporation of the surface water and the water bound by fibre swelling (→ Swelling, water of) whilst still retaining the natural moisture content of the fibre. The loss of normal moisture content is due to the use of excessive heat and overdrying which generally has negative consequences for the quality of the material. For this reason, efforts have been made to achieve a more gentle drying technology, i.e. by giving consideration to the control of air movement and the control of heated air supply. Each intensification of these conditions (drier heat, shorter drying times) is made at the expense of the → Capillary water (i.e. the fibre's natural moisture content) and leads to brittleness, hardness and

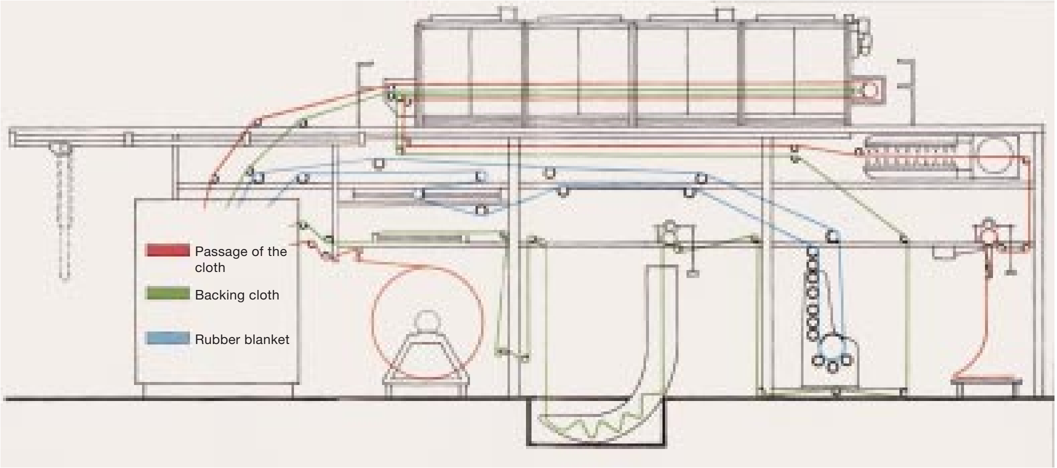

Fig.: An overhead drying loft to dry printed goods (red) and laundered backing cloth (green).

fibre degradation (losses in strength and extensibility). Drying performance may be increased through the use of higher air speeds, lower air humidity or more turbulent air movement in the drier. Drying is an increasingly important cost factor in textile finishing. Reductions in drying costs are possible by avoiding intermediate drying stages, by wet-on-wet application techniques, by giving a maximum mechanical → Water extraction treatment before thermal drying and by the avoidance of overdrying, i.e. drying only until the fibre's normal residual moisture content has been reached (use of appropriate measuring and control systems). →: Drying systems; Drying technology.

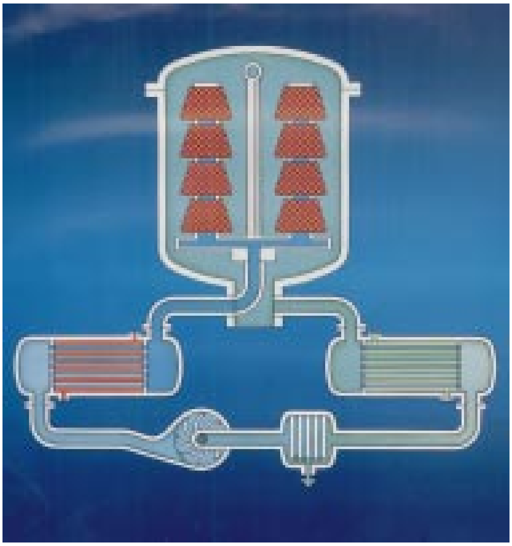

Fig.: Then yarn package drier.

Drying of yarn packages A mechanical → Water extraction (centrifuge, suction or pressure extraction) must be given before thermal drying. For hydro-extraction in the centrifuge, the yarn packages have to be taken off the material carrier and packed into a centrifuge basket (protection of rigid centres from distortion due to high G forces necessary). Alternatives: centrifuging of single packages with automatic loading. Suction and pressure extraction takes place on the material carriers (without repacking). Suction extraction is carried out in a vacuum extractor whilst pressure extraction is carried out in a closed vessel (e.g. in the dyeing machine itself). In rapid driers, warm air is blown through the packages on the material carrier after pressure extraction. The drying time may be reduced still further if drying is carried out in high pressure driers with overpressure (see Fig.). Vacuum drying offers a further possibility (two-phase drier), by alternately blowing partially saturated hot air through the packages and applying vacuum extraction to achieve a uniform residual moisture content (no risk of overdrying in this case, but the drying times are somewhat longer than in the high pressure drier). Another option is the use of RF driers after mechanical hydro-extraction.

Drying oils, e.g. linseed, wood, poppyseed, nut, sunflower oils. Consist to a large extent of linoleic and linolenic acids and to a lesser extent oleic acid. Due to the presence of predominantly unsaturated fatty acids with several double bonds,

$$CH_3–CH_2–HC=CH–CH_2–HC=CH–CH_2–HC=CH–(CH_2)_7–COOH$$

Linolenic acid

the drying power is at its most pronounced in comparison to ➝: Non-drying and Semi-drying oils. Of importance for oil sizing. (➝: Oxidation of oils; Oils).

Drying power A measure of the water absorbency of hand towels for surfaces to be dried (e.g. the body, crockery, glassware). The more quickly and completely the water is removed from surfaces to be dried, the greater the drying power. It is dependent on time (e.g. approx. 10 s for the drying of hands), pressure (approx. 3–6 kg pressure applied for drying), and the quantity of water (e.g. 30–50 g of hand towel fabric per g of body surface).

Drying reel in screen printing, obsolete drying device in screen printing, whereby the goods were hung from bars in loops to dry; slow air circulation from top to bottom.

Drying rigidity ➝ Drying stiffness.

Drying/setting stenter, for woven and knitted fabrics (especially with selvedge spreaders and expander rollers with adjustable angle of wrap) in nominal widths of 1200–1300 mm with 2–8 sections, speed range 1.6–160 m/min; special jet design (with two axial fans) with air circulation sections arranged in interchangeable design. Special evaporative capacity/section/h under normal conditions is 45 kg H_2O/m^2 with a nominal width of 1600 mm. Vertical warp run. Overfeed of the order of –15 to +50%. Total air volume may be controlled by adjusting the rotational speed of the exhaust fan depending on the goods to be dried. High jet exit velocity of max. 33 m/s, short heating-up times, short setting times.

Drying stiffness (Drying rigidity). The stiff handle of a textile caused by a phenomenon arising from the combined effects of a wet treatment involving movement of the material (e.g. washing in drum-type washing machines) and drying without movement. The disordered state of the textile surface produced by intensive mechanical action during washing becomes fixed when the material is dried without movement. This problem is particularly noticeable in textiles where softness and fluffiness are usually expected, i.e. textiles worn close to the body such as underwear, terry materials, diapers, nappies, etc. The problem can be avoided by drying in a ➝ Tumbler drier (movement of material) or by using ➝ Fabric softeners.

Drying systems Ever since textile fabrics, either as wovens or knits, have been cleaned and consolidated (relaxed) in pretreatment and coloured in dyeing and printing, they have been required to undergo subsequent finishing after such wet processing treatments. Drying is the stage between wet processing and dry finishing. The drying process has to be carried out in such a way that the consolidated state of the textile is maintained and set. Tension-free drying is therefore indicated when the textile fabric is required to withstand subsequent steaming treatments (pressing in garment manufacture) and washing processes (e.g. domestic laundering) without shrinkage. Drying may be regarded as a setting process to the extent that after removal of the surface and capillary water (de-swelling), the “enemy of hydrogen bonds”, i.e. water, is withdrawn during further application of energy so that the secondary valency bonds are locked into the polymer network in the state in which the textile material finds itself after drying.

Correct drying makes a significant contribution towards maintaining the quality of the material during finishing. It is not only the regenerated cellulosic fibres, but also the natural fibres, that exhibit reduced water inhibition values after e.g. repeated drying, which can be attributed to a change in the fibre structure. Drying is also one of the energy-intensive processes of textile finishing so that overdrying (during the drying operation) should, if possible, be avoided for this reason. Overdrying can be avoided through contact-free measurement of the residual moisture content of the textile as it leaves the drying machine.

Each type of fibre has its own natural moisture content, unique to that particular fibre, which must be maintained. If the moisture content falls below this limit during drying, then overdrying is said to occur. The residual moisture content of the material being dried is therefore used as a measurement parameter for the control of drying machines.

The various alternatives illustrated in Table 1 are available for heating textile driers. Direct heating with natural gas has become more and more widespread, even in textile finishing plants, as it is quick to reach operating temperatures, environmentally-friendly and adaptable. Gas jet burners represent a modern form of gas heating. For cost reasons, electrical heating on its own is only used in exceptional cases. Electrical heating does, however, find application in supplementary heating, e.g. for infra-red radiation. Two types of IR radiators are encountered in textile plants, bright radiators at a wavelength of approx. 1.3 µm and dark radia-

	% efficiency
superheated steam up to 180°C	**70**
hot water up to 180°C	**80**
oil circulation up to 270°C	**80**

hot air generators	**75**
electrical heating	**98**

Tab. 1: Efficiency (in relation to energy utilization).

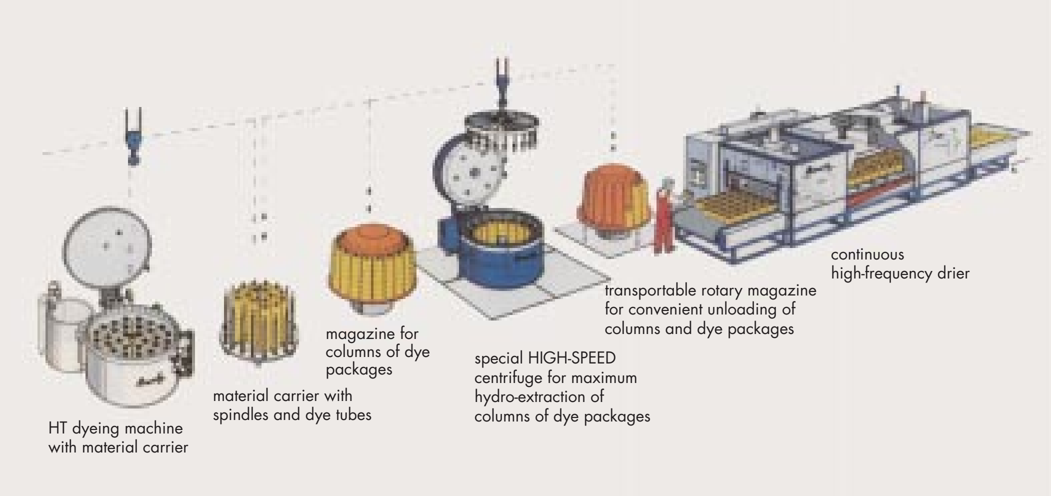

Fig. 1: Operating procedure of the Krantz-HF drying system for yarn packages.

tors at a wavelength of approx. 3.6 µm. The surface temperature of 750°C is high, with a correspondingly high risk of overdrying which is why IR-radiators are used for pre-drying in conjunction with conventional thermal drying systems. High-frequency driers (radio frequency, microwave and dielectric driers), see Fig. 1, are used for drying loose fibres (loose stock), tow, muffs, yarn packages, etc. The advantage of high-frequency drying is the short drying time and the environmentally-friendly process. The material being dried is transported continuously between condenser plates and subjected to a high-frequency alternating electrical field. The interior of the material is heated up rapidly to the evaporation temperature of water irrespective of the thickness of the layer. Driers of this type with wattages up to approx. 140 kW are available from several manufacturers. For knitted and woven fabrics, however, high-frequency drying is still uneconomic. An unconventional drying technique is the Remaflam process of Hoechst in which the material to be dried is passed through a mixture of methanol/water. After squeezing to remove excess, the evaporating methanol is ignited which results in subsequent evaporation of the water. A suitable machine for the Remaflam process is manufactured by Brückner.

Drying with hot air (convection drying) and contact heat are examples of conventional drying processes. Drying in hot air involves the following stages:

1st stage: heating of the material with temperature rising to the wet bulb temperature.

2nd stage: establishment of constant temperature conditions until all the water has been transported to the surface of the material. This wet bulb temperature is independent of the temperature and moisture content of the air used for drying. A high evaporative capacity is achieved with high temperature air circulation.

3rd stage: a further increase in temperature occurs when all the water has evaporated; at this point the material assumes the same temperature as the drying air.

In contact drying, e.g. on the cylinder drier, the fabric assumes the same temperature as the evaporating water

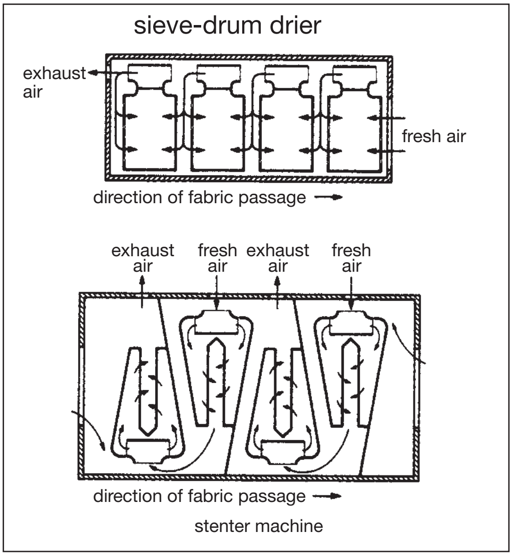

Fig. 2: Comparison between the air passage, based on the counter-current principle, in the sieve-drum drier and in the stenter machine.

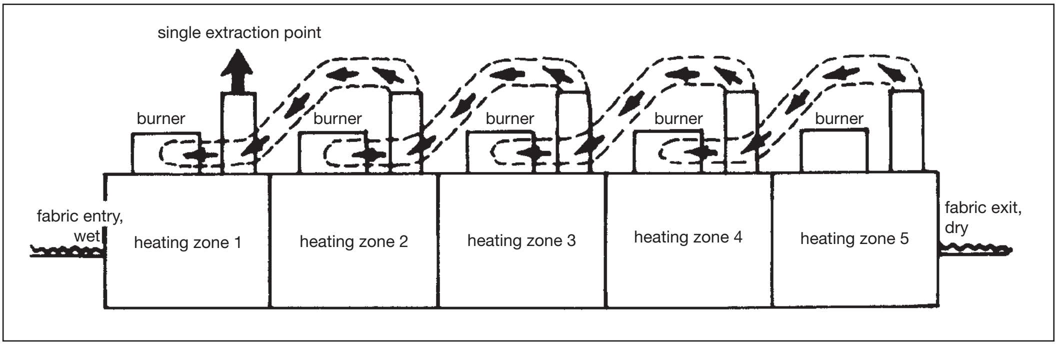

Fig. 3: Counter-flow principle in convective drying based on the “Rickbourg Wilson Flow-Through Progressive Recycling” method with only one exhaust air extraction point – material flow from left to right; energy and air flow from right to left.

in the second phase no matter how hot the cylinders are. As soon as the water has evaporated, a further rise in temperature takes place.

To achieve better heat utilization and more gentle drying of the material, some convective drying machines work on the multi-stage (Fig. 3) or the countercurrent principle (Fig. 2). In the first zone, the material is heated as quickly as possible; in the middle zones this temperature is maintained and in the last zone the temperature is lower. Moisture-laden air is extracted at the entry of the drier and fresh air enters at the exit end of the drier. This is not the case with the stenter, however, where several exhaust air extraction points (for the various drying sections) are provided.

The main focus of development in recent years has been directed towards achieving better insulation of driers, control of exhaust air moisture content and heat recovery from the exhaust air, in order to gain the most positive energy balance possible (Fig. 4). Exhaust air cleaning systems are based on adsorption, condensation or combustion of the pollutants present in the water vapour of the exhaust air.

Installations for drying loose fibres (loose stock) are designed as follows: the block of fibres from the packing press are torn apart from each other in an opener and the loose material is fed into the driers via a hopper feeder. Cabinet and chamber driers are batchwise systems with air flow from top to bottom or vice versa. The material lies on trays. Continuous drying is carried out in conveyor driers in which the fibres are transported through the drying chamber on an endless conveyor belt. In the sieve-drum drier (Fig. 5), the fibres are transported as a fibrous web over perforated drums through which hot air flows from outside to inside. Installations for drying card slivers, tops and tow: in contact driers the card slivers are transported over heated drums and in cabinet driers the sliver runs through the hot air on skeleton drums. Sieve-drum driers and contact driers (Fig. 6) are used for combed slivers. Installations for drying hanks of yarn must be fed by hand. For higher performance, continuous driers are available in which the hanks are passed slowly through a heated channel. Other systems use support rods, which are capable of rotating to some extent, attached to endless chains. In another model, the hanks are suspended individually on clamps and are transported through the drier on a chain. The point where the hanks are supported changes several times during their passage through the drier (Fig. 7).

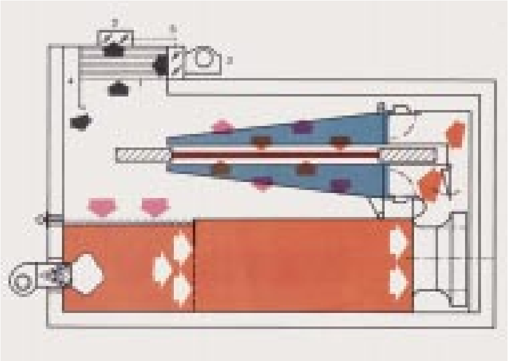

Fig. 8: Air passage in a Monforts single-layer stenter with heat recovery in the exhaust air ducting (Montex system). 1 = hot exhaust air; 2 = exhaust air ducting with flow control; 3 = fresh air intake with flow control (5); 4 = pre-heated fresh air flows to the gas heaters and is forced into the nozzles by the fans.

Installations for drying yarn packages (cheeses, cones, spinning cakes, muffs) are based on thermal or electrical systems. Tunnel driers are continuous machines: the packages run through the drying zone on a conveyor. For large packages, the yarn to be dried is wound off the packages and laid spirally on the endless conveyor of the drier. Rapid driers include various systems for drying yarn packages. A common feature of all these driers is the circulation of hot air through the yarn package from inside to outside by means of fans. In the so-called “half rapid drier” machines, the hydro-extracted yarn packages or insert-free packages are placed on perforated spindles. Depending on the model, these spindles are mounted on a carousel or a wagon. The spindles are connected to a hot air blower which causes the carousel to rotate; the transportable wagons with the wet material are wheeled into closed containers. The hot air now circulates through the packages from inside to outside. The flows of exhaust air and fresh air can be regulated. In addition to this air circulation, a further separate ventilation of the packages can take place from outside.

For yarn packages, replacing the dye tubes on to the drying spindles is too labour intensive. In rapid driers, the dye tube is therefore placed in the drying machine together with the yarn package. In basic rapid driers, the exhaust air is vented directly into the atmosphere which results in significant losses of heat. The other two systems are air-recirculation or air circulation systems. Even with air circulation driers, part of the air must be vented into the atmosphere after reaching a certain moisture content and has to be replaced with fresh air. In the pressure drier, the system is completely enclosed and under pressure (up to 8 bar). The moisture is extracted from the circulating air through a condenser and returned to the drying vessel again after reheating, whilst the condensed water is discharged to the drain through a separator.

The drying of woven and knitted fabrics is mainly carried out on stenters or tumblers. The means of heating such driers is, in each case, adapted to local requirements. Many driers are not only designed for drying but also for carrying out hot air treatments (heat setting, thermofixation of dyes, etc.). For stenters which, in addition to special driers, are often used for intermediate drying, the introduction of hot air (Fig. 8) is supplied in such a way that uniform drying across the entire width of the fabric is ensured. For extensible fabric qualities, stenters with “carrier nozzles” are used in which the fabric is supported on an air cushion. The stenter chains are individually adjustable in width throughout the length of the fabric passage.

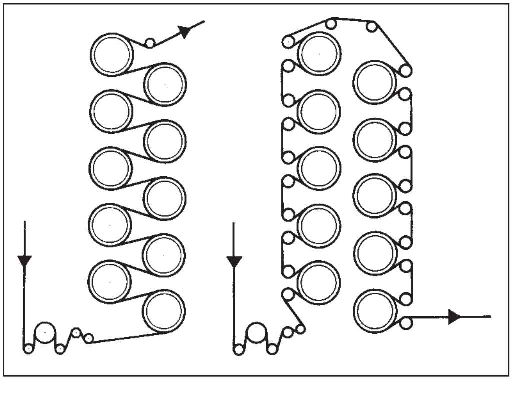

Fig. 9: Monforts cylinder drier with fabric contact on one or both sides.

Drum or cylinder driers are available in all sizes from units with just a few cylinders to driers with 40 or more. The latter can be divided into groups thereby allowing a stepwise increase in the degree of heating. With such driers, intermediate drying of fabric padded with dye liquor is possible without migration. Cylinder driers are less suitable for structured fabrics due to the flattening effect under tension. The cylinders are made of stainless steel and, under certain circumstances, may be coated with Teflon (e.g. for sizing machines, etc.). The fabric passage can be arranged so that either one or both sides are in contact with the cylinders (Fig. 9). In order to reduce the lengthwise tension on the fabric in cylinder drying, special cylinder drives have been developed, e.g. electrically controlled multi-plate clutches where the driving force can be predetermined, and slipping clutches or spring clutches instead of gears. When cylinder driers are used to pre-dry fabrics for subsequent dyeing, consideration must be given to the fact that, under certain circumstances, excessive temperatures can have a negative influence on the levelness and colour yield of the dyeing. The efficiency of cylinder driers can be considerably increased by installing the cylinders in enclosed housings and blowing hot air on to the fabric. An IR-preheater is often retrofitted to existing hot air driers when the performance is unsatisfactory.

For the intermediate drying of fabrics padded with dye liquors, only those systems with absolutely uniform air circulation both above and below the fabric are suitable. A selective change of the upper and lower air flow is a prerequisite for the gentle drying of sensitive fabrics. This applies particularly to knitted fabrics. These textiles are usually highly elastic and must therefore be dried without tension. For this purpose, either festoon driers or, for preference, short loop driers, horizontal driers or the efficient sieve-drum drier are used.

For tubular knitgoods, special driers which extend the fabric to the desired width and bring the knitted courses into parallel alignment are available. Warp-knit fabrics, or opened tubular knits, are often dried on the pin stenter which can also be used for heat-setting.

Drying principle	Advantages	Disadvantages	Comments
Contact drying (cylinder drier)	– Good heat transfer – Relatively low power consumption – Low consumption of heat energy – Low investment costs	– Losses in width due to lengthwise tension – Not a universal machine (rarely used for knits, unsuitable for pile fabrics) – Marking off with dyed fabrics – Smooth ironed effect occurs when fabric is almost dry – Creases are “ironed in”	– Used almost exclusively for intermediate drying – Only suitable for final drying of lower quality or non-sensitive fabrics
Convection drying	– Versatile application – With direct heating, some of the evaporated organic substances are burned off – No creasing problems – Problem-free shrinkage – Fabric width can be set in the stenter – Uniform and gentle drying especially with festoon driers	– High heat transfer losses with indirect heating – High energy consumption – Relatively large floor space requirements	– The stenter is the most frequently used machine of this type (fabric is set to the required weight during drying) – Energy consumption is highly dependent on machine design (e.g. counter-current passage of fabric and air, effective sealing). Float-on-air type driers rel. energy-efficient, tumblers are the least efficient
Combination of contact and convection drying	– Less floor space requirements compared to stenters – Relatively gentle and uniform drying	– Setting of fabric width more difficult than on the stenter – Relatively high investment costs – Unsuitable for pile fabrics – Marking off with dyed fabrics	– The most frequently used type of drier after the stenter
High-frequency drying (RF drying)	– Compact machine with high drying performance – Uniform drying even for material with a non-uniform moisture content – Gentle drying conditions – Energy requirement is precisely adjusted to the particular material	– High investment and running costs – For microwave systems, regulations for the protection of personnel have to be observed	– Particularly suitable for very sensitive thick materials
Infra-red drying	– Rapid heating of the material – low space requirement	– Surface drying – Higher energy consumption	– Used as a pre-drier for textile prints and some continuous dyeing processes

Tab. 2: Advantages and disadvantages of various drying systems.

Stenters with carrier nozzles are particularly suitable for such fabrics. Continuous tumblers are also used for knitted fabrics. For tubular knitted fabrics in particular, a tension-free drying process plays a decisive role in achieving shrinkage values below 2% in the finished fabric. Tumblers attempt to achieve shrinkage values below 5% with vibration and a convenient supply of air. When tubular knits are dried in the open-width, particular care must be taken to ensure that the paths from the feed roller to the chain are short. Clip stenters have proved unsuitable for knitted fabrics since they do not provide much overfeed and produce clip marks in elastic materials. By contrast, clips have proved more gentle to the selvedges of very wide woven fabrics. With knitgoods the edges must be bonded with a suitable adhesive and cut away again on exit from the stenter. The bonded edges are cut either beyond the pins (at the chain side when viewed from the pins) or, more generally, on the inside of the pins (i.e. towards the body of the fabric when viewed from the pins). It is helpful to equip the pin stenter with an additional open-mesh conveyor (e.g. composed of aramid fibres) which assists the fabric to pass through the drying zone without tension but at a specified width. The tumbler drier is used for drying individual knitted garments. The advantages and disadvantages of the most popular drying systems for textiles are summarized in Table 2.

Drying technology Textile materials are dried after each wet processing stage when further wet treatments have to be carried out on dry material. The fixation of dyes by dry heat (e.g. thermofixation) can also be carried out in suitable driers. The drying of textiles is to be regarded as a process of heat and mass transfer in which a quantity of heat Q is transferred from the drying medium (air) to the wet material. This state is characterized by the air-jet temperature t_{jet} and the prevailing partial vapour pressure of the air. This partial vapour pressure again determines the temperature t_{fabric} established on the fabric surface F during the free evaporation stage. The transfer coefficient α is a drier constant and is determined by the intensity of the air-jet flow, the air-jet geometry and the air-jet/fabric separation distance. The temperature difference

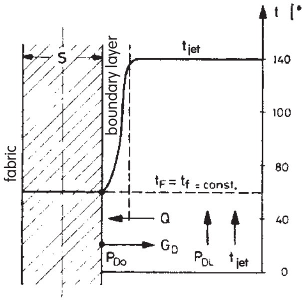
$$t_{jet} - t_{fabric}$$

determines the quantity of heat transferred. A mass transfer also takes place in parallel with the heat transfer which is due, of course, to the diffusion of evaporated water from the fabric into the drying medium (air). Like the temperature gradient during heat transfer, it has been recognized that the decrease in vapour pressure here

$$p_{DO} - p_{DL}$$

(together with specific constants) is decisive for the quantity of water evaporated G_D in unit time (p_{DO} = vapour pressure at the fabric surface; p_{DL} = partial vapour pressure in the drying stage).

In the stationary state, a corresponding quantity of water G_D is evaporated by the quantity of heat Q so that, by including the heat of evaporation r of the water, the heat and mass transfer can be compared (Fig. 1). (Strictly speaking, these mathematical relationships only apply to the so-called first drying section).



(1) Heat transfer : $Q = F\alpha\,[t_{jet} - t_f]$

$$\parallel$$

(2) Mass transfer : $[r]\,G_D = F\frac{\beta}{R\,T}\left[P_{Do} - P_{DL}\right][r]$

(3) $G_D = \frac{Q}{r} = \frac{F\alpha}{r}\left[t_{jet} - t_f\right]$

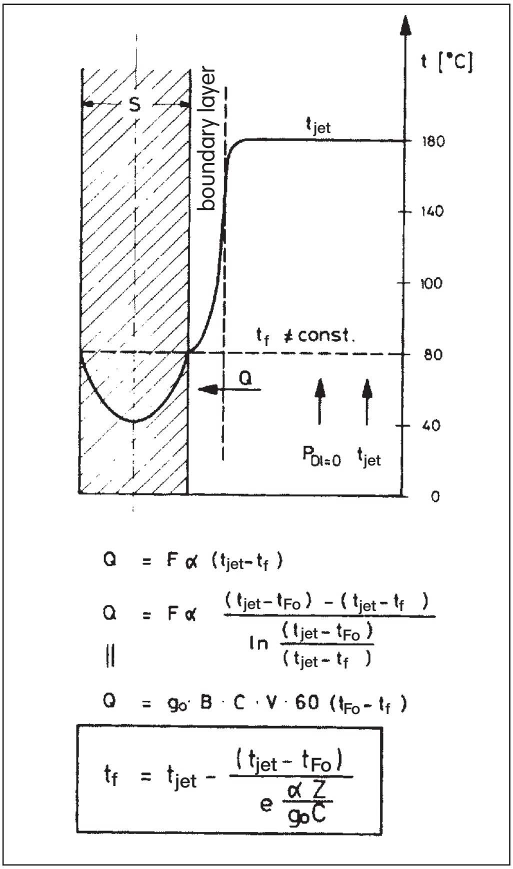
Fig. 1: Heat and mass transfer during drying. The fall in temperature of the circulating air in the laminar boundary layer region to the wet-bulb temperature should be noted here (source: Monforts).

During the thermofixation of dyes, the drier constant α is also significant for the heat transfer (Fig. 2). An important criterion here is the heating of the fabric to the thermofixation temperature and to know the point in the hotflue at which the fabric has reached its target temperature = air-jet temperature. After reaching this point, the fabric must remain at this temperature for a certain period of time in order to allow the dye to diffuse into the (polyester) fibre.

Two process variants are used in practice for the thermofixation of dyes:

1. Drying of the padded fabric (1st passage) followed by thermofixation of the dried fabric (2nd passage).
2. Drying and thermofixation in a single stage.

The heat energy required for drying and heating up the textile fabric is transported by the air. The impinging air is cooled through the evaporation and heating of water and leaves the surface of the textile at a lower temperature. The difference in temperature (Fig. 3) between the incoming and outgoing air flows is therefore directly



$$Q = F\alpha\,(t_{jet} - t_f)$$

$$Q = F\alpha\,\frac{(t_{jet} - t_{Fo}) - (t_{jet} - t_f)}{\ln\dfrac{(t_{jet} - t_{Fo})}{(t_{jet} - t_f)}}$$

$$\|$$

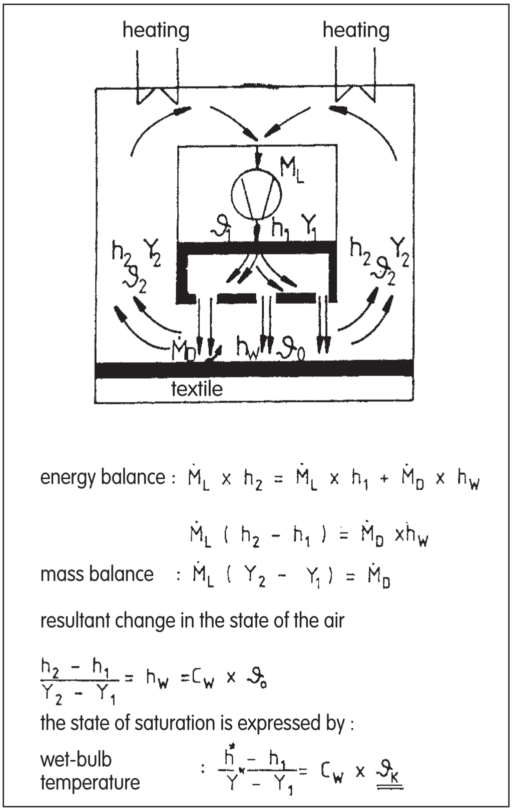
$$Q = g_0 \cdot B \cdot C \cdot V \cdot 60\,(t_{Fo} - t_f)$$

$$\boxed{t_f = t_{jet} - \frac{(t_{jet} - t_{Fo})}{e^{\frac{\alpha Z}{g_0 C}}}}$$

Fig. 2: Heat transfer during thermofixation (source: Monforts).

t_f = temperature of fabric at a certain point in time Z (°C),
t_{jet} = air-jet temperature (°C),
t_{Fo} = temperature of fabric before thermofixation (°C),
a = drier constant (kJ/m^2h °C),
Z = thermofixation time (s),
g_0 = weight of fabric per square metre (g/m^2),
C = mean specific heat capacity of the fabric (kJ/kg °C).

dependent on the quantity of evaporated water, the change in the temperature of the textile and the residual moisture content still present in the textile material. When the difference in temperature is zero, the textile is dry and already heated up. Unfortunately, however, there are a number of other factors which greatly reduce the accuracy of this procedure. Errors arise, for example, as a result of variations in the quantities of circulating air, poor air flow across the temperature sensors and malfunctioning or incorrectly set temperature regulators. These effects are easily transferred to the running fabric. Whilst the drying of a stationary textile material yields time-dependent temperatures, the temperatures of a running fabric are location-dependent (Fig. 4). The



energy balance : $\dot{M}_L \times h_2 = \dot{M}_L \times h_1 + \dot{M}_D \times h_W$

$$\dot{M}_L\,(h_2 - h_1) = \dot{M}_D \times h_W$$

mass balance : $\dot{M}_L\,(Y_2 - Y_1) = \dot{M}_D$

resultant change in the state of the air

$$\frac{h_2 - h_1}{Y_2 - Y_1} = h_W = C_W \times \vartheta_0$$

the state of saturation is expressed by :

wet-bulb temperature : $\frac{h^* - h_1}{Y^* - Y_1} = C_W \times \underline{\underline{\vartheta_K}}$

Fig. 3: Basis for determining the fabric surface temperature by the creation of a heat balance (Krantz).

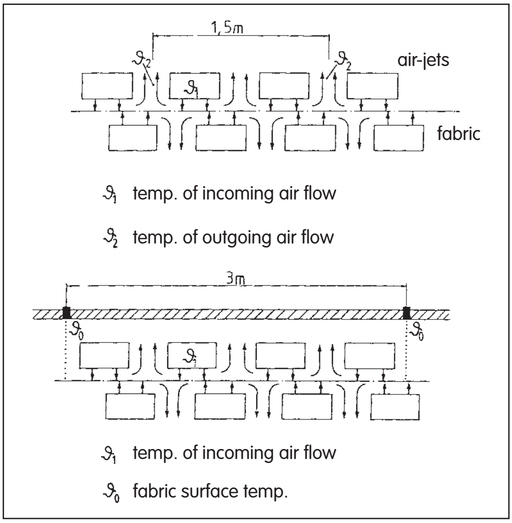


Fig. 4: Location-dependent siting of temperature measuring sensors to establish a heat balance in a short resp. long drier section.

temperature difference progression must therefore be determined from numerous measuring points along the direction of fabric passage through the machine. By this means, for example, a typical temperature difference progression may appear as the one shown in Fig. 5.

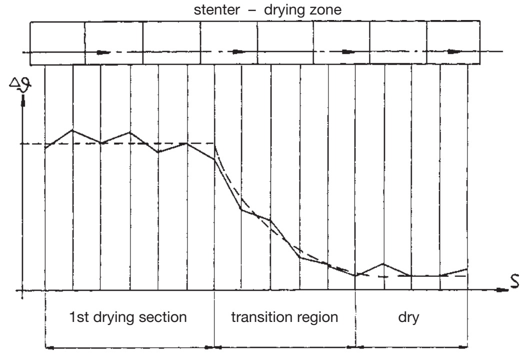

Fig. 5: Typical temperature difference progression during drying; curve adapted by software.

Establishing a constant small temperature difference to define the point of drying can lead to highly variable data for the actual values and result in a discontinuous control response. In the so-called 1st drying section, the temperature difference progression has been adapted to give a straight line. The wet/dry transition region has been brought more into line by means of an exponential function. The dry region has been represented as a straight line. Depending on the position of the wet/dry transition point, three curve adaptations have been carried out. A temperature difference is then defined as the point of drying on the exponential function of the transition region.

In a drier, water is evaporated from a textile material into the air flowing over it in the 1st drying section. The energy required for evaporation is supplied only by the air itself. Under such circumstances, the textile material acquires an almost constant temperature. The air becomes saturated with moisture on the surface of the textile material, and the temperatures of the air and the surface of the textile in the boundary layer are the same. The temperature achieved at this point is known as the → Wet-bulb temperature and represents the state of equilibrium between the air and the moist material. As drying progresses, the moisture level in the interior of the fibre recedes; the surface dries out and the surface temperature rises. The completely dried textile material finally acquires the same temperature as the air flowing over it.

The surface temperature of the textile material can be measured accurately and without contact with radiation pyrometers. As a rule, there is far less deviation in these measurements than in the measurement of temperature differences. This more precise measuring technology suffers, however, from the disadvantage that far fewer measurements are normally available. The measuring distance is increased, and it is seldom the case with long single-layer stenters that the entire length of the drying zone is monitored with pyrometers.

The progression of drying may be represented (see Fig. 6) by

- the effective temperature of the fabric at each point in time or at each point of drying and
- the drying progression curve.

In this process, the differences between convection drying and radiation are to be noted (Fig. 7).

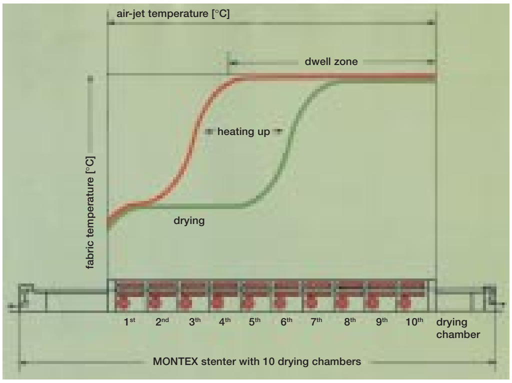

Fig. 6: Progression of fabric temperature during the drying and heat-setting of blend fabrics (source: Monforts).

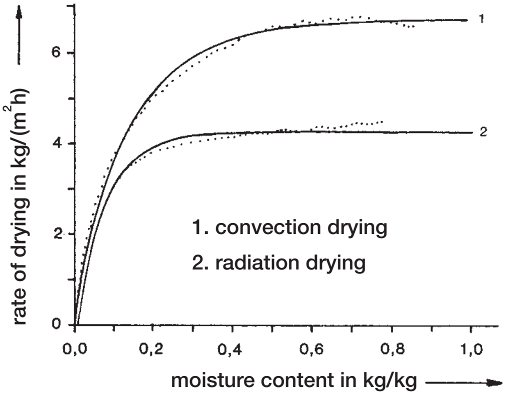

Fig. 7: Drying progression curves with adaptation functions for different drying techniques (source: Heidemann).

An important opportunity to increase the speed of drying would be to increase the heat transfer coefficient α. With air-jet application, for example, in the form of fan nozzles to achieve increased turbulence in the vicin-

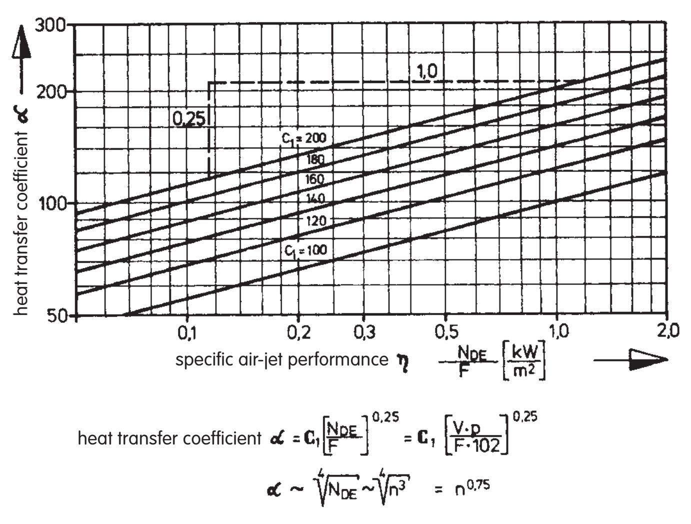

Fig. 8: Dependence of the heat transfer coefficient on the air-jet or air flow performance.

ity of the textile material, a corresponding increase in the heat transfer coefficient α results from an increase in the performance of the air flow rate to the 4th root.

By taking a close look at the formula for the transferable flow of heat resp. the transferable quantity of heat,

$$N \approx Q = \alpha \cdot F \cdot \Delta T \text{ [kJ/h]},$$

the dependence on the heat transfer coefficient, the surface area and the temperature difference between the impinging air flow and the fabric can be seen. In this relationship, the effective drying surface is defined as the length multiplied by the working width, i.e. this value is fixed before purchasing a particular drier. In the end, only the heat transfer coefficient and the temperature difference are available for effecting changes to increase the heat flow. To increase the heat transfer coefficient by increasing the performance of the air flow would be no problem. In most cases, however, this is not possible due to the fabric requirements. For good fabric quality, however, the finisher desires a uniform mild air flow. Moreover, the guiding principle of achieving "increased evaporation performance without additional expenditure of energy" runs counter to this solution. Other ways of approaching the problem must be pursued by taking into consideration the three basic conditions for optimum geometry of the air-jet systems (Fig. 9). These are:

$$a)\ (H/D)_{\text{opt.}} = 5.$$

$$b)\ \left(\frac{F_{\text{air-jet}}}{F_{\text{subjected to air impingement}}}\right)_{\text{opt.}} = 2\%.$$

c) optimum separation = 1.4 H.

H = air-jet/fabric surface separation;
D = air-jet diameter;
F = surface area.

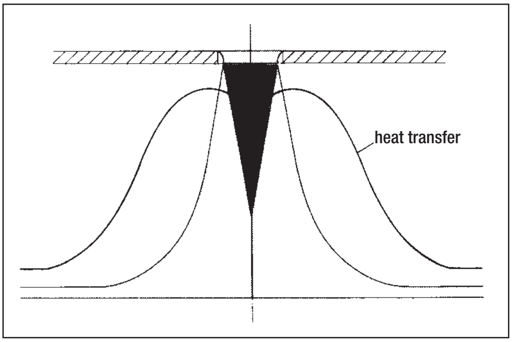

Fig. 9: Schematic representation of the heat transfer of an individual air-jet (source: Babcock).

A high heat transfer is observed in the region of an impinging air stream. The heat transfer is correspondingly reduced if the impinging air jet changes to a tangential flow. This observation applies to a fan jet as well as to a round air-jet.

In the first driers used for textile finishing applications, the air flow was blown parallel to the fabric from the front to the back of the drier. A considerable in-

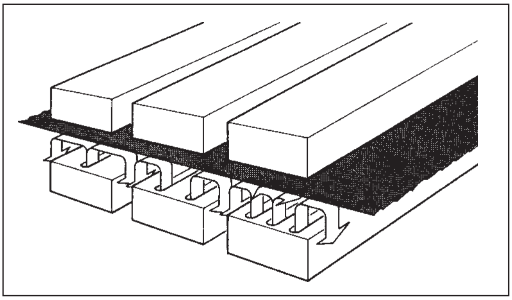

Fig. 10: A standard nozzle finger with different numbers of fan jets (Babcock).

crease in performance was achieved after the introduction of air-jet systems. Fan jets were used initially (Fig. 10). One air-jet was installed on each nozzle finger. However, this arrangement in no way provided an optimum separation. Wide stretches of the running fabric were still receiving only a tangential impingement of the air flow. The introduction of two air-jets per nozzle finger improved the optimum separation. This modification also resulted in a higher heat transfer.

With fan jets, a further increase in performance was not possible. A third row of fan jets on one nozzle finger only resulted in a tendency for a tangential flow to develop since the air-jet in the centre caused the two outer air streams to break up due to its outflowing air stream, thereby rendering them virtually ineffective.

The next stage in air-jet development led to the adoption of round nozzles distributed throughout a single nozzle finger. In this way, several rows can be accommodated within the surface area of a single nozzle finger. This arrangement also presented a certain obstruction to the individual air jets although, in the case of round nozzles, the exhaust outflowing air can find a path between the individual air jets which keeps the degree of obstruction within acceptable limits. The increase in heat transfer between the fan jet and round jet system is approx. 15%.

Drying with infra-red radiation Principle: heat transfer by radiation and absorption of the radiation by the textile material. The depth of penetration of IR radiation in textile materials is dependent on the wavelength of the radiation and the degree of absorption of the textile material itself. → Infra-red drying.

Drying zone part of the → Heat treatment zone in drying and stentering machines.

Dry lamination The dry laminating process (Fig.) enables two, three or more substrates to be laminated under the actions of temperature, pressure and treatment time, each factor being capable of individual regulation. The necessary adhesion between the substrates is achieved by the use of film, powder or fusible fibres.

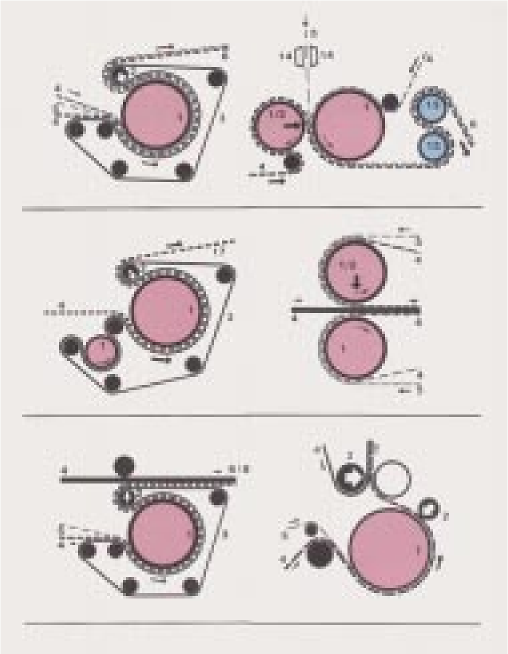

Fig.: Stork dry lamination options.
1 = (teflonized) heating element; 2 = press roller;
3 = (silicon-coated) belt; 4 = substrate; 5 = heat-activated film; 6 = laminate; 8 = coated end product; 13 = cooling; 14 = heating zone; 17 = double-heat-treated end product.

Dry mercerizing → Mercerizing of dry cotton or cotton/viscose fabrics. Mostly carried out on grey goods (→ Mercerizing of grey goods). Disadvantges: the finish is not as good as on scoured fabrics; heavy contamination of the caustic soda solution (size, lignin, etc.), addition of expensive wetting agent necessary (effluent problems). The advantage, however, lies in the mercerizing of blended fabrics with regenerated cellulose, as with dry mercerizing the swelling and dissolving range of 12–13°Bé caustic soda where these fibres are particularly at risk is not undergone twice, as happens in the mercerizing of wet goods. The → Mercerizing of grey yarns and fabrics is what is usually understood by dry mercerizing.

Dry setting → Heat setting.

Dry spinning A spinning process for man-made fibres in which the polymer, dissolved in an organic solvent, is converted into filaments by extrusion through spinnerets and subsequent evaporation of the solvent in warm air which allows the bundle of spun filaments to harden. The dry spinning principle is used for the production of acetate, triacetate, acrylic and polyvinyl chloride (PVC) fibres.

Dry steam → Steam without water droplets. Contrast → Wet steam.

Dry strength → Tensile strength.

DS process A direct stabilizing process for textile fabrics developed by Kannegiesser and Stockhausen. Instead of using adhesive interlinings the outer material is coated in stripe form.

DTA → Differential thermal analysis.

DTNW, abbrev. for: Deutsches Textilforschungszentrum Nord-West e.V., Krefeld (German Textile Research Centre North West); → Technical and professional organizations.

DTV, abbrev. for: Deutscher Textilreinigungs-Verband e.V., Bonn (German Textile Cleaning Association); → Technical and professional organizations.

D-type drum division (Pullman division), a “D”-shaped division of the inner drum cross-section into two chambers of equal size.

DU (Delft unit). An arbitrary unit for the proteolytic activity of enzymes and biologically active washing agents: e.g. the enzyme preparation has a protease activity of 1000 DU/g if 1 ml of a 2% solution of the enzyme preparation gives an extinction difference of 0,400 under experimental conditions.

Dual-action (Flip-flop mechanism). This is the oloephobic-hydrophilic behaviour of certain fluorine compounds, as opposed to oleophobic hydrophobic systems of known oleophobic finishes. Dual action compounds contain both hydrophilic segments and oleophobic-hydrophobic fluoric traces. The fluoric trace in the film coating the fibre has an oleophobic and hydrophobic action when it comes into contact with air, and when transferred into water the entire polymer is rearranged with hydrophilic groups projecting outwards and available for the dispersal and removal of soil in the washing solution (Fig.)

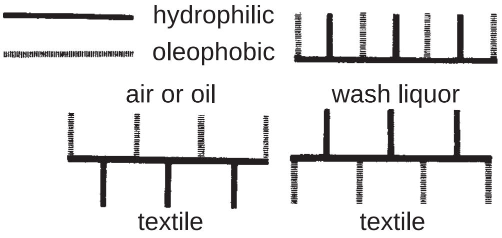

Fig.: Dual action.

Dual anchor Name for → Reactive dyes which have two or more reactive groups in the dye molecule. These kinds of dual anchor reactive dyes can have two “anchors” to the OH groups of cellulose molecules, e.g., i.e. enter into a dual reactive bond (→ Bifunctional).

From an ecological point of view there are two problems with reactive cold pad-batch dyeing, which are its cumulative AOX parameter and its colour persistence. The AOX parameter means the chlorine, bromide and iodine halogens that are contained within organic compounds and adsorbed by active charcoal, and is also an indicator of “hazardous substances” in industrial effluents as defined by § 74 para. 1 sentence 1 of the Federal Water Resources Management Act. The reactive group of the majority of conventional monofunctional reactive dyes has more than one halogen atom and varying degrees of reactivity, which also gives the hydrolysate a considerable AOX content, which can exceed the discharge threshold value of 3 mg/l suggested in appendix 38. Colour persistence is due to the dye hydrolysate, which is extremely soluble in water. Only a small amount of this dye is absorbed in activated sludge, meaning that the rest enters the sewage system. Colour persistence is therefore always an aesthetic topic of discussion between the processor and the authorities, particularly when an unacceptable proportion of reactive dye effluent is discharged to municipal sewage. In a meaningful comparison between cold pad-batch dyes and conventional monofunctional reactive dyes or dual anchor dyes, both systems would have a high AOX value in the original dyebath. Whereas only about a third of the AOX load in previously-used reactive dyes has disappeared after 24 hrs. of hydrolysis conditions, the AOX value of dual-anchored dyes is only slightly above the threshold value suggested in appendix 38, which determines whether or not a discharge requires treatment. In practice it would be feasible for the dye padder residue after completion of the padding process containing a mixture of dye and alkali, to be transferred to a secondary vessel to allow time for full hydrolysis, and then sent for biological treatment as industrial effluent.

Dual process (Dual technique, dual phase), cleaning method for use on industrial clothing which uses successive solutions in the same washing machine, mainly consisting of either water or solvent (tetrachloroethane, white spirit). Particularly used for industrial clothing that cannot be adequately cleaned in water or solvent, depending on the type of material. Although it was already known that dual processes could improve dirt removal using relatively little power and water compared to wet washing, greying of whites is still a problem.

Duchese satin, a heavy satin fabric woven on an 8-end or 12-end repeat, formerly with a grey warp and a tram weft. Now produced from acetate or viscose filaments, also with a fine cotton weft for dress fabrics and blouses.

Duffel (duffle), a heavy, low quality woollen cloth, napped on both faces. Napped duffel is similar to eskimo and is mainly woven in a 4-end warp cross twill construction. Other duffel qualities are given a melton finish. Used for short coats and certain types of military or contract cloths.

Duhamel wool washing process, circulating process possibly including wool fat recovery. The process uses potassium carbonate to remove the suint in several becks with increasing washing activity until an optimum is reached. The wool is treated with lukewarm water without additions, the bath is dropped, and the liquor centrifuged to separate undissolved matter (possibly multistage), and the liquor pumped back for reuse in washing.

Dull colour, consists of grey elements, i.e. white and black, in addition to colour. The opposite is → Clear colour.

Dummies,

I. → Steam ironing dummy.

II. Dummies are used for simulation of those processes which cannot be carried out on humans. Protective clothing must, for example, be designed in such a way that it protects the wearer from burning in the event of fire. With this aim in mind, safety clothing materials are to be developed and the necessary test methods to achieve this performed on dummies. The dummy test (Fig.) helps provide solutions. Numerous sensors are attached in and on the body of the burning dummy, enabling measurements of the degree of burning and therefore giving information about the performance properties of a protective garment on the human body. Similarly, clothing physiological tests are developed on test dummies (→ Copper man).

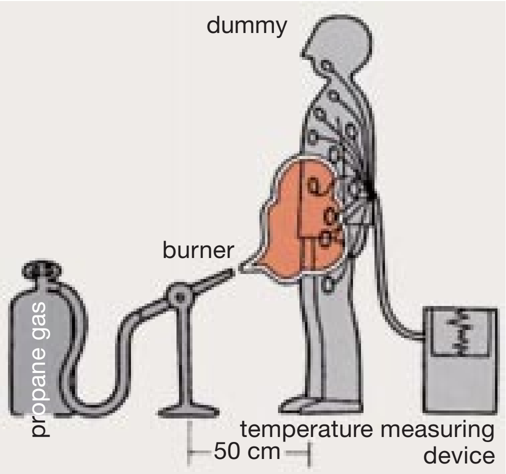

Fig.: Test dummy for flame test: a gas flame (1200 °C) is directed at the clothes for 10 s.

Duotuft, special tufting technique in which some of the pile loop that has already been tufted is re-engaged. This part of the pile loop is then pulled into the next pile loop. This improves cover whilst being relatively economic in pile yarn consumption.

Duplex machines,

I. In general, two machines running in tandem.

II. Special Sanforizing or Montforts compressive shrinkage machines with two felt calenders.

III. Special roller printing machines for printing both sides of a textile fabric.

Duplex printing process Double sided patterning is possible using the duplex printing process, which can be carried out in both screen and roller printing. There are 2 screens and/or rollers per pattern and these print the pattern identically on both sides of the fabric. This is predominantly used for blankets and towels.

Duplosolv process A continuous 2-stage process for desizing fabrics which have been sized with polymer sizes. In the first stage, the size is swollen with water (80–150% based on weight of fabric) and brought into solution. In the second stage, this solution is displaced by tetrachloroethylene. The size can be regenerated from the aqueous solution. Manuf.: Brückner.

Dupont bleaching system Cotton and cotton/synthetic fibre blends are bleached with hydrogen peroxide using J-boxes as reaction dwell chambers. After impregnation with bleach liquor, the goods are heated to the bleaching temperature by steam in a steam chamber immediately prior to entry to each J-box.

Dupont Minute Bleach process A 2-stage continuous scouring and bleaching process: 1. alkali scour stage; 2. peroxide bleach stage. Each stage involves a 2 min. steaming treatment in a normal Mather-Platt continuous steamer.

Dupont shrinkage test (boiling test). A test method for determining the dimensional stability of textiles made from synthetic fibres to treatment in boiling wash liquors or for determining the efficiency of heat setting. A square of specific dimensions is drawn on the material, after which it is boiled for 30 min. in soft water in a washing machine, hydro-extracted, allowed to dry in air, and the square measured again. The difference in the dimensions of the square before and after the wash test provide a measure of the dimensional stability of the material.

Duralized A commercial term for the effect produced on a fabric, preferably of pure cotton, by treatment in liquid ammonia (Duralized process). Manuf.: Cluett, Peabody + Co. (licensor).

Duromers → Duroplastics.

Duroplastics (Duromers), plastics (synthetic resins) made from three-dimensionally cross-linked macromolecules that can be thermally hardened by means of cross-linkage. The thermal hardening process is irreversible (compared to → Thermoplastics). These materials cannot be melted and are insoluble in organic solvents, e.g. phenol-formaldehyde resins of the Bakelite type. Also logically includes rubber vulcanisation.

Dust Suspended particulate matter in gases or in the air which are able to remain in suspension for a relatively long time due to their low particle size. In respect to the effect of dust on human respiratory organs, it is not dust in general, but fine dust which is significant. But dust is also unwelcome in the product and on/ in the machine. Lower dust content gives improved product quality. Dust can be released on the machine in a large variety of places, and consequently there are considerable problems to solve in textile machinery design in order to achieve the required levels. Suitable finishing agents (anti-dust compounds) are available with which in many cases, a reduction in fine dust emissions and fibre abrasive wear with both cotton and blends with synthetic fibres can be achieved without other accompanying negative phenomena.

Dust extraction units for printing machines In order to remove lint, loose fibres and other loosely adhering matter from the surface of textile fabrics to be printed (which could impair printing quality, e.g., local resists and screen blocking problems, etc.) a dust extraction unit is installed, e.g. immediately before the printing zone (see Fig.)

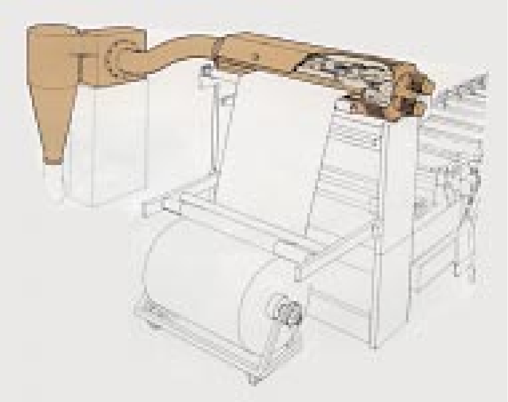

Fig.: VIP heating, brushing and suction extraction machine with cyclone unit and rotary screen printing machine ionisation.

Dust filtration In the textile industry, dust filtration entails the removal of dust particles of various sizes from the discharge (air extracted from the working environment) of air-conditioning units. Other extraction systems of various types deal with the extraction of dust from the actual textile machine. Air from all these sources is recirculated to provide uniform air engineering and energy saving in production premises. Exhaust filters must be used to keep the dust content of the air in the production environment within the permitted limits. Both the air from the production environment and the machine exhaust contain dusts and fibres in various forms. The filtering of exhaust air can, therefore, be divided into two tasks:

1. Filtering out the fibres and fibre accumulations.
2. Fine filtering the exhaust air so that it can be recirculated back to the production environment without exceeding the maximum permitted levels of respirable dust in the air.

There are no filter media available which can be used for all situations to optimum effect. The difference in composition of discharged air which contains dusts of many different types and long and short fibres is too great. In some cases, these discharges may contain sticky components as well. Problems of this nature can be solved by experience or trial and error with different filter media. With its various surface or fibre treatments, needlefelt in particular offers possibilities where the cleaning of the filter medium can also be improved. What is important, is that the low limits of the OSHA guidelines can also be maintained using state-of-the-art filtration technology. Equally important is the knowledge that the production machines themselves produce dust directly. This problem must also be borne in mind especially in view of the constant increase in throughput per m^2 production area with the same or slightly greater generation of waste.

Dust in cotton spinning Dust in cotton spinning may be roughly divided into the following categories:

1. Mixed dusts of inorganic/organic components consisting of natural dusts or impurities from leaves, seed capsules, harvesting methods, etc., adhering to the fibres.
2. Technical dusts mainly arising from fibre debris and fragments of various sizes which are added to the naturally occurring dusts during mechanical processing. The composition of these dusts extends over a broad spectrum with particle sizes ranging from < 1 μm up to fibre fragments of several mm in length.

The yarn quality is primarily influenced by coarse to medium-sized dust particles whereby impurities adhering to the fibres become separated by mechanical cleaning processes during fibre preparation. Lubricants and spin finishes would more likely lead to undesirable effects on fibres which have not undergone a preliminary cleaning stage. By contrast, fine dusts are usually only released in the actual spinning process (abraded fibres, fly) and can be positively influenced by the presence of spin finishes especially with regard to expectations of higher productivity performance. The fine dust remaining in the material should be a “spinnable dust” (i.e. dust which does not adversely affect the spinning process) and which can be removed in subsequent finishing processes.

Dust/lint eliminator (for printing). There must be no dust particles on the print ground as it passes into the printing zone, as these would act as resist agents.

Dust/lind removal

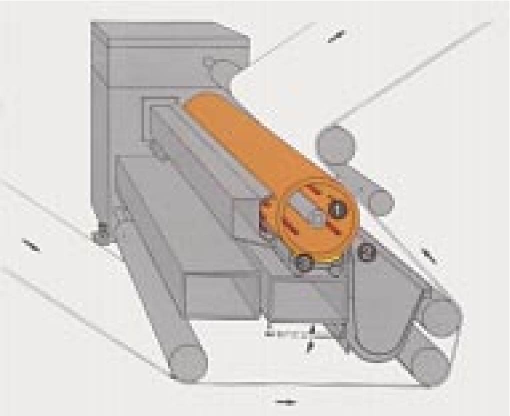

Fig.: Stork dust eliminator with application of adhesive in the adhesive trough (3); transfer of lint from the fabric passing tangentially to the adhesive cylinder (1) and stripping off the adhesive/lint mix with the doctor blade (2).

The ground is therefore cleared of dust by suction or adhesive techniques (Fig.).

Dust/lint removal This takes place on the finished fabric by beating or brushing or a combination of the two processes. Dust which has accumulated from fibres and finishing agents is extracted through extraction slots. The removal of dust from printed fabric takes place immediately before the fabric enters the printing zone (Fig. 1). Distinction is made between dust removal using a dust extractor and dust removal using a dust-removal unit with adhesive-coated rollers.

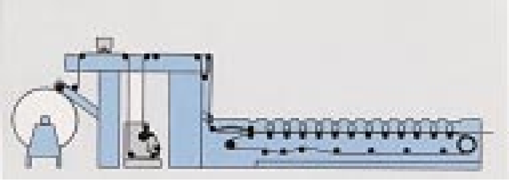

Fig. 1: Dust extraction unit before entry into the printing zone.

Extraction units are available in three different designs: a simple extraction unit for one side of the material, two extraction units attached to a single fan for one or both sides of the material and two extraction units each attached to its own separate fan for removing dust from one or both sides of the material. Extraction is carried out as follows (Fig. 2): the contaminated material is transported by the extraction unit itself. A specially designed nozzle guarantees high extraction efficiency and uniform extraction over the full width of the material. Fans and noise insulators ensure a powerful but almost noiseless extraction of lint and threads. Lint and dust are finally collected in a filter plant.

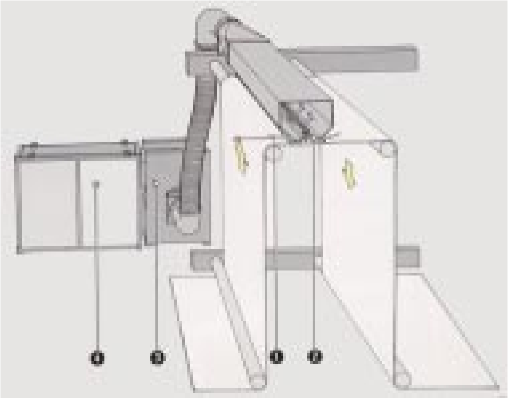

Fig. 2: Dust extraction on a web (contributed by Stork). 1 = fabric; 2 = extraction slot; 3 = dust extraction unit; 4 = electrical installation.

The adhesive-roller device (Fig. 3) operates as follows: fabric is transported to the adhesive roller before entering the printing or finishing machine to ensure the complete removal of microscopic dust particles. The adhesive applicator roller rotates slowly in the opposite direction to that of the fabric. The lower part of the roller is immersed in a trough of adhesive where a thin layer of adhesive is applied to the roller. The roller is

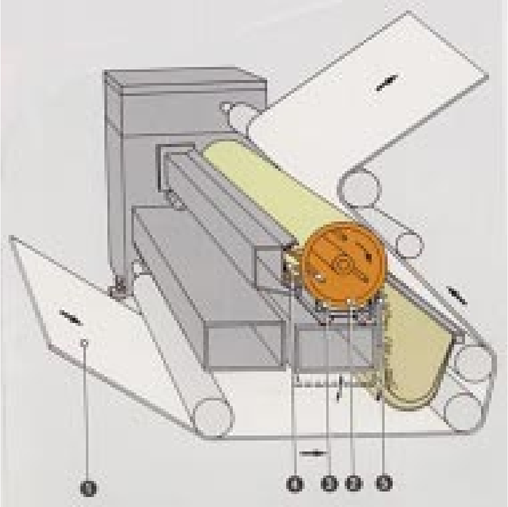

Fig. 3: Dust extraction unit with adhesive roller (source: Stork).
1 = fabric; 2 = rotating screen for adhesive coating;
3 = doctor blades; 4 = adhesive coating.

heated internally and externally, thus drying the adhesive. As the material runs past, the dust and lint particles adhere to the adhesive roller running in the opposite direction. A doctor blade removes the spent adhesive and adhering dust and lint particles and fresh adhesive is automatically taken up from the sizing pan.

Dust measurement Dust contamination can have a negative influence on production processes and also represents a source of nuisance and risk to the health of operatives exposed to dust-laden environments. For the industrial monitoring of dust pollution levels, a distinction is made between total dust and fine dust pollution. For health risk assessment, the particle size range of fine dusts is of particular interest whereby textile dusts, with their diverse particle forms and compositions, pose additional problems for dust measurement technology.

One way of determining dust concentrations involves collection of the airborne dust. In this method, a specific air flow is drawn by suction through a fine pore filter on which the dust particles are filtered out. From the known air flow and prescribed period of time, the dust concentration may then be determined by subjecting the filter element to gravimetric analysis.

For many investigations, it is necessary to obtain information relating to the particle size distribution of the dust particles. This applies particularly to tests for determining the efficiency of filter media and filtration plants. An important characteristic of a filter is the so-called "separation curve" T(d) which, in contrast to the total degree of separation, is expressed in the form of a function of the degree of separation for each particle size d (Fig. 1). The separation curve therefore provides much more comprehensive information on filtration properties than the total degree of separation. In order to determine T(d), it is necessary to measure the particle size distribution in dust-laden air H_s(d) and in the filtered air H_r(d) with two separate measuring instruments as simultaneously as possible. The distributions H_s(d) and H_r(d) indicate the proportion of a specific particle size d, either in number or mass-related terms, or a size group (d_1 to d_2) present in the total dust; they are correspondingly identified by means of a supplementary index letter "m" for mass and "n" for number-related values. If number-related particle size distributions are measured, the separation curve is calculated from the formula

$$T\,(d) = \frac{N_S \cdot H_{S,n}\,(d)}{N_r \cdot H_{r,n}\,(d)}$$

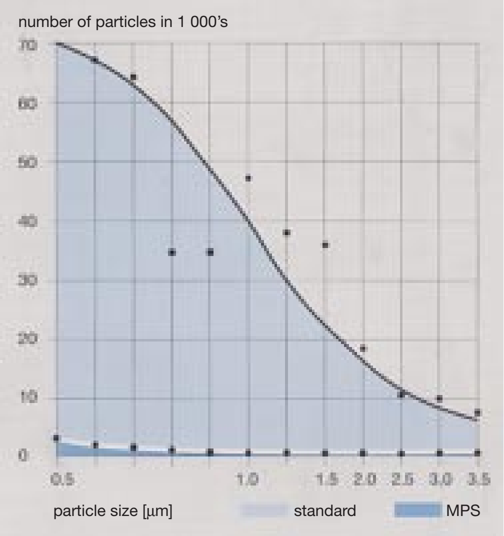

Fig. 1: Separation curve for dust separation on standard filters or on micropore filters (BWF).

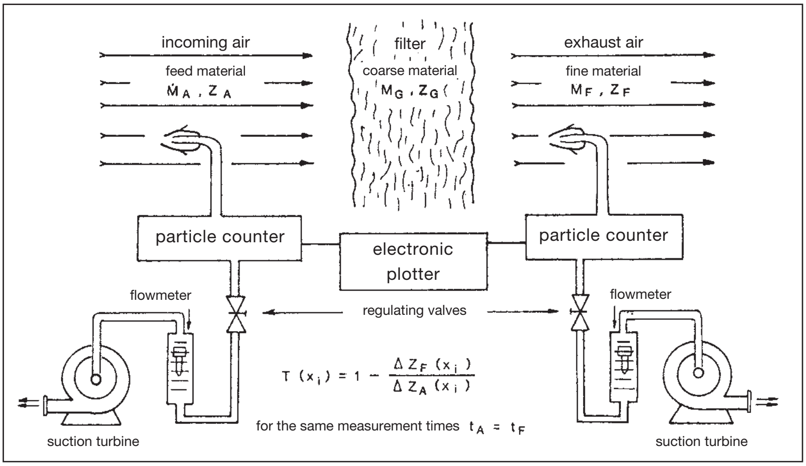

Fig. 2: Schematic representation of the measuring procedure to determine the separation curve of a filtration plant (source: Bahners).

with the total particle counts N_s and N_r recorded within the measurement time t_m. The measurement procedure is represented schematically in Fig. 2. For an appropriate test on industrial filtration plants, a small partial stream is therefore withdrawn before and after passing through the filter and is led to the respective measuring system. In order to meet the requirements for rapid measurement, optical particle counters are suitable which utilize the scattered light or even the diffraction effects produced by the dust particles in order to obtain size-dependent signals.

The instrument consists essentially of a filter housing with a membrane filter disc and an impeller type centrifugal fan mounted behind it to produce a specified air flow volume. The dust filtered out onto the filter disc as well as the fibrous components caught in the fibre catcher pan are usually determined gravimetrically.

The Andersen sampler is used primarily for the fractional collection of fine dust for particle size analysis. The dust particles are filtered out in the measuring instrument, according to size, into 8 separate fractions on the impaction principle. A corresponding mass-related particle size distribution is obtained by weighing the fractions. By adding up the collected dust quantities, the total dust quantity and, consequently, the fine dust concentration can be calculated as well.

Samples collected in industrial plants can, amongst other things, be further classified in the laboratory with a so-called Coulter counter. With this instrument, volume-related particle size distributions of collected dusts can be determined on the basis of conductimetry (source: Bahners).

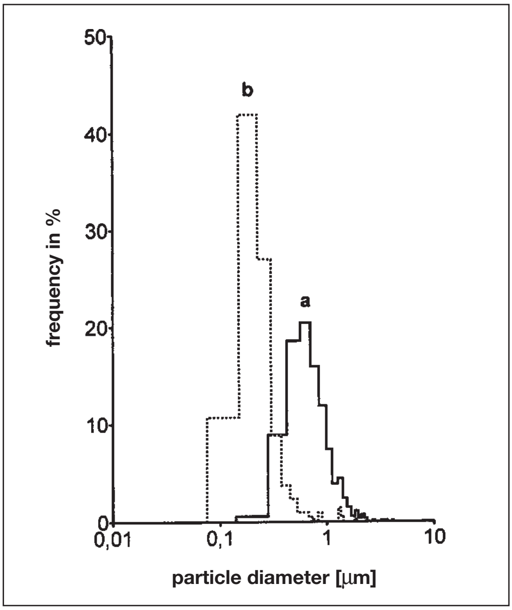

Fig.: Number-related frequency distributions of the smallest particle projection diameters $d_{Fe, min}$ of a cotton dust in weaving (distribution a: sample taken from an air-jet weaving machine processing unsized rotor-spun yarn) and a mixed dust present in the aerial environment of a surface treatment on fabrics made from PES resp. PA microfibre yarns (distribution b: single roller emerizing machine (according to Bahners and Schollmeyer).

Dust problems → Dusts are solid particulates dispersed in a gaseous medium (usually air). Dusts from dyes are generated during handling, e.g. dispensing, transfer to other containers, "strewing-in" when preparing print pastes, etc. The particle size distribution is largely independent of the form of the dye itself. Depending on the severity of the mechanical stresses imposed, large quantities of dust are also dispersed into the surrounding air during processing of textile fibres in the spinning, throwing, weaving and dry finishing stages of manufacture. The dusts involved here are either mixed dusts composed of particles of fibres and fibre impurities adhering to the raw material which are simply set free during mechanical processing, or fibre fragments of various sizes that are only formed as a result of the action of the processing machinery itself. These waste products of transition and attrition which, in the form of finely dispersed particles having a wide particle size distribution (see Fig.), are carried along in gaseous (air) currents. For technical, economic and/or work hygiene resp. health reasons, these dusts must be removed from the air environment as close as possible to the source of generation in order to prevent quality deficiencies due to inclusions of dust particles in textile structures and unnecessary wear and tear to machine elements due to dust accumulations, as well as to avoid health risks to the operatives. For this reason, very high demands are placed on effective cleaning and → Dust filtration in the production of rotor yarns from low-grade cotton.

The air in a textile manufacturing plant is in continual circulation. It is extracted at appropriate locations, e.g. at the machines, and treated for dust removal. In addition, dust extraction plants of various types are used which are based on different physical principles. The treated air is then returned to the production departments as "clean air". After a certain period of time (corresponding to the effective range of the dust extraction plant) a stationary state for the individual particle fractions is established in this cycle. Since very fine dusts (< 5 μm particle size) are only filtered out inadequately by this means, dusts in this size range accumulate. Filtration separators are usually employed for dust removal in spinning plants which filter out, in successive stages, the coarse contaminants including long fibres and fine dusts contained in the air extracted from the machines and the production departments. Wire gauze is mainly used as a prefilter, the mechanical blocking action of which filters out the coarse dust particles whereas a variety of textile materials including woven fabrics, nonwovens, pile fabrics and felts are used to filter out fine dusts. Virtually all the processing operations in a spinning plant right up to the spinning machines themselves participate in dust removal from fibrous materials. For this reason, dusts should be filtered out as early and as completely as possible. The problem therefore lies in the requirement to significantly improve the removal of fine dusts by filtration effectively and in an economically viable manner.

In the processing of raw cotton, the amenability of the fibrous material for effective cleaning is an important quality criterion. To determine cleaning efficiency the raw fibrous material is subjected to a dust and trash test. The percentage of dust and trash is determined which:

– can be released in fibre-to-fibre and metal-to-fibre friction during processing into yarns;
– constitutes fibre fly (short fibres < 5 mm);
– constitutes trash (particles ≥ 500 µm).

Wool yarns which have been dyed with chrome dyes can generate dust during the rewinding process and impair the running properties if excess chromium is adsorbed on to the surface of the fibres during treatment with dichromate.

Dyestuffs in solid form are available in various physical forms (e.g. powders, granules). The particle size distribution of commercial dyes varies to a great extent. The average particle diameter may be less than 50 µm but can also be as much as a few millimetres. Moreover, the particle size distribution may be narrow or wide. In all handling operations with solid dyes, the formation of dust is to be expected and the amount of generated dust is dependent on the handling operation as well as the particular product. In order to prevent the exposure of operatives handling dyestuffs in colour kitchens (and laboratories) for textile dyeing and printing, special downdraught dust control booths are now available for weighing and dispensing operations, etc. The quantity of dust generated by products from the same manufacturer is a quality characteristic of the product (source: Schollmeyer and Bahners).

Dustprone fabrics, goods which are prone to dust due to the fact that quantities of non-bound finishing agents (kaolin, delustring agents etc.) are too high.

Dust removal plants There are two stages in removing dust from environmental air or exhaust air from machines (Fig. 1). The core of a plant such as this is the drum filter with prefiltration discs built into the entry. The exhaust air to be filtered passes through the circular prefiltration discs into the filter drum. From here, the air passes outwards through a filtration medium which covers the circumference of the drum.

Fibres are filtered out by the prefiltration discs and removed from this by a suction slot. The dust passes through and is first deposited inside the filter drum which acts as a fine filter. The stationary, non-rotating drum made from filtration fabric has a forced outward air flow so that the contamination remains inside the filter drum and the environment in which the drum filter is situated stays clean (Fig. 2).

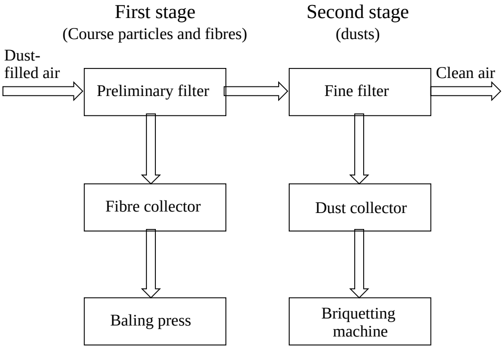

Fig. 1: System for exhaust-air dust filtration.

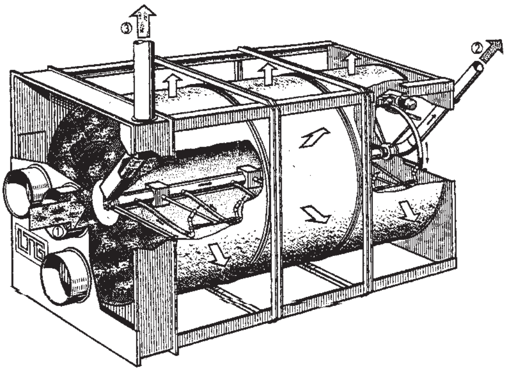

Fig. 2: Drum filter with prefiltration discs fitted to the entry (source: LTG).

The filtration fabric is cleaned by moving suction nozzles which rest on the filter fabric under spring loading. The nozzles are moved by means of a hollow shaft to which the nozzles are attached and which takes away the contaminated air stream. A second cross-recess shaft superimposes rotational and reciprocating movements so that the extraction nozzles cover the entire surface of the filter.

The fibres extracted from the prefiltration disc by the suction slot are collected internally on a perforated sheet-steel cone in the fibre compactor (Fig. 3). The fibre web which forms on the cone is stripped in a downward direction by a rotating worm screw, precompressed and pushed out through a spring-loaded panel. Dust which still remains in the air stream is fed

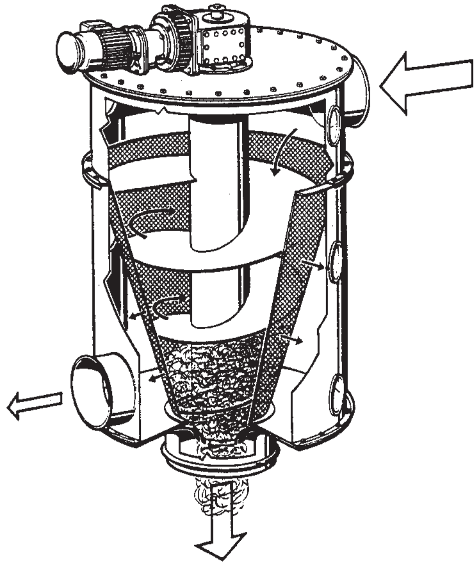

Fig. 3: Fibre compactor with perforated sheet-steel cone (contributed by LTG).

back to the drum filter for fine filtration. If the precompressed fibre is of uniform composition, this is fed directly to a baling press. If there are several types of fibre present, a silo collector is used. The collected fibrous dust is compacted and made into briquettes (Fig. 4).

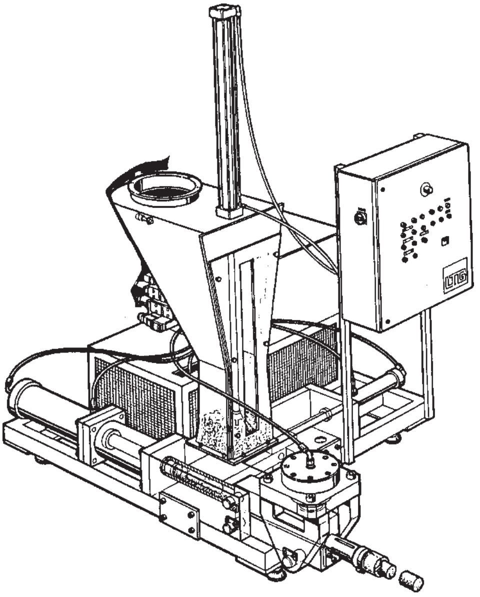

Fig. 4: Briquetting machine for collected dust (source: LTG).

Duty free tax import for finishing Customs authorities of many states grant customs facilities for temporary import and/or export of goods as a result of applications. This system is also significant for the textiles industry to a certain extent, depending on the economic situation. Duty is deferred for goods which are imported from abroad for finishing and goods are exempted from customs duties on proof that the goods have been exported. This is commonly referred to as duty free tax import. Commission processing transactions occur almost exclusively between neighbouring states. A distinction is made between active and passive tax import. It is passive if finishing takes place abroad, and active if foreign goods are imported for finishing. Reasons for recourse to duty-free tax imports can be economic (lower prices) or qualitative (special finishes). It is also used by companies whose operations are situated in different countries and who wish to take advantage of the favourable cost structures in these countries. In addition to known finishing operations, the following are also examples of processes included in duty free processing: embroidering fabrics, cutting of pile fabrics and also redyeing materials which have already been dyed. In order to guarantee the identity of textiles sent for finishing, the customs authorities make appropriate regulations, taking finishing requirements into account.

Duvetine (duvetyn, duvetyne) from Fr. *duvet* = down. Originally of cotton warp and spun silk weft. Sometimes made of fine woollen yarns. Constructed of six-, seven-, or eight-shaft satin weave and face finished to give a smooth, plush texture. The down-like surface, produced by several napping, shearing and brushing operations is characteristic of duvetine fabrics. In comparison to velours, the surface pile is shorter and less pressure-sensitive. Duvetine is mainly dyed in the piece. Soft handle and appearance similar to suède, drapes well, wears well, but spots easily. Used for ladies' outerwear, costumes and coats.

DVM abbrev. for: Deutscher Verband für Materialprüfung e.V. (German Association for Material Testing).

DVM softness, a specialized system of notation mainly used only in laboratories in Germany for measuring the softness of rubber and synthetic rollers and suchlike. The softness corresponds to the respective depth of impression in 0.01 mm increments produced by a steel ball of 10 mm diameter with a test load of 1 kg.

Dwell chambers In order to complete the process, in many finishing stages it is necessary to batch the fabric or knitwear impregnated with chemicals for a period of time. This can take place in air, steam or gas. Two transport systems are used for this: conveyor belts and roller conveyors. The conveyor belts can be arranged in one or several levels above one another (see Fig.). This is the most common design. In addition,

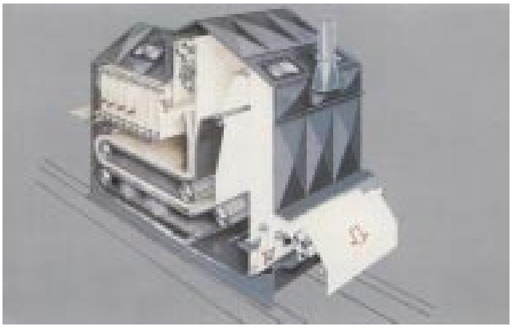

Fig.: Dwell chamber in a Küsters' steaming machine.

there are carousel type devices and towers, in which the conveyor belt is arranged in the form of a spiral.

Dwell process, bleaching and dyeing process for fabrics and knitwear, whereby goods impregnated with chemicals or dyestuffs are rolled up in open width and are stored for the necessary length of time at room temperature or in heated chambers (e.g. pad roll chamber).

Dwell time, phase of the processing cycle during which the actual reaction takes place, e.g. at the final temperature reached. Finishing processes where fibres, finishes or coatings undergo heat treatment generally do not achieve optimal finish as neither the period of time nor the result is continuously monitored. There is no direct method of measuring which can define the set in a length of cloth which is in motion, and it difficult to check objectively the degree of vulcanizing, e.g. of carpet backing which is still in the coating unit. Therefore in practice, all of these processes are carried out empirically using formulae as far as possible, and these often take into account a considerable safety factor in terms of dwell time. Naturally it is not possible to speak of optimisation in terms of economy and technique given these conditions; many products are also unable to withstand a process time which is either too long or too short, which means that the increased safety factor is no guarantee that the final finish of the goods will be correct. During curing and pre-setting for example the temperature of the goods and length of time the goods should dwell at process temperature are prescribed. Heating up to this temperature takes varying lengths of time depending on the goods; the heating time is especially variable if drying needs to be carried out immediately before heating. The heating process also generally requires more time and greater energy consumption than the actual fixing or curing. Conditions for producing coatings are similar. Depending on the type and weight of the application, drying and heating take different lengths of time, while dwell times which must be strictly adhered to are prescribed for the actual development process (vulcanizing, polymerisation).

Dwell units (cloth accumulators). Machines which subject the textile goods to a finishing process for a period of time (of up to 24 hours) in order to expose them to the effects of chemicals or dyestuffs. For shorter periods of time, guide roller systems are used for this purpose in the continuous method, inclined accumulator chutes, J-tubes (J-boxes) or → Rebatching chambers. For longer periods of time, i.e. in batch processing, frames or trolleys are used. The goods are laid down or rolled up in open width in these for the dwell period. Rolls are generally rotated slowly in order to avoid the fluid settling. →: Mobile dwell chambers; Circular accumulators. Rope-dyeing machines also have a dwell unit (Fig. 1).

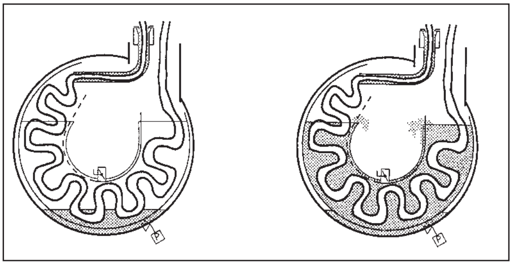

Fig. 1: Diagram of the full-flooding device: left short liquor operation; right full flooding in the dwell unit of a rope-dyeing machine (Scholl).

There are different designs depending on use (see Fig. 2):

I. Conveyor dwell unit: Also to be retrofitted into existing plants. Goods are transported by means of traction via the wetting-out trough into the bath and deposited evenly in the liquor between two driven conveyor belts by reciprocating bars. Spray pipes are used to spray the relatively loose cloth assembly upwards whilst in the liquor, (= even distribution of chemicals and temperature, liquor exchange/movement of goods). Options: above/below liquor, cold/hot, at boil, tight/loose assembly (depending on proneness of goods to creasing).

II. Dwell unit for steaming processes:

a) Perforated belt steamer: operated with saturated steam, proved to bleach delicate fabrics. Fabrics after impregnation are inverted between belts via intake conveyor. They are heated rapidly in extended state, then flat folded for the lengthy process taking 20–40 min.
b) Roller steamers (→ Roller conveyor steamers): Also operated at saturated steam temperatures, particularly used for goods which are subject to creasing which require controlled fabric transport.
c) Universal combination steamer (see Fig. 3): Fills

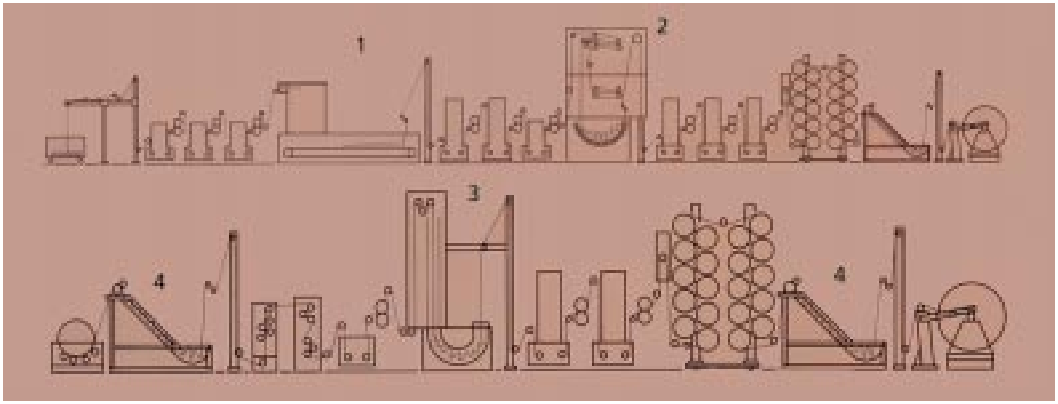

Fig. 2: Various dwell units in pre-treatment lines (Morrison).
1 = perforated-belt dwell; 2 = U-box; 3 = J-box; 4 = trough dwells.

the gap in dwell time between perforated steamers (20–40 min) and roller steamers (1–2 min). Consists of a roller section for controlled transport of cloth. Improves trash elimination in cotton goods with a slightly longer dwell time of approx. 7 min in both alkali and peroxide stages, making better use of the bleaching chemicals employed, i.e. lays down folded goods without risk and without disturbing marks as long as they are not assembled too densely and if possible there is no compressive load on the assembly. Fabric feed via air locks until the swelling process is completed, depending on the capacity of the steamer and the speed of travel with controlled transport 0.5–1 min treatment time, then laid down via reciprocating roller in loose folds. Remove goods at the end of the conveyor and exit via the water lock. Inflow and outflow locks and production of steam in the sump ensure air-free steam atmosphere and even temperature distribution. "One-stage bleaching line" comprising the following components – perforated drum washing unit, impregnation conveyor and combination steamer – are particularly useful for printing plants, as optimum pre-treatment can be carried out on cotton, cotton/polyester and knitted goods.

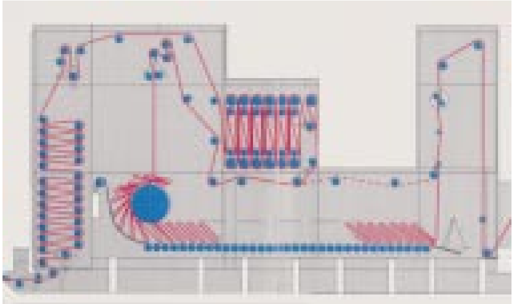

Fig. 3: Combination steamer (Küsters).

III. J-tube: J-box for 80–200 m cloth capacity with direct/indirect heating, with/without circulation of liquor, max. temperature 98°C.

DWF, (Ger.) abbrev. for: Deutsche Wäschereiforschung (German Laundry Research Organization); → Technical and professional organizations.

DWI, (Ger.) abbrev. for: Deutsches Wollforschungsinstitut, Aachen (German Wool Research Institute); → Technical and professional organizations.

DWV, (Ger.) abbrev. for: Deutscher Wäscherei-Verband (German Laundry Association); → Technical and professional organizations.

Dy, chemical symbol for Dysprosium (66).

Dye → Dyestuff.

Dyeability As a prerequisite for the use of textile fibres, one of their most important properties is dyeability. Consequently, the range of application of some synthetic fibres has been, and still is, limited either because they have poor dyeability or the problem of dyeing these fibres has not yet been satisfactorily solved. For example, when $2^1/2$ acetate fibres were first introduced, they were not successful for a long time because they could not be dyed with the known dye classes at that time. Indeed, it was only after the discovery of disperse dyes that acetate fibres gained wide acceptance. The same problem applies to polypropylene fibres although, in this case, appropriate modifications have provided a partial solution. Comparable examples are the attempts to develop polyester fibres with a higher dye uptake as well as the efforts to produce a polyamide fibre with differential dyeing characteristics (→ Differential dyeing) which has had a favourable influence on their range of application. Some textile fibres may be dyed with several technologically different dye classes capable of achieving relatively good colour fastness; others, however, can be dyed with one particular dye class only (and, even then, not without difficulty in some cases).

In practice, the dyeability of a textile fibre is determined by the rate of dyeing and the degree of saturation which can be achieved. For example, the different dyeing properties of mercerized cotton compared to non-mercerized cotton can be characterized by results from the time of half dyeing (i.e. the reciprocal of the rate of dyeing) and the saturation concentration of the substantive dye.

Dyeability is dependent on the following factors:

a) Chemical composition of the fibre: fibres of native and regenerated cellulose differ from each other, for example, in their physico-mechanical structure but, despite this, they can be dyed with the same classes of dye. The same situation applies to protein fibres (a gram equivalent of wool is 1200 g and that of silk is 4200 g for reactions as bases) as well as for polyamide and polyester fibres.

b) The coloristic dye class resp. the entire dyeing system including additions to the dyebath: certain dye classes are only suitable for one particular type of fibre, i.e. either the dye is not capable of dyeing certain fibres, or can only dye them very slightly resp. stain the fibre; this can, however, be caused by unsuitable dyeing conditions, e.g. by using an inappropriate dyebath pH.

c) The geometrical form of the fibre, the fibre dimensions as well as the morphological and histological structure of the fibre (the cuticle in cotton, the scale layer of wool and the skin effect in viscose fibres) and the fine, or supramolecular, structure of the fibre, whereby each change in fine structure results in a change in dye uptake: e.g. mercerized or non-mercerized cotton, different regenerated cellulose fibres, drawn or heat-set synthetic fibres.

Those changes which, for example, involve changes in the ratios of crystalline, oriented and amorphous regions due to the ageing of cotton or changes in the pore size, can be attributed to changes in the accessibility of the fibre to certain reagents. The relationship between fibre accessibility A% and the degree of crystallinity K% can be derived as follows:

$$A = (100 - K) + \alpha K$$

α is a constant which is related to the crystalline part of the fibre. It can have values from 0–1. An ideal substance with hundred percent accessibility would be represented by $\alpha = 1$. The first part of the formula represents the amorphous part of the fibre φ, and the second part represents the accessible surface of the crystallites (if $\alpha = 0$, this surface would be inaccessible):

$$A = \varphi + \alpha K$$

In the case of high tenacity viscose fibres K can vary, for example, between the limits of 33–49%, $\alpha = 0.09–0.67$. The accessibility A represents an appropriate numerical criterion of dyeability. It is an absolute parameter which represents a previously given property of the fibre and, in general, gives expression to the requirement for its dyeability in achieving dark shades or black within an acceptable dyeing time provided the dye has adequately high build up properties. The fact that, in isothermal dyeing, dyeability decreases with the time of dyeing and that a fibre has a greater affinity for the dye at the beginning of the dyeing process than at the end, is well known to every dyer. It is also possible to assess dyeability from the standpoint of the momentary quantity and rate of dye uptake by the fibre at a given time. The relative dyeability is always a kinetic parameter which is related to a specific dyeing system. If it is assumed that at time t, a dye concentration c_t exists in the fibre, then the reciprocal of this parameter c_t^{-1} is the dilution of the dye in the fibre at time t. At the start of dyeing, the dilution reaches a value which increases beyond all limits (apart from the dye adsorption on the fibre surface at time t = 0; the dilution has a value of $c\infty^{-1}$).

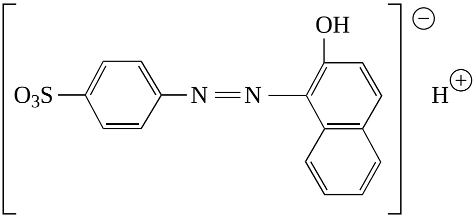
The dilution of solutions behave in an analogous manner: before a substance dissolves in a solvent, the dilution is infinite (since the reciprocal value, i.e. the concentration, is equal to 0); with increasing concentration the dilution decreases (not, however, to 0 but to a certain value which corresponds to the dilution of the substance in a saturated solution). The rate of dyeing at any time of dyeing t is proportional to this dye dilution:

$$\frac{dc}{dt} = \frac{K}{c_t}$$

The dyeability of the fibre at time t is the dye dilution related to a unit of time, i.e. $(c_t \cdot t)^{-1}$. It is infinite at the beginning (if the dye adsorption at time t = 0 is disregarded) and decreases with the time of dyeing (usually very quickly) and is equal to 0 at equilibrium. According to experience, the fibre is now no longer capable of absorbing any dye from the dyebath (only an interchange of dye particles between the fibre and the dyebath takes place as a result of the dynamic equilibrium which exists in reversible processes).

Dye absorption index (fibre affinity index SF), fibre characteristic which gives information on the max. dyestuff affinity of an acrylic fibre for cationic dyestuffs.

Dye acids These are organic acids consisting of the hydrophobic dye residue and the hydrophilic auxochrome groups. The latter are mainly sulphonic acid ($-SO_3H$) and/or carboxyl ($-COOH$) or hydroxyl groups ($-OH$) which, with their acid character and negative charge, make the dye residue function as a dye acid and become a dye ion. Free dye acids exist, for example, in the acid dye range, either in the commercial form itself or they are formed by the addition of acid in an acidic dyebath:



The dye acids formed during the vatting of vat dyes are known as → Vat acids. Due to their ionic behaviour in aqueous solution, formation of the dye acids and their alkali salts (→ Dye salts) occurs in contrast to → Colour bases, i.e. the main group contained in cationic dyes (→ Dye ions).

Dye affinity In simple terms, dye affinity (also neutral affinity) is the dye absorbing capacity (of textile fibres). It varies between wide limits depending on the state of equilibrium between the fibre and the dye in solution. A number of factors play an important role in this process, e.g. liquor ratio, dye characteristics, additions to the dyebath (such as acids, salts and dyeing auxiliaries), dyeing time, dyeing temperature, and the degree of purity, extent of drawing and degree of crystallinity of the fibre being dyed, as well as the number of dye bonding groups available in the fibre. For affinity-controlled dyeing processes, a temperature is selected at which diffusion proceeds at a relatively fast rate. If it is assumed, as a model, that a bath exhaustion equilibrium is established momentarily at any one time, then the kinetics of exhaustion are given by the change in equilibrium. For polyamide fibres and wool, the equilibrium between the dye in the fibre (concentration C_F) and the dye in the liquor (C_L) can be approached by a superimposed Langmuir and Nernst distribution:

$$C_F\,(pH) = \frac{k_L\,(pH) \cdot S_L\,(pH) \cdot C_L}{1 + k_L\,(pH) \cdot C_L} + k_N\,(pH) \cdot C_L$$

with the pH-dependent distribution coefficients k_L and k_N, and the saturation value S_L. The pH dependencies are both dye and fibre-specific.

Dye affinity of wool, treatments to improve,

a) Pretreat for 1 h at the boil in a 5% potassium thiocyanate solution, rinse, dye in the presence of 20% sodium sulphate and 5% acetic acid 30%;
b) Bring the yarn to the boil in a solution of 2,5–4% solution of sodium thiosulphate or neutral sodium sulphite or sodium tetraborate, boil for 1 h, hydroextract and dry;
c) Treat the wool for 20–30 min. in a liquor containing 1–1,5% active chlorine under weakly acidic conditions, treat in a fresh bath with 1–2 g/l sodium dithionite as an antichlor and bleach.

Dye ager A horizontal continuous-dyeing machine for all conventional textile fabrics (including difficult qualities such as cotton velvet and lining fabrics) with all classes of dye, by the pad-steam process and the wet-in-wet process of vat dyeing voluminous fabrics in which dye is applied on a preceding padder and the reducing agent padded on directly before the ager entry using a special applicator unit. A high degree of reproducibility is achieved by the ager.

Dye analysis → Dye tests.

Dye anions → Dye ions.

Dye application – control methods in continuous dyeing In continuous dyeing, the quantity of dye applied to the textile fabric can be measured indirectly from the amount of moisture (liquor) applied by the padder (e.g. by means of microwaves). It would be even better, however, to measure the quantity of dye applied to the running fabric by taking reflection measurements on the wet fabric shortly after it leaves the padder nip since, in this case, it would be possible to make any necessary corrections from direct readings and the short control loop. Other control possibilities opened up by reflection measurements on the wet fabric include:

1. Concentration distribution of dyes and auxiliaries applied from the pad liquor (side, centre, side).
2. Localized pick-up of liquor by the fabric (in relation to its dry weight before padding).
3. Localized residual moisture content of the fabric entering the liquor and the exchange coefficient between water and product.

It is to be understood in this case that the directly measurable dye pick-up parameter desired (Fig.) does not have to be replaced by a group of measurement parameters which can, in principle, be handled but which require very involved measurements (the exchange coefficient is likewise not amenable to direct measurement. However, since it is only used as a correction parameter, it can be applied as a value capable of interpolation from a series of trials).

Before a decision is made to invest in an elaborate measuring system of this kind for a particular process stage, it is of course necessary to establish first of all whether or not sufficient control would be achieved by measuring the dyed result at the end of the dyeing process and only then make any necessary corrections to the two factors exercising the greatest influence on the process, i.e. the dye liquor itself and the dye liquor pick-up. Colour measurement on fabrics at the point of delivery from a continuous dyeing plant with a drier is

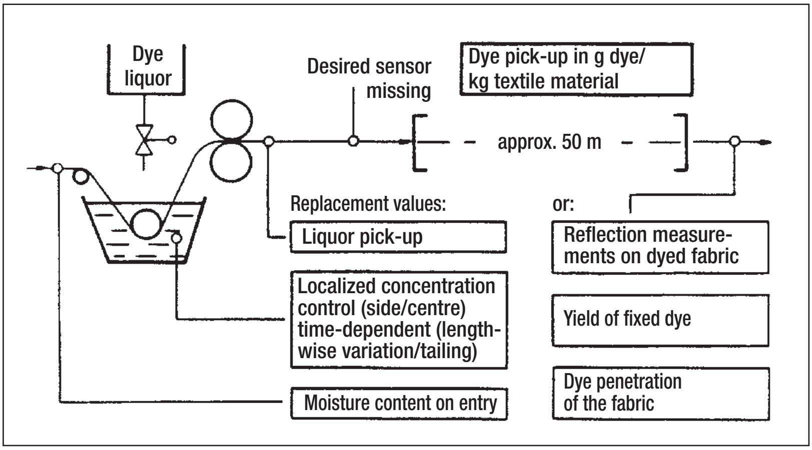


Fig.: Sensors for the measurement of dye pick-up in continuous dyeing.

state-of-the-art technology. Measuring sensors are already available which can take reflection measurements across the full width of dyed fabrics (by means of a single traversing measuring head or 3–5 dixed measuring heads) and display from the standard. The main problem here lies in the time response of the control system rather than in the measuring sensors.

Measurements are carried out approx. 30–100 m after the point of dye application. There is consequently a long time lag, i.e. under these conditions, many metres of fabric have to pass through the dyeing plant after a correction has been made to the dye pick-up before the point of change in the fabric reaches the measuring head.

Dye batch A → Batch of textile material dyed in a single process cycle (→ Charge).

Dyebath exhaustion, difference in concentration, measured by colorimetry, in the dyebath before and after dyeing. It is quoted as a percentage of the original dye concentration. The colour of the exhausted dyebath is measured against the full colour. Dye exhaustion is of course also dependent on the composition of the dye concerned.

Dyebath finish application → Softening of textiles.

Dyebath preparation is the preparation of a dyebath incorporating additives and chemicals or dyeing assistants using dispersing agents, sometimes solvent accelerators, and in the case of disperse dyestuffs also carriers, ethoxylates etc., usually in pourable form as dye pastes of varying viscosity. Weighing apparatus may be connected to the dissolving plant (Fig. 1). The transfer of the weighed-out dyestuff to the dissolving plant is improved in health and saefty respects by the use of robots (Fig. 2).

Dye beam A perforated cylinder (usually of stainless steel) on which woven or knitted textile fabric to be dyed in a → Beam dyeing machine is wound.

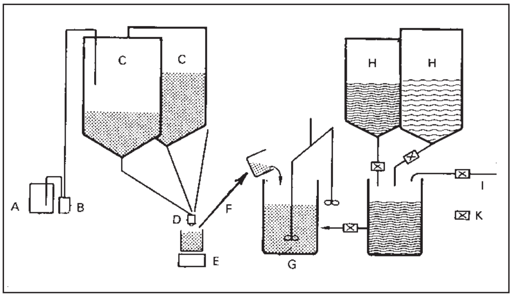

Fig. 1: Dyestuff weighing/dissolving plant.
A = dye container; B = pump; C = dyestuff reservoir; D = metering device; E = automatic balance; F = robot; G = formulating vessel and agitator; H = chemical solutions; I = water; K = flow meter.

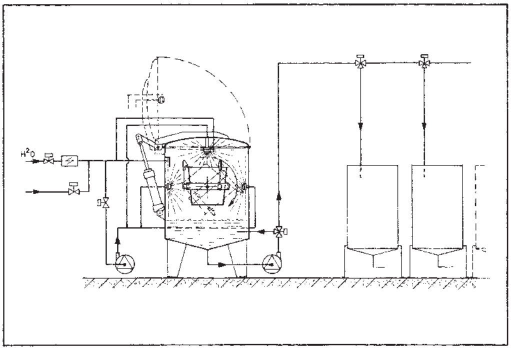

Fig. 2: Lawer robotic dyestuff dissolving plant.

Dye beam batcher Special batching unit for batching textile fabrics on to dye beams before dyeing and debatching after dyeing. The debatching operation takes place in the wet state.

Dye carrier → Carrier.

Dye cations → Dye ions.

Dye/chemical dispensing Weighing dyestuffs and textile auxiliaries in the → Colour kitchen.

Dye class identification on fibres, if the fibre material is unknown, → Fibre identification should be carried out first.

Tab.: Dye class identification for various fibres.

The most well-known dye class identification systems on fibres are:

I. Krefeld method:

a) For cellulose fibres: dissolve sample in suitable solvent, sulphur test (for sulphur-based dyes), blind vat (oxidation and cationic dyes), stripping and staining reactions (for mordant, acid, direct and diazo dyes), dimethyl formamide test (for reactive dyes), glacial acetic acid test (for vat, naphthol and phthalocyanine dyes).

b) For animal fibres: paraffin test, blind vat and reoxidation (for vat and naphthol dyes), detection of metals (metal complex and chrome dyes), cold glacial acetic acid (cationic dyes), suitable solvent (reactive, acid and direct dyes).

c) For synthetic fibres: a caprolactam melt is prepared or stripping by means of glacial acetic acid carried out. The melt and the solution are mixed with ether and processed further. Dye classes which can be identified are disperse, metal complex, chrome, acid, cationic and naphthol dyes.

II. Reutlinger method:

a) For cellulosic fibres: water, wash, paraffin, pyridine, glacial acetic acid, hydrogen sulphide, chlorine, benzene tests and blind vat.

b) For animal fibres: water, wash, paraffin, glacial acetic acid, ammonia, pyridine, benzene tests and blind vat.

c) For synthetic fibres: →: Acetate, Polyamide and Acrylic dyes.

III. In accordance with the AATCC guidelines for cellulosic, animal and synthetic fibres.

Dye classification A distinction is made between the following methods of classification:

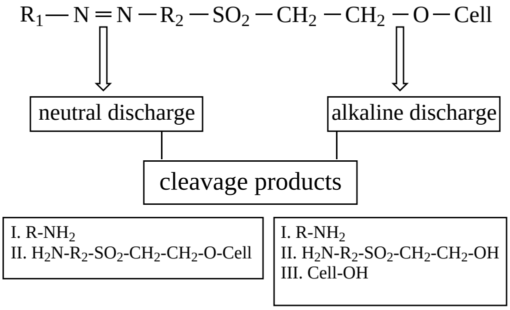
I. Scientific classification of dyes based on their chemical structure, e.g. anthraquinone, azo dyes, etc.

II. Technical classification of dyes based on their dyeing properties, e.g. direct, acid, wool dyes, etc.

III. Commercial classification of dyes based on various aspects according to the manufacturer, e.g. according to fastness properties such as Sirius Light, Indanthren, etc. or according to the method of dyeing under collective names, e.g. Remazol = reactive dyes (Dystar), Palanil = disperse dyes (BASF), etc.

Dye cleavage → Cleavage of dyes.

Dye cleavage product → Cleavage of dyes. When discharging a reactive ground with vinyl sulphone dyestuffs, the dye cleavage product which contains the reactive group remains in the neutral region, as is the case with a dyestuff with other reactive groups bonded with cellulose. In contrast to the latter, the vinyl sulphone group is split off from the cellulose in the alkaline region, this being the basis for the good dischargeability of these dyestuffs:



Dye concentration – colorimetric evaluation, is carried out after measuring the → Reflectance using the Kubelka-Munk function and Lambert-Beersch's Law. The reflectance R is measured close to the absorption maximum. The following formula applies when calculating the concentration C:

$$A \cdot C = \frac{(1-R)^2}{2R}$$

where the factor A must be found for the dyestuff on the basis of calibration dyeing with known concentrations.

Dye, definition of Dyes are coloured compounds which are absorbed or adsorbed by the fibre from a solution or suspension where they are subsequently fixed and are thus used for the coloration of textiles. The term also applies to certain colourless compounds (optical brighteners) and those which only form an insoluble dye through combination on or in the fibre (e.g. naphthols and Turkey Red). Between these groups are the mordant dyes. The final colour obtained on the fibre with these dyes is formed by applying the dye to a textile previously treated with a metal salt (mordant) or vice versa (colour lakes). Pigments do not fit this definition since they are water-insoluble colorants having no affinity for textile fibres and, for this reason, have to be applied with a binder capable of bonding to the fibre. Consequently, pigments must be regarded as a special case in textile coloration

Dye developer → Developer.

Dye diffusion (→ Diffusion mechanisms in dyeing). Two mechanisms are compared below:

1. The pore mechanism: in this case, dyes dissolved in the aqueous liquor diffuse through the water-filled pores in the fibres and are adsorbed on to the walls of the pores at the same time. This case applies particularly to cellulosic fibres and porous acrylic fibres. According to Valko, the dye molecule is dissolved in the aqueous liquor first and subsequently becomes attached to a cellulose crytallite within the pore.
2. The mobile-segment or free-volume mechanism describes the dyeing process as diffusion through the less ordered, amorphous regions of a polymer substance. The rate of diffusion of the dye molecule is determined in this case by the mobility of the segments in the polymer chain molecules. The segment mobility starts at the glass transition temperature at which point the non-crystalline regions of the fibres or polymers are transformed from a glass-like into a viscoelastic state. Free-volume diffusion is particularly dominant in the case of polyamide.

Dye dispersing agents → Dye solubilizing and dispersing agents.

Dye exhaustion rate → Exhaustion rate of dyes.

Dye extraction from dye liquors in dyeing The difference in concentration, determined colorimetrically between the dye liquor before and after dyeing; it is expressed as a percentage of the original liquor concentration. The coloration of the extracted liquor is determined by measurement of the full colour. The extraction of dye from the dye liquor is, of course, also dependent on the respective dye structure.

Dye fastness Although colour fastness ratings are given by the dye manufacturers for each of the dyes they produce, it is the colour fastness of dyeings or prints (→ Fastness testing) which have been dyed or printed on a given material under normal production conditions that is important in practice and for which standard fastness test methods are used.

Dye/fibre bonds These are the bonds formed between dyes and the fibre through surface energy and intermolecular forces, covalent and/or ionic bonds or dipole forces, hydrogen bonds or Van der Waals forces.

Dye finish is dye supplied in a form which in addition to the dyestuff itself also contains → Extenders. Both consitutents are ground in a mill into a powdered, liquid or pasty end product (→ Dyestuff formulations).

Dye fixation efficiency in exhaust dyeing An estimate of the average proportion of dye actually fixed on a textile substrate carried out by the OECD in 1975 revealed very wide variations which, on the one hand, can be attributed to different products within any particular dye class and, without doubt, to the different methods of application used in practice (which could be further improved in many cases) as well. The results of one study to investigate the proportion of unfixed dye remaining after the completion of dyeing, i.e. the proportion of dye lost in spent dyebaths and rinse water are given below:

– sulphur dyes	30–40%
– reactive dyes	20–50%
– vat dyes	5–20%
– direct dyes	5–30%
– naphthol dyes	5–10%
– disperse dyes	8–20%
– metal-complex dyes	2–5%
– cationic dyes	2–3%
– acid dyes	7–20%

Dye formulation, instrumental → Computer colour matching.

Dye formulations → Dyestuff formulations.

Dyehouse An industrial (→ Textile dyehouse) or commercial plant (→ Garment dyeing) for the dyeing of textiles (Fig.).

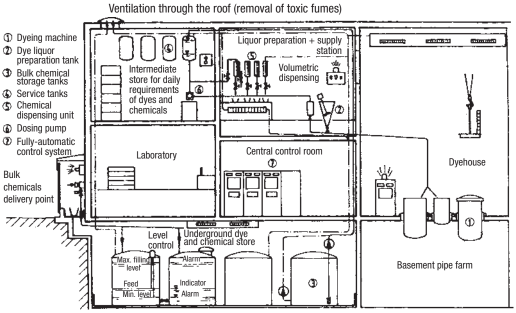


Fig.: Dyehouse plant.

Dyehouse communication (for fully automated dyehouse). Manual interventions to control a dyeing machine must be reduced in order to allow the operators sufficient time to be able to respond appropriately to system reports and messages. With the aid of an operator control panel in the form of a visual display unit (monitor screen) and a data printer, it must be possible to obtain an overview of the process status at all times and deal with any malfunctions that may arise. Moreover, it must be possible to present the process objectives in simplified form, i.e. with dying-specific data resp. parameters. In addition to possible malfunction reports, the daily progress of various batches as well as the consumption of chemicals, dyes and energy involved can be printed out on a daily, weekly or monthly basis, or as required.

Dyehouse installations and equipment These include, e.g. fog dispersal systems, dyeing machines, dye vessels, colour kitchen, computer colour measurement systems as well as the dyehouse laboratory.

Dyehouse laboratory A laboratory under the control of the dyehouse mainly intended for carrying out laboratory dyeings and tests in addition to dyeing-related analytical procedures in many cases.

Dyeing Dyeing is carried out in a dyehouse with dyestuffs and is used in (textile) finishing. The process depends on the type of fibre and form of the material in dyeing vessels, dyeing apparatus or machines. The dye is applied to a given substrate by a technological process, mainly consisting of deposition or adsorption and fixation (both processes being carried out simultaneously or in succession). If necessary the process is preceded by pre-treatment and followed by post-treatment of the substrate.

Dyeing accelerator → Carriers.

Dyeing and finishing combination processes Combination processes for dyeing and finishing in a single operation: Delaware Process; Procion-Resin process.

Dyeing auxiliary products →: Stripping auxiliary, Stripping agent, Mordanting, Fastness improving agents, Levelling agent, Dyeing Oils, Wetting agents for dyeing and dyeing oils, Dye solubilizing and dispersing agents, Fibre protections agents, Wetting agent, Retarding agent, Overboiling inhibitor.

Dyeing centrifuge for yarn dyeing In order to achieve a more intensive liquor exchange during the rinsing of dyeings, and consequently reduce the consumption of rinse water, it is recommended to centrifuge the batch in the dyeing machine after each rinse cycle (Fig.). A suitable system was introduced by Flainox in 1991.

A yarn dyeing carrier divided in two halves is placed in the dyeing cylinder to prevent deformation of the yarn packages before the large drum rotates on its axis during centrifuging. Dyeing is carried out by circulating the liquor as usual through the yarn packages supported on dye spindles.

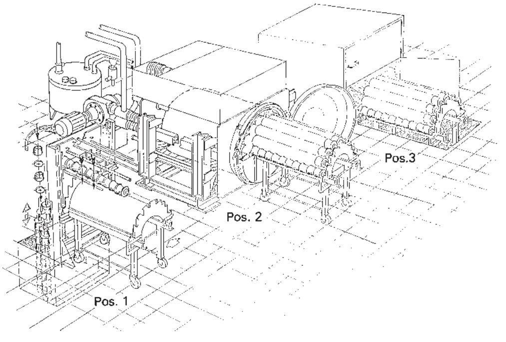

Fig.: Position 1: loading the yarn dyeing carrier, Position 2: dyeing centrifuge, Position 3: drying.

Dyeing curves → Reflectance.

Dyeing equilibrium A concentration equilibrium between the amount of dye on the fibre and the amount of dye in the dyebath which becomes established by the end of every dyeing process.

Dyeing faults, all causes which result in defective dyeing or unacceptable dye batches.

Dyeing in standing bath → Standing bath dyeing.

Dyeing kettle, hemispherical or cylindrical vessel (copper, stainless steel or ceramic) for dyeing material in hank or rope form, garments, etc. Usually having double (part-removable) perforated floors under which are steam tubes for heating the liquor; may incorporate a winch.

Dyeing kinetics, physico-chemical processes during the dyeing process which, for the main part, are characterised in mathematical terms (→ Kinetic equation in fibre loading). Three kinetic steps are involved:

1. transfer of dye from the dyebath to the fibre surface,
2. adsorption of dye onto the fibre surface,
3. diffusion of dye into the fibre.

Dyeing laboratory → Laboratory.

Dyeing machine for garment panels Finished garments or panels can be dyed in special machines. Paddle machines were used formerly, whilst more modern machines seek to reduce the liquor ratio.

Dyeing machines Devices in which the material which is to be dyed (as distinct from → Dyeing machine, circulating) is agitated in more-or-less stationary liquor – for example: padder, rope-winch vat, jigger, continuous dyeing machine, paddle dyeing machine, star frame and, among others, modern processors such as the pad-jigger, pad-roll, pad-steam, pad-wet and pad-winch processes. The dyeing machines which are in use today for batch dyeing consist of the following basic elements:

- the vat as the stationary zone,
- the pump for circulating the liquor,

- the mechanical elements for controlling the liquor (pipes and valves),
- the heat exchanger (heating unit),
- the mechanical elements for transporting the material and circulating the liquor, such as guide bars, reversing winches, transporter winches, material carriers and immersion wetting-out apparatus.

Dye movement in the solution is brought about by convection whilst liquor movement is brought about by agitation or circulation pumps. High temperatures and liquor exchange accelerate this process so that the overall dyeing speed is not adversely affected by diffusion. Diffusion is the dynamic dispersion of dye particles caused by the system's tendency towards a state of equal concentration of particles throughout the liquor irrespective of the liquor movement. Optimum flow at the interface and through the textile material to produce the highest possible degree of levellness depends on the liquor-exchange system of the dyeing machine in question. High flow rates accelerate the dye absorption, the various machine designs produce different types of flow (Fig. 1).

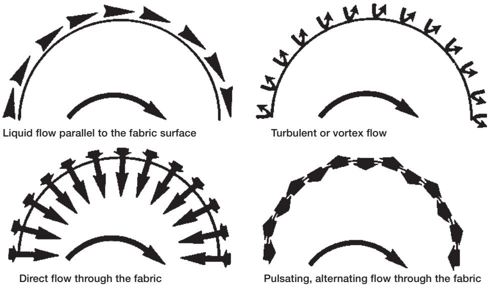

Fig. 1: Types of flow between fabric and liquor.

Different machines or apparatus are used according to the material being dyed. There are dyeing machines in which the liquor is stationary and the material is moving and dyeing machines in which the liquor is moving and the material is stationary (Fig. 2).

Dyeing is carried out according to the makeup of the material to be dyed:

I. Dope-dyed synthetic fibres: In synthetic fibre production the dye pigment (insoluble but finely divided dyestuff) is added to the spinning solution so that a coloured fibre is produced when extruded through the spinneret.

II. Loose stock dyeing: Loose stocks can be dyed by batch (non-continuous or continuous methods). In the case of batch dyeing, the fibre material is packed in a perforated vessel through which the dye liquor is forced. Coloration is not always evenly distributed but this is immaterial as the loose fibres are subsequently dispersed in the spinning mill and evenly mixed so that the colour ultimately appears to be uniform. In the case of continuous dyeing, dye solution is continuously applied to the stock on a padder and the dye fixed in a steam ager. The material is then washed and dried. Stock of different colours can be used for colour blending.

III. Sliver dyeing (slubbing dyeing): top or combed sliver consists of a continuous sliver from which the short fibres have been combed out on a combing machine. This sliver can be, for example, dyed in ball form. There are several areas where slubbing dyed material can be used in coloured wool yarn production.

a) Sold shade yarn: the essential advantage of dyeing combed sliver is the high fastness achieved. However, it is only economically viable where large batches are involved.

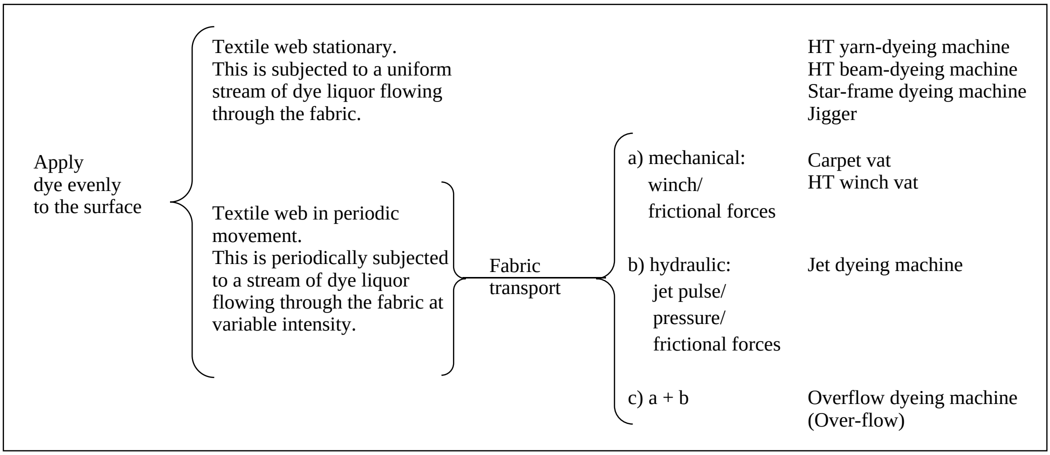

Fig. 2: Characteristics of dye units in relation to fabric transport.

b) Melange yarn: in a melange yarn specified percentages of combed slivers are dyed in different colours. These different-coloured slivers are then mixed together at the drawing stage and spun.
c) Vigoureux yarns: In this case, printing paste is applied at different intervals by means of a printing roller and fixed.

When the combed sliver is drafted during the spinning cycle, the coloured and non-coloured areas intermix so as to create the characteristic melange yarn. In the vigoureux printing process, the individual fibres are striped zebra fashion. The patterning in the finished product resulting from this process is so small that the eye can only perceive a mixed colour. For example, from a mixture of black and white stripes the resulting colour is grey. In melange products, on the other hand, the eye is still able to identify the individual black and white fibres.

IV. Yarn dyeing: The following different machines are used for dyeing yarns:

a) Hank dyeing machines: the yarn is wound into hanks, the individual hanks laid on a roller conveyor and the hanks passed through the dyebath on the rollers.
b) Spray-dyeing: in this case, hanks are laid over a perforated tube out of which the dye liquor flows. The hanks are placed at regular intervals so that dyeing is uniform. The amount of dye liquor required for this machine is significantly less than for a).
c) Pack cage: the hanks are placed in a cage and dyed in a similar way to the loose stock dyeing process.
d) Assembling columns of cross-wound packages and subjecting these to a stream of dye liquor in an autoclave.

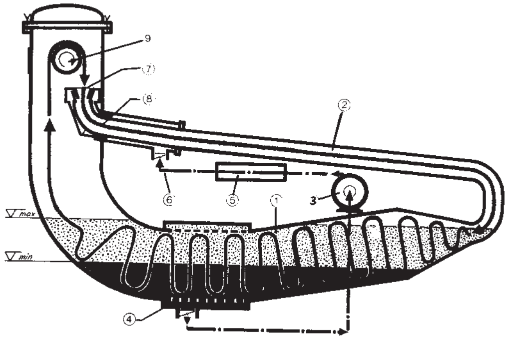

Fig. 4: "Krantz" overflow machine for fabrics in rope form. 1 = dwell chamber; 2 = liquor-exchange pipe; 4 = circulation pump; 5 = liquor extraction; 6 = heat exchanger; 7 = liquor injection; 8 = wetting-out device; 9 = wetted-out fabric; 10 = return winch.

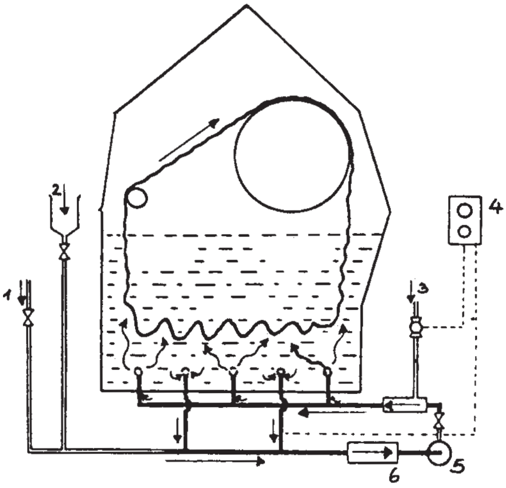

Fig. 3: Classical winch vat (IWS model). 1 = water supply; 2 = dye metering; 3 = steam supply; 4 = controller; 5 = pump; 6 = filter. Fabric throughput 20–40 m/min, liquor temperature 96–98°C.

V. Piece dyeing: there is a whole series of machines which can be used for dyeing fabrics. Modern dyeing machines operate via mechanical systems using program controllers or microprocessors, the whole dyeing process being controlled by a program.

a) Winch vat: these machines are suitable for qualities which are not subject to running cracks. The cloth is passed through the dye liquor at boiling point as a continuous rope with a rotating winch providing the traction. Temperatures can be as high as 100°C (Fig. 3).
b) Jet dyeing machine or Overflow machine: the overflow machine has been especially designed for dyeing fabric which is sensitive to tensile stress. These fabrics can be dyed using this apparatus with the minimum possible tensile loading. In this type of machine (Fig. 4), both the fabric and the liquor are in motion. The construction can be either vertical or horizontal. In jet dyeing machines, the liquor is caused to move by jets from nozzles, thus causing the fabric to move at the same time. In most cases, the fabric is also driven by means of a winch.

Dyeing machines, circulating liquor type These are differentiated into package systems, Hussong-type systems and spindle-and-separator systems. The principles differ according to working methods: stationary liquor - moving material (dye machines: padder, winch vat, jigger, roller box and hank-dyeing machine); stationary material - moving liquor (less significance, particularly common for loose stock and bulk dyeing in, for example, garment dyeing and hat dyeing; garment-dyeing machines and paddle-dyeing machines). Examples of these are:

a) Cheese dyeing machine: the packages are on perfo-

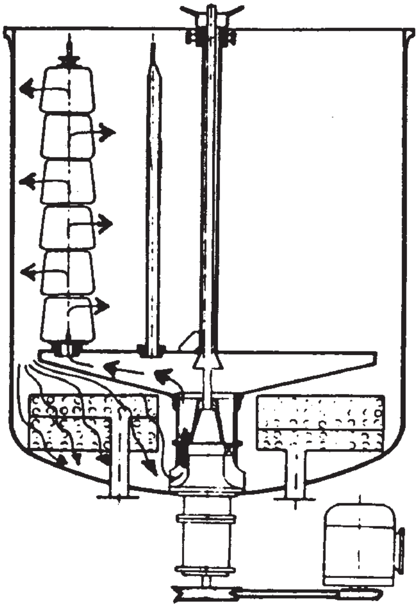

Fig. 1: Cross-wound package yarn dyeing machine.

rated plastic tubes which are stacked on perforated spindles and then put into a sealed vessel (Fig. 1). In this vessel the dye liquor can be forced through the packages under pressure. Dyeing temperatures > 100°C are possible.

b) HT Beam dyeing machine: In this case, dyeing is carried out at temperatures above 100°C. The fabric is wound on to a perforated cylinder and inserted into a sealed vessel (Fig. 2). The dye liquor can be pumped in an inward or outward direction through the rolled fabric.

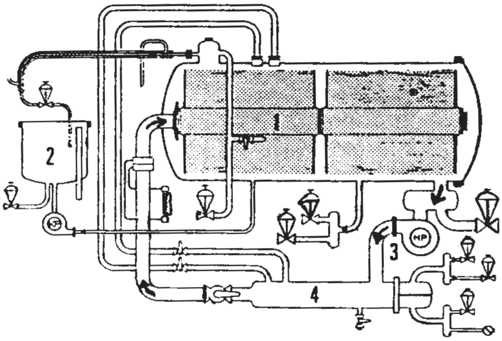

Fig. 2: Operational cross-section of a dyeing machine for open-width piece dyeing.
1 = coupled dye beams with outward circulation; 2 = stock reservoirs with separate pump; 3 = main pump; 4 = heat exchanger.

Dyeing methods These have been the subject of continual development over the years especially because of the need to rationalize or for reasons related to colour levellness and dye compatibility or because of new problems appearing with new substrates. Thus, there is a whole series of possibilities for variation such as short-liquor dyeing, foam applications, thermosol processes, jet dyeing (jet-dye machines), overflow dyeing, (overflow dyeing machines), HT dyeing processes, pad-steam dyeing processes and continuous wet-steam processes among others. In order to optimise the dyeing-process, the dyeing procedure is controlled according to a program and process control systems are used to control the operations. This means that a set of measurement instruments of maximum reliability continually records certain parameters and issues appropriate commands to the valves etc. Actuators, for example, are used for speed/time control and other operational control aspects for individual forms of apparatus, machine or automatic process management and control systems. Development in the area of textile dyeing and dyestuffs and in relation to technical applications is very dynamic.

Dyeing of acetate fibres (→ Dyeing of triacetate fibres). Disperse dyes are predominantly used both for acetate and triacetate fibres and are mainly used in exhaustion processes. As is the case for polyesters, triacetate must be dyed either with the addition of carriers or under HT conditions. In the case of acetate, selected cationic and naphthol-based dyestuffs can also be considered. There are only limited possibilities for using the padding process as the thermosol dyeing process cannot be used for acetate fibres and can only be used for triacetate fibres when lighter shades are being applied.

Dyeing of acetate/wool cotton unions,

I. Acetate white, union coloured: single-bath dyeing with suitable neutral-dyeing acid, direct or union (mixed fibre) dyes. Two-bath method, this is possible by pre-dyeing the cellulosic fibres with direct dyes at approx. 70°C, rinsing and filling in the wool with acid dyes from an acidic bath.

II. Acetate coloured, union white: it is questionable whether a satisfactory union reserve is possible as even the most suitable acetate dyes cause staining of the wool.

III. Acetate and union in two colours: single-bath method using a combination of dyes according to I. + II. (if necessary II. + union dyes) in a neutral sodium sulphate bath (Glauber's salt). Two-bath method by pre-dyeing the acetate, filling in the union and rinsing.

IV. Acetate, union in three colours: single-bath method using dyes which reserve the other fibres completely by dyeing according to dyeing methods I.–II. in a neutral bath. Two-bath method as single-bath with filling in of the vegetable fibre.

V. All fibres dyed the same colour: dye with a combination of direct-dyeing union dyes and acetate dyes.

Dyeing of acrylic fibres These fibres can exhibit very different dye affinities. Acrylic staple fibres are more easily dyed and in greater depths than filaments. The dyeing of acrylic fibres has proved difficult to the extent that whilst polyacrylonitrile fibres only begin to exhibit adequate affinity at relatively high temperatures of 70–85°C (depending on origin), the rate of dyeing is virtually doubled with an increase in temperature of around 3–4°C. Moreover, only a very low degree of migration takes place at the usual dyeing temperatures, i.e. as a rule, uneven dyeings cannot be levelled out adequately.

I. Cationic dyes: suitable for pale to dark shades; pale to medium depth shades are usually dyed using cationic or anionic retarders at the boil. The HT process is only suitable for acrylic filaments and fibres of low affinity. Continuous methods are used for loose stock, tow and combed sliver as well as, to some extent, acrylic/cellulosic blends (fixation medium = saturated steam). The thermosol process is of practically no significance (levelling problems, unsatisfactory reproducibility and effect on handle).

II. Disperse dyes: the material is introduced into the dye bath at 70°C, brought to the boil quickly and dyed at the boil for 1 h. The thermosol and pad-steam processes are of secondary importance.

Dyeing of acrylic/wool blends Dyeing methods: single-bath single-stage, single-bath two-stage or a two-bath process. Cationic dyes are used to dye the acrylic component and acid, 1 : 2 metal-complex and reactive dyes are used to dye the wool component. When dyeing acrylic fibres and wool, the cationic dyes stain the wool component first. As the boil is approached during dyeing, they transfer slowly from the wool on to the acrylic fibre and if the proportion of wool is at least 30%, retarders are not necessary. The transfer of cationic dyes from the wool is dependent on the quantity of dye, dyeing time, dyeing temperature and the pH. In the case of deep shades, a dyeing time of 45–60 min. at the boil is necessary to achieve a good wool reserve. With falling pH, the wool reserve increases. A good wool reserve is a prerequisite for the achievement of optimum wet and light fastness properties.

Dyeing of cellulose fibres ➝: Dyeing of cotton, Dyeing of linen, Dyeing of jute, Dyeing of regenerated cellulose.

Dyeing of coir Method as for jute – dyeing is usually carried out using direct or acid dyes under mildly acidic conditions (cationic dyes have inadequate light fastness). Coir is also dyed before spinning using oil-soluble dyes in the spinning oil.

Dyeing of cotton The affinity of cotton for dye varies according to its history. The adsorption capabilities of cotton are increased by caustic solutions or mercerization. There is a huge selection of dyestuffs available for cotton: substantive dyes, vat dyes, sulphur dyes, leuco-ester vat dyes, reactive dyes, naphthol dyes and phthalocyanine dyes. Of less importance are pigment dyes and chrome dyes. Cationic, aniline black and mineral khaki dyes do not have any significant application. There is a clear trend towards dye groups with high fastness properties. A continual problem for the finisher is the proportion of immature or dead fibres (dead cotton) which give rise to the appearance of bright spots in coloured fabrics. These faults are significantly reduced by treating the fibre with caustic solution or by mercerization.

Dyeing of cotton/acetate or cotton/triacetate blends,

I. Acetate or triacetate white, cotton coloured: dyeing is usually carried out with selected substantive dyes which reserve the acetate and triacetate. The dyeing temperature must not exceed a maximum of 80°C with acetate since staining of the fibre occurs at the boil. Acetate which has been scoured at too high a temperature and which is partially saponified will no longer be reserved. Even for acetate and triacetate which have been delustered in spinning a good reserve is more difficult to obtain.

II. Cotton white, acetate or triacetate coloured: this is a considerably less favourable combination as disperse dyes stain the cotton to a greater or lesser extent. An afterclear treatment is necessary with sodium dithionite, sodium hypochlorite or potassium permanganate.

III. Cotton/acetate or triacetate dyed tone-in-tone: usually carried out by single-bath dyeing with substantive and disperse dyes. Two-bath method : a) the acetate or triacetate is dyed with diazotizable disperse dyes; b) then using a fresh bath for the acetate or triacetate, the cotton is filled in with substantive dyes.

All the above variants are carried out by exhaust dyeing; pad dyeing is only used in exceptional cases.

Dyeing of cotton and wool ➝ Dyeing of wool/cotton unions.

Dyeing of cotton/regenerated cellulose blends Cotton/regenerated cellulose blends are dyed using the same classes of dyes as for cotton. The achievement of tone-in-tone uniformity between cotton and regenerated fibres is problematic due to the greater dye affinity of the latter (greatest with cupro fibres and weakest with high-wet-modulus fibres). The dyeing method, especially for substantive dyes, must be appropriately adapted with regard to salt additions and temperature, i.e. dyeing must be carried out with less salt or no salt at all and at lower temperatures. If necessary, dyeing is started at the boil with a portion of the dye, and the rest is added to the bath after cooling down. Padding methods are more suitable than exhaust methods for vat, leuco-vat ester and naphthol dyes. Causticizing before dyeing improves the affinity of the cotton. However, despite all these measures, tone-in-tone dyeing is not achievable with dark shades.

Dyeing of cotton/regenerated cellulose with polyamide blends Tone-in tone dyeings with a single class of dyes are only achieved with great difficulty. In most cases, one or other of the fibre components will have to be filled in with specifically appropriate dyes. Exhaust methods: selected substantive and vat dyes (for which the semi-pigmentation process is particularly suitable) are capable of producing tone-in-tone dyeings in pale shades by using appropriate dyeing methods. A single-bath method with substantive and metal-containing disperse dyes can be used here. For dark shades, the polyamide must be dyed first with metal-containing disperse dyes followed by the cellulose in the same bath with substantive dyes. A single-bath two-stage method may also be used with selected reactive dyes. In this case, either the cellulose is dyed first under alkaline conditions followed, after acidifying the bath, by the polyamide or, the polyamide is dyed first at pH 5 and followed, after neutralization, by the cellulose. Two-bath two-stage method: metal-containing disperse or 1 : 2 metal complex and reactive or vat dyes. Pad dyeing: pigments may be used for pastel shades. Where high fastness is required, each fibre component must be dyed separately by the methods customarily used for it. For the polyamide component, metal-containing disperse dyes are by far the most important, and vat, sulphur or reactive dyes for the cellulosic components. Selected acid dyes may be applied together with vat dyes by a single-stage method, e.g.: both classes of dye are padded together, followed by acid steaming, drying, thermofixation, padding with caustic/sodium dithionite, then steaming, oxidizing and washing. Phthalocyanine dyes may be employed for turquoise shades.

Dyeing of flammé effects This process is mainly carried out on hank yarns. This is effectively done by tying off the hanks individually at the sites where they are to be dyed in one particular colour first. Dyeing is then carried out in the customary way with the liquor just reaching the ties. The hanks are withdrawn and thoroughly rinsed by immediately spraying them with cold water in an upward direction. The ties are undone (after an intermediate drying step if necessary), rehung and tied again for the next dyeing with another dye, as already described, and rinsed down again etc. until the whole hank is dyed in the various colours desired. Two, three, four or more different colours may be involved and these may be interspersed with non-dyed areas or the colours may be adjacent to each other or even overlapping. Instead of obtaining flame effects on non-dyed yarn, hanks can be pre-dyed in a certain shade and then dyed in certain places as described above. Instead of using the technique described above, dyeing is also carried out using a pulley lifting system without tying off the hanks. → Dyeing of ombré or shaded effects.

Dyeing of garments → Garment dyeing.

Dyeing of glass filaments, fabrics In this case, it must be taken into consideration that, under normal circumstances, there is no affinity between fibre and dye and that no penetration of the dye into the fibre is possible, only surface coloration. The following overview includes patented processes which must be regarded as being legally protected:

I. Fused mass coloration: using coloured metal oxides yielding weak colours only as the colour intensity inevitably decreases with the cross section of the filament.

II. Dyeing of activated surfaces: predominantly older processes of relatively little practical importance and usually yielding weak coloration, deficient in crocking fastness and, almost without exception, having a tendency to damage the fibres.

III. Direct dyeing methods: without pre-treatment, using conventional dyeing techniques and, in this case, yielding surface coloration which is barely acceptable. Methods involving the deposition of water-insoluble dyes are exceptions to this but usually only weak coloration can be achieved, e.g., when using sulphur or vat dyes.

IV. Pre-mordanting dyeing methods: a) metal-salt process gives strong colours in some cases but almost always with insufficient crocking fastness, b) cation-active process gives very strong colorations which, with the right choice of dye, can have good fastness properties against water and light but only moderate crocking fastness.

V. Bonding-agent dyeing methods: coating with dyeable or dyed films: a) pigment dyeing methods are the most elegant and simplest to use. Pale to medium shades are possible with maximum light, water and crocking fastness (with the right choice of dye) while the properties of the dark colours (marine and black) are frequently much worse. The principle consists of fixing the pigment using synthetic resins. b) Other bonding-agent dyeing methods are to some extent still very inconvenient and unsatisfactory (especially with regard to crocking fastness). Exception: → Corona discharge process with good overall fastness but crocking fastness and grease resistance are not completely satisfactory. No dark full shades obtainable.

Dyeing of hat bodies → Hat dyeing.

Dyeing of hats → Hat dyeing.

Dyeing of hemp (→ Dyeing of linen), this is of no significance as the products manufactured from hemp are almost exclusively used for technical purposes (fire-engine hoses and belts, etc.).

Dyeing of hat trimmings of straw, panama and sisal,

1. For dyeing straw: acid and 1 : 1 metal-complex dyes
2. For dyeing panama: disperse and cationic dyes
3. For dyeing sisal: direct, acid, and 1 : 1 and 1 : 2 metal-complex dyes.

Dyeing of iridescent effects by piece-dyeing A prerequisite is that the warp and the weft have different affinities – usually acetate/triacetate or triacetate mixtures. Single-bath dyeing can be carried out with direct and disperse dyes, usually giving contrasting shades.

Dyeing of jute (→ Dyeing of cotton), the high proportion of non-cellulosic material gives jute an affinity for cationic dyes (mordant unnecessary) and acid dyes. Unlike cotton, jute is sensitive to alkalis. The light fastness of jute dyeings is poorer than on cotton.

Dyeing of leather(goods) Because of the wool-like chemical nature of leather, appropriately modified dyeing methods are used depending on the type of tanning process. The usual treatment with aqueous dye solutions given to new articles (by brushing on or dipping) has only a limited application for second-hand goods (garment dyeing). For expediency, dyeing is carried out using tried and tested commercially available → Leather dyes. → Leather dyeing.

Dyeing of linen (flax). In principle, dyeing is carried out using all the dye classes that are suitable for cotton (→ Dyeing of cotton). Dye penetration is generally more difficult, especially in the case of vat dyes. The best penetration and levelness is achieved with reactive dyes.

Dyeing of loose material (loose stock, loose fibre), advantages: any unlevelness in dyeing is evened out during the subsequent spinning process, large quantities can be produced to one shade by blending several batches and a low liquor ratio is possible in dyeing. Disadvantages: satisfactory processing in spinning is usually only achieved through the application of spinning oils and dressings. The spinning of coloured yarns demands total separation of different shades in spinning and laborious cleaning is necessary when changing colours. Unavoidable co-processing of short fibres and dyeable impurities. Continuous dyeing can be carried out by a pad steam process (e.g. the Smith Piston Pad Dyeing Machine).

Dyeing of modacrylic (acid dyeable)/wool blends This blend can only be dyed in solid shades with difficulty because of the considerably higher affinity of the acid dyes for the wool component. The best possible solid shade dyeings are achieved with the Chem-Acryl process and other process variants (manufacturer: Chemstrand Corp., Decatur, Alabama/USA). An addition of the following auxiliaries is necessary: cationic and non-ionic dyeing assistants which retard the exhaustion of selected acid dyes and bring about a satisfactory balance between the dye on both fibre components in the sulphuric acid bath.

Dyeing of modacrylic fibres → Modacrylic fibres.

Dyeing of ombré or shadow effects, shadow dyeing on one and the same hank, e.g. by hand using square or U-section rods. Firstly, the palest colour is dyed from a full vat then, after dropping a little of the bath, a dye addition is made and a somewhat darker shade is dyed – this procedure is repeated with the increase in depth of shade becoming less and less as ever smaller additions of dye are made. In this way, light to dark shadow effects of the same colour, i.e. so-called tonal gradations, are obtained. Ombré variations are produced by using different dyes. Excellent ombré dyeings are obtained on thoroughly pretreated dry goods by employing a material-specific dye selection (hot and cold dyeing types and no pre-mixed dyes if possible) as well as the absence of wetting agent (undesired upward migration of dye) with, if necessary, controlled additions of salt and temperature regulation. The most efficient results are obtained on the hank dyeing machine where good dye penetration is achieved by raising and lowering the entire yarn carrier assembly. With increasing depth of shade, the hanks are lowered to a lesser and lesser extent into the dye liquor which is correspondingly increased in strength with additions of dye. By dropping the liquor level approx. 5 cm for each individual shade a reduced depth of immersion is achieved. After reaching half the original bath volume, the yarn carrier assembly is lowered to a reduced depth. For piece goods, dyeing on the star frame is very practical (star dyeing machine) by continually raising and lowering the frame with the aid of a beam assembly (a cable running over a boom-arm); this method has proved particularly suitable for sensitive qualities (e.g. pure silk).

Dyeing of polyamide fibres Various dye classes of dye are suitable for dyeing polyamide fibres, and dye selection is based on the form of the material, the fastness requirements and the dyeing properties.

I. Disperse dyes: these dyes have good affinity and levelling properties. Affinity differences in the fibre are easily levelled out. The wet fastness properties of medium to deep dyeings are unsatisfactory.

II. Acid dyes: the most widely used class of dyes for dyeing polyamide fibres. They offer a wide colour gamut and good fastness properties, especially following an aftertreatment with products to improve the wet fastness. For combination dyeings it is essential to use dyes with similar rates of exhaustion. The selected dyes must not exhibit any blocking action. In order to cover up affinity differences in the material, anionic levelling agents, which possess an affinity for the fibre, are used in the dyebath.

III. Metal-complex dyes: these dyes have good light and wet fastness properties. Their use is limited (except for black) since differences in the polyamide material cannot be levelled out in most cases. Fastness properties can be improved with a tannin/tartar emetic (potassium antimony(III) tartrate) aftertreatment.

IV. Metal-containing disperse dyes: the fastnesses properties are the same as those of the metal-complex dyes. Material-dependent affinity differences are largely covered in dark shades. Improved fastness properties are possible with a tannin/(tartar emetic) (potassium antimony(III) tartrate) aftertreatment.

V. Reactive disperse dyes: dyeable as disperse dyes; chemical bonding with the fibre takes place following an alkaline aftertreatment thereby giving good wet fastness properties.

VI. Direct dyes: the selection is limited: used chiefly for reasons of shade and price.

VII. Naphthol dyes: of no importance.

VIII. Chrome dyes: of interest only for black shades (applied by the so-called Metachrome process in which dye and mordant are applied simultaneously from a single bath).

IX. Reactive dyes: the light fastness of these dyes varies appreciably on polyamide. Wet fastness properties are good. Any affinity differences that may arise are not covered in all cases. Combination dyeings are only possible to a limited extent. The build-up is also limited.

X. Logwood black: This dye is of interest for reasons of shade and fastness but, the method of dyeing is very involved.

Dyeing of polyester/acrylic blends Single-bath and two-bath exhaust processes are used with disperse dyes for the polyester and cationic dyes for the acrylic fibres.

Dyeing of polyester/cotton or polyester/regenerated cellulose blends These mixtures occupy a very large share of the market, and the blend ratio is nearly always 67% polyester and 33% cotton; with regenerated cellulose, the ratio is often 70 : 30 in many cases. Disperse dyes are almost exclusively used for the polyester component and reactive, vat, vat leuco ester or sulphur dyes for the cellulosic component. Direct dyes are used only occasionally. In most cases, a tone-in-tone dyeing of both types of fibre is required, for which special ranges of pre-mixed dyes are available from different manufacturers. The formulation of these mixed dyes has been fine-tuned so that both fibre components can be dyed to the same shade by exhaust as well as continuous dyeing methods.

I. Exhaust method: for the dyeing of yarns this process is only of secondary importance. Dyeing is carried out on cross-wound yarn packages or warp beams by the single-bath single-stage or single-bath two-stage process. Direct dyes can be used for cotton in the single-bath single-stage process provided they have sufficient resistance to carriers. With the single-bath two-stage process, the cellulosic component is dyed first in the case of reactive dyes whereas the polyester component is dyed first in the case of vat dyes. In two-bath processes, the polyester is likewise dyed first followed by the cellulose with appropriate dyes for each fibre. Where the cellulosic fibres are too heavily stained with the disperse dyes, an intermediate reduction clear with dithionite must be given (as well as for processes involving the use of carriers in order to remove carrier residues). The exhaust method is also used for lightweight woven fabrics as well as knitgoods. Dyeing equipment as for 100% polyester fabrics.

II. Continuous method: this process is used for all other qualities and offers numerous possibilities. Intermediate drying is critical as a certain amount of dye migration can take place at this stage. Most of the disperse dye on the cellulose is transferred by diffusion on to the polyester component during thermofixation.

Dyeing of polyester fibres Polyester fibres are hydrophobic, have a very low swelling capacity and, with the exception of copolymer fibres, have no reactive groups and no affinity for water-soluble dyes. Dye accessibility must be achieved by the addition of carriers or the use of high temperatures (→ High-temperature dyeing). The heat-setting of polyester before dyeing has a considerable influence on dye affinity, especially in exhaust dyeing with carriers. Oligomers also have an effect on the dyeing results. Exhaust processes are of importance for disperse dyes and naphthol-based diazo combinations. In continuous dyeing processes, pigments are used for pastel shades whilst vat and vat leuco ester dyes are likewise only used for pale shades. In general, disperse dyes are applied by the heat-set thermofixation process. For dyeing polyester loose fibre and card sliver, HT circulating liquor dyeing machines with the material press-packed into cages are used; card sliver can also be dyed by continuous methods. Smooth yarns in the form of cross-wound packages and textured yarns in the form of cross-wound muffs loaded on to spindles are likewise dyed in HT circulating liquor dyeing machines. For woven and knitted fabrics, HT winches or HT jet and HT beam dyeing machines are available. Thermosol plants are used for the continuous dyeing of woven fabrics. Polyester copolymer fibres (modified polyester) contain anionic groups and can therefore be dyed with cationic dyes as well. Optimal batchwise polyester dyeing processes are characterised by coordinated temperature control and liquor circulation. In this connection, it should be noted that an increased rate of liquor circulation leads to improved levelness. As a result, the critical rate of dyeing increases in proprtion to the rate of liquor circulation. However, an increased rate of liquor circulation through the textile material only leads to optimum levelness up to a certain limit. Moreover, with increased liquor throughput, increasingly unlevel results are observed. The conditions for this minimum unlevelness are to a large extent independent of the rate of heating.

Dyeing of polyester/natural silk blends The polyester component is dyed first with disperse dyes in a single-bath two-stage or two-bath process, followed by an intermediate reduction clear if necessary. Finally, the silk is dyed with acid dyes.

Dyeing of polyester/polyester copolymer (cationic dyeable) This mixture is only seldom encountered. Disperse dyes are used for the polyester and cationic dyes for the modified polyester fibres in a single-bath two-stage or a two-bath process. For continuous dyeings, the modified polyester fibres are pre-dyed with cationic dyes on the pad-steam range, then disperse and vat dyes are applied on the padder followed by thermofixation and development on the pad-steam range. In the knitgoods sector, two-colour effects are produced as well as solid shades. Acid-modified polyester with a high rate of dyeing: carrier-free dyeing at the boil with suitable disperse and cationic dyes.

Dyeing of polyester/wool blends The blend ratio is mainly 55% polyester and 45% wool. For the highest quality it is recommended to dye each fibre separately. Optimum fibre protection is not possible. As there is nothing to be gained by two-bath dyeing, it has been substituted by single-bath processes. A major disadvantage in dyeing this fibre blend is the fact that disperse dyes result in a more or less pronounced staining of the wool component and this staining has no colour fastness to speak of. A strict selection of those dyes which exhibit the least possible staining on wool is therefore necessary. Dyeing is carried out by the exhaust process at 105–107°C if possible, and with reduced amounts of carrier. Disperse dyes are used for the polyester and 1 : 2 metal-complex dyes for the wool. Pre-mixed dyes are also available from a few manufacturers.

Dyeing of polynosic fibres → Dyeing of regenerated cellulose fibres.

Dyeing of polyvinylchloride (PVC) fibres Polyvinylchlorid fibres are mainly dyed with disperse dyes. Cationic or metal-complex dyes are also frequently used. Pigments are seldom and naphthol dyes only occasionally used. The dyes must be carefully selected and, depending on the type of fibre, are dyed with or without the addition of a swelling agent (carrier) or dyeing is carried out under HT conditions, whereby polyvinylchloride filament yarns have a considerably lower dye affinity than polyvinylchloride staple fibres.

Dyeing of regenerated cellulose fibres (Viscose, cupro fibres, high wet modulus /polynosic fibres). In principle, all dyes used for dyeing cotton are suitable for dyeing regenerated cellulose fibres (→ Dyeing of cotton). The most important dyes are substantive and reactive dyes, with preference being given to hot dyeing types. The affinities of fibres produced by various manufacturers differ and can even vary from batch to batch from the same manufacturer. Textiles made from these materials are sensitive to pressure, friction and tension and this must be taken into account during the dyeing process. A well-known fault is the streaky appearance of woven or knitted fabrics due to slight variations in fibre manufacture. This streakiness can be avoided to some extent by selection of suitable dyes. The pronounced swelling properties of these fibres must be taken into account from the dyeing kinetics point of view (exothermic swelling) so that a fibre-specific processing sequence is necessary.

Dyeing of silk Like wool, silk is a protein fibre and can therefore be dyed using the same methods as for wool dyeing (→ Dyeing of wool). As silk is considerably more resistant to alkali than wool, dyeing processes which are carried out under weakly alkaline conditions are also used. In this regard, it must also be borne in mind that under alkaline conditions, high temperatures and conditions of high mechanical stress at the same time, individual fibres (fibrils) can split away from the silk filaments giving the material a fluffy and rough appearance. Compared to wool, silk also has a distinctly lower affinity because of its weaker acid binding capacity. Additional factors influencing the affinity of silk are its origin, extent of degumming, the yarn quality (tram silk, organzine) and whether the silk has been weighted or not. In general, it can be said that, under the same dyeing machine conditions, level dyeings are less problematic to produce on silk than on wool. The dyeing temperature should not exceed a maximum of 80°C since temperatures at the boil have a negative influence on the lustre and handle of silk.

Silk is dyed in all its commercial forms but is best dyed in the form of hanks (yarn) and piece goods. In principle, all the well-known types of dyeing machine can be used if they have been suitably modified to take into account the sensitivity of silk to tension and mechanical stress. The most important types of dyeing machine include:

a) Hank dyeing machines: no hank deformation (with double stick systems), no filament splitting, level dyeings obtainable provided the rate of liquor circulation is adequate;
b) Spray type dyeing machines for hank yarn: good liquor circulation and therefore hardly any levelling problems, hank deformation and filament splitting is possible; particularly suitable for high-twist and folded yarns;
c) Package dyeing machines for cross-wound packages: short liquor ratio, no levelling problems with adequate liquor circulation, no filament splitting, uniform winding of packages important because of the risk of channeling;
d) Star frame: suitable for all types of woven silk fabrics, no chafe marks, low productivity, high energy and water consumption (liquor ratio 100–300 : 1);
e) Winch: good levelness is possible, high productivity, average liquor ratio, high risk of chafe marks,
f) Jigger: high productivity possible, extremely short

liquor ratio, risk of moiré formation, good levelling resp. slow-exhausting dyes are an advantage here;

g) Jet-dyeing machines: good levelness, high productivity, short to medium liquor ratio, especially suitable for jersey and crêpe fabrics (due to the virtual absence of fabric tension), possibility of chafe marks;
h) Beam dyeing machines: good to excellent levelness, short liquor ratio 10–20 : 1, no chafe marks, especially suitable for heavy and smooth silk qualities, risk of moiré formation.

Dye class	Field of application	Advantages and disadvantages	Fastness ratings at 1/1 standard depth (Average ratings)		
			Xenon light	Bleeds on to silk	
				Water severe	Perspiration alkaline
Direct	Piece	Simple dyeing method Good light fastness in some cases Low wet fastness	4–6	3–4	2–3
Acid	Yarn and piece	Simple dyeing method Good light fastness in some cases Brilliant shades in some cases Low wet fastness	2–5/6	2–4	1–4
1:2 metal-complex	Yarn and piece	Simple dyeing method Good light fastness High degree of exhaustion Dull shades Moderate wet fastness	6	3–4	3–4
Reactive for CO	Yarn and piece	Suitable for cold-pad-batch methods High wet fastness Moderate to good light fastness	3–6	4–5	4–5
Reactive for WO	Yarn and piece	Brilliant shades in some cases Good light fastness High wet fastness High degree of fixation	6	5	4–5

Tab.: Fields of application, advantages and disadvantages and fastness properties of various dye classes suitable for dyeing silk.

Practically all classes of dye can be used for colouring silk (see Table). There is hardly any other textile fibre for which this is possible. Nowadays, silk is mainly dyed with direct, acid, metal-complex or reactive dyes.

a) Metal-complex and acid dyes: from the dye classes listed in the Table the 1 : 2 metal-complex and acid dyes are the most important in practice. Apart from a few exceptions in the acid dye range, they can all be applied from a weakly acidic bath (Fig. 1) and exhibit good levelling properties. By careful selection, all fashion shades, including those specific to silk, can be dyed although, from time to time, the colour fastness has to take second place. Thus, for the brilliant shades, red, blue, turquoise and green, often only moderate light fastness ratings and, in deep shades, only moderate wet fastness ratings are achieved (e.g. colour fastness to water severe, alkaline perspiration and washing at 40°C).

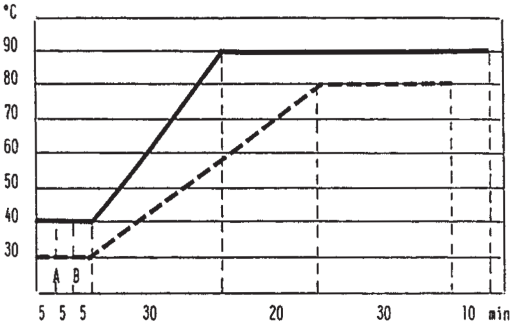

Fig. 1: Method and dyeing recipes for dyeing silk with metal-complex and acid dyes (Ciba-Geigy).
- - pale shades; — dark shades.

b) Reactive dyes: These are being used to an increasing extent (Fig. 2). They are characterised by their brilliance, high degree of fixation, high light fastness and outstanding wet fastness properties. In general, they are not very substantive although differences exist between the individual types. Consequently, the aim should be to use the shortest possible liquor ratios for these dyes. Dyeing is carried out first of all in a neutral bath with the addition of sodium sulphate at temperatures of 60–70°C, with the exception of black dyeings which are dyed at 90°C. Only in the last 15–20 min. at the end temperature is an addition of sodium carbonate made to adjust the pH of the dyebath to 8–8.5 for dye fixation. After rinsing, the dyeing must still be soaped in order to remove the unfixed dye which is not covalently bound to the substrate (source: Flensberg and Hammers).

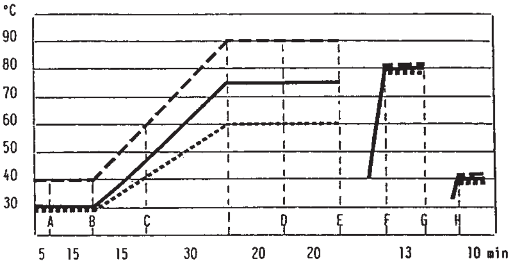

Fig. 2: Method and dyeing recipes for dyeing silk with reactive dyes (the dyeing time can be reduced for pale shades).
.... Cibacron F dyes; — Lanasol dyes; - - Lanasol Black B and Cibacron dyes (Ciba-Geigy).

Dyeing of silk/wool/polyamide blends In general, these fibres have (in some cases very) different dye affinities which must be taken into account.

I. Silk/wool: a) solid shades: dyed with acid dyes. A low temperature, and high quantities of acid, promotes a deeper dyeing of the silk whereas intense boiling and low quantities of acid promotes a deeper dyeing of the wool. b) two colours: the wool is pre-dyed with acid or chrome (mordant) dyes and the silk is cross-dyed with suitable cationic (low rub fastness) acid or direct dyes. c) white silk: dyed mainly with selected acid dyes (womenswear) or mordant dyes (menswear).

II. Wool/polyamide: (solid shades) usually dyed with carefully selected acid or mordant dyes and the controlled addition of acid for pale to medium shades accompanied by the addition of polyamide-retarding auxiliaries. In cases where the dyeing on the polyamide component is too light, shading additions with disperse or acid dyes must be made in order to dye the polyamide to a deeper colour.

Dyeing of textured polyester goods Woven and knitted fabrics of textured polyester occupy a large market share of polyester products. In general, disperse dyes are used for dyeing by both the carrier as well as the HT process. A strict dye selection is necessary since there are some products among the disperse dyes which react strongly to differences in texturing and others which are hardly affected so that, in the latter case, streakiness is avoided. The addition of carriers and use of high temperatures reduce the incidence of streakiness. Yarns are dyed either as press-packed muffs or on elastic tubes in liquor circulating machines. Flat woven fabrics are dyed on HT winches, HT jet dyeing machines or beam dyeing machines depending on the weave construction and weight. Knitgoods are mainly dyed in tubular form. Only unsatisfactory results are obtained if dyeing is carried out in open winches. The thermosol process is also used for dyeing woven and knitted fabrics made from textured polyester.

Dyeing of tow (card sliver, sliver, roving), advantages: any unlevelness is corrected by the subsequent blending of several dyed lots into large batches. Low liquor ratios are possible; short fibres and impurities are removed (e.g. comber waste for carded wool spinning). Semi-continuous and continuous dyeings produced by the pad-steam process are usual here. Disadvantages: The spinning of coloured yarns demands a thorough cleaning of the spinning machines when a change of colour is made but no cleaning of the carding machines (a particularly lengthy procedure).

Dyeing of triacetate fibres The affinity of triacetate fibres lies somewhere between that of acetate fibres and that of polyester fibres. The rate of saponification at the boil and pH 9–9.5 is insignificant. Only disperse and disperse diazo dyes are of interest on triacetate. The former is the most important dye class but careful selection is nevertheless important. The liquor ratio should be as short as possible and the dyeing temperature must be at least 95°C or higher. For dark shades produced with 2–4% of dye, there is a tendency for surface saturation to occur as well as streakiness so that the addition of a carrier here offers significant advantages. Full depth fast black shades are almost impossible to achieve with direct-dyeing disperse black brands which is why a diazo black, applied by the process normally used for polyester fibres, should be employed for deep black shades. In principle, it is recommended to heat-set triacetate fibres after dyeing since, if carried out beforehand, the reduced dye affinity can sometimes give very variable results and the colour fastness is also poorer in most cases.

Dyeing of wool Dye selection is dependent on the colour fastness required, the brilliance of the shades and the form in which the wool material is to be dyed. The most important classes of dye are as follows:

I. Acid dyes, for brilliant and well covered shades with average to good colour fastness and very good application properties in general.

II. Chrome dyes, for very good wet fastness, average to good light fastness but mainly dull shades (especially black, dark brown, navy blue; mainly used for loose fibres, combed sliver and Vigoureux printing). The use of these dyes can give rise to problems with chromium in the effluent.

III. 1 : 2 and 1 : 1 metal-complex dyes, with good to very good colour fastness to light and good wet fastness but mostly dull shades (especially black, dark blue, navy blue; used mainly for loose fibres, combed sliver and Vigoureux printing).

IV. Reactive dyes, for very good wet fastness and good to very good light fastness, and brilliant shades. In general, dyeing is carried out at 80–90°C (fibre protection, savings in energy and water consumption); dyeing is mainly by the exhaust process.

Dyeing of wool/cotton unions,

I. Neutral dyeing process: this method has proved itself in practice over many years and the dyeing results are good, although there is little fibre protection and the quality of the wool fibres is consequently impaired.

II. Acid dyeing process: in practice this method is used particularly for wool and mohair plush, since it offers a large degree of protection to the wool and mohair fibres and allows a good degree of process control. Suitable levelling agents are available for wool dyes as well as retarding agents for substantive wool dyes. Union dyes are suitable for solid shades and mixtures of wool and direct dyes are suitable for solid shades as well as the achievement of two-colour effects.

Dyeing of woven and knitted fabrics Compared to dyeings on yarn, the dyeing of woven and knitted fabrics in the piece offers the manufacturer a cheaper production route and a more flexible response to changing fashion trends. A wide selection of batchwise methods (winches, beam dyeing and HT jet dyeing machines, jiggers and star frames), semi-continuous methods (pad-jig, pad-roll, pad-batch) and fully-continuous methods (pad-steam, pad-dry-bake, thermosol) is available to the dyer. The last-mentioned processes are only used for long runs because of the high investment costs for the necessary plant and machinery as well as the need for laborious and intensive cleaning when a colour change is made.

Dyeing of yarn in hank form, advantages: good dye penetration, levelness and handle. Disadvantages: costly process due to a high liquor ratio (low capacity of the dyeing machines), re-reeling in hank form and subsequent rewinding on to cross-wound packages or weft cops. Automatic hank-yarn dyeing machines have not been a success. More economical variants in common use are, e.g. jumbo hanks from rocket muffs as well as high bulk yarns and soft muffs especially in the case of acrylics.

Dyeing oils, a now largely obsolete term for → Wetting agents used in dyeing which confer additional softening effects on the textile material.

Dyeing parameters These include all the factors exercising an influence on the dyeing process.

Dyeing processes Dyeing processes can be carried out by the direct application method or the exhaust method (Figs. 1 and 2). In the exhaust process, the dyebath is set with the necessary chemicals and then adjusted to a pH appropriate for the actual dyes/s being used. The textile material is then entered into the bath, during the course of which, a good wetting-out of the material as well as a uniform distribution of chemicals in the dyebath are important objectives. The establishment of a pH equilibrium between the material and the liquor is necessary before dyes are added in the exhaust process and the dyebath starts to be heated up. The well-dissolved dye, together with other chemicals and auxiliaries, depending on the particular dyeing process, is metered into the dyeing machine at 30–50°C (Fig. 3). Then the temperature is slowly raised up to the boil (depending on the required heat-up rate) and dyeing allowed to proceed at the boil for the specified time until a sample is taken for colour matching and before the dyed material is thoroughly rinsed after completion of dyeing.

Levelling is to be understood as the most uniform possible distribution of dye both on and within the fibre during the dyeing process. In the case of a uniform (level) dyeing, different parts of the same dyed fabric,

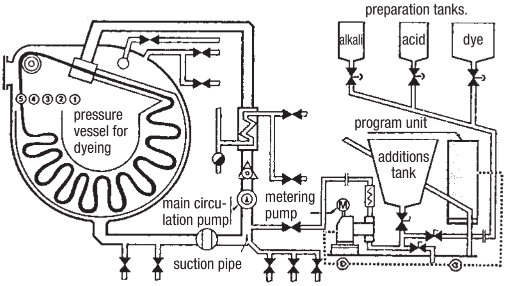

Fig. 2: Microprocessor-controlled machine for the dyeing of cellulosic/synthetic blends by the exhaust process involving movement of fabric.

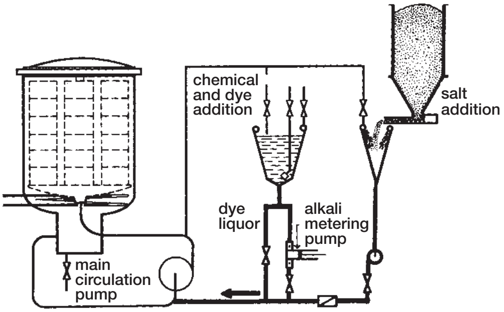

Fig. 3: Metering system for chemicals, dyes and electrolytes in package dyeing with stationary material and movement of liquor by the exhaust process.

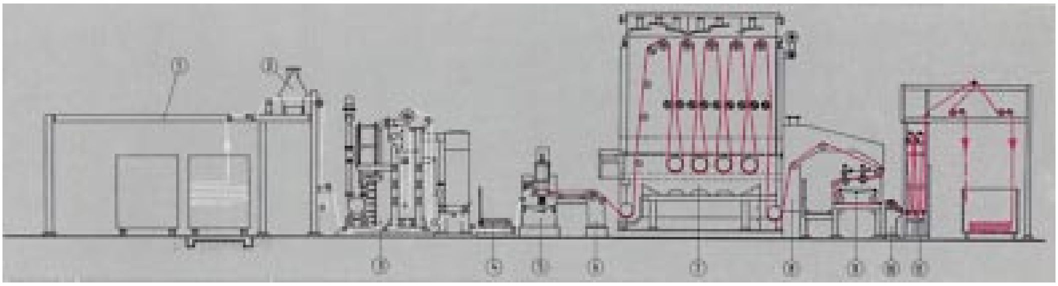

Fig. 1: Design of a typical carpet-dyeing plant for the direct application of dyes (source: Küsters).
1 = fabric infeed; 2 = presteamer; 3 = jet bulker; 4 = working platform; 5 = fluid dyer; 6 = draw rollers; 7 = loop steamer; 8 = steam hood; 9 = vacuum extraction washer; 10 = draw rollers; 11 = plaiter with fabric accumulator.

when placed side by side, should exhibit no perceptible difference in depth or tone. To achieve level dyeings, a distinction is made between two dyeing techniques (Fig. 4):

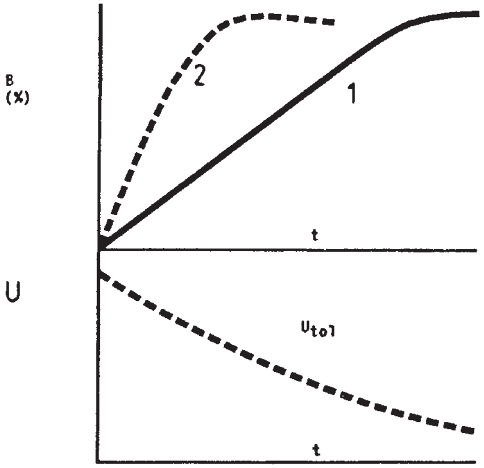

Fig. 4: A comparison of dyeing according to the principle of controlled sorption (1) and the migration principle (2) in exhaust dyeing.
B = bath exhaustion; U = degree of unlevelness; U_{tol} *= acceptable unlevelness (tolerance limit); t = time.*

1. The migration process: in this process unlevelness occurs during the short heating-up phase which is subsequently evened out (levelled) during the course of the long migration and fixation phase at the boil.
2. The controlled exhaustion process: in this case the dye is allowed to exhaust uniformly on to the fibre during a long heating-up phase. After this, a short fixation phase at, or above, the boil is given to complete the dyeing process.

$$t = \frac{100}{C \cdot E}$$

E = relative bath exhaustion/contact, in order to stay below the unlevelness tolerance limit U_{tol};
C = number of contacts per unit time, e.g.:

$$C = \frac{\text{liquor circulation (l/min)}}{\text{liquor content (l)}} \text{ for package dyeing machines}$$

$$C = \frac{\text{liquor circulation}}{\text{liquor content}} + \frac{\text{fabric speed (m/min)}}{\text{fabric length (m)}}$$

for jet dyeing machines.

The danger of the migration process lies in the fact that not all dyes level out at the boil. The rate of dyeing is dependent on the diffusion properties and, above all therefore, on the size of the dye molecule. Dyes with large molecules have a relatively low rate of exhaustion because their mobility in the liquor and, especially in the fibre, is limited. Besides the size of the dye molecule, interactions between the fibre and the dye also influence the rate of dyeing. The so-called “critical rate of dyeing” describes the heating-up curve which is just still capable of giving level dyeings. After the dye has penetrated the fibre from the liquor, it is bound to sites capable of bonding within the fibre. As a result, a typical ratio between the quantity of dye in the fibre and in the liquor is established on completion of dyeing (bath exhaustion or degree of exhaustion). This dyeing equilibrium is dynamic, i.e. dyes which have already become bound to the fibre can, depending on the class of dye, be easily detached again to a greater or lesser extent. These dye molecules are thus able to diffuse again and this occurs, in fact, from regions of high to regions of low concentration (migration). Levelling dyes with small molecules migrate well due to the low degree of bonding with the fibre through forces other than electrostatic bonds and because of their high diffusion properties which therefore compensates for the main disadvantage of these dyes, i.e. a high rate of exhaustion. Dyes with large molecules, on the other hand, exhibit a high affinity for the fibre with a low diffusion capacity and therefore have poor migration properties but, precisely because of their large molecular size, these dyes have high wet (wash) fastness properties.

Dyeing/sizing combined process → Warp sizing and dyeing.

Dyeing skeleton This involves selectively dissolving out (destroying) one fibre component of a fibre blend as an aid in the colour matching of fibre blends (e.g. in order to visually establish whether both components of a fibre blend have been dyed to the same tone and depth). For the production of dyeing skeletons, only those solvents and compounds with a hydrolizing action are suitable which have the least possible effect on the remaining fibre component and which have no influence on the shade of the remaining dyeing.

Dyeing stick (dye stick). Dyeing sticks are used for the following purposes:

I. In yarn-dyeing for suspending the hanks (hardwood dyeing sticks made from hazelnut, hickory etc., with a synthetic resin/ebonite coating as well as aluminium or toughened glass, bent into a U-shape).

II. In garment dyeing for moving/turning the goods during dyeing.

Dyeing time The dyeing time is the speed at which dyebath exhaustion is accomplished (it is temperature-dependent). Because of the need for level dyeing, the temperature of the dyebath cannot be raised at just any speed. The quantity of liquor in relation to the quantity of textile material and the rate of liquor circulation are also important. After reaching the dyeing temperature, the dyeing time is dependent on dye diffusion. The term “dyeing time” must include the entire treatment time required for the batch, i.e. the times required for the pretreatment, clearing, rinsing and aftertreatment stages in addition to the actual dyeing time. As far as the entire dyeing process is concerned, the dyeing time is further extended by the → Setting-up time.

Dyeing time controller → Passage counter.

Dyeing theory,

I. Cellulose dyeing: the relationships involved during the course of dyeing with substantive dyes are explained under → Substantivity. They may be subdivided into the following processes: a) fibre swelling in the liquor; b) (→ Adsorption) accumulation of dye at the fibre surface (salt addition); c) → Diffusion of dye molecules into the interior of the fibre.

II. Wool dyeing: the individual processes which take place in the dyeing of wool are as follows : a) adsorption of dye molecules at the fibre surface; b) diffusion of dye molecules through the fibre surface into the interior of the fibre to sites containing basic groups capable of reaction; c) formation of linkages with the colourless acid (e.g. sulphuric acid) in the interior of the fibre; d) displacement of the colourless acid ions by dye-acid ions in the fibre interior and e) the formation of salt linkages between the dye-acid ions and the basic groups of the wool protein.

III. Acetate dyeing: the uptake of dye in this case may be described as follows: the acetate fibre behaves as a solvent for disperse dyes so that, during dyeing, the dyes are adsorbed preferentially by the fibre to form a solid solution (solution mechanism).

IV. Polyester and triacetate dyeing: during the first stage of dyeing these fibres, the disperse dye accumulates at the fibre surface (adsorption) before subsequently diffusing through pores between the fibre molecules into the interior of the fibre. The rate of diffusion increases by raising the temperature (high temperature process) or through the use of carriers.

V. Polyamide dyeing: in the case of disperse dyes, the process is similar to triacetate. With acid dyes, the adsorption and fixation of dyes occurs through interactions between polar groups on the fibre and those on the dye (salt linkage mechanism). With metal-complex dyes, the salt linkage mechanism and the solution mechanism are superimposed.

VI. Acrylic dyeing: with disperse dyes a solution mechanism is involved. In the case of cationic dyes, on the other hand, a salt linkage mechanism between the polar groups of the fibre and those of the dye is mainly responsible.

There is no generally applicable theory of dyeing capable of explaining all dyeing phenomena satisfactorily. However, various models are available which provide a basis for the study of dyeing systems. Already around the middle of the 19th century, Fick had discovered that the rate of particle diffusion through a section of unit area (ds/dx) is proportional to the concentration gradient of particles measured in the direction of diffusion.

$$\frac{ds}{dt} = D\frac{dc}{dx}$$

This so-called first → Fick’s law of diffusion contains the diffusion coefficient D as a proportionality factor and characteristic system constant for the particular system involved. It represents, first of all, nothing more than a definition of the diffusion coefficient in a steady state.

$$D\frac{d^2c}{dx^2} = \frac{dc}{dt}$$

Fick’s second law of diffusion refers to non-steady state conditions, i.e. under conditions where the concentration gradient changes over time. The left-hand side of the equation corresponds to the quantity of dye which diffuses into or out of two adjoining boundary surfaces of a volume element per unit time. The right-hand side of the equation corresponds to the quantity of dye which accumulates in this volume element. Fick’s second law is therefore nothing more than a mass transfer balance. With D, a constant is obtained for a particular diffusion process.

Theories of dye kinetics are concerned with the nature of dye diffusion in solid polymers. Essentially, they are based on two important fundamentally different models for dye diffusion in fibres, namely the pore-diffusion model (Fig. 1) and the free-volume or mobile segment model (Fig. 2) (→ Diffusion mechanisms in dyeing).

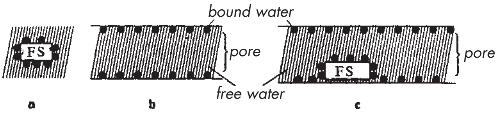

Fig. 1: Schematic representation of the change in hydration due to the attachment of dye molecules (FS) to the fibre (pores).
a) a dye molecule enveloped by hydration water in the solution; b) longitudinal section through an intercrystalline channel (pore) in the swollen fibre; c) longitudinal section through an intercrystalline channel (pore) in the swollen fibre with dye molecule attached.

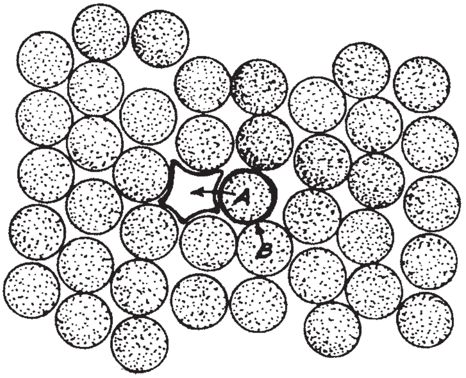

Fig. 2: Displacement of a molecule or chain segment A, the original position of which is now occupied by B, in a schematic cross-section through spherical molecules or a segment of parallel-oriented cylindrical polymer molecules.

The pore model represents the fibre as a solid structure with a network of interconnected channels or pores which are filled with the dyeing liquid, which is normally water. The dissolved dye diffuses through these pores, where it can be simultaneously adsorbed on the walls of the pores. For quantitative expressions of the rate of diffusion, the porosity P, i.e. the proportion of pores in relation to the total volume of the fibre available under the conditions of dyeing is of primary importance as well as the adsorption equilibrium. In 1966, Weisz developed a mathematical model for diffusion processes which is overlaid by an adsorption/desorption equilibrium of the dye liquor at the external and internal boundary layers of the fibre. The pore model presupposes, of course, that the pores are connected to each other as well as to the external dyebath and that their diameter is sufficiently large for the dye molecules to find room in them. Model concepts for dye uptake on cellulosic fibres are generally based on the pore model. According to this, a network of pores swollen and filled with water is present in the fibres within which dye diffusion and sorption takes place followed, if applicable, by chemical reactions as in the case of reactive dyes.

The first mechanistic hypotheses on the uptake of anionic direct dyes soon after their discovery were based on the assumption that these dyes form colloidal particles in the fibre voids. Later, these views were expressed more precisely and, on the strength of various experimental findings, it was concluded that substantivity is largely based on the fact that the dye molecules which have diffused into the fibre form aggregates in the cellulose pores. Likewise assisted by experimental findings, the mechanism of monomolecular adsorption in the pores has found support for low to medium depth dyeings at least. It is well-known that the dyeing results on cellulosic fibres are greatly influenced by the fibre's physical structure. This explains the different dyeability of various types of regenerated cellulosic fibres; in this case it is known that differences exist between the regenerated cellulosic fibres and cotton, and that the country of origin, maturity and pretreatment can influence the results of dyeing on cotton fibres.

Fig. 3: A longitudinal view of the Rosenbaum model. A bundle of chain molecules in the non-crystalline region of a fibre lies above the glass transition temperature and has a fraction of free volume. Dye molecules enter the free volume through a series of location-changing leaps.

In contrast to the pore mechanism, the free volume model describes the dyeing process as diffusion of the dye through the less ordered ("amorphous") regions of the polymer matrix (Fig. 3). The rate of diffusion is therefore determined by the mobility of the polymer chain segments. The most important support for this theory comes from the observation that the temperature dependence of the rates of dyeing for a particular type of fibre is less above a certain temperature. The resistance of the solid structure of the fibre to the penetration of dye is much lower above this temperature. This is referred to as the glass transition temperature of the fibre in question (T_G), or more precisely, the glass transition temperature under dyeing conditions or the dyeing transition point (T_D), since the classical glass transition temperature is a parameter which is measured in the dry state. Both parameters, T_G and T_D, correspond to those temperatures at which, from a microscopic perspective, the less ordered component of the polymer is converted from a glass-like state into the viscoelastic state, or, at a molecular level, at which the less ordered segments of the macromolecule move against each other, i.e., become, in effect, like "micro fluids". This model does not come from dye research but from the physical properties of the macromolecules. The glass transition temperature plays an important role here. It corresponds, at a molecular level, to the temperature at which the amorphous regions of a polymer are converted from a glass-like state to a gummy (i.e., viscoelastic) state. Above this temperature, parts of the polymer chain (thread) molecule become mobile. This segment mobility (Fig. 2) causes an uninterrupted change in the spatial arrangement of the chain molecules in these regions. "Holes" are formed above T_G and disappear again or occur at neighbouring sites of the polymer segment involved. In the viscoelastic state, therefore, the polymer structure cannot be conceived in static terms; the structure changes constantly. The possibility for the diffusion of relatively small molecules through such a

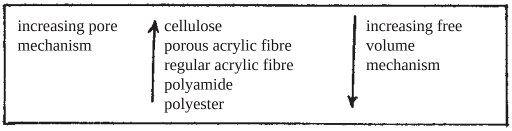

Fig. 4: Relationship of the pore mechanism and free volume mechanism for dye diffusion in different substrates (source: Zollinger).

structure is a problem of probability (or expressed in physical terms, it is a question of entropy) as to whether "holes", "channels" and adsorption sites for small molecules are formed by segment mobility.

With the majority of dyeing systems there are fluid transitions between the pore model and the free volume model (Fig. 4).

The cuticle of wool represents a hydrophobic, highly crosslinked barrier to the penetration of chemicals. During the dyeing process, the dye diffuses from the liquor to the fibre surface (Fig. 5) where it is then adsorbed. After this, the dye must diffuse from the surface of the fibre into the fibre interior. This last-mentioned step is the slowest and determines the rate of dyeing. Under normal circumstances, this penetration only takes place at temperatures above approx. 70°C. This is associated, on the one hand, with the degree of dispersion of the dye since only individual dye molecules can normally diffuse into the fibre. Dye aggregation decreases with increasing temperature. On the other hand, the wool only appears to be accessible to the dye at high temperatures.

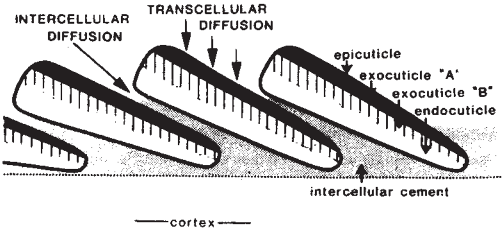

Fig. 5: Schematic representation of the cuticle cells with intercellular cement (source: Leeder).

At the start of dyeing, the dye migrates preferentially through the intercellular cement, i.e. it penetrates into the putty-like substance between the cuticle cells. From there, it enters the other non-keratin regions of the fibre. After this, the dye migrates through the endocuticle (low sulphur content) into the sulphur-rich exocuticle. The dye enters the matrix at the end of the dyeing time. The route, therefore, passes through the "soft", highly swollen regions into the less polar regions which have a high affinity for the dye (source: Zollinger).

Dyeing tube changing device, for the stripping of stiff package tubes and the introduction of dyeing tubes which are usually flexible.

Dyeing tube paper, filter paper for use in dyeing crosswound packages. Used to filter impurities from contact with the goods and prevents yellowing when drying bleached packages in the rapid drier. Crocking fastness is improved when dyeing darker shades (specifically vat dyestuffs).

Dyeing tubes for yarn dyeing Substantial changes have taken place in the field of yarn dyeing. To summarize, the following developments can be stated:

- Winding technology: introduction of progressive precision winding, which is especially suited to compression systems.
- Tube systems: polypropylene tubes with secure thread reserve. The dyeing packages can be transferred on for use in weaving without the need for rewinding.
- Stacking systems: stable, leakproof dyeing columns with special seals to prevent leakage by "sagging" of the columns of packages.
- Instrumentation: comprehensive automation of all functions including metering systems. Installation of frequency controlled motors for optimum adjustment of the flow rate at each stage of the process. Turbulence-free flow at low speeds with minimal loss of pressure in the pipework.
- Drying systems: high-frequency drying.
- Laboratory engineering: dyeing of "mini-packages" in realistic liquor ratios with fully automatic control of all procedures.

The most important ways of assembling dry packages are:

- Self-supporting systems: usually conical dyeing tubes of V4A steel or polypropylene (4° 20' taper) with spacers.
- Stack system: rigid cylindrical reusable polypropylene dyeing tubes which are stacked together without spacers.
- Compression system: cylindrical, axially flexible disposable polypropylene dyeing tubes, which are pushed together to form a column.

In practice, 54 mm cylindrical compression tubes have proved best for the dyeing of yarns. To achieve optimum liquor flow in a package the ratio spindle diameter : outer package diameter should not exceed 1 : 3.5–4. Modern automatic winders can easily produce dyeing packages of 300 mm diameter and 8-inch traverse. This enables weights of over 3 kg per package to be achieved on compression tubes with a 69 mm diameter. This is not however done in practice, not only because of the limitations of process technology, but also because of the problems associated with the unwinding qualities of such packages or potential difficulties encountered in circulatory flow drying (but not with HF drying). When compressing the columns of dye packages the stroke should be such that the column is compressed evenly from edge to edge. The usual compression, depending on tube length, is 13–30%, with a package density before compression of 330–380 g/dm^3, depending on yarn quality and winding system. In order to ensure even compression throughout the column the number of packages per column is limited according to the stacking system. For this reason, double spindles are often used. Package density and degree of compression must be set precisely for each yarn quality. In the case of liquor flow from outside inwards, the columns sometimes tend to sag, which can give rise to leakages at the package interfaces. In order to prevent this, they are connected either by sprung snap-fasteners or auto-locking slide fasteners. The latter do have the disadvantage that the package column may become locked, and when dyeing with outward-flow the mass of yarn material is made more dense.

Axially flexible, cylindrical plastics tubes are manufactured by injection moulding. The principle functions of an injection moulding machine are shown in Fig. 1. The rotation of the feed screw delivers the granules of plastic to the cylinder where they are plasticized. The feed screw then sprays the moulding material into the mould cavity with the two halves of the tool together. After hardening the two halves are separated and the piece is removed from the mould. The pressures generated during the filling of the mould are so great that forces of several hundred tonnes are needed to keep the two halves together, dependent on the diameter of the tube and the number of cavities operated in parallel in the machine.

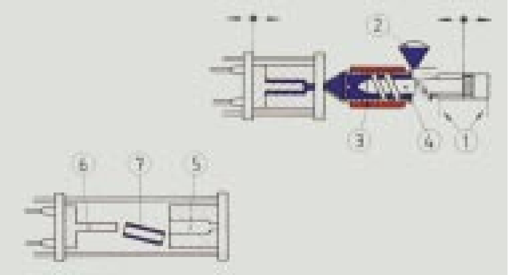

Fig. 1: Injection moulding machine.
1 = connections to hydraulic system; 2 = feed funnel;
3 = cylinder heating; 4 = feed screw; 5 = die; 6 = mandrel;
7 = plastics tube.

The desired qualities of the injection-moulded articles, such as the avoidance of burrs, the extrusion quality and the colour consistency are ensured throughout the production cycle by optimum machine adjustment and its reproducibility. These requirements are fulfilled by computer-controlled injection moulding machines, which, subject to certain tolerance limits, are capable of adjusting the machine to deal with differences in operating conditions, such as stock feed variations, ambient temperature and humidity. The use of state-of-the-art technology for the development, design and production of plastic package tubes contributes to the level of quality assurance available to the end user in the textile trades.

Fig. 2: Flexible disposable dyeing tubes for compression systems (for key to numbers see Table).

For package dyeing there are various types; cylindrical or conical tubes form corresponding package builds. Sun-spools or Barber-Coleman packages are a special type of cylindrical package where the traverse is less than the diameter. Another type is the rocket (bottle) package, where the diameter does not increase as yarn is added, but the winding increases in height. Packages are often supplied for dyeing with cardboard tubes, which then have to be rewound onto stainless steel or plastics tubes. Automatic tube changing machines are available for this purpose. Rigid or flexible tubes are used dependent on yarn type (see Table):

1. Rigid tubes: the tendency here is to use → Disposable dyeing tubes of polypropylene. In this case there is no need for rewinding back on to cardboard tubes. Polypropylene tubes may also be re-used, but are usually crushed after use and recycled in granular form for the manufacture of tubes or other articles. Triangular or rhombic shapes are sometimes used instead of round holes. This is an attempt to prevent the yarn from being forced into the perforations at high flow rates.
2. Flexible centres (dye-springs, Fig. 2): these can be compressed axially and are thus suited to shrinkable yarns arranged radially. A knitted sleeve separates tube and yarn packages, not only for the purpose of filtering out impurities, but also to spread the pressure distribution evenly. The yarn must be wound under constant pressure, and the wound package

Tab.: Flexible disposable dyeing tubes for compression systems.

should not be too hard. The evenness of the dyeing depends on the evenness of the winding. All packages in a batch must be equally dense.

A disadvantage of conical packages lies in the differences in pressure distribution within a package and the package column during dyeing. With cylindrical tubes, random wind is distinct from precision wind. Random wind is carried out on a helically grooved drum consisting of winding element and yarn guide element, in such a way that the traverse tapers from the small to the large diameter while the angle of winding remains constant (e.g. 30°), e.g. the Autoconer by Schlafhorst. Precision wind is carried out initially at 45°, subsequently changing to 18°. Yarn guide and drive are separate functions, thus generating by mechanical means pattern-free winding (e.g. by Schärer). An ideal system somewhere between random and precision wind is provided by the Digicon winder (Schweiter). Digicon packages are random wound via variable speed gears; they have straight end surfaces and are pattern-free; they do not tend to swell as is the case with precision wind. Practical dyeing results will show whether the precision-wound package with its wind angle narrowing as the diameter increases will ensure better liquor distribution at the edges of the package during the dyeing process, due to the liquor flow from inside outwards. The tighter structure towards the top of the package could create a form of backward pressure in the liquor, which would provide a more effective penetration of the package. This would make it possible to make the package more dense than is possible in the case of random wind. It has been shown that a precision-wound package can be fully penetrated by the dye at a density of 0.43 g/cm^3; random-wound packages also allow densities of up to 0.45 g/cm^3.

Dyeing tube stripping machine, used in wound package dyeing for stripping the cardboard tubes before dyeing or the steel tubes after dyeing.

Dyeing vat (beck, tub), four-sided vessels for dyeing, bleaching etc. made of wood, metal, earthenware, tiled or similar for hank yarn and loose stock; may be fitted with two squeeze rollers or with winch for piece dyeing. Heated by means of open (and/) or closed steam pipe.

Dye ions Dye ions, which represent by far the greatest proportion of the dye molecule, and which are responsible for the dyeing properties at the same time, dissociate in aqueous solution. The resultant dissociated ions of the considerably smaller fraction of the molecule, which have opposite charges, are referred to as counter ions. All dyes which form dye salts or dye acids contain both types of ion together. The respective charge of the dye ions allows the following distinctions to be made:

I. Dye anions, which are formed from anionic dyes, include acid, most direct dyes, wool/cotton union, vat, sulphur, naphthol and vat leuco ester dyes. The acidic auxochrome groups (→ Dye acids), which are built into the dye molecule to confer solubility in water, are responsible for its anionic character and that part of the dye molecule containing these groups dissociates as the so-called dye acid residue.

II. Dye cations are formed from basic (cationic) dyes which contain cationic nitrogen groups (→ Colour bases) as auxochromes. Their properties are the opposite of I above.

III. Dye anions and dye cations are contained in zwitterionic dyes. These include, e.g. direct dyes which, besides anionic acid groups, also contain cationic basic amino groups (NH_2), which may also be capable of dissociation depending on their position in the dye molecule. Such dyes are representative of the diazo dyes. Depending on the proportion of acid or basic groups capable of becoming charged which predominate in the system, more or less anionic or cationic zwitterions are formed or, when the charges are equal, isoelectric zwitterions.

Dye jigger → Jigger.

Dye kitchen → Colour kitchen.

Dye liquor, also called dyebath. The dye liquor consists of liquid medium (usually soft water), the dye and the additives necessary for the dyeing process in question such as levelling agents, retarding agents, padding auxiliaries and dispersants etc. Concentrated liquor is used for padding textile fabrics. Dilute liquor is used for exhaust dyeing.

Dye-liquor colorimetry Ongoing analytical monitoring of a dye liquor in a continuous process is important both from an economic and ecological point of view. The dyeing process can be monitored and optimised by checking the individual agents in a sample extracted from the bath. Individual components which become prematurely exhausted can be objectively replenished. This minimises both chemicals consumption and the associated chemical loading in the effluent. One measurement technique uses a form of absorption spectroscopy. An aliquot of the liquor flows continuously through a measurement cell. However, the volume of liquid flowing through the cell is so small in comparison to the total cell volume that the system can almost be regarded as closed. The cell stands in the light path of a broad-band light source and a monochromator which scans the entire spectrum. The individual substances absorb light at characteristic wavelengths and the energy absorbed by the solution causes the temperature to rise. This increase in temperature, which is recorded using sensitive sensors with a rapid response time, is proportional to the concentration of the substances in the solution (source: Schollmeyer).

Dye liquor volume calculation → Liquor calculation.

Dye loading of fibres The supply of dye to the fibre is an "active" step in the dyeing process whereby the dye is transported to the surface of the randomly oriented mass of the textile material and is held in the interstices of the fibre mass (e.g. as in dyeing on the padder or jigger), or the dye is transported to the surface of the fibre mass from the continuously circulating dye liquor throughout the entire time of dyeing (e.g. as in the beam dyeing of piece goods and hank dyeing). During this process, water is indispensable as a solvent and transport medium for the dye. As shown in the Fig., where the weights of dye in the ratio G_{PT}/G_P [kg of dye on the textile material/(kg of dye in the textile material and in the liquor)] are applied in accordance with the liquor ratio $e_F = G_F/G_T$ [kg of liquor/kg of textile material], the weight of dye actually used to dye the fibre is dependent on the distribution coefficient K [–] of the dye and the liquor ratio e_F [–] of the dyeing machine. Experience has shown that practically no savings in water are to be achieved for the supply of dye to textile fabrics if part batches, reliability of dyeing and uniformity of handle are taken into account. An interesting alternative in this regard, which offers the possibility to work with shorter liquor ratios, e.g. where $e_F = 2–4$, is provided by the Then-Airflow machine in which the fabric rope is transported by a stream of gas instead of the dye liquor.

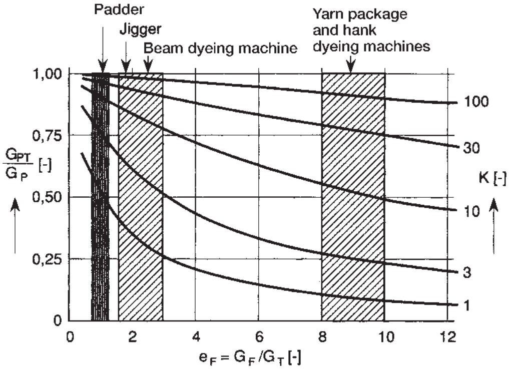

Fig.: Dye loading of different types of textile materials in various dyeing machines dependent on the liquor ratio e_F and the distribution coefficient K (source: Kretschmer).

The loading of a textile material with dye is also an "active" step in the dyeing process, in which more dye than that actually used to dye the fibre is continually being supplied to the material during dyeing. The resultant loss of dye makes the costs of dyeing more expensive and increases the pollutant load of the effluent and its cost of treatment. The ratio of the weights of dye G_{PT}/G_P is characteristic for the loss of dye resp. the pollutant load of the effluent, i.e. the higher the ratio G_{PT}/G_P, the lower the loss of dye or the pollutant load of the effluent. According to the Fig., the highest G_{PT}/G_P value is achieved with the short liquor ratio dye loading on the padder whilst the G_{PT}/G_P value obtained with the long liquor ratio of the hank dyeing machine is appreciably lower. From this it follows that, in principle, a realistic reduction in the quantity of water or effluent cannot be achieved in the "active" step of loading a textile material with dye. It also follows that the losses of dye, which increase the pollutant load of the effluent as well, are determined exclusively by the type of machine used to load the textile material with dye and the distribution coefficient of the dye itself since the coloristic and article-dependent requirements of the customer limit or reduce the choice of suitable dyes and consequently the pollutant load of the effluent (source: Kretschmer).

Dye : metal ratio, the ratio of dye molecules: met-

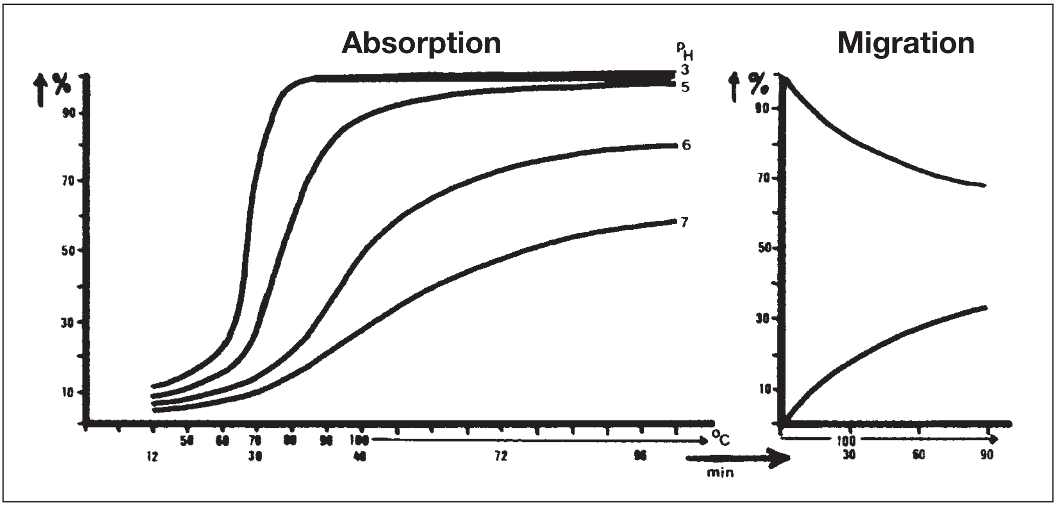

Fig.: Migration test of a wool cloth (right) which has been dyed at pH 3 with 2% Supramin Yellow RN (Bayer).

al atoms in metal complex dyestuffs. Opposite notation principle to that shown in → Complex formation.

Dye migration,

I. Reduction of depth of colour in wool dyeings. Dyestuff migrates across to adjacent undyed wools. Migration test: test for migration propensity of a dye (see Fig.).

II. In union dyeing, the migration of individual dyes to specific fibres, e.g. acrylic/wool mixes: cationic dyestuffs to acrylic, anionic dyestuffs to wool.

Dye migration in drying This undesirable phenomenon causes previously level dyeing to become uneven due to incorrect drying. This migration phenomenon (→ Migration during intermediate drying) mainly arises when dyeing with dyestuffs with low or no fibre affinity (but also in the case of proofing, synthetic resin finishes or similar). Typical dyeing processes include in particular undeveloped pigment padding and leuco vat ester dyeings, non-coupled naphthols, and also disperse and similar direct dyeings. The dyestuffs (dyestuff pigments) affected are always those which are intercalated to a greater or lesser extent mechanically; since they do not display fibre affinity, they have a tendency to migrate as the water evaporates. Thus the dye is concentrated around the hotter sites in the fabric, producing an uneven, cloudy final colour. There is a critical water content level, above which migration may occur. This is 36% for wool, 40% for viscose, 21% for cotton, and approx. 10% for polyamide 6.6. Dye distribution also causes migration. For this reason when dyeing using the pigment padding process, a padding additive such as sodium alginate or a specific textile auxiliary is recommended. When cylinder drying, where the contact principle leads to a tendency towards temporarily intensive surface drying, especially at the start, a compensatory effect can be achieved by constantly alternating the upper face of the fabric from cylinder to cylinder. In the case of the air-drying process a medium air speed is recommended. The drying temperature also has a significant effect on dye migration. Preliminary drying at a relatively low temperature can limit dye migration at higher temperatures. Dye migration (areas of lighter colour) may also be observed if stain removal is incorrectly performed, with the steam gun placed directly on the surface of the fabric (temporary predominance of internal drying).

Dye mist, a dye liquor which has been atomised by passing it through fine jets.

Dye mixtures, dyestuff formulations preconstituted by the dyestuff manufacturer for various fibre blends e.g. for

I. Wool/cellulose: mixtures of acid dyes and direct dyes with neutral or weakly acid affinity.

II. Wool/polyester: mixtures of acid dyes and/or 1 : 2 metal-complex dyestuffs and/or reactive and disperse dyes.

III. Cellulose/polyester: mixtures of vat and/or leuco vat ester dyes and/or reactive and/or sulphur dyes and disperse dyes.

Use: mainly to achieve solid-shade dyeing on fibre blends. As the dyes are adjusted to certain types of fibres in a specific mixture and liquor ratio, in some cases it is necessary to tint one fibre or another. Dye mixtures are used to dye yarn and pieces, including reclaimed fibres and rags or in garment dyeing where necessary.

Guidelines for solid-shade dyeing:

I. Half-wool (wool/cotton, wool/viscose): a) neutral dyeing method b) weakly acid dyeing method. At boiling point, a deeper dyeing of the wool generally occurs, when the dyeing temperature is falling (bath exhaustion) and if salt is added, a deeper dyeing of the cotton or viscose is achieved.

II. Wool/polyester blends: dye mixtures of selected polyester disperse dyes, which stain the wool component as little as possible, with wool dyes with weakly acid to neutral affinity: a) dyeing at the boil and addition of carrier; b) dyeing at approx. 105°C with added carrier.

III. Cellulose/polyester blends: dye mixtures are principally used a) in high temperature exhaust dyeing (120–130°C); b) in thermosol dyeing (continuous method).

IV. Polyamide/wool blends: use of wool dyes which dye both fibres equally deeply as far as possible. For light and medium depths of shade polyamide is generally coloured more deeply. By choosing suitable dyes and blocking agents, it is possible to achieve solid-shade dyeings.

V. Acrylic/wool and/or acrylic/polyamide: ready-made dye mixtures are not available for these fibre blends. Dyeing is generally carried out as a one-bath process using cationic and wool dyes (reactive, 1:1 metal complex and acid dyes) in association with appropriate dyeing auxiliaries.

Dye mixtures, fastness properties The dye mixtures available provide dyes with good to very good fastness. A dyeing after-treatment is generally necessary when dye mixtures are used for wool/cellulose fibres with higher fastness requirements.

Dye mordants → Mordanting.

Dye package, shrink, cross-wound bobbins with flexible → Dye tube which permit shrinkage of the yarn by radial elasticity.

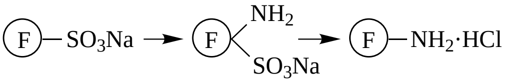
Dye pasting and dissolving agents → Dye dissolving and dispersing agents.

Dye preparation, a dyestuff within a combination of substances designed to facilitate application or subsequent use. → Yarn preparations.

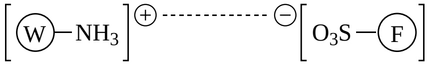
Dye recipe formulation Before dyeing, the most cost-effective recipe must be established, i.e. with the fewest possible or least expensive dyes and the shortest possible dyeing time. Thus, a dyeing process must be found which minimises the recipe costs (dyes and auxiliaries) and the dyeing time for the particular dyeing machines available. The selected dye recipe must also be capable of achieving the desired requirements profile in terms of colour match and fastness properties against the approved sample. A record is kept of the established recipes for each article number and the quantities are "scaled up" appropriately for a specific order.

Dye resisting agent → Retarding agent.

Dye salts, salts of → Dye acids or → Colour bases.



Examples of this type include, e.g. some commercial dyestuffs (substantive dyes, vat leuco ester dyes, etc.) or they may be formed temporarily during dyeing, as in the case of vat and sulphur dyes, which are present in the alkaline dyebath as the sodium salts of the corresponding leuco compound (vat acid). Dyeings produced on wool with acid dyes, in particular, are also representative of typical dye salts.



Dye-selection criteria, the criteria for selecting, for example, the dyestuff group or the dyeing process etc. to obtain a certain → Requirement profile. When dyeing using disperse dyestuffs, for example, the dye-selection criteria determine whether preference is given to azo or anthraquinone dyes. For example:

1. Azo dye applications:
   - where high wet-fastness is a requirement
   - cellulose resists
   - in rapid dyeing
   - in yarn dyeing
   - in the thermosol process
   - under difficult dyeing machine conditions such as HT beam or high-density packages
   - for acetate, triacetate/polyester mixtures and acetate/ polyamide mixtures
   - for economy dyeing.

The azo dyestuffs are more economic and satisfy the technical application requirements and specified fastness requirements in the dyeing of outer wear. Plus factors: wet-fastness properties, level dyeing characteristics and fastness to sublimation.

2. Anthraquinone dye applications:
   - where high light-fastness is required
   - for polyester/wool mixtures
   - where there is a risk of cloth streakiness
   - for neutral to weakly alkaline dyeing conditions
   - where there are reduction problems.

Anthraquinone dyes are used in large quantities in polyester dyeing. They will also be in demand in the future for certain fibres, fastness requirements and applications. Their strengths are light fastness, level dyeing and reproducibility and they can be used at boiling point or high temperatures.

Dyes of vegetable origin, the (historically) most significant → Natural dyes of vegetable origin are →: Indigo, Madder, Woad and Logwood.

Dye sensitivity to metals, property of numerous dyestuffs during the dyeing or printing process or on completion of dyeing or printing to produce dull or different coloured tints in the presence of metal ions or on contact with metal surfaces. The following are particularly dangerous: copper, nickel, manganese, iron, chromium. Remedy: addition of ammonium rhodanide, polyphosphates, EDTA.

Dyes for summer or winter clothing → Infra-red reflecting dyeings.

Dyes of animal origin → Cochineal, Kermes, Purple.

Dye solubility in water is determined by the presence of solubilizing groups in the dyestuff molecule. These are usually sulpho groups, carboxyl groups and hydroxyl groups. In the case of the last named the result may often be dyestuffs of only extremely low solubility, depending on the constitution of the dyestuff.

Dye solubilizing and dispersing agents are used in dyeing and printing for paste preparation, dissolving and dispersing of the dye, thus satisfying the prerequisites for a perfect dyeing or printing operation (yield, penetration, evenness). These are surface-active organic products (→ Solvents for dyeing and printing), such as fatty acid esters and fatty acid amides, fatty acid condensates, alkylaryl sulphonates, hydroxyalklylation products and derivatives of aliphatic amines.

Dyes on textiles, quantitative determination of,

I. Extraction method: the dye is detached from the fibre by extraction with a suitable solvent or an azeotropic mixture. The concentration is determined through photometric evaluation of the extract by comparison with known extinction coefficients. With this method there is a risk of the dye undergoing irreversible change due to the long extraction time at high temperatures. Furthermore, only a limited number of suitable solvents and azeotropic mixtures are available. For small samples of material this method is less efficient.

II. Solution method: by dissolving the fibre and dye in an appropriate solvent (e.g. polyamide in 85% formic acid and in m-cresol or cellulose in 80% sulphuric acid). This method is quick to carry out but does not have universal application. There is a risk of clouding due to the delustrant, discoloration of the dye due to substrate decomposition and poor substrate solubility after cooling down.

III. Residual dyebath method: this method is based on determining the non-exhausted dye. The method is somewhat involved since dye, which is still removed in subsequent washing, off must also be taken into account.

IV. Repeated boiling in solvents or solvent mixtures. The fibre material is heated repeatedly with fresh solvent. This procedure is very versatile, and protects the dye. There is also a greater choice of solvents capable of swelling the fibre or even causing it to lose its form.

V. Specific methods of detection for a few characteristic elements, e.g. the colorimetric determination of copper, nickel, iron, cobalt, etc.

VI. → X-ray fluorescence.

Dye springs, dye centres which intermesh elastically and can be compressed slightly. Often used in the place of perforated tubes for dye packages in order to achieve better dye penetration.

Dye stability to diazotize, the behaviour of dyes on the fibre in the presence of nitric acid in aqueous liquors.

Dye structure and formation The specific properties of a dye, such as its colour and dyeing properties, are given by its molecular structure or chemical structural formula. The elements which participate in dye structure are mainly those derived from coal and tar starting products such as carbon, hydrogen, oxygen, nitrogen, sulphur (hence the now obsolete term “coal tar dyes” from the early days of the synthetic dyestuffs industry) and to a lesser degree, also chlorine, sodium and bromine, etc. Since only relatively few elements are contained in the great majority of different dyes, their ability to form bonds with chemical groups, complexes, molecular chains and nuclei plays a very important rôle. → Coloured compounds.

Dyestuff (dye). Of several tens of thousands of chemically different dyestuffs known, approximately 3000 are used industrially and a few hundred of these in large quantities. The remaining multitude has arisen as a result of the need to dye the various fibres in the greatest possible number of different shades as well as to dye them with the desired fastness properties in each case.

Classification: dyestuffs may be classified according to the fibres on which they are used (see Fig. 1).

1. For cotton, viscose, modal fibres and linen:
   - Direct (substantive) dyes: anionic dyes which exhaust directly on to the fibre, i.e. without premordanting. They have only moderate wash fastness and some have very high light fastness.
   - Reactive dyes: anionic dyes which exhaust directly and react chemically with the fibre. Consequently, they are very fast to washing and offer a brilliant range of shades.
   - Vat dyes: These are water-insoluble pigments which are dissolved (vatted) by reduction and dye the fibre in the reduced form. After subsequent oxidation, the original pigment is restored on the fibre. Vat dyes are very fast to washing and light (Indanthren) but there are no brilliant shades.
   - Sulphur dyes: some sulphur dyes are available as unmodified pigments which are dissolved by reduction during dyeing, others are available in a pre-reduced form. Subsequent oxidation restores the original pigment on the fibre (analogous to

1. cellulosic fibres		
reactive dyes	**no** extraction with DMF, DMF/H_2O (1:1) or pyridine/H_2O (1:1)	acid or alkaline decomposition on boiling chromatography
vat dyes	bleeds heavily with DMF	redox reaction with an alkaline/acidic vat
naphthol AS dyes	bleeds heavily with DMF	reductive decomposition chromatography
direct dyes	bleeds heavily with DMF/H_2O (1:1) or pyridine/H_2O (1:1)	re-dye on to cotton chromatography
sulphur dyes	virtually no bleeding with DMF	change of colour on reduction test for sulphur
2. synthetic fibres/wool		
disperse dyes	the dye is stripped with pyridine or glacial acetic acid	re-dye on to acetate fibre chromatography
cationic dyes	more easily extracted with glacial acetic acid than with pyridine	re-dye on to PAN chromatography
acid dyes	bleeds heavily with pyridine/H_2O (1:1) or ammonia/H_2O (1:1)	re-dye on to wool test for metals chromatography
metal-complex dyes	slight to heavy bleeding with pyridine/H_2O (1:1)	test for metals chromatography
afterchrome dyes	slight to heavy bleeding with pyridine/H_2O (1:1)	test for metals chromatography
reactive dyes	no bleeding	strip with alkali chromatography

Tab. 1: Application-related analysis of textile dyestuffs: extraction of dyestuffs from the fibre.

  vat dyes). Economical, but the shade gamut is restricted to browns, olives, dark blues and blacks.
  - Azoic colorants: the dye is formed on the fibre in two stages, i.e. by pretreatment with a naphthol followed by a second treatment with a diazonium salt. High fastness properties.
  - Pigments: these are deposited on the fibre and fixed mechanically with binders. They have low rub fastness but are very fast to light. They are used for dyeing pale shades and for printing all depths of shades
2. For wool, silk and polyamide fibres:
   - Acid dyes: anionic dyes. These include acid levelling dyes with moderate wash but high light fastness and milling dyes with high wash fastness.
   - Chrome dyes: anionic dyes which are bound to the fibre in the form of chromium complexes by means of an aftertreatment with chromium salts. Very high wash fastness.
   - Metal-complex dyes: anionic 1 : 1 or 1 : 2 metal-dye complexes. They are characterized by high wash fastness and very high light fastness but include no brilliant shades.
   - Reactive dyes: see 1, used especially for machine-washable wool.
3. Dyes for acetate, triacetate and polyester fibres:
   - Disperse dyes: these are non-ionic dyes which are only sparingly soluble in water and are therefore applied as dispersions.
4. For acrylic fibres:
   - Cationic dyes: these are characterized by high wash and light fastness.

Another classification system for dyestuffs is based on their chemical structure.

Among the chemical test methods for dyestuffs, the extraction of dyes from the fibre occupies a very important position (see Tab. 1). For tests on dyed textiles, extraction is a preliminary requirement for subsequent dye analysis. The behaviour of a dye bound to a textile substrate in different solvents permits a rapid but nevertheless reliable determination of the dye class. Since the trend in analysis is towards short tests and rapid methods of detection, a scheme is presented here with the aid of which conclusions concerning the presence of certain important dye classes, depending on the type of fibre, can be drawn. The important dye classes and their ease of extraction in different solvents as well as any further necessary analytical steps are given separately for the different groups of fibres. However, this scheme represents a very idealized form of analysis. In reality, each dye class contains examples, the behaviour of which may deviate to a greater or lesser extent from the scheme. In order to be able to recognize such dyes with confidence, considerable experience in the behaviour of dye classes is necessary.

Since a dyestuff was first characterized by a few properties and its colour fastness (50 years ago, for example, by its fastness to water and washing and today by its resistance to "chlorinated city water", its dispersion stability or its hygienically problem-free handling), the catalogue of requirements has changed and continued to grow in size (Tab. 2). New properties such as these, play a far more important role in modern finishing technology than those few characteristics which confronted the finisher at that time. The finished material has become more expensive and, with the high degree of rationalization in dyehouses and printing establishments, sources of potential problems can no longer be afforded. The quality and quality assurance of dyestuffs are now indispensable requirements and are indeed demanded by the purchaser; the consequences of product shortcomings have now become more far-reaching, more expensive and more irksome during the production process than hitherto.

Commercial forms: dyestuffs have a diverse requirements profile. The commercial form of the various dyes classes has long been recognized as one of the

property	effect on
solubility/ solution stability	liquor preparation, depth of shade, colour yield, appearance of the goods
dispersion stability	state of the liquor and appearance of the goods, depth of shade, soiling of machinery
commercial form	transport, shelf-life, handling
metal content/ type of metal-complex bonding	effluent
colour yield	value for money, competitiveness
degree of purity	shade, solubility, dischargeability, colour fastness
gelatinization	handling, colour yield
washing off properties	colour fastness, effluent
degree of hydrolysis	shade, colour yield, colour fastness, effluent
staining of other fibres	resist or multicolour effects, processability in garment manufacture
dyeing behaviour (e.g. migration) compatibility with dispersing agents, thickeners and auxiliaries resp. finishing chemicals	Applicability in well-established processes, combinability with other dyestuffs, ecology, economy, behaviour in garment manufacture, storage life

Tab. 2: A selection of dyestuff properties and some of their (negative) consequences.

auxiliaries	chemical name
dispersing agents surfactants	ligninsulphonates, naphthalenesulphonate and formaldehyde adducts, ethylene oxide propylene oxide copolymers
salts	sodium sulphate, chloride
antidusting agents	mineral oils, paraffin oils (+additives)
defoamers	ditertiary acetyleneglycols
antifreezing agents	glycerine, glycols
thickeners	carboxymethylcellulose polyacrylates
buffer systems	phosphate, acetate

Tab. 3: Commercial forms-additives.

most important quality characteristics (Tab. 3). With disperse dyes in particular, the physical properties have a crucial influence on dyeing behaviour. Thus, for example, the behaviour of the dispersion in the dyebath, the rate of diffusion into the fibre as well as undesirable and inappropriate behaviour (such as the formation of specky dyeings) are all properties influenced by the particle size. Similar direct effects on the results of dyeing may also be encountered with vat dyes and pigments. However, for dyestuffs which participate in the dyeing process in the dissolved state, among which the reactive dyes are a typical example, the commercial form was still of secondary importance until a few years ago. The main requirement was ease of removal from the supplier's drums without excessive dusting. For as long as it remained usual practice to heat up the dye solutions by inserting a steam pipe into the dissolving vessel, solubility behaviour was determined almost exclusively by the solubility of the molecule. The only recently specified new requirements placed on the commercial form of reactive dyes are based on various developments especially with regard to their handling and application:

- automated metering systems which are intended to simplify work in colour kitchens,
- cold-water dispersibility is desired in order to make the preparation of dye liquors easier,
- the scaling up of dyeing machine capacities has placed new demands on the removal of dyes from their containers,
- occasional cases of sensitization after inhalation have led to far-reaching requirements with regard to dusting properties,
- the increasing problems of drum disposal calls for high dye concentrations and high powder density.

The profile of requirements for the commercial form of reactive dyestuffs has now become firmly established even though the priority attached to the individual properties varies to a considerable extent geographically throughout the world. Several of the individual and important requirements mentioned above could certainly be fulfilled in a liquid form but unfortunately reactive dyes are subject to serious limitations in this respect, i.e.:

- liquid formulations with good physical stability can only be produced with dyes having outstanding water solubility;
- highly reactive dyes in particular (e.g. dichloroquinoxaline, difluorochloropyrimidine, fluorotriazine or vinylsulphone) tend to hydrolyze to a greater or lesser extent in the dissolved state, which can result in a chemically limited shelf life and, on prolonged storage, to reduced colour yields and problems in washing off;
- in conventional colour kitchens, the handling of liquid forms is somewhat more complicated than is the case with commercial dyes in solid form;
- the, in most cases, relatively low-percentage formulations calls for large-volume deliveries with their associated costs and problems, including, among other things, the disposal of empty containers;
- as far as the physiological effects are concerned, it should be mentioned that sensitizations and allergic reactions can also be caused by sprays or by the formation of aerosols.

New → Formulations of textile dyestuffs have been especially geared towards easier handling by the customer. Dyestuffs should therefore be:

- clean and dust-free,
- easy to dispense, even with automated metering systems,
- easy to prepare in solution (i.e. without boiling), readily soluble and, in stock dye liquor preparations, there should be no limitations on mixing with other dye liquors.

In addition, much effort is being directed towards the achievement of more simplified manufacture and advantages in ecological aspects as well as in the transport and storage of large quantities. These objectives should be achieved without incurring any severe penalties and justify the generally somewhat higher production costs. Examples recently introduced on to the market include new liquid formulations and various granular formulations, especially for reactive and disperse dyes as well as for acid and cationic dyes. In addition to the general requirements already mentioned expected of modern formulations, still further requirements are also placed on liquid dyes:

- high stability during storage, transport and dispensing, no precipitation, no changes in particle-size distribution and crystal structure, the least possible sedimentation, no phase separation, and no chemical changes (hydrolysis in the case of reactive dyes);
- high concentration in order to keep transport costs, storage space and bath volumes low;
- constant flow properties;

- no drying out or encrustation;
- easy homogenization in the event of freezing and thawing out;
- high miscibility with water and, if possible, with other dyes;
- no promotion of corrosion;
- dyeing properties to be as close as possible to, or better than, those of the standard brands [up to same depth of shade (concentration)].

Not all of these requirements and expectations have to be fulfilled in every case. Depending on the type of dye (reactive, disperse, vat or direct dye) and the specific method of application (exhaust process, textile printing, continuous dyeing), the dye formulations contain special additives which confer optimum properties on the commercial form with regard to shelf life, handling, dyeing results, etc. Because these substances do not exhaust on to the fibre, they pass into the effluent after completion of the dyeing process. Some of the larger dye manufacturers with a few hundred dyestuffs in their product range will often produce several commercial forms of these (tailor-made for different applications). In their formulation, hundreds of different products and product qualities find application in the case of surfactants and dispersing agents alone which may be further combined with each other and with other auxiliaries.

Since there is usually a considerable amount of know-how involved in dye formulations, no dye maker is interested in disclosing his recipes. A technician working on the development of commercial forms of dyes is therefore quite happy to know just a part of the product range of his own company. The composition of commercial forms produced by other dye makers can only be determined with the aid of complicated analytical procedures, so that any knowledge gained is, of necessity, selective and only fragmentary. However, some general information on this topic can be given. As this is not possible for all classes of dyes two important ranges, i.e. disperse and reactive dyes, have been selected as examples here.

From the point of view of technical application, the quality of the finish for disperse dyes must take into account the following aspects:

- particle size distribution in the stock liquor dispersion and at the start of dyeing,
- dispersion stability under dyeing conditions,
- redispersibility resp. the redispersion of agglomerates.

Disperse dyes in the form in which they are produced by dye synthesis are usually obtained in a more or less coarse crystalline state. The coarser the dye crystals obtained in synthesis, the easier it is to separate them from the reaction solution, but the greater is the effort required to finish the dye in order to achieve a uniform fine dispersion. The main task of the finish, in the case of disperse dyestuffs, is, therefore, to break down the crystals formed during synthesis into sufficiently fine particles. This comminution is achieved by kneading or milling. Finally, a dispersant is added to the dye, the purpose of which is to ensure that the dye disperses easily and completely in water at a later stage. The maximum size of the dispersed dye particles requires that approx. 100 billion particles are formed from 1 g of the coarse crystalline dye. The size of the dispersed particles is, as a rule, not uniform. This gives rise to the following problem: any dispersion consisting of more or less sparingly soluble particles of different sizes is thermodynamically unstable, since a solution in which the smallest particles are in equilibrium is oversaturated as far as the larger particles are concerned. The result of this is that, at a sufficiently high temperature and especially during intermediate cooling, a continual growth of large particles takes place at the expense of the smaller particles. This process is often referred to as Ostwald ripening and has been frequently discussed. The system is only stable when all the particles are of the same size. From a practical dyeing standpoint therefore, a disperse dye consisting of uniform, medium-sized particles, e.g. around 0.5 mm, is regarded more favourably than a dye of identical chemical constitution, the particle size of which varies between 0.1 and 0.5 mm since, in this case, the larger particles will continue to grow in size under favourable conditions. As far as dyeing behaviour is concerned therefore, dyes with a different particle size composition but the same chemical constitution cannot be described as identical.

Toxicology: the ecological and toxicological testing of intermediates, dyestuffs, dyeing processes and effluents is now of paramount importance. Through the foundation of ETAD (Ecological and Toxicological Association of the Dyestuffs Manufacturing Industry) all large dyestuff manufacturers throughout the world (with the exception of East European dye makers) have demonstrated that they can deal with these problems successfully on their own initiative.

As far as the carcinogenic effects of colorants on humans are concerned, no conclusive evidence can be drawn from available epidemiological data and studies. However, a few dyestuffs have produced such effects in long-term tests on animals. After a painstaking evaluation of the available test results from long-term animal tests according to the criteria used e.g. by the IARC (International Agency for Research on Cancer), sufficient experimental evidence of a conclusive carcinogenic activity exists at present for only seven dyestuffs (Fig. 2). However, the fact that a whole series of dyes are strongly suspected of being carcinogenic is justified on the basis of certain indications. For example, the metabolism of benzidine dyes in animal and human organisms results in the formation of the carcinogenic benzidine through reductive cleavage of the azo group

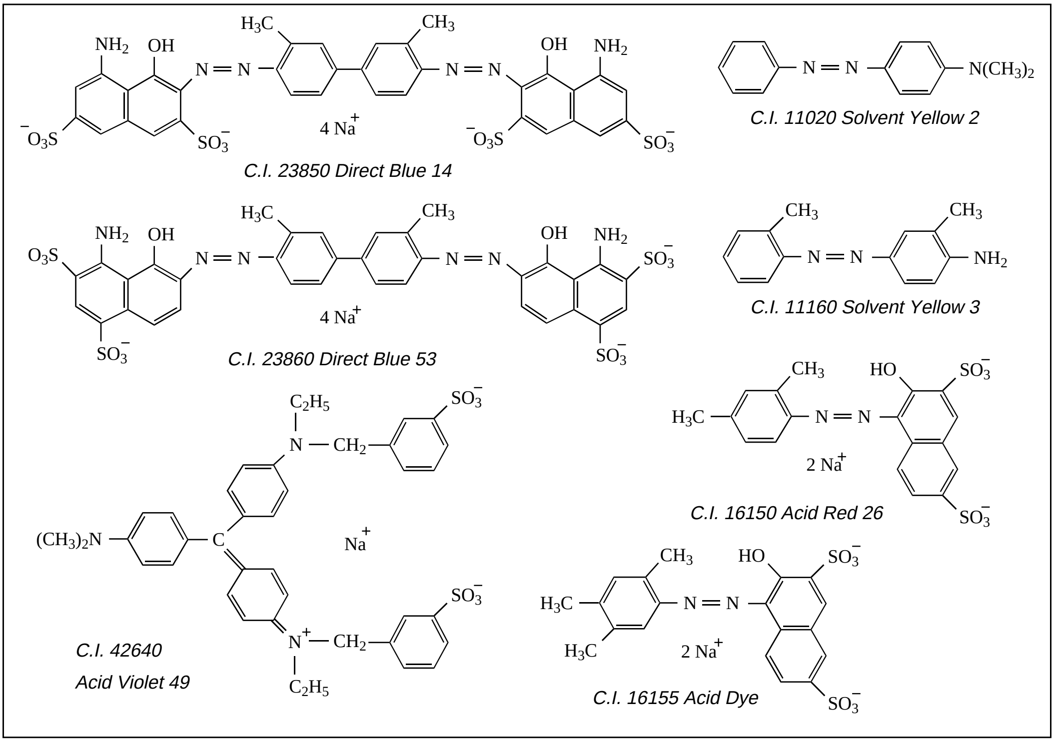

Fig. 2: Dyestuffs found to have a conclusive carcinogenic activity in animal tests.

(Fig. 3). With the ingestion of large quantities of such dyes, an increased risk of bladder cancer can no longer be ruled out.

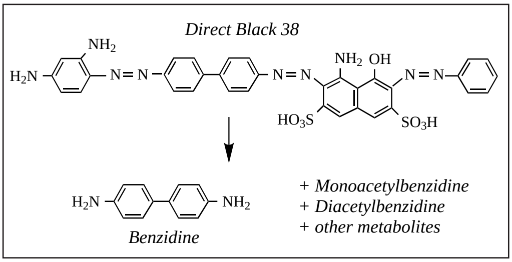

Fig. 3: Metabolism of Direct Black 38 (a benzidine type) in the hamster.

The general reaction which proceeds at azo groups has been known for a long time. Only the red dye Prontosil will be referred to here which was first synthesized by Mietsch and Klarer in 1932. Its antibacterial properties, discovered by Domagk, ushered in the era of sulphonamides. The active principle, p-aminobenzosulphonamide, is formed by a similar primary metabolism (Fig. 4).

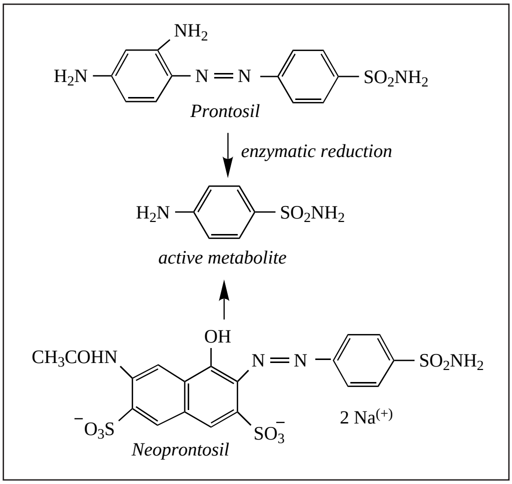

Fig. 4: Enzymatic reduction of azo dyes. (Both have found application as sulpha drugs; the metabolite has an antibacterial effect in the blood).

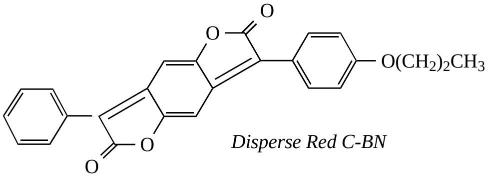
In recognition of the above-mentioned facts, a significant proportion of the efforts of the ETAD Committee on Toxicology is devoted to the ongoing evaluation of new data from tests on carcinogenic as well as mutagenic effects in relation to possible cancer risks, the realistic assessment of which is not without problems. It is precisely in this field that the dyestuff manufacturing industry sees itself as being confronted with controversial interpretations of data, with effects which are the result of absurd levels of overdosing, with opinions that are not based on scientific facts and questionable conclusions relating to structure/effect analogies. Because of the relatively low general toxicity of colorants, the administration of very high doses is possible. The toxicological effects, which are usually only produced by high doses, must be extrapolated to the trace exposure level which is lower by many orders of magnitude. The relevance of the findings from tests such as these is also uncertain. However, it is known that in many cases where excessive doses are administered, a carcinogenic effect is only triggered by overtaxing the deactivated metabolism and/or by severe primary damage to organs or tissues (e.g. a hepatoxic condition or tissue damage caused by repeated subcutaneous injections).

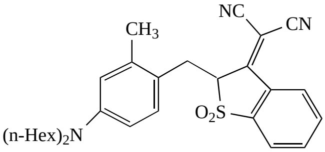
Development: the dyestuff's industry is sometimes accused of neglecting "textile engineering" considerations by giving priority to marketing concerns. It invests, for example, hardly any effort in traditional dye research because the costs involved in the development and introduction of new dyes are too high. Under these circumstances, how can the development of new chromophores be expected? Electronic data processing is also important in the development of new chromophore systems. This began in the 1950's with Kuhn's electron gas model. Thanks to the computer, very reliable predictions concerning the absorption spectra of new dyes which have not yet been synthesized can be made. However, this does not mean that traditional organic dye chemistry has become in any way superfluous. In the 1980's, at least three new chromophore systems were discovered and realized on a commercial scale. There are no grounds to assume that this will not continue to be the case in future. These three systems are summarized in the formulae given below:

– Disperse Red C-BN (C.I.Disperse Red 356) of ICI has probably the best thermomigration properties of all red disperse dyes known up to now.



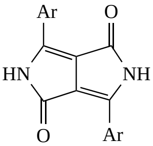
Disperse Red C-BN

– Foron Brilliant Blue S-R (C.I. Disperse Blue 354) of Sandoz is at present the most brilliant disperse blue ever produced.



Foron Brilliant Blue S-R

– Irgazine pigments of the 1,4-diketopyrrolo-(3,4-C)-pyrrole type of Ciba-Geigy (C.I. Pigment Red 254 and 255) have, up to now, been mainly used for the coloration of plastics and, only to a lesser degree, for textile applications.



Irgazine pigments

Dyestuff commercial forms Dyes are available commercially in powder form or, for improved metering, as liquid dyes in easy-pour paste form (e.g. vat or disperse dyes) or as dustless granules for easier weighing. Dyes in paste form are usually used in printing to ensure improved distribution during inspissation. As well as the standard types, most dyes are also available as concentrates. These are designated by percentage (e.g. 150%, 200%) and are then reduced to a lesser extent or possibly used as straight dyes (→ Dyes without extender). The purpose of reduction is to ensure accurate repetition of the dyeing recipe, whereby any manufacturing fluctuations are balanced out. The diluent, extender and reducing agent take the form of neutral additives, dependent on dye type, such as sodium sulphate, sodium carbonate, starch, sodium chloride etc.

Dyestuff for coupling, specifically diazo dyestuffs where the developer is coupled with the dyestuff by diazotization (usually diazotized p-nitraniline).

Dyestuff formulations, form of supply as → Commercial forms of dyestuff (including all additives, e.g. extenders etc.). Depending on dyestuff type (reactive, disperse, vat, direct dyestuff) and application type (exhaust dyeing, printing, continuous), dyestuff formulations contain specific additives which give the commercial form the best possible properties in respect of storage stability, handling, results etc. As these substances are not absorbed by the fibre, they are discharged with the effluent on completion of the dyeing process. As a considerable degree of specialist knowledge is required for dyestuff formulation, manufacturers do not readily allow their recipes to be revealed. The composition of the commercial forms can therefore only be discovered by means of complicated analysis, so that the knowledge is of necessity selective and patchy. Some general observations, however, may be made on the basis of the patent literature.

Auxiliary	Chemical designation
Dispersants Surfactants	lignin sulphonates, naphthalene sulphonate, formaldehyde addition compounds, ethylene oxide-propene oxide-copolymers
Salts	sodium sulphate, sodium chloride
Dust-bonding agents	mineral oils, paraffin oils (+additives)
Antifoams	ditertiary acetylene glycols
Antifreezes	glycerine, glycols
Thickeners	carboxymethyl-cellulose polyacrylates
Buffer systems	phosphate, acetate

Tab. 1: Principal additives used in dyestuff formulations.

A quantitative evaluation of the environmental safety of the additives shown in Tab. 1 is difficult, as there is a great number of testing methods making it a difficult matter to collect comparable data. In addition, the test methods used often show considerable variation, and finally different countries attach different weight to various parameters, thus for example the COD which is significant in Germany is not relevant in Switzerland.

From industrial health and ecological aspects, dyestuff formulations should ensure that the following requirements are satisfied:

- capable of being cleanly removed leaving the minimum possible residue,
- do not generate dust,
- easily metered (including by automatic systems),
- easy to set (soluble without boiling),
- can be mixed with stock solutions,
- manufactured without potentially toxic additives.

In general it may be stated that the dispersants and surfactants shown in Tab. 1 are not toxic to fish. Thus in all cases the LD_{50} values are above 1000 mg/l. Bioaccumulation and heavy metal activation are also unknown. Other investigations do however lead to the suspicion that in a few cases products are still being used which are potentially harmful. Reference must be made here to e.g. condensation products of formaldehyde with phenol or cresol, which always contain small amounts of the primary substances toxic to fish. Furthermore, alkyl phenol ethoxylates should also no longer be used, as they generate metabolites toxic to fish on decomposition. The salts, buffer systems, thickeners and antifreezes shown in Tab. 1 do not present a problem in respect of toxicity to fish. It may therefore be generally said that dyestuff formulations must not contain any auxiliaries toxic to fish. If this is the case in individual products they should immediately be replaced, as there is a sufficient range of alternative products available.

The situation is different regarding biodegradability (Tab. 2), which is of great significance in effluent treatment. Some of the products used as antifreeze agents are compounds which are to an extent degradable, but at least capable of elimination. The thickeners most frequently used (especially the polyacrylates) are at least largely capable of elimination. Dispersants and surfactants, on the other hand, only decompose slowly. This is due on the one hand to their polymer structure, on the other to their aromatic components. The products identified are partially eliminated by adsorption on digester sludge, but the adsorption rate is not high. In general, such elimination is welcome in terms of effluent pollution but only represents the second-best solution. The main objective must be to achieve complete decomposition at the biological treatment stage. Salts and buffer systems are usually not retained by an effluent treatment plant, with the exception of phosphates, which can be removed by precipitation. As the usual dust-bonding agents all contain oils, they too are only minimally degraded.

Auxiliary	COD	BOD_5	TOC
lignin sulphonates	approx. 1200	approx. 50	approx. 15%
naphthalene sulphonate formaldehyde addition compounds	approx. 650	approx. 50	approx. 15%
propene glycol		approx. 10	approx. 95%
glycerine		approx. 780	approx. 90%
carboxymethyl-cellulose		approx. 0	approx. 30%

Tab. 2: Biodegradability of certain additives in dyestuff formulations.

Among the thickeners there are numerous degradable alternatives (e.g. based on biopolymers) which are capable of use in the majority of formulations. The agents currently used as antifoams have no easily degradable replacements with a broad spectrum of activity. As antifoams are only present in the formulations in small quantities, this is not an urgent problem. The same can be said of the dust-bonding agents, although here new, environmentally-friendly solutions are expected to be available soon. A more important development, however, would be degradable dispersants and surfactants, as these constitute the main volume of auxiliaries contained in dyestuff formulations. Among these are e.g. fatty alcohol ethoxylates, alkyl benzene sulphonates or alkyl polyglycosides. These products were formulated above all for use in washing and dry cleaning agents, which is where their strengths lie. In most cases they are poorly suited to use in dyestuff formulations, for instance as dispersants for HT exhaust dyeing on polyester. Formulations based on this auxiliary would cause serious loss of quality (e.g. poorer levelness). However, use could be considered in such cases where surfactants are used to improve the wettability and as an extender. Even here, there is the problem of the tendency of the products indicated to generate substantial volumes of foam which then necessitate extensive use of antifoams either in the formulation itself or by the dyer. Overall, at the present time, there are no real alternatives to the surfactants or dispersants at present used in dyestuff formulations. On the other hand, it is certain that such alternatives are possible and that they are also under development.

Solid and liquid commercial types are distinguished by their water content (Tab. 3). Thus the ratio of dyestuff to auxiliaries in the case of powders and granules is max. 2 : 1, in the case of liquid types 3 : 1. On average it may be assumed that the liquid form at similar concentration contains around half, in better cases only around 25–35% of the auxiliaries of the solid type. This should mean a substantial reduction in effluent pollution. The reason for these huge differences lies in the fact that the small dyestuff particles obtained by wet grinding must be prevented from agglomerating during drying, and this is only achieved using a substantial dispersant content. Even if the volume of auxiliaries does not vary so substantially, liquid formulations are often more ecologically advantageous, as the antifreeze agents they contain are either degradable or at least capable of easy removal.

Formulation component	Powder form	Liquid form
Dyestuff	30-50 %	20-40 %
Dispersants	40-60 %	10-20 %
Salts	0-20%	–
Dust-bonding agents	0-5 %	–
Antifoams	0-5 %	0-5 %
Antifreezes	–	10-15 %
Thickeners	–	0-5 %
Water	5-10 %	40-60 %

Tab. 3: Components of solid and liquid dyestuff formulations.

In the case of reactive dyestuff formulations (Tab. 4) the liquid forms are clearly lower in auxiliaries. For powders in favourable cases a dyestuff/auxiliary ratio of 5 : 1 is achievable, in the case of 15 : 1 solutions. As less additive is needed, however, for reactive dyestuff formulations, and in the case of the powders high concentrations of dyestuff can be achieved, the absolute differences between solid and liquid forms is lower than is the case with disperse and vat dyestuffs (Tab. 5). In addition to the differences described between solid and liquid commercial forms, in individual cases there are also differences between different solid commercial forms of the same dyestuff. For example if a dyestuff exists in commercial forms of 100% and 200% high-concentration, the latter will with certainty be the more environmentally friendly.

Formulation component	Powder form	Liquid form
Dyestuff	50-80 %	15-30 %
Salts	0-10 %	–
Surfactants	10-40%	0-15 %
Dust-bonding agents	0-5 %	–
Buffer	5-10 %	1-5 %
Water	3-10 %	65-80 %

Tab. 4: Components of reactive dyestuffs in liquid and solid formulation.

When considering the environmental impact of commercial forms, the packaging should also be taken into account. Solid forms are usually supplied in drums, liquid forms in canisters or disposable containers. All these containers are usually retained by the purchaser and require disposal. Although polyethylene is used as the material, this can be a problem, especially if the packaging drums still contain traces of the product. This is where the type of commercial form is again of significance: good granular types are removed from their packaging leaving practically no residues; this is not the case to a sufficient extent with powders or liquids, so that they must be rinsed out. Regardless of this aspect, endeavours are being made to design drums which are themselves more environmentally friendly. For example, in the place of barrels, cardboard containers with polyethylene liners could be used, with a resultant 90% reduction in the amount of plastic used. In addition the paper and polyethylene constituents of the packaging can easily be separated, thus facilitating separate dumping or recycling. A shift towards such drums can be regarded as a contribution towards more environmentally-friendly commercial forms of dyestuffs. Similar developments also exist for liquid forms. Consideration is also being given to the feasibility of reusable drums. This is probably only suitable for large-capacity vessels, and careful evaluation must be made to ascertain whether this option is really ecologically and economically the best option. Separating and recycling the compacted or shredded materials of the drums

	Powder, 100% (standard) concentration	Powder, 200% concentration	Liquid, 100% concentration
Percentage of crude dyestuff in commercial dyestuff	25%	50%	25%
Percentage of dispersant in commercial dyestuff	30%	47%	12,5%
Dispersant concentration in the liquor from the dyestuff	0,9 g/l	0,7 g/l	0,38 g/l
Dispersant addition when dyeing	1,0 g/l	1,0 g/l	1,0 g/l
Total dispersant concentration	1,9 g/l	1,7 g/l	1,4 g/l

Tab. 5: Contamination of effluent by dispersants when dyeing with disperse dyestuffs in powder and liquid formulation (calculation for typical dyestuff composition, liquor ratio 1:10, 1 g/l dispersant addition, depth of colour equivalent to 3% of fabric weight, powder dyestuff 100% concentration).

could well be more beneficial than the traffic generated by transportation of empty drums. A further alternative, suitable for and already being practised by large users of liquid commercial forms, is delivery by tankers (according to Möckel and Beckmann); there is also the possibility of the supply of dyestuff powder in water-soluble foil packaging.

Dyestuff identification (by chromatography). Dyestuff mixtures are extracted from the textile with the following solutions:

I. General and for almost all anionic dyes: ammonia/water 1 : 10, 100°C, water bath.

II. General and very good for dyes plus optical brightening agents on cellulosic and polyamide fibres: dimethyl formamide/water 2 : 1, 100°C, water bath.

III. For disperse dyestuffs and optical brightening agents on polyester: dimethyl formamide, boiling (153°C), 1–2 min.

IV. For disperse and cationic dyestuffs on acrylic fibres: dimethyl formamide/water 3 : 1, 100°C, water bath, or nitromethane-methyl-n-propyl-ketone, 90–100°C.

V. For disperse dyestuffs on acetate: dichloromethane, room temperature.

VI. For disperse dyestuffs on triacetate: acetone/water 4 : 1, room temperature.

VII. For optical brightening agents on cellulosic fibres: methanol, Soxhlet extractor.

The dyestuff mixture extracted is broken down into its constituents using paper or thin-layer chromatography or paper or thin-layer electrophoresis. These constituents then undergo the following tests for definitive identifcation:

1. Minidyeing: various fibre types are dyed in solutions of the individual dye constituents and chemically tested or compared with sample cards.
2. Comparative tests and matching with chromatograms of known dyestuffs or dye classes.
3. Comparative fluorescence spectra of dyestuff constituents and standard substances.
4. UV and IR spectrophotometric reflectance curves are compared with the equivalent curves of known dyestuffs.
5. Finally, chromatograms of the tested dyestuffs are compared with those of the known dyestuffs. Before chromatographic analysis, preliminary tests are carried out to determine the dye class (microscopic tests and solution tests).

Dyestuff origin → Natural dyes, mineral dyes, pigment colorants.

Dye tests,

I. In substance: a) for uniformity →: Chromatography, Capillary analysis, Fractional dyeing, Fractional solution of dyes, Blow test; b) to identify dye class; c) for constitution; d) for competitiveness by means of comparative dyeing.

II. On the fibre → Dye class identification.

Dye toxicity → Dyes are included in the legal regulations governing toxic substances. Dye manufacturers avoid the benzidine dyestuffs and developers for diazo dyes which are considered carcinogenic. The degradability of dyes in waste water should also be considered (→ Waste water evaluation). Even if a dye is non-toxic, the question still remains of the degradability of any residues (metabolites) in the waste water which may result from its degradation. → Fish toxicity of waste water.

Dye-tube changer (for tube changing machine), automatic device for replacing paper tubes, etc. with rigid or flexible dye tubes or springs in cross-wound packages.

Dye tubes, tubes on which yarn is spooled for dyeing in the form of yarn packages (→ Dyeing tubes for yarn dyeing), → Disposable dye tubes made of plastic, flexible tubes (flexible either axially or radially) for yarn with pronounced shrinking properties, non-disposable dye tubes made of plastic such as Biko dye tubes (which can also be made from stainless steel) and dyesprings.

Dye tube, split → Flexible dye tube made from perforated stainless steel, slit open in order to make it radially flexible.

Dye uptake,

I. The dye uptake is the quantity of dye absorbed by the fibre.

II. → Substantivity, exhaustion (diffusion) model.

Dye-weave process, polychromatic dyeing process in which the dye is supplied by moving nozzles. The jets of dye solution are directed onto the surface of an angled plate, from where they impinge upon the substrate and are then squeezed out on a vertical two-bowl padder.

Dye winch (Paddle-dyeing machine, Paddle vat), dye vat of hemispherical or $^3/_4$-spherical form made of wood, copper or stainless steel with a rotatable hank winch or paddle as a "moving device" sitting horizontally and to one side on the top. The ends of the winch or paddles extend down into the top of the liquor and when put into operation, they provide continuous movement to the liquor and material. It is sometimes possible to sit the paddle up, thus converting the apparatus into a → Winch vat for piece dyeing. Also made with a hood, which can be fully closed, or with hinged or sliding glazed hatch. Application: widely used for dyeing cloths in general and also much used for stockings packed in small sacks. Advantages: universal application, very efficient use of dye, economic use of steam as liquor bath ratio, 1 : 20–25, can be shorter than for paddle. Rapid rinsing (half the time and quantity of water), gentle handling of material (minimum abrasion against the vat walls).

Dyewoods → Natural dyes.

Dye works, dye manufacturing plant (dye factory).

Dynamic viscosity → Rheology.

E

EA → Elastane fibres, → Standard abbrev. for textile fibres, according to the → EDP Code; DIN standard abbrev. → EL.

Easy-care finishes In order to eliminate creasing (wrinkling) of cotton fabrics during wear and service (washing, drying, ironing) as far as possible, i.e. to make ironing or pressing superfluous if possible, cotton materials are treated with crosslinking agents (→ Wash and wear finishing). The effect of an easy-care finish is influenced by different fabric pretreatments (Fig. 1).

a) Pretreatments: causticizing, mercerization, hot mercerization, stenter causticizing with caustic soda or caustic potash liquor, Sanfor-Set process with liquid ammonia. The increased fibre strength which results from such mercerization processes compensates for the inevitable strength losses in easy-care finishing.

b) Bleaching: peroxide bleaching, in particular, has a positive influence on creasing propensity (Monsanto ratings 1–5) and, in combination with an easy-care finish, causes the least loss in strength.

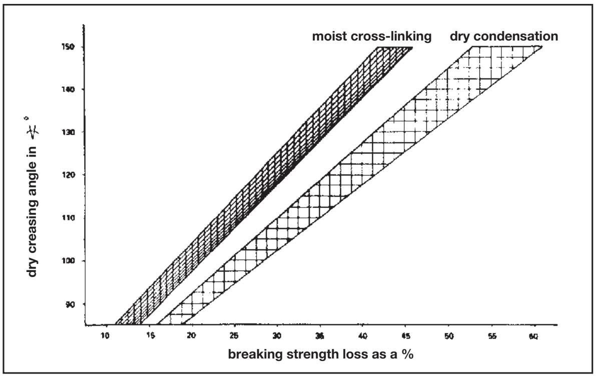


Fig. 2: Dry-crease angle/breaking strength ratio in dry (right) and moist cross-linking (left).

Fabric moisture during crosslinking has a positive effect on the unavoidable losses in strength (Fig. 2). For the same crease recovery angle (e.g. dry crease recovery angle 150°) the strength loss is approx. 40% under moist crosslinking conditions and 55% under dry

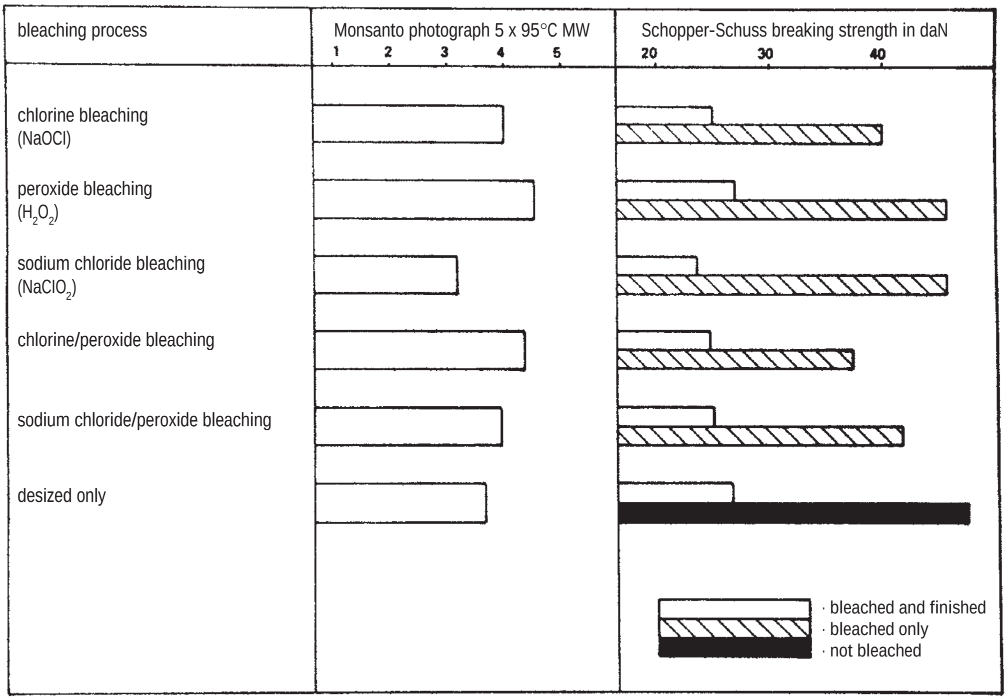

Fig. 1: Monsanto photograph and breaking strength after different bleaching processes.

cross-linking process	woven fabric moisture content %	liquor pH value	cross linking temperature (°C)	cross-linking duration	fibre condition	effect/strength ratio
classic dry condensation	0– 2	4–7	150–160	5– 4 min	unswollen	good
rapid curing	0– 1	4–7	140–220	10–10 s	completely unswollen	good
low curing	0– 3	3–5	130–180	50–30 s	unswollen	varying moderately good
moist	5– 7	0.5–1.8	25– 35	16–24 h	partly swollen	very good
wet	50–80	< 1	15– 25	20 h	swollen	optimal but no dry creasing angle
wet/dry	50–80	< 1	15– 25	20 h	swollen	good/very good
	0– 2	5–7	140–160	30 s–5 min	unswollen	moderate dry creasing angle

Tab.: Cross-linking process, application conditions and effect/strength ratio.

crosslinking conditions. The various crosslinking conditions used in easy-care finishing are compared in the table.

Easy foaming quality Ability to generate considerable quantities of → Foam, mainly very aerated, at low temperature, low concentration and with minimal labour consumption, e.g. using the coconut oil soap type. In general, this foam is neither stable nor achievable at high temperature.

Eau de Javelle (eau de Javel). Named after the district of Javel in Paris. Originally a clear aqueous solution of potassium hypochlorite also containing potassium chloride. Used for bleaching cellulosic fibres. Potassium hypochlorite solution has now been largely substituted by a cheaper but similar sodium hypochlorite solution under the same name.

Eau de Labarraque Sodium hypochlorite solution named after its French discoverer. Also commercially available as → Eau de Javelle.

Ebonit → Hard rubber.

Ebrú process The precursor to → Aquagraphics. This is an 800 year old Turkish printing method which uses animal waste products including ox bile and boiled papyrus. Method as for aquagraphics.

ECE (Ger.), abbrev. for: Europäische Convention für Echtheitsprüfung (European Convention on Fastness Testing); → Technical and professional organizations.

Ecobalance Comprises the description and listing of the primary effects of specific processes on the environment, i.e. on air, water and soil, taking additional account of energy and raw material requirements. The balancing of all environmental effects and loads, which can occur in the production, use and disposal of no longer usable products, also raises the question of how protractedly the environment will be polluted in future by production, consumption and disposal. Ecobalances are first of all emission balances, i.e. all outflowing substances from basic commodity raw material production and product use and disposal are collected and compared with each other, along with noise pollution, for the products and application processes to be tested. An ecobalance includes the various costs and environmental loadings which ensue in the production of textiles and in the subsequent disposal of by-products: substance emissions, including airborne pollutants, effluent, waste and residual matter together with heat emission, raw and auxiliary material requirements, water and energy plus space requirements, and also the effects on the function and use of ecosystems, including the recording of the external cost of treating pollutants in outside plants. The ecobalance is a comparison of input and output, quantitatively recording as emissions and immissions the sum of all bulk flows such as air, water, waste and energy flows, and all products and raw materials used. Classification of the pollutants and their quantities, determined in accordance with environment endangering criteria, is followed by ecological assessment of the item under examination.

An ecobalance should express by means of objectively produced figures the effects on humans, animals, plants and their environment occurring over the entire life cycle of a product. To this end, the life cycle of the product to be tested is first of all subdivided into self-contained part processes. All statistically ascertainable effects on the environment will then be determined for

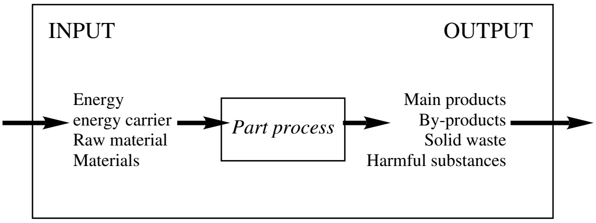

Fig.: Input/output analysis in producing ecobalances.

each part process in an input/output analysis in accordance with the illustration.

The following factors are determined in input/output examination:

1. Input:

a) Raw materials: each stage of the total incoming material, in the form of raw materials and semi-finished or finished products, is recorded in units of weight. In the case of materials which are themselves the result of preliminary stages or recycling processes, the cost of energy and environmental pollution resulting from preliminary production processes must be taken into account in the process.

b) Energy and energy media costs: the consumption of energy in the form of process heat or electrical power, plus the quantity of energy media not used for energy purposes, is determined. In the case of fossil fuels, the entire route from deposits through to utilisation is taken into account. The fact that energy also has to be used to produce energy (e.g. power) is taken into account by calculating back to the so-called primary energy with the degree of efficiency of the energy supply. In the energy medium balance, the quantities of energy contained in the product (e.g. wood or polyvinyl chloride in window frames) are determined by their net calorific value. In the case of subsequent energy utilisation, this can flow back into the system.

2. Output:

a) Main/by-products: first of all, main and by-product quantities are obtained as the result of each production process. They are not emitted into the environment in the sense of an environmental balance, but are prepared for use and application processes. At the end of a life cycle, the products are either re-used from the material or thermal standpoint, or disposed of in dumps.

b) Environmental pollution: whilst energy and material flow analysis is comparatively unproblematic (the distribution key to the proper allocation of pollution to those causing it should be produced analogous to weight, volume or price relationships), pollutant recording presents bigger problems. The decision as to which substance emissions in general, and from what threshold, are damaging or environment endangering is alone difficult to make. The national regulations for maintaining the cleanliness of air, water and soil contain lists of many hundreds of pollutants and their limit values. The fact that, in the case of many pollutants, their limit values are indicated very differently in different regulations, reveals the continuing uncertainty of toxicologists, ecologists and politicians in this area. This can only be resolved by additional experience. Furthermore, international conventions are required in this respect to decide which pollutants should basically be included for comparison. In addition to the generally measurable ecobalance dimensions described to date, there are additional environmentally relevant criteria, which are sometimes difficult to evaluate statistically, and cannot therefore be represented in ecobalances. These include the quality of the workplace directly associated with production, the susceptibility of processes to problems and accidents, the general availability of raw materials (how long will fossil raw material supplies last, and at what extra cost can residual stocks be exploited?) and also the assessment of risks (assessing environmental catastrophies, e.g. tanker accidents, nuclear power plant problems etc.). To begin with, these factors should not be directly included in the ecobalance, but should not – particularly if they are very important – be ignored, and therefore should at least be qualitatively described.

In order to make clear and comprehensible environmental assessments, and to enable comparisons to be made with other product balances, all assumptions made in the course of an operation must be documented. These include primarily the so-called balance and system limit data (which processes have been recorded by what means and with what target parameters?). As a rule, these boundary conditions are selected in such a way that all important pollutants can be recorded at reasonable expense. Whilst on the energy side for example the immediate production energy must be directly determined, secondary energy consumption (for lighting, heating and air-conditioning the production and administration buildings for example) is ignored in many balances. In addition, the question as to whether the so-called grey energy used in producing the production premises, production machinery and vehicles should be included must be laid down in the system limits. In most of the ecobalances produced to date, this energy figure is still not included for reasons of simplification, although its proportion can lie between 5 and 100%. Of significant importance for an ecobalance is the assumption of the degree of efficiency for energy utilisation and supply. Different energy media can be used in various proportions in producing power and heat. This must be represented and taken into account by a specific split, expressing the proportions in which power is produced, e.g. thermal, nuclear, hydraulic or others. Depending on circumstances, it is possible to undertake the division purely in plant terms (in-house energy supply), or regionally, nationally or internationally. The data can be had from national and supranational energy supply statistics. In any case, the division, which concerns not only the primary energy cost but also the energy-dependent emissions, must be indicated in the marginal balance conditions. The same applies to the basic data listed below, which can be of importance to the correct interpretation of an ecobalance:

- basic transport data (e.g. energy cost and emission factors per unit of weight and length of journey),
- assumed average transport distances,
- maintenance expenditure,
- average length of service life of products and buildings,
- assumed recycling figures and disposal splits.

The quantitative recording and listing of the energy and pollutant flows in an ecobalance make the ecological classification of different products possible only to a limited extent. Whilst the consumption of fossil raw materials and primary energy for two products of identical economic value is directly comparable one with the other, a clear ranking order of the numerically listed pollutant emissions into the above-mentioned environmental areas can only be established within each environmental factor if the same product (or process) comes off better. As this is seldom the case, the individual material flow data must be transformed via evaluation models in a second environmental evaluation stage in such a way that its environmental effects are more comparable. In consequence of the complexity of the subject, there is no universal evaluation method for this. The most frequently used model to date transforms the pollutant emissions within the individual component areas by weighting with the immission limit values. If, in a production cycle for example, 5 g of dust, 3 g of nitrogen oxide and 2 g of sulphur dioxide are emitted, and assuming the immission limit values of the TA_{air}, the volumes are loaded up to the legal limits. This does not take account of possible decomposition and synthesis effects between different pollutants. It is also assumed that the same environment area reference unit, e.g. 1 m^3 of air, may be charged by only one pollutant in each case. As long as identical immission limit values have been used in different ecobalances, the critical volumes produced with this model can be directly compared with each other.

With ecobalances, important decision bases can be provided, enabling

- ecologically damaging processing stages to be recognised within existing production and processing operations, and their improvement immediately to be checked statistically in terms of the evaluation criteria provided;
- different products and materials with the same performance characteristics to be compared directly with one another in order to recognise the most environment-friendly variants.

The complex ecobalance production procedure necessitates making a multitude of assumptions and decisions which have a very pronounced effect on trial results, and must be absolutely understood in order to be evaluated and interpreted. Since there are as yet no international conventions on ecobalance production, the results of different studies should not be compared without detailed checking of the system and the boundary conditions.

Ecolabelling of textiles For identifying the

- physiological and toxicological properties of the product in wear,
- disposal or recycling of “used” articles of clothing,
- ecology and human ecology of the production process.

The problems lie in environmental pollution during cultivation and production as uncontrollable preliminary stages, i.e. as early as fibre cultivation and preparation up to spinning, be it wool, cotton, silk, ramie, linen or regenerated fibres like viscose. Whether the natural resources are carefully treated here, defoliants, fungicides etc. are dispensed with, harmful substance emissions minimised, and the workplace polluted as little as possible with noise, dust, heat and toxic substances, is as a rule still beyond the knowledge of the buyer. Then there are other environmental problems associated with yarn and piece dyeing, printing and finishing, processes which are often carried out in suppliers’ works.

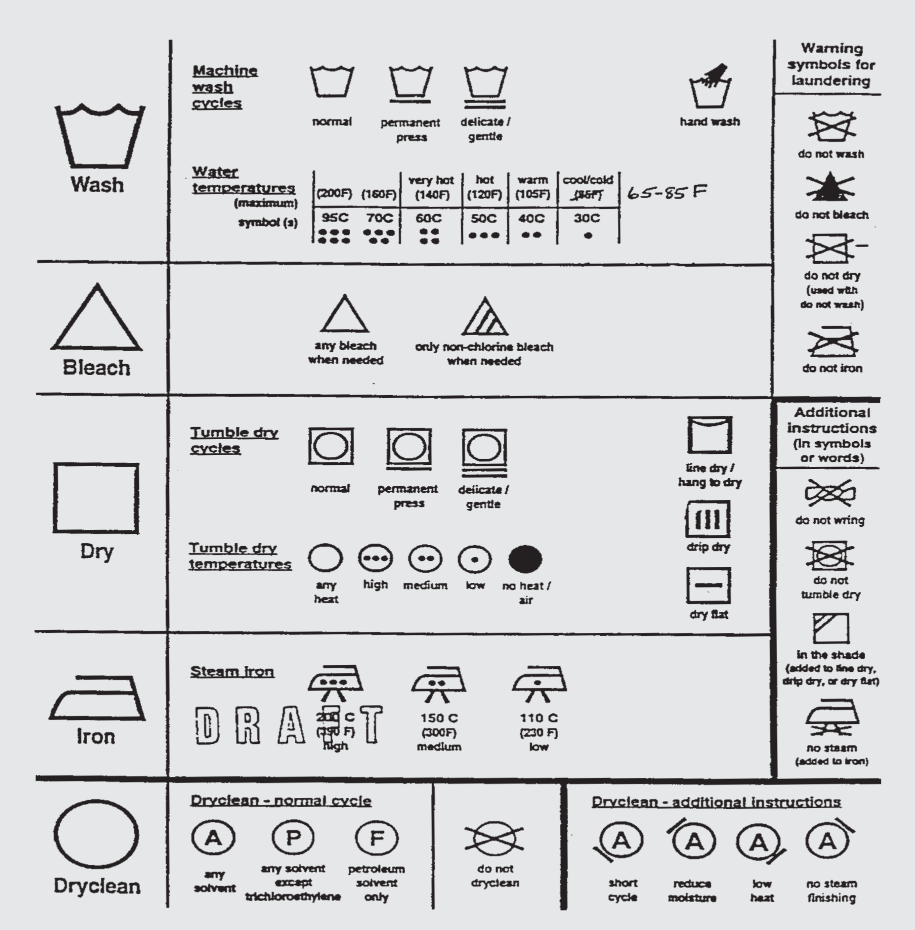
The natural fibre cotton, with over 40% representation in clothing and household textiles, reveals on the one hand severe chemical contamination due to growth, cultivation and harvesting through the individual stages, and, on the other, the need to apply carefully selected chemical finishing processes in order to be able to produce clean, wearable, functional and skin-friendly textiles from this fibre.

In earlier times, textiles were predominantly looked at from the economic, functional (Tab. 1) and clothing fashion standpoints. For some time, end-users and their initiatives have imposed extensive requirements which involve the health safety factor of textiles and also to some extent the ecology of textile production.

Against this background, different textile manufacturers, makers-up and merchants throughout the world have taken care to ensure that textiles meet specific criteria. Thus, some firms have stopped using

- chlorine bleaches,
- azo dyestuffs, which can split off during decomposition into carcinogenic amines according to MAK lists III A or III A 2,
- washing and cleaning agents containing APEO.

Furthermore, there is a prescription to keep below specific limits for a series of parameters, although no criteria of any kind are defined in the case of some collection specifications. The specifications serve only as a marketing instruments.



Tab. 1: ASTM Guide to care symbols (labels for function of textiles).

There are some very diverse initiatives:

- producers and chemical finishers who put ecological collections onto the market (Tab. 3),
- makers-up and merchants with their own ecological collections (Tab. 2),
- trade associations (e.g. Textile Clothing Dialogue, Tab. 4),
- associations, institutes and firms which have laid down the test criteria as a basis for brand names, ecolabels, seals etc. The tests are mainly conducted by independent institutes. Some firms also test in their own laboratories.
- European syndicates (e.g. Textile Clothing Dialogue, EPG, GUT, eco-tex).

I. The “Dialog Textil-Bekleidung” (DTB) (The Textile Clothing Dialogue) has produced for its over 100 member firms from 7 European countries with an approximate total turnover of 10 billion DM an Eco-Info as a complement to the Product-Info already in existence for quite some time. From the ecological standpoint, product requirements should be the determining factors in intercourse between the partners of different production stages. Indicated in it are limits for specific criteria relative to purpose of use, together with the relevant test criteria (Tab. 4 + Tab. 5).

II. The OTTO mail order company in Hamburg, in which environmental protection is an acknowledged company aim, specifies ecological textile material requirements for natural fibre textiles, and also includes them for synthetic fibre textiles. The different limits for content substances and properties such as natural fibre textile pH and colour fastness are listed in Table 6, a distinction being drawn between clothing worn next to and away from the skin and also baby clothing.

In addition to the requirements of individual textile firms, there is also quite a number of brand names, ecolabels and seals for textiles offered by associations, societies, institutions and also service firms (Fig.). Most initiatives start in fact from the Federal Republic of Germany, but claim to be valid throughout Europe (sometimes throughout the world).

Examples are:

- eco-tex (eco-audits of the eco-tex consortium),
- EPG (The European Project Guarantee of ELTAC = Europe’s Largest Textile and Apparel Companies),

Company	Collection	Testing in accordance with	Testing station*	Comments
C & A, Düsseldorf		Minimum in-house requirements	in-house	no company label, generally strict ecological requirement
Esprit, Düsseldorf	»ecollection«	no in-house testing		highest standards condition: non-contaminated condition »What isn`t in there can`t come out« 12 stores
Hess, Bad Homburg	»Hess-Natur«	in-house quality guidelines	in-house laboratories Bremen Institute for the Environment	
Lucia, Lüneburg	none	M.S.T. Eco-Tex	Zugel, laboratories Hohenstein	all collections must comply with eco-standards
Neckermann, Frankfurt	»Neckermann« Eco-quality	No in-house testing		purchases only from firms with Neckermann certificate award
OTTO, Frankfurt	environment-friendly textiles	Hansa-Control Hamburg		OTTO-Requirement profile
Quelle, Fürth			in-house laboratories External laboratories	purchases from firms with eco-collections
Rödel, Freiberg	R-line	Eco-Tex	Hohenstein Zürich (testex)	
Steilmann, Bochum- Wattenscheid	»Britta Steilmann«	Klaus Steilmann Innovation (KSI) EPG/ELTAC=M.S.T.	EPEA-Umweltinstitut, Hamburg	undyed, unbleached cotton
Triumph, Heubach	Slip-Programme	Eco-Tex		planned: eco-Programme
Tumlin, Stockach		Testing for: • Heavy metals • Pesticides	GFIT, Bernstadt	

Tab. 2: Ecotextile makers-up and traders, Germany (according to BASF).

- GuT (Signet der Gemeinschaft umweltfreundlicher Teppichboden = Seal of the Environmentally Friendly Carpeting Association), founded by well-known European carpet firms),
- GuW (Signet der Gemeinschaft umweltfreundlicher Wohntextilien = Seal of the Environmentally-friendly Domestic Textiles Association),
- M.S.T. [Markenzeichen schadstoffgeprüfte Textilien des Vereins für verbraucher- und umweltfreundliche Textilien e.V. (VvuT) = Harmful Substance Tested Textiles Trademark of the Consumer and Environment-friendly Textiles Association],
- M.U.T. (Markenzeichen umweltschonend hergestellte Textilien des VvuT = VvuT Trademark of Textiles Produced by Environmentally-friendly Means),
- Eco-Tex (a label of the International Association for Research and Testing in the Field of Textile Technology Eco-Tex),
- TOX-PROOF (a German Control International criterion catalogue).

The above-mentioned trademarks, eco-labels and seals extensively comply with the following requirements for textiles so distinguished:

- They contain no dyestuffs which can be regarded as cancer inducing, or can split off into cancer inducing products.
- Products for infants or small children below two years of age may not release dyes in contact with saliva or perspiration.
- The concentration of heavy metals released when affected by perspiration may not exceed the limits for drinking water.
- Pesticide residues may not exceed the limits admissible for foodstuffs.
- They contain less free formaldehyde than prescribed by law.
- The pH should be equivalent to that of human skin.

In addition to the above-mentioned labels, the following initiatives are important:

- AKN (Arbeitskreis Naturtextilien e.V. = The Natural Textiles Association, with approximately 20 members).
- EU ecobabel and eco-audit.

III. The eco-tex label of the eco-tex consortium, founded by Scotdic, Textile Farben GmbH, Cologne, and tdg,

Fig.: Ecolabels: the new Eco-Tex label: Confidence in textiles – textiles tested for harmful substances in accordance with eco-Tex standard 100 (top); three water droplets in a circle as the symbol for 92% water recovery in the Brinkhaus textile finishing works (centre); the vauDe symbol (bottom) for 100% single component material sportswear.

Features	Supplier details specification*	Production note	Test specification a) obligatory b) recommended
1. Formaldehyde	( ) < 1000 ppm ( ) < 300 ppm ( ) < 75 ppm	Recommended among other things for: • outerwear, lining fabrics, clothing not in contact with the skin • shirts, blouses, knitwear, clothing worn next to the skin • underwear, nightwear	a) Acetyl acetone method in accordance with Japanese Act 112
2. Pesticides	( ) pentachlorophenol (PCP) max. 0.5 ppm ( ) total pesticides max. 1 ppm ( ) (DDT, HCH, lindane, aldrin, dieldrin, 2,4-ditoxaphene and 2, 4, 5-tritoxaphene) ( ) ensure that fabric has been scoured or washed (80°C)	1. generally relevant only for natural fibre products which have not been subjected to wet pretreatment (e.g. scouring, washing) 2. from experience, leather contains higher proportions of PCP/pesticides, recommended limit: 5 ppm	a) extraction in accordance with eco-tex standard 200 b) subsequently GC, HPLC, DC
3. Azo dyes which can split off amines on MAK lists III A 1 and A 2	benzidene-based dyes 3,3-dimethylbenzidene 3,3-dimethoxybenzidene 3,3-dichlorobenzidene o-toluidine ( ) not used ( ) used ( ) check, as not known		b) DC, HPLC
4. Skin neutrality (pH value)	( ) pH 4.5 – 7.5		a) DIN 54 276 DIN 54 275

* In each case, the specification indicates various limits/content substances which are to be marked with a cross by the supplier.

Tab. 4: DTB eco-info (1) (according to BASF).

Textile Design Group, Milan. The consortium is a consultancy and service organisation which offers its services for all textile stages from the fibre to the market for developing "ecologically optimised" textiles. The label comes in three different categories, the awarding criteria for which are listed in Tab. 7 and Tab. 8. 0.5% of turnover must be earned from ecological products in order to be able to use this registered trade-mark. The RAL seal has been awarded for this label in order to make eco-tex an ecolabel.

IV. By producer request in accordance with an idea of July 1992, the ELTAC EPG European Product Guarantee is to be awarded via ELTAC by way of international criteria catalogues and test procedures, taking special account of ecological and physiological clothing aspects.

The limit values resemble those of M.S.T. (Tab. 9 + 10). Quality requirements such as technical data (e.g. tear strength) are additionally required. In addition, four of the following seven production stages

- spinning,
- weaving, knitting,
- pretreatment,
- dyeing, printing,
- finishing,
- cutting,
- sewing

should be carried out in Europe. EPG can be traced back to activities on the part of the Steilmann company in Bochum (Germany).

V. Die Gemeinschaft umweltfreundlicher Teppichboden, GuT (The Association of Environmentally-friendly Carpeting) was founded in 1990 by well-known firms in the European carpet industry, and currently has approx. 80 members. GuT awards the "Teppichboden schadstoffgeprüft" seal ("Harmful substance tested carpeting" seal) if a carpet fulfils the criteria listed in Tab. 11 which are tested by institutes in the Federal Republic (TFI), Belgium, Denmark, and, in the future, Austria. GuT members undertake moreover to maintain their production machinery to a high technical level so as to pollute the environment as little as possible. The GuT seal is recognised in the sector and in the market, and is accepted by the consumer.

VI. As with the carpet sector, household textile producers also want to set up a Gemeinschaft umweltfreundlicher Wohntextilien GuW (Association of Environmentally-friendly Household Textiles), and award a seal.

VII. At the suggestion of Gesamttextil, the "Association for Consumers and Environmentally-friendly Textiles" was set up in July 1992 as a sponsor company for awarding the M.U.T and M.S.T. manufacturers' labels. All producers of textile products in the EU and EFTA, together with textile and clothing industry associations, can become full members of the association. Merchant houses, trade representatives, textile and clothing industry suppliers, associations from these fields and testing institutes can become support members. The association currently has approx. 60 members. First of all, manufacturers' labels are awarded only for products sold in the Federal Republic; full European introduction has been postponed. The guaranty seals can be applied for irrespective of association membership; for members however the associated cost is small. According to association rules, guaranty seals can also be awarded for foreign products irrespective of production location as long as they fulfil the criteria laid down. The label erects no trade barriers in this respect.

The M.S.T. differentiates between six product groups:

1. Clothing textiles:
   - outerwear, lining fabrics, industrial protective clothing
   - shirts, blouses, sportswear
   - nightwear, underwear, stockings
   - baby clothing and small children's wear.
2. Home and household textiles:
   - table linen, decor fabrics, curtains, furnishing fabrics
   - bed linen, blankets, bath textiles.

The criteria are grouped in Tabs. 12–14.

Features	**Supplier details specification***	**Production note**	**Test specification** **a) obligatory** **b) recommended**
5. Heavy metals	( ) Cr (total) ≤ 20 ( ) Cr (VI) = undetectable ( ) Cu ≤ 100 ppm ( ) Ni ≤ 10 ppm ( ) Co ≤ 10 ppm ( ) Other...		a) extraction with perspiration solution in accordance with DIN 54 020 (test solution 2) b) AAS
6. Nickel content in accessory components, extractable proportion	( ) Ni ≤ 10 ppm		a) extraction with perspiration solution in accordance with DIN 54 020 (test solution 2) b) AAS

Odour testing	textiles may not reveal an odour foreign to the product		

Tab. 6: OTTO, Hamburg, ecotextile material requirements (according to BASF).

As a manufacturers' label, M.U.T. guarantees very far-reaching requirements as regards environmentally compatible production processes in addition to the product-related criteria of M.S.T., e.g. in effluent purification, clean air maintenance and waste disposal. In addition, specific substances must not be employed in production (Tabs. 15–18). This manufacturers' label is to be provisionally awarded for preliminary stage products, but not for finished products. The seal was introduced to the market after overcoming objections by the federal environment authority and consumer organisations, that "only" the legal regulations in the Federal Republic are stipulated here. New criteria (e.g. specific loadings in regard to effluent, exhaust air etc. relative to the finished material) are also under consideration.

VIII. The foundation of the International Association for Research and Testing in the field of textile technology (Eco-Tex) with various standards was announced at Interstoff 1993 in Frankfurt by the Vienna and Hohenstein textile research institutes. The association is now active in over 10 countries. With the label "Tested for harmful substances in accordance with eco-tex standard 100", the eco-tex standard includes general conditions for labelling entitlement. The eco-tex standard differentiates between 12 different product groups:

- general award conditions – 100
- textile fabrics (woven and knitted fabrics and nonwovens) for clothing, excluding baby clothing – 101
- clothing accessories, excluding baby clothing (e.g. zip fasteners, buttons, fasteners, shoulder pads, nontextile applications) – 102
- clothing, excluding baby clothing – 103
- textile fabrics (woven and knitted fabrics and nonwovens) for baby clothing – 104

- baby clothing accessories (e.g. zip fasteners, buttons, fasteners, shoulder pads, non-textile applications) – 105
- baby clothing – 106
- textile floor coverings – 107
- textile wall coverings – 108
- decor fabrics and curtains – 109
- furnishing fabrics – 110
- blankets and pillows – 111
- bed linen – 112
- test procedures – 200.

Tab. 19 shows the human ecological limit values suggested for the individual product groups. The eco-tex standard is to be flexible; accordingly the limits are therefore to be adapted to the latest information. It is understood to be a scientifically based list of criteria for the human ecological properties of textile products with their associated testing and control system, which represents the basis of label entitlement.

IX. TOX-PROOF: German Control International, a subsidiary of the TÜV Rheinland, has designed a criteria catalogue with three different requirement profiles which are listed in Tabs. 20–22. The tests are implemented by the Textil-Express-Service of German Control International, which guarantees a laboratory and analysis service with certificate within 5 working days at a fixed price per test sample and test type.

The requirements laid down for awarding the labels discussed above

- eco-tex,
- EPG,
- M.S.T.,
- TOX-PROOF

are similar in many cases; there are differences however. The criteria for the various labels plus requirements by Eco-Info for better comparability are compared in Tabs. 23–25.

X. Der Arbeitskreis Naturtextilien e.V. (AKN) (The Natural Textiles Association) has been in existence since 1991, and includes approx. 20 home and foreign textile firms. The purpose of the association is

- to promote the production and use of natural fibres,
- to dispense with chemical finishing processes,
- to dye only with vegetable or harmless synthetic dyestuffs,
- to allow independent institutes to conduct regular tests on any residues (pesticides, herbicides, formaldehyde, heavy metals).

XI. EU environment trade-marks and eco-audit are not exclusively relevant to textiles. They can however be used for textile products and processes too.

1. EU ecolabels: on 23.3.1992, the EU Commission laid down Regulation No. 880/92 of the Council in which a system valid within the EU for awarding an ecolabel was established. The aim of the Commission is to promote the development, production, sale and use of products which have a negligible effect on the environment throughout their service life.

The ecolabel can be awarded for products which comply with the above-mentioned aims and the health, safety and environmental requirements of the Union. The conditions for awarding the ecolabel are deter-

Parameter	eco-tex **(Traditional)** **February 1993 status**	eco-tex **(Human)** **February 1993 status**	eco-tex **(Natural)** **February 1993 status**

award conditions	not known

Tab. 10: EPG award criteria (2) (according to BASF).

Ecolabelling of textiles

mined by product group. The EU Commission has already formulated an initial list of product groups, for which however award criteria still have to be drawn up. Denmark is currently empowered to clarify whether an EU label is appropriate for T shirts and bed linen.

The award system is based on voluntary participation. Currently existent national ecolabels can be retained. In the longer term however, the EU will be introducing a standard ecolabel. After being awarded, the ecolabel may be used in advertising the specific product. Producers and importers in the EU can submit applications for the award of an ecolabel only to an authorised office. This is named by the member state in which the product is marketed for the first time.

2. EU Eco-Audit: EU Ministers for the Environment have formally passed the EU Eco-Audit guidelines in Luxembourg. In accordance with this regulation, No. 1836/93 of the EU Council/Commission of 29.6.1993, industrial firms in the EU have the possibility of participating in periodic voluntary tests designed to record the constant improvement of industrial environmental protection. The EU has created an association system for environmental management and environmental plant testing, and will select and accredit testers in the member states.

Test for freedom from harmful substances
- Pentachlorophenol
- Formaldehyde
- Pesticides
- Butadiene
- Vinyl chloride

Excluded from use
- Asbestos
- Highly volatile chlorofluorocarbons
- Dye carriers
- Azo dyestuffs, the amine components of which are grouped in MAK III A 1

Emission, limit for individual components [mg/m^3]

• Toluene	0.2
• Styrene	0.01
• Vinylcyclohexane	0.002
• 4-Phenylcyclohexen	0.03

Emission, limit for individual Total parameters [mg/m^3]

• Aromatic hydrocarbons	0.5
• Volatile organic substances	1

Odour test*: < 4

*score1 – 5	1 odourless
	2 light odour
	3 tolerable
	4 disturbing
	5 intolerable

Tab. 11: GuT award conditions (according to BASF).

Parameter	Testing method	Requirement
No use of dyes which can split off amines on MAK lists III A 1 and III A 2. No use of other dyes which are classed as cancer-inducing	Extraction, reductive splitting off, identification of cleavage products by DC or spectroscopic methods	Undetectable
No use of dyes which give rise to the "leggings" allergy with acetate (C.I. Disperse Blue 106 and 124)	Extraction, identification with DC or spectroscopic methods	Undetectable
No use of organic chlorine carriers in the dyeing process	Extraction/GC	Undetectable
No flame retardant finishing		Excludes award
No biocide finishing		Excludes award
Attendant fabric staining in accordance with	DIN 54 020	Attendant fabric staining is no criterion for harmful substance availability. From the ecotoxicological standpoint, textile working group results are awaited by the Federal Health Authority.
Attendant fabric staining in accordance with	DIN 54 006

Ecolabels

Ecolabels An ecolabel with well-founded, verifiable criteria provides the industry with the motivation for ecologically optimising textile products, security for the trade and confidence for the consumer in the textile product purchased. In this way, it fulfils the producer's obligations as to information on the one hand, and the buyer's safety requirements on the other. The textile chain should really be in a position to solve the problem of textile ecology itself, yet the German parliament had already set up a commission of enquiry in April 1992 into "Protection of mankind and the environment", involving itself in the "Textiles and clothing" study field for weighing the commercial benefit from clothing against the risks to mankind and environmental pollution, with the ultimate aim of "ecologically transforming" the industrial firm. Furthermore, in 1992, the Federal Health Authority set up a "textile" study group to determine the type and quantity of auxiliary textile products and dyestuffs remaining on textiles, and to evaluate their relevance to health. The most important instrument of a credible product seal is the basic criteria catalogue and the exact verifiability of all quoted data, for nothing would damage the standing of the textile sector more than disillusioned confidence in tested products as a result of the consumer's discovery of the contrary. An ecolabel based on this level can have a positive effect on ecology-oriented industrial standards as regards the product and its manufacture if it achieves a high requirement level, e.g. with the quality and reputation of the IWS virgin wool label. In this way, it largely ensures harmonisation of the ecolabel requirement profiles in the industrial sectors concerned. The specification of high but justifiable test criteria ensures confidence in the label, and, despite the cost, ultimately offers unequivocal market advantages for participating firms. On 3.6.1992, the "Consumer and Environment-Friendly Textile Association e. V." was founded. Since January 1993, it has awarded the "Harmful substance tested textiles label" and the "Environmentally friendly textiles label". One of this association's technical committees has laid down the product and production-related award conditions in accordance with joint suggestions on the part of the partners involved, and has formulated well-founded criteria catalogues for both labels, which have been available since January 1993 for the following collections. On acceptance of the design, the labels will comprise an uncomplicated logo with a "T" and a test number which can be followed up if need be. Notwithstanding, there are other ecolabels with high requirements too. The first to mention is the EU environmental label designed to inform the consumer before his or her decision to buy that the greatest possible level of environmental compatibility has been observed in every case at all stations of the life cycle of the product distinguished in this way (Fig. 1). A jury will decide whether to award the environmental label or not. This label does not however make a statement about the human ecological nature of the product, but it is well suited to enlighten the end-user on textiles.

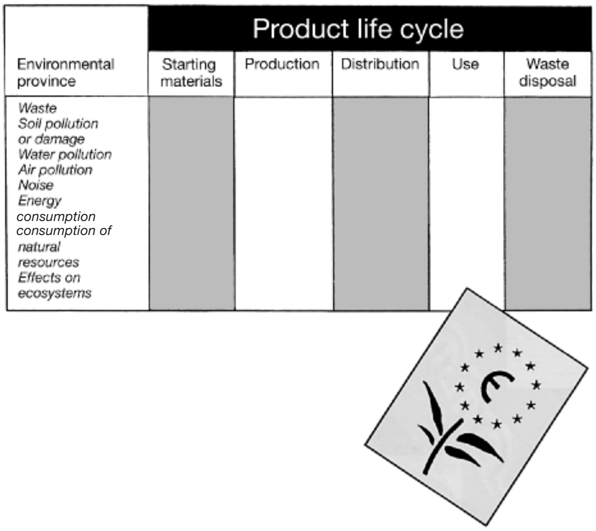

Fig. 1: Sketch of the EU eco-oriented quality label which covers the entire life cycle of a product.

The "Textiles tested for harmful substances in accordance with → Eco-Tex Standard 100 label of the International Association for Research and Testing in the field of textile ecology (supported by the Hohenstein Research Institute and 15 other European institutions) can already look back on international experience and a lengthy market presence (Fig. 2). Depending on end-

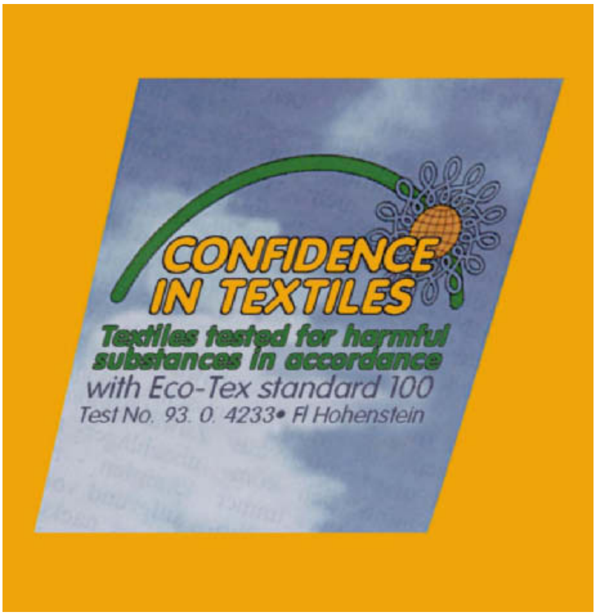

Fig. 2: Eco-Tex label of the International Association for Research and Testing in the textile technology field as an institutional initiative in cooperation with M.S.T. (Translation)

use, there are standards specific to product groups, and in eco-tex standard 200, a comprehensive, well-founded compendium of suitable test processes for granting entitlement to the eco-tex label, which others, be it by way of guidance or as a test institution to be brought in, make use of. This therefore involves an institute label which is available to anyone for his collection in availing himself of the test institution and complying with the product-related specifications for product labelling (also with a test number). Consequently, despite the same background, there is a definite difference to be seen in label entitlement by a national brand label sponsors' association.

A third initiative was also presented to technical circles on the occasion of the autumn Interstoff 1992 as a company-oriented industrial consortium eco-quality label, also based on a well-founded criteria catalogue. Under the "eco-tex" brand label (Fig. 3), this industrial consortium can, to its advantage, quickly react, stand by as a partner in an advisory capacity in fibre procurement, recipe and process creation, can arrange tests, and more quickly achieve success in the market from the advertising standpoint, particularly since the parties interested in this system, based on a legal guarantee of test results produced, exist on a wider basis.

Fig. 3: "eco-tex" label of an international consortium as a company initiative.

The "Eco-Info" of the "Textile Clothing Dialogue" is in fact also based on the test criteria of the ecolabels quoted, though no additional competitive label is to be created here. The initiators rather have in mind the rapid realisation within the member firms of the basic ecological requirements relative to the textile product in order to arrive quickly at clothing which is exemplary from the human ecological standpoint, and guarantee it accordingly. The Eco-Info therefore becomes a component of supply agreements between producer and customer. Target orientation is ultimately the same in this respect however (according to Hemmpel).

Ecological problems in textile dyeing, printing and finishing Textile problems form part of the overriding aspects of environmental protection, and are consequently stamped by the laws of growth, intensification and problem postponement. Evidence for this statement can be furnished by world textile consumption. If e.g. 30% of the cotton were to be replaced by synthetic fibres, approx. 200 g of bread could be produced per person per day by the increased foodstuff production made possible by that. Quantitative growth must of course be taken into account in the case of world textile consumption. The problems associated with this are revealed by the life cycle of a textile product. The associated field of requirements on "production, utilisation and disposal" life cycles must always be regarded as a complete package (Fig. 1).

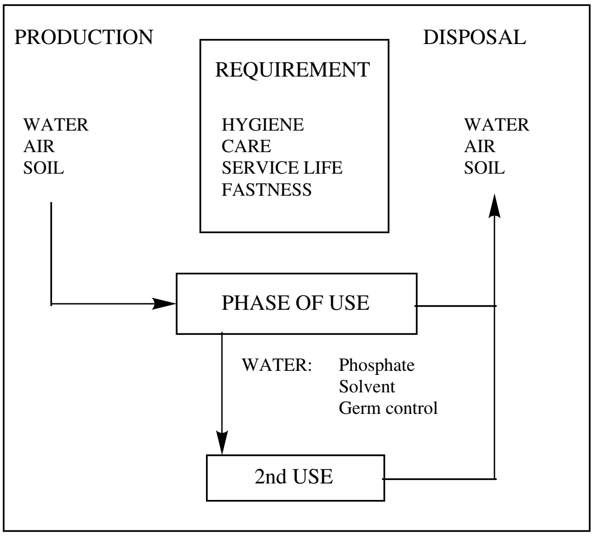

Fig. 1: Problem water, soil and air cycle in textile production.

A certain amount has already been achieved in the soil/water/air fields, but despite all these measures, consumer consciousness ultimately plays the decisive role, yet how is the consumer to decide whether he or she should buy wool, cotton or synthetic trousers (presuming identical shape and colour)? An integral way of looking at this is fundamentally necessary in the future. Environmental problems are of course evaluated differently depending on one's view of things. Objective discussion from the entrepreneur's standpoint appears to be a good prerequisite for influencing the bureaucratic handling of environmental regulations by the authorities. Difficulties with public sewage treatment plants understandably lead to requirements by textile finishers on their suppliers for dyestuffs and auxiliary products and also to doubts by entrepreneurs about their location in the Central European environment. The dyestuff and auxiliary product manufacturers rightly refer in this connection to the high cost of their environmental research, and make their advice available. The problem of the existence of textile finishing agents has received further publicity from an accident which happened at Sandoz in Basel on 1.11.1986, giving rise to significant warehousing changes after the nearby Rhine was contaminated by large quantities of water used for fighting a fire in a large dyestuff store.

The material classification situation as regards storage risks is not very clear at the national and interna-

Category	Characteristics	Danger symbol CEA/BVD	Examples
1.	Explosion hazardous/especially easily combustible substances	Ex	Picramic acid Sodium azide
2.	Spontaneously reacting, self-igniting substances	Fa	Acrylate Catalysts
3.	Combustible with water or developing combustible gases	Fh	Alkali metals Metal hydrides
4.	Developing toxic gases with water	Gh	Acid chlorides Fuming sulphuric acid
5.	Combustion-promoting, highly oxidating substances and peroxides	Ox	Nitrate of ammonium Hydrogen peroxide
6.	Combustible liquid substances with a flash point below 55°C	Fe	Acetone Toluene
7.	Combustible solids/combustion number 4+5	Fe	Activated charcoal Gamma acid
8.	Toxic, malodorous, water-endangering substances	Tx Yl Zl	Formaldehyde Thiourea Chloroform
9.	High pressure gases or liquefied gases in mobile pressure containers Spray cans, aerosol packs	Gp	Chlorine Ammonia Crop protection spray
10.	Not very critical solids/combustion number 1-3 Not very critical liquid substances with a flash point above 55°C	Fe Xn Nn	Maize starch Magnesium hydroxide Benzaldehyde Polyethylene glycol

Fig. 2: Storage categories.

tional levels (Fig. 2). The trend is towards detailed, danger-specific classification. In 1987, Sandoz was faced with the problem of undertaking a more sophisticated classification of its materials into storage categories. 10 categories were defined, and all materials handled by Sandoz (approx. 8000) classified accordingly. A specific order of danger in the event of fire can be deduced from the class sequence, class 1 being rated as the most dangerous, class 10 the least dangerous, though not rated as safe. The new danger symbols suggested by the European Insurance Board are included in Fig. 2. Danger-specific requirements for storage premises are laid down with this storage classification. The prerequisite for material classification in accordance with an improved system is however the availability of relevant analytical data. Unequivocal criteria are being produced for defining the danger to the atmosphere for example. The large majority of dyestuffs can be classed in category 10. There are however those dyestuffs in categories 6, 7 and 8, which, depending on whether they contain solvents (6), are more flammable (powder form) (7) or may have a toxic effect on human beings and the environment (8), i.e. nitrogen, sulphur, phosphorous or halogens are present.

Commercial forms of dyestuffs are not chemically homogeneous products. In order always to guarantee the same colour intensity, they are mixed during production with “standardising agents” (adjusting agents) such as different types of salt, complex formers, buffer substances, dedusting agents (mineral oil, phthalic ester), dispersing agents, emulsifiers and other substances which subsequently contaminate the effluent. For the purpose of better applicability, dyestuffs are marketed in different commercial forms: powder, granulate, paste and liquid dyes; the latter are relatively new, and have specific advantages. Initially, sulphur, vat and disperse dyes were offered in liquid form, followed by cationic and direct dyes, and, recently, reactive and acid dyes too. Liquid dyestuffs have the following advantages:

- they are dust-free;
- they need neither pasting nor dissolving, boiling nor cooling;
- they can easily be automatically metered.

Synthetic dyestuffs are dyed at temperatures between room temperature and 130°C; thermosol processing temperatures up to 200°C are also usual with polyester fibres. Selected auxiliary products are used for dyeing in order to achieve optimum results in terms of dyeing quality and the quality of the textile material produced in this way. Dyeing conditions depend on fibre material and class of dyestuff. Conversely, both dyestuffs and auxiliary products have been adapted to the constant development of textile fibres, dyeing machinery and processes and to ecological and economic requirements, or have been newly developed to that end. Current dyestuffs achieve bath exhaustion levels as high as 99%. On economic grounds, attempts are being made to improve yields in so far as levelness permits, as every kilogram of unused dyestuff which runs into the effluent has been paid for in vain.

Dyes which reach the sewage treatment plants are not usually decomposed during their dwell-time in aerobic biological sewage plants, but are largely adsorbed on to the sewage sludge, and consequently eliminated from the effluent. This also applies to many textile auxiliary products. One exception is reactive dyes which are only 80–85% fixed on the fibre at the maximum, and are not adsorbed on to the biological sludge to the same extent as other dyestuff classes either. Of the heavy metals which should be regarded as critical from the ecological standpoint, and the introduction of which into surface water courses and public sewage plants is strictly limited, only copper, chromium, nickel and cobalt occur in any quantity worth mentioning in premetallised dyestuff form. Here, the metal is coordinatively bonded as a central atom, and is adsorbed on the fibre with the entire molecule, depending on the degree of exhaustion in each case. Tetrachlorozincate is contained as a counter-ion in some cationic dyestuffs. Effluent contamination by heavy metals also occurs in textile finishing during the following processes: for wool dyeing, dyes which have to be after-treated with potassium dichromate in order to form a complex which is difficult to dissolve can be used for achieving particularly high fastness levels. The appearance of chromate and chromium(III) in the effluent is therefore inescapable, but is very limited legally.

Following the undisputed successes in the water protection field, interest is becoming increasingly concentrated on sanitary measures in regard to residual pollution flows from sewage plants, which are quantitatively small but difficult to combat. This largely involves organic chemical compounds from households, trade and industry which are difficult to break down. The textile industry, in which numerous chemicals are used in wet processing, is no exception here, often leaving a number of these "refractory" substances detectable in its effluent even after biological purification. DOC (dissolved organic carbon as an overall parameter for organic compounds as a whole) is also almost always increased; specific analysis, e.g. gas chromatography, may additionally indicate in detail the chemicals which are involved, yet the decisive question as to the effect on the environment of such small concentrations of residual impurities can hardly be answered: ecotoxicology is in fact under lively discussion internationally, but will be able to put forward better founded results only after intensive basic research. In the meantime, residual organic pollution must on the whole be regarded as a serious source of danger, and reduced if possible within the meaning of the legal definitions. To be handled with particular caution in this respect are substances, as listed in the table, which time and again, on the basis of long-standing observation and the interchange of experience with industrial specialists, continually give rise to effluent problems.

The degree of danger of processing materials, i.e. "classification" in terms of toxicity, is weighted with the main emphasis on acute oral toxicity and on the basis of the primary caustic or irritant effects. In each case therefore, testing is carried out first of all by means of basic tests. The results are communicated on safety data sheets. Acute oral toxicity is quantified by measuring LD_{50} values. According to German chemicals legislation, the LD_{50} (lethal dose) is the quantity of the product in mg/kg of body weight at which (with a single oral feed) 50% of the experimental animals die within 14 days. The following classifications are applied on the basis of the test results:

– very toxic	<25 mg/kg
– toxic	25 – 200 mg/kg
– negligibly toxic	200 – 2000 mg/kg
– unclassified	>2000 mg/kg

According to an ETAD study, the LD_{50} values of approx. 4500 commercial dyestuffs are

82%	>5000 mg/kg
10%	2000 – 5000 mg/kg
7%	250 – 2000 mg/kg
1%	<250 mg/kg
0%	<100 mg/kg

According to this, less than 10% of dyestuffs are in the health-endangering or toxic product group, the harmful effect in some cases possibly being due not to the actual dyestuff but to the auxiliary substances. To an increasing extent however, the potential long-term effects play a role in evaluating danger. In the sense of lasting environmental compatibility, this involves the so-called

Ecological problems in textile dyeing, printing and finishing

Substance group	Danger to water courses or sewage treatment plant	Necessary measures
Detergents (washing powders, wetting agents, auxiliary dyeing products etc)	Biologically difficult to break down products still on the market with consequently high residual ARA let-down pollution, particularly as dissolved organic carbon (DOC)	Change over to easily degradable products. Declaration of composition and biological degradation required
Organic complex formers	Difficult to break down types (particularly EDTA) can bring toxic heavy metals into solution (danger to water courses)	Water hardness agents (Ca, Mg) should be precipitated by inorganic softening agents, dissolved by degradable organic complex formers (e.g. NTA) or dumped.
Dyestuffs	Difficult to break down. Legal requirement (no receiving water discolouration) can often fail to be complied with. Ecotoxicological effects cannot be excluded in every case	Where necessary, dyestuffs should be precipitated from concentrated residual liquors in the works
Organic chlorine compounds (chlorinated solvents, rot resistant agents, specific carriers)	Environmentally dangerous substances which are generally difficult to break down. Water soluble compounds endanger water courses, while those which are not easily water soluble endanger the sewage sludge	Change over to products with no organically bonded halogen. Example: chlorine-free phenol derivatives as carriers are the lesser evil in comparison with chlorobenzenes! Pentachlorophenol (PCP) should be avoided as a rot-proofing agent
Sulphites, hydrosulphite, thiosulphate (stripping dyes, generally as reducing agents, e.g. “antichlor”)	Disruption of the biological stages of the sewage treatment plant by oxygen supply. Possible reduction to sulphide (toxic effect on microorganisms)	Limitation of use to the absolutely necessary. In use as “antichlor”, safety reserves are to be avoided. Special metering equipment has proved good in practice
Heavy metals (Cu, Cr, Zn, Cd and others)	Heavy metal compounds are mainly concentrated in the sewage sludge, endangering the soil in agricultural usage.	Use auxiliary products which are most free of heavy metals

Tab.: Water course endangering content substances of textile effluent.

“CMT effects”, i.e. carcinogenic = cancer-inducing, mutagenic = genotype-changing, and teratogenic = deformity-inducing effects.

The MAK commission has decided to insert a paragraph on “azo dyestuffs” in the section on cancer-inducing processing materials in the annually published MAK list. In this respect, the impression has been given by the media that all azo dyes are cancer-suspect, representing a health risk to processors and consumers alike. This kind of all-embracing statement is untrue however, because there are many substances in this class which have revealed no evidence of cancer-inducing potential in relevant animal experiments. Only a few azo dyestuffs used in practice, like benzidine dyes for example, have up to now provided any evidence of carcinogenicity in animal experiments. So-called azo splitting plays a part in evaluating the toxicity of azo dyes. Azo splitting means that azo dyes are reductively split under quite specific conditions, and aromatic amines (R-NH_2 and R’–NH_2) can form in consequence.

This process can be triggered both by reducing agents and in the organism, as long as the compounds are "bioavailable", and are evaluated under the effect of enzyme systems. With each substance of this class therefore a check should be made as to whether azo splitting can actually occur, and whether the potential occurrence of aromatic amines can be a health risk. In total, azo dyestuffs are a substance group embracing several thousand products. Health risks to the user can be suspected in only the small number of those azo dyes which contain carcinogenic aromatic amine components. Dyestuffs based on human carcinogenic amines, like benzidine dyes for example, have not been produced or marketed in many countries for a long time.

In the textile dyestuff field however, there are still amine-based dyes on the market which were carcinogenic in animal experiments. Further processors of the producing firms amalgamated with the ETAD have been voluntarily informed since the beginning of 1987 by means of customer circulars, safety datasheets and appropriate Xn and R 40 labelling (= possible irreversible damage) of the possibility of reductive splitting and the consequently conceivable potential dangers in the handling of these products. Use of these dyes for textile dyeing also appears quite safe for the future, as long as it can be ensured by appropriate work hygiene measures that exposure can be kept low enough virtually to exclude health risks. It can be said in terms of potential risk to the end user that the American Consumer Protection Safety Commission (CPSC) has carried out a series of trials on the extent to which this kind of dyestuff can be absorbed through the skin. No measurable skin penetration has been established in these trials, i.e. there is no danger to the end user from these types of textile dyes as far as is currently known, and textiles dyed with these azo dyestuffs can be worn quite safely. A series of screening tests, which are carried out with bacteria or on isolated cells for example, is available for testing for mutagenicity. Among the most well known is the Ames test, the value of which in terms of evidence is however disputed. Its importance lies particularly in the fact that further tests should be conducted in the event of a positive Ames test. Mutagenic (changing genetic make-up) and teratogenic (causing malformation in unborn children) effects due to the practical handling of textile dyestuffs and auxiliary products have not been noted to date. In addition to the CMT effects, potential sensitising effects also merit particular attention. Allergies cause irksome skin reactions (e.g. itching or weeping eczema or pustule formation) and also, in rare cases, dangerous respiratory disorders, which, beginning with sneezing and running eyes, can extend to asthmatic attacks. By far the largest number of allergies are triggered by natural products like plants or plant particles (hay fever), flour or fish and other food proteins. Of the products used in the textile industry, auxiliary products which split off formaldehyde, and some reactive dyestuffs, have triggered allergies during processing in a few cases.

Environmental protection regulations require the responsible use and management of solvents in textile cleaning with the aim of preventing solvent loss. Waste resulting from blowing and filtering is registered as special refuse, because it contains residual matter. This type of waste is therefore removed by special firms, and environmentally responsibly processed. The American Environmental Protection Authority (EPA) has developed a special refuse model which can be used in graphic combination on cartridge and filter powder residues. Source reduction and prevention have priority, followed by re-utilisation, combustion (heating value) and dumping.

The variety of environmental protection problems faced by the textile sector is evident. All environmental protection regulations related to material have their origin in good analysis. This complicated field of activity is called "environmental analysis". It is understandable that, with this variety of materials and the constantly changing concentrations and mixtures of substances in effluent, complete logging and control of all substances must remain impossible. Environmental analysis presupposes a great deal of well-founded knowledge, and requires a good deal of understanding of the interrelationships. In addition to well-founded textile chemical knowledge of the substances employed in textile finishing, the analyst has to be familiar with the typical chemical functions of all product groups such as textile auxiliary products and finishing agents for example.

a) Chemically unchanged oils and fats:
- lubricants, flushing oils, sizing agents, auxiliary chemical finishing agents.

b) Surfactants:
- wetting, scouring and fulling agent,
- boiling off, kiering, bleaching and mercerising auxiliary products,
- dyeing and printing auxiliary products,
- levelling and brightening agents and emulsifiers.

c) Polysaccharides:
- sizing agents,
- finishing agents,
- thickeners.

d) Enzymes:
- desizing agents.

e) Synthetic polymers:
- permanent finishing, anti-felt finishing,
- water repellence, oil repellence,
- antistatics, flame retardant finishing.

Without environmental protection analysis,
- the extent of the presence of substance pollution cannot be established,

- no targeted measures can be initiated for preventing environmental pollution,
- the success of such measures cannot be established,
- pollution limits cannot be defined and established,
- no legal requirements can be laid down for eliminating existing pollution and preventing fresh pollution.

Consumer protection, legal liability, quality awareness, and price-oriented and above all cost-conscious purchasing behaviour have encouraged complaints, for the frequency of claims on the part of the consumer has increased. The textile industry sees itself facing a changed situation. It is no longer possible for producers to exclude or limit their responsibility by their own general trading conditions, and consequently liability claims are on the increase, and additional costs for new liability insurance are also in store for textile mills. The end-user expects high-quality characteristics in accordance with the promises made in advertising and product labelling, for quality textiles are not cheap. The textile finisher has to guarantee this property profile, which is based on promises and expectations. To this end is a wealth of national statutory regulations covering garanties in respect of product deficiency and also in the case of damage which a product causes to people or other material goods (standard EU product liability for so-called damage due to defects). A range of important focal points in regard to quality assurance, planning, control and testing stems from the standpoint of this liability on the part of the textile finisher, and therefore of all producers of consumer goods. Safety data sheets are important in considering a situation, as the textile finisher can easily be the cause of environmental damage. Numerous environmental regulations control textile chemical finishing processes in the Federal Republic of Germany. On this point, the European Common Market will encroach on states not yet affected, and will not make textile finishing any easier. This concerns not only the handling of chemicals, but also the danger to effluent, the pollution of exhaust air and the production environment, the disposal of residual liquors, waste and sewage sludge and also the physiological effect of "chemistry" on the consumer by way of textile products. Concepts such as environmental liability legislation and environmental criminal law underline the entire problem.

In the future, textile chemistry, and consequently textile finishing too, can no longer be divorced from environmental requirements. Problems like reducing the quantities used, optimum utilisation of liquor baths, residual liquor disposal, effluent disposal in chemical finishing, after-burning or cleaning stenter exhaust air etc. raise questions which affect the textile finisher more than ever. Legal requirements on water treatment and exhaust air emission are already in existence. Legal measures like environmental liability legislation and environmental criminal law are already in place in many European countries. Few fundamentally new finishing agent or dyestuff discoveries are to be expected in the future, particularly as there is hardly any profit in announcing completely new chemical compounds. There will however be continuous product optimisation and also the creation of new ready-for-use preparations which will enable the textile finisher to optimise application and effects, and to gain quick access to market requirements, creating new requirement profiles for textile products. This however is the textile finisher's great opportunity for innovation.

Future developments are currently aimed for example at micro-encapsulating the widest variety of active substances, at seamless sewing techniques, textile auxiliary products which destroy themselves at the end of the process for ecological reasons, and also, for example, structuring smooth fibres by laser beams, a process which can produce interesting effects. However, future activities not only involve the diverse technical developments. For the future, the "province of the textile finisher" will rather set the dominant tasks, such as quick adaptation to market requirements, reducing energy and water requirements, improving effluent treatment, eliminating exhaust air problems, reducing handling, automating production technology, measures for quality assurance and attention to product liability questions. This includes moreover improving measuring and testing methods, guaranteeing physiologically safe textiles, and all this in collaboration with the upstream and downstream links of the textile production and sales chain (according to Brune, Dierkes, Rosenthal, Wentz, Loss, Widmer, Schefer and Hemmpel).

Ecology (Greek: oikos = dwelling; logos = science). Concept of the science of relationships in the living organism/environment system introduced in 1866 by Ernst Hackel. Ecological equilibrium is based on the natural capacity for self regulation between different links of a long-term relationship (xenobiosis). This equilibrium is affected, disrupted or even broken up by massive environmental pollution. Ecological problems upset nature's equilibrium. This happens to some extent in the textile industry due to textile finishing. All resources are ultimately converted into waste by human activity. Positively expressed, waste is therefore resources in the wrong form, in the wrong place or wrongly distributed, being found, in thermodynamic terms, in a condition of increased entropy, mainly in mixed or diluted forms. Generally speaking, with all energy conversion, i.e. with all civilising activities like industrial production or motoring, entropy is produced in the form of heat emission to the environment, pollution emission into the air, on to the ground or into the water. Due to the constantly increasing quantities required by the earth's increasing population therefore, human/environment relationships are characterized by increasing utilisation

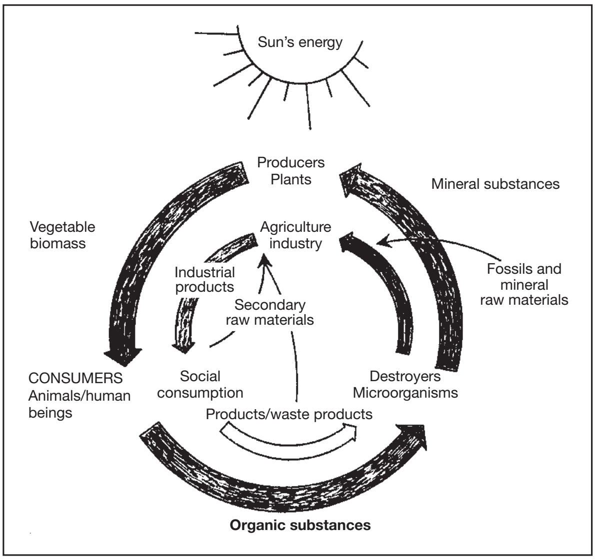

Fig. 1: Metabolism between mankind and nature: outer, natural cycle with the synthesis and break-down of substances of an organic nature, to which many products of the inner, industrial product cycle can be transferred only with great energy expenditure (according to DTNW).

of and changes in the natural environment. The resultant intensified metabolism between mankind and nature (Fig. 1) gives rise on the one hand to decreased dependency on the natural environment, and also a weakened relationship with the environment in the sense of the physiocentric concept of "the age we live in". The build-up and extension of the self-created environment creates fresh dependencies on the other hand due to the extent and the intensification of natural resource utilisation. Awareness of the need for protective measures for maintaining the natural equilibrium of the ecosystem, and therefore for the basis of existence of mankind and nature, is becoming increasingly commonplace. Here, comprehensive technical information for the general public on scientific and technical relationships, ecotoxicological substance properties and basic concepts of risk and danger evaluation are of particular importance. It is never in fact possible to exclude all dangers to the environment, but the aim must be to reduce the risk, i.e. the probability of the occurrence of damage, to a reasonable dimension. The necessary measures do not however concern the natural environment alone. In a technical and industrial society, environmental protection embraces three protective aims, i.e. worker, environment and consumer protection. If one becomes involved in the subject of environmental research, and comes to the conclusion that more has to be done in this field, one quickly concludes that environmental research also represents a sub-system with many complex interrelationships in the overall "earth" system. We must particularly learn how to understand the relationships reproduced in Fig. 2.

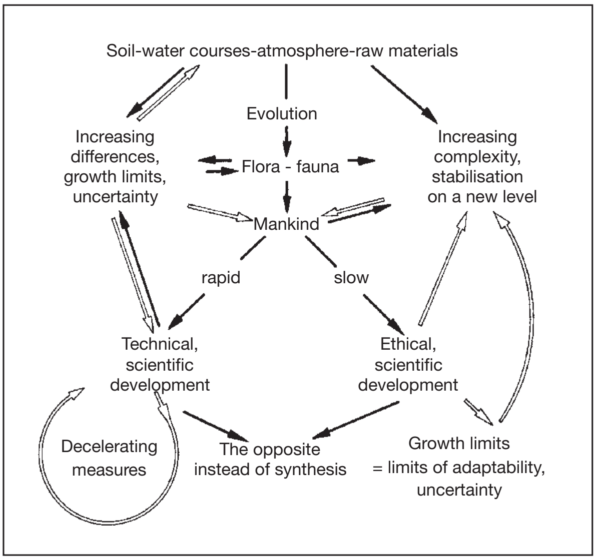

Fig. 2: Effects of time on the earth's ecosystem.

Here, the effects over time of the developments taking place in the "earth's ecosystem" are summarily reproduced, the processes exerting a braking effect being illustrated in broken lines. It is particularly important that the increasingly short-term thinking phase aimed at countering momentary difficulties makes room for longer-term thinking (lastingly environmentally friendly!) in all decision stages. This change is difficult to realise of course in a period of increasingly quickly changing situations, but does nevertheless require constant encouragement. In this sense, basic research in relevant areas, in addition to applied research, is hugely justified, particularly when we try to understand interrelationships by interdisciplinary means, and to work out from them the important targets which should be set (Fig. 3).

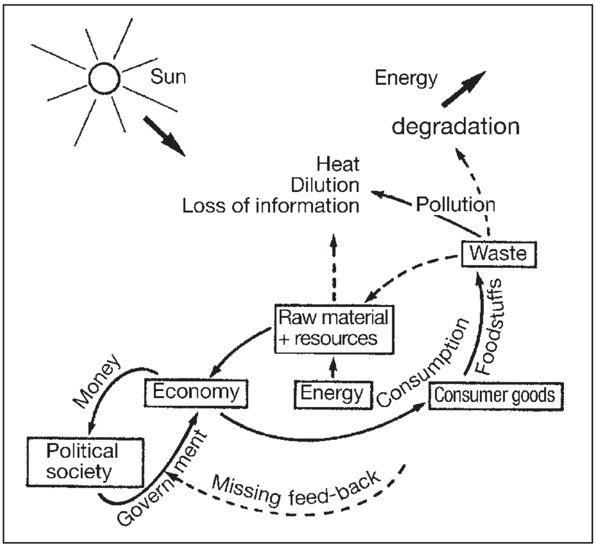

Fig. 3: System earth.

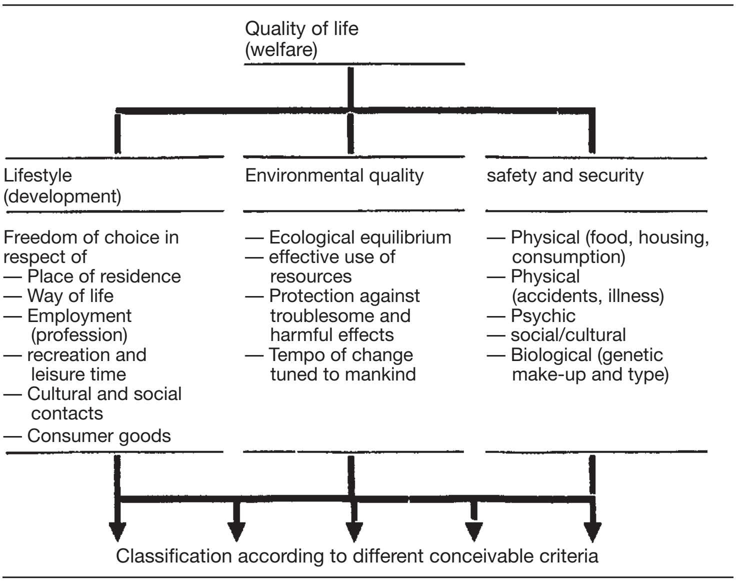

Fig. 4: Ecological target hierarchy.

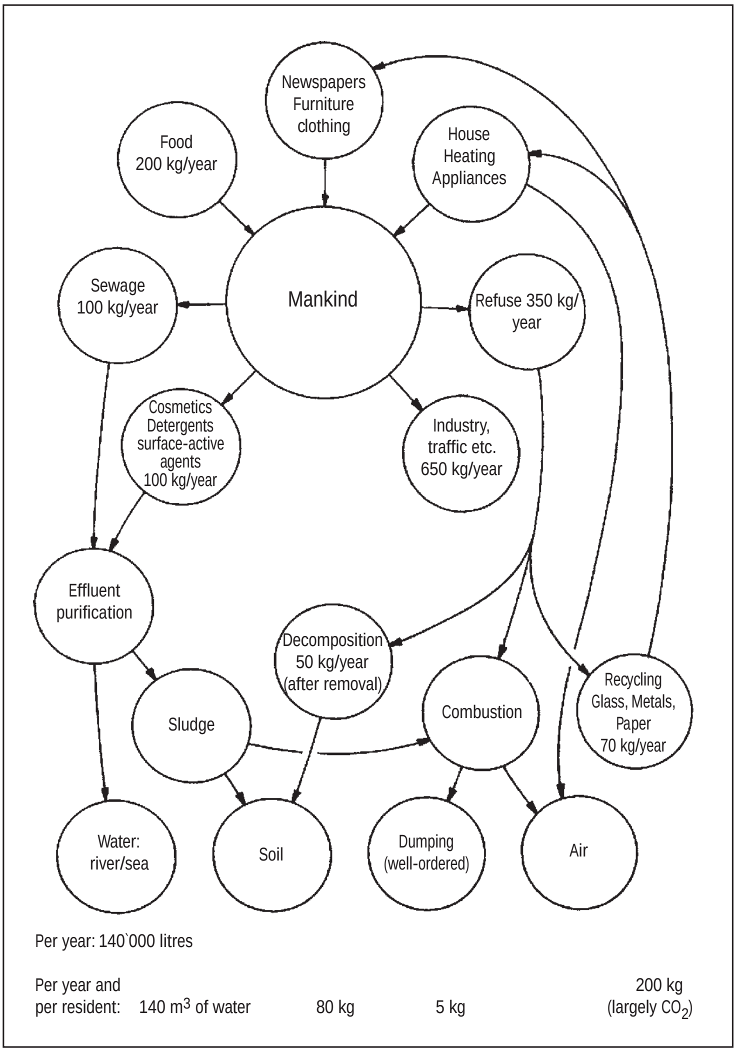

Fig. 5: Mankind's ecological environment (excluding traffic, industry).

Life means: converting energy from the directed state (low entropy) at a high level (thermodynamic) into final states at a low energy level with high entropy (i.e. massive uniform distribution of energy in the cosmos). This process is described as "heat death": all movement comes to a stop, and all heat differences are equalised; no further energy conversion takes place.

Life consists of organic processes obtaining their energy ultimately from the sun, and excessive energy being radiated out into space (Fig. 4). From the sociopolitical standpoint, optimum quality of life is to be aimed for in a form which produces a balanced relationship between "lifestyle" and "security", partial aims of these competing with each other in evenly matched stages. Environmental protection is concerned with maintaining environmental quality, involving keeping water courses and air clean, and also involving noise pollution plus waste disposal and energy recovery together with the product-related concept of environmental protection. If the economic effects of environmental quality assurance are balanced, positive and negative effects for the individual plant and for society are qualitatively opposed to one another with no possibility of quantitative evaluation.

There is a tendency to consider only partial aspects of ecology as a whole (Fig. 5). The problem area of water, soil, air, waste and disposal are focal points. →: Ecobalance; Ecological problems of textile finishing.

Economy trough Padding trough normally supplied with high performance padders. Low liquor content to prevent tailing problems, etc. The fabric immersion path is designed to be as long as possible and the trough liquor volume is reduced by means of a → Divider.

Econ-Tex This Babcock scouring machine looks like a roller vat at first glance (Fig. 1). It has actually taken over the roller vat's vertical fabric guiding system in single and double loop feed, with the possibility of scouring sections with different fabric contents, which can be adapted to different function definitions. The Econ-Tex however eliminates a roller vat disadvantage: the bath in a large liquor

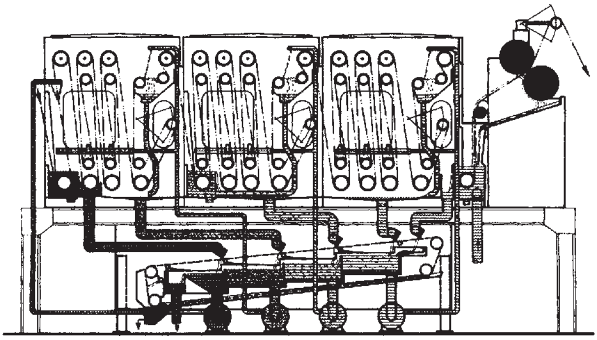

Fig. 1: Babcock Econ-Tex.

trough. The large bath content is only incompletely renewed by the liquor contraflow, because back currents and dead corners and angles are unavoidable, and therefore only part of the bath content takes part in the actual scouring process at any one time. The Econ-Tex has no liquor trough; all sections have a common, steamproof housing. Water seals are located at fabric entry and exit. During the scouring process, the fabric remains in the steam chamber, providing excellent prerequisites for the scouring process.

The total contraflow liquor circulation, which runs through a band-pass filter located near the machine, is superimposed by liquor circulation in the scouring sections. The scouring liquor is therefore brought into contact with the fabric a number of times, and is consequently continuously filtered. In the first section, the fabric is sprayed on both sides with the most heavily contaminated liquor (Fig. 2), the fabric being wetted out and surface impurities removed. In each section, part of the circulated liquor is fed via distributor pipes directly into the fabric/roller nip. Intensive fabric perfusion due to the hydrodynamic nip pressure and additionally to the centrifugal force on each deflecting roller, reinforced by the lack of liquor counter-pressure on the bottom rollers (no bath), produces an excellent scouring effect. The other part of the circulated liquor is used in each standard Econ-Tex section for spraying the fabric with penetrating flat jets shortly before it leaves the section. This spraying effects liquor exchange in the fabric. Kinetic energy improves the scouring effect, particularly when washing out gels or highly viscous substances. Integral intermediate squeeze units can be used for precise liquor separation instead of the spray line. As a rule, an Econ-Tex scouring machine has only one final squeeze unit. The liquor dripping from the fabric is caught on the bottom plate in each section, and fed to the band-pass filter battery, which has a collecting dish and a circulating pump (Tischbein) for each section and for the entry spray unit.

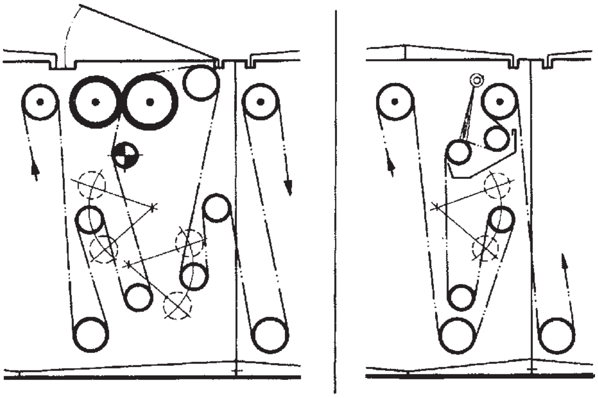

Fig. 2: The internal squeeze unit (left) as an alternative to the spray line (right) in the Babcock Econ-Tex open-width scouring machine.

Econtrol reactive dyeing The Econtrol concept has been developed jointly by Monforts and Zeneca Colours to provide a simple, rapid and economical continuous coloration process with minimum chemical usage (Fig. 1). Econtrol brings together the innovation of the Thermex Hot Flue from Monforts with Procion reactive dye technology from Zeneca.

The innovation utilises the physical laws of water evaporation from cellulose to provide the optimum temperature and moisture conditions within the Thermex Hot Flue drier, ideal for the efficient fixation of the specially selected Procion dyes. The control (Fig. 2) and maintenance of the humidity level in the drying process avoids the use of large quantities of chemicals such as urea and sodium chloride (salt).

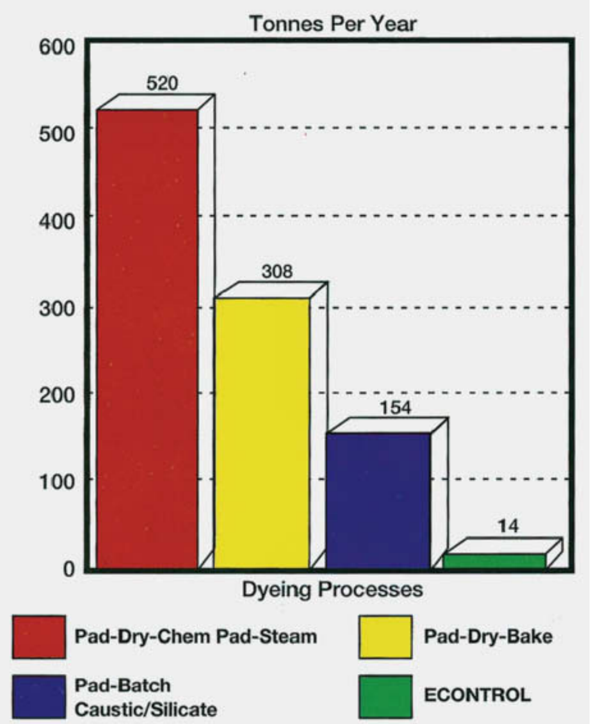

Fig. 1: Chemical consumption per 10 mill. metres.

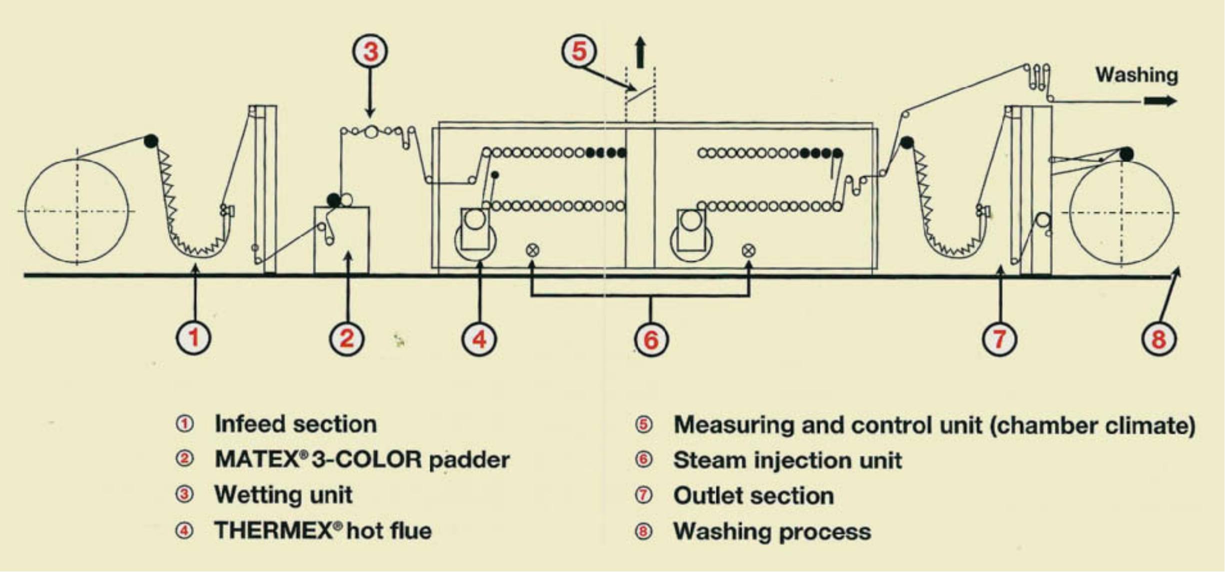

Fig. 2: Econtrol reactive dyeing.

The relative humidity in the hot flue dictates the cloth temperature when wet, with the actual temperature controlling the time spent on the fixation plateau before drying takes place. The Procion reactive dye reacts with the cellulose rapidly under these conditions.

The Thermex Hot Flue (Fig. 2), under normal running conditions, utilises the evaporating moisture from the fabric and injected steam at start-up, to achieve the required degree of humidity by use of moisture meter and control of the exhaust fan. The Monforts innovation involves the special steam injection technique to give the optimum conditions of temperature and humidity.

The corresponding recipe contains only:

x g/l Procion MX dye
2 g/l wetting agent
10 g/l sodium bicarbonate

Ecosystem → Ecology.

Eco-Tex Standard 100 An ecological quality mark should embrace the following ideas:

- a textile product the nature of which is free of harmful substances and is skin-compatible,
- a method of production (fibre cultivation, fabric production, finishing and making-up) which is perfectly ecologically harmless and environmentally compatible,
- easy to dispose of in order to get rid of the used textile product by recycling, decomposition or combustion.

Important, and at the same time achievable, is at least the pragmatic implementation of point 1. The heart of the Eco-Tex Standard is the testing of fabrics and clothing in human ecological terms (Fig.); this relates to the effect of textiles on human beings, i.e. on their immediate environment.

Here, specific substances ecologically harmful to human beings are analysed, and compared with scientifically based limits. Production and disposal ecology are not taken into account in this process. The clothing textile, accessory, household textile and baby clothing sectors have laid down their own standards and test processes. Standardisation of values makes possible a high degree of flexibility in adapting to new information, which would not be possible in DIN standardisation. Tests are conducted in accordance with the current standard in terms of:

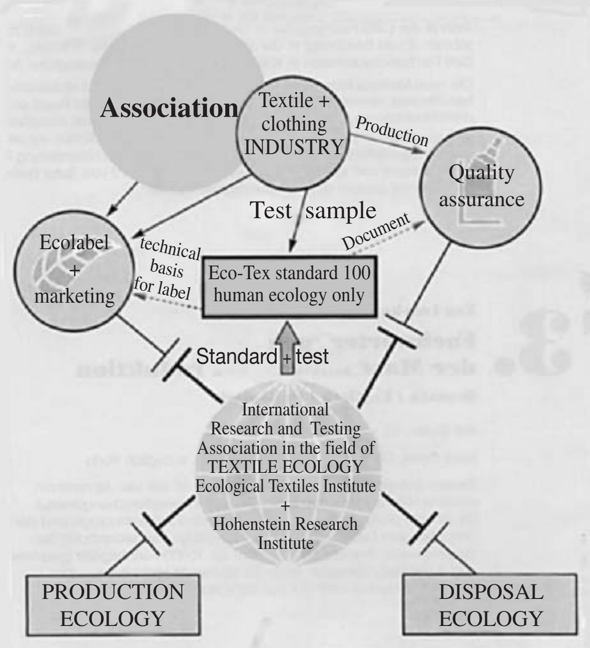

Fig.: Tying the Eco-Tex Standard 100 into the whole environment of ecological endeavours in the textile sector.

- pH (pH 5–7);
- the formaldehyde component which is free and can be split off, particularly with cotton and pigment dyestuffs (here, there is already a DIN labelling obligation at values exceeding 1500 ppm, which is not met in textiles as a rule); baby clothing: 20 ppm, underwear: 75 ppm, other articles of clothing: 300 ppm;
- heavy metals;
- pesticides in natural fibre textiles (e.g. PCB);
- indication as to whether fission products, which can be carcinogenic under certain circumstances, occur in the case of dyestuffs;
- colour fastness (fastness to rubbing, perspiration, water and washing).

Research institutes test the textiles presented singly, using a comprehensive questionnaire for obtaining a maximum of preliminary information. Depending on the number of tests carried out, the current cost lies between 1000 and 3000 DM. In theory, each product colourway must be tested separately; in practice, many articles can be combined according to the dyestuffs employed for example. Guarantees to the effect that the production quantities conform to the tested sample must be given by individual firms. In Eco-Tex Standard 100, the concept of harmful substances is defined as follows: “harmful substances in the sense of this guideline are substances which are contained in a finished textile product in excess of a laid down measure, or occur in excess of a laid down measure in normally expected use, and can in some way have an effect when normally worn by people, and can be a danger to peoples’ health according to the current level of scientific knowledge”. It is improbable that harmful substances can occur “in normal, prescribed use”, but it is incorporated as a precautionary measure in the definition here. The limitation that a substance is a harmful substance only when it has some effect on people in normal, prescribed use excludes substances which are chemically bonded in the textile product in such a way that they cannot migrate either due to inhaled air or to water, perspiration (in the case of clothing), saliva (children’s clothing) and skin contact. Important too is the limitation “normal, prescribed use”. This does not of course include burning and the combustion gases CO and CO_2 which occur, as with any organic material, during the combustion process. The list of substances which can be regarded as harmful is reproduced in product-specific Eco-Tex Standards 100/1 to 100/7. These lay down the limit concentrations above which a substance is harmful in the sense of these standards. These standards also lay down the test procedures as to how these harmful substances and their emission into the atmosphere are determined by aqueous extraction etc. These tests are conducted, targeted towards harmful substances laid down in the standards. The conditions and procedural method for awarding the “Free from harmful substances in accordance with Eco-Tex Standard 100” are laid in Eco-Tex Standard 100. This begins with a precisely laid down request for the sample material to be presented, the submission of a statement of responsibility, and ends with the test. The statement of responsibility contains:

- liability for the statements made,
- responsibility for immediately informing the awarding authority of any change in the technical data,
- agreement that authorised people can at any time inspect product manufacture without notice, and can take away samples of all kinds,
- responsibility for doing everything to prevent misuse of the label,
- responsibility, following expiry or cancellation of labelling entitlement, for ensuring that further product labelling will not take place.

Finally, Eco-Tex Standard 100 also contains the definitions for granting entitlement, entitlement period and cancellation, and type of label. It would be nonsensical and economically unrealistic, if the award of entitlement to label a product with the seal of quality were to be limited to only one random sample which is tested for every only possible harmful substance. One must proceed from the fact that a firm which wishes to distinguish its products with “Free from harmful substances in accordance with Eco-Tex Standard 100” applies no harmful substance to its products deliberately and intentionally. → Ecolabelling.

Ecotoxicology A term which combines → Ecology and → Toxicology. By ecotoxicology is meant the effect of a substance on biological species (plants and animals) or an entire biocoenosis. The simulation of natural conditions is laborious and complicated and can only be carried out for individual model substances. Safety data sheets contain information concerning acute ecotoxicological effects on individual organisms (fish, daphnia, algae, bacteria) which have been determined in short-time tests of approx. 1–96 h duration. These values are useful in comparison with short-term shock loads in waste waters. The chronic effects must be related to a substance concentration determined in a specific catchment area. Such tests are only possible in individual cases and are not, as a rule, contained in safety data sheets. Important parameters for acute ecotoxicity are the so-called EC_0 and LC_0 values which correspond to test concentrations with no toxic effect, resp. the EC_{100} or LC_{100} values which represent a 100% effect on the test organism. For comparison purposes, the EC_{50} or LC_{50} values are the most commonly used for statistical reasons.

Ecru (Fr.). In general, the colour of fibres, yarns, or fabrics that have not been subjected to processes affecting their natural colour, i.e. untreated, unbleached, undyed. Specifically: (1) ecru linen → Unbleached linen;

(2) ecru silk (bast silk) is barely degummed silk (maximum 4% loss) – only grease, wax and resinous substances removed.

ED, → Elastodiene fibres, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

EDANA, abbrev. for: European Disposables and Nonwovens Association, Brussels; → Technical and professional organizations.

EDCO, abbrev. for: Editing Committee. Special committee responsible for the editing of ISO recommendations; → Technical and professional organizations.

Edge abrasion resistance → Flexing abrasion resistance.

Edge/centre evenness testing (printing) → Formatted piece method.

Edge crease offsetting device Attachment for device with tricot padding machine to avoid edge creases with tricot pads.

Edge curling A fabric defect which arises in the processing and finishing of woven and knitted fabrics due to faulty construction. In woven fabrics it is due to excessive tension of warp threads in the selvedges (tight selvedges) or an unsuitable woven construction. Knitgoods, in general, are particularly prone to edge curling. In the case of fabrics composed of synthetic fibres, the problem is prevented by heat setting. On entry to processing machines, edge curling is prevented by appropriate → Expander.

Edge curling of knitgoods Problem encountered in processing knitgoods in the open width state. The cause is mainly due to tightness of the fabric edges and is largely prevented by → Edge gumming.

Edge cutting and sealing machine Tubular knitgoods are cut lengthwise in this machine to produce open-width fabric and both cut edges are glued at the same time. A chemical auxiliary is applied as an adhesive to prevent → Edge curling.

Edge glueing device Device for glueing the edges of open-width knitted fabrics.

Edge guider (→ Expander). Selvedge guiding device →: Edge uncurling device; Edge guiding sensors; Overfeed devices; Selvedge monitor, device to remove the fabric using clip openers or to lift the fabric from stenter pins and fabric take-off mechanism.

Edge guiding sensors Sensors used for fabric edge detection in the entry zone of stenters and drying machines. Function: mechanical (mechanical feeler lever control), electrical (electrical feeler lever control), photoelectric (with light beam and photocell) or pneumatic (with air supply).

Edge gumming A necessary measure to prevent the → Edge curling of knitgoods. The edge adhesive is applied from a special edge glueing device by spraying and drying, or by roller application from the edge glueing units on a stenter.

Edge roll → Edge curling.

Edge stitching (French: piquer = to quilt), lockstitch-type sewing of → Padding and its permanently elastic binding with the outer fabric (by means of an edge stitching machine).

Edge-to-centre levelness Side-to-centre levelness of shade across the width of a textile fabric. An important quality parameter in continuous dyeing which can only be ensured by completely uniform dye uptake across the entire fabric width in pad dyeing.

Edge-to-edge unevenness → Listing.

Edge trimmers With suction device. Used to trim the needled edges of the run of cloth and to simultaneously aspirate the trimmed selvedges on exit from stentering and drying machines. The run of cloth is transferred from the needles on the unneedling wheel with the aid of the supporting roller from the needles on the flange of the chain guide and fed to the cutting apparatus. The unneedling wheel can also be fitted with a second row of needles to adapt to different types of goods. The height of both the unneedling wheel and cutting apparatus can be continuously adjusted, enabling adjustment of the edge stress at the point of intersection. It is therefore possible to adapt the cutting capacity of the goods precisely. The insertion depth of the revolving blade in the unneedling wheel can also be continuously adjusted. The lateral adjustment of the revolving blade to the unneedling edge depends on the type of goods and can be carried out in accordance with arrangements I–III (see Fig.).

- Arrangement I: Only suitable for types of goods where the selvedge can be stretched in such a way through the suction current of the strip suction device that it is possible to make a cut. Minimum sel-

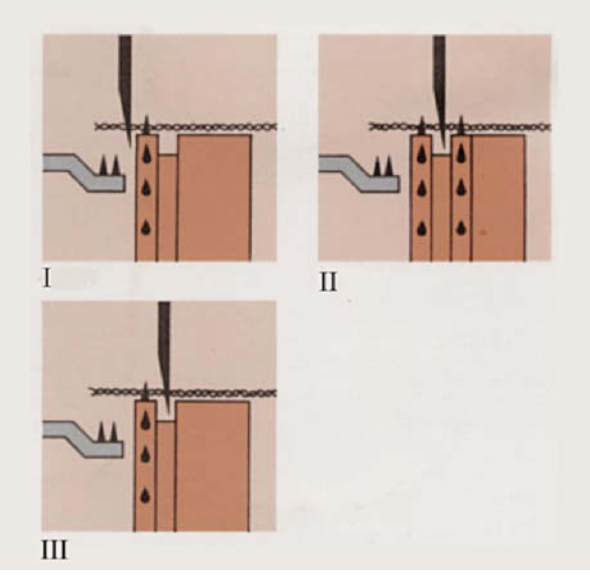

Fig.: Three possibilities of edge trimming: arrangement I–III.

vedge trim 3.5 mm from the raw edge up to the first needle row of the stentering machine.

- Arrangement II: This is the most common arrangement. The trimmed goods do not have needle impingement. Minimum selvedge trim 9 mm from the raw edge up to the first needle row of the stentering machine.
- Arrangement III: During the cutting process, the goods are held by an additional needle row on the unneedling wheel. This prevents breakage or further tearing when the goods are stretched laterally. Minimal selvedge trim 9 mm as with arrangement II.

Edge uncurling device Device used to remove the curl from selvedges that have a tendency to roll and make processing difficult.

Edging (Fr.), → Binding, edge binding, border on woven textiles and knitwear.

EDIFACT, abbrev. for: Electronic Data Interchange for Administration, Commerce and Transport. → EDITEX.

EDITEX A project group, founded by the European technical clothing organisation AEIH in coordination with the textile clothing discussion group. The governing body of the AEIH Commission decided in agreement with Comitextil to give the EDITEX group active support from all countries. The objective of the EDITEX group is to develop a set of standards specific to the field of textiles, EDIFACT, taking account of the various specialisms such as the cataloguing of data on sizes and colours. The swift exchange of information should in future produce a quicker reaction time, living up to the slogan "Quick response". In order to facilitate a cost-efficient transfer of data, the Datenzentrum Einzelhandel (DZE; = retail trade data centre) was established as a clearing centre for the textile industry in Germany. The transfer of data takes place via the worldwide IBM telecommunications network. → Technical and professional organizations.

EDP Code → EDP key system.

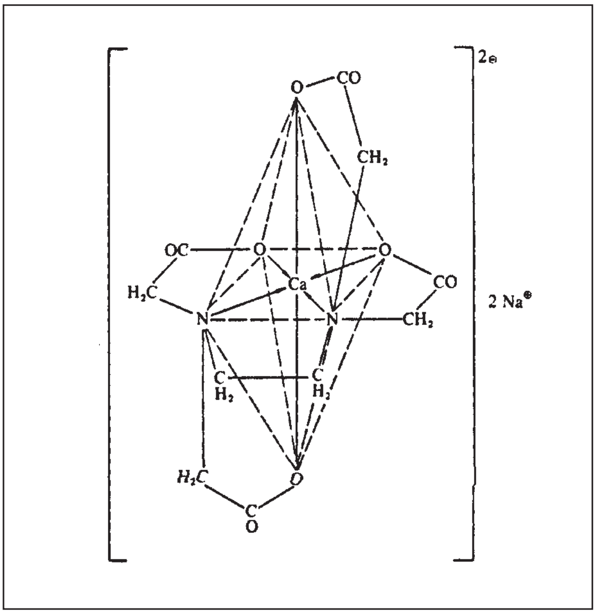

Fig.: Ca-EDTA-complex.

EDP fibre identification code → EDP Code.

EDP key system A system of abbreviations for fibres agreed at the beginning of the 1970s between the EEC member states according to EDP guidelines (→ Textile fibre symbols).

EDPM, abbrev. for: electronic data processing machine.

EDTA, abbrev. for: → Ethylenediaminetetraacetic acid. Complexing agent which can be used as a water softening agent by direct addition to hard water (see Fig.).

eee pretreatment system (eee = efficiency, economy, ecology), Sandoz, Basle, Switzerland, offers the eee system, a series of tried and tested process combinations for all pretreatment requirements, which comply with strict quality control measures (see Tab.). The term for this complete system of recommended proc-

	Desizing	Alkaline treatment	Boiling off	Bleaching	for
Proc. 1				Pad batch (room temp.)	Dyeing
Proc. 2		CRC process		as required	Dyeing, printing, deep shades,
Proc. 3	Pad batch with enzymes	Mercerization	Pad steam or U-box	Pad steam or U-box	Dyeing, printing, quality goods
Proc. 4		Sandoflex		Under-liquor	Dyeing, white goods, knitted goods,
Proc. 5				Pad batch/ pad steam combined	Ultra-white
Proc. 6	Pad batch with enzymes			Pad steam or U-box	Dyeing, printing
Proc. 7	with enzymes		Pad steam or U-box		dark dyeing

Tab.: Possible processes for the pretreatment of cotton fabrics to achieve certain effects (eee pretreatment system/Sandoz)

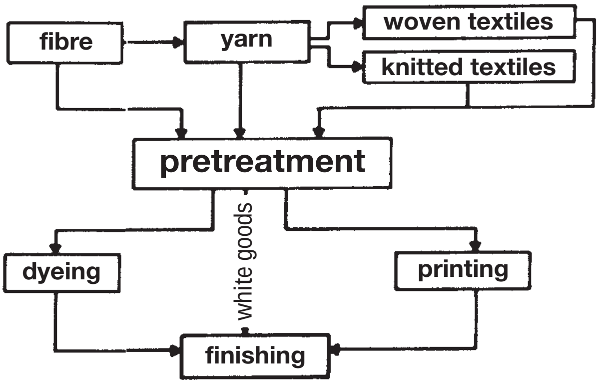

Fig.: Sequence of pretreatment operations in textile finishing.

esses and special products for pretreatment stands for efficiency, economy and ecology, and all processes and products covered by the system must fulfil all three criteria. The eee system therefore corresponds mathematically to the average of all three criteria:

$$I = e_1 + e_2 + e_3$$

The factor e = efficiency, for example, comprises all those active qualities which fulfil the following criteria:

- activity (ability to achieve an effect),
- efficiency (maximum efficiency),
- selectivity (effect relates to the desired function).

The term “pretreatment of textiles” (see Fig.) covers a range of cleaning operations on a fibre, starting from the grey state.

The aim is to prepare the goods for the subsequent finishing processes (dyeing, printing, finishing). The different operations include desizing, boiling off, alkaline treatment (mercerizing, caustic treatment) and bleaching. The resultant loss of weight is a clear indication of the success of the cleaning. The grey goods contain natural impurities such as fats, pigments or mineral substances, and artificially or accidentally introduced substances such as sizings, traces of mineral oil introduced during weaving and similar (e.g. fungal traces, water, rust). Everything has to be removed, as it is detrimental to subsequent finishing. Precise analysis determines the various criteria of a given pretreatment effect. Special machines, processes and products are required in order to remove impurities from the fibre without causing actual damage to the fibre:

- mineral oil stains are difficult to remove;
- unless the fabrics are cleaned sufficiently, it is impossible to achieve perfect dyeing or printing;
- imperfections in pretreatment (e.g. silicate stains on cotton goods) can adversely affect the goods; for this reason silicate-free peroxide bleach treatments are recommended;
- traces of iron can lead to catalytic damage, thus chelating agents should be used to mask the harmful element.

A variety of machines can be used. For continuous processes the main types are the pad-steam, J-box, U-box and under-liquor systems. An essential factor is the speed of throughput of the goods. Below 50 m/min is considered low speed and above 100 m/min high. Pretreatment is also carried out discontinuously, using a winch beck, jig, jet or autoclave. The liquor ratio is of essential importance here. Liquors are classified as short (<1:5) and long (>1:10). The individual stages of the process (desizing, boiling off, bleaching) are sequential. With semi-continuous processes around 2,000–5,000 metres are impregnated and left to dwell for 12–24 h at room temperature (pad batch) or 1–3 h in saturated steam (pad roll). The pretreatment is therefore dependent on the substrate (natural or manmade fibre), the make-up (woven goods, knitted goods, yarn etc.), the machinery (continuous, discontinuous, semi-continuous) and the chemicals (enzymes, wetting agents, detergents, chelating agents, stabilizers, reduction or oxidation agents, antifoams, etc.) (source: Fornelli).

Effective temperature of synthetic fibres Thermal analysis is used to measure the stability of reciprocal intermolecular action or the stability of frozen-in crystalline systems in thermoplastic fibres. This is done, for example, using → Differential Thermal Analysis. In a differential thermogram, in addition to the main melting (e.g. polyester at approx. 256°C), a characteristic subsidiary melting is observed at each preceding fixed temperature point. This is the melting of crystallites, which have been formed under the set conditions of previous treatments. The melting temperature of these crystallites, defined as the peak maximum, is a measure of the thermal stability of the physical network of the synthetic material. It is described as the effective temperature of the thermal treatment.

Effectivity factor (EF), the effectivity factor is extremely useful for the (relative) evaluation of the finish effect of various resin treatments:

$$EF = \frac{\text{TKW (resin finished)} - \text{TKW (non-resin finished)}}{\text{RFV (warp) \%}}$$

TKW = dry crease recovery angle
RFV = loss of breaking strength

Optimum values lie between 2.5 and 3.5. EF values >4 indicate under-cured goods; values <2 indicate overcuring.

Efficiency rate Ratio of actual to possible production performance.

Efflorescence Problem of finishing agents crystallizing out as powdery grey deposits on textile surfaces.

Effluent fining pond Naturally situated water reservoir at the end of an industrial effluent treatment cycle, used to make a final adjustment of the water to the natural balance - in a stretch of water (biozonosis pond) - before the water reaches the receiving stream.

Ehrlich's reaction Test reaction for the detection of urea, amines, imidazolidones and triazones in resin finishes. Reagent: 1 g p-dimethylaminobenzaldehyde in 100 ml 2n hydrochloric acid. Reactions:

1. Immediate formation of brilliant yellow stains = imidazolidone.

2. Formation of pale yellow stains after a few minutes = urea.

3. Gradual development of weaker stains = amines, triazones and other heterocyclic substances with primary amino groups.

Ejector Pneumatic device for mock cake for connection to a compressed air supply.

EL

I. → Char length

II. → Elastodiene fibres, standard abbrev. according to the → EDP Code; → ED.

III. → Elastane fibres, → Textile fibre symbols according to DIN 60 000 T4/08.91.

Elastane fibres Manufactured fibres composed of at least 85% segmented polyurethane (→ Polyurethane elastomer fibres). Elastane fibres can be extended reversibly up to 500–700%. Compared to natural rubber fibres, they have the following advantages: almost white in colour (even transparent elastane fibres are commercially available), higher strength, good resistance to oils and cosmetics, more easily dyed.

Structure: the macromolecules of elastane fibres contain hard (highly inextensible) segments alternating with soft (highly extensible) segments. The hard segments can form quasi-crystalline structures. Physical interactions between the hard segments of different molecules provide the necessary mechanical stability for a textile fibre. The hard segment structure is also responsible for the behaviour of elastane fibres at high temperatures as well as their setting characteristics. The soft segments are formed from special polyethers or polyesters and exist in a quasi-liquid state at room temperature. This physical state ensures high mobility of the soft segments and is the basis of the high extensibility of elastane fibres (see Fig.). The soft segments are also responsible for the thermal behaviour of these fibres.

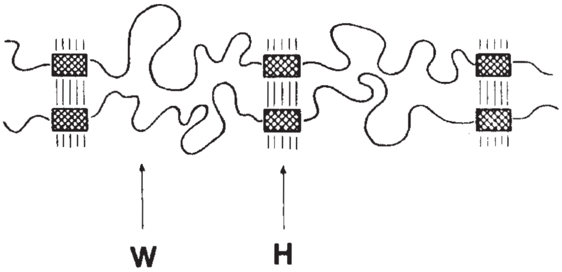

Fig.: Structure of elastane-polymers.
W = soft segments; H = hard segments.

Fibre production: the technique used in spinning elastane fibres depends upon the type of polymer that is spun. Some segmented polyurethanes, for example, are essentially linear molecules, and are soluble in solvents. Other segmented polyurethanes may be branched or crosslinked structures which are insoluble. The dry spinning process, in which the prepared elastane solution is spun through spinnerets into heated spinning cabinets, is preferred by the majority of elastane fibre manufacturers. The drawing tension of the take-up winders forms individual fibres of specified strength. In practice, filament fineness usually lies between 4–20 dtex. The individual filaments are brought into contact with each other by false twist whilst still in the viscous state in the heated spinning cabinets, resulting in their adhesion to one another.

Elastic band consists of textile warp threads and elastic threads, which are generally not covered by spinning, positioned between these at specific intervals.

Elastic calender bowls (elastic calender rolls). These are made from paper, cotton, jute, plastic, etc. The elastic material is pushed on to a steel axle in the form of individual slices (e.g. approx. 20 000 per metre width), pressed hydraulically under high pressure (up to 1000 t), and held together at both ends by iron flanges. The steel axle must be of a suitable diameter to prevent distortion of the elastic calender bowl under load. The surface of an elastic calender bowl produced in this way is extremely hard and can only be turned down to the desired final diameter with a diamond tool.

Elastic extensibility → Tensile elasticity.

Elasticity As in the case of strength, a distinction is made between the various types of elastic stress →: Tensile elasticity; Bending elasticity; Torsional elasticity. In each case, the elasticity may be permanent or temporary. Inferences can be drawn from these parameters concerning dimensional changes in textiles which are of practical value with regard to their serviceability.

Elastic recovery → Recovery capacity of fibres.

Elasticum According to Allwörden, a putty-like substance made up of carbohydrates in → Wool structure.

Elasticum reaction (Allwörden's reaction), a microscopic test for the detection of chemically damaged wool. Method: degrease the wool with ether, and spot with chlorine water under the microscope. Undamaged wool: strings of semi-circular pearl bead-like blisters over the entire fibre surface (→ Elasticum, swollen out of the fibre). In the case of alkali damage as well as chlorinated wool, the reaction is either negative (due to removal of the epicuticle) or only very weak.

Elastified or modified resins → Alkyd resins.

Elastin Connective tissue protein, major component of elastic fibres as in blood vessels, ligaments, etc.

Elastodiene fibres Generic name for man-made fibres based on polyisoprene, or polymerized dienes (polybutadiene), with or without vinyl polymers. Extensibility characteristics similar to → Elastane fibres.

Elastomer fibres →: Elastane fibres; Elastodiene fibres.

Elastomer filaments → Polyurethane elastomer fibres.

Elastomers Elastic polymers. As originally defined, this term refers to a group of synthetic thermosetting high polymers (such as polyisobutylene and its copolymers, polyurethane, "Thiokol", etc.) having properties similar to those of vulcanized natural rubber, namely the ability to be stretched to at least twice their original length and to retract very rapidly to approximately their original length when released. The term was later extended to include uncrosslinked polyolefins that are thermoplastic; these are generally known as TPO rubbers.

Electrical attraction → Fibre attraction.

Electrical conductance (G) is the reciprocal of electrical resistance R. The derived unit is the Siemens (unit symbol: S). 1 Siemens is equal to the electrical conductance of a 1 Ω (ohm) resistance conductor:

$$1\,\mathrm{S} = \frac{1}{1\,\Omega} = 1\,\Omega^{-1}$$

Electrical → Conductivity K is the reciprocal of specific resistance.

Electrical double layer Occurs in dyeing from aqueous electrolytic solutions at the liquor/substrate interphase. Electric charges can be present at the interphase, i.e. the substrate surface, building up an electric field out into the liquor. This can be a question of ionic groups, adsorbed ions etc.

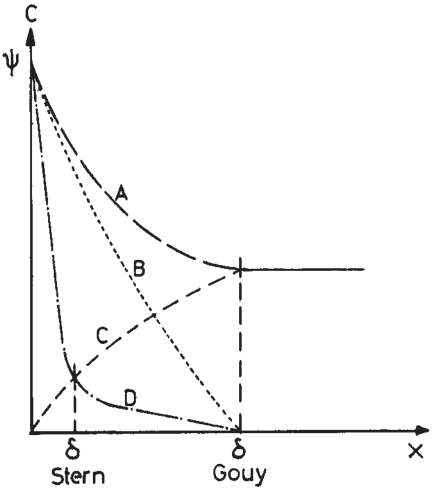

Fig.: Stern and Gouy model.
Ψ = electrical potential; c = concentration in mol/l (ordinate); δ Stern = Stern layer thickness; δ Gouy = Gouy layer thickness; A = counterion concentration curve; C = equally loaded ion concentration curve (as surface loading); B = Potential curve according to Gouy; D = potential curve in Stern layer; x = distance from surface.

Ion distribution and the electric field can be quantitatively described with the aid of Poisson's electrostatic differential equation and Boltzmann's distribution. Gouy's simple model was extended by Stern by the inclusion of a linear voltage drop in the immediate vicinity of the interphase (illustration). The following electrostatic relationships apply to this layer.

$$\frac{\partial^2\psi}{\partial x^2} = -\frac{4\pi}{D'}\sigma$$

$$\frac{\partial\psi}{\partial x} = \frac{\psi_0 - \psi_{St}}{\delta_{St}}$$

$$\rho = -\int_0^{\delta St}\sigma\,dx = \frac{D'}{4\pi}\int_0^{\delta St}\frac{\partial^2\psi}{\partial x^2}\,dx$$

$$\rho = \frac{D'(\psi_0 - \psi_{St})}{4\pi\,\delta\,St}$$

Electrical heating, of textile finishing machines. In comparison to the heating of machines involving thermal treatments with other energy carriers (steam, gas, hot water, hot oil circulation) electrical heating is, in certain cases, simpler to install from the machine construction point of view, e.g. for revolving calender bowls (see Fig. 1 and 2).

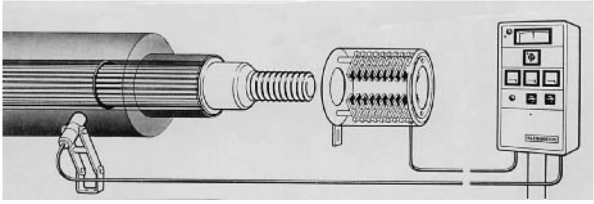

Fig. 1: Electrical heating for calender bowls.

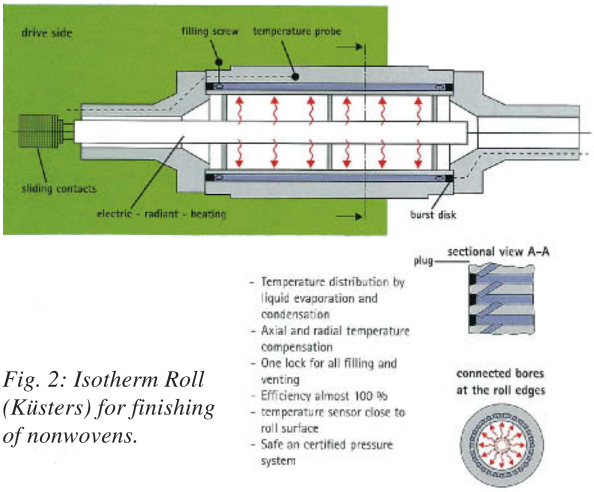

Fig. 2: Isotherm Roll (Küsters) for finishing of nonwovens.

Electrically heated pressboards → Pressboard.

Electric motors Electrical machines for transforming electrical energy into mechanical energy. Motors run hot during operation, part of the electrical energy being transformed into heat energy. If the electrical energy cannot be converted into mechanical energy because of motor stoppage due to overloading for example, the whole of the electrical energy is transformed into heat energy, and the motor "burns out". In the case of electric motors where electrical power is taken from the mains, and is transmitted to the drive shaft as mechanical energy, eddy current, frictional and air vortex losses occur due to the Joule effect. Here too, part of the energy supplied is lost; this is referred to as power loss.

When operating in humid premises or where other dangers do not permit high voltage connection (380 V for example), safety transformers reduce the voltage down to 42 V or 24 V. Machines are often switched on and off via contactors with the aid of lower control voltages (Fig. 1). New developments in drive technology – brushless electric motors – are in the offing.

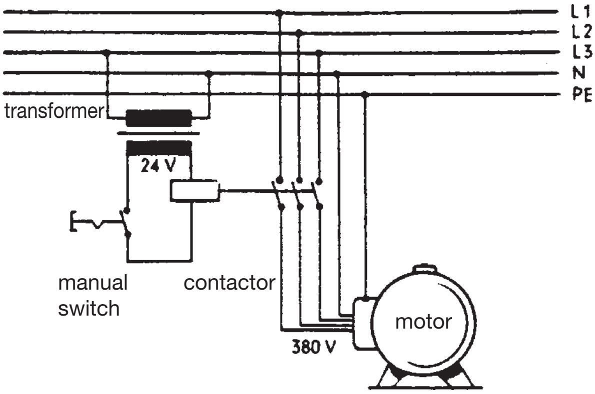

Fig. 1: Switching on a high voltage motor via a low voltage contactor.

On finishing equipment, electric motors are used for driving pumps or rollers. Normally, liquor pumps in dyeing machines are equipped with constant speed drives. This solution is useful in max. pressure and flow operating conditions. In many cases of application however, different flow quantities are required during the dyeing process, this being made possible either by means of a by-pass control unit, a differential pressure valve, or by speed control (Fig. 2), alternating current or three-phase motors etc. being controlled in terms of required power by means of current frequency, while direct current motors can be steplessly controlled via resistors. Currently, control via direct current motor is the most cost-effective solution, while the frequency solution requires a 30% higher investment. Speed reduction means reduced pump motor power input, because performance is reduced by the power of three.

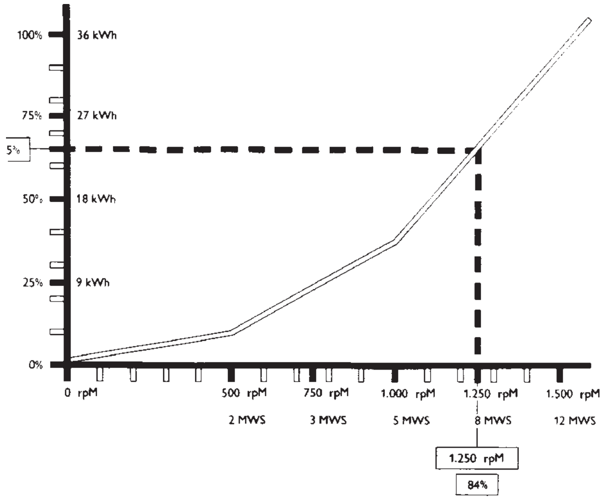

Fig. 2: Current consumption of an electric motor relative to speed and pump capacity (contributed by Thies).

The output of a centrifugal pump can be adapted to the textile material to be dyed relative to the pump's characteristic curve. A slower reduction in differential pressure and an adapted number of jet passages in jet bleaching can reduce power consumption by almost half, while the Thies SDC-System (Synchronous Dyeing Control System) reduces power consumption during dyeing by one third.

If, with the use of direct current motors, a large tractive effort is necessary on machine start, a so-called series wound motor is used. It is externally recognizable by the thickness and low number of field coil windings. The direct current shunt wound motor keeps its speed constant within specific load limits, which makes it suitable for precision instruments. It is externally recognizable by the large number of field coil windings. Speed requirements can be set by connecting resistors into the shunt circuit. The compound motor with combined series and shunt wound circuitry combines high tractive force with approximately constant, easily controlled rpm.

With alternating current motors, a distinction is drawn between synchronous and asynchronous motors. In the case of synchronous motors, the stationary component receives single or multiphase alternating current, and the rotor separate direct current. For running up to synchronous speed, the motor requires an auxiliary unit. With the asynchronous motor, the stator receives alternating or three-phase current, while the rotor current is generated by induction. Rotor speed maintains a specific slip behind that of the rotating field. Asynchronous motors have either short circuited (squirrel cage) or slip ring rotors. Asynchronous motors are self-starting; their tractive effort depends on rotating field strength and armature current intensity. High speed and starting under load require slip ring rotor motors with rheostatic starters. In the case of commutator motors, alternating current is fed not only to the stator but also to the rotor via a commutator (as in the case of direct current motors). Their speed can be constantly controlled within wide limits.

Due to progressive automation and rationalisation in the textile finishing industry, there is a demand for a) integrating as many machines as possible into machine combinations, and b) fewer restrictions on production changes by means of wide variation potential within the existing machine park in order to be able to adapt to the relevant market and fashion conditions. Both measures place new requirements on production machine drives. The combination of individual drive motors into a motor system goes hand in hand with the combination of machines into machine systems. This results so to speak in a new configuration, the multimotor drive. One frequently encountered multimotor drive variant is the use of direct current motors within the framework of Ward-Leonard control, e.g. for synchronized open-width scouring machines (Fig. 3). The basic speed of all component motors is set by the Ward-Leonard voltage. Speed differences between the motors due to fabric length change or load variation are compensated in the motor fields via dancing rollers. In a manner of speaking therefore, this can be regarded as coarse basic speed setting and fine motor speed control for synchronization. One of the motors has a fixed set field, and consequently indicates the control speed to which the subsequent component motor has to be adjusted. This again determines the control and slave speed for the subsequent component motor.

The much used dancing roller (Fig. 4) is a roller suspended in a fabric loop and free to rotate around its axis. A fabric length change produces vertical displacement, which is converted via deflector rollers into a rotary motion, and is used for potentiometer actuation. The advantage of the dancing roller is that, independently of the actual position, constant fabric tension is maintained by loading or counter weights. Other synchronizing devices are rocking roller arrangements with fewer bearing points.

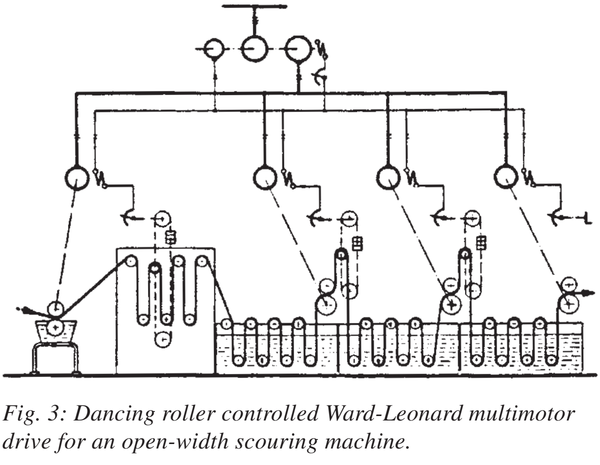

Fig. 3: Dancing roller controlled Ward-Leonard multimotor drive for an open-width scouring machine.

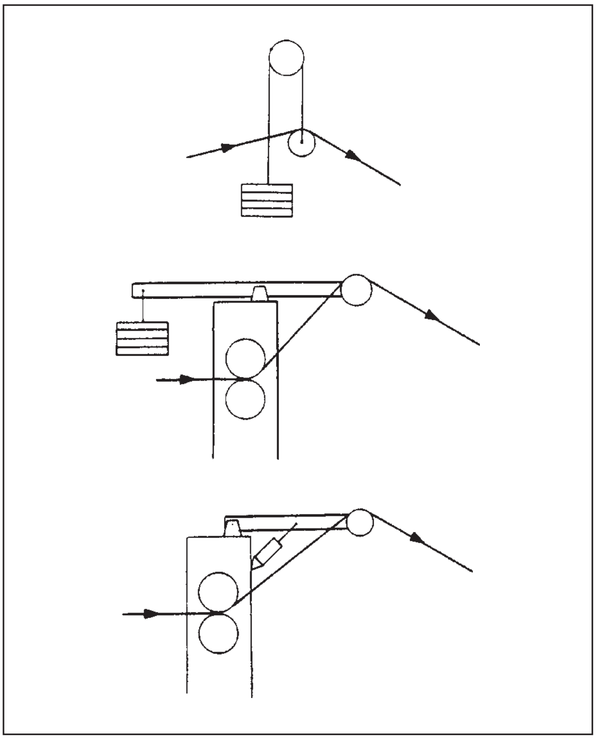

Fig. 4: Various roller layout possibilities for transposing fabric shortening or lengthening on a potentiometer (for controlling the subsequent machine's direct current motor); top dancing roller, centre and bottom rocking rollers.

Fabric take-up varies relative to the position of the rocking roller, and the short fabric feed between top and bottom rocking roller positions can also be a disadvantage. Today, synchronisation is controlled to a large degree by photoelectric sensors, a method which is particularly useful with especially tension-free fabric runs via a festoon control system.

Textile machinery drive technology requirements have also become more stringent due to increasingly better processes for producing and further processing textile raw materials and intermediate and end products. In the first place, variable drive motor speeds are required in order to enable production processes to operate at the technical optimum for specific products, and consequently to achieve high quality standards. Until a few years ago, these applications could only be realized by means of controlled direct current motors, the machines' disadvantages, such as wearing parts (brushes and commutators), the low degree of protection against fly and humidity, and also the relinquishing of high primary speeds all having to be taken into account. There remains no doubt that the speed controlled direct current machine has complete supremacy in some applications. Extruder drives may be an example of this. In the case of the majority of industrial textile drives however, the brushless three-phase motor has predominated. Examination of the marginal drive conditions in the textile industry reveals that a drive unit has to meet the most varied requirements. In addition to wear-free construction designed for a long service life in continuous operation, a high degree of protection against humidity, fly and dust should be provided together with compact and standardized structures. Of all electrical machines, these requirements are best met by the three-phase motor. There are also both diverse and quite specific application possibilities for the different asynchronous, reluctance and permanent synchronous motor versions. However, the three-phase motor also has disadvantages. Due to the machine's winding configuration, only speeds which correspond to an integral feeder mains frequency number can be attained. The formula:

$$n = \frac{f \cdot 60}{p}$$

n = synchronous speed in rpm,
f = feed frequency,
p = number of pairs of poles.

applies.

Thus, synchronous operating speeds of 3000 rpm, 1500 rpm or 1000 rpm are obtained from a mains feeder frequency of 50 Hz and 1, 2 or 3 pairs of poles. Adaptation to the actually required machine speeds can be effected via fixed or variable transmission ratio gears. A further disadvantage is that, due to its physical structure, the three-phase asynchronous motor, when under load, varies its speed in terms of the load. This divergence from synchronous speed is described as slip. In the case of three-phase motors, allowance has been made for variable speed requirements with the development of static frequency converters. These electronic instruments supply the motor with a variable frequency three-phase alternating current. The motor terminal voltage also varies simultaneously with the rotating field frequency variation so that the motor can operate with almost constant magnetic excitation, enabling it to deliver constant torque over a wide speed control range. In contrast to the direct current machine, actual shaft speed feedback is as a rule unnecessary. With the asynchronous motor, the stator is connected to the mains with three-phase current winding, producing a field rotating at synchronous speed (3000 rpm at 50 Hz and with a 2-pole motor). The rotor has transformer stampings with short circuit winding. This is a cast aluminium squirrel cage for example, and the motor itself is consequently simply and robustly built. The motor takes blind current from the mains in all operating circumstances. Torque is produced by relative movement of the rotor to the stator field which runs at a fixed speed. At synchronous speed torque is zero, because there is no relative movement between rotor and stator field. The characteristic torque curve then rises steeply to breakdown torque. It can be seen from this characteristic curve that the motor is not very easy to control in speed terms, as it has a rigid speed/torque curve in the usable range. When the motor is running at a speed/torque point determined by the load, the following formulae apply if stator losses are ignored:

mechanically delivered power: $P_{mech} = M \cdot \omega_R$

electrical power: $P_{el} = M \cdot \omega_S$

rotor losses: $P_R = M \cdot (\omega_S - \omega_R)$

with angular velocity $= \frac{2\pi \cdot n}{60}$

n = speed,
R = rotor,
S = synchronous.

The frequency converter operates with pulse-width modulated (PWM) high pulse frequency output voltage which is substantially close on average to the ideal sinus form. The additional losses in the motor due to the frequency converter feed are therefore negligible. The three-phase asynchronous motor connected must not be overdimensioned. These characteristics should be taken into account in comparison with other frequency converter systems which operate for example with impressed intermediate current circuits, with square wave voltage blocks or at a lower pulse frequency. The 3-phase mains voltage is rectified by 6 input diodes (active power drawing only). On the intermediate circuit condenser therefore, there is a direct current voltage which is equivalent to that of the peak value of the linked mains voltage. The intermediate circuit capacity charging current is limited at switch-on in order not to load the mains and the circuit fuses with maximum current. In order to prevent unnecessary conduction losses, the charging current limit is bridged by a relay point after capacitor charging. A pulsed mains supply circuit (SMPS), which operates with a high efficiency factor on the blocking oscillator principle, produces from the intermediate circuit voltage the potential-free supply voltage for the electronics and for power semiconductor control. The control electronics are therefore independent of the mains frequency. Even short-term mains voltage drops have no effect on reliable frequency converter operation. Depending on dimensions, the inverter component consists of power field effect transistors or of high-speed frequency thyristors. In the output phases, these power semiconductors control varyingly wide voltage zones, the mean

d = generator operation, anticlockwise.

values of which approximate substantially to the ideal sinus form.

Electric motors should not cover more functions than the purpose requires. In specific cases, they must also be able to run in 2 directions, or also be able to brake. Clockwise and anticlockwise operation is possible with all three-phase current drives. With mechanically stepless transmission with torque-dependent contact pressure on the other hand, driving and braking require appropriate pressure curve configuration. With these drives, energy feed back into the mains is always possible during braking. With purely electric drives, energy feedback requires appropriate frequency converter design. With the use of a brake chopper this does in fact permit braking, but no energy feedback. The quadrantal form is usual in cartesian coordinates for representing operational methods (Fig. 5).

Electrochemical displacement series (electrochemical series, electromotive series) → Standard electrode potential.

Electrochemical series → Standard electrode potential.

Electrochemical techniques Widely used in the textile industry for analytical and measurement applications as well as in the supply industries for the manufacture of basic chemicals. Up to now, only a few of the great number of electrochemical processing techniques have found a direct application in the textile finishing industry (see Table). The main emphasis of development in the textile industry so far has been particularly concerned with measuring sensors for the monitoring and control of different processing parameters.

Electrochemistry in vat dyeing Comprehensive tests using electrolytic processes have shown that a direct cathodic reaction of dye pigments under usual application conditions is not possible. An electrochemical reduction may, however, be achieved by indirect electrolysis, by the selection of appropriate systems. During indirect electrolysis the reduction/oxidation of substances takes place through mediators or electron transfer substances. These renewable redox systems (mediators) are reduced/oxidised at the electrode and with appropriate orientation of their potential in the solution can reduce any substances present. The

mediator system is thus oxidised and in the next stage of the reaction renewed at the cathode (Fig. 1).

Fig. 2 shows the basic layout of laboratory apparatus for the indirect eletro-chemical reduction of sulphide and vat dyes. In this method, direct-voltage electrolysis areas enable the reduction effect at the cathode to be used for indirect reduction of the dye. The reoxidation of the reduced molecules at the anode, causing the release of oxygen, is prevented by a diaphragm (according to Bechthold).

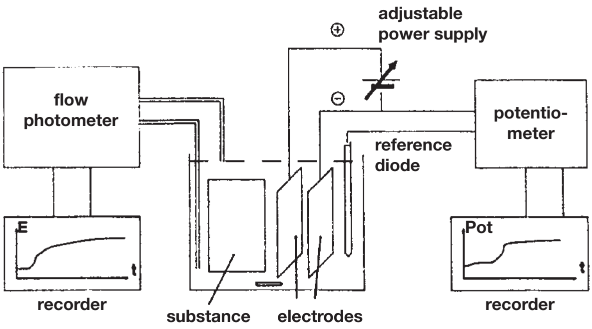

Fig. 2: Trial apparatus for the electro-chemical reduction of dyes (principle according to Bechthold).

Electrodes Electrical conductors (plates, sieves) as used, e.g. in electrolysis (electroplating, electro-deposition, etc.). Positive pole = anode, negative pole = cathode.

Electrokinetic interfacial potential (EP → Zeta potential), electrical charging and voltage ratios at so-called interfaces (fibre/water, fibre/dirt, dirt/scouring liquor) in aqueous solutions. EP is determined by the inherent charge (fibre/dirt) and foreign matter charge, which can be like or opposite (repulsion or attraction/affinity). It is therefore dependent among other things on solution pH and the adsorption of ions on the way from the treatment liquor to the fibre interior. Cellulose fibres for example always have a negative charge, as do protein fibres above pH 3–5. Below this value however (i.e. even more acidic), protein fibres are positively charged. The maximum EP of the fibre in alkaline solutions (negative charge) is at approx. pH 11; in addition, protein fibres have a lower maximum in highly acidic solution (positive charge) below pH 3–4. Between pH 3 and 5, both fibre types have practically no significant electrokinetic potential against the aqueous environment. In practice, the EP maximum coincides with the optimum values: a) of fibre swelling, which is at its maximum at pH 10–11 (minimal at pH 4–6); b) of the scouring power (scouring process) of anionic products (soap etc.), which is at its maximum in alkaline solutions at pH (9.5–) 10.7 (at its lowest at pH 4–6), or of cationic products with scouring power below pH 3. The fact that emulsified dirt particles for example exhibit the smallest charge in aqueous solution complements in practice the importance of EP explained above. The practical inference: textile fibres have a negative charge in pure water:

wool	– 48 mV
cotton	– 38 mV
acetate	– 36 mV
cupro	– 5 mV
viscose	– 4 mV
silk, degummed	– 1 mV

Impurities of all kinds are also negatively charged by contact with water, and this can be significantly increased by soap or other anionic scouring media (Table).

dispersed »dirt particles«	ζ in mV, in water	in soap solution
liquid paraffin	—86	—151
cotton seed oil	—74	—140
dyestuff	—62	— 79
carbon	—60	— 71
bacteria	—34	— 49
iron oxide	—28	— 78

Tab.: Zeta potential of dispersed dirt particles in water and soap solution.

The negative charging of fibre and dirt is explained by the preferred adsorption of hydroxyl ions from the water which is to a degree continuously dissociated. If the charge of the same polarity between dirt and water does not make sufficient electrostatic forces effective in repelling dirt from fibres, it is a consequence of the still too low EP. For this reason, the negative charges are increased vis-à-vis the fibre, achieving an effective potential difference by adding hydroxyl ions to the water in the form of scouring alkalis on the one hand, which already loosen and partly repel dirt, and, on the other, surface active scouring agent anions. A combination of electrokinetic tests with solvent extractions enables theoretically based zeta potential values to be obtained, and consequently to reach definite conclusions on the ionogenic nature of extraneous fibre substances.

Electrokinetic potential (→ Electrokinetic interfacial potential; Zeta potential). The adsorption of surfactants also affects the electrical charge of solid surfaces, which come into contact with the surfactant solution. When e.g. an anionic surfactant is adsorbed, the dissociated anions form a diffuse layer close to the surface so that the adsorbed long-chains form an excess negative charge at the surface. This is expressed in the so-called electrokinetic or zeta potential. Solid surfaces which come into contact with pure water or surfactant-free aqueous solutions also almost always have a surface charge which is predominantly dependent upon the adsorption of ions or the dissociation of surface groups. The polarity of this surface charge frequently depends on the pH. The addition of ionic surfactants therefore causes an increase in the surface charge where the polarity is the same and reverses the charge where the polarity is different. For example, negatively charged carbon black in pure water undergoes a charge reversal when the cationic surfactant dodecyl pyridimine chloride is added at a concentration of less than $1 \cdot 10^{-4}$ mol/l.

Electroluminescence → Luminescence.

Electrolyser Apparatus for the automatic production of sodium hypochlorite from sodium chloride (5–25 wt. %) for bleaching. Principle: an ordinary solution of sodium chloride is allowed to flow through the Electrolyser (see Fig.) where, under the influence of an electric current, a ready-to-use sodium hypochlorite solution is formed without any evolution of chlorine gas. After dissolving the required amount of salt and switching on the current, the electrolysis proceeds automatically without maintenance or supervision. Operating data for the smallest unit: current rating at 110 volts = 5 amps, at 220 volts = 2,5 amps, power consumption = 0,55 kWh, salt consumption = 1,3 kg/h, output (at 3 g/l active chlorine) = 90 g in 1 h, active chlorine in 24 h = 2160 g.

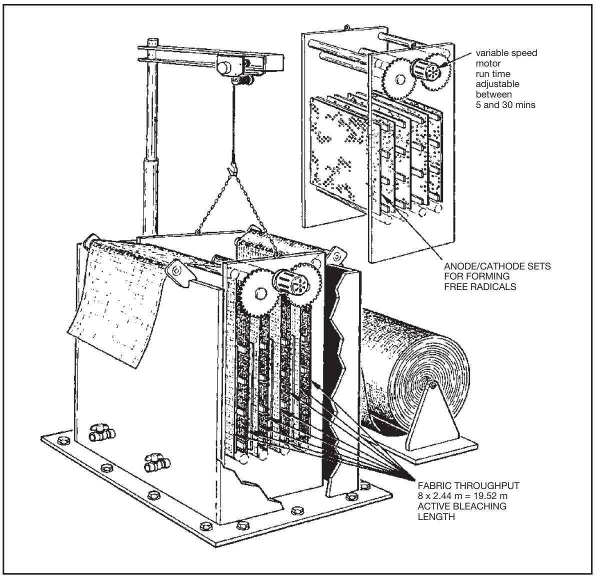

Fig.: Electrolyser-based (Ster-O-Lizer Manf. Corp.) woven fabric bleaching.

Electrolysis Decomposition of chemical compounds dissolved in water (→ Electrolytes) by the application of an electric current in which the (positive) cations migrate to the cathode (negative pole) and the (negative) anions migrate to the anode (positive pole), e.g. sodium chloride (NaCl): Na = cation, Cl = anion.

Electrolyte addition in dyeing In certain dyeing processes, dye exhaustion is not controlled by diffusion. Rather, levelness of the dyeing is controlled by addition of an electrolyte (in the form of metered salt additions). Such processes may be described as "affinity-controlled". A temperature is selected at which diffusion proceeds rapidly. At the point when the equilibrium bath exhaustion momentarily ceases, the kinetics of dye exhaustion are due to the change in equilibrium. For cellulosic fibres the equilibrium distribution of direct dyes can only be represented approximately by a Freundlich or Langmuir isotherm because, e.g. strong associations of large planar dye molecules can be present in the bath. It is exactly these associate equilibriums that are influenced, both within and outside the fibre, by the addition of electrolyte (e.g. salting out of dyes). Thus, in the case of linear salt dosing in a cellulose-direct dye-water system, dye uptake by the fibre rises more strongly at first and then becomes less (see Table). Salt should therefore be added at an increasing dosage rate in order to provoke a linear exhaustion of dye.

The amount of salt should be measured in such a way that a high colour yield is achieved which is insen-

Shade depth (% of fabric weight)	**Salt quantity (% of fabric weight) with**

Tab.: Salt quantities for substantive dyes for cotton dyeing.

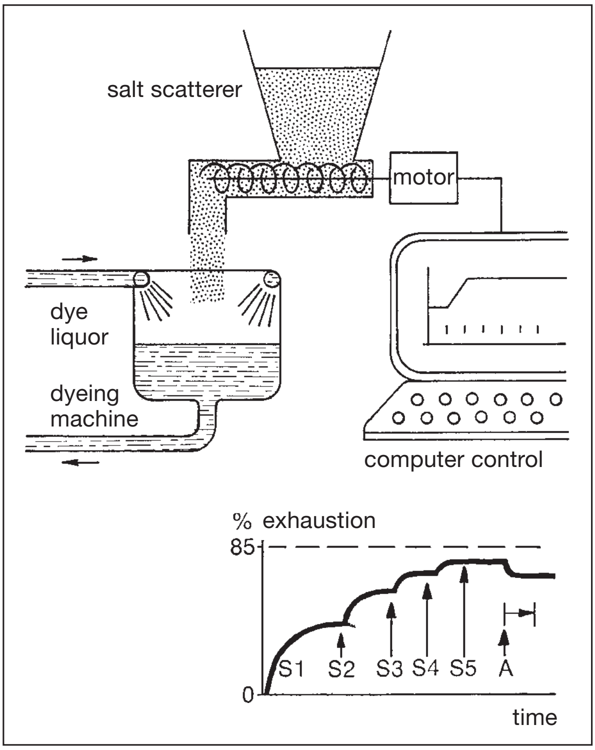

Fig.: Control of electrolyte admixture in the reactive dyeing of cellulose by the exhaustion method by means of so-called "poly product injection" – Thies in cooperation with BASF. S1–S5 = salt dosing; A = alkali addition.

sitive to slight variations in the electrolyte content of the liquor. The amount depends on the type of steel from which the dyeing machine is constructed, as well as the depth of shade, the liquor ratio, and the fibre. A few details for direct dyes are given in the table where the dyes have been subdivided into three groups depending on their salt requirement (this subdivision is somewhat different from the usual SDC classification; these figures also relate to migration properties). Reactive dyes need higher amounts of salt which makes metering more difficult. Since reactive dyes migrate well in the substantive phase, salt should be added from the beginning provided this does not have an adverse effect on levelness (salt dosing is controlled by conductivity measurements or a computer control system) (see Fig.).

Electrolytes Substances which undergo partial or complete dissociation into → Ions in solution (in water or other solvent). The solution then acts as a conductor of electricity. The most important groups of electrolytes are acids, bases and salts. Colloids with electrical properties are known as → Colloidal electrolytes. Electrolytes are frequently employed as diluents for dyes and textile auxiliaries (sodium chloride, sodium sulphate) and to promote exhaustion in dyeing (e.g. salt addition in dyeing with direct or reactive dyes).

Electrolyte sensitivity A characteristic property of synthetic thickeners based on acrylic acid and maleic anhydride: the electrolyte sensitivity manifests itself as a sharp to total loss of viscosity with negative charges on the thickener molecule. It can be prevented, where permissible, by mixing with high-viscosity grades of modified natural thickeners, e.g. carboxymethylcellulose.

Electrolytic bleaching Vegetable or animal fibres are either immersed in a bleach bath, or saturated with bleach liquor, and subjected to the action of a medium to high frequency alternating current.

Electrolytic corrosion plays an extensive role in the → Corrosion of metals. Principle: formation of galvanic elements or electrical currents between metals of different electrode potentials in the presence of low amounts of moisture (as an electrical conductor). It is dependent on local structural differences of the metals (composition, welded areas, etc.). "Anodic sites" are the metals themselves (the more negative ones being placed below each other) and "cathodic sites" are formed by oxide or surface skins, metal additives (carbon) as well as more noble (less negative) metals. In the condensing kettle for recovery of chlorinated hydrocarbons in drycleaning the following course of action takes place:

1. Localized electrolytic corrosion: Acid-containing condensate droplets are formed in the air space of the distillation apparatus and recovery tank after cooling on the metal surfaces. Anodic dissolution of metal takes place in the middle of the droplets (selective corrosion, pitting) and corrosion begins.

2. → Pitting corrosion: further condensate is deposited in the now porous areas of the metal; pitting continues to eat through the metal to the outside until complete perforation occurs.

Electrolytic water purification Processes based on electro-osmosis for the softening of boiler feed water and removal of salts.

Electro-m-process An electro-chemical process for → Waste water treatment. It involves breaking down water by electrolysis. Impurities are oxidised or reduced by the resultant oxygen and hydrogen at the nascent stage. May be supplemented by the perco-filter process (a series of multi-layer adsorption and filtration processes operated under 5 bar pressure), giving water practically of drinking quality.

Electron acceptor/electron donator One way of categorizing the wide variety of reaction types in organic chemistry is into electron or ion reactions. Thus in the case of substitution reactions (e.g. at the benzene nucleus), the controlled effects of existing substituents arise as a consequence of their electron-attracting or electron-repelling (electron transfer) characteristics, and also dipole elements of organic compounds result from electron displacements within the molecule.

There is a difference in terminology depending on whether the reaction is a result of electron migration or whether an electron pair is "borrowed". It thus follows that an electron acceptor is an oxidation agent, the electron donator a reducing agent. Thus, for example, the weak dyeing (λ 330 nm) of azobenzene (azo dye) can be traced back to the migration of one of the two lone electrons to the azoic nitrogen. By introducing an electron acceptor group, e.g. $-NO_2$, in the 4 position, a clear bathochrome migration (λ_{max} = 478 nm) takes place, with visible bands which analytical findings have found to correspond above all to the electron migration of the azobenzene.

Electron donor → Electron acceptor/electron donator.

Electroneutral compounds arise from the conversion of aqueous solutions of cation-active and anion-active compounds of sufficient molecular size. Electroneutral compounds are used as antistats, lubricating agents, etc.

Electron formulae → Atomic bond.

Electronic engraving An electronic scanning and engraving system which converts the reflected light from a design sketch by means of an optical sensor into electrical signals which are transmitted to the engraving system via a computer.

Electronics A branch of electrical technology concerned with electrical circuits developed from electrical or magnetic fields, electrical currents, heat, light or other radiation sources in which the motion of → Electrons is controlled for technical applications in communications, control systems, or computing.

Electron microscope A microscope which uses electrons for imaging instead of light. Quantitative and qualitative application. Principle: a directed electron beam, which impinges on the examined test specimen in a vacuum, brings about the emission of an X-ray spectrum which is characteristic of the elements contained in the specimen. From this spectrum, conclusions can be drawn as to element type and concentration. Either a point on the test specimen (point analysis) or an area (scanning) can be sensed with the electron beam. Construction: consists mainly of electron sources and three vertical coil or electron systems (in an approx. 1 m high vacuum tube), which act as lens sets (from top to bottom): 1. condenser for condensing the electron beam on to the object, 2. objectively, and 3. projectively. These current traversed coils act on the directed electron beam passing parallel to their axis relative to current strength (adjustable focal depth) as so-called magnetic lenses. Electric lenses also have the same action (charged pin diaphragm). The magnified object appears as an image on a fluorescent screen or photographic plate. Direct magnification up to x 150 000. Total magnification with optical after-magnification (light-optical microscope) up to 1 million. The resolving power depends on the electron beam wavelength, i.e. its speed (at 10 000 volts, approx. 60 000 km/s wavelength approx. 12 billionth of a mm), and the spherical error of the electron lens. Achievable resolution up to approx. 1 millionth of a mm. Used for research purposes (also on textile fibres). → Scanning electron microscope.

Electron number → Atomic number.

Electron pair bond → Atomic bond.

Electron polarization → Polarization.

Electrons (Greek), electronegatively charged particles of an → Atom, the unit charge of which (in contrast to the positive electricity of positrons) can exist (cathode and X-rays) dissociated from the material, i.e. in the "flying off" of an electron from an (electrically neutral) atom, a positive charge is produced in the nucleus, and consequently a monovalent positive ion. With the expulsion of two, three etc. electrons therefore, bivalent, trivalent, tetravalent and multivalent positive ions (cations) are formed. Conversely, a monovalent, bivalent, trivalent etc. negative ion (anion) is formed with the joining of one, two, three etc. electrons with a neutral atom. If numerous electrons are involved in these processes, "electrical phenomena" occur. The speed of an electron is 2000 km/s. The "mass" of an electron is approximately $^{1}/_{1800}$ of the atomic weight of hydrogen. An electron should therefore be regarded as the smallest quantity of electricity capable of existence.

Electron shift → Standard electrode potential.

Electrophoretic coagulation A process for bonding fibrous webs with acrylic and polyurethane binders.

Electrophoretic mobility describes the velocity of migration under direct current influence of colloidal particles in an aqueous medium to the plus or minus pole. It is of a similar order of size as with conventional ions, which is perhaps due to an increase in electrical charge with increasing particle size. Electrophoretic mobility represents for example an electrical component phenomenon of the scouring process, involving detached pigment particles in the liquor, in which an increase in electrophoretic mobility makes itself apparent by increasingly affecting the fibre/dirt system. →:

salts		EB 10^{-4} cm/s

	sodium metaphosphate	5.5
	magnesium chloride	3.9

Tab.: Electrophoretic mobility (EM) of soot particles with the addition of inorganic electrolytes.

Zeta potential and suspending power are closely associated with electrophoretic mobility. In an approx. 2.9 g/l fatty alcohol sulphate (sodium dodecyl sulphate) solution, the electrophoretic mobility of soot particles for example changes with the addition of inorganic electrolytes in equivalent concentration (Table).

Electrophoretic mobility is accordingly slightly increased by monovalent cation salts (sodium example above), but reduced by the magnesium salt. Reduced electrophoretic mobility also produces higher scouring substance concentration.

Electroplating (electrodeposition). The deposition of a layer of metal (typically silver, nickel, zinc and chromium, etc.) by electrolysis. The object to be plated forms the cathode in an electrolytic tank or bath containing a solution of a salt of the metal to be deposited.

Electropolishing Surface treatment of rollers to prevent the build-up of deposits and stains.

Electrospray process (→ Spray printing). This process is more rapid than mechanical spray printing methods and allows the production of finer details. Not yet applied in textile printing except, to some extent, carpet printing, because of high investment costs and the lack of genuine textile printing effects. On the other hand, it has found wide application in coding systems and the production of printed letters and policies, etc.

Electrostatic bond → Ionic bond.

Electrostatic charge Electrical surface effect on textiles, machines, fluids etc. Actually "at rest" electricity (static), but which moves anywhere with extreme rapidity at the moment of perception, only then being observed as attraction or repulsion. The occurrence of electrostatic charges is almost always accompanied by unwelcome difficulties in processing operations and in use. They are particularly production disrupting and quality impairing phenomena, such as the splaying out of electrically charged fibres, yarns (fly and tangle formation) and the bellying of charged fabrics (difficulties with plaiting, folding, cutting etc.), the unwanted "clinging" together of oppositely charged clothing during wear, the "sticking" of textiles to oppositely charged machine components, tenaciously adhesive light-coloured fly, yarn waste etc. on other, dark-coloured, types of textile material, the difficult to remove soiling of machinery by dust etc. from the atmosphere, the not infrequent electric shocks to personnel (assisted by rubber shoes) through to open sparking, fire and the danger of explosion (e.g. in dry cleaning plants). The causes are due to surface contact, especially in association with rapidly interrupted contact (e.g. high fabric speed), mainly during or after mutual contact and friction (e.g. textile/textile, textile/machine component, textile/hot air in drying processes, water/air in the case of nozzles), by distortion pressure (e.g. on calenders and printing bowls) and due to temperature change (variously on drying units, tumblers etc.). Familiar causes are often simultaneously involved too. The electrostatic fibre charging process is essentially explained as the effect of a charge transfer on the surface due to (the above-mentioned) mechanical causes.

In this connection, any tendency to electrostatic charging (coulomb forces) is generally more pronounced with higher electrical resistance, i.e. lower electrical conductivity (affinity), which again mostly equates with lower (fibre and air) humidity (wool is a particular exception) and vice versa. The electrostatic range illustrated in Tab. 1 has been compiled in accordance with these standpoints. Broadly speaking, it can be said that the upper list of fibres is positively charged by the effect of friction for example, i.e. chiefly by other, lower list fibre types or yarns. Conversely, the lowermost fibres are negatively charged by friction on other fibres listed above them. As charge polarity can sometimes also be markedly overridden by impurities, the presence of residual charges and so on, relationships in the middle of the list are less pronounced and increasingly uncertain.

In addition to a glimpse of quite normal charge levels, it can be seen from Tab. 2, in this case at two different

charge	material range	specific electrical resistance (ohm x cm) §	% approx. water content mean value
		at 20 °C and 65 % r. h.

Tab. 2: Electrostatic charge depending on relative humidity and different take-up speeds.

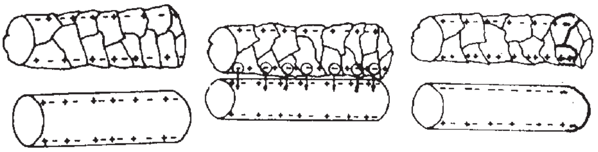

Fig. 1: Electrostatic charge reversal of polyester fibres and wool.

ent processing speeds, that higher humidity alone creates a tendency to reduced electrostatic charging and consequently to better behaviour.

Accordingly, where it is important in practice to prevent difficulties with complete reliability, care should be taken to ensure rapid discharge of the electrostatic charge produced, for which the numerous possibilities with suitable → Antistatic agents (with dry cleaning → Antistatics in drycleaning) are of great importance.

In the initial state (Fig. 1, left), both fibres wool/synthetic are electrically neutral (as many positive as negative charges). With mutual friction (Fig. 1, centre), electrons are transferred from wool to synthetic, resulting in uneven charge distribution: wool now has fewer electrons than in the initial state, while synthetic has more. This fact is visible in the electrostatic charge effect (Fig. 1 right).

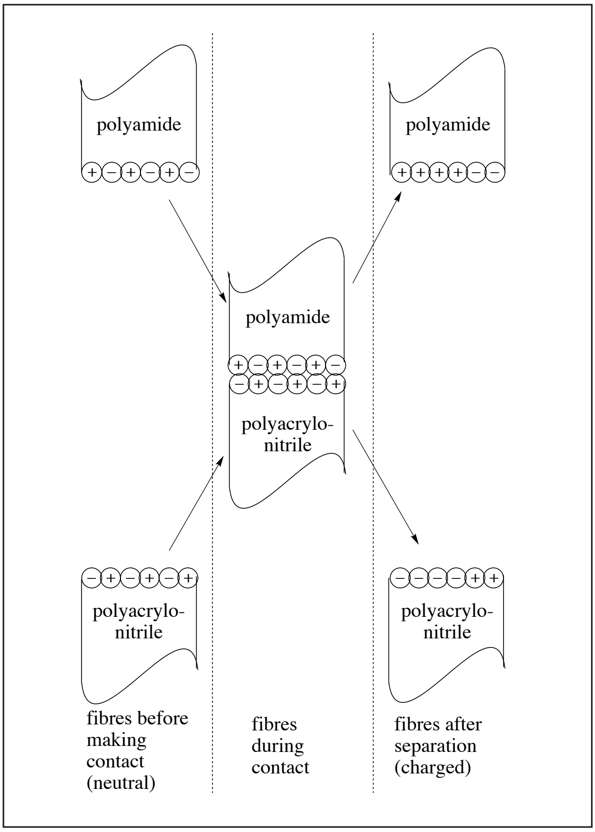

Fig. 2: Electrostatic charge separation.

On the surface of a body the molecular charge distribution is no longer in equilibrium. The mutual interplay between nucleus and electron sheath is disturbed at the boundary layer, resulting in a specific surface potential which is dependent on various factors, e.g. on the polarisation potential of the molecules, i.e. on the mutual transferability of the positive and negative charge focal point, on the orientation of the molecules to the surface, and their packing density. If now the surfaces of two different bodies come into mutual contact, the two electrical field margins overlap. A double electric layer forms, corresponding to the difference between the two surface potentials, the distance apart of the opposing surface points and the size of the area in contact. After subsequent separation, the body with the higher permittivity carries the positive charge. This can be simply illustrated if two materials of polyamide and polyacrylonitrile are rubbed together (Fig. 2). The electrostatic charge is a surface effect, permittivity on the other hand is a dimension which comprises the total volume of the body. Deposits on the surface of the fibre material, which need only be present in a molecular layer, such as humidity, impurities, surfactants etc. for example, can significantly affect the charge polarity sign and level, while the electrical characteristics of the material are hardly affected by it.

Electrostatic charge elimination Can be achieved by:

I. The deposition of chemical substances which increase the conductivity of the substrate to which they are applied, thereby increasing the mobility of ions through the material. Such substances include: polyhydric alcohols, polyethylene glycol derivatives, organic nitrogen compounds such as amines, ammonium salts, amides, etc., as well as derivatives of phosphoric and sulphuric acids.

II. The topical application of → Antistatic agents: in general, cationic and amphoteric antistatics are more effective than anionic and non-ionic types. The presence of an antistatic causes the formation of a thin but uniform film of moisture on the fibre surface which consequently increases its conductivity.

III. Metallic needles and brushes are brought into close proximity to the surface to be neutralized without actual contact. Provided the electrostatic charge is sufficiently high, it will be discharged discontinuously.

IV. → Ionizers.

Electrostatic charge, measurement of Electrostatic charges disrupt both the production and use of textile products. Utilisation problems frequently involve safety interests, e.g. in flameproof zones, in computer areas, in handling fine-grain solids. When these utilisation dangers have to be evaluated, they are assessed on the basis of appropriate specifications regarding surface and volume resistance (DIN 54 345 T1; and, in accordance with DIN 54 345 T5, in the presence of conductive fibres), raising the question of the charge level at the centre point, which can be answered with adequate accuracy by means of resistance measurement. Electrostatic behaviour is not just a safety-relevant characteristic, but is also of importance as a material property, i.e. as a functional characteristic (similar to strength or air permeability) or as a product distinguishing feature. This can be the case for example in flocking, filtration (gas dedusting), in special (electrostatic) spinning processes, in the development and production of antistatic equipment, electrically conductive fibres and yarns, and also soiling process evaluation. From experience, the differentiability of surface resistance and penetration resistance characteristics is insufficient to allow electrostatic behaviour to be described as a material property with adequate precision. In the case of textiles containing conductive yarns or fibres, resistance measurements in accordance with DIN 54 345 T1 can produce physically absurd results. It should also be remembered that the local charge density on an electrically charged fabric surface can not only be inhomogeneous but that the character of the charge also varies locally (negative and positive charge islands).

Electrostatic behaviour is a typical product characteristic because of its distinct dependency on the textile make-up form. Its peculiarity consists of it being equally

- a material property,
- a surface property,
- a property markedly dependent on environmental conditions.

In describing electrostatic behaviour as a product characteristic, both charge capability and discharge behaviour have to be taken into account. Charge state and discharge behaviour can be described by known dimensions like charge and field strength and also by change relative to time, e.g. in half-life form. The charge on the sample to be tested can be the result of

- sliding friction and charge separation,
- charged particles deposited on the test specimen surface,
- a charge character suitable for ions (produced with the aid of corona electrodes, i.e. spray electrodes),
- by direct current voltage above 1 kV.

2 mechanisms play an important role in discharging:

- charge leakage conductance,
- charge decay (on the spot).

In this respect, half-life as a feature of discharge rate varies within extremely wide limits; it is approx. 0.1 s at the minimum, and weeks at the maximum. This data should be taken into account if the "electrostatic behaviour" product characteristic is to be reproducible and quantitatively characterized. If electrostatic behaviour is regarded as a product characteristic, the test component should obviously be charged under conditions close to the practical, friction being a possibility in many cases. Numerous test processes are open to choice if the resultant electrostatic behaviour, i.e. the effective triboelectric behaviour in a simulated wear test, is to be characterized, the test specimen surface being subjected once or a number of times to frictional stress, producing charges the number of which depends among other things on friction duration and discharge rate (Fig. 1). Some triboelectric behaviour characterizing processes have been standardized, including for example:

- DIN 53 486 for laminates, e.g. conveyor belts;
- DIN 54 345 T2 for textile floor coverings;
- DIN 54 345 T4 for textiles in general.

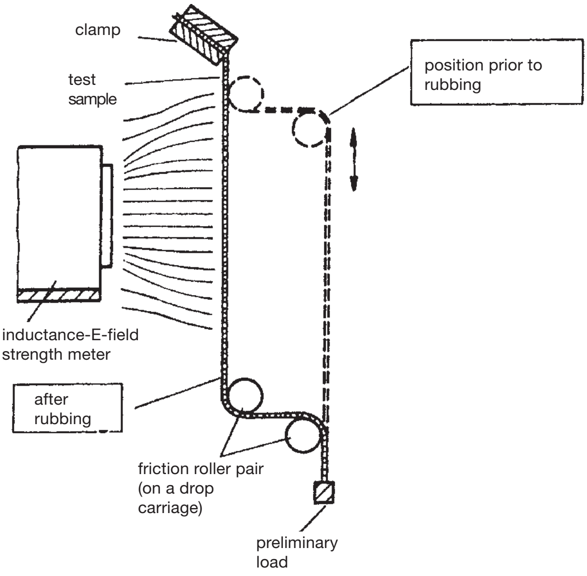

Fig. 1: Schematic diagram of the test set-up in the triboelectric behaviour determining process.

The principle of throwing charged test samples quickly into a Faraday beaker after a friction process, and measuring their voltage is not only described in DIN 54 345 T4 but also by two Japanese standards particularly specified for clean room textiles: JIS L 1094-1980 and JIS T 8818-1983.

In the so-called "Cling test" (AATCC Method No. 115) too, the test sample is charged by friction. It is not of course the field strength or the charge which is used as the criterion but the adhesive tendency of the test sample to a standardized surface. Another charging principle is discussed as an alternative to friction stressing: the "corona" effect, where a test sample, first of all discharged, is charged with spray electrode ions and its discharge behaviour evaluated.

In addition to the above-mentioned standardized processes, there are other methods: in measuring triboelectric behaviour, the experiments concentrated on a single friction process of short duration. Considerable information loss is feared with multiple rubbing or longer duration rubbing of a test sample unit: with multiple rubbing and with longer-term rubbing of the same test sample unit, charging and discharging processes overlie each other in a way which is impossible to monitor. The disadvantageous effect of this overlapping is expressed for example with conveyor belts when testing is effected in accordance with DIN 53 486. These overlapping influences are again reflected in the considerable effect of a walk test in accordance with DIN 54 345 T2.

The following needs go beyond the obligatory requirements for reproducibility, comparability and calibration facility:

- single rubbing process;
- short-term contact between frictional body and test sample;
- short total rubbing process period in order to be able to keep the overlap of charging and the onset of discharging at a minimum;
- rubbing speed: depending on the sliding friction level of the sample to be tested in each case;
- recording both charge and discharge behaviour.

The last-named requirement is essential, because electrostatic behaviour can only be meaningfully recorded in terms of both values. With regard to normal wear factors, a low discharge rate always conceals the danger that the charge level will be disturbingly high. Independently of the charge level, a low discharge rate is therefore regarded as particularly critical.

The following process has been developed with regard to these requirements (Fig. 1): the test sample, one end clamped in an earthed clamping unit, is subjected to a single frictional stress process with the aid of a controlled low-friction drop carriage. Field strength relative to time is measured by an electrostatic induction field meter positioned near the test sample (Fig. 2). The following parameters are used:

1. the field strength level E_0 (maximum field strength) attained at the end of the rubbing process as a measure of charging capability.

2. the discharge rate characterized by the half-life or by the residual field strength (E_{30}) attained after 0.5 min.

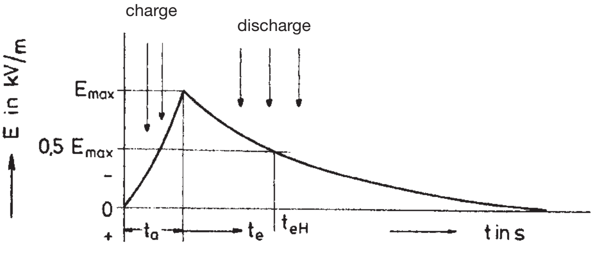

Fig. 2: Typical measurement graph for evaluating the charge and discharge capability of a test sample in the triboelectric behaviour determining process.
t_a = charge period; t_e = discharge period; t_{eH} = discharge half-life; E = electric field strength (kV/m); E_{max} = maximum charge.

In this type of test, numerous influencing factors play an important role. They are controlled as far as possible: distance apart of test sample plane and field strength meter: adjustable; standard 55 mm. An "electrostatic induction E field strength meter" (Eltex-Elektrostatik GmbH) is used. Drop carriage mass: 1 kg. friction roller: as required; standard: 2 x 15 mm diameter cylindrical polyethylene rollers (HDPE = low friction level and low charge capability). Effective test sample length: 150 mm. Test sample width: 50 mm. Preliminary test sample load: depending on fabric: woven fabric 1.3 N/50 mm. Test sample discharge before testing with the aid of a spray electrode. Despite these measures, different friction levels cannot be prevented from occurring in the test (depending on the fabric to be tested in each case). Whether this difference in level has an effect on the maximum field strength depends again on triboelectric behaviour: fabrics with a high charge tendency vary their field strength maximum relative to the friction level (this maximum increases as the friction level rises). This factor is not process-determined, but is a result of electrostatic behaviour mechanisms and of the requirement for simulating frictional conditions closely similar to those in use. As we know, ambient conditions have a considerable effect on electrostatic behaviour, and are also adapted to the conditions of use in each case (standard test atmosphere 22°C and 50% relative humidity). Although this air humidity level is comparatively high (DIN 54 345 T1: 25% relative air humidity), the test process is capable of a high degree of differentiation even under those conditions (contributed by Ehrler and Schmeer-Lioe).

Electrostatic filters The separation of exhaust air pollutants can be intensified by means of electrostatically charged filtration media. Since the discovery of the „Hansen filter“ in 1930 it has been known that, be-

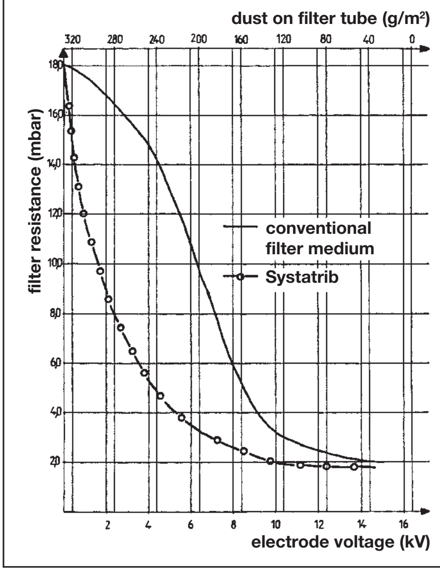

Fig. 1: Effect of electrode voltage on filter resistance.

sides other separation mechanisms such as diffusion, inertia, gravitational force and blocking effects, electrostatic forces have a great influence on the separation performance of fibre filters (Fig.1). Synthetic fibres, in particular, are susceptible to electrostatic charges. Despite having been known for a long time, the exploitation of electrostatic forces in fibre filters only achieved significance in the middle of the 1970s. However, in electrostatic fibre filters the charges on the electrostatically-charged fibres are of a semi-permanent nature only.

Despite the significant structural surface of synthetic fibres in the fine and very fine titre range, actual test bed investigations have revealed that the natural, i.e. production-determined morphology of synthetic fibres used in modern filter media is insufficient by itself to fulfil the requirements relating to separation efficiency and filter resistance. It is only possible to meet these requirements if a sufficiently large filtration surface is available together with an appropriate cleaning system for regeneration of the filter. Even the naturally available and detectable electrostatic influencing variable normally present in all synthetic fibres and dusts is incapable of meeting all the requirements on its own, although it is known that

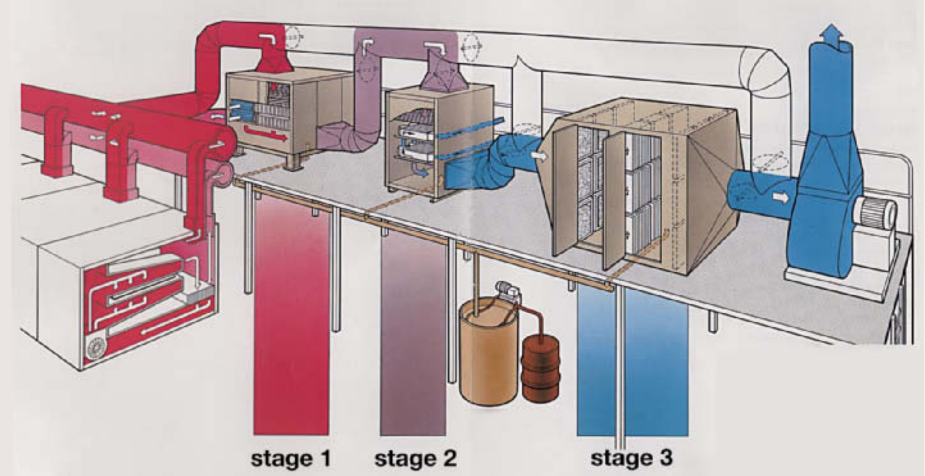

Fig. 2: Electrofilter as stage 3 in a Behr stenter exhaust air cleaning plant.

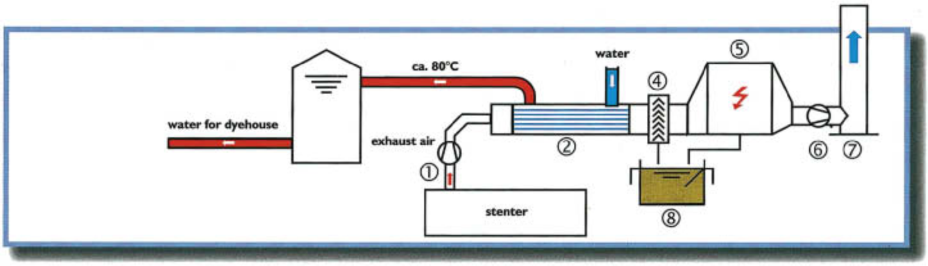

Fig. 3: Condenser air/water with mist collector and electrostatic precipitator (e.g. water heating for dyehouse).

the exploitation of electrical or electrostatic forces improves separation as well as the storage capacity and regeneration properties. It is for this reason that the combined application of an electrostatic filter with other methods of exhaust air cleaning is recommended for optimum performance (Figs. 2–5).

Electrostatic generator Device used as a source of high tension for electrostatic flocking and flock printing. When connected to an alternating current supply (100–250 V) it delivers a high tension direct current (approx. 20–100 kV) which, depending on the equipment, can be regulated steplessly. Energy consumption is generally low and less than 200 W/h. Various models are available commercially, either as single units or integrated units in complete plants. Electrostatic generators are now supplied with a safety relay which provides protection against short stoppages, accidental contact, and overloads by means of an automatic circuit breaker.

Electrostatic series → Electrostatic charge.

Electrovalency → Ionic bond.

Electroviscous liquids (EVF), liquids based on silicone oils which contain a suspension of fine, non-metallic hydrophilic particles with a low proportion of adsorbed water. These suspensions have the quality of changing their viscosity within milliseconds. Depending on the strength of the electrical field applied, the viscosity can be modified from free-flowing to a congealed, plastic state. In order to congeal an EVF, relatively high field strengths of several kV/mm are needed, but the currents are very low, so that the electrical output (several watts) of a standard commercial high-voltage module is usually adequate.

To explain the electroviscous effect, the particles in suspension should be envisaged with an electrical charge and surrounded by a diffuse cloud of counterion. By applying an electrical field the clouds of ions are distorted to such an extent that they overlap. Thus the particles restrict each other's movement, manifested as an increase in viscosity. The effect may also, however, be explained by the solid particles assuming an ordered arrangement in the electrical field (formation of chains).

Because of this property, the EVFs have numerous applications in industry and engineering, especially in situations where mechanical forces are transferred hydraulically and need to be controlled by electronic switching with low electrical rating. A particular feature of EVFs is that they are particularly compatible with and stable in the presence of elastomer materials, have a high flash point (>250°C, DIN 51376), are physiologically safe and environmentaly friendly. In addition, they are resistant to cold and heat across a wide temperature range, and their electroviscous property is only dependent on temperature to a relatively slight extent.

Elementary fibrils → Fibrils.

Elementary filament (Filament, single fibre, filament fibre, capillary filament). A virtually continuous structural component of the → Filament yarn, i.e. in the case of silk, the fibroin thread, in the case of man-made filaments, the continuous filament formed by extrusion through the individual spinneret holes.

Elements Chemical "raw materials" consisting entirely of → Atom of the same → Atomic number, and which cannot be decomposed into simpler substances by normal chemical methods. At present, 104 elements are known of which 92 occur in nature. The → Periodic system of the elements begins with the lightest, hydrogen, and ends with the heaviest, Kurtschatow. Elements are the building blocks of all chemical compounds and are subdivided into → Non-metals and → Metals.

Elevated temperature dyeing machine A description for low pressure dyeing machines (winches, yarn dyeing machines) which, in contrast to HT-dyeing machines, only permit dyeing temperatures up to a maximum of 106/108°C.

Elimination potential (Lat.: eliminare = remove, leach). Elimination is used, for example, to describe the removal of the impurity content of effluents in treatment plant (see Fig.). The term does not imply whether the substances removed are biologically degraded or adsorbed on to sludge. Even in the case of elimination by biodegradation, polluting metabolites could arise from the original substances.

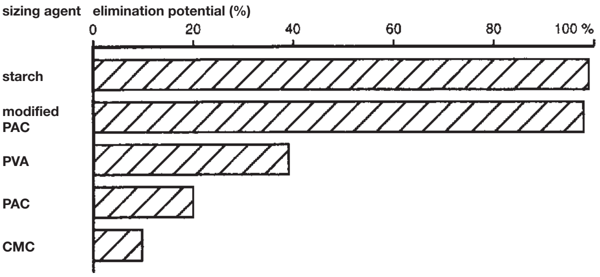

Fig.: Biological elimination potential of sizing agents (source: Sandoz).

Starch, alone or in combination with other products, is still the preferred sizing agent. It is clear from the Fig. that certain sizing agents are only eliminated, and should therefore be replaced by other, more degradable products. Polysaccharides, which include starch, will be of growing significance in future due to their good biodegradability.

Elmendorf tear strength tester A test apparatus originally designed to determine the tearing strength of paper, but which is now specified as a standard test (BS 4253:1967 (1986); ASTM D 1424-83; M & S P-29) to measure the tearing strength of very lightweight fabrics and resin-finished apparel fabrics. A trapezoidal fabric test specimen is employed.

ELMO, abbrev. for: European Laundry and Drycleaning Machinery Manufacturers Organization, Brussels.

Elongation Simultaneous extension which arises during the → Tensile strength test and leads to a break. The elongation at break is expressed as a percentage. It is derived from the (reversible) elastic elongation and the (irreversible) permanent stretch (→ Elasticity of elongation). →: Tensile strength; Fibre strength.

Clothing restricts the freedom of movement of the wearer. According to the activities carried out, certain elongation demands are made at particular points of the garment (Fig. 1). The cut of a garment, especially whether it is close-fitting or loose-fitting, is of essential importance in determining the type and extent of the elastic elongation properties. In principle, close-fitting garments require two-way stretch, whilst elasticity in one direction only is better suited to a more loose-fitting garment.

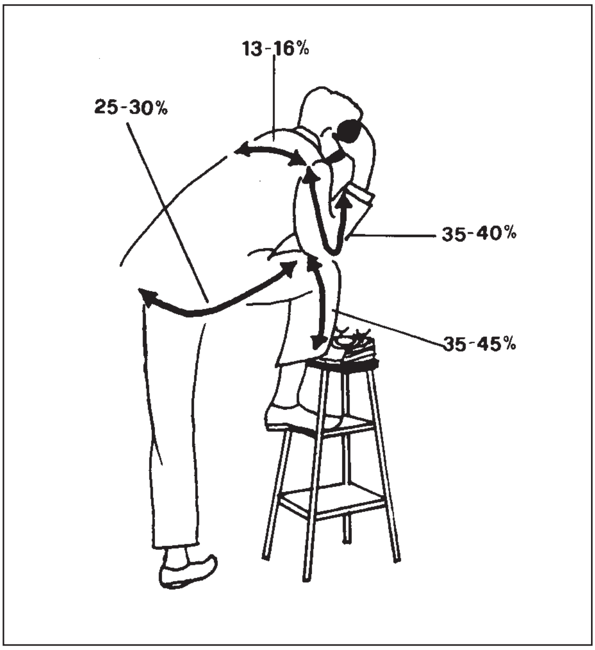

Fig. 1: Example of posture showing the relevant elongation behaviour of clothing.

The drape of the fabric, the factor which determines the aesthetic appearance of the garment, is only sufficiently evident in the case of unidirectional elasticity. Two-way stretch fabrics are more comparable in character to knitted goods.

The elasticity of fabrics made from polyester/elastomer blends is developed by a hot wet finishing treatment. The fabric thereby contracts until all the picks are close together (Fig. 2). If the fibre density now needs to be opened out, thus making the fabric lighter, or the width increased in the case of a filling sateen, the fabric can be heat set under tension. Consideration must, however, be given to the fact that during heat setting a degree of strength, specifically of the elastomer fibres, is permanently lost, thus having a considerable effect on the properties of elastic recovery. It is therefore important to adjust the composition of the fabric accordingly.

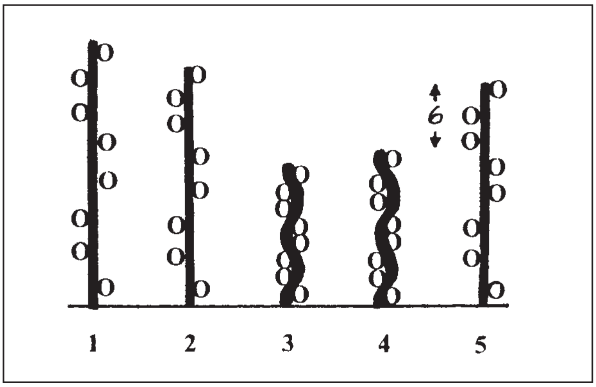

Fig. 2: Changes to the warp length and position of the weft following finishing processes.
1 = as on loom; 2 = off the loom; 3 = boiled; 4 = finished, relaxed; 5 = finished, stretched; 6 = elasticity.

In addition to heat setting temperature and duration, the degree of elongation of a textile fabric during heat treatment is essentially influenced by the later service properties. The elongation or a certain elongation property during processing is also determined indirectly by testing using the usual methods. A change in length is marked on an external device (e.g. stenter frame, elongation testing equipment) and is applied as actual elongation of the test subject along its full length. It is at the stage of correcting the width of the goods when the edge – middle – edge elongation profiles arise, which can have a negative effect on the properties of the textile.

It may be that case that a fibre is required to contribute to the stability of form of a fabric. It is then recommended that fibres are used with a higher modulus of elasticity. For example, fibre type A (Fig. 3) is more

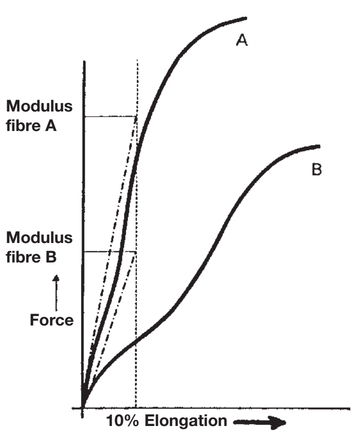

Fig. 3: Two fabrics with varying elongation properties (moduli).

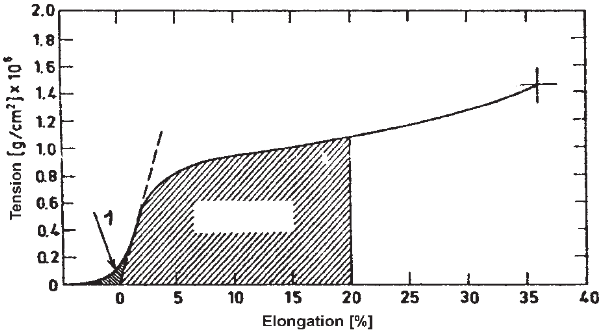

Fig. 4: A typical stress-strain curve for wool with de-crimping region (1), Hooke's area, yield and post-yield region. Hatched area: Stretch recovery at 20% elongation.

stable than B under the application of lower deformation forces. Whether this advantage has an effect depends to a great extent on the design of the goods, i.e. in particular the type and number of the crossing points.

Of course, the change in fibre microstructure is reflected in the elongation of the modulus (mechanochemistry). Thus wool has a greater tendency towards attaining its elongated condition the damper it is. If a wool fibre, having passed through the de-crimping region, is stretched in cold water, it will follow Hooke's Law of linear stretch, up to a change in length of 2%. At this point it enters the yield region, which extends to a change in length up to 30% (Fig. 4). During this elongation process the radiogram of the wool changes critically: within the microfibrils the α-keratin in the form of the α helical structure is reversibly transformed into β-keratin in a folded structure (Fig. 5).

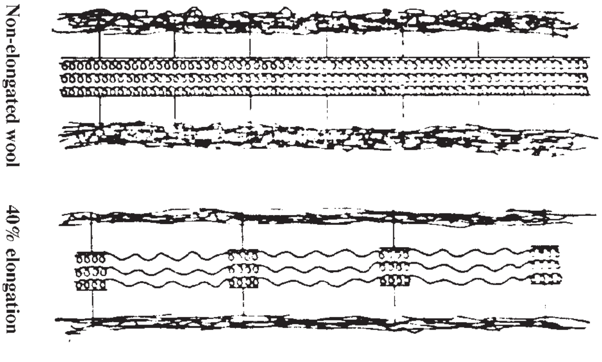

Fig. 5: Two-phase model of the polypeptide chain molecules in wool which is not elongated and wool elongated by 40%. The partially crystalline microfibrils contain helical chains (a-helices). The amorphous regions (matrix) consist of partially oriented chain bundles.

Elongation at break The quotient of the change in length (→ Elongation) and the original length obtained in a → Tensile strength test. In practical tests it is the increase in length when the last component of the specimen breaks.

Eluent (eluting agent). An auxiliary consisting of pure solvent or a multicomponent solvent mixture used in → Chromatography. The glass separation vessels used in chromatography (normally circular for paper chromatography and of square section for thin layer chromatography) are filled with 50–100 ml (approx. 5–10 mm height). All tests should be conducted at a constant room temperature. Depending on carrier and eluent, the running time is variable.

Embossed transfer printing paper Transfer printing paper with an embossed effect which is "permanently" fixed in the textile material after transfer printing.

Embossing (Embossed finish, goffering, gauffering, fluting, schreiner finish, silk finish, high-lustre finish), impressing of patterns on normally smooth textile surfaces, produced under high pressure and at high temperature on the →: Embossing calender (Fig. 1); Schreiner calender, etc., between a heated embossing cylinder and a mating or elastic counter roll. Distinction is made between embossing of unfinished fabric (fast to washing and ironing) for special crepe fabric (→ Creping) and embossing of finished fabric. The latter applies chiefly to cellulosic fabrics. It is only through resin finishing agents (preferably melamine formaldehyde compounds, reactant resins) that a permanent embossed finish (e.g. Everglaze™) is produced. This provides a good opportunity for dimensionally stable finishes, which can be just as resistant to laundering and dry-cleaning as they are remarkably creaseproof and shrinkproof at the same time. Typical embossed finishes include:

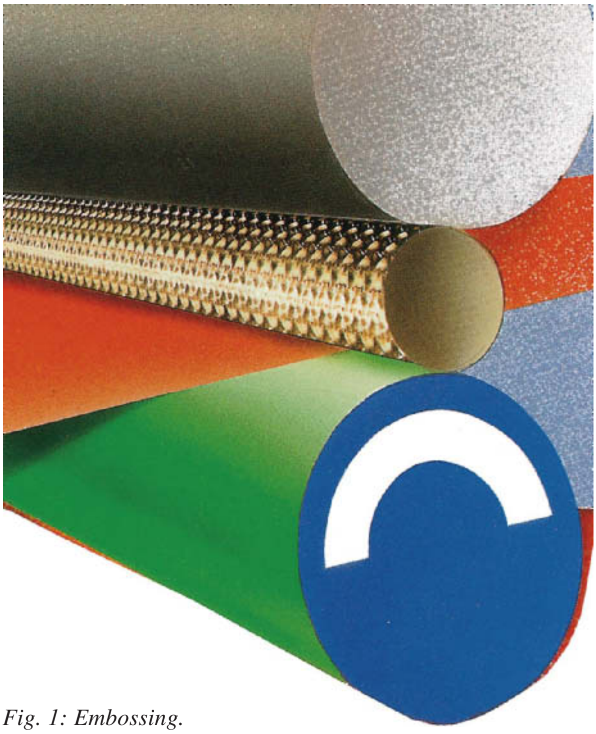

Fig. 1: Embossing.

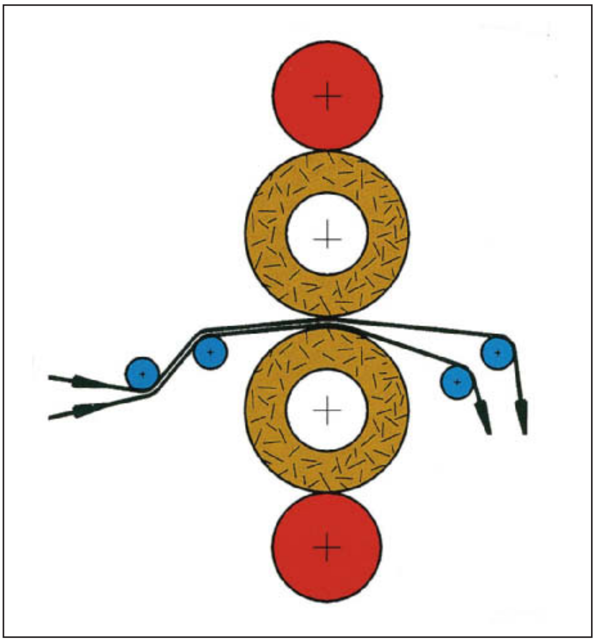

Fig. 2: Embossing with smooth paper-rolls.

I. Deep embossed finishes: Simulated weave designs produced by relief engraving (e.g. honeycomb piqué), geometric motifs, figured designs and the like (Figs. 3 + 4).

II. Silk finish: Not produced by the fabric design but rather light reflectances resulting from imprinting fine ripple lines ranging from a soft, silky matt shimmer to a high lustre, associated with virtually all possible handle variations (via the schreiner calender).

III. "Echolux" finishes: A type of silk finish involving light-and-shadow effects created by the diverse directions of the ripple lines defined by the design.

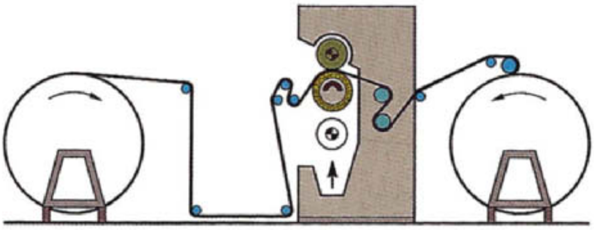

Fig. 3: 3-Roll Calender, Schreinerfinish or other embossing effects.

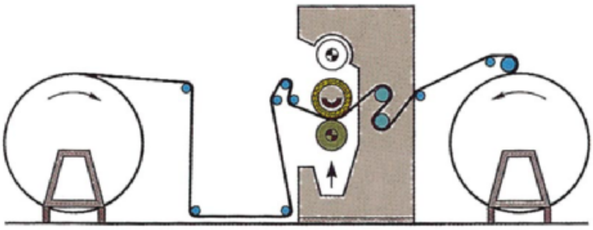

Fig. 4: 3-Roll Calender, mat-, rolling-, smoothing-, glazing-, Chintz or a further embossing effect.

IV. Embossed moiré finish: Varied matt-lustre patterned finishes created by fluted embossing (→ Moiring) (Fig. 5).

V. Lustre finishes: Vary in extent and definition, ripple lines follow the design or fill out the design areas framed by contours.

VI. Ciré finishes: Produced (in contrast to II.–IV.) not by fluted engraving, but by relief engraving with a smooth surface, which involves operating against smooth, relatively hard mating rolls (ciré calender with a heated engraved steel roll, a cotton roll and, to retain the smooth finish, a heated plain steel roll), in other words without forming a reverse image. The design is "fused in" between the smooth faces of the embossing cylinder and the cotton roll (e.g. into acetate fabric). With moiré relief engraving: ciré moiré finish.

VII. Embossed finishes: Simulated lace and embroidery and burnt-out patterns (finely perforated contours and burnt-out designs), also delightful combination effects (burning-out and embossing, or printing and burning-out and embossing) on, acetate and synthetic textiles, produced on the same calender with steel roll relief engraving and at high temperatures (electric heating).

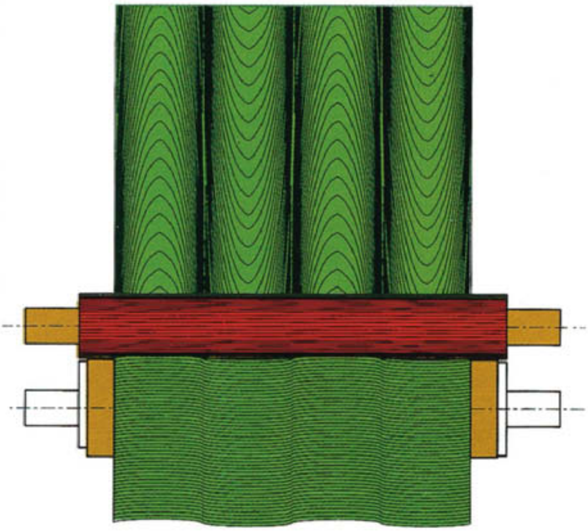

Fig. 5: Genuine Moiré Effects with corrugated roll.

VIII. Colour embossed finishes, etc. (→ Emboss printing) also represent a valuable option for creating sophisticated designs.

Suitable fabrics: Generally bleached, dyed or printed fabric of even wetting capacity, singed, possibly with preliminary finish but chemically unmodified. Loss in tensile strength: min. 10–30% (weft normally more at risk), largely dependent on and controllable via suitable fibre quality (long-staple cotton, fine yarn), weave density (not too loose) and, above all, residual moisture prior to embossing (observe guide values).

Delustring impairs the embossing efficiency on viscose fabric; wash resistance of the finishes generally inferior to cotton.

For embossing in particular a variable adjustment of the working pressure is necessary. The working pressure is dependent upon the quality of the fabric and also the embossing design because of the different pressing areas given by each design. Moreover the requirement of even pressure across the full width should not be neglected.

Embossing calender (goffering calender, crêping calender), is used for → Embossing pattern designs on woven fabric surfaces. It consists in principle (similar to → Schreiner calender) of two rollers: heated top steel roller (pattern engraving mainly in relief, more rarely indented) and elastic cotton or paper counter roller below (both linked by 2:1 gearing). The negative pattern is impressed into the paper roller against the steel roller by → Conditioning of calender bowls. For colour embossing, additional equipment with colour unit, as may be required, at the fabric entry end (colour embossing unit, dyes deeper places during embossing, i.e. embossed ground; colour paste drying by the heated steel roller during embossing) and at the fabric exit end (cross-dyeing unit, dyes high spots immediately after embossing; additional infra-red drying for example before fabric batching). On its way to the batcher, the hot fabric runs over a driven chromed cooling roller on leaving the embossing nip. A double let-off and batching system is provided for the back paper which is additionally necessary for colour embossing and overdyeing.

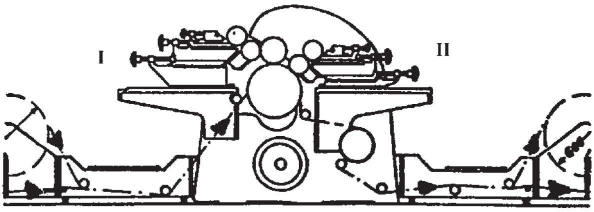

Fig.: Kleinewefers KTM pneumatic embossing calender. I = colour embossing unit, II = over-dyeing unit.

Multipurpose embossing calenders (Fig.) are commonly used for preference, practically every type of embossing and every fabric being possible with the aid of accelerated top engraved roller changing (less than 30 min.) (eccentric snap lock), e.g. the following combinations (figures denote max. pressure):

- 10 tonnes for viscose crêpe, burnt out and ciré effects (three rollers),
- 20 tonnes for additional moiré effects and permanent embossing,
- 30 tonnes (50 tonnes) for additional schreiner finish (special requirements).

Heaviest models (30 tonnes, 50 tonnes) should be equipped for chintz effects with additional bottom roller drive (0–200% or 1:1–3:1 stepless degree of friction control. Colour units can be fitted to all models, (with eccentric quick lift unit, steplessly controlled). Hydraulic-pneumatic pressure control (quick pressure relief potentiality for seams, also automatic). Operating speed can be controlled between 6 and 30 m/min. Heating by steam, gas or electricity.

Embossing felt Usually tubular wool felt, 7–9 mm thick multiple fabric, for heated cylinders, ironing presses, etc. → Tubular felt.

Embossing foil To produce shadow effects, transparent embossing foils with a granular surface are used for colour separations. They are laid on the design and the drawing is transferred with a suitable chalk. The shadow effects are created by applying heavy and light pressure when tracing.

Emboss printing (Relief or surface printing), offers various application options for producing single- or multi-coloured print designs alongside or combined with permanent embossed finishes, for example:

I. Localized emboss (colour) printing: Principle of a local synthetic resin application (by means of roller or screen printing), which is embossed in the customary way on the → Embossing calender and then cured. This produces a washproof design fixed on the synthetic resin sites, similar to → Chintz printing, and is a coloration process provided that the synthetic-resin precondensate printing paste contains suitable colorants. Printing is followed by predry, emboss, dwell, cure, etc.

II. Tip printing: Only the surface of the embossed sites of the fabric is dyed on the embossing calender directly after embossing, namely by means of an overdyeing unit situated on the cloth delivery end. An intensified relief effect is relatively easily obtained by this process. Localized tip-dyed effects can also be produced with suitably engraved rollers.

III. Deep emboss printing: Coloured embossed finishes in which the embossing roller on the embossing calender operates simultaneously as a printing roller. Immediately before embossing, the upper areas of the heated relief roller are supplied with dye paste by means of a colour embosser situated at the cloth entry end and this paste then spreads straightaway into the embossed, deep parts of the fabric. Only suitably heat-resistant emboss printing pastes can be used for this purpose. To prevent any soiling of the paper roller serving as a matrix, a paper backing sheet or similar is used in the embossing process.

Unlike I.–III. the combination of first print and subsequent embossing over the entire fabric surface should not be regarded as genuine emboss printing technique.

Emerizing Surface character processing of woven or knitted fabric. Through emerizing, the fabric structure is masked by a fine pile without destroying the knitted or woven construction. The effect is dependent on yarn and fabric structure. The shorter and finer the fibres in the yarn, the easier it is to produce a better pile. The finishing stages preceding emerizing also have an effect.

Two different machine types are available in practice for surface changing mechanical finishing: multi-roller machines for surface emerizing or single-roller machines for → Sanding. In the first case, the tensioned fabric is drawn over four to seven emery paper covered rollers which rotate with or against the fabric run, the fabric rubbing against the emery surface under more or less adjustable contact pressure. Through emerizing, projecting fibres are split open, producing a velvet-like but very low fibre pile. The effect is also finer or coarser relative to emery grain size. Many products are emerized first of all on relatively coarse and then on fine emery rollers. In the case of woven microfibre fabrics however, the reverse sequence is more successful. In practice, multi-roller machines offer significant advantages over single-roller machines:

- yarn knots can avoid contact, and, at a relevant setting, are not emerized and opened up.
- the emerizing rollers are hardly heated. This makes for a longer emery paper service life.
- the mechanical energy is distributed over the number of emerizing points, and is therefore lower.

In the case of single roller machines, the sanding depth can be precisely adjusted, although all thickness differences are ground down. This means that yarn knots are opened up, and proud selvedges and fabric edges can be ground off and destroyed. Natural thickness differences in the material (e.g. tight warp ends and shrinkage differences) are increased, limiting the application potential of this machine. The multi-roller machine offers greater potential for variation. Only part of the total emerizing energy required is transmitted to each roller. Individual roller coverings can differ in grain size, and a choice of different running directions is possible. Finishing works with a constantly changing product range and special customer requirements should therefore operate predominantly with multi-roller machines.

Emerizing technology has learnt and adopted a great deal from raising. The illustration (Fig. 1) shows how to achieve optimum emerizing effects, and indicates the direction of rotation of the emerizing rollers relative to the fabric direction. With the majority of products, the first roller is allowed to run counter to the fabric direction, raising the weft ends. The second roller then runs in the fabric direction, emerizing the raised weft. The third roller again runs counter in order to intensify the process. Rollers four and five again turn in the fabric direction in order to subject the emerized pile to a light brushing process. Uniformly higher fabric tension is employed with microfibres and fine-fibril yarns, allowing them to make only light contact with the emerizing rollers (tangential contact).

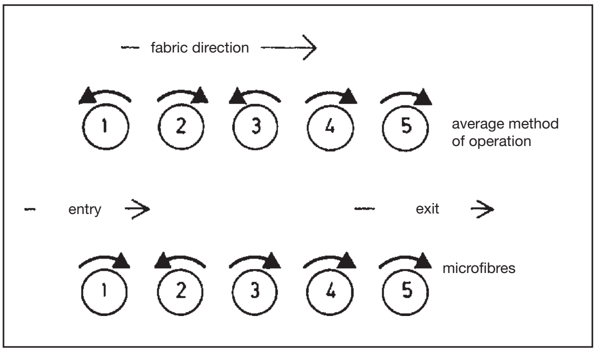

Fig. 1: Optimum emerizing effects, direction of emerizing roller rotation relative to fabric direction (Menschner).

The individual emerizing rollers can be obtained in two versions – cylindrical and lattice rollers. Lattice rollers raise, emerize and brush the weft with an intensive mechanical action. Suitable paper granulation for this purpose is within the 80 to 120 range. This intensive mechanical action is not recommended for women's outerwear fashion fabric. The zone between "too weak" and "good tear strength" is then so narrow that it can no longer be controlled with certainty.

Lattice rollers are of advantage when plain cotton, viscose or woollen piece goods are to be emerized for a "woollier" effect. Cylinder rollers are preferred for microfibre qualities, as the mechanical action on the fabric is not so intensive. Silk or high/low jacquard woven fabrics can only be emerized with solid rollers. Cylinder roller emerizing machines are so silent that only the noise level of the extractor is of any consequence. In practice, the possibility of changing individual emerizing rollers is regarded as a great advantage. The table summarizes and compares operating data.

The emerizing machine is a "shredding" tool. With a coarse tool (80–120 granulation), the floating weft ends can be picked up and raised. The end is subsequently pulled open, and then brushed in the required direction.

	cylinder roller	lattice roller
fields of application	silk, low-high jaquard woven fabric lightweight women's outerwear products (100–180 g/m^2)	plain cotton/viscose or wool piece goods over 200 g/m^2 (mainly coarse graining: 80–120)
noise	very low level	high level
grain size	280/320 with lightweight women's outerwear qualities, 400/500/600 with fine-fibril polyester yarns and microfibres	80–120

Tab.: Comparison of cylindrical and lattice emerizing roller operating data.

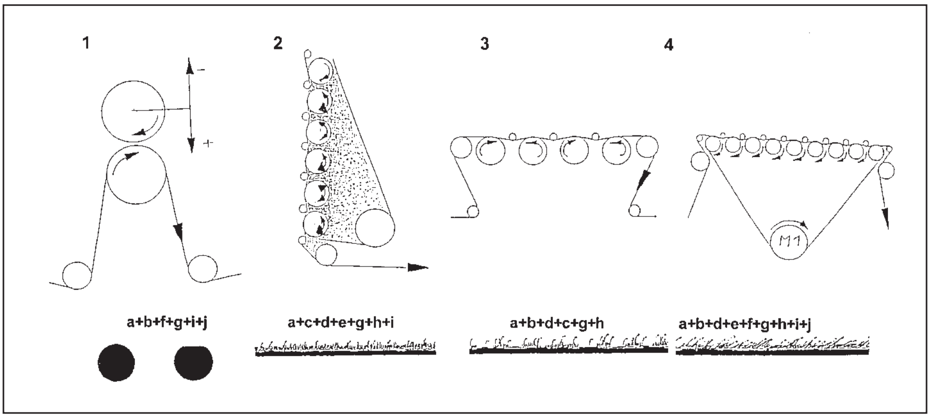

Fig. 2: Various systems of Emerizing/Sueding involving following problems. a = tension problems; b = fabric strength; c = dust back to the fabric; d = high temperature (pilling); e = only long pile; f = one way emerizing only; g = emery paper only short time; h = difficult for micro fibre; i = not for elastic fabrics; j = stripes and marks (no oscillation).

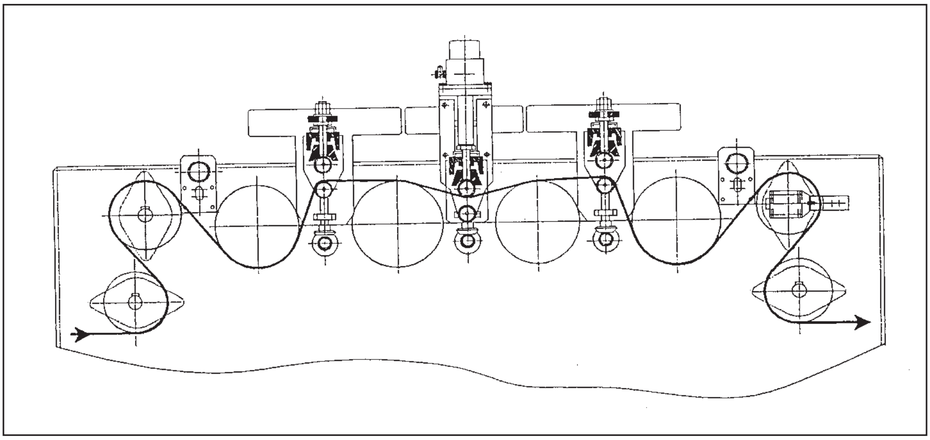

Fig. 3: Fabric feed for knitted goods.

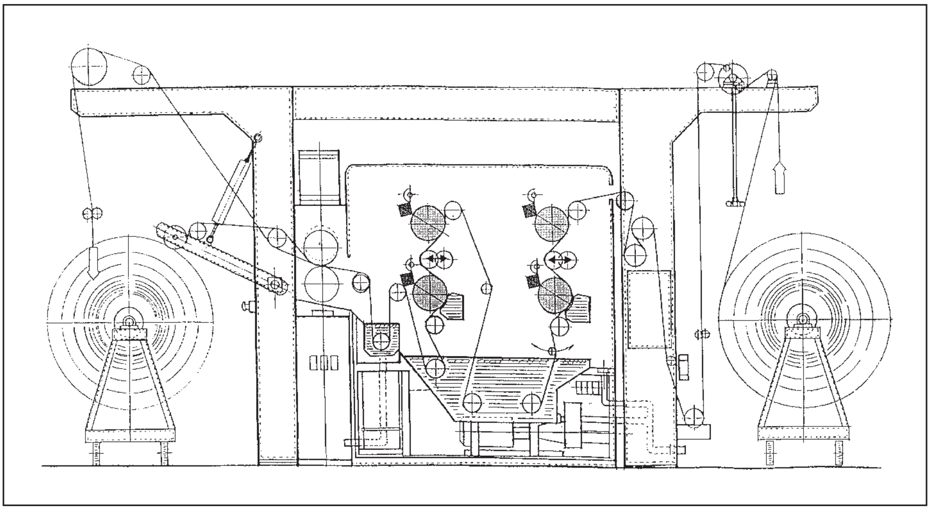

Fig. 4: Wet sueding unit (BM 4 from Naigai/Japan).

The result of this coarse grain processing is a denser, longer pile. If woven cotton or wool fabrics come out too boardy, while a “woolly surface” is required, a grain size between 80 and 120 should be used. Lattice rollers produce the best effects here, and they are therefore mostly covered with coarse paper. Lightweight women’s outerwear products weighing between 100 and 180 g/m^2 should be given a short, dense pile. Grain sizes between 280 and 320 have proved effective with these types of fabric. Fine-fibril polyester yarns and microfibres are emerized with 400/500/600 grain sizes. Still finer grain sizes, around 600–800, are not normally used because they really “polish” rather than emerize.

Fabric tension in the actual emerizing zone is of decisive importance for a good emerizing effect (Fig. 2). It must be adjustable relative to the product and easily readable. Set tension values must be kept constant, and automatic readjustments made if the material stretches. It is particularly important that tension units, which may be located at the machine entry or exit, do not influence the emerizing effect (contributed by Riedel).

Emerizing can be carried out after bleaching and before dyeing. This has the advantage that the colour is not changed by subsequent emerizing (shade change). One disadvantage could be dyeing machine contamination by emery dust, or different fabric dyeing behaviour. Other users carry out this dry finishing as the final processing operation on the finished fabric, shade changes sometimes being targeted effects. With patterned woven fabric, e.g. shirtings, there is no shade change effect. It should be noted here though that the emerizing effect is reduced by subsequent permanent finishing. This has to be compensated for during emerizing by correspondingly more intensive processing.

On jeans fabric, the emerizing process should be carried out prior to sanforizing in order to guarantee the required residual shrinkage value of <1%. The sanforizing effect would be impaired by the fabric tension within the machine. Another emerizing application is the preparation of fabric for a subsequent raising process, in which the fibre capillaries pulled out of the spun yarn during processing can be more easily caught up by the raising fillet card wire points and further processed. This reduces the number of raising passages required. A classic example of this case is warp knitted interlinings (Fig. 3). From the textile technological standpoint, the application of a finish is necessary for both raising and emerizing. These softeners can be applied during the spinning process etc.

Different stages in which emerizing can be effected:

1. After bleaching, before dyeing, e.g. woven polyester microfilament fabrics.
2. After bleaching, before dyeing or in the finished product, e.g. the finish emerizing of outerwear fabrics, depending on the works' organisational structure and the type of effect aimed for.
3. Emerizing only on the finished product, e.g. scoured silk.
4. Emerizing as a preparatory process for raising, e.g. interlinings.
5. Wet emerizing (Fig. 4).

Emission (Latin: emissio = let out),

I. Radiation of electromagnetic waves by atoms or molecules. Antonym → Absorption. The radiation emission of all bodies has a fixed relationship for every wavelength, dependent only on wavelength and temperature to its absorption capacity for the same wavelength. By the total emission capacity of a radiator, we understand the relationship between the total radiation emitted and that of a black body at the same temperature. The spectral emission capacity of a body has the same value as the spectral absorption capacity. Emission bands (emission spectra) are so-called band spectra of coloured lines or bands or from a continuous coloured spectrum, as occur for example in fluorescence and luminescence. →: Reflectance; Optical brighteners.

II. Air impurities, noise, vibration, radiation and other phenomena coming from a plant (emitter). Typical example: tetrachloroethane in the exhaust air of a dry cleaning plant. In the case of chlorinated hydrocarbons, emission forms by far the largest proportion of solvent losses. Technical measures for preventing these losses are contained in VDI guideline 2280. In accordance with dry cleaning plant regulations (amendment to the 2nd BImSchG of 1990), these types of plant should not emit more than 30 ppm, and from 1993, 20 ppm of tetrachloroethane. Exhaust air emissions from stenters are another typical example. Emission measurement as vapour and gas concentrations in exhaust airflows (mg/m^3 or ppm) or as a pollution quantity in kg of solvent/hr or kg of solvent/tonne of fabric treated.

Emission register Expresses integrally (e.g. from the manufacture of a dye through its application to its behaviour on disposal) information on the emissions of a textile finishing agent (see Fig.).

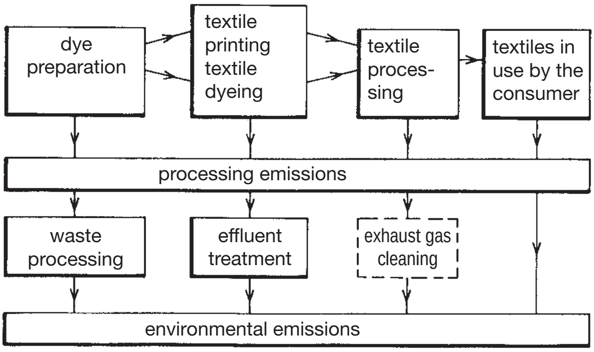

Fig.: Example of an emission register for a dye.

As a consequence of the tightening-up of environmental protection laws and the increasing awareness of the general public, the industry is obliged to undertake comprehensive ecological studies. The full analytical understanding of the present situation which is necessary to ensure compliance with the legal requirements is very difficult to achieve in the field of textile finishing because of the wide variation in substances and application methods used. For this reason, efforts are currently being made to establish time-saving yet meaningful emissions prognoses using theoretical estimates and simulation trials.

Emissions, measurement of in effluent or exhaust air. Precise exhaust air and exhaust gas measurements are used for example for establishing whether limits are exceeded. A variety of measurements are necessary of course for assessing plant effectiveness.

Emissions potential

Exhaust air emissions can be measured by various processes:

- exhaust air and gas quantity flow: Prandtl's pitot tube with bent tube manometer, revolving vane speedometer;
- temperature: thermocouples, resistance thermometer;
- pressure: box barometer;
- moisture: aspiration psychrometer, silica gel tube;
- oxygen: paramagnetic O_2 analysis;
- carbon monoxide: infra-red absorption;
- nitrogen oxides: chemiluminescence analysis;
- aldehydes (e.g. formaldehyde): test tube method, DNPH process, HPLC method;
- hydrochloric acid: wet chemically with NaOH;
- dust: gravimetric dust measurement;
- organic carbon: flame ionisation detector, silica gel adsorption;
- odour: sensory odour determination (olfactometry);
- individual organic components: gas chromatographic method, possibly with selective detectors;
- total harmful substance in the exhaust air (gases, vapours, aerosols, solid particles): cooling and condensation or admixture of dry, oil-free air to reduce moisture, heated filter and adsorption to silica gel.

One important measurement function is determining the concentration of organic components. In many cases, the substitute dimension of the "total quantity of organically bonded carbons" (total C) suffices instead of measuring the individual components. Special problems are still currently posed in measuring the hydrocarbon content in unpurified exhaust air, for here all kinds of unknown compounds (aerosols, solid particles, vapours etc.) can occur. The illustration shows by way of example emission and immission measurement on stenters.

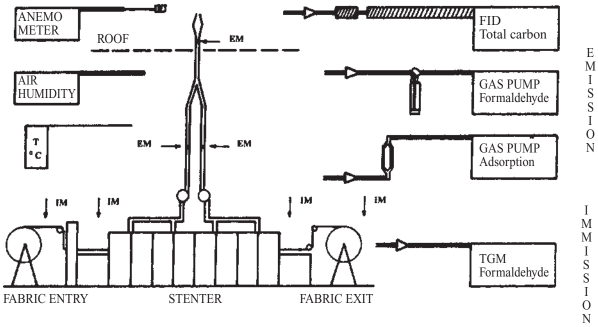

Fig.: Emission (EM) and immission (IM) measuring positions on stenters.

Emissions potential In the Federal Republic of Germany, the exhaust air situation is legally regulated by federal immission protection legislation (BImSchG). In the case of air emissions, specific mass flow and concentration limits are to be complied with irrespective of the legal emission protection status of the plant in question. The practical interpretation of these regulations is effected by the Technical Air Instructions. When the 4th Federal Immission Protection Directive (BImSchV) comes into use, it will be designed from experience, in that in the case of an industrial plant not only will the individual emission point in isolation form the basis of evaluation, but in all cases a combination of equipment with all its associated emission points, which can be based on a technical process. For the chemical finishing industry for example, this means that total organic mass flow limitation is effected not for a particular stenter but rather for the sum of all technical operation related exhaust air producing heat treatment machines. The most elegant possibility of reaching this situation would be a purely theoretical estimate of the emission potential of textile product and chemicals during a heat treatment process. With precise knowledge of the chemical product composition, and taking account of all parameters of a technical process nature, the potential emissions would have to be precisely projected. Such a plan runs aground first of all in that the finisher does not have precise information on the chemical formulae and product composition of textile auxiliary products and dyestuffs. The data relevant to this on the safety data sheets is inadequate for estimating emission potential (in effluent, exhaust air and waste).

A simpler equivalent is to outline the emission potential within a definite framework, e.g. in a low volume car interior. 80% of the heat in the car comes through the windows to produce a greenhouse effect by which endogenous emissions are increased. Individual temperature measurements revealed for example:

Air in the interior at head height	70°C
Instrument panel surface	105°C
Inside roof surface	67°C
Upholstery surface	48°C
Hat rack surface	108°C

Endogenous pollution sources are dyestuffs, paints, adhesives, sealing compounds, fuel evaporation from the tank and jerry can, fuel lines, anti-drumming materials, waxes, packing materials, and plastic and textile car furnishing materials; nor should those which are due to smoking (CO, NO_2, aldehydes, nitrosamines, smoke particles, polycyclic and aromatic hydrocarbons) remain unmentioned. Exogenous pollution sources are due to nature, occurring through human civilising practices, particularly road traffic itself. The outside air is of considerable secondary importance for the emission potential of interior fitting materials. The following applies to the chemistry in the passenger seats: the air in the interior can be no better than the outside air (despite the fact that forced ventilation produces six changes of air per minute).

Next Page

In this case, distinctions are to be drawn between air impurities according to their origin in car production, interior fittings (→ Fogging) and driving. Interior fittings represent an emission potential in two respects: on the one hand from the material standpoint and, on the other, as temporary emission and immission material media. Fitting materials consist of a variety of substances and 3-dimensional forms, e.g. injection moulded parts or textile coverings. These are based on plastics, elastomers and natural materials, as alloys and mixtures. They always contain additives. Corresponding to this width of variation, the emissions are also multilateral, particularly in terms of type and quantity; the number of product types could be well over 1000.

Discovery of the emission potential of a material, and consequently the strategies for preventing emission from interior fitting materials, necessitates a special type of analysis (FMEA = Failure Mode and Effectiveness Analysis). It has a reference to simultaneous engineering, and must be continual because there may be interference. Chemical technology identifies those effects and possibilities of intervention relating to the raw materials which have to be taken into account in processing the material components, and can ultimately be relevant in use, i.e. in material ageing. A simple FMEA for plastics runs from the monomers through the polymers and also additives up to processing. Once again, additions can be made here too. In the end, the actual usage requirements become significant (according to Eisele).

E modulus Modulus of elasticity; → Tensile elasticity.

EMPA, abbrev. for: Eidgenössische Materialprüfungs- und Versuchsanstalt, Zürich and St. Gallen (Swiss Institute for Material Testing and Research Centre); → Technical and professional organizations.

Empirical formula (molecular formula, total molecular formula, total formula) → Formula, chemical.

Empirical formula, total molecular formula Modulus of elasticity; → Tensile elasticity.

Empirical test for water repellency (Non standardised test). A rapid and demanding assessment for water repellency often used by garment manufacturers. Literally, a handful of water is thrown against a hanging fabric sample. There must be no water penetration or wetting out of the fabric surface. Few fabrics are considered likely to pass this test.

Emulsification The preparation of a finely distributed suspension or emulsion of mutually immiscible liquids.

Emulsified oil sizes → Oil size.

Emulsified textile lubricants → Textile lubricants.

Emulsifier A product which makes the formation of an → Emulsion possible or easier; e.g. in the production of emulsified textile lubricants, finishes and preparations, etc., to achieve specific effects. Emulsifiers are surface-active substances with an ambiphilic character, or preparations containing such substances. The lipophilic part of the molecule is formed from straight, branched, or cyclic hydrocarbons. In contrast, a considerably greater variety of structures for the hydrophilic part of the molecule are possible (see Table).

The basic building blocks include: soaps, alkyl sulphates, alkyl sulphonates, fatty acid condensation products, polyglycol esters and ethers, besides fatty acid esters of polyhydroxy compounds.

lipophil end groups	hydrophil intermediate groups		hydrophil end groups		class
 alkyl residue  alkyl residue, unsaturated  alkyl residue, branched  aryl residue  alkyl aryl residue	$\overset{\text{OH}}{\overset{\vert}{—}}$ —COO— —SO$_2$NH— —CONH— $\left[\text{CONH}\right]_n$ $\left[\text{NH}\right]_n$ —N═ —O— $\left[\text{O}\right]_n$	hydroxyl group ester group sulphamide group amide group polyamide group polyamine group amine group ether group polyether group glycerine group sorbite group pentaerythrite group saccharose group	$—COO^{\ominus}$ $—SO_3^{\ominus}$ $—OSO_3^{\ominus}$ $—OPO_3^{\ominus\ominus}$	carboxylate sulphonate sulphate phosphate polyphosphate lactate citrate tartrate	anionic emulsifiers

Previous Page

Emulsifying liquid A liquid which is capable of forming the discontinuous phase of an → Emulsion.

Emulsifying power The capacity of a product to facilitate the formation of an → Emulsion.

Emulsion An emulsion is a disperse system of two immiscible liquids in which one of the liquids (disperse phase) is distributed in the form of fine droplets in the other liquid (continuous phase or dispersion medium). The most well-known example of an emulsion is milk. Emulsions in which an oil is dispersed in water are described as oil-in-water (O/W) emulsions whilst those in which the water forms the disperse phase are water-in-oil (W/O) emulsions. Washing is an example of an emulsifying process in which fats and soil are emulsified in water by the washing agent so that they may be easily rinsed out. The particle size of an emulsion is greater than 0.1 µm since otherwise a colloidal or true solution would exist. A distinction is made between macro and micro-emulsions which differ mainly in their particle size and optical appearance. Macro-emulsions have a particle size of 100–0.5 µm and appear milky-white to bluish milky-white due to light scattering. Micro-emulsions with particle sizes of 0.5–0.1 µm have an almost transparent appearance with a bluish sheen.

Emulsion breaking After the washing stages of textile finishing the washing water contains, in addition to tensides and emulsified oils, solid particles and possibly coarse impurities such as fibres etc. These are removed by a suitable coarse separator. The o/w emulsions formed during washing are broken down using organic cleavage products. The action is shown in the Fig.

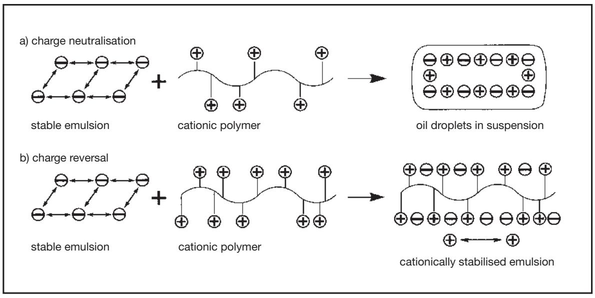

Fig.: Action of organic cleavage products.

Generally speaking, this mechanism is also used for the destabilization of fine-particle suspensions. In this case the negative surface charging of the particles is neutralized, enabling them to coagulate into larger agglomerates. The oil or sludge phases thus formed are separated from the washing water by flotation or sedimentation. Flocculants are often required in order to accelerate the solid/liquid separation. Both weakly and strongly anionic products have proved useful.

Chemical emulsion breaking, combined with membrane filtration, is the most reliable method for the disposal of highly stable effluent emulsions. Various water-soluble chemicals can be used for chemical emulsion breaking according to the stability of the emulsion, their effectiveness depending on the charge neutralisation of the tensides contained in the emulsion. The chemicals neutralise the tenside groups so that the new cleavage chemical/tenside/oil compound no longer floats. The stable emulsion is separated from coarse impurities, and an initial cleavage according to charge takes place in a reactor vessel; the metered, volume-related addition of the chemicals is carried out as the reactor vessel is filled. After a timed reaction and separation phase, the cleavage oil and water are removed separately from the reactor vessel. The oil phase includes the emulsifier, oil sludge, free oil and the chemicals. The residual water content of the oil phase should, however, be less than 10%, so that combustion is possible. Membrane ultrafiltration is used to filter the cleavage water from the preliminary separation; the residual oil content of the permeate is reduced to 5 mg/l. A subsequent neutralization process is not usually necessary in the majority of applications. The concentrated residue is returned to the emulsion reservoir and undergoes a repeat of the cleavage process. The permeate from the ultrafiltration plant may be released indirectly to the main outfall, following any necessary neutralization.

Emulsion lubricant → Textile lubricants.

Emulsion pad process A pad-dyeing process in which low solids water-in-oil emulsions are used as thickeners for the pad liquor. Disperse, acid and metal-complex dyes are applied to synthetic fibres, and vat dyes to cellulosic fibres. The process has not found wide application in practice.

Emulsion polymerization The main textile application of emulsion polymerization is the production of latex emulsions, e.g. for carpet backcoating. In contrast to polymerization processes in the mass (in which the polymer being formed remains for a certain time dissolved in the monomer during radical polymerization) or polymerization in solvents, emulsion polymerization is a multiphase (often three-phase) reaction system (see Fig.) including additions of appropriate emulsifiers which later remain in the latex emulsion after polymerization.

Emulsion printing Textile printing in which emulsion or half-emulsion thickeners are used in the preparation of print pastes.

Emulsions on acrylic basis for coating Among the many uses for acrylic emulsions is the backcoating of fabrics. Fabrics are coated for many reasons: to obtain dimensional stability, to prevent ravelling, to modify hand, to add scale weight, to provide opacity, to permit easier handling when cutting and sewing, to pre-

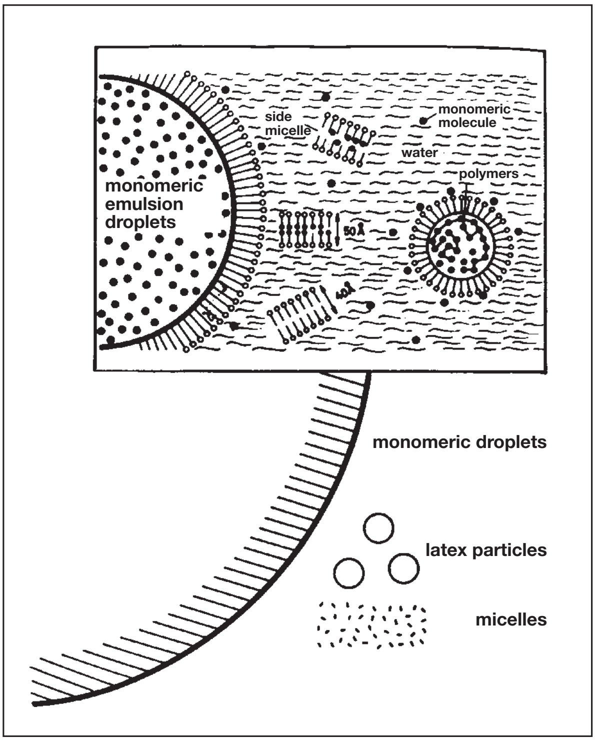

Fig.: Dimensional comparison of the participants of emulsion polymerization.

vent distortion of patterns and to minimise seam slippage. While many different effects are required to satisfy particular end-users, the versatility and diversity of the Primal range of acrylic emulsions qualify them for practically all of these uses.

Films of these acrylic emulsions are colourless and odourless while exhibiting good adhesion to a variety of substrates, both natural and synthetic. If any one characteristic were to be singled out which makes these products so useful for fabric coating, it would be their outstanding resistance to the degrading effects of ultraviolet light, heat and ozone. Unlike conventional latices, Primal acrylic emulsions will not yellow and stiffen with age or heat as they retain their clarity and flexibilty over an extended period of time and wear. This factor is of prime importance in quality fabrics.

The internally plasticised Primal acrylic polymers offer an additional advantage, in that the desired degree of flexibility results from the composition of the polymer and not from the separate addition of a plasticiser. Therefore, no plasticiser migration can rob the backing of its particular degree of softness or stiffness. These acrylic emulsions, supplied as milky-white liquids, are also stable over a wide pH range. Their ease of compounding, coupled with their ability to be applied on conventional coating equipment, demonstrates that their superior properties can be obtained at little or no added cost when compared to conventional coating materials.

Emulsions on acrylic basis for coating

One of the most common methods of coating is kiss roll application. The fabric passes over a roller partially immersed in the thickened mix, or over a roller in contact with a transfer roller which is immersed in the mix. The acrylic mix is usually thickened to a viscosity of about 3000 to 5000 mPa for this particular mode of application. There are many variations of this type of equipment, some of which are:

a. A second roll situated directly above the kiss roll applicator which can be pressed against the face side of the fabric to push the fabric backing firmly against the kiss roll applicator. The purpose of this second roll would be to obtain maximum penetration of the coating into the fabric.

b. In addition to doctor blades used to remove any excess acrylic resin from the fabric, doctor blades can be placed in contact with the kiss roll applicator to control the amount of resin picked up by the roll before it makes contact with the fabric, thus controlling the amount of coating applied.

The rheology, viscosity and solids of the mix, as well as the speed, direction and contact pressure of the roll and fabric, are variables which determine the amount, uniformity and penetration of the backing.

A single doctor blade or floating knife is another means of coating fabric. The coating mix, thickened to the desired viscosity, is poured directly onto the fabric and spread across the fabric by the forward motion of the fabric as it passes under the knife. A movable dam at each selvage prevents spillage sideways off the fabric. The backing material must be properly metered by the knife to avoid uneven results. Strike-through, a disadvantage of this method of application, can be minimised or eliminated by proper thickening. Strike-through can be caused by the mix being poured onto the fabric and allowed to remain in one place for some time, such as during machine shutdown. In addition, the pressure of the coating blade can also cause penetration of the backing material into the fabric. The knife coating technique is also used with plastisols, organosols and solvent-based resins.

The frothing method simply dilutes and thickens the binder with air rather than water and thickener. When compared to other processes, froth coating reduces energy costs and lowers drying requirements, as from 50 to 75 percent less water is used. Froth coating also provides a softer hand and equal strength at equal or lower binder add-on. Froth coating can be used on any type of fabric. It is particularly useful on loose weave, nubby polypropylene fabrics. Primal acrylic emulsions can be frothed straight out of the drum without adding stabilisers or foaming aids. When curing conditions are less than optimum and durability is required, catalysts can be added. These emulsions can also be formulated with fillers and pigments to obtain the desired effect.

Foam coatings are recommended for hard-to-coat, porous, ribbed fabrics. The foam back-coating not only imparts opacity but also provides good thermal insulation. As with froth coating, energy costs are reduced, a softer hand and equal strength at equal or lower binder add-on can be achieved. Durability can be maximised by selecting the right Primal acrylic emulsion. Pigments and fillers can be used to obtain opacity. Foam is a very aesthetic coating that is widely used on draperies and mattress tickings.

Coating automotive upholstery fabrics will usually extend their wear life. The backing prevents distortion of the fabric not only when in use but also when being cut and sewn. The backing also prevents ravelling, improves abrasion resistance, aids in ease of cutting, and helps the fabric to lie flat when being handled. With proper formulation, it can also impart low flame response properties. The backing also provides a further benefit, in that it reduces seam slippage. The repeated stresses to which automotive seat fabrics are subjected puts a tremendous strain on the seams of the fabric. The pull of the threads used to sew the seams can cause them to work through the fabric. If the fabrics are properly backcoated, the seam slippage is virtually eliminated. Primal acrylic emulsions excel in this application because they impart the necessary stabilisation and tensile strength without objectionable build up of hand. Because upholstery in cars is constantly subjected to extremes in heat and cold as well as prolonged exposure to direct sunlight and high humidity, the resistance of the acrylic emulsions to heat and ultra-violet light makes them outstanding for this application. Acrylic emulsions also have excellent adhesion to both natural and synthetic fibres used in automotive upholstery. The minimal temperatures needed to dry and cure the polymers also permits the use of heat-sensitive yarns such as polypropylene in the construction of the fabric. From 12 to 100 g/m^2 of fabric are usually applied. If the fabric is yarn-dyed and not post-dyed, and does not require durability to wet processing, the Primal polymer does not have to be crosslinked.

Like automotive fabrics, the design and construction of furniture upholstery fabrics ususally necessitates a backing material to impart dimensional stability and to prevent seam slippage. Some furniture upholstery fabrics are post-dyed, and a complaint often raised is that the backing dyes off-tone compared to the face of the fabric. This becomes a serious problem with fabrics having open weaves because objectionable “grin-through” is further amplified by the colour difference. Conventional SBR latices tend to resist dyeing or can preferentially absorb one of the dyes in the colour formulation with a resultant change in case. The dyeing characteristics of the Primal acrylic resins closely resemble those of cellulose acetate and nylon fibres, so that dyes used to colour these fabrics also colour the acrylic backing. Any grin-through can be effectively camouflaged by the addition of disperse or nylon dyes to the dye bath if they are not already included in the dyeing formulation. Most backings used for furniture upholstery are loaded with clay or whiting. A filler can be used for one or any combination of the following reasons: to reduce tack; to add weight; to extend and thus reduce the cost of the formulation; to colour the backing. Usually, from 80 to 120 g/m^2 of fabric are applied.

Certain furniture fabrics are post-dyed rather than yarn-dyed and therefore must be able to withstand the severity of a dyeing cycle. These dyeing cycles can be anywhere from 6 to 8 hours in length at 170°C to boiling. When matching a difficult shade, fabrics can stay much longer in the hot dyeing water; thus, water-soluble antioxidants and other components in conventional SBR backings can be extracted, resulting in greatly reduced resistance to ageing and dusting. Primal acrylic backings are not so effected because they contain no antioxidants. With the wide range of upholstery fabrics used in the industry today, various backcoating methods are used to achieve different effects. Frothed backcoating methods are easily applied to bulky, loose weave polypropylene fabrics, whereas plush fabrics can be coated using standard clear or filled formulations.

Rohm and Haas has developed a processing method that imparts an ignition resistance to all classes of upholstery fabric. It incorporates a protective aluminium barrier which transfers heat from a cigarette, thereby preventing combustion of fillers or padding. It is used on fabrics that have had a conventional backcoating previously applied.

Curtains are lined to give them opacity to light and to prevent colours from fading. Lining not only takes time but also involves costly and detailed work. In addition, it is usually recommended that curtains that are lined should be drycleaned. Although drycleaning is expensive, if the curtains are washed, the lining can shrink more or less than the curtains themselves. The opacity achieved by lining can be more easily obtained by backcoating the curtains with a filled/pigmented Primal polymer formulation. This type of backcoating not only imparts opacity but also thermal insulation. The desired durability of the backing to laundering and drycleaning can be obtained by the proper selection of Primal emulsion and proper formulation. Usually from 45 to 70 g/m^2 of fabric are applied. While these backcoatings can be applied by several methods, they frequently are applied by crushed foam coating to produce a uniform coating on textured curtain fabrics.

Emulsions (O/W) type, determination of water content This involves ascertainment of the maximum solubility of electroytes: approx. 5 g of the emulsion is precisely weighed and approx. 1 g of dried electrolyte (preferably sodium chloride) is added. The emulsion is then heated and allowed to cool back to room temperature. The electrolyte precipitated out from the saturated aqueous solution is filtered off, washed, and determined analytically.

Emulsion stability The capacity of an → Emulsion to remain stable, i.e. not to “break” or separate into its component phases.

Emulsion thickener A thickener for textile printing consisting of → Emulsifier, water and a water-immiscible liquid (chiefly kerosene or white spirit). Depending on the type of emulsifier, either a water-in-oil or, as generally preferred in practice, an oil-in-water emulsion is formed. Emulsion thickeners have found the widest application in pigment printing. For other classes of colorants, particularly reactive dyes, half-emulsions are generally used, i.e. emulsions to which conventional thickeners have been added (e.g. alginates) in order to achieve improved stability.

Enamel (vitreous enamel). Protective glazed coating applied to metal surfaces. It is produced by the application of finely powdered glass containing lead or boric acid in an aqueous paste followed by fusion in an oven.

Encapsulated dyes Dyestuffs of various classes (cationic, acid, reactive, disperse, and vat dyes) which have been encapsulated in fine granular form with hydrophilic film-forming substances of high molecular weight (e.g. gelatine, pectin, agar agar, methylcellulose or polyacrylic acid) by the microcapsule technique. The microcapsule diameter lies within the range of 10–200 µm. Dyes in this form can be applied together with reactive compounds without any initial reaction; reaction eventually takes place during a subsequent steaming or other thermal treatment. Special effects, e.g. in → Speck printing.

End

I. An individual warp thread (weaving).

II. Each passage of a length of fabric through a machine as, e.g. in jig-dyeing.

Ending A dyeing fault consisting of a change in colour from one end of a length of fabric to the other, or a difference in colour between the bulk and the end of a length of fabric.

Endless belt batcher → Paternoster batcher.

Endless conveyor Continuous conveyor for piece goods. An enclosed track (rail) consisting of an electrically driven endless chain or endless rope. Goods are carried mounted on hangers. Possible configurations include horizontal, inclined, vertical running, also for horizontal and vertical bends. Max. single load 1 t, up to 6000 m, velocity of up to 0.4 m/s; so-called light circular conveyors for up to 30 kg/hanger, up to approx. 40 m, velocity from 0.1 m/s; gradients also possible to a limited extent.

Endless felt → Tubular felt.

Endless screen Further development of the large-repeat rotary screen, whose scope is restricted for reasons of stability. With the endless screen, an endless loop runs across three rollers which are arranged in the form of a triangle. This makes it possible to achieve very large repeats at high printing speeds even when using narrow print widths in screen printing.

Endocuticle → Intermediate membrane.

Endocuticula The innermost cuticle layer. In → Wool structure it is the so-called inner scale-cell layer.

Endophilic (Greek), turned inwards, e.g. tendency of a hydrophilic molecular group to enter into or remain in the aqueous phase, or of a lipophilic group towards the organic phase (solution). Characterized by the reduction in chemical potential as a function of concentration and temperature. Opposite → Exophilic.

Endosperm (Gk. *endo* = inner, within; *sperma* = seed). The nutritive tissue surrounding embryo in most seeds.

Endothermic An adjectival term used, e.g. to describe a chemical reaction which is accompanied by the absorption of heat. Compare → Exothermic.

Endotoxins Toxins contained within the protoplasm of an organism, especially a bacterium, and liberated only at death. (Opposite term: exotoxins which are produced by living bacteria and secreted into the surrounding medium). An endotoxin is a bacterial toxin that is an integral component of the cell. → Byssinosis.

End ring Metal ring introduced into each end of a rotary printing screen to obtain a stable cylinder. End rings are bonded to the screen with a special adhesive.

End ring glueing device A vertical or horizontal unit designed for the glueing of → End ring to rotary printing screens (see Fig.).

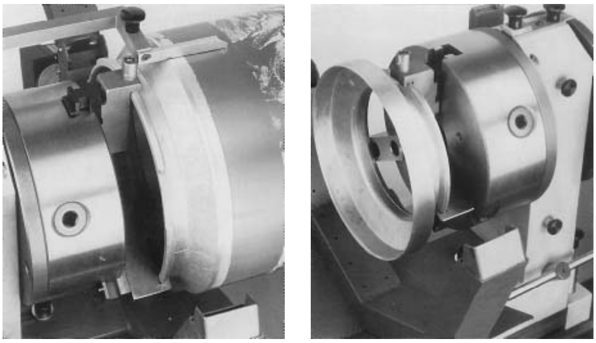

Fig.: Harlacher end ring glueing device for rotary printing screens.

End-to-end uniformity A term used for piece-dyed goods which exhibit the same shade throughout the entire length of the batch, in contrast to defective dyed goods where ending or tailing problems have occurred during dyeing .

Energy Available power. The capacity of a body or system to do work. The first law of thermodynamics states that energy can be neither created nor destroyed but can be converted from one form into another. Energy is available in various forms which, apart from two exceptions (electromagnetic waves and heat radiation), is always associated with matter. Energy exists as mechanical, thermal, electrical, magnetic, chemical and nuclear energy.

Energy carriers Raw materials from which energy can be released, e.g. coal, gas, oil, nuclear fuels, and the potential energy from hydroelectric sources. Primary energy carriers supply existing energy in its original form (solar power, wind power).

Energy consumption It is recognised that the treatment temperatures for pretreatment, dyeing and finishing of the same article can vary widely and depend above all on the following conditions:

- quality or fastness requirements of the consumer;
- cost and profit considerations of the dyeing process;
- available machinery and capacity.

There is a great number and variety of pretreatment, dyeing, printing and finishing machinery types, whose energy consumption can vary widely for the same production purposes. An additional factor is that numerous fibre types are processed, singly and in blends, which also give rise to substantial differences in energy consumption for similar articles. In order to remain in control of the present and future energy supply situation, the energy supply must be analysed accurately and energy-saving measures implemented wherever weaknesses are discovered.

Energy consumption, optimisation of The textile finishing industry uses optimising systems in the case of the energy media electricity and gas. Energy cost optimisation means limiting energy procurement within a unit of time to a specified maximum value; i.e. in the case of electricity, not to exceed an average power consumption figure in kW over a measuring period of 15 or 30 min, during which short-term peak values are quite possible, as only the mean value within the measurement period will be taken into account in calculation. This power consumption limit is the main concern of optimising systems. If production machines are exclusively connected to an optimising system, power purchases can be transferred only to other measuring periods which are not normally so high. Within the daily load curve then, this means transferring to the trough periods. In this case, there is no work saving (kWh). If however peripheral production plant and machinery (e.g. heating, air conditioning, ventilation, lighting) are connected to the system, the number of kilowatt hours consumed is additionally reduced.

Gas presents a similar picture. The quantity consumed per unit of time (1 hour or 1 day depending on contract) is limited. Here too, peaks may be recorded within a measuring period; the aim should be not to exceed the purchase quantity agreed in the contract. The optimising system prevents exceeding the limit by reducing the quantities consumed by individual consumers together with total consumption projection to the end of the period. Here too, quantity limitation acts as a cost reducer. If quantities cannot be varied, one must consider substitution with the aid of other suitable energy media, the utilisation period of which is computer monitored and controlled. An optimising system economises on cost, nevertheless it is generally called a "savings system", since the false conclusion that something must be dispensed with could easily be drawn. This is not the case however when using an optimising system. Power supply companies generally divide the daily supply period into high tariff and low tariff periods. Up to the limits imposed by technical plant layout, there are normally scarcely any limits in the low tariff period as regards the energy quantity which may be drawn over a 15 or 30 min. measuring period. It is a different matter in the case of the high tariff period, where stipulated agreements are to be found.

Energy recovery → Heat recovery.

Energy use, efficiency of Ratio of obtained, released energy to energy used, expressed as a percentage.

English black A term used to describe a black dyed with → Logwood.

English blue A collective term used in the 18th century for processes involving the local application of indigo directly in the vatted form (→ Orpiment).

English print A French method similar to Orbis printing using polychromatic rollers which have the required design on the surface made up of a pattern of dye platelets (number of colours optional). Printing (depending on colour layer thickness, 3,000–25,000 m of cloth, 20–40 m/min) is carried out on damp cloth (prewet, with additional additives after dyeing) with simultaneous steam injection, followed by usual fixing.

English tulle → Bobbinet.

Engraved printing roller, production of → Engraving.

Engraved roller printing → Gravure printing.

Engraving There are three classical options available for the engraving of rollers for textile printing:

1. Mill engraving: This can be described as a predominantly mechanical process. The pattern is firstly engraved manually onto soft metal rollers/plates. The design will be transferred onto hardened steel rollers, the circumference of which corresponds to the repeat of the design. The steel rollers are given a light electroplating of copper. The design is traced onto the soft plates using a sulphur-containing colour paste. The design is then laid over the steel rollers and gently heated. This causes the sulphur to combine with the copper. On those places where the design has been attached, the copper becomes black, rendering the design visible on the steel roller.

The outlines and the edges of the surfaces are then chiselled out manually. The roller is then coated with an acid-resistant lacquer and the engraving is made onto the coat of lacquer using a scutcher or stamping machine. An etching process etches the hatchings imprinted even more deeply. The master roller produced in this way is hardened. In use it is pressed against a second soft steel roller on the relief engraving machine. This has an integrally larger circumference, whereby the engraved areas of the master roller impress onto the so-called relief roller. This relief roller is used to produce the printing roller. The relief roller is pressed against the copper roller of the printing roller on the so-called mill engraving machine. This imprints the embossed pattern deep into the roller. With this type of milling, the pressure must always be uniform and the distance between the milling cycles must be accurate to a fraction of a millimeter. If this is not the case, gaps will become visible. Mill engraving is used for small patterns such as needlepoint and dog's-tooth checks etc.

2. Pantograph engraving is suitable for larger area patterns. After being enlarged several times, the pattern is transferred onto zinc plates. Depending on the size of the repeat, several plates are laid next to each other. The edges are manually chiselled as an outline on these plates and the surfaces relating to the various colours in the pattern are labelled according to each colour. The pattern is transferred to the printing roller using a special machine, the so-called pantograph. The engraved plates are used as a model. Several engraving levers corresponding to the number of repeats are actuated across the width of the roller using a pantograph. A diamond is inserted into the tip of each of these levers. Using these diamonds the pattern is engraved into a coat of lacquer with which the roller is evenly coated. The outlines are then retraced. The hatchings are later added using a hatching plate. The roller scored in this way is etched more deeply in a nitric acid bath. A further development of this is the photoelectronic pantograph, which consists of two separate units. In the first unit, there is a roller to which the design is attached. The roller to be engraved in stored in the second unit. The design is in black/white and is scanned using a photoelectric cell. The light impulses obtained are converted into electric impulses. These are then chiselled relative to their intensity. The chisel impressions are made onto a roller, which has been coated in lacquer and their close location forms into lines. Up to three rollers can be engraved at one time using this method.

3. Photo-engraving enables smooth surfaces and short runs to be printed. Firstly, colour separations are prepared from the design; i.e. each colour is transferred separately onto a film with an opaque colour. A reproduction camera is then used to copy the appropriate screen or hatching into the design by means of a screen plate or hatching plate. In the meantime, the printing roller (copper roller) is given a light-sensitive chrome gelatine coating. The design is presented to the prepared roller and the whole assembly is exposed to light. The non-engraved areas are covered during this process. The exposure causes the chrome gelatine areas to be hardened. The areas that are not exposed remain water-soluble. When the process is complete, the entire roller is rinsed off. The remaining chrome gelatine is hardened by heating and the roller is placed in an etching solution (iron chloride) which slowly etches away the copper from the non-exposed areas. In addition to the chemical etching process, electrolytic etching also takes place. Using the principle of electrolysis, the roller to be etched becomes the anode and the positive copper ions migrate to the cathode. The ions are prevented from migrating to the areas covered in hardened gelatine, with the result that the copper coating may only be corroded in the free areas.

Manufacturing of flat screen and screens for rotary film screen printing takes place in special companies or in separate departments at the printers. After a repeat design drawing and a resulting colour separation have been drawn up, either the flat screen is manufactured using the photochemical method or the rotary screen is manufactured using the galvano-plastic method (or less frequently using the photo resist method). Where screen meshes are made by specialist companies, the fabric is dyed in specific colours in order to eliminate the effect of underexposure (reduction of areas to be printed). During copying, the light falls through the negative onto the fibres of the screen gauze, and is reflected in the case of white fabric and underexposes the positive in the covered areas. With dyed fabrics, part of the light is absorbed by the dyeing; only the remaining part of the spectrum is reflected and underexposes the positive to a significantly lesser degree, with the result that sharper outlines arise. The carrier layer is produced by coating with gelatine. The gelatine contains ammonia and potassium dichromate. After exposure, those layers which are not exposed continue to be soluble and may subsequently be rinsed out. Water-insoluble chrome gelatine forms after the photochemical reaction (Fig. 1):

$$Cr_2O_7^{2-} + 2\,HO^- \rightleftharpoons 2\,CrO_4^{2-} + H_2O$$

$$3\,e^- + CrO_4^{2-} + 6\,H^+ \rightleftharpoons CrO^+ + 3\,H_2O$$

$$CrO^+ + \text{Gelatine} \rightleftharpoons \text{insoluble chrome gelatine}$$

Fig. 1: Photochemical formation of chrome gelatine.

The galvano-plastic method to produce rotary screens uses more seamless, thinner nickel foil rollers. These are perforated and must have uniform thickness. The fineness of the perforations is selected depending on the print. 25 holes/cm (approx. 60 mesh) are chosen for blotch prints, 30 holes/cm (approx. 80 mesh) for small

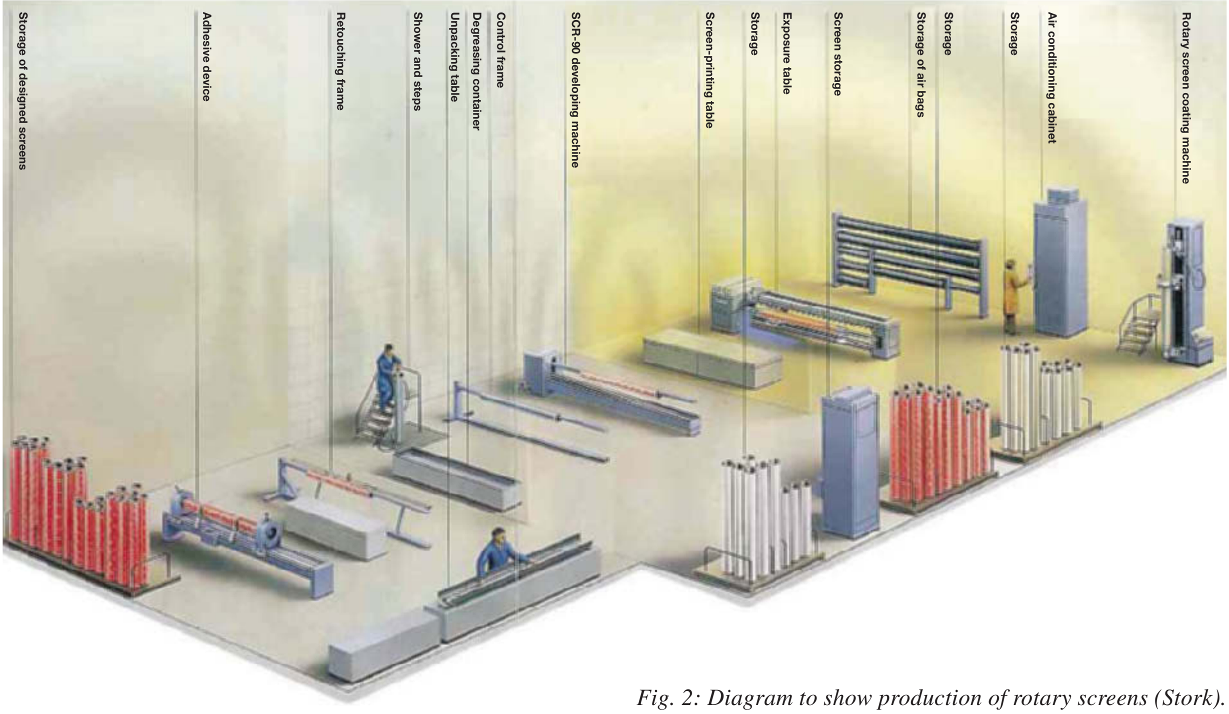

Fig. 2: Diagram to show production of rotary screens (Stork).

figures and edges, and for very slight application of print paste, 40 and more holes/cm (corresponding to 100 mesh and more). With the galvano-plastic designed screen, the sealed nickel coating is still in place on the areas which have not been printed, whereas the screen is located on the areas which have a pattern. The work processes in the galvano-plastic process are as follows: a light-sensitive layer is applied to the carrier roller. A negative film with delayed solubility is then copied onto the carrier roller. The photo layer must be developed and hardened on this before a separating layer is applied to the carrier roller. The nickel sulphate roller is nickel-plated in the galvanising process before the nickel screen is separated from the carrier roller. The mesh count gives the number of openings per linear inch (corresponding to 2.54 cm).

In principle, a total engraving system comprises the following finishing equipment:

- Unpacking table,
- Degreasing container,
- Coating machine,
- Air conditioning cabinet,
- Exposure machine,
- Developing equipment,
- Retouching frame,
- Polymeriser,
- Shrinkfit frame,
- Stripping tank.

Auxiliaries such as films, lacquers, retouching lacquers incl. chemicals, supporting hooks, various auxiliary rings etc. are also required. The engraving department is made up of the rational arrangement of all machines in the space available. Fig. 2 shows an example of how to set up and divide the department. The division into three functional areas should be noted:

- A preparation area for unpacking, milling and hardening the screens;
- An area for wet processes such as degreasing, rinsing and developing;
- An area for drying and exposure.

When planning an engraving department, requirements such as specific light sources, temperature control, power supply, transport and floor coverings must all be taken into consideration. The screens are particularly sensitive due to the extreme thinness of the nickel. They are therefore packed with extreme care to avoid damage. The screens are stacked in long cartons. There is a risk of bending the screens when unpacking or pulling them apart. This can be avoided by using the special unpacking table, which is twice the length of the actual screen. Slight pressure is applied to the reel of screens using a travelling roller. This enables the screens to be easily removed individually from the reel from the inside.

Laser engraving essentially enables the significant acceleration of preparatory work (transfer without film) up to the production of the ready-for-press rotary film printing screens. Stork (STK) and Zedco (Piolat) demonstrated the direction in which colouring and screen manufacturing are heading. In rotary screen production, higher precision is achieved by the use of laser engraving, whilst the automatic combination of CAD and engraving is becoming increasingly widespread. The use of laser engraving does away with lighting, development and polymerisation in comparison with conventional processes. Engraving takes only approx. 15–20 min.

Engraving chisel Tool used in the repair of damaged gravure printing rollers. Also used in pantograph engraving to engrave the zinc or aluminium plates.

Engraving company A company specialising in the production of gravure rollers for printing. The machinery and methods used for the manufacture of Gravure rollers is varied and expensive and for this reason, it is normally only feasible for a textile printer to commission the production of new rollers or the machining, re-coppering and re-engraving of old rollers with new designs. The staff must be especially skilled to carry out this work. Smaller printers therefore often send this work to specialised engraving companies.

Engraving depth In gravure printing the engraving depth is dependent on the number of → Hatching per cm, which in turn is dependent on the fabric to be printed. The larger the number of hatchings, the lower the engraving depth. → Engraving.

Engraving designer The engraving designer produces colour drawings according to a design in the relevant individual colours.

Engraving die This is used for engraving. The finish hardened relief cylinder is pressed against the copper roller of the printing roller in a special machine, the so-called mill engraving machine. The raised pattern is then engraved/ indented into the cylinder. The roller undergoes a special treatment before this. The necessary capacity is then established by allowing the engraving machine to “run over”. The necessary copper layer is then wrung off. Rod steel which has been diagonally ground is used for this, in order to achieve machining which is as even as possible. In order to achieve total smoothness of the surface, an “engraving planer” is passed over, the machining being “smoothed down”. The engraving planer is also referred to as an engraving die.

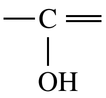
Engraving hammer One of a number of special tools required when repairing damaged gravure printing rollers.

Engraving of embossing rollers Engraving of steel rollers for → Embossing calender.

Engraving quarter tones The printing roller is initially pre-etched and the areas of the pattern, which need to be engraved less deeply, are coated with lacquer. The free areas can then be subsequently etched at the desired depth.

Enol form →: Enols, Ketones.

Enols Organic compounds characterized by the presence of a double bond and neighbouring hydroxyl group, i.e. containing the group –CH=C(OH)– in their molecules, e.g.



$$-\underset{\mathrm{OH}}{\underset{|}{\mathrm{C}}}=$$

The term “enol” is a compound of “en” (double bond) and “ol” (from alcohols). → Ketones are practical examples of the enol form.

Enthalpy Thermodynamic variable (H), defined as the sum of the internal energy and the displacement energy (pV) of a system, being the product of the volume under constant external pressure (p): H = E + pV. The enthalpy is equal to the heat content under constant pressure. Chemical reactions in a system at constant temperature and constant pressure only take place spontaneously towards a reduction in the free enthalpy G ($\Delta G < 0$). The relationship shown in the Fig. applies to the system.

free enthalpy (tendency to react) = tendency to minimum enthalpy - tendency to maximum entropy

$\Delta G_{\text{system}} = \Delta H_{\text{system}} - T \cdot \Delta S_{\text{system}}$

free enthalpy = maximum amount of work the system can support

Fig.: Statements on enthalpy changes ΔH in systems: the enthalpy itself cannot be measured.

Entropy (Greek entropein = turn), thermodynamic measure of order or disorder. The second law of thermodynamics states that in a closed system, the entropy cannot decrease. When the original energy of a reaction is present at a high level, the entropy amount is low, in the opposite case it is correspondingly high. In other words, the deeper the quality of the energy form, the greater is the entropy amount arising from the conversion of a unit of energy. If energy conversions are also accompanied by material conversions and blending effects, these are also contained in the definition of entropy. The entropy of a system is a measure of a lack of information or, simply, a measure of disorder. For calculation purposes the entropy is subdivided into separate amounts capable of addition. The two most important are the thermal and configurational amounts. As a rule of thumb the following can be observed: the thermal entropy proportion increases as the temperature of a system increases, that is as the movement of the smallest particles (molecules, ions, atoms) increases and the average space between particles widens.The information on the resting place and direction of travel of the individual particles is reduced as the temperature increases, and the disorder is increased. The configurational entropy proportion, that is, the entropy of the arrangement of the atoms in a molecule, a lattice or a system, increases the more a system is blended, and the less precisely the location of the individual particles

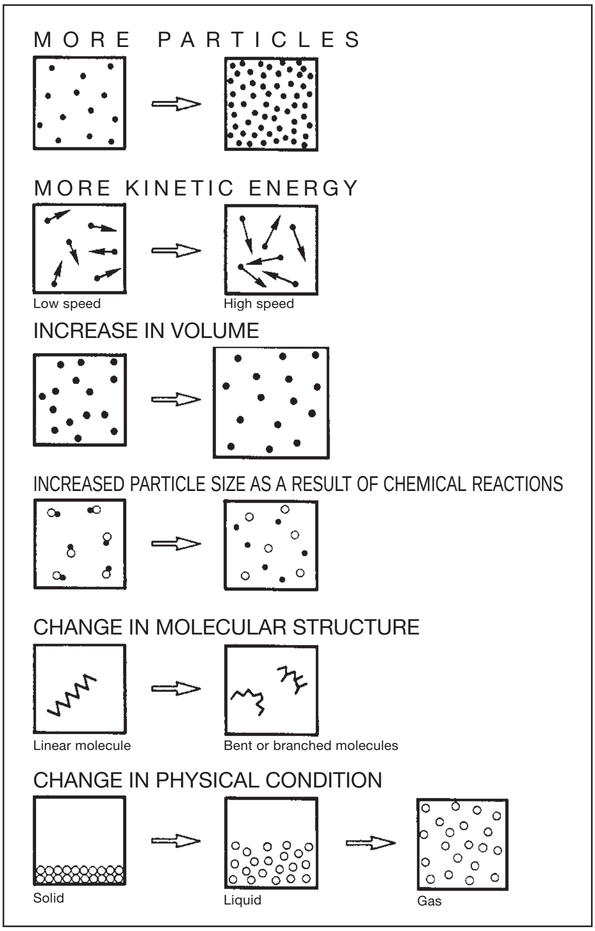


Fig.: Possible causes of increases in entropy (source: Tyler Miller).

can be described. The total entropy of a system is therefore the sum of all the entropy parts. For simple ecological considerations it therefore applies that during warming and/or blending or thinning of a substance the entropy of the system increases (see Fig.).

Entropy is therefore used in defining the second law of thermodynamics: in irreversible (i.e. self-contained) processes in an isolated system the entropy always increases. Put another way: a process in which a transfer of energy takes place can only continue spontaneously if the entropy of the system and the surroundings increases overall. The entropy of the system alone may decrease, but then the entropy of the surroundings must increase by a corresponding amount. Given this aspect, the second law of thermodynamics limits all efforts towards environmental balance to a finite degree. Every resource is ultimately converted to waste by human activity. Waste is therefore, put positively, a resource in the wrong form, the wrong place or the wrong distribution. From the point of view of thermodynamics, waste is therefore in a state of high entropy, usually resulting from blending or thinning. Generally, every instance of energy conversion, therefore also every case of civilizatory activity, e.g. industrial production or car usage, produces entropy in the form of heat emissions into the environment or pollutant emissions into the earth's atmosphere, ground or water (source: Kummert and Strumm).

Entry zone of a stenter or drying machine is the area in which the edges of a textile fabric are taken up on pins or held by clips.

Environment The surroundings of a living creature, the milieu. The study of environmental interrelations is referred to as → Ecology.

Environmental compatibility assessment Biological degradation represents both in the aqueous environment (sewage treatment, surface water) and in the soil the main mechanism of natural processes that cause compounds introduced into the environment to be dissipated. It therefore has a crucial influence on the environmental concentration of substances and is a key factor in environmental compatibility assessment, where the environmental concentration and the active ecotoxicological concentration of a substance are compared. The speed and completeness of biological degradation determine whether and to what extent the ecotoxicological potential of a substance comes to bear on the environment; hence environmental compatibility assessment will frequently refer to "biological degradation priority".

Environmental compatibility assessments are officially demanded whenever large-scale projects (e.g. of an industrial nature) threaten to fundamentally alter an environment (residential area, natural environment) if brought to fruition.

In textile finishing aspects of environmental compatibility and the efficiency of materials used, together with the demand to save on energy and labour costs, are acquiring major significance. Some of the tenside classes developed in recent years go a considerable way towards satisfying these requirements. To be able to assess the environmental impact of any organic substance, however, those properties that are especially important ecologically first need to be clarified. There is a definite ranking order to these:

- quick and complete degradability,
- elimination in treatment plant or by special procedures,
- exclusion of any accumulation in the food chain,
- zero or low ecotoxicity.

This ranking order may be described as follows: if a higher placed criterion is met, then the one below it is of lesser importance. Thus, for example, high fish toxicity is of major significance for a substance of low degradability and one that cannot be eliminated since it could cause the destruction of fish stocks if it should enter the waterways in a high concentration via the sewage system and sewage works. A degradable or eliminable substance, on the other hand, cannot possi-

Tab.: Test methods for determining biodegradability.

Test Method	Dwell Time	Test Concentration [mg/l]	Principle	Analysis	Advantages/ Disadvantages
OECD 301 D – Closed Bottle Test (GF)-Test	30 d	2–10	static, test substance is sole carbon source	BOD	+ proof of biological degradation - extremely severe
OECD 302 B – Zahn-Wellens test	28 d	200–500	static, test substance is sole carbon source	COD carbon decrease	+ indication of fundamental degradability - elimination may simulate degradability - not severe enough
Coupled Units Test	3h or 6h	10–20	continuous, organic base substrate	carbon decrease	+ simulation test - quantification - elimination may simulate degradability

BOD = Biological Oxygen Demand
COD = Chemical Oxygen Demand

bly enter the water since it is already eliminated in the sewage treatment plant.

There are several methods available (see Table) for testing the most important parameter, biodegradability (→ Surfactant biodegradability).

They are all suitable for evaluating the degradability of water-soluble organic substances, by testing their complete degradation, i.e. their mineralization to carbon dioxide and water. Methods do not only differ considerably in terms of test procedures, but also in the transferability of their findings to actual circumstances in a surface waterway or in a water treatment plant (source: Schlüter).

Environmental ethics It is important for the textile industry to understand the technical and legal dimensions of environmental problems and that the concept of the environment and environment law has moved further away from the anthropocentric approach, centred around human beings, towards a central nature conservation law under the motto “Nature doesn’t use people, but people use nature”. In this respect, human activity must be regarded as fundamentally disruptive, something which should be legally limited as far as possible. These activities should at the very least be in harmony with nature, working with the environment, rather than against it (physiocentric philosophy of Meyer-Abisch).

The German Water Resources Act (WHG) has accordingly developed away from a prescriptive law into a water conservation law. The Federal Pollution Control Act has less to do with health and safety, in contrast to the trade law on which it is based; the Waste Avoidance and Waste Management Act is increasingly both directly and indirectly concerned less with the removal of refuse than with its prevention. The Soil Conservation Law has developed similarly into an independent area as a third central issue.

Environmental impact Increasingly, integrated methods have gained in significance in recent years in the study of the environmental impact of products or systems. All developmental stages of a product from acquiring the raw materials through manufacture and end-use right down to disposal at the end of its useful life are included in this process. A characteristic variable is the “cumulative energy expenditure” – the sum of all energy expended during the life cycle of a product. The ecobalance, a new instrument still in the process of perfecting, goes a stage further in additionally examining the effects on the natural environment of, for example, emissions or the consumption of resources.

Environmental legislation Environmental legislation has developed exponentially since 1970. Textile finishing is affected by this in the following areas:

I. Handling of chemicals:

1. (German) Federal legislation on chemicals:
   a) Hazardous Substances Regulation (Ger.: Gefahrstoffverordnung, GefStoffV) with Annexes I–VI;
   b) classification and identification of hazardous substances and formulations;
   c) dangerous substances which are carcinogenic, genetically damaging and cause infertility;
   d) toxic, caustic, irritating and chronically harmful substances;
   e) medical check-ups;
   f) classified hazardous substances and formulations.
2. MAK list (workplace threshold limits).
3. BAT list (biological materials tolerances).
4. TRK list (technical standard concentration)
5. Legislation on combustible liquids (VbF).
6. Storage of chemicals and technical materials.

II. Waste water pollution: Water Management Act (WHG), regional regulations, Schedule of Water Pollutants, Laundering and Cleaning Agents Act, Tenside Regulation, Effluent Discharge Levy.

III. Emissions and atmospheric pollution: Federal Immission Protection Act and its legal regulations.

- TA (technical) guideline on air,
- TA guideline on noise.

IV. Disposal of residual liquor, effluent and clarification sludge: waste legislation, implementation regulations, clarification sludge regulation.

V. Physiological effects of textile material: Hazardous Substances Regulation with Annexes I–VI, allergic effect, odour, skin tolerance, prevention of domestic toxins (home textiles).

VI. Environmental liability legislation (risk liability): legislation governing liability for environmental damage and for amending the Water Resources Law and the Federal Immission Protection Act (Ger.: Bundesimmissionsschutzgesetz, BImSchG, 1990/91).

VII. Environmental criminal law: 2nd Act for Combating Environmental Crime (1991/92).

VIII. Heat Utilization Regulation, Draft 5.9.1991: decision-making criteria and operators' obligations.

At the same time, the Self-Monitoring Regulation envisages for the future in-house supervision of all potential causes of environmental pollution.

Through the environmental provisions that have been made particularly in recent times, a new action requirement has been placed on many companies (Table 1). The need to examine existing waste disposal arrangements in regard to current regulations, for instance, is always paramount. At the same time, trends need to be recognised and addressed, which is only possible as a rule through knowing the relevant legislation. While the content of the major environmental legislation is generally familiar to the planning engineers, technicians are not usually up to date in following the ongoing legal judgements. Hence collaboration with suitably experienced legal experts is proving to be very useful in many cases today.

To achieve a certain security in dealing with the regulations, it is sensible to first familiarise oneself with the basic system of environmental legislation, which is divided into four major areas:

- the law governing prevention of water pollution with its "guiding act" WHG (Ger.: Wasserhaushaltsgesetz = Water Resources Law),
- the law governing clean air with its "guiding act" BImSchG (Ger.: Bundesimmissionsschutzgesetz = Federal Immission Protection Act),
- the law governing waste disposal with its "guiding act" AbfG (Ger.: Abfallgesetz = Waste Act),
- the law governing nuclear energy with its "guiding act" AtomG (Ger.: Atomgesetz = Atomic Act).

Fig. 1 provides an overview of the provisions regulating prevention of water pollution, clean air, waste disposal and nuclear energy.

In all areas two legal policy principles are applied as the basis of all provisions, namely the principles of precautionary measures and the polluter and cause. A further principle that needs to be observed consists in ensuring that technical progress is put to use in the field of environmental protection. The relevant state-of-the-art technology should be made use of. This has even found legal expression to a certain extent. Laws which directly impinge on future measures are the Waste Disposal Act and the Hazardous Substances Regulation, which provides, among other things, for a reduction of emissions in the handling of dangerous substances in line with the technological state of the art.

With the Industrial Effluent Discharge Levy (Ger.: Abwasserabgabengesetz, AbwAG) the classic regulatory instrument of the Water Management Act has found a legal counterpart in fiscal terms. The amending law of the AbwAG extends the liability to levy payment to the group of organic halogen compounds, such as the heavy metals chromium, nickel, lead and copper. The amount of administration required for implementing

Regulation	Action (examples)
Water Resources Law	Monitoring, updating of sewage plants taking into account the state of the art or the a.a.R.d.T. Monitoring of production plant in regard to the handling of water pollutant substances Water economy measures
Effluent Discharge Levy	Pollutant reduction measures
Hazardous Substances Regulation; Regulation Governing the Storage of Water Pollutant Substances	Inventory of stored chemicals (stock list) Fire prevention provisions (collection of water for fire fighting)
Federal Immission Protection Act	Monitoring of the certification compliance of existing equipment Monitoring of the certification status of modified equipment
Technical Guideline on Air Quality	Refurbishing of old equipment to comply with new requirements
Emergencies Order	Monitoring of the need for emergency analysis Action planning to avoid emergencies
Waste Act	Monitoring of waste disposal for recycling opportunities

Tab. 1: Operational consequences arising from the changing environmental legislation.

the act is visibly reduced. Anyone failing to observe the discharge levels, will be liable to pay a higher effluent discharge levy. Whoever employs state-of-the-art effluent treatment will receive a sizeable effluent discharge levy reduction; while anyone who, provided that no hazardous substances are present, makes even more strenuous efforts that go beyond the treatment techniques usually employed can expect even greater levy concessions. Further investment incentives are offered through the possibility of offsetting the effluent discharge levy against the costs incurred for investing in progressive cleaning technology.

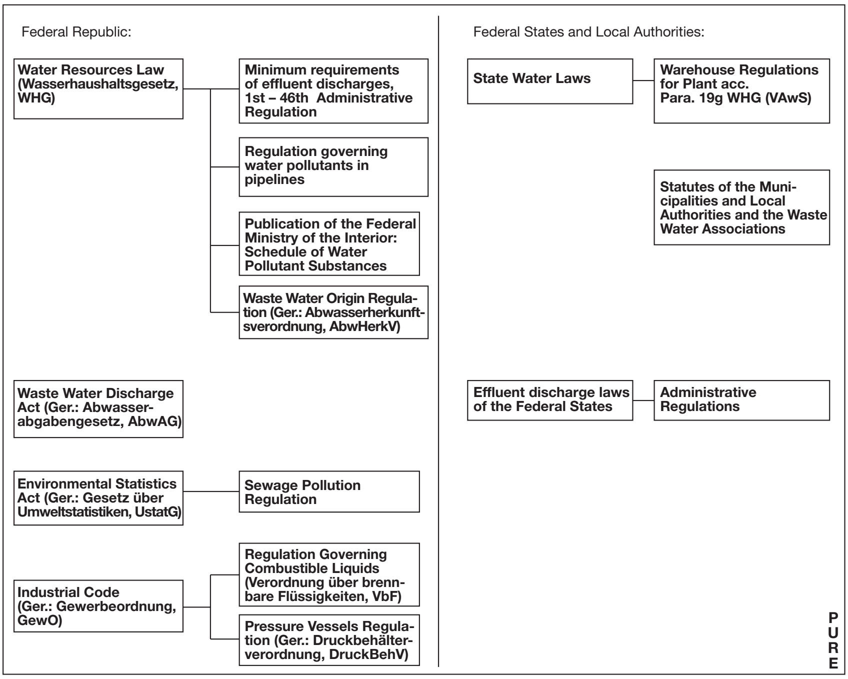

Fig. 1: Important legal provisions in the area of water pollution control.

With the revision of the Washing and Cleaning Agents Act (Ger.: Wasch- und Reinigungsmittelgesetz, WRMG) the aim is to reduce the pollution of water and effluents by washing agents and detergents. The environmental compatibility of these products should be continually improved in accordance with technical progress and consumption limited to the quantities sufficient for cleaning. The scope of the act has been extended to include, for example, anhydrous detergents (solvents, certain paint thinners, etc.) and a series of textile finishing agents that are mainly released in cleaning. The subsequent introduction of requirements affecting industrial laundering and cleaning equipment is aimed at optimizing the overall system of machine/chemical product in regard to water pollution control.

The Water Resources Law (WHG) makes the following provisions: effluents containing hazardous substances must be treated in future by processes that conform to the state of the art. These new, stricter requirements will also apply in future to the public sewerage system. Hazardous substances, as a matter of priority, should be reduced as far as possible at source or preferably avoided altogether. Another priority is the reinforcing of ground water protection. Systems which handle water pollutant substances are subjected to the strictest protective measures of the WHG.

Fig. 2 depicts the statutory instruments for improving water quality. It is the aim of the WHG to keep hazardous substances away from water resources. A further objective is the safeguarding of ground water so that, ultimately, effluent discharge pipes that might or actually contain water pollutant substances must be enclosed in walled conduits. This applies to virtually all effluents from laundries and dry cleaners.

There is also an obligation to obtain authorization for discharging effluents into the public sewer system, which includes the class of “hazardous substances”. Should there be any suspicion of substances of this kind being discharged into the public sewers in high concentrations or loads above a certain threshold value, then informal approval must be sought. Non-action can lead to considerable penalties being imposed.

Permission to discharge effluents may be refused under certain conditions relating to the pollutant level of the effluent or may be linked to the imposition of tertiary treatment. Numerous heavy metals, such as arsenic, lead, cadmium, chromium, copper, nickel and mercury are included here, as well as halogenated hydrocarbons or halogenorganic compounds (AOX) and free active chlorine. All these substances can in principle end up in the detergent solution and hence the effluent from soiled materials or through corrosion

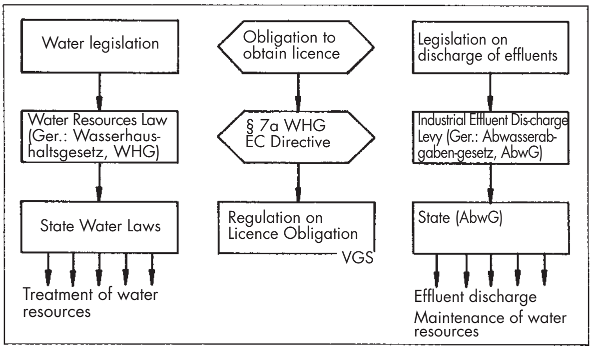

Fig. 2: Statutory instruments for water protection.

(of copper, zincification) or through the process itself (halogenated hydrocarbons in dry cleaning, AOX and free chlorine due to the use of active chlorine with bleaches and disinfectants in laundering).

§ 19g of the Water Resources Law stipulates that for equipment used in the storage, filling, handling, production, treatment and use of water pollutant substances certain precautions are necessary. Water pollutant substances are solids, liquids and gases that are capable of adversely affecting the physical, chemical and biological properties of water. Equipment must be designed in such a way that "there must be no risk of any contamination of water or any other adverse change to its properties." Likewise, water pollution is an important criterion in the classification prescribed in the safety guidelines of the Association of the Chemical Industry for cooling water and fire protection resources in chemical stores.

Water Pollutant Classes (WGK):

WGK 0: generally not pollutant,
WGK 1: slightly pollutant,
WGK 2: pollutant,
WGK 3: severely pollutant.

Criteria behind the water pollutant classification:

- acute oral mammal toxicity LD_{50}
- acute bacterial toxicity EC_0
- acute fish toxicity LC_0
- merit rating due to
  - biological degradability
  - solubility
  - carcinogenicity
  - mutagenicity
  - bioaccumulation
  - photolysis, etc.

Many plant operators erroneously hold the view that producing a licence for their system protects them from further action on the part of the authorities and they therefore try to claim rights of protection. In fact, the holder of a licence is permitted to operate a system in the manner specified. A licence, however, only states that a system complies with the law in force at the time of issue. It does not represent a "privilege" for all time. This is due to the fact that environmental technology is developing rapidly and that, in the interest of environmental conservation, both legislation and legal judgements need to be able to respond to new technologies. The legislator has therefore made provision for various ways of responding, even in retrospect, to material changes that occur. Hence, § 17 BImSchG (Ger.: Bundesimmissionsschutzgesetz = Federal Immission Protection Act) allows for authorities to issue supplementary directives and § 5 BImSchG subjects the operator of any system in need of a licence to a variety of obligations: he must set up his system in such a way that adverse environmental factors, hazards and nuisances to others are avoided, residual substances are either eliminated or recycled, and heat emissions are put to optimum use. This means, first and foremost, for operators of systems requiring a licence that they are required without official notification to observe and implement the statutory requirements. Likewise, operators of systems which do not require a licence should also endeavour to behave appropriately and adapt to the changed legal position, because it is quite likely that given continued technological developments the legal provisions will become more strict.

Which regulations should be complied with in each case is determined by the activity carried out by the plant operator. First and foremost the operator should follow the official advice. This makes clear the main requirements, though it will frequently contain references to other mandatory regulations, directives and legal provisions, too, the requirements of which are not specifically related to the addressee in the order notice, however.

Plant operators who work with chemicals are urgently advised to produce and continually update detailed storage lists. For systems requiring a licence there is a statutory duty to do this (§ 6 Incident Regulation, Ger.: Störfallverordnung). Lists of this kind do not merely provide an up-to-date overview of the quantities stored, but also, given proper design and detail, allow quick and deliberate accessing of all the relevant data on handling the substances, be it for example on the measures needed to be taken in the event of unforeseen emergencies or if a competent member of staff should wish to find out the type of storage most suited to a particular substance, or whether or not only trained personnel are permitted to handle the substances (Fig. 3).

A stock list like this should be subdivided into different categories:

1. Stock data:
- Inventory/material number
- Stored quantity
- Size of container
- Consumption/rate of throughput.

2. Safety data:
- Special storage requirements,
- Special knowledge requirement,
- Risk class VbF,
- Ignition point, flash point,
- EU classification codes for handling and using hazardous substances

3. Environmental data:
- Workplace threshold limits,
- Water pollutant class,
- Concentration and mass flow rates as per Technical Guideline on air quality and Part 2 of BImschV.

Environmental monitoring Temporal and quantitative monitoring of water, air or waste pollution in a particular ecosystem. Phosphates have been used for a long time in detergents, for instance, to absorb water hardness; these contribute significantly to phosphate pollution of waterways (see Fig.).

From 1980 onwards reduced phosphate detergents were introduced, and by 1989 all detergents in Germany had switched to phosphate-free formulas. These measures, along with the introduction of tertiary treatment in sewage plants, have considerably reduced phosphate pollution in waterways. Boron is also found in detergents in the form of sodium perborate. Through the use of bleaching activators it has been possible to improve the effectiveness of sodium perborate and reduce the quantity used.

Environmental pollution Physics tells us that material objects change in time and space under energy defined conditions. Environmental problems arise because man exploits nature to satisfy his own needs. All interventions in the eco-system affect the ecological balance. Safe and environmentally correct production alone is not enough. It is necessary to reduce the potential for risk by technical control, monitoring impact and using effective waste disposal techniques. More importantly, it requires reduction in potential risks and minimising the quantity of waste produced. The key to this is in the development of integrated environmental control procedures that take into account the aspects of safety, environmental protection, energy consumption and the efficient use of resources, without compromising product cost or quality.

When the extent of environmental impact is considered, three areas can be distinguished. According to Cmelka, these areas can be separated by the following boundaries: be-

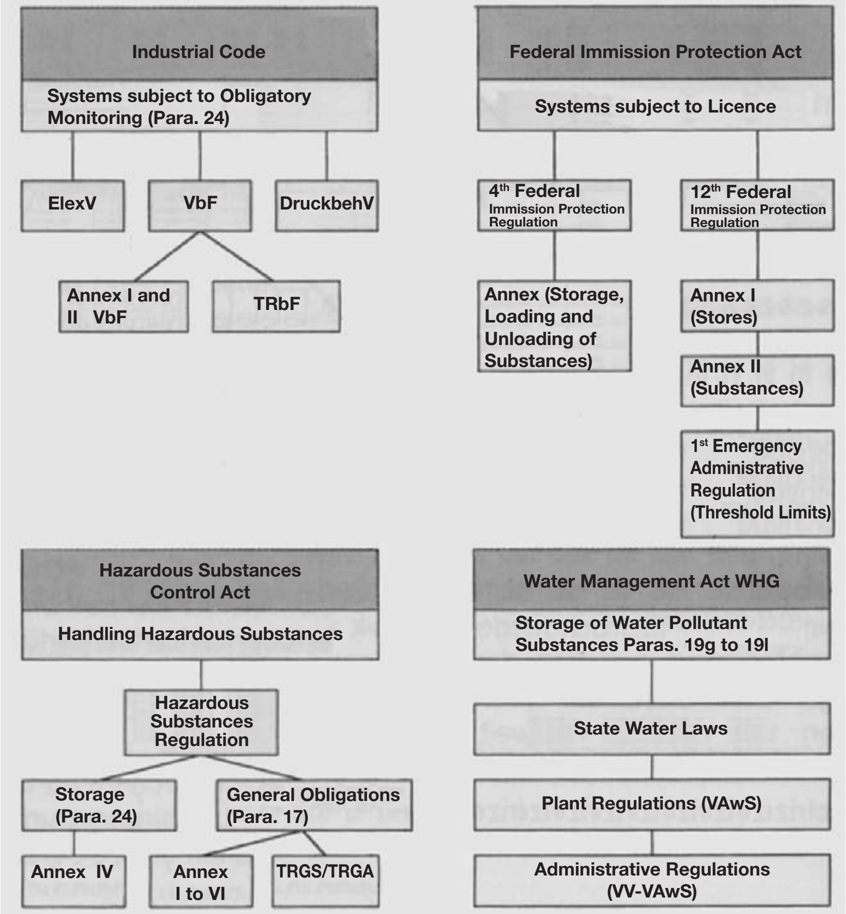

Fig. 3: Overview of the major regulations governing chemical storage.

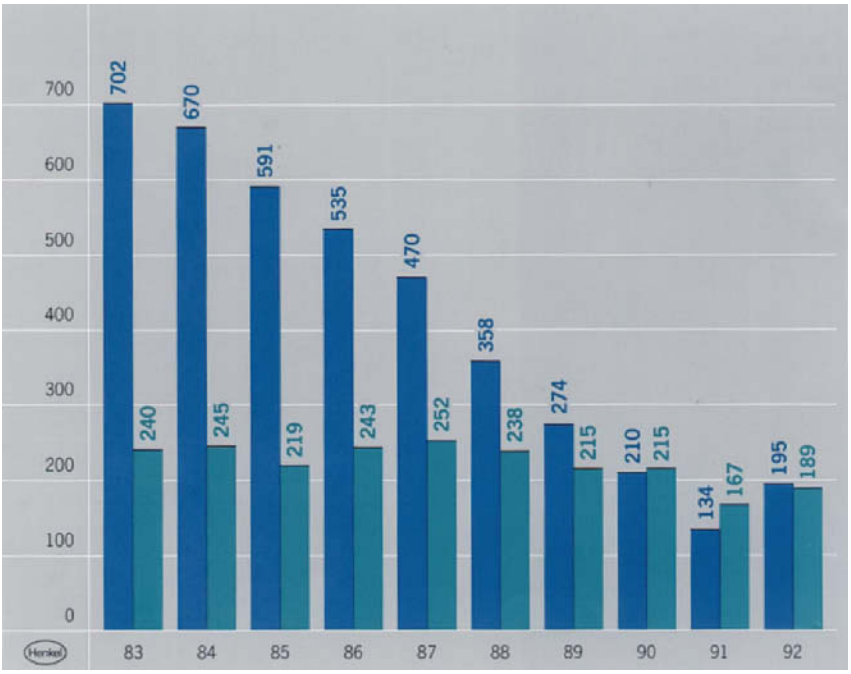

Fig.: Environmental monitoring – boron and phosphate (annual mean values in g/s) in the Rhine (control point: Düsseldorf-Himmelgeist). Blue = phosphate (phosphorus); green = boron.

tween environmental compatibility and environmental impact is the start of statutory regulation, between environmental impact and environmental damage is the start of environmental loading. Environmental compatibility is distinguished by the perceptibility threshold. The size of the individual areas can be quantified for the individual eco-systems, e.g. how high the limit for introducing statutory regulations has been set in relation to the overall magnitude of the potential effect of the environmental factors. Scientific or medical phenomena may be related to the recommended concepts, and these can be traced back to interventions in the eco-system in question. Although this scheme is simple, the limits of its application can be seen if we consider the global eco-system, the biosphere: other factors, such as susceptibility, adaptation, accumulation and synergies also come into play.

Definitions:

- Neutral effect: no measurable difference to the eco-system, any changes remain within the range for these parameters in an undisturbed system.
- Environmental compatibility: measurable change of one component of the eco-system, any effects remain within the range of the range of fluctuation for these components in an undisturbed system.
- Environmental nuisance: subjective influence on the well-being without effects that can be detected objectively. These must be kept to a minimum, taking into consideration both economic aspects and whether it is technically possible to avoid the nuisance.
- Environmental pollution: in the short term, no significant effects, although these do occur in the long term. The effect is reversible, and returns to the original state after the factor is removed.
- Environmental threat: Significant, but reversible effects, even after a short period of exposure. Effects are irreversible after a longer period of exposure.
- Environmental impact: Irreversible effects even after a short period of exposure.
- Detection threshold: This must be stipulated on the basis of scientific data concerning significant affects on eco-systems as a result of environmental factors (noise, contaminants, etc.).
- The introduction of statutory requirements must be stipulated on the basis of environmental quality standards. Although the process of marking out the boundaries includes scientific data, and takes into consideration the regional situation, it is eclipsed by political decisions.
- The limit of load capacity refers to the eco-system in question. It must be stipulated again using environmental quality standards, but this time including a risk factor as regards possible environmental threat. The stipulation of the risk factor is again a political decision.

In textile finishing, environmental pollution can be caused by:

- Effluent,
- Air exhaust,
- Waste,

or by consuming resources:

- Finishing agents,
- Energy.

The Table summarises by way of example the material parameters used to assess effluent from textile finishing, which may involve critical values and require measures to be taken to avoid pollution or to treat the effluent before discharge to the municipal sewage system.

Environmental profile of polymers More environmentally-friendly products are being developed for the application of polymers. Table 1 depicts an environmental profile for dispersed polymers. From the packaging through to the properties of the dispersed poly-

● Systems comprising polymers, water, dispersants, additives (solvent free)

Packaging: type, storage, shelf-life, return, reuse, disposal

Disposal of product residue

Handling: protective measures, pourability, mechanical safety, risk in fire, means of disposal (odour, emissions, effluent, burial), toxicology, physiological characteristics

● Application: from water, pH-values above 2 and below 11

Disposal of residual liquor: recycling, incineration, dumping

Waste water from production:
- reclamation
- receiving stream
- clarification sludge → disposal

Emissions from textile production:
odour
- cleaning → disposal

● Characteristics on the product: health and safety, food legislation, allergies, odour, fogging, poluting, burning

Packaging: type, storage, shelf-like, return, reuse, disposal

Handling: mechanical equipment

Disposal of the textile and industrial product: recycling, incineration, dumping

Disposal of a complex system comprising textile, metal, plastic, glass, e.g. motor vehicle: recycling, incineration, dumping

Tab. 1: Environmental profile of dispersed polymers for textile and industrial applications (source: Fischer).

Parameters	Baden-Württemberg regulations (1978)	ATV worksheet A 115 “Gelbdruck” (April 1981)	Principal source of pollution in the finishing process
1. Heavy metals			
Chromium VI Chrome total +	0.5 mg/l 2 mg/l	0.5 mg/l 3 mg/l *	Chrome dyeing (wool), dyestuff oxidation with vat and sulphur dyeing
Copper ++	2 mg/l additional limit on heavy metal fractions required	2 mg/l *	Coppering dyes, poss. certain reactive dyes
Zinc +	5 mg/l	5 mg/l *	Cross-linking catalysts (resin finishing), stripping faulty dyeing
2. Anions (non-metallic)			
Sulphide +	10 mg/l	2 mg/l	Sulphur dyeing (cotton)
Sulphite	50 mg/l	only in such a low concentration to give no anaerobic effects in the public sewers	Vat dyeing, reductive aftertreatment of disperse dyes on polyester
Nitrite	10 mg/l	20 mg/l (possibly higher fractions)	Various dyeing processes
3. Organic parameters			
Hydrocarbons +++ (especially Baden-Württemberg)	20 mg/l pretreatment plant required	20 mg/l where separation of volatiles includes the removal of hydrocarbons (Hydrocarbon controls as per DIN 38 409 T 18)	Fibre lubricants (synthetic fibres), spin finish, white spirit and mineral oils (pigment printing)
Chlorinated solvent or	5 mg/l as Cl at the point of discharge		Tetrachloroethane,spotting agent, poss. chlorobenzene carrier
halogenated hydrocarbons		10 mg/l as organic bound halogen	
4. General requirements			
Colour +++	Effluent may only be discharged in so far as any colour it may contain can be removed by the Municipal Sewage Treatment Plant	Dyestuffs may only be discharged at concentrations that do not appear coloured after mixing in the entry to a mechanical-biological effluent treatment plant	Total elimination of colour and Reactive dyestuffs in particular is not possible in a mechanical-biological effluent treatment plant
Toxicity	Effluent may only be discharged as long as it does not carry the potential to impair the biological processes in the sludge treatment plant nor impairs the effectiveness of the sludge	Effluent may be discharged only when: – it will not affect the health of staff working in the municipal effluent treatment plant – it will not affect the continuing operation of municipal effluent treatment plants – ground water is not polluted above permitted levels nor adversely changed – no effluent smells are given off in the municipal effluent treatment plant Otherwise the effluent must be treated before discharge or other suitable measures taken.	Potential pollutants in textile effluent: Chrome VI Conc. alkaline solution Sulphide Hydrocarbons Carriers Cationic auxiliaries (when they are not balanced with sufficient anionic auxiliary discharge) etc.

Tab.: Earlier example (circa 1980) of material parameters to assess effluent from the textile finishing industry.
** Where sewage sludge is used in agriculture, the best method of sludge disposal in terms of recycling where there is a well-situated area for the sludge to be deposited, the relevant explanatory documents must be noted and if necessary, the heavy-metal fractions from the waste must be controlled.*
+,++, +++ Relevant to effluent discharge from the textile finishing industry according to actual experience of the water regulatory authorities.

	EVA dispersion 50% T_G – 18°C	dispersed polyacrylic 50% T_G – 40°C
chemical oxygen demand (COD), determined by dichromate oxidation (DIN 38 409, Part 41)	1000 mg O_2/g	940 mg O_2/g
organic carbon, determined by combustion and CO_2 test (DIN 38 409, Part 3)	300 mg C/g	330 mg C/g
eliminability through activated sludge (biodegradability as per OECD Test 302 B)	>80%	>80%
precipitability	with aluminium sulphate	with aluminium sulphate
bactericidal action (fermentation tube test)	>1000 mg/l	>1000 mg/l
water-pollutant class (1 = substances of low pollutant potential)	1	1
acute, oral toxicity (LD50, rat)	>2000 mg/kg	>2000 mg/kg
skin irritation (rabbit)	non-irritant	non-irritant
mucous membrane irritation (rabbit‘s eye)	non-irritant	non-irritant
European Standard EN 71, Part 3, Safety of toys: chemical properties	heavy metals Sb, As, Ba, Cd, Cr, Hg, Pb are not present	
Disposal as per TA technical guidelines for waste/types of waste schedule of the German Federal Environmental Protection Agency	hazardous waste incineration, for polymer dispersions or, if need be, physico-chemical treatment also, e.g. filtration Waste schedule: 57303 (dispersed synthetic), 57702 (latex)	

Tab. 2: Environmental data for dispersed polymers (source: Fischer).

mers and those of the finished textile, from the system of fibre plus polymer with dispersant right down to disposal, the environmental profile of polymers can be characterized in such a comprehensive manner that many technical properties are comparatively overlooked.

The environmental details in Table 2 provide information about aqueous dispersions composed of polymer, dispersant and processing aid. Only when applied on the textile material, dried and cured can the total system, consisting of fibre, additive, dispersion with polymer and processing aids, be ecologically and toxicologically evaluated. Both dispersions (which are free from plasticizers) conform to the recommendation of the Federal Health Ministry, Berlin, for dispersed synthetic substances as defined by the Foodstuffs and Commodities Act (Germany). According to this act, plasticizer-free dispersions of synthetic substances may be used if certain conditions are met, i.e. if the chemical substances specified in the recommendation, certain polymer components (monomers), certain processing aids used in specified small quantities, e.g. certain catalysts, stabilizers, protective colloids, thickeners, emulsifiers, defoaming agents, are components of each of the dispersions being evaluated. “Commodities as defined by the Act are: items designed to be used in the manufacture, treatment, marketing or consumption of foodstuffs and therefore come into contact with these foodstuffs or have an effect upon them.”

Recommendation XIV of the German Federal Health Office on dispersed polymers corresponds to the draft of the new EC Directive No. 128/90 on “Materials and objects made of synthetics designed to come into contact with foodstuffs.” In this EC Directive, the substances also recorded in the dispersion recommendation are divided into two groups:

Group A: The permitted monomers and other parent substances, e.g. acrylic ester, vinyl ester, styrene, acrylic nitrile, butadiene, vinyl chloride, ethene, known monomers and maleic acid, melamine, ethene oxide.

Group B: Monomers and other parent substances where no decision has been made about incorporating them into Group A, e.g. acrylamide, N-methylol acrylamide, reactive monomers capable of being incorporated in the dispersed polymers.

The subject of emissions specified in the environmental profile (Table 1) needs to be examined more closely in regard to C-emissions. The debate on emissions has focused on two particular aspects:

- the concept of “synthetic resins” in the 4th Regulation in the Protection Against Harmful Effects on the Environment Act for machinery, including stenter frames, requiring certification,
- the Technical Guideline on air quality.

The “synthetic resin” concept should initially include various substances used in textile finishing, dressing, easy-care finishing, proofing, etc. It is sensible to understand it in terms of the familiar chemical concept for synthetic resin, which includes the actual synthetic resins alkyd, phenol, epoxy and melamine resins, i.e. three-dimensional cross-linkable products. What should not be included, however, are cross-linking agents that used to be described as easy-care finishing resins, which exist and are used in monomolecular form (as monomers) or are not self-crosslinking dispersed polymers.

In future the OECD definition (Tables 3 and 4) as found in the 7th revision of the Directive on hazardous substances should apply to the concept of a polymer (source: Fischer).

- Molecules comprising a series of one or more monomeric units
- Molecules with > 50% by weight having at least three covalently bonded monomeric units
- Molecules with < 50% by weight having the same molecular weight
- Such molecules must show a molecular weight distribution

Monomeric unit: Reacted form of a monomer to polymer

Tab. 3: OECD polymer definition (for 7th Amending Directive for Dangerous Substances).

M – M – M	S – M – M		
M – M – M – M	S – M – M – M	< 50%	> 50%

M – M – M ... M – M	S – M – M ... M – M	< 50%	

M = Monomeric unit (also of varying type)
S = Starter molecule

Tab. 4: A polymer according to the OECD definition.

Environmental protection regulations In order to decrease risks when handling environmentally hazardous substances, regulations for equipment using water polluting toxic substances are established in the Water Resources Act (WHG) in accordance with the precautionary principle. The regulations stipulate that leakages from engineering equipment, official procedures and recurring tests must be excluded and work on equipment should basically only be carried out by specialist companies authorised by the water authorities. The scope of these regulations has been extended to cover equipment used in manufacturing, treating and using water toxic substances in the interests of an improvement of water protection in the WHG which is a necessary precaution. The state regulations fulfilling federal law are contained in the "Ordinance on equipment for storage, drainage and transforming water toxic substances".

In the meantime, operational regulations have been drawn up concerning storage and drainage and conversion of water toxic fluids. These describe safety systems in the form of technical directions (TA) which will have to be adhered in future due to a danger analysis which is to be undertaken in individual cases. It is therefore possible

- to demonstrate to plant operators which requirements the plants must fulfil,
- to give experts a framework for suggestions concerning additional requirements on existing plants,
- to simplify the task of the authorities to ascertain whether existing plants are suitable as well as their assessment.

Environmental reporting The results of a survey of a company's environmental actions. May be used as the first steps leading to an → Ecobalance.

Environment problems in pigment printing Compared with other textile printing processes pigment printing is of major importance. Today pigment printing is the most important printing technique worldwide having a market share of more than 50%. Its advantages are as follows:

1. simple technical application: the application consisting of printing, drying and fixing is basically very simple. Due to this short process pigment printing is quite cheap and one of the most ecologically favourable textile printing processes;

2. applicability to all kinds of fibres: pigment printing can be applied to all kinds of fibres which have sufficient thermostability;

3. wide range of colours, high fastness to light: in pigment printing we have at our disposal a wide range of colours with a high fastness to light;

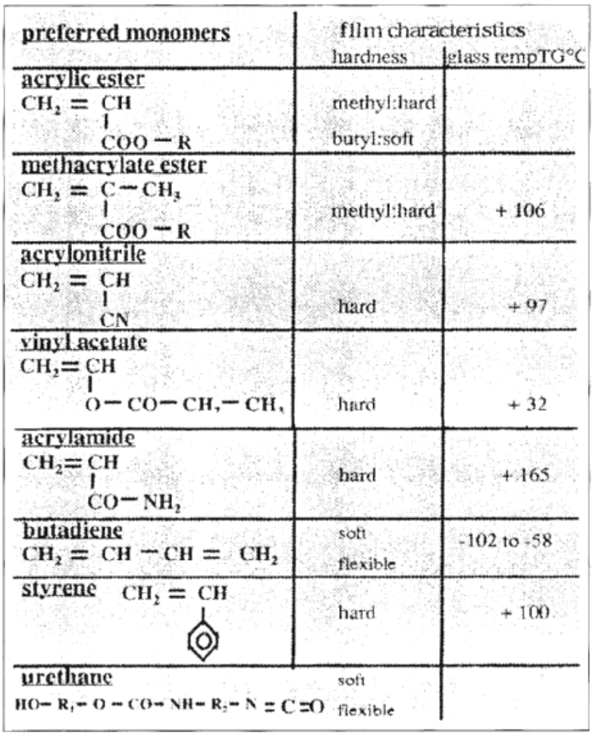
4. special printing processes: a range of special printing processes such as white, bronze and pearl prints can be carried out with pigment systems.

A pigment printing paste consists of the following ingredients:

- water
- antifoaming agent
- emulsifier
- binding agent
- softening agent
- agent improving the running properties
- thickener
- pigment dye
- cross-linking agent
- acid donor

1. Antifoaming agents: One generally recommends adding an antifoaming agent to prevent foaming during the production of printing pastes or during printing.

2. Emulsifiers: Apart from their emulsifying effect these products aim at stabilizing the whole pigment printing system, i.e. preventing dyestuff agglomerations, reemulsifying dried particles of the binding agent



preferred monomers	film characteristics hardness	glass temp TG°C
acrylic ester $\begin{array}{l}CH_2 = CH\\ \quad\;\, \mid\\ \quad COO - R\end{array}$	methyl:hard butyl:soft	
methacrylate ester $\begin{array}{l}CH_2 = C - CH_3\\ \quad\;\, \mid\\ \quad COO - R\end{array}$	methyl:hard	+ 106

butadiene $CH_2 = CH - CH = CH_2$	soft flexible	-102 to -58
styrene $CH_2 = CH$	hard	+ 100
urethane $HO - R_1 - O - CO - NH - R_2 - N = C = O$	soft flexible	

Fig. 1: Binding monomers and their impact on their films.

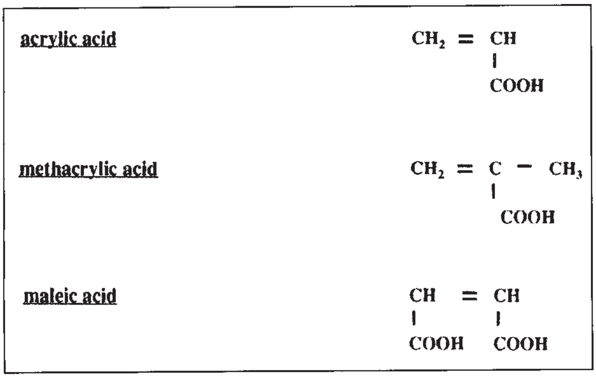
and improving the running properties of the printing paste.

3. Binding agents: Three groups of binding agents are essentially of importance for the fixation of the dye pigments on textile surfaces (see Fig.1). Binding agents based on acrylate stand out due to their good fastness to light and heat. Depending on the polymer structure the films they produce range from being hard to soft and very soft. The polymer structure also influences the fastness levels to dry cleaning and washing. Binding agents based on butadiene are very sensitive to temperature and light, i.e. the films turn yellow and embrittle. On the other hand, they produce soft printing paste films with good binding strength on natural and synthetic fibres with good to excellent fastness levels to washing and dry cleaning. In pigment printing butadiene binding agents are mainly used as a mix with acrylate binding agents. The aqueous dispersions of binding agents based on polyurethane physically form the binder films. The printing paste films are very flexible and can also be fixed at low temperatures above 110°C for 8–10 min. Their fastness to light as well as their fastness levels to washing and dry cleaning on heat-sensitive textiles are good. It is possible to offer a binding agent which meets all requirements of textile printing. Thus, the printer can choose from several types of binding agents to be able to meet the customers' demands in terms of fastness levels and handle.

4. Softening agents: It may be necessary to add a softening agent for the individual modification of the handle depending on the customer's demand. Due to the use of binding and wetting agents and of synthetic thickeners pigment printing has the disadvantage of producing a stiff handle. Thus it works with selected softening agents which have a perfect softening effect without impairing the fastness levels of the prints to a high extent. Non-volatile fatty acid esters, mineral and silicone oils serve as softening agents.

5. Agents improving the running properties: Specific climatic conditions and the use of highly pigmented printing pastes necessitate the addition of so-called moisture regulators or evaporation retardants to the printing pastes in order to avoid screen blockage. Glycols, glycerine and urea are used.

6. Thickeners: Those based on white spirit are not common any more in pigment printing mainly due to ecological requirements. Today the salts of the polyacrylic acid and its copolymers are almost exclusively used (see Fig. 2). For pigment printing mainly ammonium salts are used since during drying and heat-setting of the prints ammonia can escape leaving only the polyacrylic acid. These acids are hardly water-soluble so they have the effect of a catalyst. The rheological properties of the synthetic thickeners are similar to those of thickeners based on white spirit. They can also be used in low amounts to achieve printing pastes with an acceptable viscosity. The effect of synthetic thickeners highly depends on the pH value and they are also sensitive to electrolytes. Thus the necessary application amount of a synthetic thickener depends on the quality of the plant water, the dyestuffs used and the amount of electrolytes of the auxiliaries.



acrylic acid $\begin{array}{l}CH_2 = CH\\ \quad\;\;\, \mid\\ \quad\;\; COOH\end{array}$

methacrylic acid $\begin{array}{l}CH_2 = C - CH_3\\ \quad\;\;\, \mid\\ \quad\;\; COOH\end{array}$

maleic acid $\begin{array}{ll}CH = & CH\\ \mid & \mid\\ COOH & COOH\end{array}$

Fig. 2: Examples of thickening monomers.

7. Cross-linking agents (Fig. 3): Usually these are modified urea and melamine formaldehyde resins with as low as possible an amount of free formaldehyde. They are added to the printing pastes as crosslinking agents to improve the general fastness levels and particularly the abrasion and wet scrubbing fastness levels on synthetic fibres.

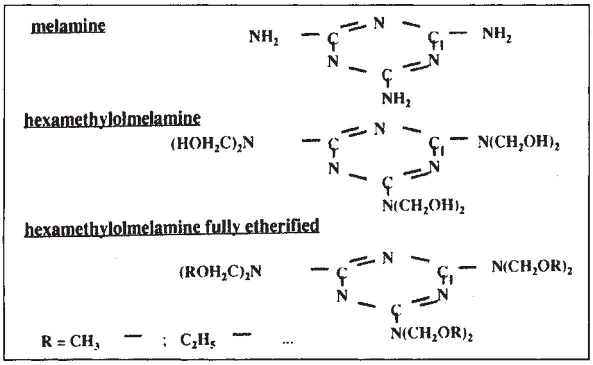


Fig. 3: Examples of crosslinking agents.

8. Acid donors: Binding agents and crosslinking agents require an acid pH value for their fixation. Additional acid donors such as diammonium phosphate are included in the printing paste to guarantee optimum fixation even if the conditions are unfavourable.

Terms such as ecology, environmental protection, ecological textiles, biodegradable products are increasingly used in our daily language. Depending on the test institute various criteria are to be tested. Thus, the recipes in pigment printing have to be adapted to the relevant requirements. Ecological pigment printing means that the environment is less damaged than with a system working with conventional auxiliaries. Different aims are to be achieved, e.g. low formaldehyde content, low APEO content, low hydrocarbon content or formaldehyde-free, APEO-free and hydrocarbon-free. The necessary recipe can be formulated with the individual products (see Fig. 4 and 5). As early as three years ago the first factory trials in formaldehyde-free pigment printing were carried out. Due to the technical problems and high costs formaldehyde-free acrylate binding agents were not taken into consideration.

water	X	g

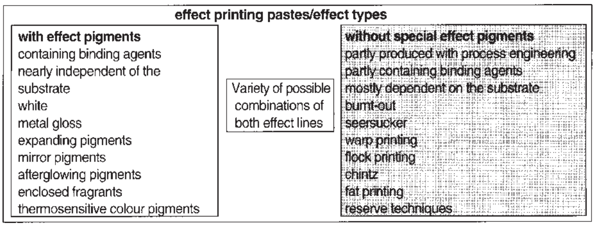
Ready-made pastes are pigment printing systems which can be directly applied. Depending on the effect desired they already contain the necessary auxiliaries to enable continuous working. The effect can be divided into two groups (Fig. 6 and 7):

- producing effects with effect pigments (containing binding agents, nearly independent of the substrate);
- Producing effects without effect pigments (partially containing binding agents; produced by means of process engineering).



effect printing pastes/effect types

with effect pigments
containing binding agents
nearly independent of the substrate

Fig. 7: Possible effects with effect pastes in continuous printing.

High quality pigment printing is the ecologically cheapest textile printing process which will be suitable to successfully meet the future requirements with its developments.

After several years of development ink-jet technology is still mainly used for sampling, quite rarely for production. This technology stands out due to its flexibility and fastness compared with common printing systems. Moreover there are no screen costs for sampling. The use of different substrates impairs its applicability because every substrate requires its own dye (dyestuff class) and a corresponding fixation process for the fixation of the dyestuffs. Pigment dyes which can be applied to nearly all substrates could solve this problem. However, they cannot be incorporated into the fibre to react with it so they have to be heat-set using suitable binding agents. Up to now this process has not caused any problems with the common printing machines. If ink-jet technology is used for pigment printing, binding agents which are to produce maximum fastness levels on the fabric may clog the jets or block them. In classical printing processes as well as in pigment printing highly fashionable designs are sometimes combined with effect pigments. These coarse-grained pigments (white/pearl/metal, etc.) produce a special effect on the fabric. Ink-jet processes are not yet considered to be suitable for the application of these pigments. (according to G. Schneider).

Environment protection in finishing (European Regulatory Requirements) Pollution from a textile finishing house can be of two main types; water-borne (effluent) and air emissions. Water-borne pollutants can be divided into three classes; firstly, toxic chemicals, which may be present in quite low concentrations; secondly, organic impurities which in large amounts can take much of the oxygen out of the water, so that it can no longer support aquatic life; and thirdly, colour, which, despite protests from technical experts that the low concentrations of dyestuffs which escape into the effluent are not a health hazard, is classed by environmental regulators as an aesthetic pollutant.

Possible solutions which the textile finishers in general will have to consider should include:

1. source reduction;
2. extraction of the pollutant;
3. treatment of the effluent to destroy the pollutant;
4. substitution with a less harmful alternative.

Source reduction is the place to start any environmental program. A complete listing should be prepared from purchasing records for all facilities, including all chemicals for production, maintenance and janitorial supplies. Minimising the variety of chemicals and dyestuffs that are purchased will take time and commitment from top management but can pay big dividends from both the environmental analysis and actual production cost standpoints.

Extraction of the pollutant, by sedimentation or filtration, for example, can lead to another challenge: how to dispose of the extract. In Europe, this is usually by landfill or incineration, as long as this does not produce further pollution hazards. Destruction, for example by bacteria or oxidation, must not result in the formation of hazardous products in the treated effluent, a theoretically possible consequence, for example, of decolorisation of dye liquors with ozone. However, another alternative, re-cycling or re-use of the offending chemical, may be available. Often the least expensive and most reliable answer is to replace the harmful substance with a less dangerous and commercially available alternative, a solution which is frequently overlooked.

Regular environmental audits are essential to ensure that the situation is kept under control, that improvements are being made wherever possible, and that changes in processing operations do not introduce new hazards. ISO-14 000 environmental management standards being developed include guidelines for carrying out such audits.

Environmental terminology and regulations affecting the textile finisher: EC Directive 76/464 covers pollution caused by certain dangerous substances discharged into the aquatic environment. List I, the “Black List”, includes pentachlorophenol (PCP), certain pesticides and organo-halogens which are regarded as so harmful that steps should be taken to eliminate pollution by them. List II, the “Grey List”, covers less harmful substances but recommends that they should be controlled and eventually reduced by environmental quality standards (EQS), and includes heavy metals such as copper, zinc and chromium.

AOX (Adsorbable organo-halogen compounds): German law limits the AOX content of effluent to not more than 0.5 mg/l, with not more than 3mg/l from a component stream (production unit). Belgium imposes a limit of 0.8 mg/l of AOX in waste water. Sweden and Finland have also enacted legislation and regulations are being prepared in the Netherlands. Although not currently an issue in the UK, this situation is expected to change in the near future.

BOD (Biochemical oxygen demand): This measures the amount of oxygen absorbed under defined biological conditions.

COD (Chemical oxygen demand): A measure of the oxygen required to oxidise organic pollutants completely to carbon dioxide and water.

VOC (Volatile organic compounds): The UK Environmental Protection Act 1990 introduced new controls on air emissions, waste and waste disposal and nuisance. Air emissions from textile processes are covered in Section 6.5B defined as coating processes. The definition of coating is not that traditionally used in the textile sector but appears to cover surface application to any substrate. (see Tab.1 for set emission limits to be met by October

Total VOC (as total C, excluding particulate matter)	50 mg/m^3
Total particulate matter (including emissions from material handling)	50 mg/m^3
Carbon monoxide (from incinerators)	100 mg/m^3
Isocyanates (as NCO group)	0.1 mg/m^3
Formaldehyde	20 mg/m^3
Dilution and odor masking specifically forbidden.	

Tab. 1: Emission limits.

1997). Similar regulation on air emissions are being, or have been introduced in other European countries.

Packaging legislation: The EC is developing a regulation on packaging and packaging waste which has now reached a fourth draft stage. This states that ten years after it comes into force 90% by weight of packaging waste must be recovered, 60% to be recycled, the remainder used for energy production or composting. Five years after the regulation comes into force no packaging can be used for which there are no established channels for its return and subsequent re-use or recovery. Germany has already a regulation of this type, Verpak VO, and France introduced a similar system in January 1993.

Environmental aspects of wet processing: The cotton fibre is one of the purest natural forms of cellulose, of which it contains between 88 and 96%. Non-cellulosic impurities will include naturally occurring organic compounds such as wax, pectins, proteins and colouring matter and minerals essential for plant development. Metal contents vary significantly between years and between growth areas; potassium is the most abundant metal followed by magnesium, calcium, sodium, iron, zinc, manganese and copper. Depending on the quality of the fibre, some non-fibrous material, for example seed-coat particles, may also be present in the spun yarn. Finally, in addition to natural impurities, grey cloth arriving from the weaver will contain warp size, and knitted fabric will contain lubricants which have been applied to the yarn to assist in the knitting operation. All these impurities must be removed before the fabric is dyed or printed. For effective and satisfactory dyeing, the material must be absorbent, reasonably and uniformly white in colour and free from non-fibrous material. This is accomplished by desizing, scouring, bleaching and sometimes mercerising. These treatments, and the subsequent dyeing or printing, may require the presence of auxiliaries such as alkalis or surface active agents, which must also be removed from the fabric after processing.

Desizing: Cotton yarns are normally sized with native starch or modified starches. Native starches consist of two components, amylose (linear chain polymer) and amylopectin (branched chain polymer). Native starches vary in their amylose content; the higher the amylose content, the easier the size is to remove in desizing. Typical amylose contents are shown in Table 2.

Sago	26%
Wheat	25%
Maize (Corn)	24%
Potato (Farina)	20%
Rice	19%
Tapioca	16%

Tab. 2: Typical amylose contents.

Native starches may be chemically treated (modified) for improved sizing properties, and these are sometimes, but not always, easier to remove than natural starch. The typical add-on for starch sizes is around 8–15% on the weight of the fibre depending upon the yarn count and the number of threads per cm. Starch and modified starch sizes must be degraded in order to effect desizing, and hence cannot be recovered and recycled. Enzyme desizing is widely practised for the removal of starch sizes, but oxidative desizing is said to be growing in importance. The preferred oxidant is hydrogen peroxide, and this has encouraged the development of combined sizing, scouring and bleaching techniques, in either continuous pad-steam or cold pad-batch processes. The effectiveness of these processes is limited by the seed fragment content of the cotton.

Synthetic sizes: Water-soluble polymers such as polyvinyl alcohol and carboxymethyl cellulose may be used for sizing cotton yarns. These are readily removed in a normal scouring process.

Size re-cycling: In vertical companies which carry out sizing, weaving and desizing operations, it is possible to recover, concentrate and re-use synthetic sizes like polyvinyl alcohol, carboxymethylcellulose and polyacrylates by swelling/removal methods, or by ultrafiltration. Size recovery systems suitable for cotton have been developed by DuPont and BASF.

Effluent from sizing materials: Size removal processes may contribute up to 60% of the total COD value in wet processing.

	COD
Starch	900–1000 mg oxygen per gm
CMC	700–800
Polyvinyl alcohol	1500–1700
Polyacrylates	1000–1200

Tab. 3: COD value in wet processing.

Starch produces higher levels of effluent CODs than synthetic sizes because of the much higher levels of application (Tab. 3). Solid add-on of starch is normally two to three times that of a synthetic size. The effluent from starch desizing is normally easily treatable by conventional means. However, starch-based baths often contain preservatives to extend the life of the bath, which incidentally can also act as anti-mildew agents on the grey cloth during transport and storage. Such substances include chlorinated phenols, sodium silicofluoride, zinc salts, salicylanilide and other. Some of these are prescribed substances under UK legislation, and finishers have experienced severe effluent treatment problems with high levels of the fungicide pentachlorophenol (PCP), for example, in imported greycloth from parts of Asia and the Far East. In countries such as the United States, PCP is not used and has never been registered for use on cotton. The practice in some countries of requiring suppliers to provide a complete listing of all chemicals and materials used in manufacturing can eliminate these problems. Much research is focusing on the need to eliminate the desizing process entirely.

Scouring: This is normally carried out by means of an alkali treatment at high temperature. Sodium hydroxide or sodium carbonate may be used; the former resulting in more complete removal of impurities. The higher the temperature, the shorter the processing time may be; for the high-speed scouring required in continuous processing the treatment may be carried out under pressure. Sometimes the alkali treatment is preceded by an acid scour, to ensure removal of the mineral content, which may otherwise interfere with subsequent bleaching and dyeing processes. Most of the effluent load in cotton wet processing comes from the desizing and scouring operations. However, these effluents are normally easily treated by standard methods. The omission of a scouring process prior to bleaching or dyeing is not to be recommended, as it can only result in low colour yields and wasted dye, with increased cost of dyehouse effluent treatment, uneven dyeing and probable rejection by the customer.

Bleaching: This is normally carried out by using alkaline hydrogen peroxide, or alkaline sodium hypochlorite, or sodium chlorite under acid conditions. Two-stage bleaching with hypochlorite followed by peroxide is also carried out. Hydrogen peroxide is very safe for the environment and decomposes into water and oxygen. It is estimated that more than 95% of cotton textiles are bleached with hydrogen peroxide. The main environmental challenges in textile bleaching in the immediate future are likely to arise with the possibility of AOX formation when using a hypochlorite or chlorite based bleach.

AOX in bleaching: All chlorine-based bleaches can give rise to AOX (adsorbable organo-halogen compounds) in the waste water. Much of the concern over AOX compounds in bleaching arises from the presence of dioxins in the effluent from chlorine bleaching of wood pulp. Dioxins, a particularly toxic group of AOX compounds, are formed by the action of chlorine on lignin, a binding agent between the cells of multicellular cellulosic materials. The cotton fibre is a single cell; and contains no lignin, so dioxins are not formed in bleaching cotton with hypochlorite. In addition, actual studies have confirmed that dioxin is not formed by chlorine bleaching of cotton. However, it is possible that hypochlorite bleaching will be phased out over the next few years in favour of peroxide, mainly for psychological rather than scientific reasons.

Sodium hypochlorite: Sodium hypochlorite (NaOCl) bleaching leaves a residue of chlorine on the fabric which must be removed by an antichlor process. This is ususally accomplished by a sulphur-based reducing agent such as sodium sulphite or bisulphite which must be washed out. Sodium hypochlorite can be given a more environmentally-friendly antichlor treatment with alkaline H_2O_2, and this is accomplished in two-stage bleaching. The concentration of AOX in waste water from sodium hypochlorite bleaching has been reported to be 10–80 mg/l. The AOX loading in the bleach discharge is much reduced when the material has been prescoured with alkali, and this is normally done.

Sodium chlorite: This produces much less AOX (about one-tenth) of that from hypochlorite bleaching. Optimum bleaching takes place under acidic conditions ($pH<4$), but the process is highly corrosive to metals and requires the use of machinery fabricated from acid-resistant stainless steel and the use of anticorrodants such as sodium nitrate in the bleach liquor. An unpleasant gas, chlorine dioxide, can be generated. Engineering controls are readily available, however, to maintain a safe workplace.

Hydrogen peroxide: Hydrogen peroxide, used under alkaline conditions, is usually preferred for bleaching cotton. The decomposition of hydrogen peroxide is environmentally-friendly, producing only oxygen and water. A peroxide stabiliser is necessary to control the rate of decomposition of the bleach bath. Sodium silicate is an effective stabiliser, but can produce a deposit of silica in the fabric under certain circumstances, and is often replaced by proprietary organic stabilisers. These are generally effective in controlling the decomposition of the peroxide, thereby ensuring economic processing, but may contribute to some degree to the BOD of the effluent. The time required to produce a good white depends on the temperature at which the process is carried out. For continuous processing at or near the boil, the time is usually 15–30 minutes, while for energy conservation batchwise bleaching can be carried out at room temperature, in which case the minimum time would be twenty hours. Peroxide bleaching is normally carried out under alkaline conditions, but in certain circumstances, for example, when processing coloured goods, a neutral or weakly acid bath may be preferred. This, of course, reduces the alkali load in the effluent, but increases the time required for bleaching, due to the increased stability of peroxide under these conditions. All traces of peroxide must be removed from the goods prior to dyeing, especially when reactive dyes are to be used. To reduce rinsing time and costs, a peroxide scavenger may be used. A single stage combined scour and bleach using alkaline peroxide can be recommended in some situations to save water, energy, floor space and equipment needs. A single stage scour/bleach can be recommended when: 1. the goods do not have excessive plant/seed coat fragments; 2. this follows an oxidative desize step; 3. the subsequent dye shade is of sufficient depth and colour as not to require a full bleach (i.e. burgundy, black, brown etc.). It has been said that AOX may be generated in peroxide bleaching of cotton due to the presence in the fibre of organochlorine-based impurities e.g. pesticides, defoliants etc., but studies reported by the Bremen Cotton Exchange repudiate these claims. Any traces of contaminants found were well below the maximum permitted levels which apply in Germany to vegetable foodstuffs.

Mercerising: Mercerisation, the treatment of cotton with concentrated caustic soda solution, causes the fibres to swell and become more circular in cross-section. The molecular and morphological changes brought about by the process lead to an apparent increase in the visual depth of colour when the fibres are dyed or printed. This effect can give an important cost saving and an environmental benefit whereby less dyestuff is required for a given depth of colour. A reduction of 20–50% may be achieved in the amount of reactive dye required, depending on the particular dye used. Recovery of caustic soda is normally by evaporation of the dilute waste liquor. The process consumes energy but minimises environmental pollution from alkali or salt. Recovery is not usually carried out during the mercerisation of grey cloth, due to the heavy load of impurities such as starch and cotton waxes in the waste liquor. To obtain maximum benefit from a caustic recovery installation, fabric finishers can carry out mercerisation after scouring or bleaching; and to avoid an extra drying stage, may elect for a wet-on-wet application of the caustic soda. Fabric moisture content and caustic soda concentration must be very carefully controlled to ensure a uniform effect.

Dyeing: The main classes of dye for the coloration of cotton are direct, vat, sulphur and reactive. Opportunities to improve the effluent centre around the use of reducing and oxidising agents in vat and sulphur dyeing, and the high concentrations of common salt often required in dyeing with reactive and direct dyes. Removal of colour from waste water is necessary with all classes of dye, but is especially difficult for reactive dye effluents. Some dyes contain heavy metals, e.g. turquoise shades, but there have been substantial reductions on average over the past two decades. Some manufacturers are now producing whole dyestuff product lines which contain practically no heavy metals (i.e. the amounts are well below the strict ETAD limits). The major dyestuff companies have invested heavily in environmental improvements. The investments have resulted in higher fixation levels and lower salt requirements, most notably for reactives. Also, effluent treatment research targeted for textile mills, has been done by dyestuff companies and equipment manufacturers. Complete environmental solutions to improve textile effluent quality are emerging, but will require additional engineering and capital expenditures. However, in some situations reasonable return on investments should be possible due to recycling of chemicals, reduced treatment costs and surcharges and energy savings. Cotton Incorporated has done substantial research in the area of colour removal using commercially available ultra and nano filtration techniques. This allows dyers to re-use spent dyebaths.

Dyeing machinery and methods: Padding application methods are more environmentally-friendly than exhaust dyeing techniques. In knitgoods dyeing it has been shown that pad-batch application consumes significantly less water than exhaust methods using winches or jet machines. Tab. 4 gives data obtained in dyehouses in Denmark.

	1	2	3
Water	87 l/kg	95 l/kg	29 l/kg
Energy (wet proc.)	13 900 kJ/kg	14 200 kJ/kg	6100 kJ/kg
Energy (drying)	8400 kJ/kg	10 000 kJ/kg	8400 kJ/kg

Tab. 4: Water and energy consumption in comparison. 1 = jet-dyeing cotton knitgoods; 2 = jet-dyeing polyester/cotton knitgoods; 3 = continuous pad-batch dyeing cotton knitgoods.

The figures also showed that the high salt content of the waste water from jet-dyeing, which makes water recycling difficult, could be eliminated by pad-batch processing. Comparing winch and jet machines, the environmental arguments are in favour of the jet machine. Lower liquor ratios mean lower energy costs and less hydrolysed dye, less salt consumption and therefore less in the effluent. For all machines, the installation of automatic controls optimises the use of energy, dyestuffs and auxiliaries, and may reduce the need for corrections.

Reduction of sulphur dyes: The traditional reducing agent for sulphur dyes, sodium sulphide, has largely been phased out, due to the limitations on the presence of sulphide in waste water. There are new sulphur dyes on the market that are pre-reduced and contain much less sulphides as compared to a few years ago. Sodium hydrosulphite (hydros) can be used for blacks and navy, although not for red-brown due to over-reduction. It is relatively expensive, but the effluent is easy to treat. Borohydride is expensive and can produce hydrogen. It is sometimes used to avoid the effect known as “bronzing”. Thiourea dioxide is another option. With current technology it is easier to control than in the past, has good stability, is economical, biodegradable and nonflammable. Proprietary reducing agents for sulphur dyes are available, for example, from BASF and Sandoz. These are claimed to be environmentally safe.

Reduction of vat dyes: The term “vatting” is used to describe the procedure in which vat dyes are transformed from an insoluble form to the sodium salt of the leuco compound which is water soluble. This is normally accomplished using caustic soda and a reducing agent such as sodium hydrosulphite. Other reducing agents have been used including sodium borohydride, thiourea dioxide and reducing sugars. The leuco compound has a higher affinity for cellulose. Subsequently, the leuco dye is converted to the original insoluble form by oxidation. The comments under “Reduction of sulphur dyes” regarding sodium hydrosulphite, sodium borohydride and thiourea dioxide generally also apply to reduction of vat dyes.

Oxidation of vat and sulphur dyes: Bichromates are not permitted in effluents; peroxy compounds are generally regarded as the most environmentally-friendly alternatives. These include sodium perborate, sodium percarbonate and hydrogen peroxide. Potassium iodate, sodium bromate (Diresul Oxidant BRI [Sandoz]) and alkaline sodium chlorate are also acceptable.

Substitution: Sometimes substitution of one dyestuff by another can be a simple alternative to the installation of expensive effluent treatment plant. For example, Sulphur Black may be an acceptable alternative to Reactive Black 5, which can be difficult to remove from effluent.

Toxicity of dyes: The ecotoxicology of dyes has been discussed in relation to carcinogenicity and the impact of dyestuffs on the environment. The manufacture of azo dyes from benzidine was stopped in 1971 by the most important dye producers. Apart from colour, dyestuffs contribute to the BOD and COD of the waste water from dyeing, although not, it is believed, the toxicity.

Heavy metal contents: For non-metallised dyes and fluorescent brightening agents ETAD (Ecological and Toxicological Association of Dyes and Organic Pigments Manufacturers) has recommended the limits for heavy metals in dyebaths which are shown in Tab. 5.

Much useful consolidated information on colorants and the environment has been published by ETAD. The values in the column labelled ETAD limits in Tab. 5 are construed as the values that meet the legal requirements and relate to a 2% dyeing and total dilution of the dye used to a ratio of 1:2500.

AOX from dyestuffs: Dyestuffs and other products that contain organically-bound chlorine, bromine and iodine may contribute to adsorbable organo-halogen. Some dyes and fluorescent brightening agents contain halogen groups. However, a halogen atom split off from a halogenated heterocyclic reactive dye is not considered to be an AOX-active halogen. Halogen-containing solvents or auxiliaries (e.g. halogen-containing carriers for disperse dyeing of polyester fibres) are other sources of AOX.

Element	ETAD Limits	Maximum content in dyebath
Ag	100 ppm	0.2 ppm
As	50	0.1
Ba	100	0.2
Cd	20	0.04
Co	500	1.0
Cr	100	0.2
Cu	250	0.5
Fe	2500	5.0
Hg	4	0.008
Mn	1000	2.0
Ni	200	0.4
Pb	100	0.2
Sb	50	0.1
Se	20	0.04
Sn	250	0.5
Zn	1500	3.0

Tab. 5: Limits for heavy metals in dyebaths.

Dyeing with indigo: The amount of unfixed indigo removed from denim yarn in the wash-off boxes on a continuous dyeing range is influenced to a marked extent by the application method. pH control is an essential factor in indigo dyeing, and products such as a buffered alkali in liquid form have been developed, which will ensure that the optimum pH range of 10.8–11.2 can be safely maintained. Attention is being paid by machinery builders to the environmental requirements of the indigo dyer. For example, a recent machinery development pays attention to the economical use, de-colorisation and recovery of water. Consumption of water in washing is said to be about 3 litres/kg of warp, while recovery of the indigo dyestuff using an ultra-filtration unit means that about 80% of the washing water can be re-used.

Natural dyes: Many old recipes using naturally occurring colouring matters, such as logwood, cutch, madder etc., have been recorded. In dyeing with most natural dyes pre-mordanting is necessary so that they will exhaust and fix on the fibre substrate, develop the desired shades, and attain the – mostly rather poor – fastness properties. As mordants, metal salts are used which, when regarded from today’s standpoint, are applied in very large amounts. Partridge gives a recipe for a “fine and permanent” madder red in which for one pound of cotton, $^{1}/_{2}$ lb. of alum is used. Other recipes require significant quantities of iron or copper salts, or the use of bichromates and arsenates, which today are unacceptable for the commercial dyer. Only cutch and indigo can be dyed on cotton without mordanting, and cutch is usually applied with the addition of copper sulphate. There are many other potential problems to consider when contemplating the use of natural dyes. With the inherent variability of natural products, they lack the high degree of standardisation necessary for batch-to-batch reproducibility and today's "right-first-time" demands in dyeing economics. Fastness tests indicate that, in general, natural dyes possess poor light and wash-fastness.

Natural dyes, except those allowed in foodstuffs and cosmetics, have been subjected to far less examination and toxicological scrutiny than synthetic dyes. Some vegetable dyes are known to have harmful toxicological effect. For example, cutch has long been known to be an effective fungicide, at one time widely used for dyeing sails and fishing nets, for which it acted as a preservative. It may also be of interest to note that to dye one kilo of cotton fibre to a 5% shade with natural indigo would require the extract of no less than 15 kilos of indigo plants. Worldwide consumption of pure indigo is estimated at 14 000 metric tons. Indigo plants are said to contain about 0.5–2.0% of pure indigo with a reported yield of about 20 kilos of pure indigo per acre. It becomes apparent that a very large area would be required to provide the world's indigo needs, using natural indigo.

Safe handling of dyestuffs: Dyestuffs, especially in fine powder form, may be inhaled, ingested or absorbed through dermal contact. Although dyes have generally low toxicity there is always the possibilty of harmful effects. Codes of practice for the safe handling of dyestuffs in colour stores are now in general use, which are designed to minimise the exposure of dyehouse workers who weigh and mix dyestuffs. Respiratory protection equipment can help to minimise inhalation, together with other measures such as the use of weighing booths with dust extraction. Dyestuff manufacturers have also minimised dusting through reformulation, the sale of liquids and non-dusting granulars. Controls to limit skin contact during weighing include personal protective equipment: gloves, aprons or smocks, and eye protection. Controls to limit ingestion include the enforcement of no smoking, eating or drinking in the colour store and dye kitchen areas.

Printing: Reactive dyes account for almost half of printed cellulosic fabrics; the remainder is dominated by pigment printing. Some printing is carried out with vat dyes; the opportunites for improvement are similar to those for reactive dyes, although the insolubility of vat dyes means that they are easier to remove from the effluent. The waste water from printed fabric washing and screen washing contains colour (reactive dye, hydrolysed reactive dye or disperse dye) and the other components (thickener, urea, auxiliaries etc.) will give rise to significant levels of BOD and COD. Most pollution from the textile printing process arises as waste print paste from cleaning the machine, squeegees, pipes and mixing tubs, etc., rather than in washing-off of the print itself. Modern machines, for example the Stork RD Direct Drive, are designed to work with a very low content of print paste in the system.

Thickeners for reactive dyes: Sodium alginate is the preferred thickener for reactive dye printing due to its lack of reaction with the dyes in the presence of alkali. Synthetic thickeners for reactive dye printing have been developed, based on polyacrylates and polyacrylamide chemistry, but their deficiences in terms of electrolyte sensitivity, leading to viscosity fluctuations, and inferior runnung properties compared with conventional alginate pastes, have limited their use. Alginate is the major contributor to BOD and COD in the effluent from a print works and at present no recovery system is available which would permit its reuse. BOD and COD are readily treated before discharge to the environment however.

Urea: Due to limitations placed on the nitrogen content of aqueous effluents in areas sensitive to eutrophication, the use of urea is a particular concern for printers in Western Europe, the USA and Japan. Urea reduction is now one of the major discussion areas with reactive dye printers in these areas. In printing with reactive dyes urea acts as a swelling agent for cellulose. It disaggregates and solubilises dyestuffs, retards evaporation of water during drying, and increases condensation of water during steaming. The benefits for the printer are an increased solubility of the reactive dye in the print paste, improved colour yield, and better levelness and smoothness of the print. With all these benefits, and the low price of urea, it is difficult to find a technically acceptable and cost-effective replacement.

Currently printers are looking at three approaches to eliminate or partially substitute urea in textile printing. These are either: a switch to two stage printing (flash age fixation), complete or partial replacement with alternative chemicals, or the mechanical application of moisture with steaming. There is at least one new system on the market from a major dyestuff company which eliminates urea completely for printing with reactive dyes. Zeneca Colours has undertaken process optimisation studies and recommends the partial substitution of urea by dicyandiamide which reduces the total nitrogen load to the effluent. This system is operating in bulk but requires careful control of the drying and steaming operations in order to achieve good results. Another system used commercially involves printing the fabric with reactive dyes (no alkali or urea) and then dry only. Next, sodium silicate is applied to the face by kiss-roll pad. Steaming follows in a special loop steamer for fixation and the process completed by afterwashing and soaping.

Pigment printing: Possible toxicological concerns from the presence of traces of impurities in the organic pigments are likely to be small because of the very low levels left in the finished pigment. Aromatic amines may be present but only in small amount. Pigments in the form of barium and manganese salts require special attention because these are subject to threshold limits (0.5 mg/m^3 for Ba, 5 mg/m^3 for Mn). Other metals are claimed to be of little concern in pigment printing. Polychlorinated biphenyls (PCBs) may be present from the manufacture of certain organic pigments such as phthalocyanines, but much work has been carried out by pigment manufacturers to decrease PCB contents to below 50 ppm. Drying and curing releases volatile components into the hot exhaust air which may include ammonia, from the print thickener, formaldehyde from the fixing agent, and volatile organic compounds from the organic solvents used for maintaining dispersion stability or from white spirit (kerosene) used in part emulsion or from water-in-oil emulsion thickenings. There are “fume oxidisers” on the market today which claim to totally eliminate Volatile Organic Compounds (VOCs). These devices simply raise the temperature of the contaminated air exhaust to totally oxidise the unwanted organic compounds to water and carbon dioxide.

Waste disposal in pigment printing: Because all of the pigment print paste formulation printed on to the fabric is retained after curing, the waste print paste formulation for each colour can be collected in concentrated form into a tank for disposal to landfill or for incineration. However the rotary screen printing machine must be cleaned and each screen must be washed, which gives rise to some waste water pollution. Some companies may be able to release all of the unused print paste formulation into their waste water. The possibility of storing and reusing any unused print paste is not usually feasible. Automated dispensing systems and modern printing systems decrease the amount of unused print paste to a minimum on each colour in the design.

Chemical finishes: For cotton fabrics the objectives of chemical finishing are generally stabilisation and appearance retention. For these purposes a crosslinking agent is commonly used. A popular product is dimethylol dihydroxyethylene urea (DMDHEU). Other cross-linking resins used to a lesser extent include urea formaldehyde and melamine. The control of free formaldehyde has been a growing concern in recent years. The level of free formaldehyde on resin-treated fabrics in the early 1960’s was several thousand parts per million as measured by the AATCC Jar Test. Today the level of free formaldehyde on fabrics is less than 300 parts per million, and formaldehyde in the workplace is controlled at extremely low levels in many countries by regulation. In the United States for example, the Federal standard is now 0.75 ppm for the workplace on an eight hour time weighted average basis. Effluent considerations in the chemical finishing of cotton will be mainly as a result of the discharge of residual liquor from mangle-boxes, make-up tanks and pipework. This can be minimised by recycling wherever possible and if necessary modifying equipment and procedures. Strict limits on air emissions from drying machines are being introduced, and the control, abatement and monitoring equipment required will increase the price of a stenter on which it is installed. Emissions from the stenter may contain formaldehyde and other volatile organic compounds released from machine lubricants or from finishes applied to the fabric. Scrubbing or thermal incineration systems may be used to remove these impurities and heat recovery systems may be installed, with hot air recirculation. Other environmental factors are the removal of lint (using wire mesh filters) from the hot air circulating in the stenter, and noise and odour if the stenter compartment doors are not adequately sealed.

Easy-care finishes: The main implications for the cotton finisher will be in the application of crease-resistant finishes based on formaldehyde-containing crosslinking agents. Afterwashing is not normally carried out, so the environmental upgrades are mainly concerned with volatile emissions from the stenter and disposal of waste liquor. Afterwashing may however be necessary if very low levels of free formaldehyde, e.g. 30 ppm, are required by the customer. This will remove most of the free formaldehyde, releasing it into the waste water, together with uncured resin and the acid catalyst as well as some of the other chemical finishes applied to the fabric if these are not durable. Some catalysts may contain metals or organic acids which could require attention in effluent treatment. Although non-formaldehyde crosslinking agents have been proposed, most of these suffer from disadvantages of toxicity, adverse effect on desirable fabric properties, low performance and high cost. One which is available commercially is dimethyldihydroxyethylene urea, produced for example by BASF as Fixapret NF. Improved technology has resulted in the development of products containing ultra-low levels of free formaldehyde, such as Fixapret CL (BASF). Wesh of SRRC shows the use of BTCA as an effective non-formaldehyde crosslinking agent.

Flame Retardants: The main durable flame retardant chemicals available for cotton are Proban CC (Albright and Wilson), Pyvrovatex CP New (Ciba) and Aflammit KWB and Aflammit P (Thor Chamicals). During application formaldehyde release may occur in drying and curing. Fume oxidising equipment can be added to the stacks of the drying and curing ovens which will eliminate formaldehyde emissions. Non-durable finishes are mainly based on inorganic compounds such as borax, boric acid and ammonium sulphate. Less soluble systems, based for example on antimony trioxide, may be termed semidurable. Care must be taken when disposing of some of these products.

Waterproofing and Showerproofing; Fungicides and Bactericides: Most waterproofing finishes are based on organic waxes which will produce VOC in the stenter. Some contain metals (aluminium, zirconium or titanium). In the treatment of shower curtains, for example, showerproofing products could be combined with fungicides which may contain prescribed substances such as PCP and organo-tin compounds. As a group these products must be disposed of with great care.

Surfactants: These are used at all stages of textile processing. They can be either anionic or nonionic, and selection will depend on compatability with other auxiliaries in the liquor. Some auxiliaries may contain small amounts of organic solvents, or may be cationic in nature. Selection must also take into account foaming characteristics, biodegradability, stability to alkalis and electrolytes, compatability with water hardness salts, wetting and detergency power and ease of washing-off. APEO-free (alkyl phenol ethylene oxide-free) surfactants are now widely used within the European Union because these biodegrade without producing metabolites toxic to aquatic life. Linear chain fatty alcohol ethoxylates, sulphosuccinates and other anionic and nonionic products have been suggested, altough the straight-chain products exhibit a moderate to high BOD.

Enzyme-based processing: Treatment with cellulose under suitable conditions weakens the surface fibres in a cotton fabric, so that they break off leaving a smoother, lustrous appearance and a softer hand. Fabrics processed in this way are described as “bio-finished” or “bio-polished”. Some loss of fabric weight and strength occurs, but these effects can be minimal when the conditions of treatment are kept under careful control. Biofinishing has been applied to both woven fabrics and knitgoods to simulate a mercerised appearance, but probably the main application to date is in the production of “stone-washed” or faded denim. This effect was originally obtained by tumbling denim jeans with lumps of pumice in industrial washing machines. It was then found that the addition of cellulose could produce the desired “wash-down” effect with less abrasion damage to the fabric. Traces of peroxide in fabric after bleaching can be destroyed with a newly-developed enzyme product, solving a long-standing problem for dyers using reactive dyes which are sensitive to peroxide, reducing rinsing times and saving water. Enzymes are completely bio-degradable, and offer the textile finisher opportunities to reduce energy consumption and effluent treatment costs. There are expectations that specific enzymes will be of value in the scouring of cotton and other cellulosic fibres, to remove natural protein material, fats and waxes gently, without need for strong alkali and high temperature. (according to Cotton Incorporated).

Enzymatic biofinish → Enzymes.

Enzymatic stonewashing → Enzymes.

Enzyme activity Enzymes are biological catalysts with a protein structure. In this role they are not subject to the stoichiometric regularity of the other reaction partner. As a result, the evaluation criterion for enzymes is not an absolute variable, such as the enzyme mass, but rather the effect of a known enzyme dose on the progression of the reaction. This characteristic variable is the enzyme activity. It tells us how much substrate is converted into product in a reaction [S (substrate) → P (product)] in a defined time period with the aid of a certain enzyme dose. A more commonly used variable is the specific activity, the increase in the product per time period and enzyme quantity, which describes the efficiency of an enzyme in relation to the dose. A well established theory on enzyme catalysed reaction originates from Michaelis and Menten: A substrate S to be converted, for example contained in waste water, forms a complex with the enzyme E, thus entering a reactive state. This makes it possible for the substrate to break down. As a typical catalyst, the enzyme is not consumed during the reaction. We can therefore formulate:

$$S + E \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \overset{k_3}{\rightleftharpoons} E + P$$

P is the product; k_1, k_2, k_3 are the associated speed constants. The change over time of the substrate concentration can be written as the familiar Michaelis-Menten equation in the form

$$v = \frac{dS}{dt} = V_{max} \frac{[S]}{K_m + [S]}$$

K_m = Michaelis-Menten constant
t = reaction time
V_{max} = theoretical max. decomposition speed

V_{max} is reached when all the enzyme quantity present is saturated with substrate and thus exists as ES. K_m and V_{max} characterize the substrate. It is clear that a high S leads to a high decomposition speed of the substrate. We can therefore kinetically quantitatively formulate the biological breakdown of substances contained in waste water. Of particular interest is the kinetics of the substrate breakdown characterized by the BOD. The basic equation of the BOD curve is familiar as the Henri equation. We can write:

Enzyme activity

$$S(t, y) = \frac{K_m}{V_{max}} \cdot \ln \frac{L}{L - y} + \frac{y}{V_{max}} - t = 0$$

L = BOD final value related to the zero point of the reaction

y = oxygen consumption, related to the zero point of the reaction

It is important to ensure that the pH remains within the range 5–9 during biological waste water cleaning. It is interesting that the temperature dependency of the kinetics of biological waste water cleaning is low, which means that there are no major differences in the decomposition rate between Summer and Winter. The task of enzyme analysis is to quantitatively describe the influence of an enzyme on a reaction S → P. Therefore an appropriate reaction is conducted under standardized conditions and the composition of the reaction mixture compared with the state before the addition of the enzyme (Fig. 1).

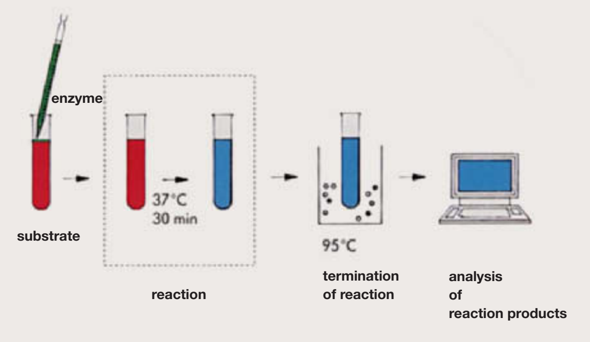

Fig. 1: Enzyme analysis.

The conditions of the experiment should naturally be selected such that the reaction result can be attributed exclusively to the added quantity of enzyme; this allows the enzyme activity to be determined. There are a few peculiarities and basic rules that should be taken into account: Almost 2000 different enzymes have as yet been identified; each is characterized by a specific catalytic activity and therefore there is at least one specific test procedure for each of these enzymes. For example: A Kilo-Novo-Alpha-Amylase unit (1 KNU) is the enzyme quantity which according to the standard method of Novo Nordisk for the determination of alpha amylases breaks down 5.26 g/h starch (Amylum Solubile) under the conditions given below:

Substrate	soluble starch
Calcium content in the liquid	0.0043 M
Reaction time	7–20 min
Temperature	37°C
pH	5.6

It is possible to derive the specificity of an enzyme, which is normally a substrate specificity, from its systematic name. A 1.4–α–D–glucosidase only releases glucose made up of 1.4–α–D–glucane (e.g. starch). Therefore a suitable substrate (starch or maltose) is also used in the analysis of this enzyme. The use of a synthetic substrate is simpler, in this case, p-nitrophenyl–α–D–glucoside, whose hydrolysis (glucose and p-nitrophenol are created) can be demonstrated by an easily measurable colour production (p-nitrophenol).

Enzymes only function when the right external conditions are in place. Normally they are a small part of more highly organised units, from micro-organisms to humans. The enzymes are suited to the conditions, to which they are exposed in their natural environment; e.g. temperature (Fig. 2). The enzymes of the human organism function optimally (not max.) at 37°C. It is a well known fact that a slight rise in body temperature is a signal of a short term increase in metabolic activity. However, temperature fluctuations are only harmless within a small range. Outside this tolerance range they can be dangerous. Enzymes can "coagulate", they lose their enzyme function and turn into "dead" protein. Enzymes also show this temperature dependency "in vitro": A higher reaction temperature normally leads to a higher substrate turnover, like in normal "life" but this effect is not unlimited. Rule of thumb: 10°C temperature increase effects approximately a doubling of the reaction speed. At higher temperatures this effect is overshadowed by the thermal inactivation of the enzyme. The reactivity of the enzyme decreases markedly. From a certain temperature enzyme catalysis is no longer possible. The temperature dependency is a characteristic variable for each enzyme and must be taken into account in analysis. The temperature range for an enzyme analysis normally lies between 25–37°C. An inactivation of the enzyme cannot be expected in this range. The prime necessity under such conditions is

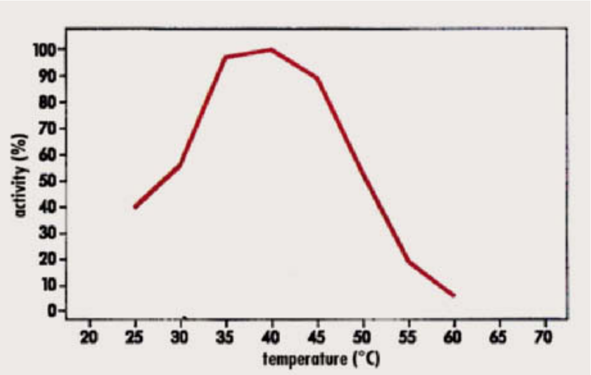

Fig. 2: Pancreas amylase and its temperature dependency when acting on starch.

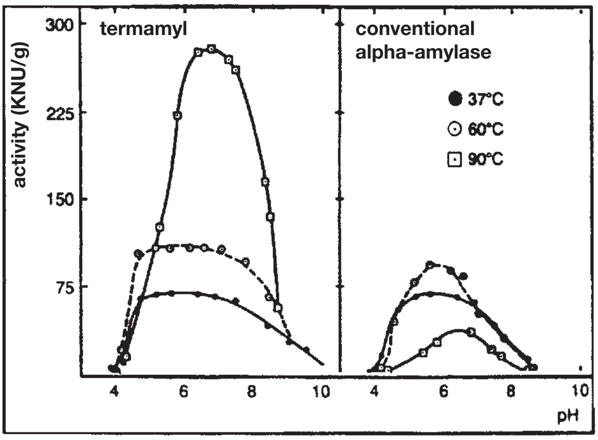

Fig. 3: Influence of the pH on the activity of Termamyl and alpha-amylase at different temperatures (substrate: soluble starch; stabiliser: 30–60 ppm calcium).

naturally a constant reaction temperature. Even temperature fluctuations of 1°C can cause a measuring error of 10%. The same applies for pH influences, which can influence an enzyme analysis in the same way (Fig. 3).

The active centre of an enzyme molecule is always located in cavities in the globular structure. In metalloenzymes the metal atom sits in the inside of a deep pocket, where there is a further cavity made of hydrophobic bits of protein, which accepts the substrate. The metal ion works electrophilically as a cofactor (coenzyme) and supports the catalyst (Figs. 4 + 5).

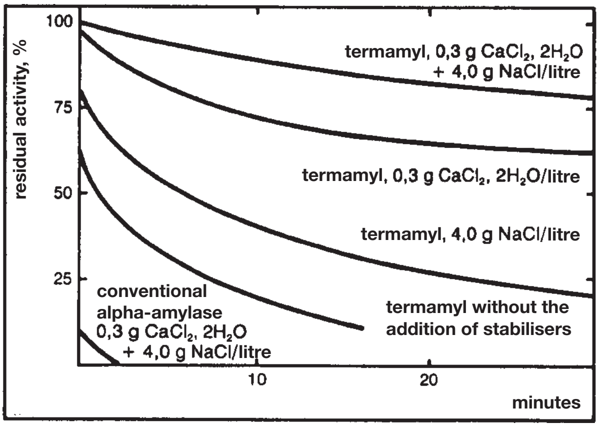

Fig. 4: Stability at 90°C and pH 6.5–7.0 of termamyl and conventional alpha amylase, in the presence of certain stabilisers.

We can see helical domains and β domains (pleated sheet conformation) in the carboxypeptidase (Fig. 6). The splitting into hydrophic, hydrophilic and ionic domains also determines the Amphilie in enzyme activity.

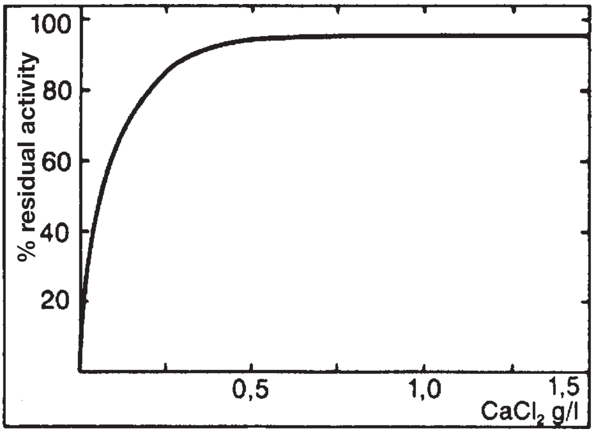

Fig. 5: Influence of the calcium concentration on the stability of Aquazym.

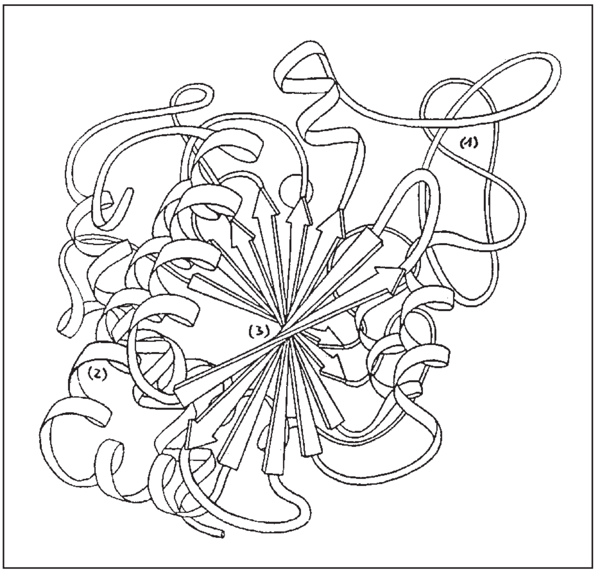

Fig. 6: Typical spatial layout of a macromolecular enzyme molecule with secondary area (1), a-helices (2) and domains (3).

Enzyme analysis Some enzymes, mainly so-called hydrolases, are used on a large scale. They are used to break down starch to sugar or to remove protein and fat spots from fabric during the washing process. Most of these “technical substrates” are high-molecular and offer access points for various enzymes. Therefore technical enzyme preparations often contain a range of different activities, that act at on this type of substrate simultaneously and can supplement each other. The enzymatic total hydrolysis of starch, for example, is normally performed using a combination of α–amylase and glucosidases. α–amylase splits the macromolecule into fragments of varying size, which can then be effectively broken down sugar for sugar by glucosidases.

There are also advantages to using this substrate in enzyme analysis: It is the best way to see the complex effect of a preparation and the synergistic effect of the

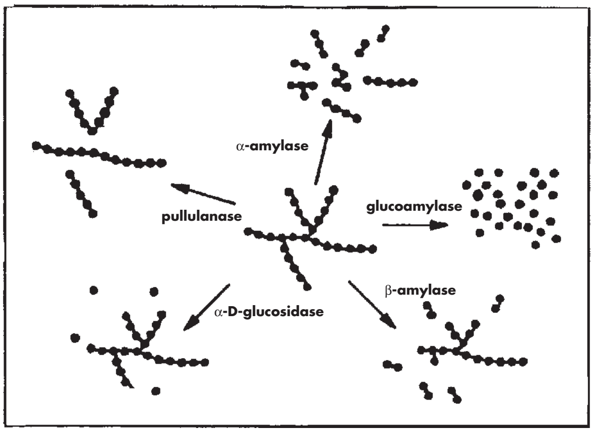

Fig. 1: Starch hydrolysis.

individual enzymes associated with it, for example those that can occur in starch hydrolysis (Fig. 1). But it can also be appropriate to test individual enzymes on these substrates. It makes a difference whether a glucosidase sugar splits from starch or a synthetic substrate (p-nitrophenyl-glucoside). It has a different affinity to the two potential substrates. A simple example should clarify the main procedure of enzyme analysis: Protein splitting enzymes (proteasen) can be simply detected in a spot test. An illuminated black and white film is used as the substrate for this: The film is coated with gelatine. Drops of the protease solution are applied to the film. This starts the enzyme reaction. Because the reaction speed is to be measured, a stop watch is a vital prerequisite. The reaction is finally completed by the enzyme that has been applied being washed off the film. Concentric spots can be seen at the points where the protease was applied; the water soluble hydrolysis products of the gelatine were washed off the carrier with the enzyme. The result can be viewed simply with the eye (Fig. 2).

This test is suitable for the rough estimation of a protease activity. The test described here is a so-called end point determination. At the moment at which the hydrolysed substrate (gelatine) is washed off, the reaction is halted. The enzyme effect between the start and end of the reaction is determined by a measured value.

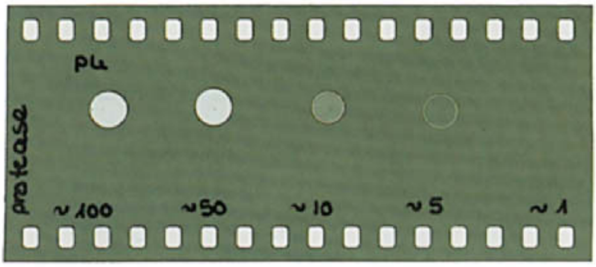

Fig. 2: Gelatine coated film on which protease has been dripped at different times.

The methods used in “professional” enzyme analysis are naturally more demanding. It mainly differs from the above-mentioned test in the minimizing of errors in performance and evaluation, and that can only be achieved at a high cost in terms of methodology and equipment. Enzyme analyses are time consuming and, if carried out manually, labour intensive. The individual work stages must be strictly timed. If several samples are processed at the same time the interconnection of the individual work sequences is unavoidable. The use of analysis machines is therefore appropriate. These machines can be classified into two different systems according to their working method.

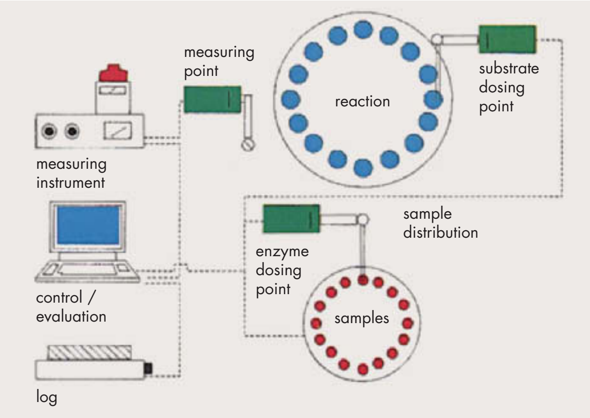

Fig. 3: Fixed volume analyser for enzymes.

Fixed volume analysers (Fig. 3), as their name suggests, operate with fixed, controllable volumes of the individual partners involved in the reaction. This working method is comparable to the work sequence that would be practised manually, but of course with the difference, that more samples can be processed in the same time, because different work processes can be carried out at different positions in the machine simultaneously. A thermostat controllable reaction room is available for the enzyme reaction. Sample, substrate and any reagents for the wet-chemical detection of reaction products are added via dosing stations. The samples pass the individual stations according to a predetermined timing sequence. An appropriate detector at the end of the reaction chain transmits measuring signals directly to the central control unit, which calculates and records the data.

The alternatives are continuous analysis systems (autoanalyser principle or flow injection procedure, Fig. 4). The characteristic feature of these analysis systems is a continuous flow of liquid. This flow is made up of several small secondary flows (= the individual reaction partners) entering a central pipe system. The individual partial reactions take place in the prescribed sequence in this large, connected, reaction area. The

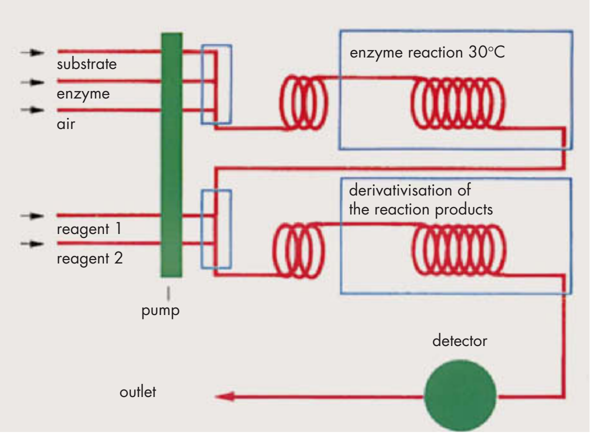

Fig. 4: Flow analysis for enzymes.

flow of liquid is only segmented by air bubbles, which prevent the diffusion of the sample segments. The length of the total system and the selected flow rate determine the dwell time of the samples in the system and thus the reaction time available to the enzyme. The sample segments pass a detector at the end of the analysis system, normally a photometer. Other possibilities are also realisable, such as, for example, an electrochemical detector or viscosity measurement (according to Gottmann).

Enzyme and hydrogen peroxide treatment → Papain.

Enzyme production Enzymes have been used for textile desizing since the beginning of the present century. The first amylases originated from malt extract. Later, pancreatic extracts were also used. The company Swiss Ferment, a forerunner of Novo Nordisk Ferment, started the production of malt extract in Switzerland in 1915 for use in desizing. The future development of enzymes for desizing had already been determined at that time. In 1917, Boidin and Effront used bacterial amylases for the first time. However, the mass production of these enzymes on a practical scale only began after the Second World War. It was found that bacteria could be cultivated under submersed conditions in fermentation tanks to produce large quantities of the desired amylases. Since that time, bacterial amylases have been used instead of the primitive enzyme preparations from malt and pancreatic extracts. These bacterial enzymes are cheaper, more effective, and less sensitive to other chemicals in the desizing liquor. Apart from the development of less temperature-sensitive bacterial amylases, enzymes for desizing have not changed much over the last 40 years. In order to improve the quality of bacterial amylases, however, Novo Nordisk has made use of the most modern tool of microbiology, namely gene technology. With this technology, microorganisms can be modified in such a way that the enzyme yield is increased. In comparison to conventional impure amylases, solutions of enzymes produced by gene technology are virtually colourless and odourless. Moreover, such enzymes also offer the advantage that no addition of stabilizing calcium salts is necessary when they are applied in soft water.

Enzymes (Greek from zymae: leaven/sour dough) Enzymes similar to the inorganic catalysts (Fig. 1) so-called biocatalysts. Technically impure enzyme products are → Diastases for example. All enzyme names end in -ase (amylase, cellulase, maltase, protease); enzyme decomposition products have the -ose ending (dextrose, maltose, glucose). Classification of the degrading enzymes in accordance with their method of reaction in the main hydrolase group (split –C–O– and –C–N– bonds) and desmolases (split –C–C– and –C–H– bonds). There are also holoenzymes (coenzymes and apoenzymes).

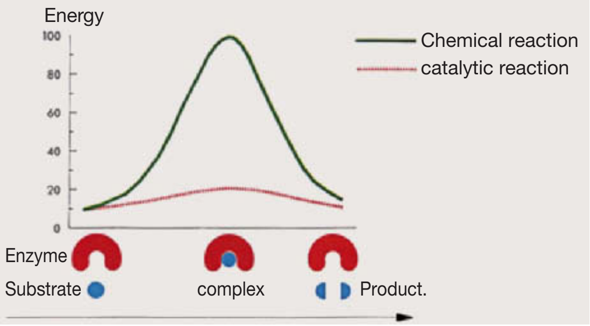

Fig. 1: Graph of a chemical reaction with and without a catalyst: the activating energy is reduced by the formation of a new transition state as a complex of substrate and enzyme to such an extent that the reaction takes place much more quickly.
Abscissa: reaction curve; ordinate: energy content.

Biochemical processes, whether hydrolyses or syntheses, are accelerated by enzymes. Organic nature can only exist at all because natural processes are catalysed by very specifically tailored enzymes. Intracellular enzymes are therefore bonded to cell membranes, while extracellular enzymes are excreted by cells and can be isolated. Enzymes are classified according to effect:

1. oxidoreductases: require oxidation-reduction processes.
2. transferases: transfer chemical groups.
3. hydrolases: split chemical bonds by taking up water.
4. lyases: remove groups.
5. isomerases: catalyse rearrangements.
6. ligases (synthetases): combine molecules.

An international numbering system identifies enzymes: each individual enzyme is allocated four numbers which are separated by full stops. The first number (1–6) indicates the class, the second figure the subclass, and the third the sub-sub-class etc.

Enzymes

Enzymes are proteins, the spatial arrangement of which is typical, and occurs through helical segments, folding leaf structures, intramolecular associations, and, particularly, by the targeted incorporation of prolin as an amino acid, which disturbs arrangement. Each enzyme has a specific amino acid sequence. Approx. 25% of all amino acid residues are found in helices of 12 amino acids in each case. The helices lie mainly on the surface of the enzyme macromolecule, which is hydrophilic for the purpose of better interaction with the medium water. In contrast, the active centre of the enzyme is mostly a hydrophobic pocket which is responsible for enzyme specificity. Emil Fischer minted the expression “key-lock principle”, by which he means: the biocatalytic process takes place in such a way that the substrate on which a reaction is to be implemented, is the key. The lock enzyme then very specifically controls the process on the key only when the two fit each other.

In the case of the enzyme chymotrypsin, for example the active centre is formed from one serine and two histidine residues. The interlaced chains of the enzyme allow the three side chains of these amino acids to protrude into a pocket in such a way that only quite specific steric residues of the substrate can make contact with the three side chains in this gap via (mostly) hydrogen bridges, which also have contact with each other via hydrogen bridges. The absolute prerequisite for these contacts is the close spatial proximity to each other, for which reason the actual biochemical reaction precedes characteristic kinetics, a pre-established equilibrium (diffusion to each other, and adsorption on each other). Michaelis-Menten’s definition runs: enzyme E and substrate S are in equilibrium with the enzyme-substrate complex ES. This complex reacts with its formation only in the speed-determining reaction in enzyme reformation (therefore catalysis) to product P. Substrate bonding to the enzyme in fact means increased order, i.e. decreased entropy; this energy requirement is overcompensated however by a change in enthalpy in bonding (adsorption). The change in enthalpy occurs through the formation of hydrogen bridges and hydrophobic interaction. The bonding energy produced by these non-covalent interactions is responsible for the sharp reduction in the activating energy of the actual reaction by the enzyme.

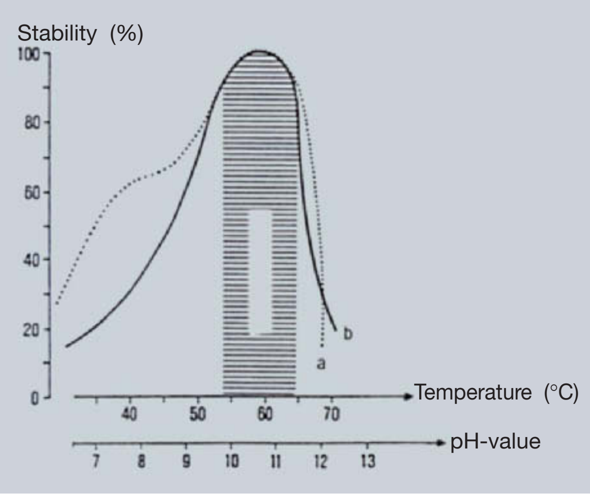

Fig. 2: Effect of pH (a) and temperature (b) on protease stability.

Enzyme action is pH specific. While the formation of the enzyme-substrate complex is implemented via hydrogen bridges, the addition or withdrawal of protons upsets this process (Fig. 2). With increased temperature, the diffusion of the partners to each other is accelerated; with a further increase in temperature however, the entire three-dimensional structure of the protein breaks down (irreversible denaturation) because the numerous hydrogen bridges in the helices and in the folding leaf structures are split. All the more astonishing is the effectiveness of new types of desizing enzymes in the pad-steam process at 100°C (in contrast to the cold-dwell process).

In the textile finishing industry or the detergent industry, enzymes are used mainly for decomposition reactions:

- proteases: splitting of albuminous proteins (into amino acids) during degumming and felt-free finishing.
- amylases: splitting of starches (into saccharides) in desizing.
- cellulases: splitting of cellulose (into saccharides) in cotton softening and in the biological degradation of cotton and also in carbonation
- ligninases: (pectinases for soaping, galacturonases): splitting of lignin during carbonisation and scouring.

Looked at from the enzyme standpoint, the following application possibilities arise:

Enzyme	Origin	Specific effect
α-amylases	Bacillus subtilis/ licheniformis	Starch desizing
Cellulases	Trichoderma reesei, Humicola insolens	Non-stone treatment of jeans, fashionable effects, CMC desizing
Pectinases	Aspergillus niger	Stripping vegetable fibres
Proteases	Bac. subtilis/oryzae	Stripping animal fibres, wool property changes
Lipases	Aspergillus niger, Muco javanicus	Removing fats and waxes
Peroxidases	Horse radish	Oxidising natural pigments

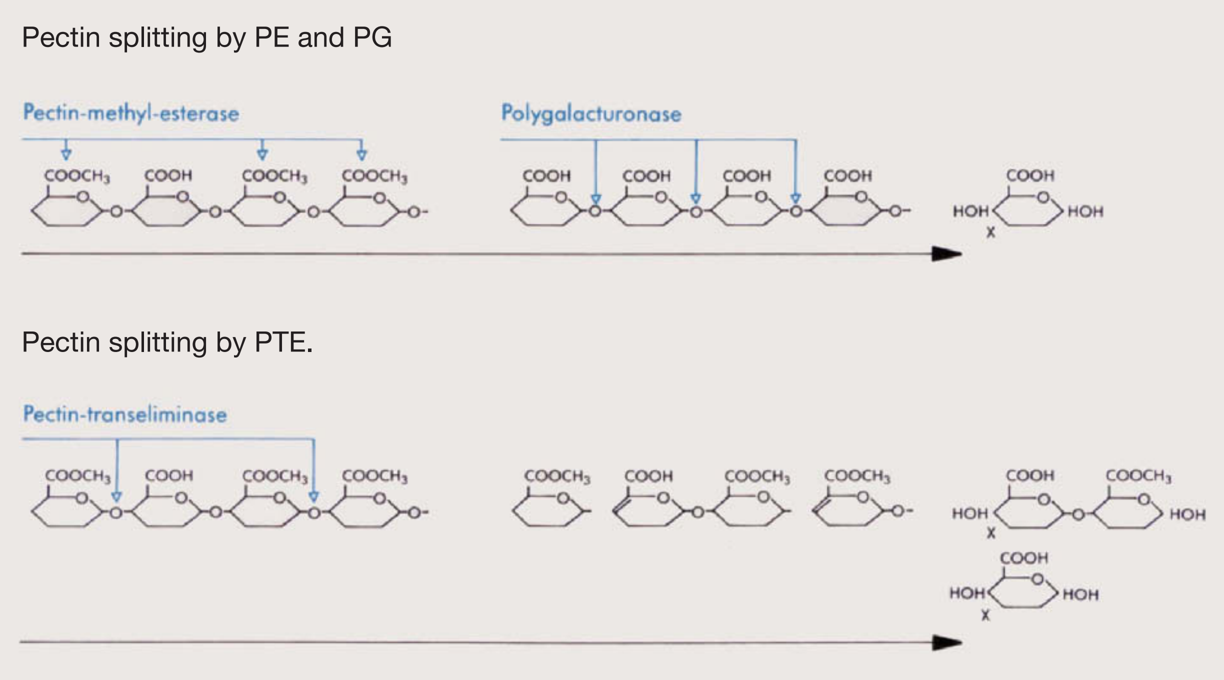

Fig. 3: Enzyme substrate specificity.

Sandoz has put forward the use of cellulases for the "non-stone" technique, jeans being first of all desized with liquid Bactosol MTN, and then treated with liquid Bactosol CE (cellulase). Thanks to the specific effect of liquid Bactosol CE, oxidative bleaches and the use of pumice stone can be dispensed with. The effects obtained are quite comparable with the stone-wash process.

Enzymes are therefore principally capable of very specifically degrading natural substances (Fig. 3). The following holds good in this respect: the more the natural substance is chemically modified, the more difficult it is to be enzymatically degraded. There are of course adaptation stages, in accordance with which degradation is possible. The enzymatic degradation of cellulose largely takes place in different processes, for example the feed-back of dead plants into nature's carbon cycle and the production of glucose and ethanol from wood in industrial biotechnology. The analysis of reactively dyed cotton has already been tried in this way too.

Two basically different test techniques are available for enzyme-catalysed reactions: initial attempts with live cultures of microorganisms and trials with enzymes extracted from them and possibly cleaned. Both have advantages and disadvantages, and are used on an industrial scale. The disadvantage of the first variant is the formation of large quantities of biomasses which make analytical recording of the products of degradation difficult. In addition, the conditions for the decomposing enzymes formed to develop their activity on the substrate to the best effect are poor (concentration, accessibility). Equivalent systems operate very slowly (e.g. the rotting of plants in nature), and are hardly suitable for the efficient decomposition of dyed cellulose. In contrast to that, pure enzymes produce highly active solutions, the action of which can be additionally intensified by the admixture of suitable components.

The cellulase-enzyme complexes are the essential part of cellulose decomposition. The complete degradation of natural cellulose is an extremely complicated process. For various reasons on the one hand, radical changes continually take place during splitting (e.g. inhibition by cellobiose, the product of degradation, or by non-degradable impurities), while, on the other, various routes lead to cellobiose or also directly to glucose. In the case of dyed starting material, cellobiose and glucose derivatives suitably modified by dyestuffs are to be expected. The most active enzyme complexes are produced from fungi of the Trichoderma viride and Trichoderma reesei varieties. Degradation complications arise from the fact that cotton consists not just of pure cellulose, but that there is foreign matter present, particularly in the outermost areas of the fibre (primary wall). One obstacle arising out of this has to be excluded by the addition of other enzymes: hemicellulases for breaking down hemicelluloses and pectinases for decomposing pectins. In this way, optimised decomposing solutions, the exact composition of which depends also on the purity and origin of the main enzyme (cellulases) are produced. One of the main problems in breaking down natural cellulose is the difficulty of access to the substance: as solids, cotton fibres are very unsuitable for enzyme penetration. The partially crystalline areas of the polymer in particular make it more difficult. The result is that chemical changes following the reaction of the more accessible amorphous areas take place only very slowly. It is necessary therefore to break up the solid, and prepare a large surface for enzyme attack. The best known method of comminution in textile analysis is cutting in a knife mill. With this technique however, the fibre interior is inadequately bared for the necessary surface increase. Additional crushing of the fragments and milling to a fine powder is required. Ball mills for example are used to this end. One interesting variant is the planet mill (planet motion of the ball container), the use of which produces fine powder within a reasonable time. The milling process has hardly any effect on the relevant chemical bonds.

Keratin fibres can be quickly broken down by proteolytic enzymes after the disulphide bonds have been split by chemical methods. Enzymatic attack on untreated keratin fibres, e.g. wool, takes place much more slowly, and appears to be limited only to the wool fibre areas which have few or no disulphide bridges, the so-called non-keratin material. This comprises the endocuticula, the cell membrane complex and the cell nucleus residues plus the intermacrofibrillar material of the cortex. In treating wool with pancreatin, 14% of the wool is decomposed after 11 days; in digestion with trypsin, a maximum of 17% is reached depending on the pretreatment conditions and the decomposition time. With the enzyme pronase, 10–20% of the wool is digested, 12% of it after 3 weeks' treatment. At the beginning of 1984, Schoeller Hardturm AG began a development programme for the enzymatic treatment of wool, setting up a development target and product arguments for enzymatic, felt-free finishing. Aims: no synthetic resin, gentle chemistry, ecological safety. Arguments: natural wool, (handle, bulk), no synthetic resin coat (for use next to the skin), natural blended fibre products (cotton, silk). Old processes with this aim have worked with the enzyme papain; sodium disulphite was used to loosen the cystine bridges. The chlorzyme process ran in two stages. The first treatment was with chlorine gas, the wool was felt-free, and then the scales were removed with papain. The process was very expensive, the wool of course had excellent lustre but a poor handle. The perzyme process is also a two-stage process: first, treatment with hydrogen peroxide, then with papain and disulphite. It is not possible however to obtain a good felt-free effect without an extreme change in handle. Weight losses of up to 3% must also be expected during the process. These types of enzyme process have been used industrially only to a limited extent and for a short time. The problem with these processes must be summarised as follows: it is difficult to limit the enzymatic breakdown process to the scales and to avoid enzyme diffusion into the cortex.

Proteases are also effective in the Mazamet wool fell-mongering process. If proteases are used for degumming silk, they break down the hydrophilic sericin component, but also attack the more hydrophobic fibroin component. In the enzymatic removal of the primary wall of cotton (scouring), the main component pectin, which is partially esterified, has first of all to be soaped by pectinases before exo- (monomer for monomer step by step) and endo- (statistically) galacturonases break down the polymer. Cotton can also be bleached with glucose-oxidase, peroxidase and catalase. Finally, the enzymatic desizing process is a breaking down of amylose and amylopectin with amylases.

Denim jeans manufacturers for many years have washed their garments with pumice stones to achieve a soft-hand as well as a desirable look. While a variety of treatments have been used in the past, the use of stones yielding "stonewashed" jeans has increased recently both in Europe and North-America. Jeans processors typically have found that they can achieve this stonewashed look by using cellulase enzyme instead of stones. Enzymatic stonewashing has thus become more widespread over the last two years. As the name indicates, cellulases hydrolyse cellulose, partly yielding soluble products such as short-chain polysaccharides and glucose.

Investigation of the mode of action on cellulose fibres has shown that cellulase attacks primarily the surface of the fibre but leaves its interior intact. This mode of action makes cellulose especially suitable for stonewashing of denim garments dyed with indigo-blue, since this dye stays on the surface of the fibre. Washing the garments with stones removes this surface dye by abrasion. Cellulases remove it by partially hydrolysing the surface of the fibre that includes the dye. Use of cellulase overcomes most of these disadvantages, while yielding the desired softening and "worn" look.

Cellulases for stonewashing are available from several major suppliers to the textile industry. They fall into one of two categories – acid or neutral. Each enzyme is produced by fermentation of a unique mould strain. The two enzymes differ in a number of ways, with the differences in pH optima being the most important for this application. In order to achieve the desired colour contrast during stonewashing it is important to minimise the re-disposition of the blue dye on the garment (backstaining). Fig. 4 shows colour-removal from denim by each type of cellulase as a function of pH. For the neutral cellulase, maximum colour-removal occurs at pH 6.0, but at pH 7.0 to 7.5 this enzyme still has above 90% of the colour-removing activity. Acid cellulase gives maximal colour-removal effect at pH 5.0, but at pH 6.0 the colour-removal effect is reduced to less than 40%. Backstaining also turns out to be very dependent on pH. It is increased by a factor

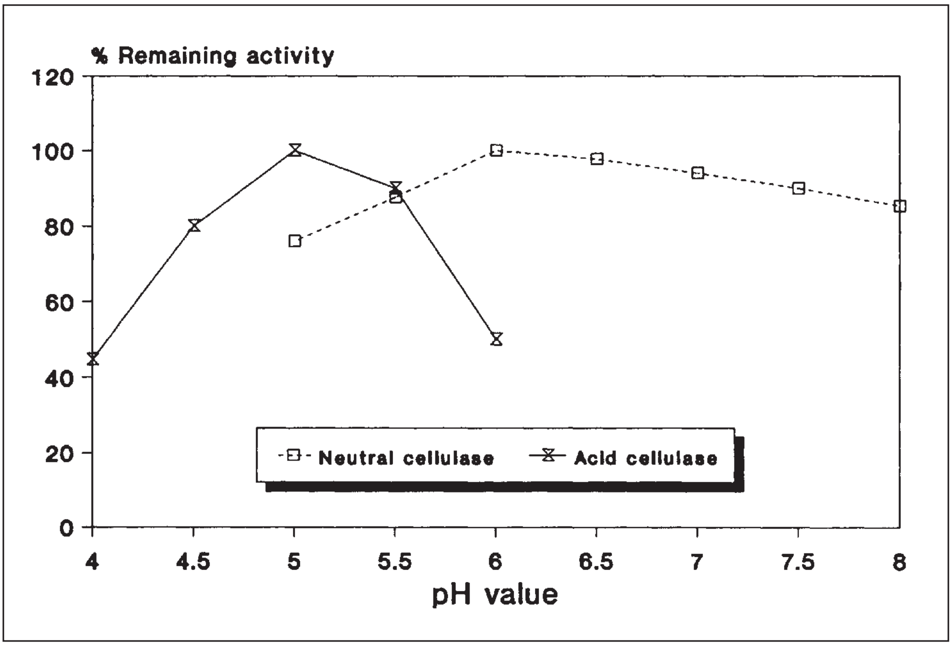

Fig. 4: Effect of pH on colour-removal activity of cellulases.

of 20 or more at pH 6.0 or less compared to the minimum value obtained at pH 7. This comparison of the pH dependence of the acid and neutral cellulases and backstaining points out that the neutral enzyme is the one of choice to minimise backstaining. As Fig. 4 shows, the pH profile for the neutral cellulase is much broader than that of acid cellulase. This results in much better reproducibility of the finished look, since the pH increase during stoning will have little effect on the activity of the neutral enzyme. Because of its much narrower pH profile, acid cellulases will require much tighter control of pH during stonewashing to achieve a high level of reproducibility. Using cellulases as a substitute for stones prevents the damages to wash-machines and the garments, eliminates the need for disposal of the used stones, improves the quality of the waste-water and eliminates the need for labour-intensive removal of dust from the finished garments. Because stones are no longer added, the garment load can be increased by as much as 50%. Some highly-abraded finishes cannot be achieved by using cellulase alone. In such cases partial substitution of stones with the enzyme can achieve the desired look.

The hard core of Sirrix Luna consists of two natural components: metamorphic microlites and microencapsulated enzymes for bringing about a controlled biomechanical erosion of textile surfaces in order to produce novel looks and sophisticated handles. Under the mechanical action of the Combisoft Jumbo, the extra-spherical geodesic dome of Sirrix Lune breaks open, liberating the enzyme which only needs to be activated. The combined physical action of the microlite and biological action of the enzyme bring about a spectacular metamorphosis of the textile substrate into an article with high value added. The physical characteristics of the microlite (very similar to the lunar stone regolite) and the biochemical properties of the enzyme have been specially studied for the purpose of obtaining shimmers, opalescences, iridescences, sheens and moonlight effects on textiles.

The Combisoft Jumbo (Fig. 5)is a versatile discontinuous machine permitting dry or wet as well as cold or hot (110°C) treatments. The tumbler is designed to soften (by breaking), dry or finish textiles through spectacular modifications of their surfaces by mechanical (tumbling), physical (microlite), chemical (pretreatment, causticization, softening) or biological (enzyme) means. It permits a wide range of uses, for small batches as well as large ones (1 to 6 pipes). Its exceptional capacity has no equal: 400–450 kg. The main characteristic of the machine is its system of transporting the fabric, which is original and patented: the fabric is conveyed on a supple elastomer belt and by air cushion at a speed of over 800 metres a minute. The kinetic energy acquired by the fabric is directed at a grill situated at the rear of the machine, after which it falls down into the main compartment, from where it enters the front of the machine, where a system of Turbo air expands and re-heats it in drying. Fabric weights ranging from 50 to 800 g/linear metre can be handled. The machine is suitable for all types of natural, man-made or synthetic fibres such as cotton, linen, viscose, cupro, Tencel, Lyocell, silk, wool, etc., as well as coated fabrics (imitation leather, etc.). The trick is to modify the substrate's reflection of light and extinguish its brilliance by means of a microabrasion of the surface of the textile substrate. These modifications are either of the microfibrillation type (visible under a microscope),

macrofibrillations (visible to the naked eye), defibrillations or destructurizations of the fabric. The nature of the dye can also intervene in order to produce worn out, “used”, washed down or distressed effects. All fibres can be treated: cotton can be transformed into microvelvet, viscose into silk, wool into cashmere and silk into angel skin, and the handle can be varied “a la carte”.

Enzyme structure Depending on the conditions of their environment (pH, temperature, solvent, coenzyme) enzymes arrange their protein chains in a three-dimensional form, or tertiary structure (Fig. 1). Ellipsoids are widely represented in such enzyme structures (Fig. 2).

Certain peptide sequences of the long α-amino acid chains (–NH–CHR–CO–) of these proteins have an inclination to form helix structures whilst others assume less ordered (“coil-shaped”) conformations. Depending on the type and sequence of the peptide groups, therefore, both helical and non-helical sequences occur in a single molecule. Under the influence of hydrophobic bonds, salt linkages, hydrogen bonds, etc., these sequences fold up in such a way that the molecule assumes the external form of a spheroid. However, these spheroids are not homogeneously filled with the building blocks of the macromolecule. Rather, the spheroids also contain pockets and canals filled with solvent. Parts of the spheroid interior are consequently relatively easily accessible for low molecular weight species. Nature exploits such structures, on the one hand, as vehicles for other substances (e.g. haemoglobin for the transport of oxygen to tissues), and as effective catalysts (enzymes) on the other. Spheres and spheroids that are not too assymetrical have low viscosities in dilute solutions. They offer only a low resistance to flow and are therefore easily transported from one place to another.

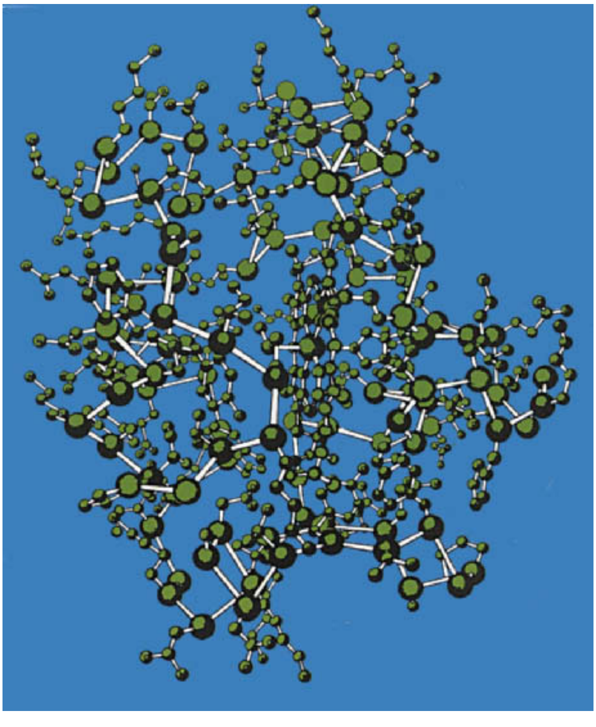

Fig. 1: Typical entwisted enzyme polymer structure.

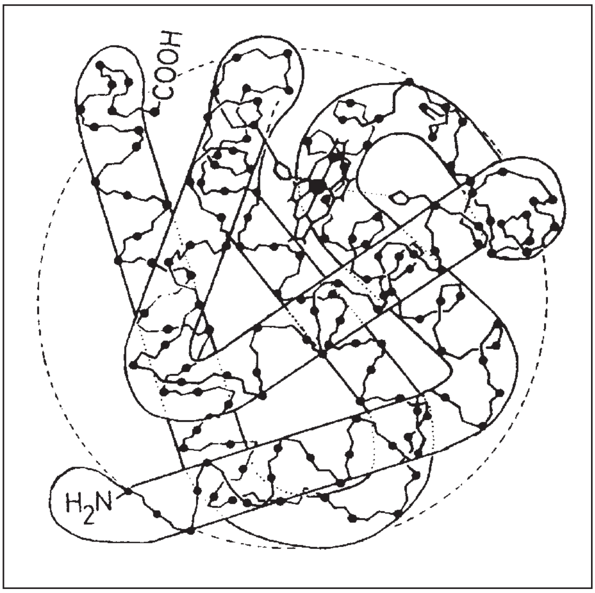

Fig. 2: Schematic diagram of the protein myoglobin. The molecule consists of rod-shaped, helical segments, which are linked by non-helical ("ball-shaped") areas. The inscribed circle shows that the molecule is not spherical but rather ellipsoid. The dots represent central carbon atoms of each peptide residue.

Enzyme wool →: Skin wool and Fleece wool obtained by enzyme treatment.

Eolienne Named from the Greek *Æolus*, the god of the winds. Originally a soft weft-ribbed dress fabric with a silk (or more seldom, cotton) weft and a worsted warp in a plain-weave construction. The cloth is a lightweight zephyr fabric and may be classed as a very fine poplin. Now also produced from man-made fibres, e.g. acetate, rayon.

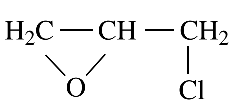
EPA

I. (Ger.), abbrev. for: Europäisches Patentamt (European Patent Office), Munich.

II. abbrev. for: Environmental Protection Agency (USA).

EPDM, abbrev. for: ethylene-propylene diene monomer. A terpolymer elastomer derived from this monomer.

Epichlorohydrin (3-chloropropylene oxide, 3-chloro-1,2-epoxypropane), C_3H_5ClO. Colourless liquid with an odour resembling that of chloroform. A toxic and carcinogenic compound used in the manufacture of epoxides and resin finishing agents for alkaline wet crosslinking. It is formed as an intermediate product in organic synthesis.



Epichlorohydrin rubber Synthetic rubber elastomer based on → Epichlorohydrin. Properties: shore hardness 40–90, moderate to good adhesion strength and abrasion resistance, moderate to good resistance to dil. acids (moderate to conc. acids), resistance to aliphatic hydrocarbon solvents is excellent and good to aromatic hydrocarbon solvents, resistant to oxidation and sunlight, excellent resistance to ozone. Epichlorohydrin rubber has only poor to moderate fire resistance.

Epicuticle The fine outer sheath of the wool fibre which covers the scale-cell layer in the form of a thin water-repellent membrane. It is the only non-protein part of the fibre, and protects the fibre like a covering of wax. → Wool structure.

Epidermal membrane A so-called intermediate membrane in → Wool structure.

Epidermicula The fine outer skin over the scale layer in the → Wool structure.

Epidermis (Gk. *epi* = outer, *derma* = skin). In → Wool structure the term is used in the widest sense to mean the scale cell covering of the fibre comprising the scale-cell double layer together with the epicuticle. In → Flax stem structure, the epidermis is regarded as the external peripheral layer consisting of an outermost thin skin which covers the → Cuticle.

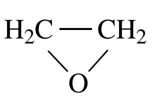
Epinglé A smooth ladies' dress fabric (silk, cotton) with a pattern of alternating delicate and heavy weft ribs.

Epithelium The outermost cell layer of the skin. In a figurative sense, the term "scale epithelium" is used in wool morphology.

Epitropic fibres (epitropics, antistatic epitropic fibres). Polyamide or polyester fibres containing embedded particles of carbon to make them electrically conductive. They are used as permanent antistatic fibres in 2–5% blends with other fibres for floorcoverings, home textiles, protective clothing and technical fabrics.

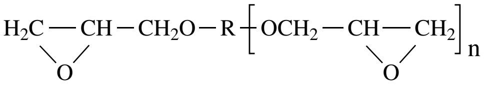
Epoxi → Epoxides.

Epoxides Organic compounds (cyclic ethers) containing one or more epoxide groups:



The epoxide group is a reactive group for crosslinking reactions, e.g. with cellulose in the presence of acidic (zinc fluoroborate) or alkaline (caustic soda liquor) catalysts. The application as resin finishing agents (e.g. diglycidyl ether, ethylene glycol derivatives, butanediol ether, glycerol diglycidyl ether) is problematic due to the toxicity of these compounds.

Epoxy resins (polyepoxides). Thermosetting resins based on the reactivity of the → Epoxides:



Epoxy resins are polyaddition products formed as epoxides with polyhydric alcohols, hexahydrophthalic acids, hydantoin, cyanuric acid, but mainly (up to 90%) from → Epichlorohydrin and Bisphenol. Depending on the number of repeating units available in the molecule, liquid (n = 0) to solid products are obtained. Numerous aliphatic and aromatic compounds may be converted to epoxides which, due to their solubility in water and aqueous alcohol, can form aqueous emulsions. Crosslinking occurs by reaction of the epoxide group with polyamines, anhydrides, polybasic acids, etc. Contraction during hardening is low and therefore the products harden without tension, do not crack, and possess high impact and abrasion resistance. They bond well to most materials, do not attack metals and are resistant to atmospheric influences, water, acids, lyes, oils, kerosene and benzene. They find application *inter alia* as adhesives and binders.

Epsom salt → Magnesium sulphate.

Equal spaced colour depth series, production of Dyeings arranged in arithmetical order, as opposed to geometric order, are not perceived by the human eye to be equally spaced. There is a logarithmic relationship between the quantity of dyestuff applied and the colour perceived (Weber-Fechner law). If three colour depths, perceived to be equally spaced, are placed between dyeings of 1.5% and 0.2%, then where

F = deepest dyeing (1.5% in this instance),
F_0 = lightest dyeing (0.2% in this instance),
n = number of dyeings (5 in this instance),
f = multiplication factor,

the following formula applies:

$$F = F_0 \cdot f^{(n-1)}; \text{ Therefore here } 1.5 = 0.2 \cdot f^4$$

$$f = \sqrt[4]{\frac{F}{F_0}}\ ; \frac{F}{F_0} = 7.5;\ \sqrt[4]{7.5} = 1.655$$

The desired order can be calculated:

		% dyeing
$1 = F_0$	$= 0.2$ (given)	0.20
$2 = F_0f$	$= 0.2 \cdot 1.655$	0.33
$3 = F_0f^2$	$= 0.2 \cdot (1.655)^2$	0.55
$4 = F_0f^3$	$= 0.2 \cdot (1.655)^3$	0.91
$5 = F_0f^4$	$= 0.2 \cdot (1.655)^4$	1.50

This applies to fully exhausted dyeings. In the case of the partial exhaustion of dyestuffs, allowance must be made in the calculation for the dyestuff remaining in the dyebath.

Equilibrium liquid One of the phases formed during → Coacervation in the Two Phase (Cibaphasol) System.

Equilibrium water Water, involved predominantly in organo-chemical reactions, which can change the direction of reaction in a reversible process. When the amount water produced in a reaction exceeds a certain concentration it will reverse the direction of the reaction. A typical example is the reaction of the pair: Esterification ↔ Saponification; e.g.

$$\mathrm{R{-}CO}\boxed{\mathrm{OH + H}}\mathrm{O{-}R'} \rightleftharpoons \mathrm{RCO{-}OR' + H_2O}$$

Equilibrium yield Classification factor for Transfer Print Dyestuffs. Describes the maximum yield obtained for each dyestuff in heat transfer printing after an excessive time (approx. 100 s) under standard conditions.

Equivalent (Lat.: *aequivalens* = equal worth). Equal or interchangeable in value, quantity, significance, etc. Balanced.

Equivalent weight The mass of an element which can substitute 1 g of hydrogen in a chemical compound. It may be calculated from the → Atomic weight divided by the → Valency.

Er, chemical symbol for erbium (68).

erg (Gk.: *ergon* = work). The use of this CGS physical unit of energy is now discouraged, and has now been replaced in the SI system by the joule (1 erg = 10–7 joules).

Ergonomics (Gk.: *ergon* = work). The study of the relationship between workers and their environment.

Ergonomics concerns the → Physiology of the worker, the resilience and reactions of the human organism during the work process, performance conditions with their (mainly emotional) accompanying phenomena, human work place layout (as opposed to technical work place layout) and environmental influences such as climate (temperature, air quality), acoustics (noise, silence), optics (light, colour) and space (area, structural layout). Ergonomics are influenced considerably e.g. by modern transport systems, and this can be either negative or positive.

Eri silk A high quality wild silk produced by the *Phylosamia ricini* larva which is found principally in East Asia. The larva feeds on the castor oil plant. This silk is highly regarded in schappe spinning.

Error limit In measuring technology, the error limit is the agreed or permitted maximum deviation above or below the desired reading or a prescribed value of the measurable variable. It must not be exceeded, irrespective of the measuring uncertainty. It comprises the systematic errors recorded as well as the fluctuations determined by technical possibilities and unavoidable variations in production and wear phenomena.

Manufacturers guarantee specific guaranteed error limits for measuring devices. These are referred to as intrinsic error limits in measuring and control technology.

Es, chemical symbol for einsteinium (99).

ESI, abbrev. for: Ethiopian Standards Institution, Addis Ababa.

Eskimo An all-wool, relatively heavyweight (approx. 800–1000 g) double-faced fabric (with 2 warp and 2 weft systems) mainly in cross-twill construction. Named after the inhabitants of Greenland. The face side is constructed mainly from fine count woollen yarns and the back side from coarser woollen yarns containing a proportion of reclaimed wool.The face side has a finely napped surface. Chiefly dyed in dark shades (black, navy blue). Used for winter coats.

Esparto Grass leaf: *Stipa tenacissima.* → Alfa grass.

Ester amides → Urethanes.

Esterases Hydrolytic → Enzymes belonging to the main group of hydrolases, which attack esters with the uptake of water, splitting off the acid (cleavage of C–O bonds). In the closest sense, esterases react specifically only with water-soluble esters. In the widest sense, they may also be classified together with the lipases (hydrolysis of fats), cerases (cleavage of waxes), lecithases (cleavage of the phosphoric acid esters of alcohols and phenols), sulphatases (cleavage of sulphuric acid esters).

Esterification Chemical reaction between an acid and an alcohol, enol or phenol, resulting in the formation of → Esters and Water.

Ester naphthol Highly-soluble → Naphthols.

Ester number → Saponification value.

Ester oils → Fatty acid condensation products.

Esters Organic compounds, comparable to inorganic salts, which are formed by the condensation of alcohols and organic acids. The following functional group is characteristic of these important compounds: R'–CO–OR–R''. Esters are frequently encountered in nature in the form of fats and fatty oils, waxes, etc. Fats are formed, e.g. from glycerol, a trihydric alcohol and fatty acids.

Ester saponification The basic saponification of an ester takes place in accordance with the reaction equation

$$R_1COOR_2 + OH^- \rightarrow R_1COO^- + R_2OH$$

practically completely from left to right. The reaction is bimolecular and of the second order. The reaction speed equation for the saponification of the ester (E) is then

$$-\frac{d\,c_E\,(t)}{dt} = k \cdot c_E\,(t) \cdot c_{OH^-}\,(t)\,,$$

where k is the velocity constant.

As in this equation two parameters, c_E (t) and c_{OH^-} (t), arise which alter with time, the reaction variable x (t) is defined using the following definition equation with concentrations c_i (t) of the reactants:

$$c_i\,(t) \int c_i\,(0) + \nu_i\,x\,(t).$$

c_i (0) is the concentration of the reactant i with time t = 0, and ν_i is the corresponding stoichiometric number.

Given initial concentrations of the esters and the hydroxyl ions a and b, this gives:

$$c_E\,(t) = a - x\,(t) \text{ and } c_{OH^-}\,(t) = b - x\,(t).$$

It follows:

$$\frac{d\,c_E}{dt} = -\frac{dx}{dt}.$$

If the above relationship is inserted, this gives for the reaction speed equation:

$$\frac{dx}{dt} = k \cdot (a - x)\;(b - x)\,.$$

By integration (initial conditions: t = 0, x = 0), the following is obtained where a ≠ b:

$$\frac{1}{a-b} \cdot \ln \frac{(a-x)\,b}{(b-x)\,a} = k \cdot t\,.$$

Estimated exhaust evaporation → Evaporation losses.

ETAD, abbrev. for: Ecological and Toxicological Association of the Dyestuffs Manufacturing Industries. As in all sectors of industry, manufacturers of dyestuffs are confronted with questions relating to work safety and environmental safety. However, safety can only be achieved through the common efforts of all participating companies. Public concern about the possible dangers posed by chemicals, on which the high living standards of industrial nations as well as the survival of developing countries depend, has in no way decreased. The various government authorities responsible for health and environmental protection have reacted to these fears and anxieties by imposing increasingly complex laws and regulations. The response of industry, i.e. the manufacturers and processors, has been to guarantee an adequate level of safety in the production and use of their products. ETAD regards this as an ongoing task.

Étamine

I. Yarn: a term used mainly for multiple, soft, gassed ply-yarns (produced from cotton).

II. Fabric: a lightweight, open, thin gauze plain-weave fabric usually with a leno or mock leno construction. Used for net-curtaining, dress goods, etc., produced from cotton, viscose, wool (combed yarns) and silk. (The name is derived from the French *étamine* = muslin, cheesecloth).

Etching Diamond slivers are used to etch (scratch) the pattern into the lacquered roll on the pantograph. → Engraving.

Etching cavities Etching cavities occur when etching printing rollers and the lacquer coating shows signs of damage or is not correctly applied.

Etching machine In pantograph engraving, a machine for etching copper printing rollers in an acid bath. In photo-engraving, a machine in which the unexposed lacquer is dissolved out of the printing roller surface.

Etching plant for copper printing rollers An etching plant in which printing rollers for roller printing, produced by pantograph, mill and photoengraving methods, are etched to deepen the engraved areas.

Etching varnish (etching lacquer). Applied to polished printing rollers for pantograph engraving. After this application, engraving and ruling lines are cut into the varnished surface by diamond points to facilitate subsequent etching.

Ethane, C_2H_6, → Saturated hydrocarbons.

Ethanedioic acid → Oxalic acid.

Ethanoic acid → Acetic acid.

Ethanol (ethyl alcohol, alcohol, spirits of wine), C_2H_5OH. Mol. wt. 46. Colourless, readily mobile, flammable and hygroscopic liquid, b.p. 78°C, f.p. –117°C, flash point +11°C. Mixtures of air and ethanol vapour containing 3,1–12,45 vol.% are explosive in the presence of fire.

Miscible with water (evolution of heat and contraction in volume), ammonia, acetic acid, glycerol, ether, acetone, benzine, benzene and organic solvents (cloudiness only in the presence of water). Uses (mostly in the form of denatured alcohol): multi-purpose solvent and wetting agent, especially in dyeing (cationic and vat dyes; naphthols by the cold-dissolving method); spotting agent for textile cleaning, solvent soaps, etc.; fuel for illumination and heating; additive in polishing, cleaning and washing agents, disinfectants, etc. Often substituted by the cheaper but toxic → Methanol.

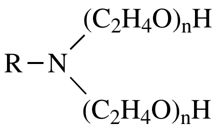
Ethanol, denatured (methylated spirit, industrial spirit). Denatured alcohol is generally composed of 95 vol.% ethanol which has been denatured with various additives depending on its field of application. For some applications, denatured ethanol can have entirely different properties compared to the pure alcohol.

Ethene (ethylene), $CH_2{=}CH_2$. A colourless gaseous hydrocarbon. Ethene is an unsaturated compound (contains a double bond) and is easily polymerized. Used as a starting product in the manufacture of synthetic fibres (polyethylene fibres).

Ethereal oils In contrast to fatty oils, ethereal oils are volatile vegetable oils with characteristic odours. (On paper they produce a volatile "grease stain" which gradually disappears whereas fatty oils leave stains which do not disappear). Used for deodorizing textiles. Terpene hydrocarbons are also used for cleaning purposes.

Ethers (Gk.: *aither* = the sky or upper atmosphere). Ethers can be understood to be the anhydrides of alcohols. They are formed from a) 2 molecules of the same and b) 2 molecules of different alcohols, with the elimination of water, e.g. by dehydrating alcohols with sulphuric acid. In case a) a simple ether (e.g. methyl, or dimethyl ether, CH_3OCH_3) and in case b) a mixed ether (e.g. ethyl methyl ether, $C_2H_5OCH_3$) is obtained.

Ethoxylated fatty amines Compounds with the general structure:



$$R-N\begin{cases}(C_2H_4O)_nH\\(C_2H_4O)_nH\end{cases}$$

These compounds are regarded as non-ionic but exhibit weakly cationic behaviour in acidic liquors. Since the non-ionic character is predominant, they can also be applied together with anionic compounds. Properties: excellent levelling action with all types of dyes.

Ethoxylated or monoacetic converted meal Ethoxylated or monochloroacetic acid substituted gum, e.g. → Carob or Guar gum. It is used as a cold water soluble coagulating thickener, especially in two-phase printing.

Ethoxylene resins → Epoxy resins.

Ethyl The group $CH_3 \cdot CH_2$, often written as C_2H_5 or in abbrev. form as Et. → Alkyls.

Ethyl acetate (acetic ether, acetic ester, ethyl ethanoate), $CH_3COOC_2H_5$, MW 88, density 0,9, b.p. 77°C. A colourless, readily flammable liquid with a pleasant fruity odour; less volatile than ethyl ether; water soluble up to 8,6%. Miscible with water (poor stability), alcohol, ether, chloroform, white spirit, etc. Uses: spotting agent for oil, grease, resin, fruit, and grass stains in particular.

Ethyl alcohol → Ethanol.

Ethylenediamine (1,2-diaminoethane), $NH_2{-}CH_2{-}CH_2{-}NH_2$, MW 60,1, density 0,9, b.p. 116°C. A colourless, alkaline liquid with an ammoniacal odour, soluble in water and alcohol. Uses: with copper salts a good solvent for cellulose (ethylenediamine copper solution); production of wash-resistant finishes with low wet crease resistance on regenerated cellulose fibres (60–90% solution); production of crease-resistant finishes, chelating agents, cationic textile auxiliaries, etc.

Ethylenediaminetetraacetic acid (EDTA; ethylenebisiminodiacetic acid; ethylenedinitrilo- tetraacetic acid), $(CH_2COOH)_2NCH_2CH_2N(CH_2COOH)_2$. An organic complexing or chelating agent of the aminopolycarboxylic acid type. As an ion exchanger, it completely eliminates water hardness salts and heavy metals in water. More expensive than polyphosphates, but more effective and more stable than the latter; EDTA is effective at all temperatures, and is resistant to alkalis and boiling temperatures. It can even bind magnesium in caustic alkali solutions, and dissolves rust and corrosion residues as well as already-formed lime soaps, but does not bind metallic iron.

Ethylene dichloride → 1,2-dichloroethane.

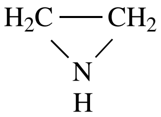
Ethylene glycol (ethylene alcohol; glycol; 1,2-ethanediol; 1,2-dihydroxyethane), $HO–CH_2–CH_2–OH$. Density 1,11–1,14, b.p. 197,5°C. A clear, colourless, syrupy liquid. Sweet taste, very hygroscopic. Soluble in water and alcohol, poor solubility in ether (in contrast to → Glycerol). Uses: solvent for cationic, acid, chrome and vat (including vat leuco ester) dyes; silk printing; finishing softener with fatty alcohol sulphates. Also used as an antifreeze.

Ethylene glycol monobutyl ether (2-butoxyethanol; butyl Cellosolve), $C_4H_9OCH_2–CH_2OH$.

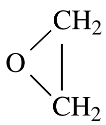
Density 0,905–0,909, boiling limits 164–176°C, flashpoint 65°C. Miscible with water in a 1:1 ratio. Uses: solvent for lacquers, chlorinated rubber, colophony, nitrocellulose, polyvinyl acetate, drying oils, vegetable and mineral oils as numerous synthetic resins.

Ethylene glycol monoethyl ether (2-ethoxyethanol; Cellosolve), $C_2H_5O(CH_2)_2OH$. MW 90, density 0,93, b.p. 130–138°C, flashpoint 40°C, evaporation number 43. Water soluble liquid, miscible with organic solvents. Does not dissolve acetate fibres. Uses: solvent in dyeing and printing for cationic, acid and indigo dyes; solvent for nitrocellulose, etc.

Ethyleneimine (aziridine, dihydroazirine) A compound very similar to ethylene oxide in many respects. A colourless, toxic liquid with a strong ammoniacal odour. Corrosive, absorbed by the skin, causes tumours. Ethyleneimine is very reactive and polymerizes readily (ethylenediamine, diethylenetriamine, polyethyleneimine; the latter corresponds to the polyethylene glycols).



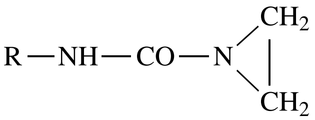
Ethylene oxide (1,2-epoxyethane, oxirane),



Colourless gas at room temperature, liquid at approx. 12°C, soluble in organic solvents, miscible with water. Extremely reactive with mobile H atoms in hydroxyl and amino groups to form numerous technically valuable products used in textile finishing, such as ethylene glycol and ethylene glycol derivatives of all types. Its principal use is for polymerization to 1,2-epoxide polymers.

Ethylene oxide adducts Addition product of ethylene oxide in fatty alcohols, fatty acids and amines. Used alone or in combination as a detergent, fabric conditioner, anti-static agent, emulsifying agent etc.

Ethylene urea (cyclic ethylene urea). Trivial name for imidazolidone-2 and derivatives, ethylene urea resins. As dimethylol compounds, ethylene ureas are important reactant resins, e.g. DMEU, DMDHEU. Linear ethylene ureas are reaction products derived from alkyl isocyanates and ethylene imine, e.g. octadecylethylene urea.

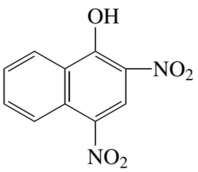


Ethyl ether (ether, diethyl ether, ethyl oxide, diethyl oxide, sulphuric ether, ethoxyethane), $C_2H_5OC_2H_5$, MW 74, density 0,72, b.p. 35°C. A colourless, extremely volatile and mobile liquid. Very flammable (vapours form highly explosive mixtures with air). Characteristic aromatic (narcotic) odour, burning and sweet taste. Slightly soluble in water up to approx. 7%. Miscible with alcohol, chloroform, benzene and other solvents, as well as in conc. hydrochloric acid. Uses: highly effective spotting agent (for oils, fats, resins, fruit and grass stains); does not affect the colour of dyed goods (provided it is not heated).

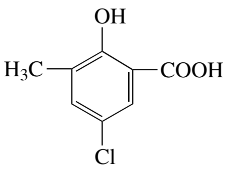
Ethyne → Acetylene.

Eu, chemical symbol for europium (63).

Eulan mothproofing treatment The development of mothproofing and beetle-protection agents for wool is relatively old and has its origins in the coincidental observation that wool dyed with Martius Yellow became resistant to moth attack, i.e. mothproof. The first commercial product of Bayer's Eulan range (chlorocresotic acid) came into being as a modification of Martius Yellow.



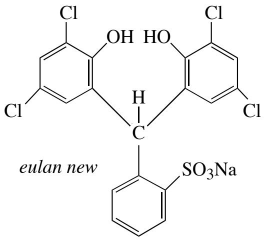
martius Yellow



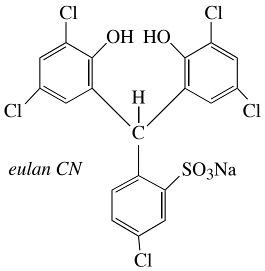
chlorocresotic acid

Eulan RHF could indeed be absorbed by wool from an acid liquor but was not resistant to washing. From

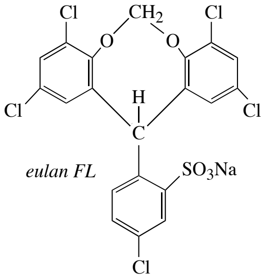
1927, therefore, a range of products based on triphenylmethane which could be applied to wool with better wet fastness properties and, through further modification, also without yellowing, were introduced to the market.



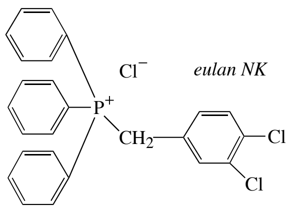
eulan new



eulan CN

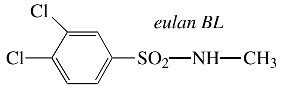


eulan FL

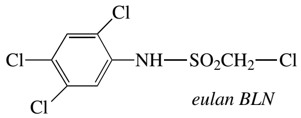


eulan NK

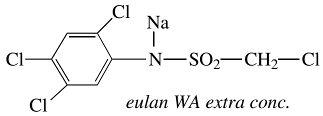
Finally, Eulan brands based on sulphonamides (also suitable for application from organic solvents) superseded triphenylmethane and triphenyl phosphonium compounds. Eulan BL, introduced in 1934, Eulan BLN in 1951, and Eulan WA extra conc. in 1952, are examples of sulphonamide derivatives.



eulan BL

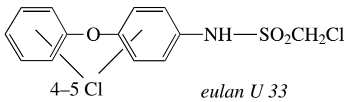


eulan BLN



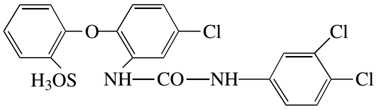
eulan WA extra conc.

The development of Eulan brands based on sulphonamides was continued, and resulted in products suitable for universal application, thereby allowing the finisher free reign to select the most appropriate stage of wet processing from which to apply the mothproofing finish. In 1957, alkyl-sulphonamidohalogen-diphenylether, as the active constituent of Eulan U 33 was launched on to the market.



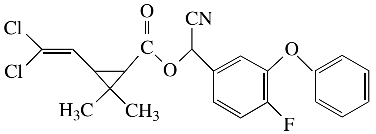
eulan U 33

Finishes produced with this mothproofing agent are characterized by very high fastness properties. For materials that are seldom washed, the cheaper brand, Eulan WA, can be used. At the beginning of the 1930s, the Swiss company J. R. Geigy began the development of mothproofing agents based on substituted ureas which led to the marketing of the product, “Mitin FF”, in 1939. This mothproofing agent could also be absorbed by wool from aqueous solutions like a dye, together with corresponding fastness properties.

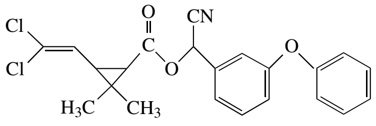


mitin FF

Agents of this type are not insecticides but have the effect of making wool inedible to parasites. They are applied in the final wet process. Individual products can also be applied in the dyebath. Commercial products of different chemical basis include: “Gardone” (Shell) and “Dicaphton” (AMCY), both of which are organophosphorus compounds. “Todmac” is an organic tin compound. The “Sylgard” finish (Dow Corning) which was introduced in the USA, contained the active substance, 3-trimethoxysilylpropyldimethyloctadecylammonium chloride. Practical experience of recommended antimetabolic agents capable of interfering with insect metabolism is not available. An agent with permanent activity is a zinc peroxide complex which relies on the continual release of oxygen. The synthetic pyrethroids also appear promising substances. A commercial product of this type is “Perigen” (Wellcome). Common to all the pyrethroids tested up to now, however, is the fact that although they are indeed highly effective against all moth larvae, moths tend to develop a pyrethroid-resistance, and these substances also offer poor protection against the Anthrenus species of carpet beetle (carpet beetle holes when applied at usual concentrations); often referred to as the “Anthrenus loophole”. Cypermethrin, an agrochemical, provides a slightly higher protection against Anthrenus species but cannot be successfully applied besides permethrin; moreover, pyrethroids have recently come under attack because of their toxicity.

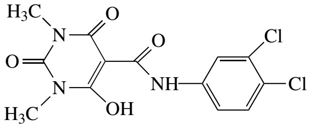


cyfluthrin



cypermethrin

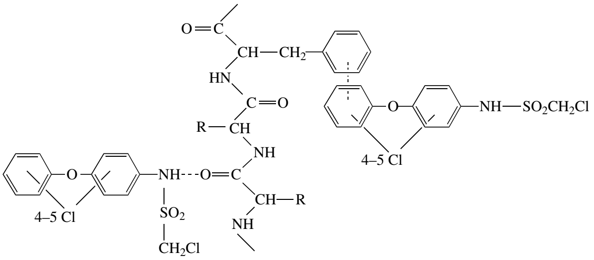
Both Bayer and Ciba-Geigy offer their own products based on pyrethroids. Eulan SP (Bayer) contains trans/cis-cyfluthrin. Mitin AL resp. Mitin BC (Ciba-Geigy) contain *inter alia* permethrin as active component in combination with hexahydropyrimidine derivatives (HHP) for protection against carpet beetles.



HHP

A comparison of the advantages and disadvantages of synthetic pyrethroids in relation to conventional mothproofing and beetle-protective agents shows that the pyrethroids offer the following properties: lower application quantities, a certain toxicity to warm-blooded species, good adsorption and degradability, control of moth larvae, and equal distribution between wool and polyamide.

The high affinity of Eulan brands, based on sulphonamides, for keratin fibres is considerable. The baths, at pH 5, are almost completely exhausted when applied either at the boil or at 40°C. Even in neutral baths the affinity is still high. Since such products exist as free sulphonamides at pH <7, and not as salts, the reason for their affinity cannot be due to a salt-forming mechanism with the wool; rather, the formation of hydrogen bonds can be regarded as the driving force here.



The finishing of wool carpet yarns, as produced in many developing countries, is a particularly interesting application. → Mothproofing and beetle protection.

Eumycetes Hyphomycetes → Moulds.

European Convention for Fastness Testing (ECE). European Colour Fastness Establishment founded in 1952. The leading European study group of dyestuff manufacturers, textile dyers and printers, textile testing institutes, research organizations, as well as fastness testing commissions, in collaboration with → ISO. → Technical and professional organizations.

European legislation relating to machinery safety Within the European Community and E.F.T.A. changes are occurring rapidly as mandatory safety requirements are introduced with the aim of providing a 'level playing field' for competition in the supply of industrial machines throughout these areas. The following Directives provide the driving force for change, the structure and content of the new standards (which are the primary means for manufacturers to ensure that they are complying with the Directives), the particular implications for the coating and laminating sector, and overall progress towards implementation.

1. The Directives: Following the Treaty of Rome, it became increasingly clear that the E.C. would need to take measures to ensure that trade within the community was not subject to national barriers which would impede free competition. Previous attempts to provide a Europe-wide framework for technical standardisation such as the Low Voltage Directive of 1973 had only been moderately successful. This was felt to be a result of two factors – firstly, the Directive was not an enforceable mandatory requirement throughout the community – and secondly, the Directive sought to provide all the technical detail within a single document produced by politicians/civil servants. It was therefore decided that the new Directives would correct these faults. There is a mandatory requirement in each Directive (subject to appropriate transition periods) that they be transposed into national law in every member country and that any conflicting legislation is removed from the statute book. In order to address the second problem, the Directives contain only principles relating to the technical performance and these are normally held in an Annex (for example Annex 2 of the Machine Directive contains the essential safety requirements or ESRs). International standards organisations (originally CEN and CENELEC, but now also including ISO and IEC) are contracted to write full standards in each area which indicate how a manufacturer may comply with the Directive.

It is still technically the legal responsibility of the manufacturer to comply with the ESRs, but compliance with the ESRs by compliance with the standards derived from them is accepted as a de facto compliance, whilst direct compliance will be much more difficult to demonstrate in a court of law because of the nature of the ESRs. Manufacturers are, except in the case of particularly dangerous or critical machines, free to self-certify compliance. However this should not be viewed as an easy option because a wide range of interests are free to challenge the compliance either through the 'Trading Standards' officers in the country concerned or through the courts of law both nationally and internationally. Interests free to do this include aggrieved customers or competitors, local workers or union representatives, and local 'Trading Standards' officers. Complying with the Directives involves generating and maintaining a Technical File for each machine type which documents all the design decisions and associated risk analysis, demonstrates that the machine complies with all the appropriate standards (by external certification where appropriate), and records all the drawings, schematics and instructions supplied with the machine. It is the manufacturers' responsibilty to determine which Directives apply to a particular machine (and it must be admitted that there is still some uncertainty about the dividing lines). The list of Directives below is not claimed to be exhaustive, and in any event the subject is undergoing a phase of rapid evolution, but most manufacturers will be covered by at least one of them.

The Machine Directive: This covers virtually every machine with moving parts and includes sections on design, materials, control (starting, stopping, mode selection), software, stability, guarding, electrical wiring, temperature, fire, explosion, noise, vibration, radiation, emissions, indicators, warnings, instructions and maintenance. It came into force on 1st. January 1993 with a two year transition period.

The Electro-Magnetic Compatibility (E.M.C.) Directive: This establishes the principles of maxima for radiated and conducted emissions, and of minima for immunity from radiated and conducted emissions. It came into force on 1st. January 1992 with a four year transition period.

The Simple Pressure Vessels Directive: This establishes performance criteria, tests and an external certification procedure for pressure vessels. It came into force on 1st. July 1990.

There are also a series of other directives which are associated with items peripheral to the core of machine design. These include:

- The Use of Personal Protective Equipment Directive
- The Use of Work Equipment Directive
- The Display Screen Equipment Directive
- The Manual Handling of Loads Directive
- The Workplace Directive

and the following proposed items:

- The proposed General Product Safety Directive
- The proposed Services Liability Directive
- The proposed Used Machinery Directive.

If a machine complies with the new regulations it is automatically exempt from the old national regulations during the transition period. This is demonstrated by placing a 'CE' mark (see inset) and the year of manufacture on the machine. Care has to be taken in using this mark because it is making a legal claim about the machine, and it implies compliance with all the applicable Directives in force at the time it is placed on the machine.

II. The Standards: Supporting the Directives the standards are structured in a three tier arrangement which provides a simple means of categorising and inter-relating them. This is particularly true of the Machine Directive, and the following examples all relate to that Directive. The uppermost layer (A-type) contains standards which delineate general principles of operation or which describe essential functions which are required throughout the design process. They apply to all machines within the scope of the Directive and include:

- General Principles for Design
- Risk Assessment
- Requirements for the Instruction Handbook.

The next layer contains most of the standards which the designer will use in his day-to-day work and is split into two sub-groups. The first (B1-type) deals with general requirements in specific areas or functions and applies to all relevant machines, whilst the second (B2-type) deals with general requirements for specific devices and applies whenever one of the devices is used. The following examples in the left-hand column are B1-type whilst those in the right-hand column are B2-type.

Safety Distances
Visual Danger Signal
Indicating, Marking and Actuating Principles
Human Body Dimensions

The final level (C-type) is machine specific and is important because these standards not only deal with particularly dangerous aspects of certain machines in detail, but may also provide alternate techniques for achieving the required level of safety in those unusual cases where the requirements of B-type standards make the machine inoperable. A few examples of these standards follow, but the most important are to be found in the standard on the safety of textile machines (prEN31111):

- Textile machinery
- Printing machinery
- Woodwork machines
- Rubber and plastics processing machines.

It is not possible here to deal in detail with the contents of each of these standards, but a few comments are necessary on some of those with a greater impact:

EN292 (Parts 1 and 2) – Basic Concepts, General Principles for Design

This standard sets out the design philosophy and process which should be formally documented and supported within the Technical File. In particular it defines all the relevant terms, deals with safety integration and with additional precautions required in unusual circumstances.

EN294 – Safety Distances to prevent danger zones being reached by Upper Limbs
prEN811 – Safety Distances to prevent danger zones being reached by Lower Limbs
prEN349 – Minimum Distances to avoid crushing of parts of the Human Body

These standards define the safe ways in which access may be achieved to a machine either for running or during regular maintenance. The distances are established using European norms for body dimensions (these distributions are defined elsewhere in the anthropomorphic standards). Care should be taken by manufacturers supplying to regions where these norms do not apply to make the appropriate modifications to distances (each change being carefully documented and justified in the Technical File).

prEN50099 (Parts 1, 2 & 3) – Indicating, Marking and Actuating Principles
EN457 – Auditory danger signals
prEN… – Visual danger signals

These standards give clear guidance on the layout and functional interaction of controls on machines, and on how to implement danger/warning signals. There are a series of associated standards which define the ergonomic needs in a range of environments and the positioning requirements to suit European characteristics.

prEN… – Principles for the design of Safety-related control systems

This is one of the most important standards mandated under the Machine Directive. It describes five categories of control system with increasingly complex protection for more serious hazards. One of the important functions of C-type standards is to define which of these categories applies to each of the machines within its scope. The standard also deals with the important issues of validation of control system function and formal verification.

prEN50100 (Parts 1 & 2) – Electro-sensitive Safety-Devices
prEN574 – Two Hand Control
EN418 – Emergency Stop Equipment

These standards deal with the devices which must be used in the control systems discussed in the previous standard. Particular importance is again attached to validation and verification and, in the case of individual devices, to testing.

EN60204.1 (1992) – Electrical Equipment of Machines
This is a major revision (in fact virtually a rewriting) of IEC204.1. The scope has been dramatically extended and now includes EMC, electronic control systems and PLCs as well as significant changes to all existing wiring and panelling requirements. This additional work has effectively doubled the size of the standard. It is absolute requirement for any machine using electricity as a source of power or control because as well as being mandated under the Low Voltage Directive, it is also mandated under the Machine Directive (according to M.G.B. Mahboubian-Jones).

European regulatory requirements concerning environment protection in finishing → Environment protection in finishing (European Regulatory Requirements).

Eutrophication (Gk.: *eutrophos* = well-fed). A process by which pollution from such sources as waste waters or leachates from fertilized fields causes stagnant or slow flowing surface water to become overrich in organic and mineral nutrients, so that algae grow rapidly and deplete the oxygen supply. The problem is particularly relevant to phosphates in washing detergents which specifically promote the growth of small algae which can result in the feared over-fertilization of surface waters with increased oxygen depletion. A monoculture of algae in a polluted (eutrophic) lake in which other forms of life can no longer exist, is the end-result of this process.

Evaporation losses (Discharge evaporation losses) include (for calculating the water consumption index) all process water losses that do not return as waste water, in particular boiler feed water, all quantities of water evaporated in drying processes, all moisture remaining in the textile substrate, etc. For the reasons specified, the amount of waste water is not identical with the process water supplied and/or extracted. In the absence of suitable water gauges and where calculating industrial effluent discharge levies is cost-prohibitive, a deductible wastage of min. 17% applies (accepted "commercial custom and practice") as a probability criterion and a basis for costings.

Evaporation number (evaporation rate). Comparative evaporation rate in relation to ethyl ether (=1).

Evaporation plant Effluent can be purified by distillation if a solution (power-heat coupling) is available from the energy standpoint. Sludges occurring during evaporation in thin-layer evaporators can be dried and dumped or incinerated in furnaces (licensing).

Wool scouring water enters the evaporation plant with a dry substance content of up to 5% for example. This is thickened to a dry substance content of 55% in 7 evaporation stages, so that approx. 2500 kg of concentrate is produced per hour. The exhaust vapour conden-

Evaporation plant

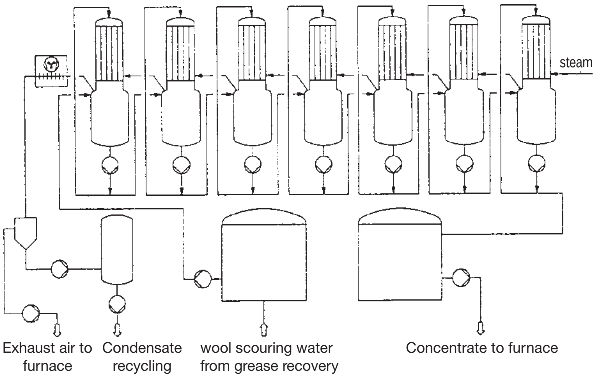

Fig. 1: Bremer Wollkämmerei evaporation plant.

sate from the evaporation plant, which is tainted with a powerful odour, can be re-used as processing water by special after-treatment in a biofiltration plant. The energy-rich concentrate from the evaporation plant has a calorific value (H_u) of approx. 8500 kJ/kg, and is fed to the furnace (Fig. 1).

Evaporation plants are classified as thin-layer evaporators, drop film evaporators and circulatory evaporators, (natural circulation evaporators, forced circulation evaporators).

I. Thin-layer distillation: the principle of thin-layer distillation (Fig. 2) is film evaporation, which represents a gentle form of evaporation. It involves single stage co-current flow distillation, the separating effect of which is equivalent to a max. of one theoretical partition stage. Partition intensity can be increased by serial installation. Trials have shown that the most important advantages of thin-layer distillation can be exploited at normal pressure and in the approximate 5 to 1 x 10^{-1} Torr range; this is because a high fluid layer is heated up, and the dwell time in the heating zone is significantly shorter. In the case of film distillation, a fine film is produced, which generates virtually no pressure increase, and runs off with a short dwell time. This type of heat protection should be used with temperature-sensitive substances. First of all, preliminary separation is effected in a narrow temperature range. If a mixture boiling at high temperature contains small proportions of low-boiling components, it is often impossible, despite increased heating, to recover all fore-running components by piston distillation. If a vacuum is used in order to prevent the high-boiling components from disintegrating, there is a danger that the fore-running components will escape uncondensed. These difficulties can be eliminated by thin-layer distillation at normal pressure.

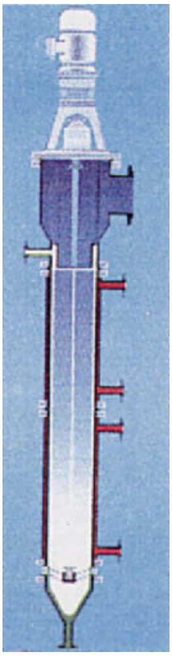

Fig. 2: Canzler thin-layer evaporator.

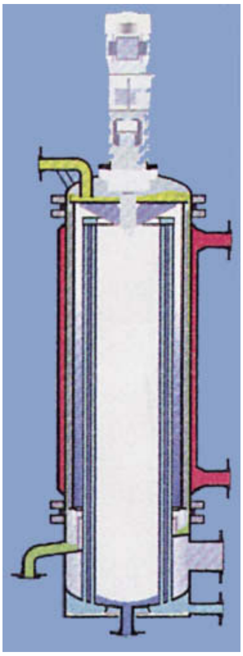

Fig. 3: Cross-section of a Canzler flash evaporator.

A frequently used type of thin-layer evaporator consists of a fairly large diameter vertical tube which can be externally heated. The bottom part forms the boiling zone, while the top part houses the exhaust vapour separator. Inside, the product to be evaporated is moved by a high-speed rotor, which both distributes the liquid entering the top part via the heating surface and prevents heating surface encrustation by means of a special wiper system. Fluids can be evaporated to a powdery consistency in a thin-layer evaporator. The dwell time in this type of plant is only a few seconds. Effluent with a tendency to foam also causes fewer difficulties in a thin-layer evaporator. For this reason, thin-layer evaporators are used mainly as the last stage of multi-stage evaporation plants. The pressure range runs up to approx. 5 mbar; evaporation temperatures are correspondingly low.

The flash evaporator (Fig. 3) finds use in distillation in the 1–0.001 mbar fine vacuum range. In the case of this type of evaporator, the condenser is built into the evaporator, with the evaporation surface directly opposite, which means that there is virtually no pressure loss between heating and condensation surfaces. Extremely sensitive products can be optimally distilled in this way. The product is fed in at the evaporator head, and distributed over the heating area by the rotor. The wiper system produces a turbulent fluid film, the product vapours being precipitated on the condenser located below in the evaporator. The distillate flows down to the condenser tubes, and then drains on to the ground. The sediment is collected, and removed via a lateral connecting stub. In the case of the thin-layer rectifier, the run-back liquid runs down against the flow of the rising vapour as a thin film. In this way, the basic rectification processes are spatially separated by being distributed over an evaporation surface and a condensation surface. One special design comprises a wave of fixed agitator blades (Sambay evaporator), making it possible to adjust the liquid film thickness automatically, depending on the viscosity of the boiling liquid and on the blade contact pressure.

II. Circulatory evaporators are built with natural circulation (automatic circulation) and forced circulation of the product to be evaporated. The operating force is the temperature difference on the liquid side of an evaporation tube. With viscous solutions, this critical temperature difference is higher than with low-viscosity ones. Circulation can come to a standstill if the temperature difference between heating and boiling sides, reduced in raising the boiling point, is small. Due to buoyancy, the liquid in the evaporation tubes rises on account of the vapour bubbles occurring during boiling and the associated reduction in density. The effect is the more intensive the higher the temperature difference between boiling and heating chambers, i.e. the larger the number of vapour bubbles formed. The higher the flow rate in the tube, the better the heat transfer, and the smaller the heating area can therefore be kept. The maintenance of high flow rates is particularly important for effluent containing substances with a tendency to encrustation.

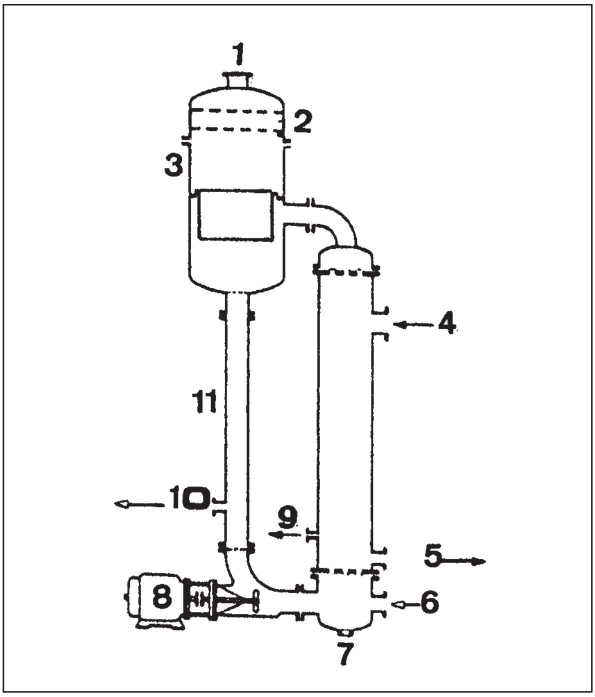

Fig. 4: Forced circulation evaporator with external heater. 1 = Exhaust vapours; 2 = Liquid separator; 3 = Vapour chamber; 4 = heating steam; 5 = Condensate; 6 = Fresh solution; 7 = Drain; 8 = Circulation pump; 9 = Gases; 10 = Lye; 11 = Downpipe.

Use of a forced circulation evaporator (Fig. 4) instead of a natural circulation evaporator can be recommended, and is essential if the danger of content disintegration is greater due to high heating surface loading. Heat transfer is improved with this evaporator. The liquid is circulated by a pump so that the flow rate can be selected independently of heating surface loading. The tendency to encrustation can be countered if boiling is prevented in the tubes. In this event, the solution must be subject to a correspondingly high static pressure ("flooding"), and then boiling begins only outside the tube after pressure release. Centrifugal separators with tangential boiling solution entry are employed for separating vapours and solution, which, if correctly designed, largely prevent solution foaming.

Technical methods of reducing power consumption: good design should take account of the operational behaviour of the solution to be evaporated (encrustation, foaming), its physical properties (temperature and viscosity dependency on concentration, solubility dependency on temperature) and its dwell times (dependent on thermal instability). Only then can power consumption be meaningfully structured. A quantity of heat q = approx. 2800 kJ/kg, taking account of the efficiency of the heat technology, is used for evaporating water up to 100°C. It is possible to reduce energy and steam consumption by multi-stage evaporation. Thus, with 5-stage evaporation, the specific steam consumption of 1 kg of steam can be reduced to 0.2 kg of steam/kg of water as compared with single-stage evaporation. A number of evaporation stages are linked together in such a way that the vapours of one stage form the heating medium for the next. The boiling temperature must be sought by reducing the pressure from stage to stage, as a temperature difference between the stages is a prerequisite. Cooling water consumption is also lower, as only the vapours of the last evaporation stage have to be condensed. The steam consumptions are 1 : 0.5 : 0.33 etc.

The following staging methods are basically available: the variant used in processing technology is cocurrent flow feeding. Liquid is first of all pumped into the stage with the highest pressure, leaving the plant in the stage with the lowest pressure. In the case of counter-flow staging, the solution enters the last stage (lowest pressure), and is pumped from stage to stage against the direction of flow of the exhaust vapour. The concentrate leaves the evaporator at the highest pressure. This possibility is of advantage for highly concentrated solutions, as they evaporate in the stage with the highest temperature, where viscosity is lower and heat transfer is better. The third version is used where the solubility limit is not reached, i.e. the solid substance crystallizes out during evaporation.

Optimum energy utilisation is guaranteed when product flow and temperature and or pressure drop are staged with or against the flow. Combinations of the

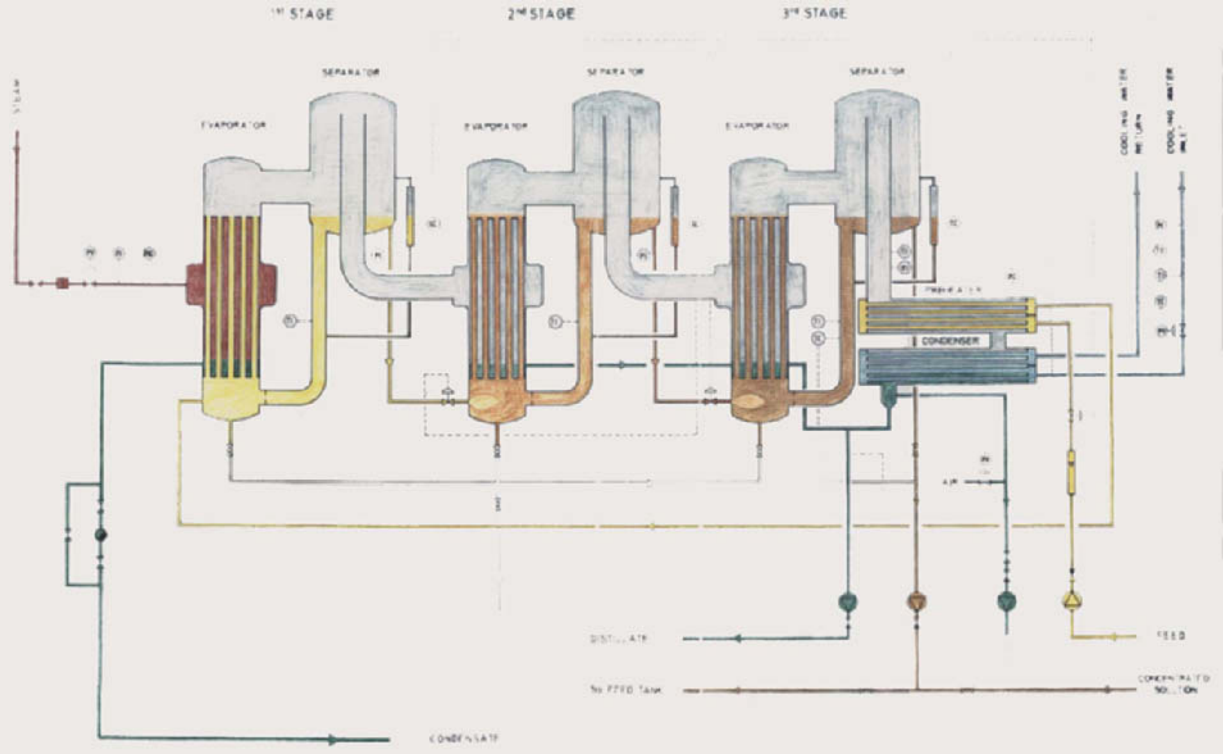

Fig.: Evaporator plant (Kasag).

two are possible. It is important to use energy by combining different evaporator models so as to adapt to changing product characteristics. Effluent evaporation and distillation should not be regarded as the exclusive method of effluent treatment. These methods should be regarded as a feasible separating process in an integral concept. In any case, suitability for problems arising should be examined for industrial scale evaporation, together with the efficiency of other effluent treatment methods if necessary. Before considering effluent incineration, it is essential to check whether advantages are offered by effluent recovery by adsorption, ion exchange, distillation, evaporation, stripping, extraction and crystallisation as alternatives.

Evaporator plant Is multistage and produces distillate and concentrate (see Fig.), with the separation efficiency being dependent on the solution concerned.

Exchange factor for continuous dyeing The ideal continuous dyeing method consists of applying the dyestuff with no affinity of any kind mechanically on the fibre and then of fixing it in situ as quickly as possible. With direct dyestuffs and leuco vat dyestuffs however, padding is characterised by a larger dye uptake than would correspond to the quantities of dyestuff effectively absorbed. This can be traced back to an affinity of the dyestuff for the fibre. During padding, the fibre undergoes a dyeing process which is more or less pronounced. The degree of affinity can be considerable (the half-life period of dyes for a range of direct dyestuffs lies between 5–25 s at low liquor ratios). As a result of the influence of this affinity, the concentration of the padding liquor diminishes from the point in time when the material begins to flow through until an equilibrium is reached (Fig. 1). The fabric undergoes a process similar to a change of shade (tailing).

In practice, the success of the pad dyeing process depends on the skill of the dyer in controlling his dyeing conditions in such a way that there is minimum

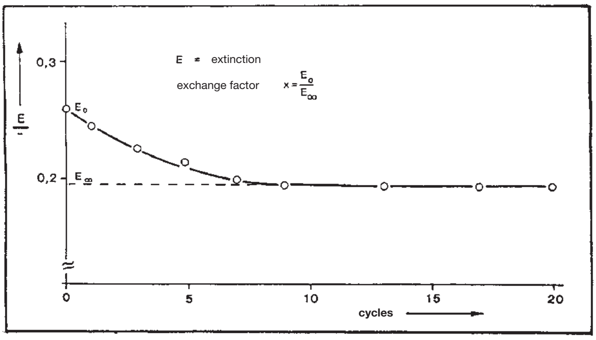

Fig. 1: Liquor concentration after simulated water extraction by squeezing.

Next Page

change in concentration. The dyer attempts to avoid a change in concentration from the outset by using a suitable balanced padding liquor. The amount of dyestuff introduced should be equal to the total amount of dyestuff absorbed by the fabric.

As the dyeing process (i.e. the interaction of dyestuff/fibre) is generally an exothermic process, attempts are made to reduce any available affinity of the substantive dyestuffs in the padding machine as the padding liquor is heated. Systematic tests attempt to clarify the fact that the quantity of padding liquor in the trough should be kept constant by adding fresh dye solution, but should differ until the amount of dyestuff taken up by the fabric corresponds to that flowing into the feed liquor.

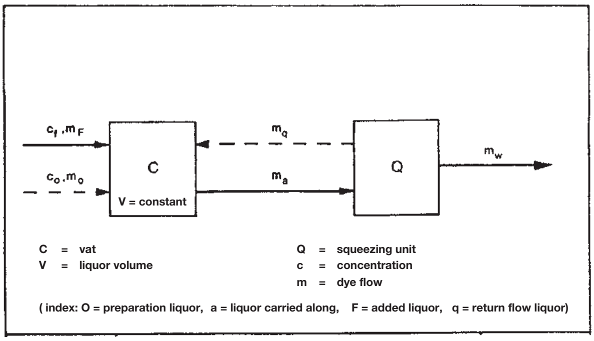

Fig. 2: Mass (dye) transport in a padder.

The temporary alteration to the concentration of the padding liquor in the trough (Fig. 2) can be calculated as follows:

$$V_B \cdot \frac{dc_B}{dt} = V^* \cdot c_0 - V^* \cdot x \cdot c_B$$

V_B = trough volume,
c_B = present concentration in the trough,
c_0 = concentration of the initial liquor and feed liquor,
V^* = liquor volume taken up by the fabric per unit of time,
x = exchange factor.

In order to solve the differential equation for $c_B = c_0$; $t = 0$ and $c_B = c$; $t = t$ an expression for the concentration in the padding trough at time t follows at constant volume flow V* of the liquor introduced to or with the textile and at a constant bath volume V_B:

$$c_t = \frac{c_0}{x}\left(1 + (x-1)^{\frac{-V^* \cdot x \cdot t}{V_B}}\right)$$

An exchange factor

$$x = \frac{E_0}{E_\infty},$$

is formulated. This can be determined by a specific liquor passage device, and gives information about the interaction in the system. The stationary condition is reached when the concentration (measured by expiry E) of the liquor collected no longer changes after various cycles (E_∞). The adjustment of this balance can be localized by appropriate presharpened and regenerated liquors. The larger the interactions in the system, the more quickly an equilibrium occurs. The exchange of liquor in the pad dyeing machine should be as large as possible and the trough volume as small as possible (Fig. 3).

Execution time Portion of → Order processing time (relating to → Setting up time) for operational outlay in time per unit as →: Basic time and allowance.

Exhaust air In textile finishing plants most of the exhaust air is produced from stenters, curing machines, hot flues, drying chambers, etc. It generally has a high moisture content and contains certain pollutants as well as energy in the form of heat. The pollutants are either removed in scrubber columns or destroyed by combustion; in the latter case exhaust heat is recovered in suitable heat recovery plants.

Exhaust air analysis Quantitative analysis of exhaust air together with analysis of the qualitative and quantitative composition of exhaust gases must be carried out in order to establish whether exhaust air quality is suitable for TA air. Quantity measurement is effected in a straight section of exhaust air ducting as a measurement of flow in accordance with VDI 2066 using a Prandtl pitot tube in combination with an inclined tube manometer. This gives an exhaust air quantity of 20 000 m^3/hr (drying 3000 m/hr of woven wool fabric) for a 9-chamber horizontal stenter.

Generally, stenters produce approximately 10 m^3 of air/kg of fabric, and curing machines only 1 m^3 of air/

Exhaust air In textile finishing plants most of the exhaust air is produced from stenters, curing machines, hot flues, drying chambers, etc. It generally has a high moisture content and contains certain pollutants as well as energy in the form of heat. The pollutants are either removed in scrubber columns or destroyed by combustion; in the latter case exhaust heat is recovered in suitable heat recovery plants.

Exhaust air analysis Quantitative analysis of exhaust air together with analysis of the qualitative and quantitative composition of exhaust gases must be carried out in order to establish whether exhaust air quality is suitable for TA air. Quantity measurement is effected in a straight section of exhaust air ducting as a measurement of flow in accordance with VDI 2066 using a Prandtl pitot tube in combination with an inclined tube manometer. This gives an exhaust air quantity of 20 000 m^3/hr (drying 3000 m/hr of woven wool fabric) for a 9-chamber horizontal stenter.

Generally, stenters produce approximately 10 m^3 of air/kg of fabric, and curing machines only 1 m^3 of air/

kg of fabric. Qualitative exhaust air measurements determine the total carbon content of the exhaust gases by the following methods:

– flame ionisation detector,
– silicagel process,
– combined gas chromatography and mass spectrometry.

Quantitative analysis of all exhaust air content substances is possible by the following method: over a 1 hr period, a defined partial quantity is taken from the works exhaust airstream by means of a vacuum pump in accordance with VDI 2457, the partial flow being passed through condensation traps (0°C) in order to remove any moisture which might impair measurement. The exhaust air content substances are then absorbed in an activated charcoal tube. This activated charcoal collection stage is replaced by carbon disulphide for organic content substance desorption in the laboratory. Any condensate collected is extracted with dichloromethane. The substance mixtures are separated by the gas chromatographic method by means of fused silica capillary columns with methyl-silicon coating, and then detected by computer-aided mass spectrometry, and identified with an electronic data processing library. After that, quantitative calibration is effected with comparative substances as external standards.

Because aromatics are relatively difficult to desorb by activated charcoal, the recovery rate is below 50%. The gas chromatographic response factors are favourable in that the substance to be quantified is used as far as possible as a standard.

Exhaust air, cleaning of Reference to: oxidation, condensation and adsorption processes.

I. Oxidation process: functions of oxidation: combustible atmospheric pollutants in exhaust air can be converted by combustion into harmless substances. In the case of complete oxidation, chemically bonded hydrocarbon compounds are converted into the products of combustion - carbon dioxide (CO_2) and water (H_2O). If the oxidation process is incomplete, carbon monoxide (CO) and formaldehyde are formed. If there are inorganic substances from oxidation processes in the exhaust air, like sulphur, nitrogen or halogen compounds perhaps, a further cleaning process, with washers for example, must follow. For these reasons, combustion is preferred for substances which are largely composed of carbon and hydrogen. A distinction is drawn between thermal combustion and catalytic combustion.

Cleaning exhaust gas by thermal reheating (Fig. 1): thermal reheating is carried out at temperatures between 750 and 1100°C. This process is readily used for exhaust gases with organic compounds such as solvent vapours and highly odorous substances and for impurities like halogen and phosphorous compounds which would destroy a catalyst. A thermal reheating plant consists essentially of the following components: blower, perhaps a heat exchanger, auxiliary heating, exhaust gas feed ducting to the combustion chamber, burner, combustion chamber, measuring and control equipment and safety equipment. The crude gas passes through a blower to a heat exchanger. In this case, the heat content of the cleansed exhaust gas is transferred to the crude gas via a heat exchanger. The crude gas air preheated in this way is brought to the required temperature in an auxiliary heater in order to attain ignition temperature in the combustion chamber. The structural shape of a combustion chamber can vary considerably in design, differing mainly in size, flow behaviour and material. The temperature distribution in the combustion chamber and the exhaust gas dwell time are changed in this way. The function of the burner is to bring the exhaust gas up to the reaction temperature. It can be a point burner for liquid and gaseous fuels or a bottle burner for gaseous fuels alone.

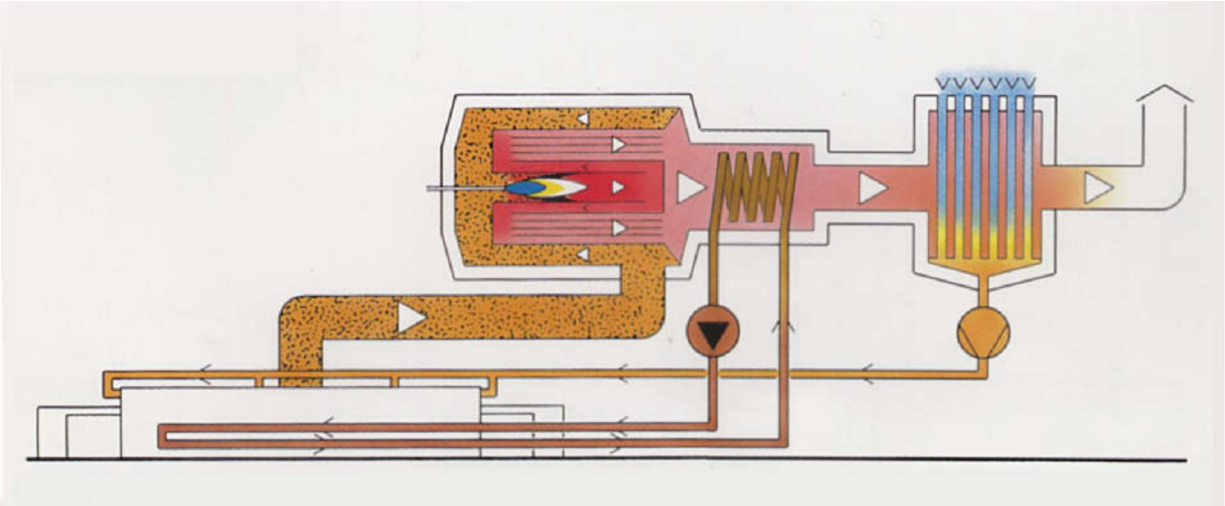

Fig. 1: Thermal reheating principle.

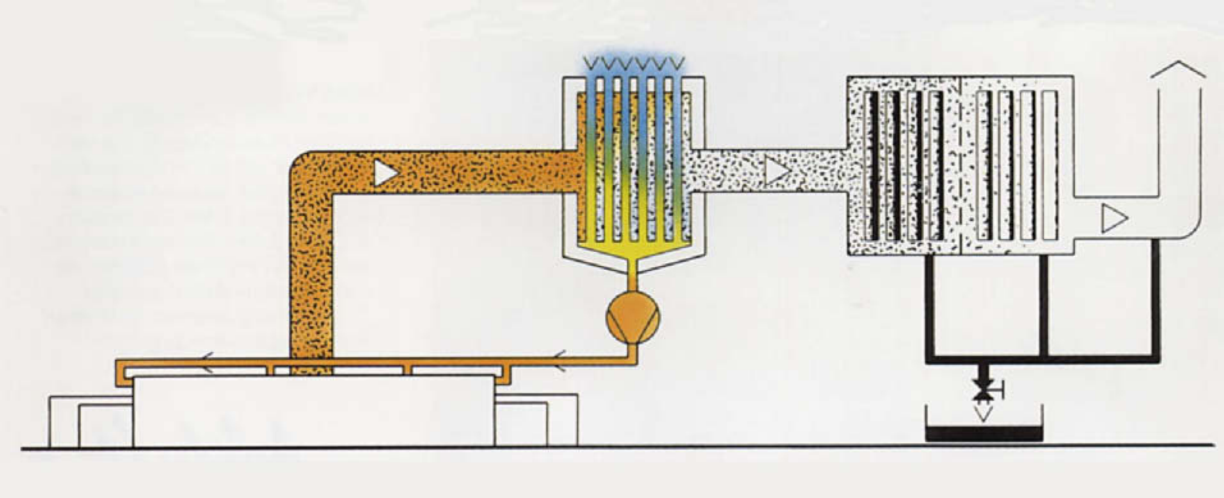

Fig. 2: Cleaning exhaust air by cooling and filtering.

A correct mixture of air and fuel guarantees complete combustion. If air is lacking, gases like CO, CH_4 or H_2 which are still combustible, escape into the flue gas; if there is an excess of air, the combustion temperature is reduced. The consequence of a temperature reduction is that ignition temperature would not be reached. Ignition temperature does however occasion rapid gas combustion. The heat generated by combustion is sufficient to keep subsequently flowing substances at ignition temperature. A measuring and control unit ensures that constant combustion is maintained.

Exhaust gas cleaning by catalytic combustion: the advantage over thermal reheating lies in the decidedly lower activation temperature of 300–450°C. This is explained by the use of suitable catalysts, which hold down the ignition temperature on the one hand, and accelerate the speed of reaction between pollutant and atmospheric oxygen on the other. They are also able to start a reaction, or guide it in a specific direction, without being consumed. Combustion equilibrium can be affected by the pressure, temperature and concentration of the reacting elements. The difference between this and thermal reheating is obvious: the exhaust gases are oxidised in the combustion chamber with the aid of an incorporated catalyst without producing flames. The heat of catalytic combustion released is used for preheating the crude gas flow. If the crude gas contains incombustible dusts, they must be removed in an upstream dust separator, as they are otherwise deposited on the surface of the catalyst, reducing effectiveness over a period. Large quantities of phosphorous compounds, halogens, silicones and heavy metal compounds should not be oxidised either, since they act as catalytic poisons.

A catalytic reaction comprises 4 stages in the heterogeneous system (heterogeneous catalysis):

- pollutant substance conveyance by convection and diffusion from the free gas chamber to the surface of the catalyst,
- adsorption on the surface (chemical sorption),
- combustion product desorption,
- combustion product conveyance by diffusion and convection from the surface of the catalyst into the free gas chamber.

II. Condensation: functions of condensation: vapours of a pure substance, mixed vapours or gas/vapour mixtures are cooled in condensers (Fig. 2), the vapour liquefying (gas/vapour mixtures consist of a condensable vapour and a non-condensable gas). The non-condensable gas is mainly air, depending on the refrigerating temperature. In order for vapour to condense on a wall, its surface temperature must be below the vapour saturation temperature. The condensate is then deposited in individual droplet form (droplet condensation) or as a coherent film (film condensation). Droplet condensation occurs only when the condensate wets the wall, but since practically all liquids properly wet out the materials used for the condensers, beneficial droplet condensation is rarely encountered. Condensation has the great advantage of valuable substance recovery.

Condensation processes and equipment: a process very frequently encountered is the cooling of exhaust gases on the external surfaces of finned evaporators. The equipment, which consists of a succession of finned tubes arranged in parallel, is constructed in the widest variety of performance ratings, materials, and tube and fin dimensions, depending on application. The gas is generally sucked or pushed through the fin system by a fan connected to the vaporiser. Frequently, water or other constituents are condensed out or frozen out during gas cooling. If solid ice forms on the tubes and fins, a second unit must be provided as an alternative for continuous operation. Hot gas from the pres-

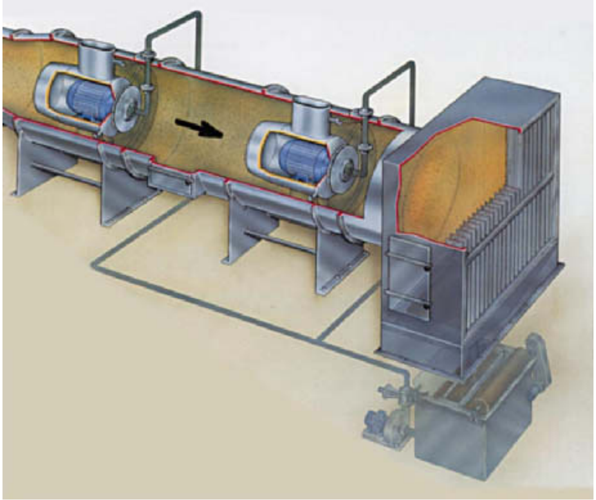

Fig. 3: Prött exhaust air cleaning washer. Arrow = Exhaust air flow direction

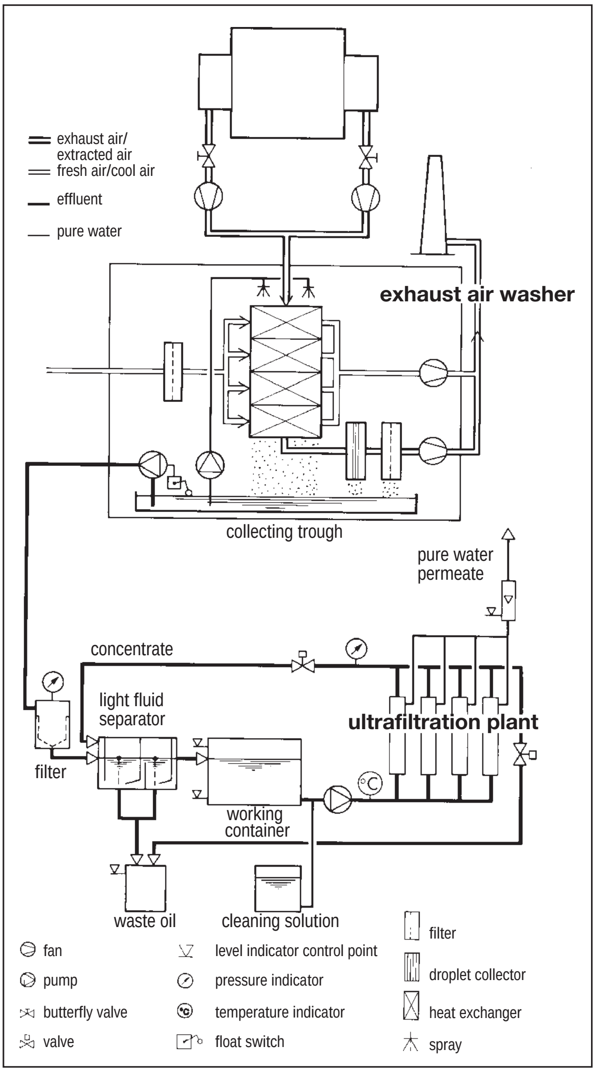

Fig. 4: Function diagram of a Behr washer with effluent preparation.

sure side of the compressor, which gives up its condensation heat to the cold surfaces of the equipment to be defrosted, is employed for defrosting. Another possibility would be to incorporate electric heating elements in the vaporising system. A cooling agent is sprayed into the fin system; the coolant is completely vaporised, and passes through the fin system. In the case of large fin network ramifications, low surface tension liquid coolant is passed through the entire system by means of coolant pumps, part of the coolant being vaporised, and the resultant vapour-liquid mixture returning to a receptacle which simultaneously serves as a coolant separator. A refrigerating agent can also be pumped through the cooler instead of vaporised coolant.

III. Washers: with the use of exhaust gas washers, there are two possibilities of separating exhaust gas content substances by the washing medium (mostly water):

1. Cooling the gases and removing a water-insoluble aerosol which has to be deposited in a sump (Fig. 3).
2. Dissolving the gases in a solvent which is sprayed.

The exhaust air problem is of course transferred to the effluent when washers are used, an integral concept therefore requiring appropriate effluent preparation (Fig. 4).

The principle of the Behr washer: the exhaust air passes through a distributor box into the washing plant, where it is fed via a spray system fed by circulating water, over heat exchangers which act as a packed column. In this way, the exhaust air is brought into intensive contact with the washing water. At the same time, the exhaust air temperature is reduced by the air-to-air heat exchanger, and the washing water kept at low temperature. After leaving the heat exchanger, the exhaust air is turned through 90°, passing into the atmosphere via droplet separators, via stainless steel filters and exhaust fans. Condensate and washing water are collected in the sump, and conveyed from there via a pump to the spray system. Due to condensation of the water-vapour-containing exhaust air in the washer and the heat exchanger, approx. 150 kg/hr of condensate passes into the plant collection container. A second pump pumps the excess wash liquor into an emulsion separator for further disposal. Cooling air is sucked in through dust filters. The cooling air then passes into air-to-air type nozzle mixing plate heat exchangers, where it is heated up by exhaust air and washing water, and finally blown into the atmosphere by means of a radial fan. Depending on the plant housing, the heated cooling air and the exhaust air coming from the washer can be combined and passed into the atmosphere via a collecting duct.

Since, in the stentering process, exhaust air and residual liquors together with dirty water occur simultaneously (Fig. 5), the obvious idea is to combine and couple exhaust air and effluent purification. This trig-

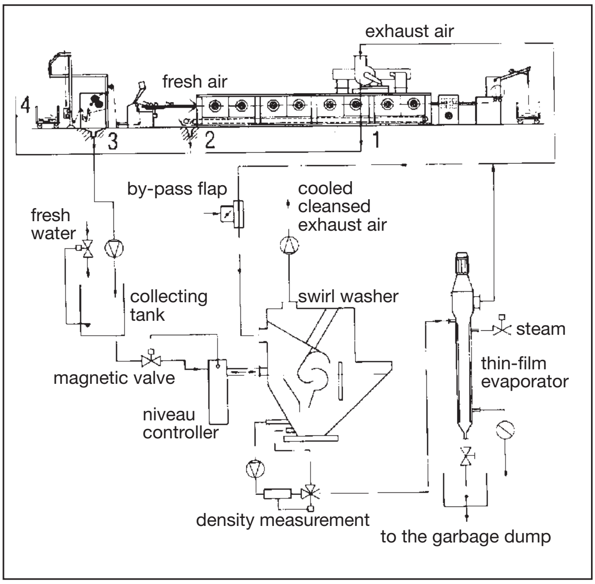

Fig. 5: Exhaust air cleaning system with concentration of residual liquors and effluent by evaporation in the swirl washer (Babcock).
1 = water from the automatic heat wheel or other recovery system cleaning unit; 2 = water from the automatic brattice cleaner; 3 = residual liquor and pad mangle cleaning water; 4 = other dirty water produced, e.g. from scouring or dyeing.

gered the idea of a swirl washer, the basic concept of which is to condense the dirty water and clean the exhaust air by washing in one operation. Processing cycle: the stenter exhaust air is fed into a swirl washer, where it is cleaned in a rotating air-water vortex and its resultant water screens (Fig. 6). Particles, fly and aerosols are enveloped by water droplets, and fall out because of their greater weight. Water-soluble gases and vapours are brought into solution by absorption. Most of the vapours are condensed into fine droplets by cooling the exhaust air to cooling limit temperature (50–65°C).

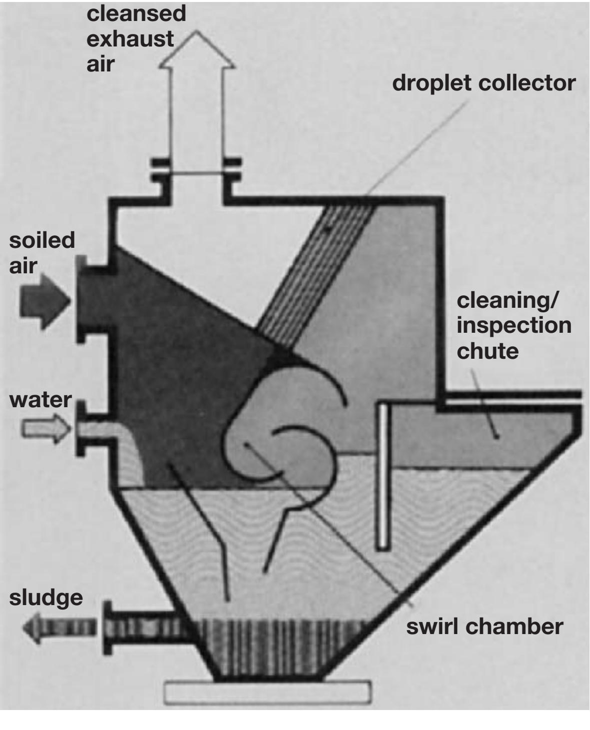

Fig. 6: Swirl washer for exhaust air cleaning (Babcock).

Droplet separators are located downstream of the swirl chamber so that no water is entrained by the airflow. The energy removed from the exhaust air during cooling becomes available for evaporating the washing water. Here are two examples for illustrating the order of magnitude:

a) Drying process:
   Hypotheses:
   – exhaust air temperature 130°C
   – exhaust air humidity 100 g/kg
   – exhaust air quantity 10 000 m^3/hr = 8759 kg/hr

This produces a cooling limit temperature of 57°C in the washer, and an exhaust air humidity level of 132 g/kg. Thus, 32 g of water/kg of air, and therefore 280 kg of water/hr are evaporated.

b) Heat setting process:
   Hypotheses:
   – exhaust air temperature 160°C
   – exhaust air humidity 30 g/kg
   – exhaust air quantity 7000 m^3/hr = 5706 kg/hr

This produces a cooling limit temperature of 48°C, and therefore an exhaust air humidity level of 75 g/kg. Thus, 47.5 g of water/kg of air, and therefore 271 kg of water/hr are evaporated.

The swirl washer liquor level is sensed via a level controller, and the evaporated water quantity supplemented from the supply tank. It is basically possible to utilise all the dirty water produced on the stenter and also other dirty water produced in the works for operating the swirl washer. Fresh make-up water must be fed to the supply tank in case of need, but in fact only when there is either insufficient dirty water available or when concentrations of slightly volatile organic substances are present in the washer.

Approx. 75% of the water content is gradually evaporated in the swirl washer, the pollutants being concentrated in the washer sump. As soon as a specifically set density is reached, the concentrated washing water is automatically conveyed into a steam-heated thin film evaporator (Fig. 7), in which the residual water is largely evaporated to a pollutant-saturated sludge. The heated washing water is distributed in a thin film on the inner wall by means of rotor blades, the water evaporating and the solid matter being scraped off. The vapours are again passed through the swirl washer in order to exclude troublesome odours during evaporation. The remaining residual sludge (max. 10% of the residual liquor content) should be dumped.

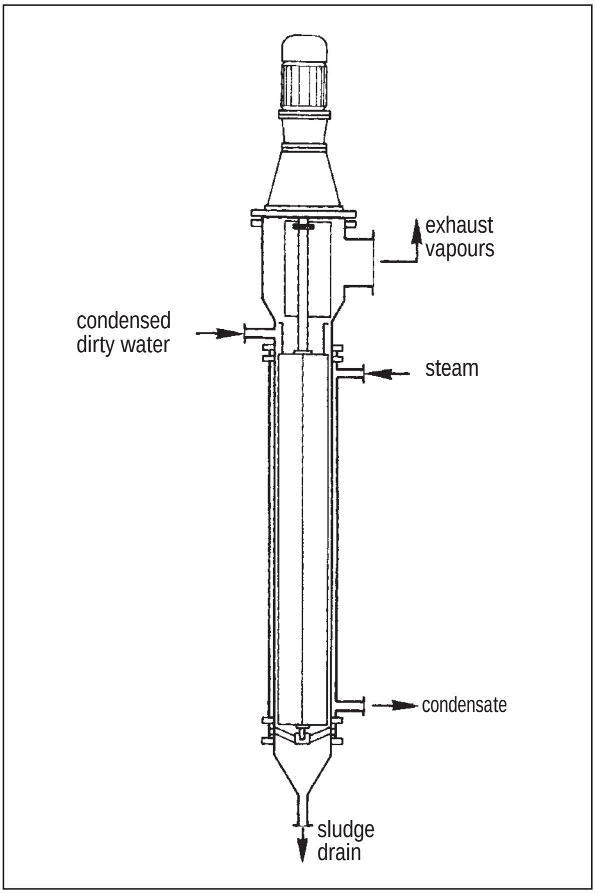

Fig. 7: Babcock thin layer evaporator.

The energy expenditure necessary for operating this combined system (necessary electrical energy relative to the above-mentioned drying process example with an exhaust air quantity of 10 000 m^3/hr) is: for the blowing operation, approx. 15 kW for overcoming the heat exchanger air resistance of approx. 200 water column, approx. 0.5 kW for the circulating pump, and approx. 1.5 kW for the thin film evaporator stirring unit. Steam is also used for operating the thin film evaporator. This requires approx. 125 000 kJ for evaporating approx. 50 kg of water/hr, i.e. 55 kg of steam/hr.

IV. Adsorption: adsorbents are substances which are capable, due to their pore volume and pore structure, of selectively bonding gases, vapours or liquids. On efficiency grounds, they should have specific properties:

- large specific surface, high porosity,
- a high degree of selectivity for the specific substances to be adsorbed,
- a high adsorption capacity for the substances to be adsorbed
- good regenerative capacity,
- resistance to chemical and physical effects (temperature and acid resistance, ignition point),
- good mechanical strength and hardness (important with moving bed adsorbers).

Adsorbents generally differ as regards pore volume and the nature of their chemical surface. Activated charcoal has a much higher pore volume than other adsorbents, and consequently has the largest specific surface. This active charcoal advantage also explains the high adsorption capacity which applies generally to organic substances. Another reason why activated charcoal is used for preference in exhaust gas cleaning is its versatility. This versatile use of activated charcoal as compared with other adsorbents clearly reveals the importance of this substance. Activated charcoal is produced (dry distillation) by heating prepared carbon-containing substances (wood, bones etc.) in the absence of air. Aluminium oxide, silicagel and molecular sieves can be used only in specific cases, and have the disadvantage of readily absorbing a great deal of moisture. In exhaust gas cleaning, granular adsorbents with a grain diameter of 1–8 mm are used exclusively. Once used adsorbents can be used again for adsorption (recovery of the adsorptive as a valuable material if need be) by regenerating the adsorption medium. Two processes determine regeneration:

- desorption,
- downstream reactivation if necessary.

As the adsorbed quantity is favoured by rising partial pressure and low temperatures, desorption should be effected as far as possible by pressure reduction (relaxation) and heating, and also by means of displacement by a slightly adsorbent substance (frequently steam). The various regeneration methods can be used in combination. The method of bonding the adsorptive to the adsorbent generally determines the following desorption methods:

a) Temperature change process: the adsorbents can be regenerated by adding hot steam or hot gas, the steam or hot gas acting as auxiliary media for absorbing and removing the released adsorptive. The disadvantage of this equipment is that long cycle times occur due to the long heating and cooling periods. This can be a matter of hours.

b) Pressure change process: the increased pressure in the adsorber is sharply reduced by pressure reduction or evacuation. The released adsorptive is carried away by a scavenging gas, or is suction extracted. This process is used when there is a high concentration of impurities, as the temperature change process would require a much longer time. An order of size of minutes is involved here.

c) Extraction with solvents: the adsorptive is brought into solution with a suitable solvent, and removed from the adsorbent surface. When extraction is complete, the adsorbent must be removed from the extracting medium. This is effected by thermal desorption.

d) Reactivation: reactivation means reproducing the adsorption capacity of damaged adsorption media, i.e. of those, the adsorptives of which cannot be separated (or can only be incompletely separated) by desorption owing to their low volatility or solubility. This applies for example to granular activated charcoal which has been damaged by organic substances because the organic impurities carbonise inside the pore space.

In addition to electrostatic particle separation (1913), the adsorptive removal of organic components (1917) is one of the oldest basic operations to have been put into effect technically in the "clean air" sense. It means in principle that adsorbents are suitable in this application range only for separating gas and vapour-state pollutant components (adsorptives) from exhaust air/exhaust gas. For separating aerosols, airborne particulates and mists, systems which are located upstream of the adsorption process itself, and are based on other processing principles, should be brought into use. The selection of adsorbents utilised for a specific purpose presupposes knowledge of their properties and of the components to be adsorbed. Influencing factors like temperature, concentration, relative humidity etc. are parameters which are of great importance as regards design. Suitable interrelationships are being worked out in laboratory or semi-industrial trials.

The effect of concentration and temperature on the load capacity of (in this case) single-pore activated charcoal can clearly be seen in the equilibrium isotherms of dichloromethane (Fig. 8). These and a range of other characteristics require thorough examination, including estimation of the serviceability limits of adsorption. Examples in this direction are available where the cleansing of large quantities of air with low pollutant concentrations are concerned, where components present in the exhaust air block the activated charcoal pore system, where reprocessing after regeneration necessitates disproportionately high expense, or where problems lately linked with odour emission crop up by way of solution. Occasionally, it has also required the conducting of semi-industrial trials, as directly as possible at the source of emission, or consideration of possible alternative solutions.

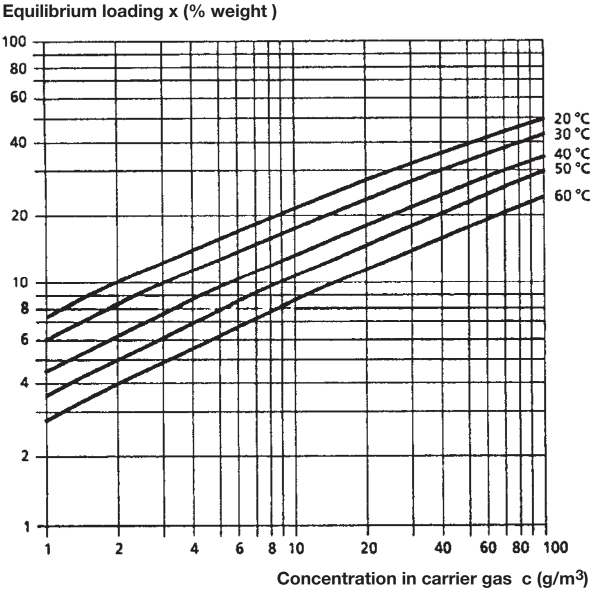

Fig. 8: Adsorption isotherms of dichloromethane on to activated charcoal with dry air.

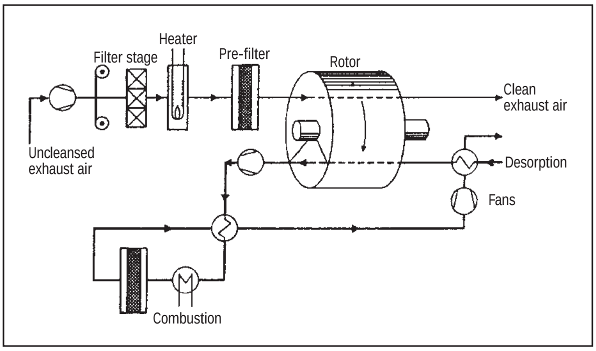

Fig. 9: Flow diagram of an exhaust air cleaning process based on the rotation principle.

In a packed bed adsorption process, at least two adsorbers should be installed in order to create a quasi-continuous method of operation. Here, the packing consists of granular carbon, normally with a diameter of 2.5–4 mm. Ball carbon (0.7 mm), with its specific properties as regards moulding, hardness, particle size, kinetic behaviour on loading and regeneration, makes use of the fluidised bed technique possible. Whilst steam regeneration is pre-eminently state of the art with the packed bed, solvent is extracted by direct heating with circulated nitrogen as the carrier medium in the case of the fluidised bed process. This dry method is indicated when recovery of water-soluble and/or easily decomposable solvents is involved.

The activated carbon fibres are bonded in different types of matrix for mechanical stability, and can be made technically applicable in the form of mats, webs, felts and fabrics. In the case of ball carbon and fine-grained activated carbon, application on ceramic material has gained acceptance. Rotors (Fig. 9) have become accepted as a constructive solution for the use of these commercial forms. These types of system are used pre-eminently for concentrating the organic components, i.e. the main fields of application will be large quantities of air with a low pollutant concentration, and other exhaust air cleaning concepts (such as thermal combustion) will be excluded for various reasons. Regeneration is mainly effected with hot air. The so-called secondary air occurring here is highly enriched with organics, and can be fed either to a small combustion unit or to an additionally installed recovery plant.

Exhaust air dampers, regulation of Drying refers to evaporation of water. The resultant water vapour must be discharged from the dryer so that new water can be continually evaporated. A mixture of hot air and water vapour leaves the dryer via the exhaust air duct. The energy required to heat the air makes up a significant proportion of the overall costs involved in operating the machine. The hot air/steam ratio is therefore a contributory factor in determining the economic efficiency of the entire drying process and must be considered more closely as the energy costs rise. The quantity of water evaporated per unit of time varies continually depending on the fabric weight, infeed and residual moisture, width of fabric and speed. It is not possible to achieve the most efficient use of hot air by constantly adjusting the exhaust air damper. Instead, the moisture content of the exhaust air must be constantly measured and the air dampers and extractor fans must be adjusted in line with the drying conditions or be automatically regulated.

Fig. 1 shows the extent to which the costs of heating a dryer are dependent on the required volume of fresh air and consequently on the steam content in the exhaust air. Whereas the evaporative capacity (A) is relatively flat, the cost index (B) rises steeply, especially where the exhaust air damper is wide open, i.e. the steam content is low. It is therefore recommendable to adjust the exhaust air damper so that there is maximum possible moisture in the exhaust air without the output being noticeably reduced. Exhaust air dampers and fans are controlled via servometers by the electronic control unit. If there are several exhaust air ducts, the various throttle valves can be tracked individually via the servo governor of a co-ordination centre. This makes it simple to take into account the different evaporative capacities within the individual drying chambers.

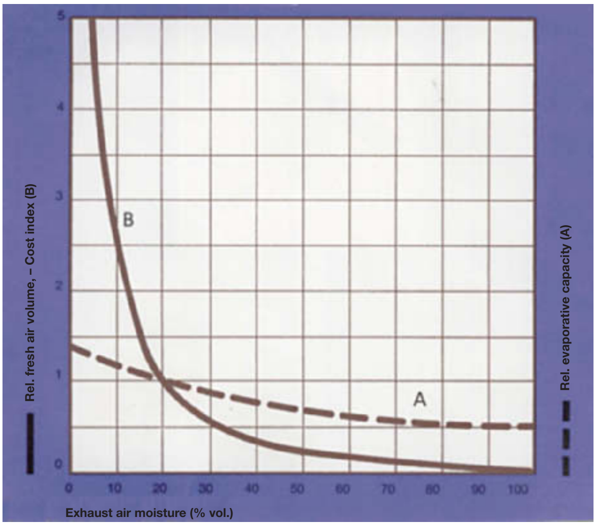

Fig. 1: Evaporative capacity and cost index during the operation of a stenter frame with different exhaust air moisture (Mahlo).

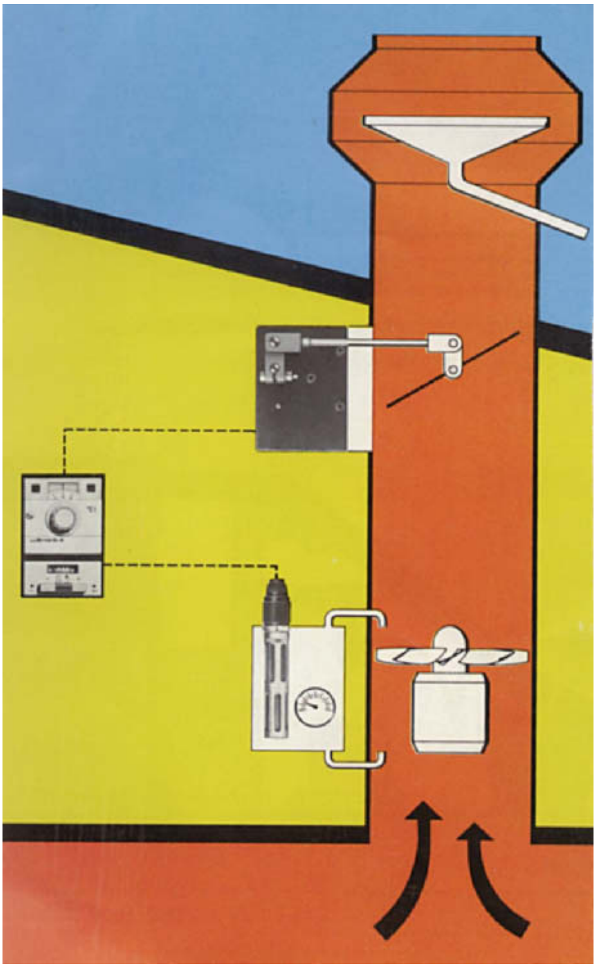

Fig. 2: Measuring the exhaust air moisture using sound in the Mahlo fluidic oscillator.

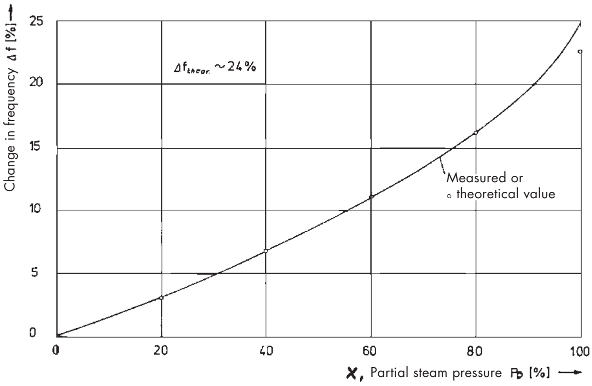

Fig. 3: Change in frequency (in %) of a fluidic oscillator in relation to the exhaust air moisture.

The measurement of exhaust air moisture is based on e.g. the different spread speeds of sound in air and water vapour (Fig. 2). A sound is produced in a source of sound (fluidic oscillator) which is directly exposed to the exhaust air stream. The pitch of this tone is dependent on the ratio of water vapour/air (Fig. 3). The frequency of the sound can be measured extremely precisely using heat-insensitive means. The influence of temperature on the pitch of the sound is compensated electronically.

The exhaust air moisture measuring systems consist of the measuring head with suction pump, oscillator, temperature compensation, sound pick-up and evaluation electronics with a display and operating elements. The measuring head can be introduced into the air evacuation duct or directly into the drying chamber as preferred (Fig. 4). An easily replaceable microfilter prevents the oscillator being contaminated.

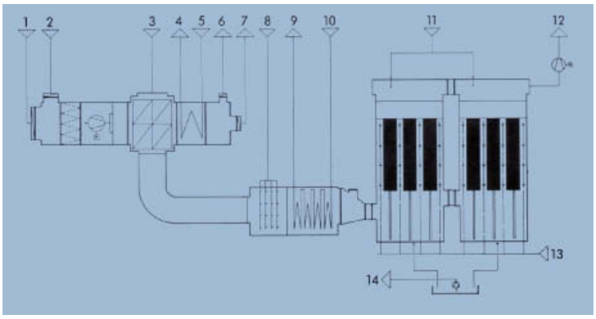

Fig. 3: Filter plant.
1 = external air; 2 + 7 = room air; 3 = crude gas; 4 + 9 = hot water; 5 + 10 = water at 20°C; 6 = exhaust air; 8 = saturated steam for cleaning; 11 = water just for initial filling; 12 = clean gas; 13 = steam; 14 = softener.

Exhaust air disposal Various processes are available for the disposal of exhaust air arising in textile finishing plants depending on the nature of the particular pollutants present:

I. Thermal combustion plants (Figs. 1 + 2) are recommended for the disposal of solvents and softeners. The solvents/softeners contained in the exhaust air are fed into a burner or combustion chamber where the exhaust air is mixed with additional fuel in order to reach the required reaction temperature of approx. 800°C for efficient combustion. Gas or heating oil can be used as the supplementary fuel.

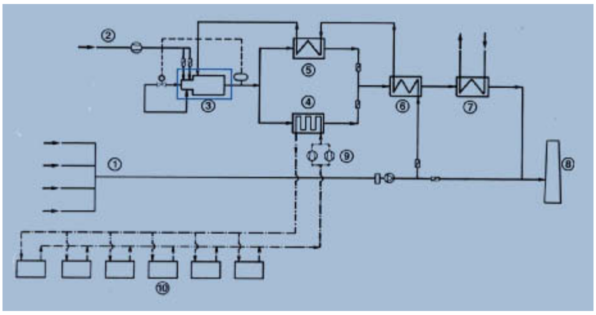

Fig. 1: Thermal exhaust air cleaning plant.
1 = exhaust air entry; 2 = supplementary fuel; 3 = two-stage burner; 4 = heating oil heat exchanger; 5, 6 + 7 = heat exchangers; 8 = chimney; 9 = thermal oil circulation; 10 = consumer.

The energy produced can be used for:

- heating thermal oil systems via a heat deflection chamber,
- preheating of incoming exhaust air via a heat exchanger,
- hot water heating systems.

Filtration plants are particularly suitable for exhaust air containing soft water vapours with aggressive pollutants (Fig. 3). The exhaust gases are cooled down to a temperature of approx. 40°C in a heat exchanger combination. The vapours are extracted through filter candles on the suction side of a high capacity medium-pressure fan which is designed as a diffusion separator. In this way, the softener aerosols which are separated off on layers of fibreglass within the filter candles agglomerate, and are drawn off as softener condensate from below. Energy liberated during the cooling process can be used for space heating or to produce hot water.

II. Adsorption and condensation plants: used in the solvent processing sector and manufactured to individual specifications.

Exhaust air, driers Drying processes produce water vapour as exhaust air (air saturated with water). This may contain pollutants. Before we consider exhaust methods for cleaning, the options to reduce emissions by using chemicals and processes which are low in emissions should be fully exploited. There is a wide range of physical, chemical and thermal methods available to clean exhaust air (→ Exhaust air, cleaning of). It has only been possible to establish a few options within the European textile finishing sector (see Tab.):

- Adsorbing substances (e.g. activated carbon),
- Exhaust air washers,
- Combustion of the exhaust air.

Process	Examples for application
Absorption	Washing columns
Adsorption	Activated carbon filter
Combustion	Introduce exhaust air into the boiler as combustion air
Condensation	Condense off exhaust vapours using condensers
Filtration	Fibrous matting
Biofilter	Conduct through special earths

Tab.: Basic options to reduce emissions in exhaust air.

The simplest and most cost-effective way to ensure low emissions from chemicals and processes is to prevent emissions occurring by selecting appropriate chemicals and processes. This avoids making repeated expensive investments and maintains operative flexibility. Unfortunately at present there are still no recognised methods and assessment criteria for testing and comparing chemicals and processes used in finishing. It is the task of the Chemical Industry and the Textile Processing Industry, the associations and authorities to complete the safety data sheets with meaningful information concerning the behaviour of exhaust air. One option is the thermogravimetric analysis (TGA) of products. With this method, a sample of the substance is exposed to a defined air stream at a prescribed temperature and the reduction in weight is recorded and assessed in relation to time. The figure shows the evaporation and sublimation losses of two fabric softeners. Substance B displays a considerably higher volatility than substance A. It is therefore to be expected that substance A results in lower exhaust air pollution.

The use of activated carbon adsorbing substances is state-of-the-art with processes using organic solvents. A whole range of plants are available in dry-cleaning and textile finishing works. If exhaust air merely contains water and solvent vapours, then adsorption and subsequent thermal desorption is in principle unproblematic. Unfortunately, exhaust air from drying machines and stenters contains emitters (e.g. lints, softeners, resin components and their cleavage/reaction products) which form greasy deposits on the activated carbon and therefore reduce the adsorption capacity. In addition to the considerable reduction in serviceable life, regeneration becomes a problem.

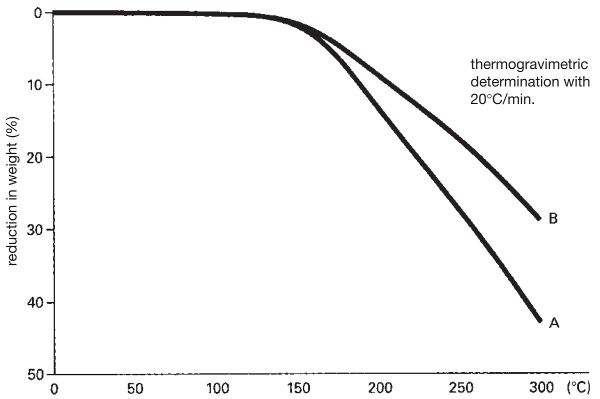

Fig.: Evaporation/sublimation of chemicals (source: Ciba-Geigy).

Exhaust air washers consist of a container in which the aqueous washing liquor (e.g. water possibly with acids, leaching solution, oxidation agents etc.) is sprayed from top to bottom. Waste air is exhausted counter to the current. Exhaust air emitters which are easily water soluble, or substances which react with the chemicals in the washing liquor are eliminated from the exhaust air. The evaporation of the water causes the air flow to cool and water-insoluble vaporous compounds are condensed out depending on the boiling point or the vapour pressure. A wide range of organic compounds remain in the exhaust air, with the remainder passing into the atmosphere as aerosol. The waste air from resin finishing processes only retains 40–60% of the carbon pollutant after being treated in the exhaust air washer. It is not possible to eliminate the remaining exhaust air pollutant using washers.

In recent years, the incineration of exhaust air as air for combustion in the boiler room has become established as an alternative. A number of textile companies have such plants. Several important prerequisites are necessary to ensure safe and economic operation:

- The resultant exhaust air should not exceed the amount of air required for combustion.
- It must be ensured that the occurrence of exhaust air coincides simultaneously with the operation of the boiler or burner.
- The introduction of the exhaust air into the boiler room represents the largest proportion of investment costs. Large distances result in disproportionately high costs.

In many cases, the amount of exhaust air is too large for the boiler room or the gas or oil fired stenters run even when the boiler room is not in operation. Under these circumstances, it can be useful to operate a spec. burner with a large air surplus as an exhaust air combustion plant. Using an economiser and warm water generation, the energy requirement for the combustion of exhaust air can be kept to a minimum. This solution would only be economically viable if there was a need for the warm water produced.

Exhaust air filter In the case of air-conditioned textile finishing departments, both the circulating air as well as the exhaust air must be filtered. Because of the high throughput volumes, large rotating drum filters are used for this purpose (see Fig.).

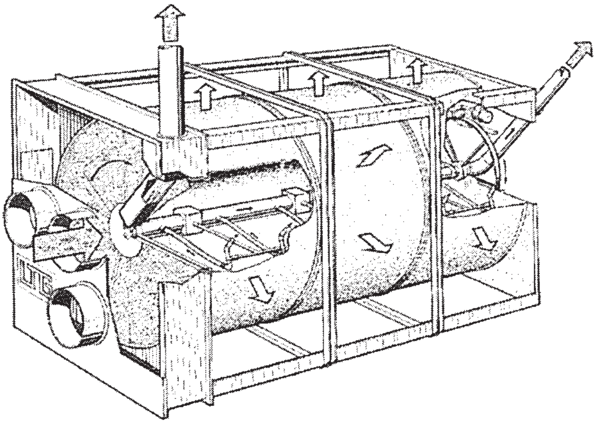

Fig.: LTG exhaust air filter with long nonwovens drum.

Exhaust air heat recovery Exhaust air from stenters, condensation equipment etc, contains a high quantity of energy in the form of heat in addition to moisture and impurities. Relative to m^3/hr of air throughput, there is, with an assumed exhaust air temperature of 80°C and 10°C outside air temperature (yearly average), a Q/m^3 air content energy loss of: Q = 1 m^3/hr, 80–10°C; 1.256 kJ/m^3 x °C = 87.9228 kJ/hr. At 3000 operating hours/year, this is equivalent to a figure of 263 768.4 kJ. Approx. 9 kg of fuel oil was required for producing this energy. A range of manufacturers offers tried and tested equipment for recovering heat from dryer exhaust air, based on the most usual air exchange. Secondary measures, which postulate the first stage of exhaust air optimisation as an effective primary measure, are involved. Heat recovery efficiency may not apparently be improved by processing with an increased exhaust air quantity, i.e. with a smaller vapour content in the exhaust air.

Heat recovery from effluent is feasible only if the temperature gradient between hot effluent and cold fresh water is big enough, and extensive quantities of fresh water and effluent can be exchanged (e.g. 6000 l/hr at any one time). The temperature of finishing effluent in wool textile finishing, especially from scouring, is only about 30°C, for which reason heat recovery in this wet finishing sector alone is not feasible. Recovery is offered in the case of exhaust air with a high energy content (on stenters).

From the processing technique standpoint, a distinction is drawn between regenerative and recuperative processes. The nozzle mixing plate heat exchanger is typical of recuperative processes. Recuperative processes are classified as follows:

- heat pumps,
- plate exchangers,
- circulation-linked ribbed pipe systems,
- tubular exchangers.

If one wishes to use the exhaust air from dryers in order to preheat fresh air in suitable heat exchangers, a number of basic prerequisites must be met: a) the energy-containing exhaust air must be available in ducted form and b) the energy content of the exhaust air must meet the specific requirements for energy recovery in both quantitative and qualitative terms in that the temperature and the quantity of air removed per hour are high enough to obtain economic recovery.

Quite the most important requirement is that energy recovery is possible only when energy is actually required at the same time and in a convenient location, to which the energy contained in the exhaust air can be returned (in fact in the linked system for example). For a stenter heat exchanger this means in concrete terms: the heat is taken from the contaminated exhaust air in order to preheat the fresh air without the two airstreams coming into contact with each other. The reheating required needs much less energy than the full heating required without energy recovery. The biggest problem is keeping clean the exhaust-side surfaces of the heat exchangers, as the exhaust air from stenters, used for example for drying wool fabrics, contains a great deal of fly and wool grease. A distinction is drawn between integrated heat exchangers per chamber of a single-pass stenter, which are easily cleaned by changing drawers, and external heat exchangers on multi-pass stenters.

Heat can be recovered via:

1. Direct air to air heat exchange (Fig. 1):

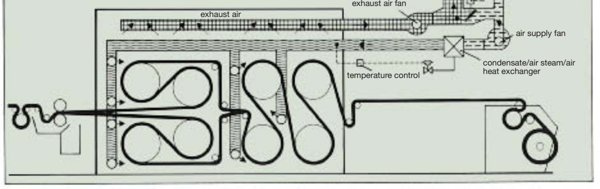

Fig. 1: Sizing machine with Wiessner heat recovery equipment (air to air).

2: Indirect air to air heat exchange via a heat transfer medium (Fig. 2):

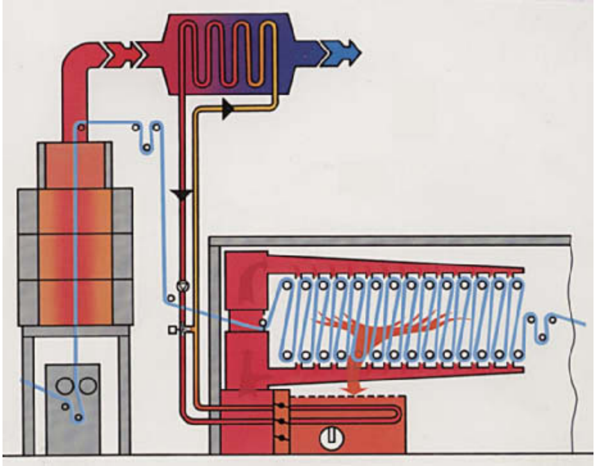

Fig. 2: Infra-red tower waste heat utilisation for heating a Hotflue in a continuous dyeing machine (Monforts).

3. Direct air to water heat exchange (Fig. 3):

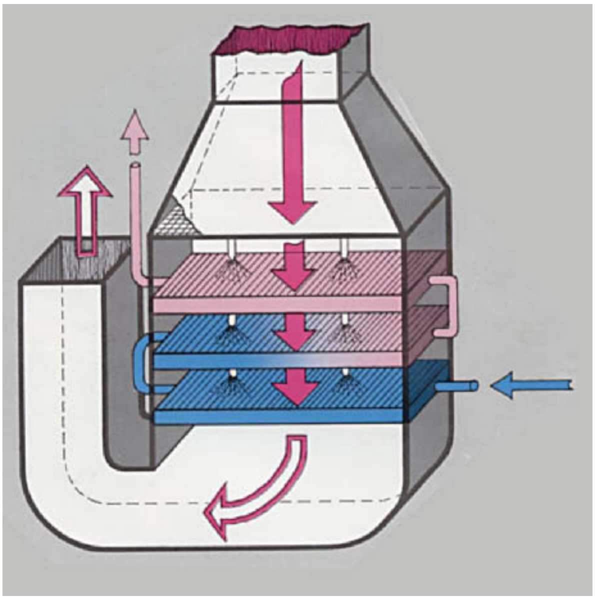

Fig. 3: Heating cold water with hot exhaust air for producing hot water (Krantz).

4. Combined air to air and air to water heat exchange (Fig. 4):

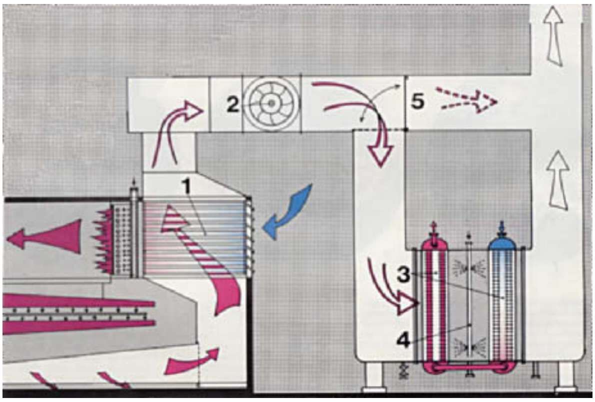

Fig. 4: Preheating stenter fresh air in a glass tube heat exchanger and producing hot water with hot air (Krantz). 1 = heat recovery; 2 = exhaust air fan, 3 = gilled pipe heat exchanger; 4 = cleaning jets; 5 = bypass flap.

Exhaust air moisture measuring systems These systems are used to measure the moisture of exhaust air in the exhaust air duct (driers) and to adjust the exhaust air dampers and fans accordingly using servomotors. This helps to prevent heat losses due to the exhaust air being too dry. Pleva FM 32 (developed by Pleva and Babcock) is almost maintenance-free and may even be used where the exhaust air is polluted. Principle: A small partial gas stream is passed through the measuring device. The actual measuring cell consists of a bare, straight stainless steel pipe in which gas is cooled below the dew point. The input and output temperature of the gas and the heat being discharged on the stainless steel pipe are measured. The gas moisture is then calculated in the computer. Measuring range: Moisture of 20–500 g/kg or from 10–250 g/m^3, at overpressures of 100–1000 Pa (0.001–0.01 bar) and temperatures between 70–250°C. The FM 915 (Pleva) operates with a lithium chloride measuring chamber.

The Mahlo AML operates on the principle of varying spread speeds of sound in air and water vapour: a sound is produced by a source of sound directly exposed to the exhaust air stream. The pitch of this sound is dependent on the ratio of air/water vapour. The frequency of the sound can be measured precisely using heat-insensitive means. The direct temperature influence is compensated electronically (→ Fluidic oscillator). Measuring range is normal up to 30% volume water vapour, and can be extended to 100% volume.

Exhaust air pollution measurement To record the emission in mass per unit of time, it is necessary to determine the concentration of the pollutant emissions in the exhaust gas and the volume flow. The following measuring systems are used exclusively to determine concentration. They are suggestions of how to record substances containing hydrocarbons and substances with intense odours.

I. Gas analysis using gas chromatography: With this method, selective adsorption is used in a column filled with an adsorbent. A small quantity of carrier gas (air, $H_2N_2CO_2$ or noble gas) is added to the vapour or gas mixture and compressed by an effective separating material (e.g. charcoal in the separation column). Pressure, time and volume remain constant. The components come together at different times and therefore reach the end of the tube separately. They can be recorded and measured or registered consecutively. The comparison of thermal conductivity between the carrier gas and the carrier gas measuring components provides a measuring voltage proportional to the gas concentration in question, which then converts an electrical potentiometric recorder into a “gas-phase chromotograph”. This method represents a quantitative analysis of gas mixtures, for the purpose of flue gas analysis, from hydrocarbon mixes and inorganic substances. A major disadvantage of this method is that continuous measurement is not possible. The equipment is both expensive to buy and to maintain. The detection limits are approx. 1–10 g/m^3 for organic carbon.

II. Olfactometer: Odour-intensive air pollutants can be recorded above the olfactory threshold value of the human nose. If the olfactory threshold of the nose is exceeded by a specific concentration, a sensation is triggered which can be divided into 3 dimensional categories:

a) The olfactory sensation can denote a specific quality. This represents the type of odour, e.g. bad eggs, released by H_2S, or fruity, released by specific esters etc.
b) The nose is capable of perceiving the specific intensity of the odour. There are several methods of scaling, the most common being the so-called category scaling.
c) The hedonistic effect of odorous substances describes the degree of acceptance between what is considered unpleasant and pleasant. It is recommended that a 9-level category scale is used to determine the hedonistic effect.

An olfactometer is a device used to dilute air samples. It can be used to dilute the odour samples to a specific concentration. Testers (known as jurors) compare the concentrations of the odour with pure air. The test is positive if the odour is detected, and negative if it is no longer possible to detect an odour. To determine the intensity of an odour, the perception is categorised into various response categories:

0 = no smell,
1 = very weak,
2 = weak,
3 = clear,
4 = strong,
5 = very strong.

The evaluation of the intensity measurements can give the olfactory threshold level. The measuring results of the various jurors are evaluated statistically; a Gaussian distribution curve is drawn up and the average value is calculated. To determine the olfactory threshold or the concentration of the odour, the unit GE/m^3 has been input with the olfactometer. With this method, continuous measurement is not possible.

III. Radiation absorption (infrared gas analyser): Gases made up of different types of atoms absorb certain areas of the spectrum from transmitted light in the ultrared and infrared areas (thermal radiation), giving rise to either spectral or absorption lines. The energy absorbed during this process causes an increase in pressure and temperature which is measured and recorded using resistance thermometers. This method also has the disadvantage that continuous measurement is not possible.

IV. Flame ionization detector (FID): This uses the ionisation of organically bound carbon atoms in a hydrogen flame as a reading. The ion current arising as a result in an electric field is strengthened and displayed electrically. The intensity of the ion current is dependent on the number of organic carbon atoms in the exhaust gas being analysed, both in terms of the form of bonding and the bonding partners and on the type of equipment and its use. The switching principle of a FID shows clearly that an electric field is connected across a pure hydrogen flame which burns when it comes into contact with air free from hydrocarbons. As soon as a measuring gas with organic bonds is introduced to this flame, a measurable ion current arises. The measuring signal is proportional to the number of hydrocarbons added which are not oxidised. In order to be able to determine the concentration of the gas to be measured, the measuring range of the device must be calibrated. In order to achieve this, a zero gas (e.g. pure N_2), which has a zero concentration of hydrocarbon atoms and corresponds to the neutral point electronically, is added to the measuring gas stream. The device is consequently set at zero. Secondly, a specific concentration of organic compounds is introduced into the device via the measuring gas stream. This is either a test gas or a calibration gas, which may be propane in synthetic air. As the proportion of carbon is known, it is possible to adjust the sensitivity of the device to the electrical value. After calibration has taken place, measuring can begin on the gas to be tested. The gas analyser requires 0.5 h before it is ready for use. A constant heating temperature is reached after this time which prevents any incorrect measuring results occurring. The sample gas pipe should also reach a temperature of up to 200°C. At this temperature, it is impossible for the exhaust gas to condense in the pipe. The sample gas pipe should also not be too long as this could cause a perceptible time delay in the measuring result. To guarantee the measurements, it is recommended that the pipes are rinsed with hydrocarbon-free gases every hour and that recalibration is carried out. The use of measuring devices with FIDs is suitable to measure the total of hydrocarbons present in the exhaust gases. Continuous measurement is possible using this method.

V. Qualitative and quantitative data (taking the recovery rate into account) is achieved by the combination of gas chromatography with mass spectrometry (GCMS) if the constituents of the exhaust air can be assigned using a computer library.

VI. Dioxin analyses are very expensive and can only be carried out by special institutes.

Exhaust air problems in textile finishing The discharge of airborne foreign matter into the atmosphere is referred to as emission, whilst the distribution, transport, and dilution of pollutants concentrated over the earth's surface is understood as immission. The pollutant concentration in a specific volume of exhaust air or exhaust gas can be measured. It is determined either as the mass concentration in mg/m^3 (generally based on standard volume, 0°C and 1013 mbar) or as the volume concentration in cm^3/m^3 = ppm (parts per million). Also expressed in emissions as the pollutant mass flow rate in kg/h.

In order to protect humans, animals, plants and material goods from harmful environmental effects, the Federal Immission Protection Law (BImSchG) came into force in Germany in 1974. The general administrative regulation contains the "Technical Instruction on Clean Air" (TA-Luft). This describes the state-of-the-art for reduction of emissions from specific types of industrial plant; dusts and gaseous pollutants are subdivided into three classes depending on the degree of environmental risk, and class-dependent maximum permissible exhaust air concentrations, so-called emission limits, have been laid down. In addition, limit concentrations for the most important air-polluting substances such as, e.g. chlorine and fluorine compounds have also been specified. The draft agreement of the German parliament of 21 February 1986 on revised limits for pollutants lays down the following emission limits for compounds in vapour or gaseous form:

1. Organic substances must not exceed the following mass concentrations even when several substances of the same class are present:

- in Class I: 20 mg/m3 at a mass flow rate of 0,1 kg/h or above;
- in Class II: 100 mg/m3 at a mass flow rate of 0,3 kg/h or above;
- in Class III: 150 mg/m3 at a mass flow rate of 3 kg/h or above.

2. Specific limit concentrations for enclosed working areas have also been drawn up. The so-called MAK limit (maximum workplace concentration) is defined as the maximum workplace concentration limit of an immission measured at breathing height.

3. The MIK limit (maximum immission concentration) of air-polluting substances is defined in VDI Guideline 2306 as "those concentrations present in layers of the free atmosphere near to the ground or, in the case of dusts, those quantities precipitated on to open ground which can, in general, and in the present state of knowledge, be regarded as harmless to humans, animals and plants after exposure for a specific period of time and frequency." (MIKD limits for continuous exposure, and MIK limits for short-term exposure).

4. Dust is understood to be the sum of all solid particulate matter in the air which is apparently held in suspension due to its high resistance. This phenomenon is based on the premise that the settling rate of particles is of the same order as the ascending thermal force or other air movement. Dusts are subdivided into 3 groups depending on their particle size:

- aerosols (<0,001 mm),
- fine dust (0,001–0,02 mm),
- coarse dust (0,01–0,2 mm).

5. The most important chemical pollutants in air are:

a) carbon monoxide,
b) nitrogen oxides,
c) sulphur compounds.
d) ozone,
e) halogen compounds: especially chlorine, bromine and fluorine compounds,
f) volatile hydrocarbons (aliphatic and aromatic) and their oxidation products (e.g. aldehydes and ketones),
g) products of incomplete combustion containing polycyclic aromatic hydrocarbons (e.g. 3,4-benzopyrene),
h) substances with foul-smelling and aggravating odours.

The polluting constituents of exhaust air from stenters in textile finishing plants include a wide range of different chemicals such as, e.g.:

- aldehydes as crack products of coning and spinning oils,
- formaldehyde from resin finishes,
- organic acids from reactive prints,
- solvents,
- carriers.

Textile fabrics can also be a source of air pollution problems (e.g. in the finished goods store of a textile finishing plant or at the consumer). The action of NO_x gases on the yellowing of white goods due to reaction with fluorescent brightening agents can also be regarded as an air pollution problem. Even the destruction of dyes on the fibre due to NO_x gases has also been observed.

Exhaust air segregation in stenters If the temperature of textile fabric being dried in a horizontal stenter is measured (see Fig.), cool zone temperatures (approx. 50–60°C) are encountered in the first sections

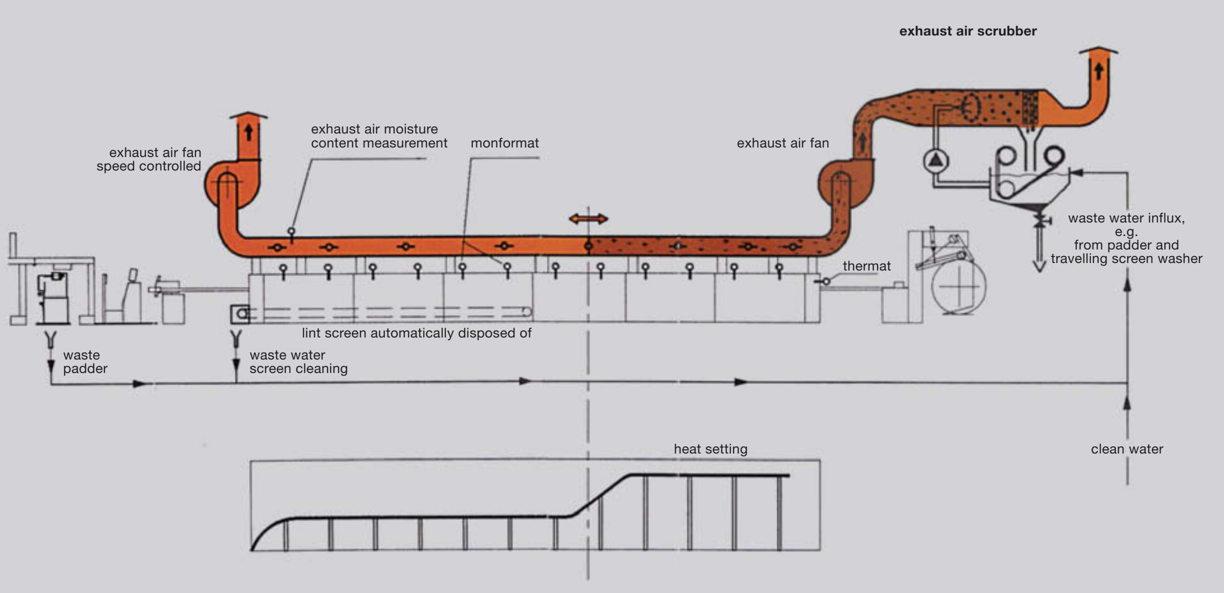

Fig.: Control of exhaust air pollution in the front and rear sections of a horizontal stenter with the Monforts Monformatic process control (cooling limit temperature measurement).

of the drier. At these temperatures, the water which evaporates from the fabric is not accompanied by large quantities of potential exhaust air pollutants which could be carried over by steam distillation or evaporation. This part of the exhaust air stream therefore only has a low level of pollution and can probably be discharged without cleaning. By contrast, the exhaust air stream from the last sections of the stenter, where the fabric temperature reaches that of the circulating air, is more highly polluted and must be cleaned before discharge.

Exhaust curves for dyes (Affinity curves, migration curves). These make it possible to take a direct reading of the quantity of dyestuff which has been absorbed by the fibre in a given dyeing time and temperature. In reactive dyeing, a distinction is to be made between the exhaust curve and the fixing curve. If the latter is subtracted from the former, the portion of non-fixed dyestuff is obtained (Fig. 1).

There are many values which can influence a dyeing process. The most significant are: temperature, pH, dyestuff concentration, liquor circulation, liquor ratio, auxiliaries, quality of the substrate etc. If a dyeing process is observed under these conditions, this can be depicted as a line (integral curve) in a three-dimensional space with the dimensions, time, temperature and absorption level (dyestuff concentration). The projection of this integral curve on the temperature/time (T/t) plane then gives the temperature programme of the dyeing process. The projection on the A/t plane (A = absorption level) is a common exhaust curve (Fig. 2).

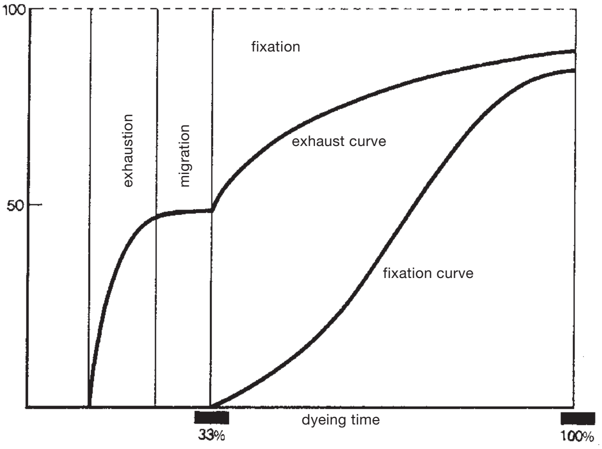

Fig. 1: Substantive adsorption and fixation of a reactive dye as a % of dye supplied.

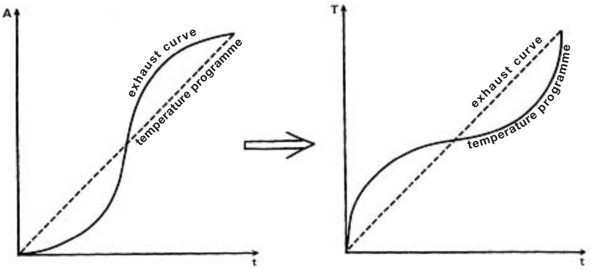

Fig. 2: Determining the temperature programme for linear exhaustion.

The temperature programme for a dyeing process with linear exhaust curve can be ascertained using rule of thumb, with the exhaust curve of a corresponding dye with a linear heating programme being reflected in this

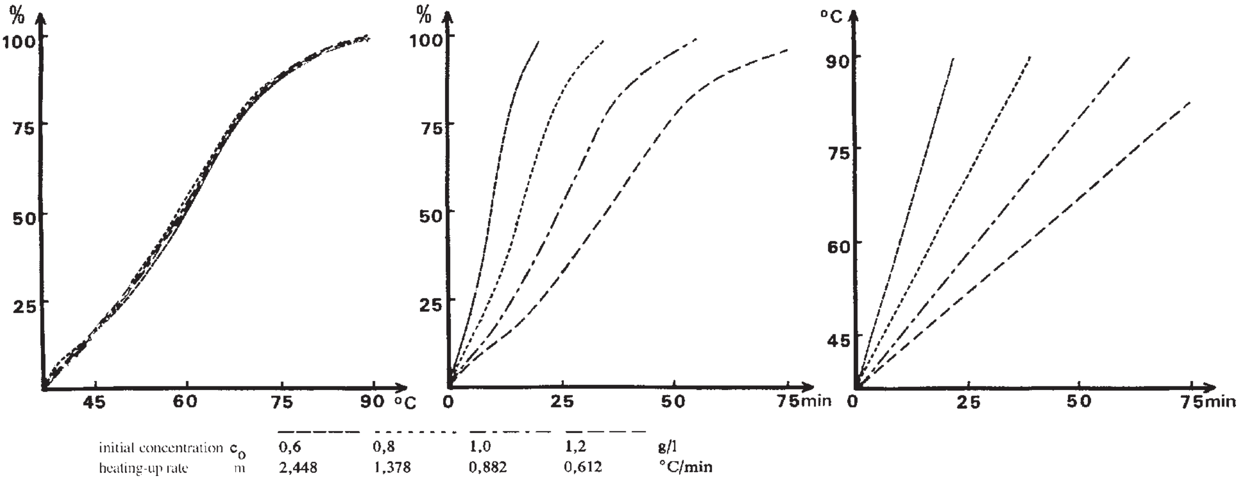

Fig. 3: Dyeing C.I. Acid Yellow 110 on Helanca polyamide 6.6 trico.
pH 5.5; auxiliary agent: 0.5 % Tinovetin JU (Ciba Geigy); liquor ratio 25 : 1.

(45° straight line). If this rule of thumb applies, then it follows that the projections on the A/T level of the integral curves of a linear heated and a corresponding linear absorbing dyeing process are the same.

Figure 3 shows the projection on the 3 co-ordinate planes of 4 different experimental dyes with linear temperature programme. It is obvious from the projection on the A/T plane that these 4 dyes have something in common other than a linear heating programme. This is not obvious from the exhaust curves and temperature programmes. The following relationship applies to the 4 dyes:

$$c_0 \sqrt{m} = 0{,}939 \text{ g/l} \cdot \frac{^\circ\text{C/min}}{2}$$

c_0 = initial concentration,
m = gradient of the temperature programme.

The initial temperature c_0 and the liquor ratio of all dyes is also the same. If the square root – time law (a law for isothermal dyeing) is fulfilled to a certain extent at every point in time and for each temperature reached, then it follows that the projections of the integral curves for these 4 dyes must be the same on the A/T plane.

Exhaust dyeing (diffusion) model The kinetics of dyestuff absorption (with no chemical reaction) by the fibre from the dyebath are described as exhaustion. After equilibrium has been reached, there is no further bath exhaustion, and the exhaustion process is terminated. The following approximate processes take place in exhaustion:

1. The dyestuff undergoes a phase change from the dye liquor in which it is dissolved by adsorption to the fibre surface, equilibrium occurring between the solid and liquid phases. The process is rapid.

2. This is followed by slow diffusion into the interior of the fibre, which is represented as a diverse consequence of desorption, diffusion and adsorption processes. Bath exhaustion is the relationship between the exhausted dyestuff quantity and the available dyestuff quantity as a function of time (t):

$$BE(t) = MF(t) / A$$

Under constant dyeing conditions, exhaustion curves show that the rate of exhaustion is initially high, but soon falls sharply. In the initial phase, BE ≅ Vt (Vt law), which approximates to Fick's diffusion with constant coefficient of diffusion D. The solution to this diffusion equation depends on the type of adsorption equilibrium: the Vt law applies both with constant surface concentration C_{ob} = saturation value S as also with Nernst distribution $C_{ob}(t) = k \times C_L(t)$ (k = constant partition coefficient; $C_L(t)$ = dyestuff concentration in the dye liquor), while an exponential law applies in the final stage of exhaustion. Complicated interrelationships apply for the radial concentration distribution of the dyestuff in the fibre, i.e. for the dye penetration time. The rate of diffusion is oriented to the dyeing temperature and the liquor/fibre concentration gradient, and therefore changes continuously during the exhaustion process in practical dyeing conditions. Diffusion models therefore describe only theoretical types of conditions.

Exhaust dyeing processes (→ Exhaustion processes).

1. Discontinuous, i.e. long reaction time: the necessary time must be allowed for dyes to exhaust from a dyebath on to a textile substrate (see Fig.)

2. Higher liquor ratios are used compared to continuous dyeing.

3. Dye concentration in the dyebath is considerably lower than in continuous dyeing.

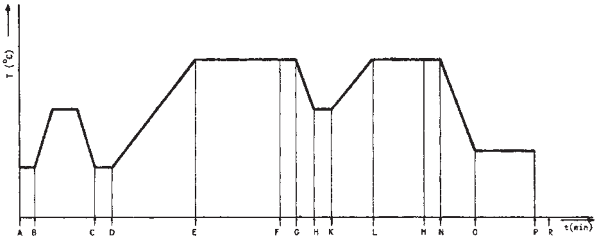

Fig.: Diagram of an exhaust dyeing process.
A = loading and filling; B = pretreating; C = dye; D = heating; E = maintaining temperature; F = sampling; G = cooling; H = adding; K = heating; L = maintaining temperature; M = sampling; N = cooling; O = after-treating; P = unloading; R = end.

Continuous exhaust dyeing is understood to take place when a textile material is run through a dyebath, and the amount of dye continuously added to the bath corresponds to the amount of dye which exhausts on to the substrate in the same time period. The term "exhaustion principle" refers to a process in which a dye previously dissolved or dispersed in a dye liquor exhausts on to a textile substrate. The process involves bringing a dye into contact with a textile substrate, its adsorption on the fibre surface, diffusion into the fibre and, finally, the physical or chemical bonding of dye to the fibre. In simplified form, this can be written as:

Textile substrate (undyed) + Dye ↔ Textile substrate (dyed).

Both the state of equilibrium itself as well as the rate of dyeing at which it is established are (together with the substrate and the dye) dependent on the following factors in the dyeing system,

- the temperature,
- the pH,
- the type of dyeing auxiliaries and their concentration, and dyeing can therefore be controlled with the aid of these parameters.

Development trends: more knowledge gained from measurements made in package dyeing should result in optimum sizes and forms of package; standardization of sizes and package density could lead to further rationalization in package dyeing. Control of dyeing processes by means of colorimetric measuring systems are already being applied to some extent. The development of new control possibilities utilizing → Exhaustion curve is proceeding apace. The standardization of programming systems for dyeing machine automation is recommended. Rapid dyeing and short-liquor dyeing technology now appears to have caught up with the advantages formerly associated with solvent dyeing. New systems must now be developed especially since dyeing from organic solvents can no longer be justified on ecological grounds. Foam and spray dyeing techniques are currently under development and, although these processes offer little chance for package dyeing, they offer greater potential in the piece dyeing sector. A certain development trend towards continuous exhaust dyeing is still at an early stage.

Exhaust gases (waste gases). Combustion gases from (coal, wood, oil, gas) fired systems, heating systems (flue gases) and internal combustion engines (engine and automobile exhaust fumes). In addition to oxides of carbon they also contain *inter alia* → Nitrogen oxide gases, traces of which can affect the → Colour fastness to burnt gas fumes of textiles dyed or printed with certain → Disperse dyes.

Exhaustion → Bath exhaustion.

Exhaustion constant SR The establishment of equilibrium is continually changed by reactive binding of dyestuff on the fibre under dyeing conditions (in the alkali area of → Exhaust dyeing processes). The exhaustion constant SR should be the ratio of fixed and adsorbed dyestuff and residual liquor in the bath:

$$SR = \frac{C_{\text{fixed}} + C_{\text{adsorbed}}}{C_{\text{residual liquor}}}$$

or

$$SR = \frac{\text{dyestuff exhausted}_{\text{(fixed + adsorbed)}}\ (\%)}{\text{residual dyestuff in the bath}\ (\%)} \cdot \text{reciprocal liquor ratio}$$

Exhaustion curve A graphical representation of the progressive exhaustion of a dyebath (bath exhaustion). It corresponds to the quantity of dye taken up by the fibre.

The distribution of dye between a textile substrate and a dyebath during the dyeing process is best illustrated by means of exhaustion curves. For practical purposes, bath exhaustion is represented as a function of time against linear increase in dyeing temperature. By comparing a number of exhaustion curves with different temperature gradients, it can be seen to what extent t the time necessary for bath exhaustion changes in relation to the temperature gradient selected (Fig.1).

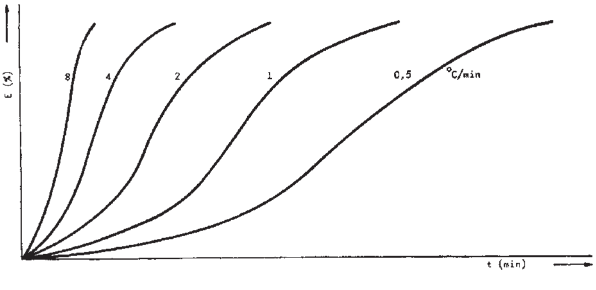

Fig. 1: Exhaustion curves at various heating rates; E = bath exhaustion.

If considerations of dye levelling were to be excluded, the conclusion that a maximum temperature gradient should be aimed at in order to shorten the process time must be reached. However, if a dyeing is to be commercially acceptable, it must possess a satisfactory degree of levelness appropriate to its end-use in addition to the desired shade and brightness which are dependent on uptake of the necessary quantities of dye. It is for this reason that there are clear limits to the max. temperature gradient which can be used in practice.

A significant rate of dyeing determined by a weighting of the exhaustion curves (integration) is responsible for dye levelling, and a critical rate of dyeing, at which the necessary degree of levelling is still assured, exists for each dyeing system (Fig. 2).

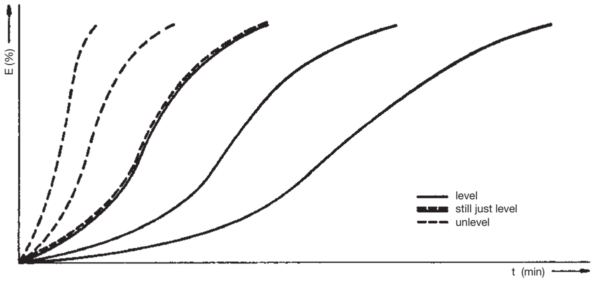

Fig. 2: Critical dyeing rate in exhaustion curves with a constant heating gradient; E = bath exhaustion.

The shortest time of dyeing can be achieved by linear dye exhaustion with the same critical rate of dyeing, although this would call for a complicated non-linear temperature progression (Fig. 3).

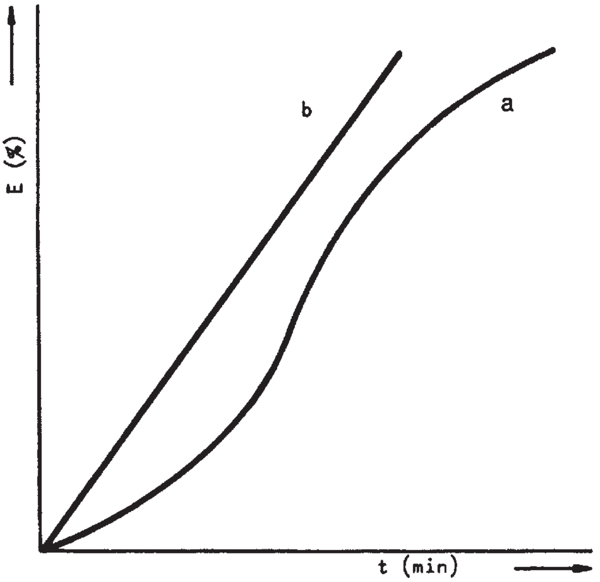

Fig. 3: Time required for heating phase at critical dyeing rate relative to the heating programme.
a = linear heating rate; b = linear dye exhaustion.

Although it has been known for a long time that the chances of obtaining a level dyeing rise with increasing liquor throughput, a connection with the dyeing machine only became possible after relating dye exhaustion to the number of liquor cycles according to the equation

$$F = \frac{100}{C \cdot D}$$

where F = minimum adsorption time,
C = liquor cycles per min,
D = relative percentual bath exhaustion per liquor cycle.

This equation does not, however, take into account the spatial characteristics of the textile material in the form of, e.g. yarn packages, as well as their likely consequences. The maximum allowed percentual bath exhaustion per liquor cycle, and therefore the shortest time of adsorption are dependent on

- the desired degree of levelling,
- the use of appropriate levelling agents,
- reversal of liquor flow,
- the homogeneity resp. non-homogeneity of the substrate being dyed.

In conclusion, it is conceivable for the heat up time to be reduced with the aid of frequent liquor reversal. On consideration of the fact that the heat up process must be able to accomodate the weakest areas of liquor penetration it is clear that, up to now, enough attention is still not being paid to the homogeneity of the textile substrate. In addition to the well-known problems caused by hard packages, variable winding densities within individual packages, non-uniform packing density of loose fibres etc., it needs to be emphasized that liquor circulation losses, in particular, can also arise e.g. as a result of incomplete sealing between yarn packages on dye columns, or incomplete coverage of dye beam perforations in beam dyeing.

Exhaustion processes (→ Exhaust dyeing methods). Processes which involve the desorption and absorption of dyes and textile auxiliaries from dyebaths due to → Substantivity (→ Affinity) for a textile substrate. The process lends itself to computer control (see Fig.). Opposite principle to → Pad process.

I. Fabric in rope form:

1. Principle: both liquor and fabric movement take place simultaneously: woven or knitted fabrics are sewn together lengthwise to form a single rope and stored randomly in the dyeing vessel in rope piece-dyeing machines (including HT versions); for small batch lots the fabric is sewn together to form an endless loop for continuous circulation with a dwell phase.

2. Continuous operation is also possible (e.g. afterwashing of prints).

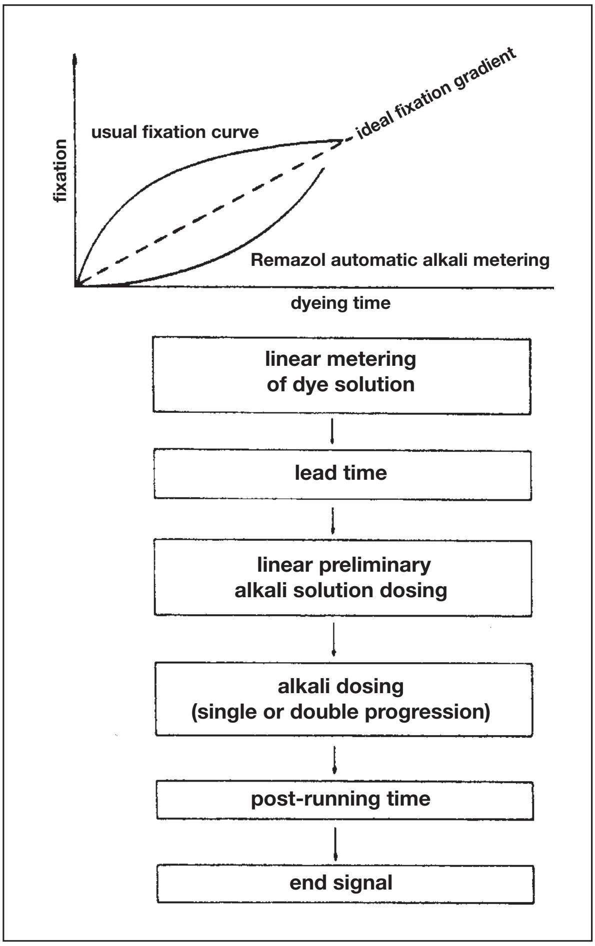

Fig.: Programming the entire exhaustion process with the Remazolautomat, ADC 200.

II. Fabric in open-width:

1. Principle: stationary fabric with liquor movement (circulating liquor): Woven or knitted fabrics are batched in a crease-free open-width state on a perforated beam for beam dyeing. Suitable for small batch lots.

2. Principle: stationary liquor with fabric movement. The fabric is batched in a crease-free open-width state and passes alternately from one batch roll to another through the dye liquor in a jigger. Suitable for small batch lots.

3. Principle: simultaneous movement of liquor and fabric: the fabric is treated in open-width and stored in widthwise folds. Suitable for small batch lots, sewn together to form an endless loop for continuous circulation with a dwell phase.

III. Textiles other than flat fabrics (loose stock, tops, yarn packages, warp beams).

IV. Made-up garment pieces (clothing, hosiery).

Exhaustion rate of dyes The time-dependent shift in the relationship between “dye in the bath” to “dye on the fibre” is dependent on the type of fibre, the condition of the fibre (pretreatment, fibre affinity towards the dye), dyeing method (liquor ratio, dyebath composition, dyeing temperature, pH), dye properties (solubility, fibre affinity, build-up properties, temperature-dependence, behaviour in combinations), and the dyeing equipment (temperature control, liquor circulation, packing of textile substrate in the case of loose fibre or yarn, movement of liquor and/or textile substrate). The exhaustion rate is also dependent on the → Levelling behaviour.

Exhaust rope piece dyeing machines The machine design trends for processing fabric in rope format focus on customising machine configuration to improve fabric appearance, reduce running costs and maximise productivity. Productivity gains are achieved by increasing machine loading and by reducing the production cycle times. These machine design trends can be summarised as follows:

- Classic woven and knitted cellulosic fabrics: low liquor ratio “Apple” configuration machines with hydraulic and/or mechanic fabric drive.
- Classic woven and knitted synthetic fabrics: “Banana” configuration machines operating at high running speeds, up to 600m/min, and in the range of 8–14:1 liquor ratio.
- Value added viscose, cupro rayon, polynosic, lyocell, polyester and polyamide microfibre and elastane containing fabrics: low liquor air configuration machines with special lifter reel and nozzle design employing hydraulic and/or pneumatic fabric drive.
- Tubular knitted cotton fabrics, perhaps containing 2–8% elastane: long liquor ratio wind-like atmospheric machines which are able to blow up the tubes thus preventing creases during mechanical drive (Krantz Blow Dye and Fong’s Dynawin).

In contrary to rope dyeing, open-width dyeing is performed on jigs or beam dyeing machines. The market trend towards short production runs has revitalised the long-established technology of → Jig dyeing for the coloration of woven fabrics. Developments in design that provide much improved wash-off performance and offer advanced levels of process control are offered. Beam dyeing, again a long-established technology is prominent. Focusing on the production of delicate and elastane containing fabrics, new designs that operate at lower liquor ratio are produced.

“Apple” Machine Configuration: The clear aim of all “Apple” machine designs is to offer the highest level of flexibility so that the widest possible range of fabrics can be processed. Common features of machine designs are nozzles to open and reconfigure the fabric rope to prevent running creases, plaiting mechanisms to prevent snagging and tangling of the rope and Teflon coated glide rods and chambers to assist the transportation of the fabric. The machine operates at low jet pressure to preserve the surface of the fabric and provide pristine fabric appearance, a key measure of fabric quality. Brazzoli and Thies offer programmable adjustment of nozzle dimensions to optimise the running properties of the fabric so that surface distortion is minimised for the full range of fabrics processed. The MCS Multiflow machine with its innovative design is unique. Its novel single rope, figure of eight, fabric transport system overcomes variations in liquor circulation that may exist in machines of generic design. By the increased number of liquor interchanges, the new liquor circulation system and the control of the liquor flow rate, it is now possible to process the entire production batch uniformly. Analogue level indicators with a memory function are an important development that allows control of fabric to liquor ratio throughout the process and will result in improved process reproducibility. Machines with the "Apple" configuration operate in the liquor ratio range of 4:1–8:1 for cellulose fabrics and 3:1–5:1 for synthetics and their blends. The design of the machines focus on a step change improvement in productivity. To achieve this step change, machine loading has been increased up to 250 kg/chamber, whilst process cycle times have been significantly reduced by the refinement of new application technology and modified operating procedures. Increased loading has been achieved by redesigning the geometry of the chamber and, in some cases, by running two ropes in each chamber. To optimise machine performance, allow a wide range of fabrics to be processed and allow smooth running of the fabric, Scholl and Thies have introduced machines with adjustable chamber size.

Progress has been made with "Smart Rinsing" technology. This option to continuously rinse with programmed volumes of hot water over a prescribed number of rope cycles and simultaneously raise temperature, inject chemical auxiliaries and cool is offered by Then. Thies offer the patented "CCR Superwash" system, Sclavos the "AquaChron" technology, Gaston County a revised "Low Wash" process and Scholl the "Pulsating Rinse". All these systems are controlled as pre-programmed functions in the machine microprocessor. These processes offer the potential to reduce the wash-off cycle time to 45–60 minutes; a saving of 60–120 minutes compared to conventional drain and fill techniques. There is scope for further productivity gains by the introduction of a simple colorimeter into the liquor circulation system. It would then be possible to wash-off to a defined endpoint and conserve water and time.

Salt injection systems have been introduced to further simplify operating procedures and reduce manual intervention. These systems can be integrated into the addition side tank (Sklavos, Thies) or can operate from a central dispensing system (ColorService, Lawer). Practical experience has shown that it is possible to make addition of chemical auxiliaries, dyes and chemicals in a very short time without disturbing level dyeing performance. The ability to add dyes in 1 minute and fixation alkali in 2–6 minutes provides new process design options and challenges the basic dyeing theory that led to the development of processes based on metered addition. Metering options for chemicals, chemical auxiliaries and dyes are standard on all machines. They offer linear, progressive and degressive addition profiles. Accuracy of dosing is enhanced when a reciprocating pump is used to continuously meter the liquor. These advances in the design of machines with "Apple" configuration complement BASF technology. The combination of BASF's drive for "Right-First-Time Through Control", the "eXceL – Controlled Coloration" concept (Fig.1) and leading edge dyestuff technology from the novel range of Procion XL+ dyes, fully exploits the best available machine designs and challenges traditional application methods. "Load to Unload" production cycle times can be slashed to ~ 180 minutes.

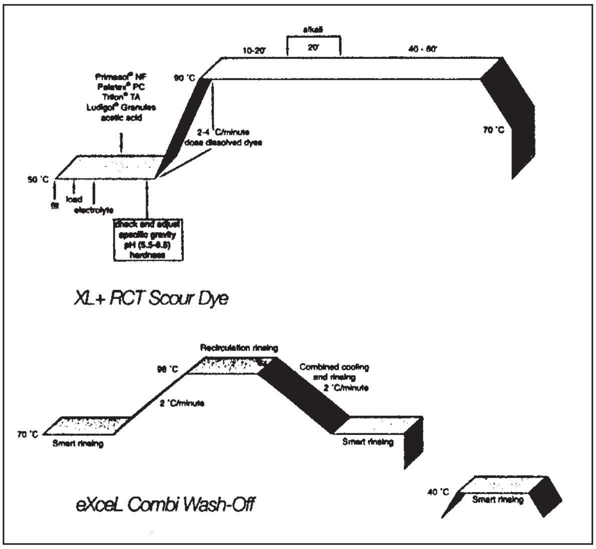

Fig. 1: XL+ RCT Scour Dye and eXceL Combi Wash-Off.

To this class of "Apple" type configuration belong also the "Aquadye" from Krantz, the corresponding Fong's machine and a Cabertex machine.

For classic fabric constructions Thies has introduced the compact eco-flow atmospheric dyeing machine with soft flow nozzle. A ballooning mechanism (air injection) provides crease free processing of tubular knitted fabrics. A feature exhibited on the eco-flow is the proVat plus system that has been jointly developed by BASF and Thies for the control of Indanthren dyeings. The system automatically monitors the redox potential of the rinsing bath. As the redox potential falls and reaches a predetermined level, rinsing is automatically stopped. This novel approach provides improved level dyeing performance, improved shade reproducibility and improved productivity. The Brazzoli Satumo HTFV 150 Superlux, a machine with Turbo-Vario nozzle design, focuses on production of Indanthren dyed fabric. The machine features ancillary equipment to maintain an atmosphere of nitrogen in the dyeing machine to reduce the concentration of hydrosulphite used in the process.

The development of upgraded, multitasking microprocessor machine controllers (Arel, Barco, Becatron, Setex, Termoelettronica) and the introduction into the basic machine format of full size stock tanks and dual-function addition side tanks, that are designed to service both the dyeing machine and the stock tank, mean that operating procedures can be carried out in parallel. By filling the machine from the stock tank the machine fill function is reduced to one minute, eliminating approx. 30–40 minutes from a traditional processing cycle for cotton. The full size stock tank can also be used to prepare the pre-treatment bath and dye bath in advance, utilising either the dual function addition side tanks to prepare the bath or by dispensing chemical auxiliaries, electrolyte and dye direct to the stock tank from the colour kitchen. These features of new operating procedures can reduce the processing time by 45–60 minutes.

Dyehouse management, who fully exploit the technical advances exhibited, have the potential to achieve a fully integrated, semi-automated piece dyehouse. This offers improved productivity without threatening Right-First-Time production rates, improved fabric appearance, reduced environmental impact of wet processing and drives down the unit cost of production. These developments in dyeing machine design and ancillary equipment complement quality and performance values set by the dyestuff and chemical auxiliary innovation programme.

“Banana” Machine Configuration: This long chamber type of jet or over-flow machine differs in downstream or up-stream flow of fabric and liquor. Developments of this machine design are aimed at improving fabric running characteristics, allowing higher productivity and greater versatility for fabrics with surface-sensitive construction or crease-sensitive synthetic fabrics. As well as dyeing set or unset polyester fabrics and polyester blends, these machines are generally also recommended for other difficult synthetics, such as lightweight woven acetates and polyamides. “Banana” machines operate between 8:1 and 14:1 liquor ratio, at maximum speeds of around 600 m/min. The latest machines from Hisaka, the Cut-SR (down-stream) and the Cut-MJ (upstream), feature a dual inner case along the dyeing tube, allowing uniform liquor drainage through a perforated plate, a wider angle of fabric over the reel and a new nozzle position, all resulting in a smoother running of the fabric and increased fabric loading. Increased productivity of 25% is said to have been achieved in practice with the new design, at speeds up to 700 m/min. together with higher product quality through reduced abrasion. Thies have improved their well-established Soft TRD machine by offering the Vario-nozzle option for greater fabric versatility. As with the “Apple” machines, a further option of a hot water tank is offered to reduce process cycles. Sample TRD machines for processing up to 50 kg fabric are now available. Brazzoli now offer a new “Banana-style” machine, the Sirio, featuring a Turbo-Vario nozzle to reach high production speeds at low pump pressure, synchronising liquor flow rate with fabric type. A bath distribution device in the top wall of the machine improves fabric/liquor interchange in weight-reduction, dyeing or rinsing cycles. The latest Rapid Suau machine from ATYC has metered liquor addition for greater accuracy in bath preparation and improved batch to batch reproducibility. To this “Banana-style” machine belongs also the Thenjet II, a configuration which is well established in wool fabric dyehouses.

Low Liquor Ratio “Airflow” Machine Configuration: Variants on the basic “Apple” design are offered by several manufacturers to deal with sensitive, high added value synthetic and cellulose-based fabrics, with and without elastane yarns, using either pneumatic and/or hydraulic fabric transport systems. Then, the originators of air-jet technology, have lowered the lifter reel and nozzle height in the Then-Airflow Aft machine. This reduces fabric tension and therefore improves fabric quality, especially in elastane-containing and lyocell fabrics. Scholl’s new Intensity machine, an evolution of their Softglider concept, is aimed at both sensitive woven and knitted fabrics. After passing through the jet nozzle the fabric accelerates down through the narrow intensive zone, before passing into the hydraulic upglide zone. Here, in the words of Scholl, “like the sky diver who opens his parachute and glides to a soft landing”, rope reorientation and efficient liquor interchange occur under tensionless conditions, minimising bruising and distortion of the surface of sensitive fabrics. Gaston County’s Millennium piece dyeing machine (Fig. 2) offers several new features designed to reduce fabric tension. A lower, high-traction lifter reel transports fabrics to the jet nozzle, from where they pass into a rectangular inclined tube. Here, cloth reorientation occurs under low-tension, “swimming” conditions.

The Thies air-stream has been designed to process modern fabrics such as lyocell, cupro, polynosic and micro-fibres. The machine operates at ultra low liquor ratio and utilises pneumatic fabric drive. MCS offers the “Air jet HT”. For dyers who find it difficult to decide between “Apple” and “Banana” configurations, Tong Geng of Taiwan presents a machine which claims to offer the best of both worlds, with their Model-ROL

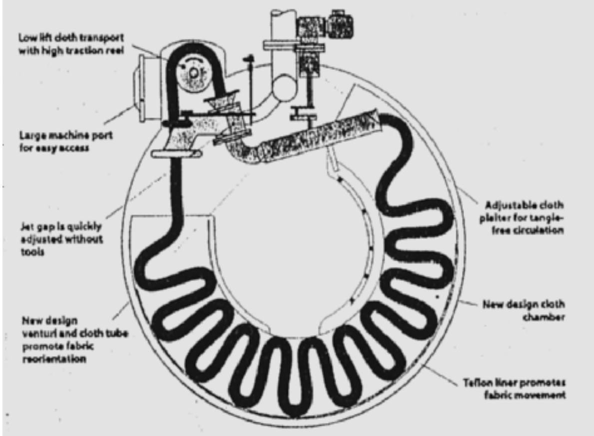

Fig. 2: Gaston County's Millennium piece dyeing machine.

machine, which combines a circular chamber with a long tube section. An air-based machine which is well established in the field of Tencel/lyocell fibrillation to obtain the so-called "peach skin effect" is the "Aero-dye from Krantz. Fig. 3 gives an overview of the process. After desizing, which is preferably carried out on the wide form, the next technical process is fibrillation inside the piece-dyeing machine. This primary fibrillation results in a very uneven, hairy look to the textile. After the primary fibrillation, a defibrillation process removes the fibrils from the surface of the cloth. During the next wet-finishing stage, for example dyeing, the so-called secondary fibrillation takes place, which produces the desired peach skin effect. The intensity of the fibrillation is affected by the following factors: 1. temperature; 2. time; 3. mechanical intensity of finishing process; 4. pH value. The sequence of these factors is not a statement as to their order of importance.

The following mechanical engineering requirements can be derived from the characteristics of the fibre which is to be fibrillated.

1. correct temperature and time control.

2. secure run of fabric throughout processing period.

3. high mechanical intensity of cloth propulsion method from high running speeds and impact zone.

4. minimal friction between textile surface and machine parts, especially where the cloth is moving at high speed.

5. good fabric transfer within the jet.

6. protective liquor feed which avoids faults in the appearance of the fabric at high liquor speeds.

7. good elimination of fluff after enzymatic defibrillation.

8. possibility of cleaning filter during operation.

Technical implementation in the Aero-dye: As to 1: Temperature and time control: Nowadays it is assumed that a machine will have a proper temperature and time control system, and there is no need to mention this as a requisite. There is a difference in the Krantz-Aero-dye

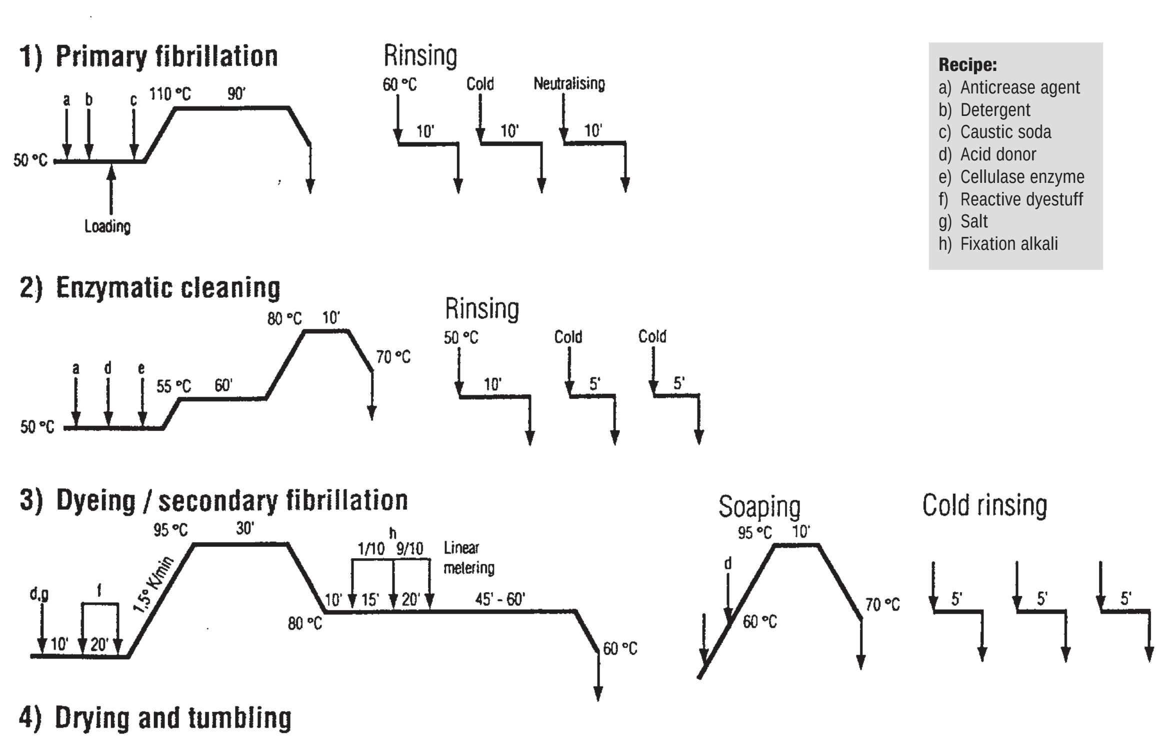

Fig. 3: Fibrillation process of Lyocell in "Aero-dye".

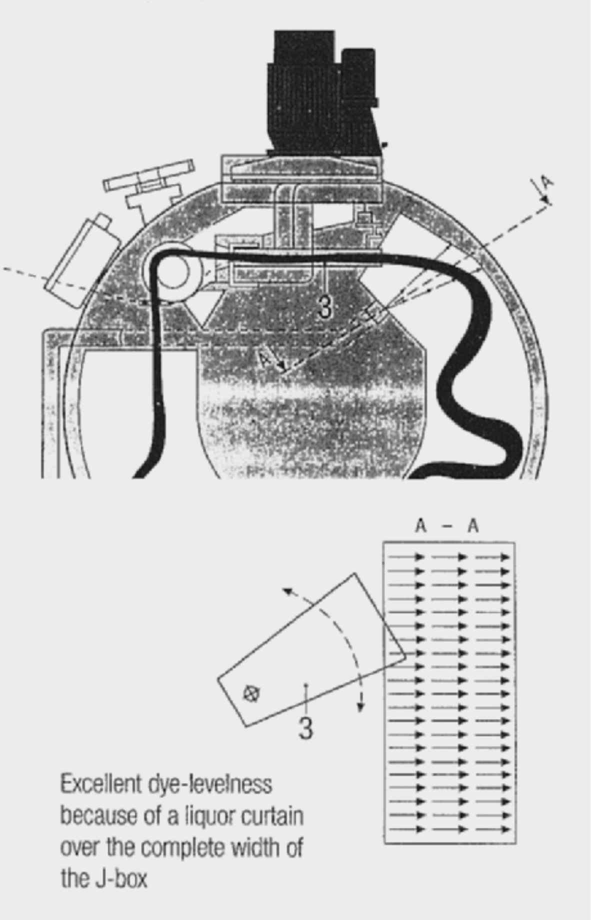

Fig. 4: Aero-dye (Krantz).

from other piece-dyeing machines with air propulsion (see Fig. 4).

In the Aero-dye the treatment liquor is fed completely separately from the propulsion system over a spray bar connected to the inner chamber. This makes it possible to circulate a large quantity of liquor without the need for high flow speeds (i.e. at low pump power). The result is an even liquor temperature in all areas of the dyeing machine. In other machines which are only circulating a small quantity of liquor due to their air drive, the liquor cools off on the way from the fabric to the pump inlet side, so that the exact liquor temperature is present only in the jet area. As to 2 to 5: Requirements numbers 2 to 5 are specifically affected by the cloth propulsion method. The Krantz Aero-dye is equipped with a special, purely aerodynamic propulsion system. For this reason no auxiliary propulsion system is used (Fig. 5).

The following arguments were decisive when selecting this propulsion method:

1. At high cloth speeds the winder drive no longer gives support. The risk of slippage points is minimised. It is interesting to consider the ratios of a combined jet/winder propulsion system in a machine with a propelled winder which is required to advance a fabric weighing 1000 g/m (wet) at 400 m/min. 60 N of force is required to propel this cloth. So the winder only supplies about 20% of the necessary propulsion. Since, in this system, the aerodynamic drive is clearly dominant, it is difficult to achieve synchronisation of the two drive systems in order to minimise the relative movements between winder and cloth. Particularly when friction impacts are used to increase the effectiveness of the winder, the danger of producing slippage points increases greatly.

2. The purely aerodynamic propulsion system is able to perform the complete propulsion power required. The mechanism of the aerodynamic drive of a rope can be described by the well-known equation for friction in pipes (Fig. 6). It is understood that the propulsion force is produced by the propelling air flowing parallel with the surface of the cloth. This model is validated by practice.

It is therefore not necessary to target the propellant air onto the rope at a greater or at a lesser angle. Rather, attempts should be made as far as possible to achieve a parallel flow. This not only allows the cloth to be propelled gently, but also achieves a jet flow that is turbulence free, and this has a positive effect on the propulsion blower capacity. This calculation model (Fig. 7)

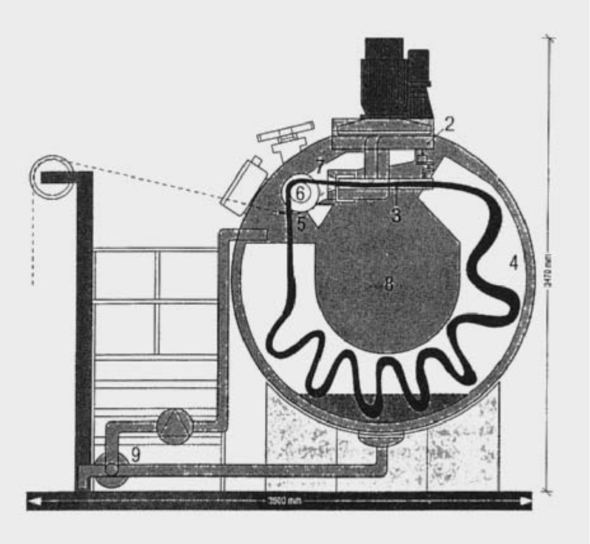

Fig. 5: Aero-dye cross-section.
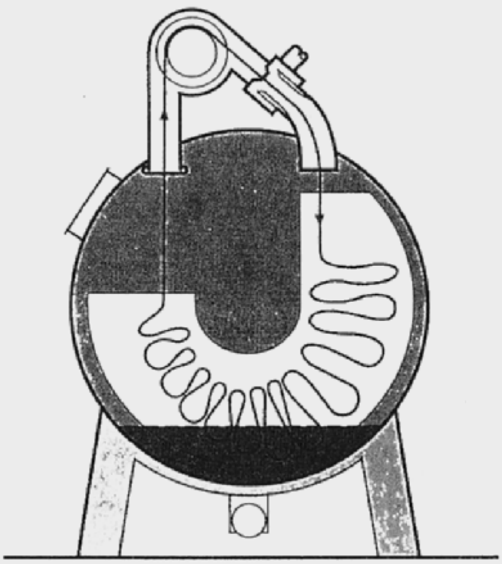
1 = One blower per rope (chamber): rope speeds separately controlled (up to 1000 m/min). 2 = Built-in blower: no external pipes, extremely low-noise operation. 3 = Energy-saving nozzle with directly connected plaiter. 4 = Teflon coated inner chamber with width graduation for trouble-free fabric run. 5 = Disentangling and fabric stop system. 6 = Fabric run monitoring and rope speed measurement. 7 = Seam seeker. 8 = Cleaning system for fully automatic internal cleaning of machine. 9 = Pipes, filters, heat exchanger below liquor level to reduce liquor ratio.

Exhaust rope piece dyeing machines



From the rope friction formula

(1) $F_{s\text{-}s} = F_{s1} \cdot e^{\mu \cdot \alpha}$

you can calculate the force F_{s1} necessary for the nozzle

(2) $F_{s1} = F_{s\text{-}s} / e^{\mu \cdot \alpha}$

With a coefficient of sliding friction $\mu = 0.12$
and an angle of wrap $\alpha = 100°$ you get

(3) $F_{s1} = 49\ \text{N}$

Fig. 6: Mechanism of the aerodynamic drive of a rope.

The following holds for the propulsion (air friction) F_r:

(1) $F_r = w_r^2 \cdot (l \cdot \rho \cdot \pi \cdot D_w) / (8 \cdot (2 \cdot \lg (D_w / k) + 1.138)^2)$

where
F_r = friction [N]
r = density [kg/m³]
D_w = rope diameter [m]
l = effective length [m]
F_r = frictional force [N]
w_r = relative speed fabric-air [m/s]
k = roughness (also known as sand roughness)

For non-round cross-sections, such as the orifice of the Aero-Dye, D_w must be replaced by the hydraulic diameter d_{hydr}, which for rectangular cross-sections is calculated as follows:

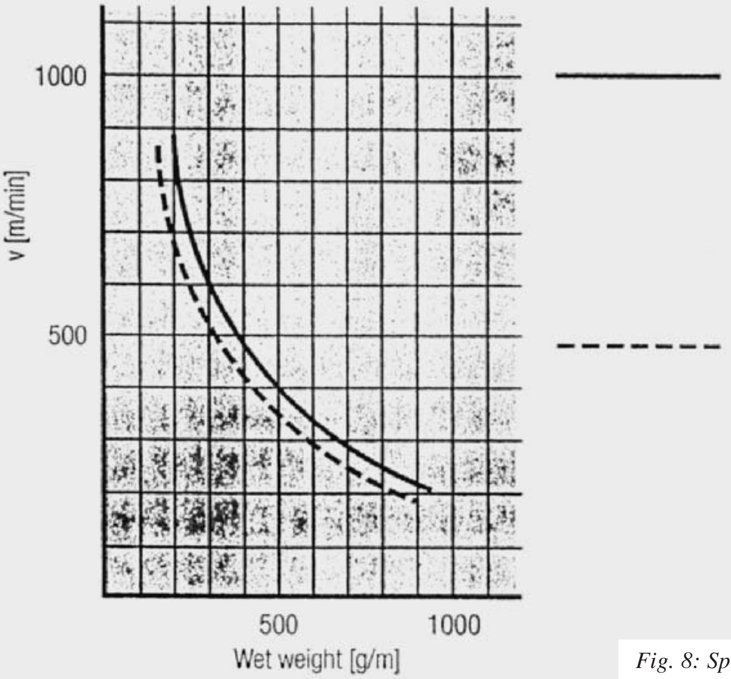
(2) $d_{hydr} = 2 \cdot b / (b/h + 1)$

where
b = width of nozzle
c = height of nozzle

Fig. 7: Diagram of flow of cloth in the Aero-dye jet and air force calculation.

describes the propulsion conditions that are in practice. It also demonstrates that, contrary to other assertions, the pure air propulsion system is also able to propel heavy fabrics.

3. Constant tension even at fluctuating speeds (Fig. 8). The relative speed is basically limited by the sonic speed, within further limits this is dependent only on



Speed attainable at constant fan speed and atmospheric pressure. At higher internal machine pressures the speeds attainable are up to twice as high.

Necessary speed for constant circulation time.

The characteristics of the purely aerodynamic transport system make it possible to dye the entire fabric weight spectrum.

Fig. 8: Speed diagram.

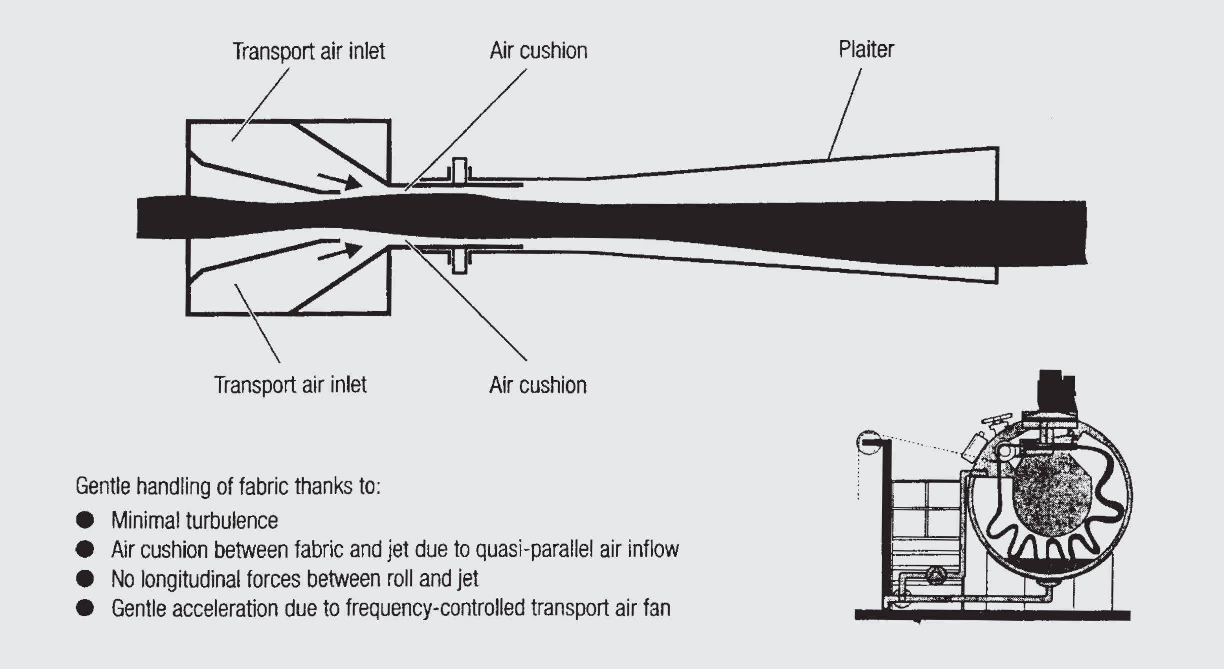


Fig. 9: Jet system.

temperature, but not on pressure. For air at 0° the acoustic velocity is 331 m/s. At higher temperatures the sonic speed increases. However, the required propulsion force is already achieved at lower speeds than “c”. The Aero-dye is therefore designed at 2/3. As the calculations show, the required air speeds are much higher than the cloth speed. Consequently, fluctuating cloth speeds have practically no effect on the propulsion. Thus, an important advantage of propulsion by air alone can be seen. The cloth is not subjected to changing forces. This applies even if the cloth stops suddenly because of a breakdown. Propulsion from aerodynamics alone is therefore particularly advantageous for cloth that is susceptible to tension.

4. Auto adjustment of air gap and excellent wrinkle offset. Propulsion is proportional to the working surface offered by the textile to the air (see air friction calculation). The larger the surface, the lower the relative air/textile speed can be, which can reduce the blower power on a cross-section of stream of flow which stays the same. The Aero-dye is therefore equipped with specially wide rectangular jets in relation to its gap height. The cloth generally fills the entire width of the jet, and therefore it adapts to the elongated shape. In doing so it offers a large working surface to the propellant air on the upper and the lower side, i.e., where the propellant air is flowing almost parallel (Fig. 9).

The gap height first of all only effects the necessary quantity of air. In the interests of reducing drive blower power, a setting that is as low as possible should be selected for this. On the other hand the aperture should be suuficiently high to allow even heavy cloth to pass through reliably. As the development work on the jet proceeds it is evident that these two facts are not self-contradictory. The high air speeds required create an under-pressure at the jet aperture which results in expansion of the rectangular rope. This results in auto-adjustment of the air aperture with the result that all qualities and weights of cloth can be processed with one jet. Furthermore, the expansion of the cloth due to the under-pressure causes excellent rope reorientation (Fig. 10).

The impact zone in the Aero-dye: For good and rapid fibrillation, the fabric must be given intensive mechanical treatment. In the Aero-dye the fabric is transported horizontally through the jet in the inner chamber. While this is happening it is advanced against the rear wall of the inner chamber and thus receives the

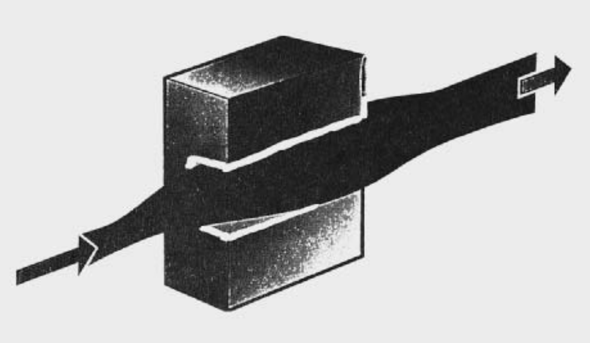

Fig. 10: The expansion of the cloth due to the under-pressure.

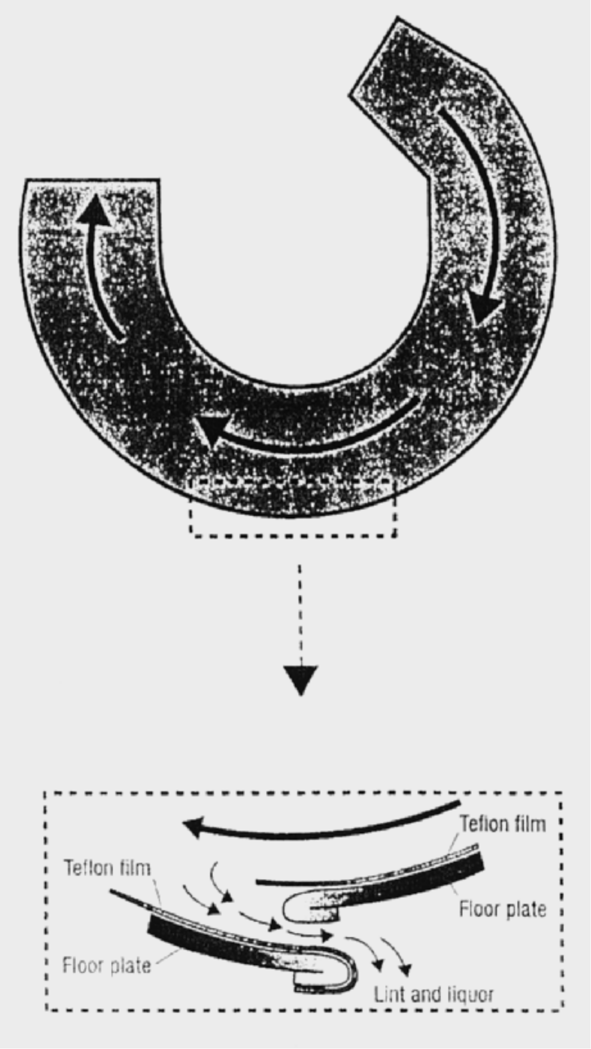

Fig. 11: Lint-intensive process.

required mechanical stress. The rear wall of the inner chamber is not perforated. So no “snags” can occur at this point. Even for very light and delicate articles there is no disadvantage by the fabric being impacted onto the rear wall of the chamber. As a result of the fact that the liquor is fed into the impact zone, and because of the high liquor circulation rate, an excellent colour evenness is achieved (Fig. 4).

As to 6: Protecting liquor feed: As already stated, the liquor is fed into the inlet side of the tank behind the plaiter. This produces a closed curtain of liquor over the entire width of the chamber. The fabric passes through the curtain and is thus thoroughly wetted. The speed of the liquor is only about 3–5 m/s. With respect to the application of the liquor the Aero-dye thus takes on a soft-flow character. Damage to the surface of the textile, which can occur in machines with liquor injection into the air flow, caused by the high kinetic energy liquor particles, is thus avoided. (Fig. 4).

As to 7 and 8: Fibre removal/cleaning: The large amount of fibres that fall during the enzymatic defibrillation process gives rise to two problems:

1. The problem of cleaning the machine.
2. The problem of removing the fibres from the surface of the cloth.

The following measures should be taken to clean the machine:

1. Inner chamber: The lower part of the chamber is equipped with a lint removal slot which makes it easier to clean the inner chamber following lint-intensive processes (Fig. 11).
2. Automatic cleaning device: The Aero-dye is equipped with an automatic cleaning system (Fig. 12). It has a fully automatic control system which provides optimum composition of the cleaning processes. At temperatures below 85°C cleaning takes place in open circuit via the attached tank. The auxiliary pump takes the cleaning liquor from the attached tank and feeds it to the jet system in the pressure container, through which the liquor is fed to the internal surfaces of the machine. The attached tank is continuously filled from the liquor circulation by means of valve (3). If the safe-

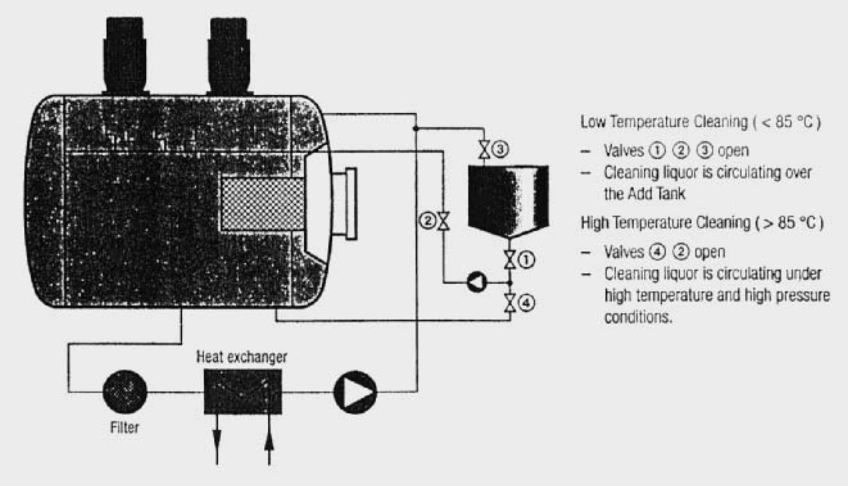

Fig. 12: Aero-dye equipped with an automatic cleaning system.

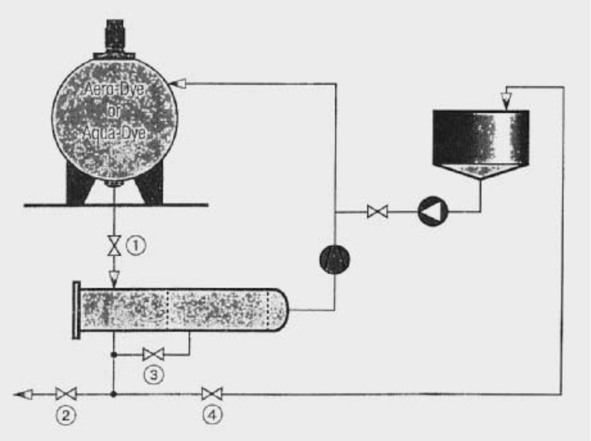

Fig. 13: Cleaning the filter during operation.

ty temperature is exceeded, the system automatically switches to internal circulation. The auxiliary pump drives the liquor through valves (4) and (2) into the cleaning nozzles.

3. Cleaning the filter during operation: If it becomes necessary to change the filter during operation, this can be done without losing any liquor (Fig. 13). The main pump is stopped while the fabric is running through, and valve no.1 is closed. Using air pressure it is now possible to push the contents of the heat exchanger and the filter into the auxiliary container. It is then possible to change the filter. Once the filter has been replaced, liquor circulation is restarted and the liquor is pumped back from the attached tank into the dye tank.

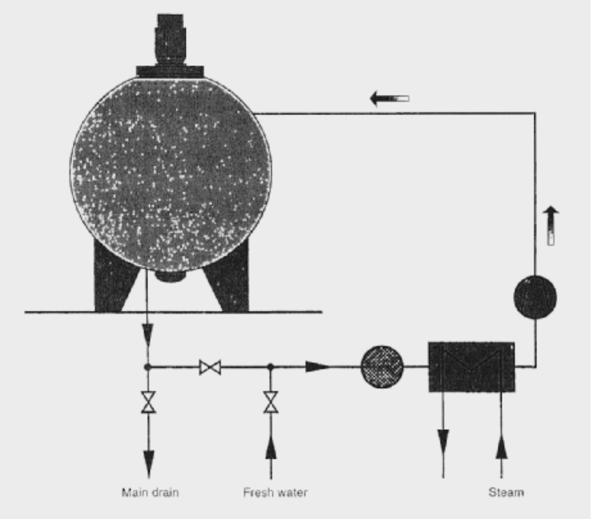

Fig. 14: The rinsing process.

The rinsing process is the principal method of removing fibres from the surface of the textile. The machine offers facilities for the standard bath change rinse method, overflow rinsing and also direct rinsing (Fig. 14). With the latter method, liquor circulation is shut off and fresh water pumped directly onto the fabric over the heat exchanger. The water can run off directly through the main outlet valve. Both, overflow rinsing and direct rinsing, are excellent methods of removing fluff from the surface of fibres.

Besides fibrillation, the powerful swelling of Tencel/Lyocell fibre impairs the wet finishing process. The swelling of the fibres causes a Tencel/Lyocell fabric when it is wet to become very stiff and hard. In this condition, the risk of causing permanent damage to the surface is very high. In addition, the ability of the machine to grasp the cloth is restricted, due to its wet rigidity. Only correct handling of the machine and cloth during the loading process can help here. The wet rigidity of the cloth needs to be moderated as far as possible during the loading process. This is possible on the Aero-dye as follows:

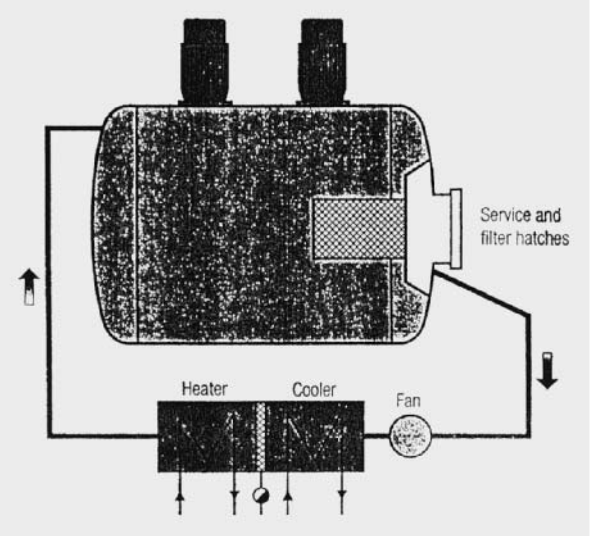

Fig. 15: Tumbler.

1. Heat the liquor to 50°C or 60°C before loading the machine.

2. Add emollient and slip additive before loading the machine.

3. Slowly feed the dry cloth at full blower power.

A slow feed at full blower power is only possible if the hank of cloth is braked outside the machine. This gives the cloth enough time to “flutter” inside the jet and in the liquor application area in order to lose most of the wet rigidity. This achieves a much greater loading capacity and greatly reduces the risk of creating slippage points.

The Krantz Aero-dye can be supplied with a tumbler or drying facility.

A special liquor pump provides the means for a temperature-controlled tumbling facility in the Aero-dye.

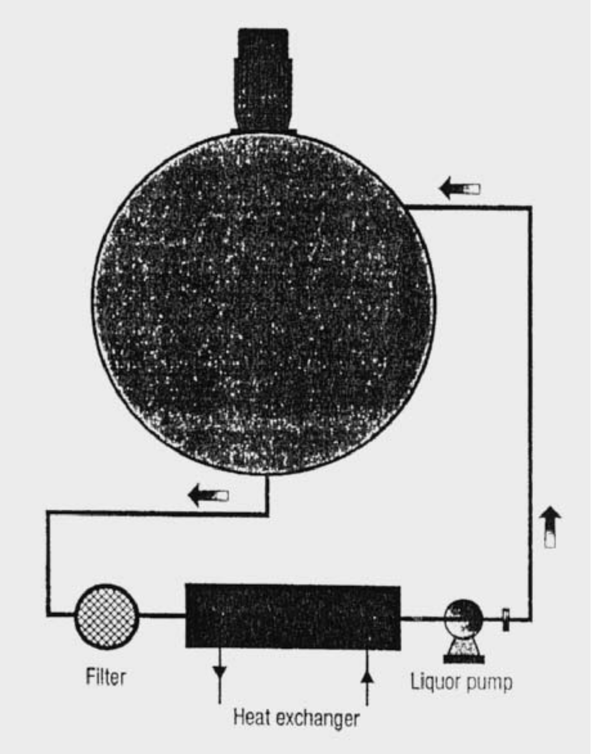

Fig. 16: Tumble and drying facility.

The pump at double speed can act as a blower, and can drive the machine's internal air over the liquor heat exchanger (Fig. 15). If a drying facility is also required for the Aero-dye, a dryer module is necessary (Fig. 16). Similar to a pressure dryer for yarn, the moist internal air in the machine is pumped into a condenser by an external blower. A separator behind the condenser removes the condensation from the air. In a subsequent damper register, the circulating air is heated to a drying temperature and fed to the inlet side of the driving blowers.

During tumbling the liquor pump (special version) functions as a blower and circulates the air in the machine via the heat exchanger. This permits temperature control during tumbling. (According to B. Böhnke and M. J. Bradbury and J. A. Bone)

Exhaust thermosol process Continuous process for (bleaching and) optical brightening of synthetic fibres (also in mixtures with cotton): exhaust treatment 2–5 min in hot optical brightener bath in dwell chamber (submerged open-width dwe ll system), finally squeeze off, dry, thermofix. In thermofixation, nonbound or diffused optical brightener is thermosoled.

Exocuticle Term given to the → Intermediate membrane of the wool fibre situated between the epicuticle and endocuticle.

Exophilic (Greek), directed outwards, e.g. the tendency of a hydrophobic molecular group not to enter into the homogeneous aqueous phase. Characterized by an increased alteration in the chemical potential on penetration of the molecular group. Opposite → Endophilic.

Exothermic An adjectival term used, e.g. to describe a chemical reaction which is accompanied by the evolution of heat. Compare → Endothermic.

Exotics Braided hats or hat bodies produced from various leaf fibres of the bast fibre group from East Asia, Africa, and Central and South America.

Exotic wools Wools from North Africa, Iran and Asiatic countries (China, India, Mongolia).

Expanded foam (Expanded plastics, cellular plastics), porous moulded materials produced from plastics with numerous gas or air-filled cells; 1 cm^3 of expanded foam contains between 10 000 and 1 million such cells with a diameter of 0.1–0.5 mm and a wall thickness of approx. 0.001 mm. Since the cells are enclosed, expanded foams have virtually the same heat insulation characteristics as static air. In flexible expanded foams, the gas or air cells compress to some extent under pressure but expand again when pressure is released. Expanded foams of this type have enormous elasticity and exhibit excellent dimensional stability even under high stress. Expanded foams are derived from ethers and esters. Flexible foams with pronounced elastic padding properties are made from (natural and synthetic) rubber (→ Foam rubber), polyvinyl chloride or polyurethane, and non-elastic foams from viscose or polyurethane; solid foams which have both supporting and insulating properties are made from rubber, ebonite, polyvinyl chloride, polyurethane and polystyrene. Rigid foams for insulation purposes, on the other hand, are based on e.g. aminoplasts or phenolic resins. Manufacture: the above-mentioned plastics are mixed with blowing agents (e.g. ammonium or sodium bicarbonate, ammonium chloride and sodium nitrite or organic nitrogen-releasing compounds such as hydrazine) or with gas-releasing plastic components and/or beaten to a foam with the inclusion of air. The mixture is then poured into moulds and polymerized (rubber is vulcanized). Uses: various heat and sound insulation applications (technical purposes, interior decoration, building insulation), upholstery (foam rubber), linings or padding for winter coats and dressing gowns; cut into strips for filling continental quilts and travel rugs; processed with other fibres for menswear and outerwear.

Expanded plastics → Plastic foam.

Expander Cloth guiders as attachments on equipment and machines which feed with the grain. Serves to reduce the shrinkage in width, to form good selvedges and to prevent formation of lengthwise creases. Simple expanders are stays produced from smooth tubes. A common expander device is the → Variable-tension rolls. (→: Expander, bowed; Slatted expander). This is suitable for processing different widths of fabric tube immediately after each other. Cutting principle controlled by helical tension springs, whereby the two expander guide rollers must simply be adjusted for each width of fabric tube (e.g. in the range of 31–45 or 33–73 cm); Adjustment using self-locking threaded spindles.

Expander, bowed Bowed, stationary rod which stretches the goods widthways depending on the curve of the rod's setting angle.

Expander filter An automatic, self-cleaning single-batch/multi-batch filter for solutions in dry cleaning. Based on stainless steel wire elements, spiral-canted, tightly coiled, extendible. → Filters.

Expander rollers Rollers made from any material which, from the centre, has grooves or threads which run opposite to each other, and which have progressive/constant gradient, to stretch piece goods to their full width on stentering and drying machines (expanders). A bowed roller with roller bodies and a closed, elastic cover to stretch goods is referred to as a so-called "banana roller". The setting angle of the curve of the roller axis is decisive here (Fig. 1).

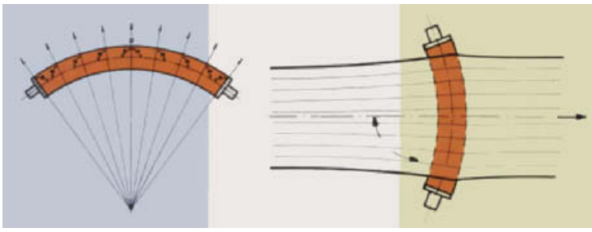

Fig. 1: Operation of a "banana" expander roller (contributed by Wittler).

The roller body which rotates around the radially bowed axis has a different angle of inclination to the adjacent run of cloth, from 0° at the crown of the roller, continually increasing to the roller ends. As a result, the cloth has the tendency to run off at right angles to the roller axis under the looping angle which is adjusted to the particular cloth structure. The resulting deviation of the cloth from the centre progressively to either side causes optimal transverse tension in this area of the roller, thus resulting in the avoidance of lengthwise creases in the cloth. The loose edges or centres of cloth and centre or edge feeds can also be positively influenced (Fig. 2).

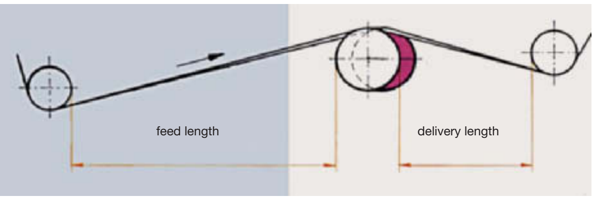

Fig. 2: Arrangement of run of cloth and expander roller.

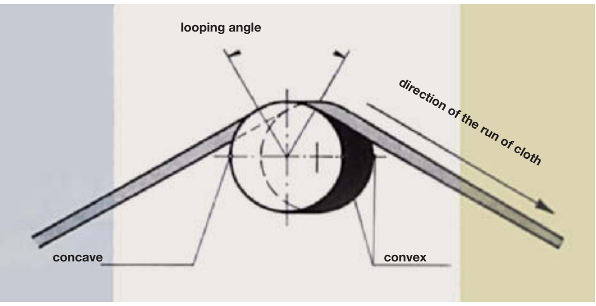

Fig. 3: Looping angle required on an expander roller.

The slats forming the cylinder jacket are moved outwards from the centre of the roller through 180° rotation by means of cam plates, by 180° rotation inwards. A mark on the cam plate indicates the end of the stretch zone or beginning of the compressing zone. The optimum stretch effect is achieved if the cloth feed length in front of the expander roller is sufficiently long and the run off to the subsequent guide roller is as short as possible. Standard values: feed length at least 3 x run off length, larger if possible. Final stretch length maximum 2 x roller diameter. Observe safety margins.

The correct looping angle (Fig. 3) is an important prerequisite for the expansion process. Standard values for bowed expander rollers: in general 40–60°, special cases 60–100°, for slatted expanders 30–180° (Fig. 4).

The same basic principles apply as for the installation of guide rollers. It is particularly important that installation is at right angles and horizontal to the run of cloth in order to achieve perfect effect and to avoid wear of the rubber sheath.

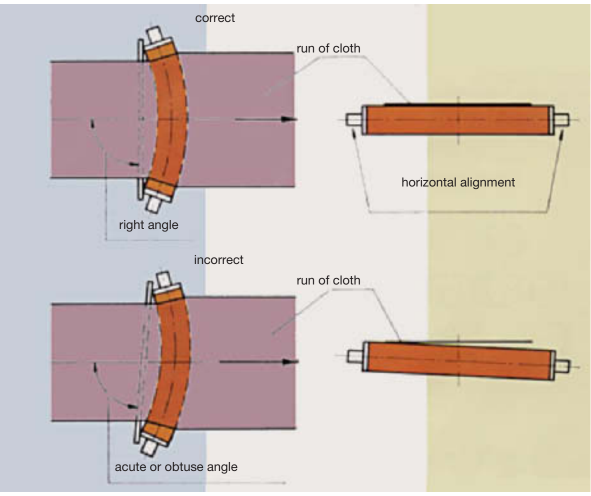

Fig. 4: Correct and incorrect arrangement of an expander roller.

Expanding device for fabric (stretcher, width expander). Device to stretch the material, to avoid crease formation and/or to roll out the selvedges during the passage of the cloth: → Expander rollers (bowed), expander, bowed, slatted expander, selvedge unroller.

Expansion tank Tank on high-temperature equipment used to equalize pressure and absorb fluids at temperatures above 100°C.

Expansion vessel Expansion tank for HT equipment.

Expert system Four complementary components combine their resources here in terms of data processing and provide information on the user interface for the user submitting the query:

1. The problem solving component processes the query submitted and expands the function of the query interpretation to enable results to be processed.

2. The explanation component records the problem solving process so that solutions which have been found can be reproduced.

3. The knowledge acquisition component is used to expand and modify the knowledge basis.

4. The dialogue component carries out both the analysis and transformation of the natural language query and also the dialogue with the user.

Documentation science, communication science, IT and specialist scientific knowledge therefore work together.

An expert system is the combination of a computer with a spec. program which consists of an intelligent shell and a specialist knowledge basis. It differs fundamentally from the previous program in that it contains a very large amount of specialist knowledge, predominantly in text form (control systems). The user no longer has to use their imagination to think up the correct question, as is the case with a database. The expert system only applies the questions relating to the problem and immediately excludes answers concerning irrelevant areas. It adheres strictly to the topic. It then tries other questions and answers to find the solution in the core area; it is not necessary to deal with noise. The so-called shell of the expert system is loaded in the computer: this shell calls a knowledge basis which has been produced with the aid of experts in the field of textiles. A knowledge engineer questions the specialist, structures the specialist knowledge and then helps to formulate the rules and questions for the screen output.

Explosion of hydrogen peroxide Bleaching with hydrogen peroxide may lead to the explosion of the bleaching apparatus. Although the cause of the accident is difficult to determine, investigations have yielded tips for avoiding such explosions. The bleaching process takes place in apparatus which is similar in design and operation to that of HT dyeing equipment. For example they have a capacity of 4500 l and are designed for a maximum operating pressure of 4 bar. They are subject to the pressure vessel act and should be equipped, set up, operated and tested according to the associated technical rules.

A bleaching process may take place as follows: The bleaching liquor, which consists primarily of water plus caustic soda liquor, wetting agents and stabilisers, is added to the fibres in the container. A pressure of 3 bar is generated in the sealed container. Then the contents of the container are heated to approximately 45°C. The hydrogen peroxide is added at this temperature. This is then heated to higher temperatures. After this temperature has been maintained for the time stipulated by the formula, the contents of the container are cooled. The bleaching process is concluded by the discharge of the bleaching liquor and several rinsing cycles. The material can then be removed from the apparatus.

Explosions generally occur before the maximum temperature has been reached. A common cause is the safety valve becoming blocked by lint. This danger is particularly prevalent if the safety valve operates frequently. The following measures can be taken to prevent the pipes to the safety valve becoming blocked:

- Adequate dimensioning of the safety valve (possibly increasing the nominal size);
- Control of the bleaching process such that the safety valve does not operate in normal operation;
- Frequent cleaning of the container and the pipes to the safety valve;
- Checking the safety valve before each new batch;
- In older apparatus the use of a pressure sensor, which opens the discharge valve when a predetermined pressure is exceeded.

The explosions are probably caused by the rapid decomposition of the hydrogen peroxide that is added. It decomposes in an exothermic reaction. The speed of the decomposition reaction sharply increases the rise in temperature. If certain catalysts are present the breakdown leads to an explosion even at low temperatures in a weak solution. Possible catalysts are a range of metals, particularly copper, but also iron(rust) and alkalis. Industry standard hydrogen peroxide contains stabilisers, which are added to hinder the decomposition process, e.g. during storage. Further stabilisers are added during bleaching. However, despite the addition of stabilisers a catalytic decomposition of the hydrogen peroxide cannot be ruled out. → Hydrogen peroxide bleaching regulators.

Explosion risk areas Areas in which the risk of explosion exists are those in which gases, vapours, mists or dusts, capable of forming explosive mixtures in air, can develop, accumulate or spread. Such areas include: enclosed rooms or parts thereof, the insides of machines (e.g. curing and drying machines), containers, channels, shafts, pits and similar cavities, entire buildings, sections of factories, workshops, warehouses and offices or any other locations where explosive mixtures can arise or be penetrated by.

Explosive limits The lower and upper concentration limits of flammable gases and vapours, or dust in mixtures with air, between which gas or vapour mixture with air can explode on ignition in a confined area. Explosive limits are usually expressed as a concentration in vol.% or g/m^3 at an initial state of 1,0133 bar and 20°C. Below the lower explosive limit the concentration is too small to cause combustion or explosion. Above the upper explosive limit the mixture is too rich in combustible component for an explosion to occur.

Exposure to dyes, auxiliaries and chemicals Exposure to certain dyestuffs, auxiliaries or chemicals during their production or use. Leading European dyestuff manufacturers have assumed an important pioneering role in ensuring and increasing safety with the foundation of the → ETAD in 1974:

1. Continual reduction of exposure by:

- Improved production technology,
- Good levels of industrial hygiene and appropriate devices,
- Personal hygiene and sufficient washing facilities,
- Good information and staff training,
- Improved physical properties of the products (e.g. non dustprone forms),
- Reduction of dyestuffs in the effluent,
- Improved applications facilities and technology,
- Use of the best applications technology available,
- Use of products with optimum fastness,
- Product innovation.

2. Constant monitoring by industry, authorities and the public:

- Monitoring the environment,
- Medical supervision,
- Epidermology,
- Exchange of scientific and technical information,
- General vigilance of workers, employers, scientists.

3. Ongoing tests:

- Tests for those substances representing an unacceptable risk which cannot be controlled,
- Development of new, shorter, economical toxicological and ecotoxicological test methods, espec. short-time tests for chronic effects,
- Basic research into the relationship between structure and effect and into metabolism (pharmacokinetics).

When assessing a risk, it must be taken into account that this is a function of a) the potential harmful effects, based on the inherent toxicological properties of a product and the extent of its bioavailability in the organism, and b) the exposure and probability of occurrence. Risk is generally quantified as the statistical probability of a particular harmful effect arising under specific exposure conditions, e.g. the amount and frequency of exposure during a specific period of time. (E.g. a risk of cancer of 10^{-6} indicates that out of every 1 mill. people exposed under clearly defined conditions, 1 of these will develop cancer). It is clear that the risk of harmful effects occurring can be decreased by reducing exposure. This is clearly the simplest means of increasing safety.

The probability that a substance will represents a hazard, i.e. the risk of using this substance, is given by the equation

$$R = G \cdot E$$

R = Risk,
G = Hazard potential of the substance,
E = Exposure.

In other words: it is possible to handle hazardous substances without this constituting a risk if exposure to the products is avoided. Potassium cyanide is a dangerous chemical even when stored in a sealed bottle, but handling it does not represent a risk if there is no possibility of exposure to the substance (e.g. by using unbreakable, sealed receptacles). It can be deduced from the equation that the risk to the consumer when using textiles which have been dyed is determined not only by the hazard potential of the dyeing agent, but also by exposure to it. The exposure of the consumer to the dyeing agent presupposes migration of the dyestuff from the substrate. This is not the case with the user, who is directly exposed to the dyeing agent. This migration indicates low fastness to washing, perspiration or crocking and is a characteristic of textiles which have not been finished optimally.

By definition dyeing agents include dyestuffs (dyeing agents which are soluble in the application medium, soluble in water and/or solvents) and pigments (inorganic or organic, coloured or uncoloured dyeing agents which are virtually insoluble in the application medium). The characteristic property of pigments is their extremely low solubility in water and in the substrate. They are also only slightly soluble in organic solvents. Due to this low solubility they are practically no longer bio-available. The fact that dyeing agents are used almost universally in almost all articles used for daily life results in an extremely wide variety of exposure situations.

The largest potential exposure exists during production (Tab. 1), but only effects a relatively small group of people trained in the proper handling of chemicals. It is also relatively simple to carry out and monitor measures to reduce exposure in workshops. During technical use, i.e. for dyeing textiles, leather, paper, printing colours, paints and plastics, exposure to and absorbance of dyeing agents by humans is also possible. The extent of this is dependent on the industrial hygiene conditions when the dyeing agent is applied. In theory, exposure could be zero, although this is not possible in practice. Despite this, the aim must be to achieve minimum exposure, although this must at least lie below the level of

Exposure to dyes, auxiliaries and chemicals

Human exposure	Exposure potential *	Measures to reduce exposure
Production		
Operating staff	1	– Improved production technology – Good industrial hygiene and installations – Personal hygiene and appropriate washing facilities – Information and staff training
Public (via environment)	3	– Reduction of effluent pollution – Controlled garbage dump or incineration of waste
Use		
Dyers, printers etc.	2	– Use of suitable application technology – Good industrial hygiene conditions – Improved commercial forms – Personal hygiene and appropriate washing facilities – Information and staff training
Public (via environment)	3	– Reduction of effluent pollution (e.g. higher exhaustion level when dyeing)

Tab. 1: Exposure to dyeing agents during production and application.
** 1 = high, 2 = average, 3 = low.*

an unacceptable risk. The most critical is exposure during handling of dyeing agents, especially during weighing and mixing. Inappropriate equipment, the lack of suitable protective gear and insufficiently trained staff can lead to unacceptable values. Products which are particularly dustprone pose the largest problem. The best solution for this is liquid products. Unfortunately in spite of concentrated efforts, manufacturers have been unable to offer all dyeing agents in this form. Intensive efforts are also being made to develop products which are not very prone to dust and have already resulted in non-dustprone, fluid forms.

Particles of >7 µm are deposited from inhaled dust, mainly in the nasal, throat and tracheobronchial tree, and from here generally enter into the digestive tract, whereas particles <7 µm (alveolar dust) enter the lung. In companies where the workers were exposed to dust from benzidine dyestuffs (which are no longer available), benzidine and its metabolites can be detected in the urine. Calculations show that inhaling 2 mg/m^3 of a benzidine dyestuff during a working day (8 h) resulted in 14–24 ppb being passed in the urine. Estimates show that passing over 100 ppb benzidine and its derivatives per day could lead to a substantial increase in the risk of cancer of the bladder. In dyestuff manufacturing and application companies where care is taken that there is a good standard of industrial hygiene these metabolites could not be detected in the urine of workers who handled benzidine dyestuffs, even using sensitive measuring methods (detection limit 1ppb). It can be assumed that the potential risk in such cases is negligible. In general, the monitoring of the concentration of aromatic amines passed in the urine of people working with aromatic amines or compounds in which a metabolic decomposition to form such amines could be expected, is a good means of testing (monitoring) the adequacy of safety methods.

Wearing textiles which have been dyed is clearly the

Human exposure	Exposure potential *	Measures to reduce exposure

Foodstuffs	1	
Medicines	2	– Use of sufficiently tested, permitted products
Cosmetics	2	

Tab. 2: Exposure of users to products which have been dyed.
** 1 = high, 2 = average, 3 = low, 4 = very low, negligible.*

most common exposure of humans to dyeing agents (Tab. 2). Exposure is extremely low where the goods are colourfast as the migration of the dyeing agent onto the skin is very slight. Standard tests which simulate perspiration suggest that the potential exposure can be estimated at well under 1 mg per person per day. Penetration of the dye into the skin, spec. with ionic dyestuffs and insoluble pigments, is low, generally much less than 1% of the amount found on the skin. Consequently it can be estimated that even in the worst case scenario, a maximum of a few micrograms would be absorbed, although on average the figure is much lower. The risk of damage to health is practically zero given these amounts. Allergic effects are an exception, however.

The use of dyeing agents in consumer goods, e.g. coloured toys or foodstuff packaging materials is legally regulated in many countries. The laws require that no visible quantities of dyeing agents should be able to migrate from dyed material. Tests are carried out using prescribed standard methods. In the case of coloured packaging materials, the detection limit is generally 0.05 mg migrating dyeing agent per kg of foodstuffs, but this depends on the colour strength. The most suitable for this use are pigments which are practically insoluble, as they also have a low acute and chronic toxicity. In the case of finger paints on the other hand, exposure is incomparably higher. For toxicological reasons, the use of permitted food colourings is suggested for this purpose. Unfortunately, these are not very suitable as they stain clothes and home textiles very easily. It is preferable to use pigments which are virtually nontoxic and which can be more easily rinsed out of textiles. To prevent children from swallowing these finger paints, it is advisable to add a bitter substance such as sucrose octaacetate. Another area of application with a potentially high, uncontrollable exposure is do-it-yourself or domestic dyeing of textiles. Only selected dyestuffs which have undergone sufficient tests should be used for that purpose.

The use of colorants in foodstuffs, medicines and cosmetics leads to a widespread, relatively high exposure of a large number of people and is rightly strictly regulated in some countries. The ADI values (acceptable daily intake) recommended by the FAO/WHO expert commission are in the region of 0.15–15 mg/kg body weight. This is the equivalent of a max. acceptable daily intake of 10.5–1050 mg dyestuff per person (70 kg body weight) per day. These values were taken from the so-called "no observable effect level" (NOEL) with a built-in safety factor of 100–1000. In long term animal experiments this NOEL was approx. 2000 mg/kg body weight for some dyestuffs. Experience has shown that the quantities absorbed by the population lie well below the acceptable levels. In the case of cosmetic dyestuffs, the potential exposure is several times lower, although the number of people exposed is still very high.

Extended length → Crimp contraction.

Extender A term used for a textile auxiliary which can improve the processing effect of another product to such an extent that its concentration can be reduced.

Typical application: microporous membranes consist of polyester or polytetrafluoro- ethylene.These are either laminated to the outer material (outer fabric/membrane lining) or applied as insert laminates (outer fabric/membrane/nonwoven lining). A water-repellent impregnation is given to the outer fabric either alone or together with the membrane to achieve an outstandingly high degree of water repellency. Although water repellent formulations based on silicones were formerly used, fluorocarbon finishes which have a higher degree of permanence as well as stain-release properties are now preferred. A nonionic fluorocarbon resin can be combined with a silicone elastomer even where the highest demands are placed on softness of handle. For blend fabrics containing cellulosic fibres, a favourably priced suitable water-repellent finishing agent is preferred as an extender so that the amount of fluorocarbon resin can be significantly reduced whilst still achieving equally good water and oil repellent effects, thereby reducing the finishing costs as a result.

Extender for tensides Inorganic or organic products, generally inactive, that are used to adjust the market form and/or the concentration of a detergent. Examples: sodium sulphate, water, alcohol, etc.

Extenders (fillers, diluents), normally specific, inert additives used for standardizing the type or the commercial form, concentrated, also used for diluting and cheapening. Usual with dyestuffs (powder products e.g. + neutral salts, dextrine. hydrotropic substances, dispersing agents, preservatives and the like, with liquid products also + water etc.) and with tensides (e.g. + sodium sulphate, water, alcohol and the like).

Extinction (E), extinguishment (of light), cancellation; e.g. the whole light-absorbing black content of any full colour in colour measurement; here black appears as an extinguisher which remits no visible radiation energy. The definition of extinction is as logarithm to base ten of the reciprocal of the transmittance, that is the ratio of the light entering a solution Φ_0 to the light emerging Φ_{trans}, assuming that only the component i is absorbed at wavelength λ.

Lambert-Beer Law:

$$E_{i,\lambda} = \log \left(\frac{\Phi_0}{\Phi_{trans}}\right) i,\lambda = \varepsilon_{i,\lambda} \cdot c_i \cdot d$$

The extinction $E_{i,}\,\lambda$ is proportional to the depth d of the solution and its concentration c_i. The factor of proportionality $\varepsilon_{i,}\ \lambda$ is given as the concentration-dependent decadic extinction coefficients. It is a specific value and under application of → Lambert-Beer Law is only dependent on the wavelength of the radiated light. This law only applies, however, provided the molecules of the absorbing medium do not undergo concentration-related changes through interaction with one another (e.g. by displacement of dissociation or polymerization equilibria) or with other components of the mixture phase (e.g. solvation), which influence their light absorption. Lambert-Beer Law is therefore first and foremost a limit law for very dilute solutions, which in addition must be optically clear and homogeneous. Cases are, however, also known in which the deviations are low even at considerable concentrations. The Law is furthermore only precisely applicable to monochromatic light.

If several components are dissolved in a homogeneous solution, which absorb at the wavelength λ, then the total extinction $E\lambda$ is equal to the sum of the extinctions $E_{i,}\ \lambda$ of the individual components i. It is then said that

$$E_\lambda = \sum_i E_{i,\lambda} = \sum_i \log\left(\frac{\Phi_0}{\Phi_{trans}}\right) i,\lambda = d \cdot \sum_i \varepsilon_i\, c_i$$

Another frequently-applied value in accordance with the DIN standards is the pure absorption coefficient (= 1 – δ) or the percentage absorption A (= 100% transparency D). In addition the extinction in the case of modern colorimeters is read off direct from the extinction scale. Not to be confused with extinction are the extinction module m as extinction of the solution or of the body at thickness 1 and the extinction coefficient k (molar, at a concentration of mole/l) or k_1 (specifically at a concentration of g/l) as concentration-independent substance constants of the coloured substance. Another form of extinction by inorganic and organic substances is known as fluorescence, which has been proposed as a possible method for the quantitative determination of organic substances.

Extract A term used for a preparation containing the active principle or concentrated solution of a material, e.g. an aqueous extract.

Extracta Open-width washing machine (Fig.) with vertical zig-zag cloth passage (more efficient washing effect compared to horizontal arrangement). The additional division of an Extracta compartment enables different processes to be carried out with appropriate liquors in the individual sections.

Consists of a 5 m washing chamber with 2 vertical roller pairs for double fabric immersion. Available with 3, 4 and 6 chamber compartment (15, 20, 30 m fabric dwell); each compartment has an integral squeeze unit with 2 or 3 t pressure. Can be combined with e.g. a pretreatment steamer. – H.: Benninger.

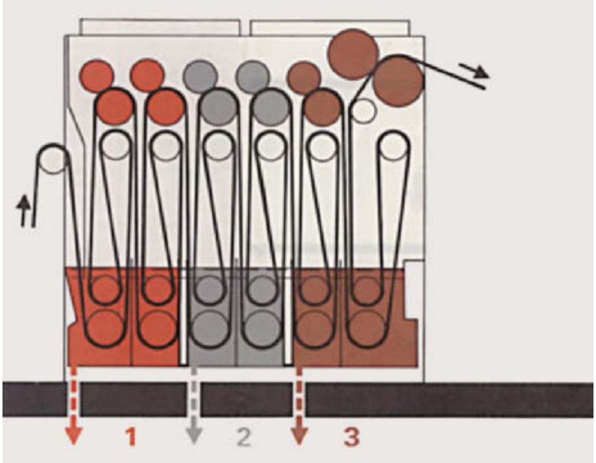

Fig.: Extracta washing machine (Benninger).

Extraction This relates to substances that adhere to fibres and are soluble in solvents, and usually takes place usually in the Soxhlet apparatus (e.g. for the determination of residual grease in wool). If the concentration gradient is significantly greater in the extraction than in the Soxhlet apparatus, i.e. if extraction is to take place with a significantly shorter bath ratio, then a continuous dosed delivery of the eluate is recommended; this way of working saves time. Using an extraction method as a system for checking residual chemicals was first thought of by Mahlo, this being the Chemocon system (Fig.) in the form of an injection of steam into the running fabric.

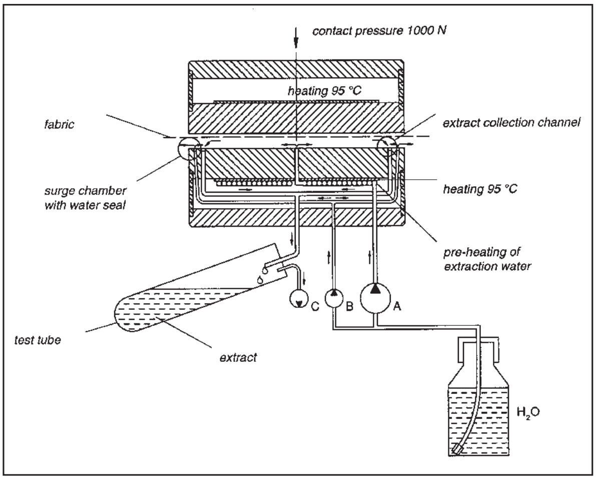

Fig.: Extraction unit according to Haus Bors . A = extraction water pump; B = water seal pump; C = vacuum pump.

Extraction of dyes from textiles → Dyes on textiles, quantitative determination.

Extraction of water from packages

I. → Marking off dyestuffs and prints.

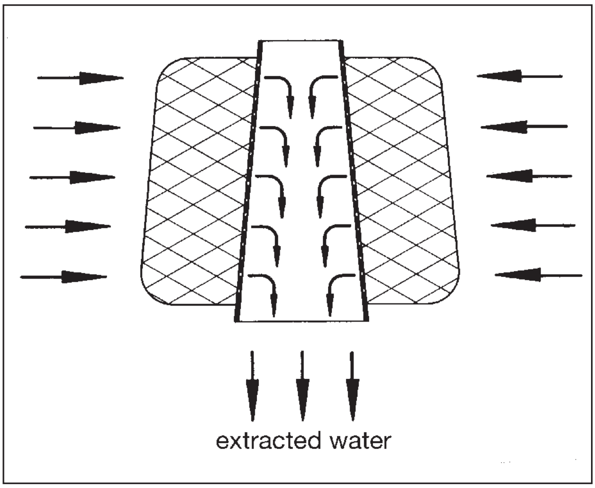

Fig.: Marking off yarn packages, flow direction outside-inside.

II. Hydroextraction of yarn packages (Fig.) in the → Pressure boiler.

Extraction scour/extraction bleach A pretreatment process chiefly used for cotton and cotton/synthetic fibre blends. Principle: the natural impurities in cotton are not only "bleached" but made soluble and washed out (extracted) by the application of appropriate wetting agents with high stability to electrolytes and complexing agents. A clean and hydrophilic material is achieved by this means without kier boiling or the use of HT steamers. The pretreatment can be carried out either as a short-dwell process (30–180 s) in the steamer, as a medium-dwell process (10–30 min) in a J-box with or without sump, or as a long-dwell process (5–10 h), e.g. in a pad-roll chamber.

Extractor fans Used in → Dust removal plants and → Fog dissipating plant. Belt, electric and steam driven (turbo-exhausters) mainly as centrifugal extractors. In the case of acid fumes the air propulsion components must be constructed of acid-resistant material.

Extract wool Term for class VI of → Reclaimed wool (regenerated wool). This is obtained from waste and rags (union knit, blended fabric) after carbonizing by tearing. As the cellulosic fibres are extracted by carbonizing, the term extract wool is still used from time to time.

Extra group Term used to indicate something additional and similar e.g. → Amino extra groups, Carboxyl extra group.

Extraneous fibres Faults arising from the presence of foreign fibres in a textile material. Generally present in low proportion and occurring as a contamination caused either by erroneous fibre mixing, residues from other processes or fibre fly from packaging material etc. that may be twisted, woven or knitted into a fabric. Consequences: irregular fabric appearance, colour differences, bleeding of dyes etc. Evidence only microscopic.

Extruded composites Flexible, net-like textile fabrics (→ Bonded fabrics), produced by extruders from thermoplastic polymer melts for felt underlays, camouflage nets and for carpet anti-skid protection etc.

Extruded tape In accordance with DIN 60 001 T2, an extruded ribbon usually from a slit-shaped extrusion aperture or a slit yarn cut from film, continuous, where appropriate drawn uniaxially, for textiles applications thickness up to approx. 0.08 mm, width 5 mm.

Extrusion coating A process used for the production of fusible interlinings. Principle: a molten thermoplast adhesive is extruded from a wide slitted jet and the resultant film is pressed on to the pre-warmed substrate (fabric or nonwoven) surface with the aid of cooled rollers.

Eyelet embroidery The ground fabric is fine count plain weave batiste. Before the actual embroidering process begins, the required eyelet effects are stamped in (openwork effect). The holes are then embroidered with grey ply yarns according to the pattern. Eyelet or batiste embroidery receives its snow white effect by bleaching. These embroideries are also offered coloured or additionally printed.

Eye sensitivity to hue, chroma and brightness Under certain conditions, the human eye distinguishes between approx. 10 million surface colours (→ Colour vision) and recognises 152 spectral colours. At different light wavelengths, however, even the normal eye (→ Colour stimulus) has a very varied sensitivity concerning:

1. Hue: most sensitive to yellow green and blue green; however weak for violet, orange and red, and zero for infra-red and ultra-violet; weaker in yellow and blue.

2. Chroma: is most easily perceived in violet and red, and least in yellow green. Extremely slight differences of 2–3% are also perceived with blue. The eye recognises average colour differences in dyeing (= differences in dyestuff concentration) of 5% and at the very best, with the same shade, of just 1%.

3. Lightness: most sensitive to yellow green, least sensitive in the range of violet, blue, orange and red (→ Adaptation). Reference should be made in particular to the difference in luminosity at low and high luminous intensity. A distinction is made between light-adapted and dark-adapted eyes. With the latter, spectral sensitivity is shifted slightly into the area of blue hues.

F

F

I. Chemical symbol for fluorine (9).

II. Symbol for farad.

III. Symbol for faraday.

f, symbol for: femto- (prefix indicating 10^{-15}), i.e. 1 quadrillionth ((US and Canada).

°F, abbrev. for degree Fahrenheit (→ Fahrenheit scale).

Fabinet A term used for a type of → Artificial leather produced from natural fibres that have been bonded together with a binding agent.

Fabric accumulators (cloth accumulators). Storage units which are in some cases identical with → Dwell units in processing machines. They include: conveyor-type accumulators, scray accumulators, roller accumulators, open-width accumulators (see Fig. 2). Fabric accumulators are important for nonstop batch changes in continuous and discontinuous processing ranges. In continuous plants they are interposed between individual machines in order to ensure a distortion-free fabric passage.

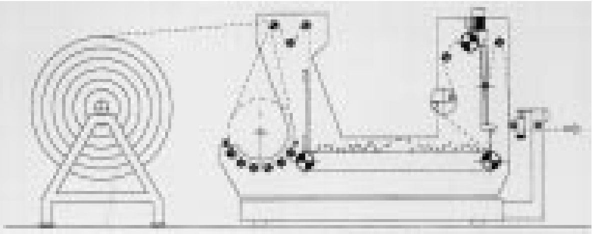

Fig. 1: Feed unit for knitted fabric from small and big roll. Placed at the inlet of printing machines, flatbed or rotary, feed unit allows to eliminate completely any tension of feeding fabric and assures a perfect alignment on the machine (Stamperia Emiliana).

Fabric accumulators for batch changing Nonstop batch changing is made possible by the installation of batch changing devices at the entry and exit of textile

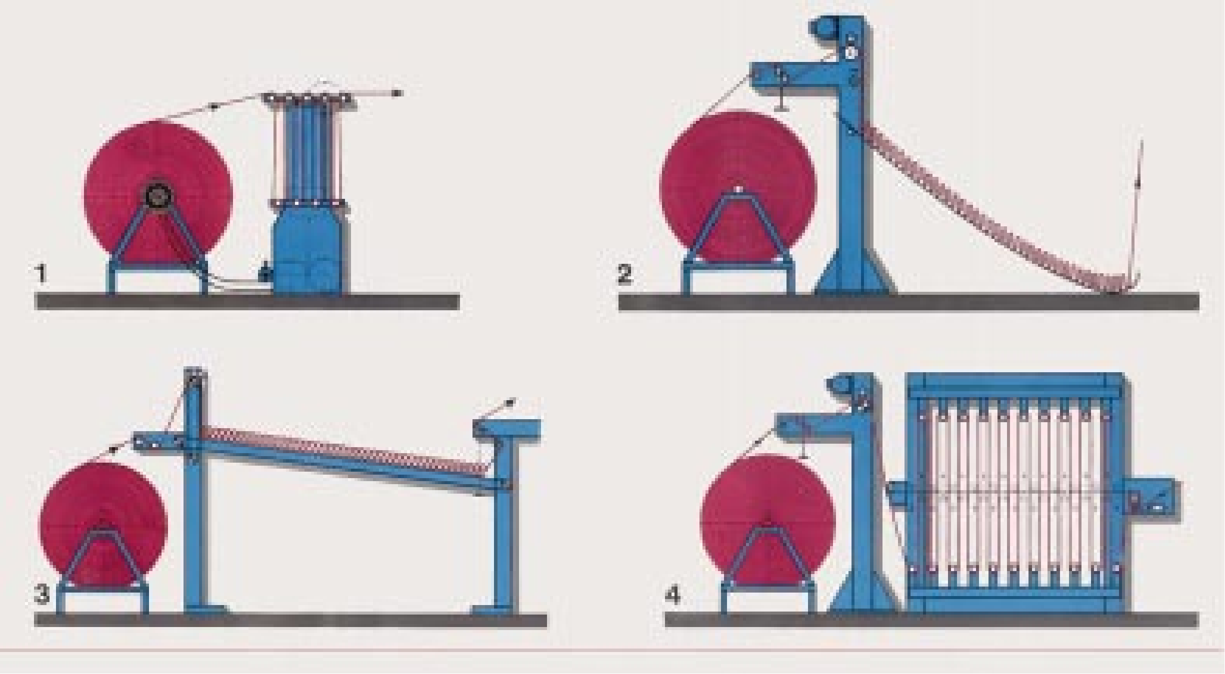

Fig. 2: Fabric accumulator examples (Krantz).
1 = large batch axial let-off with roller compensator; 2 = let-off unit with fabric trough; 3 = let-off unit and belt type fabric accumulator; 4 = let-off unit with chamber type fabric accumulator.

finishing machines. Advantages are increased productivity and more uniform processing.

Fabric bagging A fabric defect which can be caused, e.g. by milling. As a result, the longer interwoven warp or weft threads are milled to a greater extent than the shorter interwoven crossing threads.

Fabric batch → Batch roll.

Fabric batching machines → Batching machines.

Fabric clean flow wash process Two-stage hydrodynamic process performed in a Pullman laundering machine equipped with a vertical partition and a front-loading washing machine located on the same shaft. Operates with separate liquor flows, which are forced through the two internal drums. The capacity of the stage 2 internal drum is only 40% of that of the stage 1 drum. Since the liquors from stage 1 subsequently flow through stage 2 (overflow principle) there is 2.5 times more liquor on the wash load in stage 2 than is actually required to fill the drum. Stage 2 contains only fresh liquor, which changes from clear mains water to a caustic solution and then back to clear water as the temperature rises and then falls again. The hydrodynamic laundering process is suitable for the simultaneous washing of different kinds of laundry in one wash. Stage 2 is particularly suitable for heavily soiled goods.

Fabric cleaning and shearing machine Used to remove knots in loomstate fabrics using emery rollers and brushing rollers, with cropping of thread ends.

Fabric clean washing agent Detergent for clearing soiling (washing zone at maximum temperature, removes soil residues) in 2nd or 3rd wash bath using the multi-bath and hydrodynamic processes after wetting/prewashing. Compared to → Prescouring agents, clearing agents contain less alkali, a greater content of active detergent and optical brighteners, frequently also oxygen bleaches (sodium perborate, sodium peroxide).

Fabric compacting Compaction of a textile fabric, e.g. by relaxation of the yarn system or by felting as in → Milling.

Fabric content (cloth content). The fabric content of a textile processing machine or unit expressed either by length or by weight, e.g. the length of fabric (in metres) actually present in a continuous processing range (e.g. 15 m of fabric per roller vat), or in batchwise processing as the charge of material being processed (e.g. 100 kg. of fabric per tube in a jet-dyeing machine).

Fabric density

I. → Sett.

II. Signifies the apparent density of a woven fabric, e.g. densely woven cloth compared to loosely woven gauze, because the thread width in gauze is only a small fraction of the thread spacing. If the thread width is $^1/_5$ of the thread spacing, for example (calculated from the centre of a thread to the centre of the next thread) the "mesh" distance is 80%. With the same warp and weft thread density, the gauze is: $1–0.8^2 = 0.36–36\%$. In woollen and worsted cloths this is almost 100%, and somewhat lower in cambric. Fabric density in this case is a subjective factor that is rarely quantitatively evaluated. Fabric density should not be confused with → Sett. The thread density per running metre can be measured using lasers. Air permeability is also used as an evaluation criterion.

Fabric entry zone

I. General: equipment for the crease-free entry of piece goods on all textile finishing machines.

II. Specific: devices fitted to the entry zone of stenters such as overfeed, selvedge monitors, selvedge sensors, pinning-on systems, clipping-on devices, etc. (see Fig.).

Fabric feed device (automatic) → Fabric guiding/feeding device (automatic).

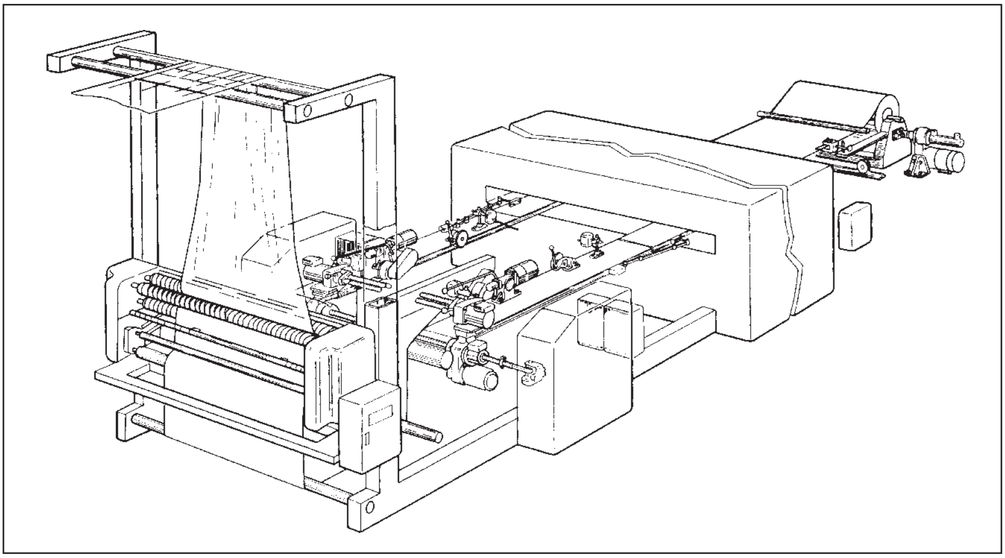

Fig.: Horizontal stenter fabric entry zone.

Fabric flow test → Fabric flow test (dyeing).

Fabric flow test (dyeing) Test for testing the fine distribution of disperse dyes that make extreme demands of fine distribution and stability in dye dispersions. The prepared dye liquor containing the product or disperse dye to be tested is pumped through a relatively large number of cylindrically arranged circular samples of polyester/viscose or polyester/wool fabric. Subsequently the separated fabric pieces are evaluated for their filtering action (deposits and fibre loss), shade and cleanliness.

Fabric folding machine Machine for folding piecegoods in layers of defined width and stack height (Fig.).

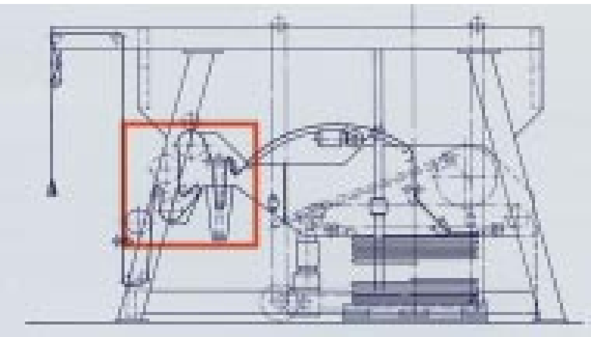

Fig.: Menzel fabric folding machine.

Fabric guiders (cloth guiders). Devices for the sideways control of fabric passage in a pre-progammed horizontal or vertical direction. Guiding elements with axially-movable profiled slats. Also expander rollers used especially for uncurling fabric selvedges, as well as swivelling rollers for the control of fabric direction. The reliable, crease-free, guiding of fabrics is a decisive quality factor for fast-running textile processing machines. Fabric guiders must be suitable for use under the widest possible range of applications as they are often exposed to caustic liquors, acids, moisture and heat. These conditions must not impair the function or precision of fabric guiders. The variety and specific properties of the materials to be processed make different control systems necessary.

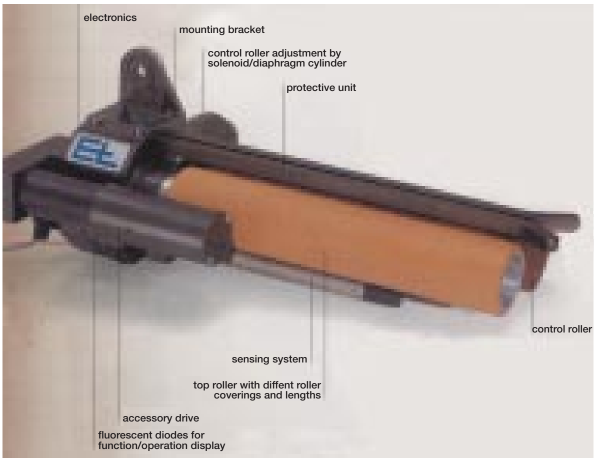

Fig. 1: Erhardt and Leimer fabric guides.

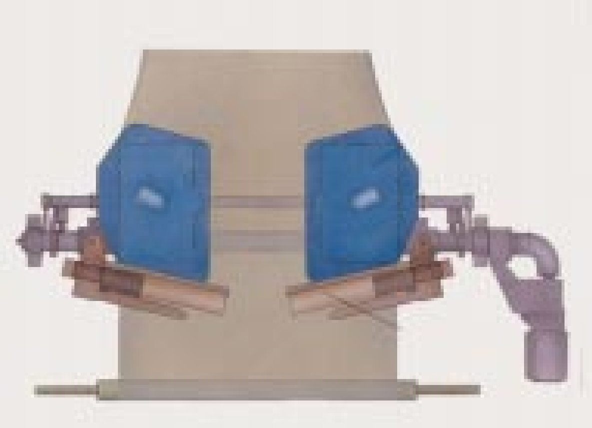

Fig. 2: Single jersey fabric guide with air jets in the top plate.

Fig. 3: Air jets on both sides in the spreader system.

Pneumatic selvedge uncurlers (Fig. 1) are used for uncurling and guiding surface-sensitive woven and knitted fabrics with curled or creased selvedges which cannot tolerate the mechanical contact of screw-spindle guiders.

This system is available in three types based on the use of air nozzles:

- with air nozzles in the lower plate for curled edges on the side of the guide rollers,
- with air nozzles in the upper plate for curled edges on the side of the upper roller (Fig. 2),
- with air nozzles on both sides (Fig. 3).

The air supply is provided by a blower with a high flow capacity and low pressure.

The selvedge uncurler is equipped with three motor-driven screw-type spindles (Fig. 4). The curled or creased selvedges of woven and knitted fabrics are

Fabric guiding/feeding device

Fig. 4: Selvedge uncurler with three threaded spindles.

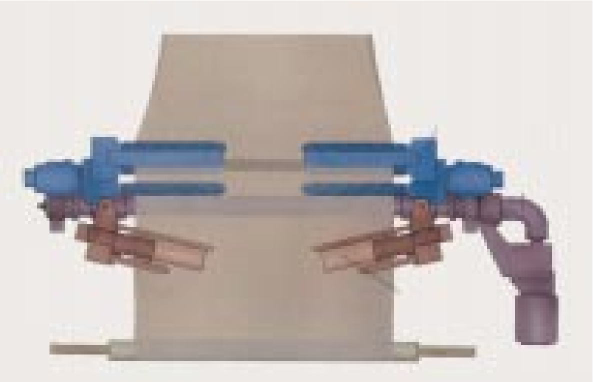

Fig. 5: Holding double jersey out to width.

opened as a result of the intensive uncurling effect above and below the fabric. Because of the swivel arrangement of the first screw-type spindle, the angle of contact and therefore the uncurling action, is progressively adjustable. By this means, double-jersey fabrics can be readily maintained in the open-width state (Fig. 5).

Fabric guiding/feeding device (automatic). Used to introduce pieces into open-width treatment machines (stenters, padders, jiggers, continuous bleaching and dyeing equipment) in an open-width state and for unrolling the selvedges of woven and knitted fabrics.

Fabric guiding systems These include entry frames, rollers, fabric guiders, guide rods, fabric spreaders (expanders), variable tension rails, reels and conveyors. Among other systems, the pin wheel used in weft straighteners represents a typical element (Fig. 1).

The correct choice of guiding system ensures the appropriate presentation of textile material (loose fibre, yarn, fabrics or made-up garments) to the mechanical and/or physico-chemical influences of the treatment medium or the finishing machine. The machine is in contact with its surroundings and the textile material by means of measurement devices and automation as well as with the treatment medium and chemical metering system. Appropriate sensors in fabric guiding applications for the development of true closed loop controls are only available to a certain extent at present.

The guiding system can be discontinuous (with machine set-up times) for batchwise operation or continuous (for long runs).

If there is movement of both the medium as well as the textile material in a particular treatment system, guidance of the material is determined by the form in which the material is being treated. Thus, loose fibres can be suspended in the medium or allowed to float in it. Combed tops or warp sheets may be wound or run continuously through the medium. Packages (yarn or fabric) are normally immobile during treatment whilst the treatment medium (liquor) is forced to flow through the package. Fabrics can be gathered in the width and processed in rope form. If fabrics are processed in the open-width state, the treatment is carried out either in tight strand form (under tension over rollers or spreaders) or in a loose (free) form (Fig. 2) where the fabric is usually plaited in the lengthwise direction on to transport systems (conveyors, roller-beds, underliquor zones). In the finishing of made-up items of clothing, the textile material (e.g. in the form of garments) is moved through the treatment medium either mounted on formers (as in hosiery dyeing machines) or in a loose random state (as in the paddle dyeing of garments).

4 = continuous chain of carrier rails.

Fabric handle A large number of subjective and objective physiological and physical characteristics are involved in the determination of fabric handle. From various studies on correlations between the handle characteristics determined by subjective and objective means, it has been found that the measurable characteristics of stiffness, bulk and surface smoothness play a particularly important role in determining the handle of a textile material.

The tactile properties of textile fabrics, described by characteristics such as “handle”, “bulk”, “softness”, etc., are extremely important for the evaluation of fabric quality. With outerwear fabrics in particular, an equally high value is placed on these characteristics as on the colour of the fabric for example. However, although the coloristic properties can be measured objectively with the aid of spectrophotometers quickly and easily, the tactile properties of fabrics are still measured by subjective means, e.g. according to the prevailing mood and personal taste of the person carrying out the evaluation. This evaluation procedure lacks any semblance of objectivity at least when compared with the assessment of colour even when, for cost reasons, the advantages of a colour measurement system have to be dispensed with, and the assessment is carried out visually by means of standard illuminants and specified viewing geometry.

The Kawabata Evaluation System for Fabrics (KES-F-System), developed in Japan, represents an instrumental system specifically designed for objective evaluation of the tactile properties of woven fabrics which in Europe, however, has mainly found application as a research tool up to now. Because of the rather cumbersome and time-consuming test procedures and high cost of the instruments required, the KES method has so far not been commercially accepted on a wide scale in Europe (→: Kawabata system; Kawabata system of handle assessment).

In the meantime, other instrumental systems have been developed, with the aid of which those fabric properties that influence the tactile character of a woven fabric can be determined. These include the FAST (Fabric Assurance by Simple Testing) system and the ITV test system for tactile properties/fabrics (ITV-PTE/F). The FAST system was not designed originally for the evaluation of tactile properties, but primarily to assess the performance of woven fabrics in making-up. The ITV-PTE/F system was indeed developed for the determination of tactile properties although, in this case, the intended application was for nonwovens.

Fabric inspection machines In order to relieve the fabric inspector of as much manual work as possible, fabric inspection machines must perform the following functions (Fig. 1):

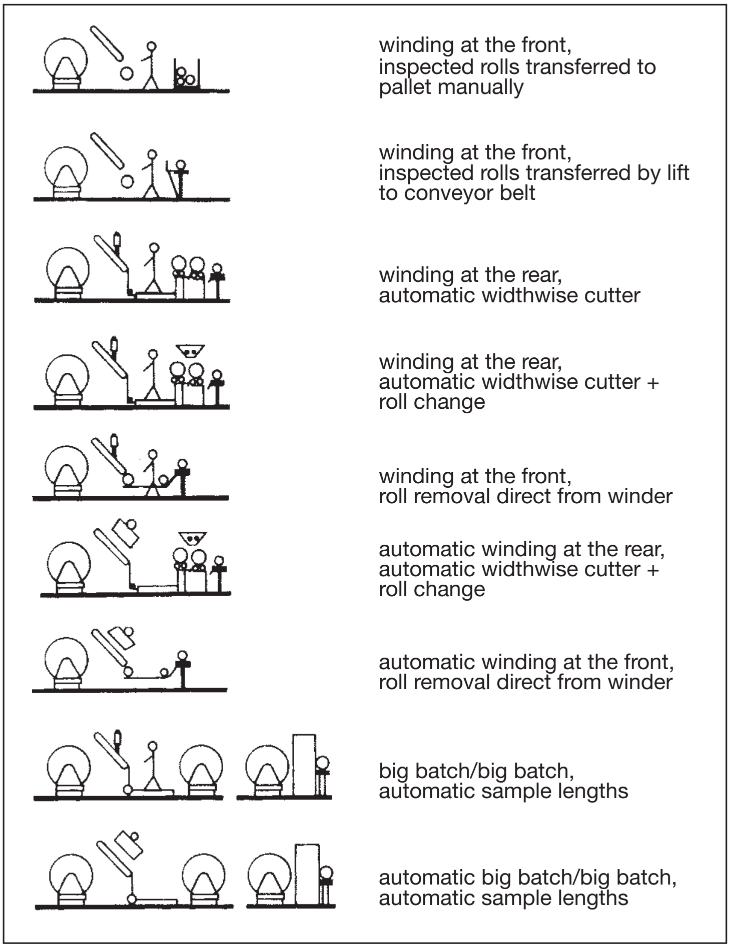

Fig. 1: Overview of fabric inspection concepts widely used in the textile industry (source: Silbernagel).

Fabric inspection machines

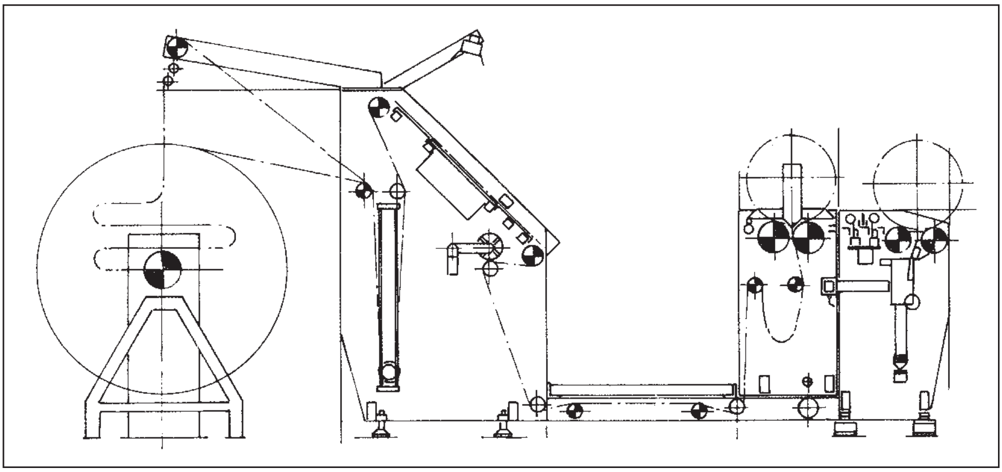

Fig. 2: Fabric inspection with unwinding of fabric from batch roll via rising roll batcher (Holthausen).

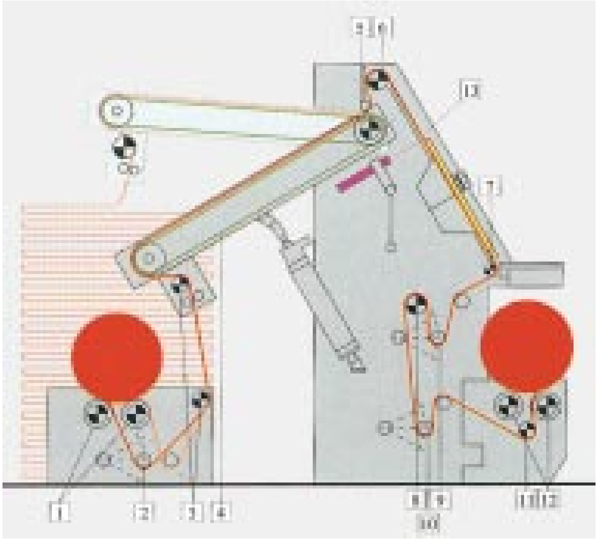

Fig. 3: Inspection machine (Menschner).
1 = unrolling cylinder; 2 = dancer with control for unrolling; 3 = spreader roll; 4 = transport belt; 5 = dancer with control for transport belt 4; 6 = transport roll; 7 = driven guide roll; 8 = transport roll; 9 = dancer with control for transport roll; 10 = dancer with control for rolling; 11 = spreader roll; 12 = rolling cylinders; 13 = measuring device.

- unwinding of fabric from batch roll via rising roll batcher (Fig. 2);
- delivery of inspected fabric rolls on to conveyors;
- automatic fault marking with automatic selvedge guiding system for the attachment of self-adhesive labels during fabric passage through the inspection machine;
- recording of faults during fabric inspection;
- automatic control of fabric width and automatic calculation of fault reimbursement;
- inspection by reflected and transmitted light with photoelectric support.

To simulate all the working functions of a human fabric inspector by means of a fully-automatic fabric inspection machine has not proved possible up to now because of the superior parallel calculating ability of humans compared to the linear operations of computers. At present, therefore, no fully automated fabric inspection machines are available in the market. Developments in measurement techniques for automatic inspection machines have been based on a virtually complete takeover of the fabric inspector's tasks by the system, i.e. the detection of faults, classification of fault types, geometric classification and recording of data.

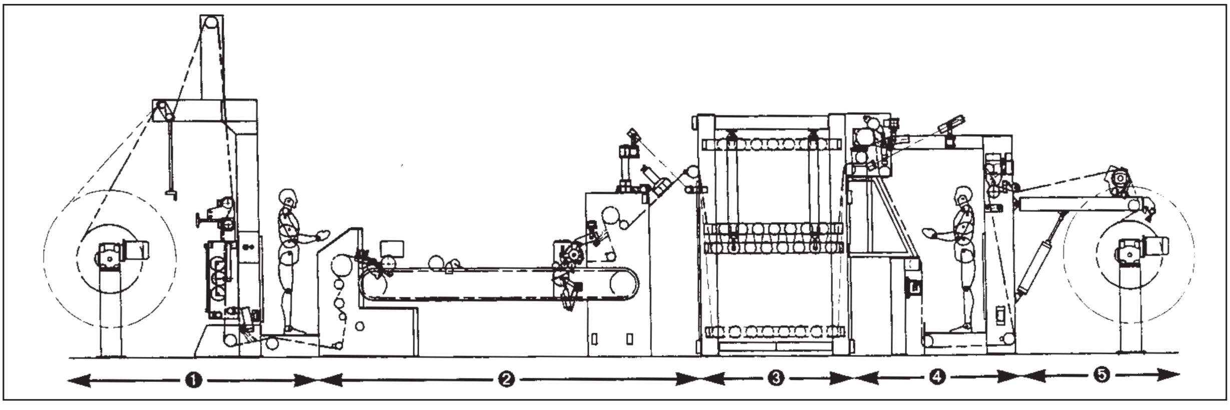

Fig. 4: Inspection unit (Erhard & Leimer).
1 = inlet; 2 = over feed shrinking and relaxation; 3 = fabric store; 4 = inspection; 5 = winding.

With fully automatic operation, there is no opportunity to carry out any corrections on the inspected fabric. In practice, it has been found that fabric inspection systems of this kind are associated with considerable technical problems and financial outlay, and often do not provide the desired efficiency and versatility.

The use of measuring technology solely for the independent detection of any deviations in the fabric appears to be a worthwhile alternative, thereby relieving personnel of actual fabric inspection. This concept allows fault classification and the reporting of data, even if technically assisted, to remain in today's well-established form. By this means, the operatives are relieved, above all, of the lifting operations involved (Fig. 5).

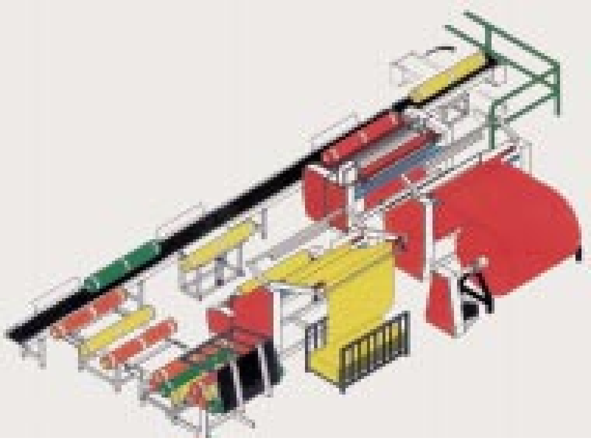

Fig. 5: Fabric inspection and making up system by ICBT.

An appropriate measuring technology performs the task of recognizing localized deviations in the fabric from fault-free material and, e.g. brings these to the attention of the fabric inspector by stopping the machine and emitting a warning signal. In the interests of technical preference, surface-related measuring technology is desirable for this purpose such as the modern image analysis methods or applications of moiré interferometry currently available. By employing appropriate image fields of individual data units (CCD cameras), the entire fabric width can be captured with just a few systems (Figs. 6 + 7). The problem up to now has been the high computing complexity, especially with regard to image analysis and the computing capacity necessary for real time measurements.

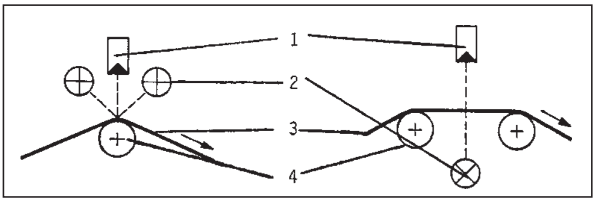

Fig. 6: Inspection by reflected light (left) and transmitted light (right) in photoelectric fabric inspection (Hell system). 1= photo element; 2 = light source; 3 = fabric path; 4 = guide rolls.

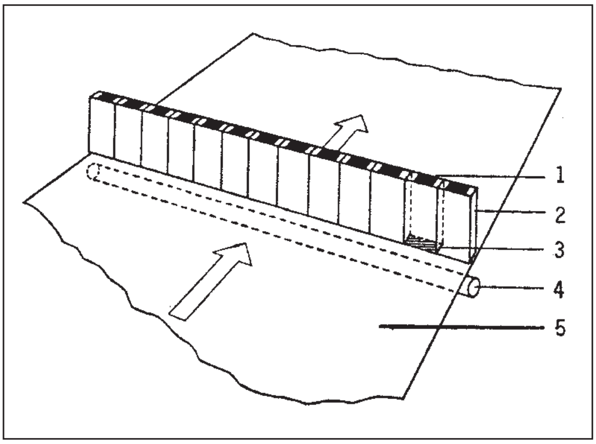

Fig. 7: Line-by-line scanning of the fabric width by means of photoelectronic inspection (Hell system). 1 = photo element; 2 = optical fibre rod to the photo element; 3 = visual range of the photo element; 4 = rod-shaped light source; 5 = fabric path.

Neural computing structures represent another alternative with a promising future. Specific algorithms capable of imitating the processes of human vision convert the imaging information into simple displays based on, e.g. one or more parameters. This image characterization is carried out in real time with the aid of hard-wired programs so that rapid image sequences (up to 50 Hz) are recorded and analyzed. The system should respond to deviations of measurements from the normal values, beyond set tolerance limits, with a standard signal, e.g. for a machine stop, or an acoustic signal to let the inspector know that an irregularity has been detected.

At present, three possible types of sensor are used in practice:

- laser scanner (telecentric and divergent),
- light scanner
- CCD camera systems.

1. Laser scanner: this consists of a laser light source (helium/neon or diode). The light beam is guided across the fabric path at high speed (approx. 6 km/s) with the aid of a polygonal reflector wheel. The scanning frequency is 3 kHz, i.e. the fabric path is scanned 3000 times per second. The size of the light spot is variable and lies between 0.1–2.5 mm. The laser scanner is suitable for reflectance and transmission measurements by the variable allocation of one or more receiving systems. In the case of the divergent scanner (Fig. 8), the focal plane and the fabric level can be made to coincide with the aid of special optics and a constant scanning speed is achieved. The angle of incidence of the inci-

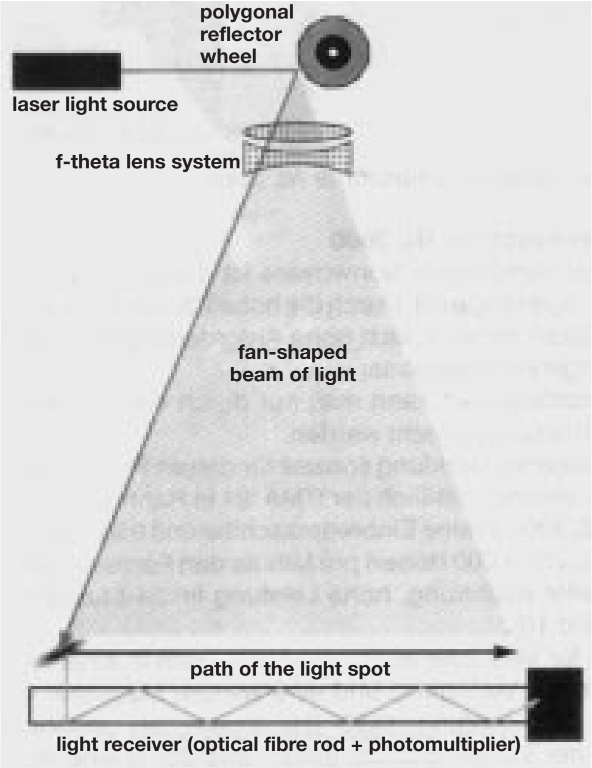

Fig. 8: Divergent scanner (opolix Opto Electronic GmbH) for fabric inspection.

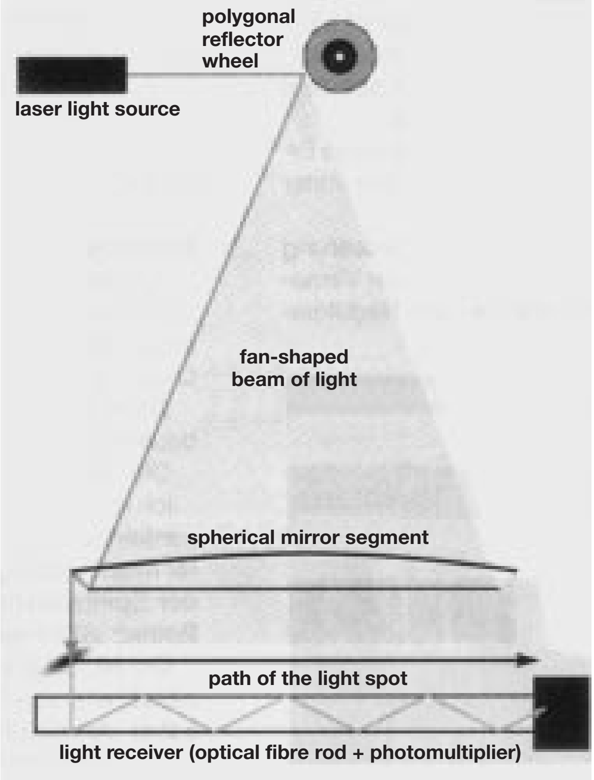

Fig. 9: Telecentric scanner for fabric inspection.

dent beam changes with the scanning location. With the telecentric scanner (Fig. 9), the angle of incidence over the scanning width is kept constant by means of a large optical element. Fabric widths greater than 2000 mm may be scanned more economically with the divergent scanner without having to accept any significant losses in fault detection. The telecentric scanner offers advantages with denser and more voluminous fabrics. Optical fibre rods which capture the transmitted or reflected light and conduct it laterally to a photomultiplier are used as receivers. Depending on the nature of the task to be performed, several such receivers can be used in parallel.

2. Light scanner: this is a scanning system in which the optical path length is contrary to that of the laser scanner. Instead of spot illumination, the entire fabric field is now illuminated with a more or less broad band of light. The advantage of the light scanner is the modular build up from 120 mm to over 6000 mm inspection width; it uses white light (fluorescent tube lighting). Because of the broad spectrum of the fluorescent lamps employed, application-specific spectral ranges may be selected which result in an extended range of appli-cation.

a) Transmission method: it is preferable to use this type of measurement if holes, thick or thin places, light or dark stains, or irregular fibre distribution have to be detected. For this purpose, fluorescent tubes are installed underneath the fabric path and the scanner, mounted above the fabric, is irradiated with their light after it has passed through the fabric. The fabric path is scanned by the scanner at high speed in 120 mm widths each time which converts the received light signals, after application-specific filtering, into electrical signals by means of photosensors which are processed by the evaluation electronics after amplification. Any width of fabric may be inspected by a combination of scanner modules. The chosen method of light guidance provides the light scanner system with a high depth of focus with the result that it is insensitive to fluttering movements.
b) Reflection method: with this procedure, surface defects in coated or uncoated materials can be detected. In this case, the light source and the scanner are mounted above the fabric path. The light reflected from the fabric is, in an analogous manner to the transmission method, detected by the scanner, converted into electrical signals and transmitted to the computer located in the evaluation unit. Through application of the so-called “averaging” process in the evaluation, even fine lengthwise faults may be analyzed. For this purpose the computer generates a fault signal average from numerous “scans” which results in a considerably improved signal-to-noise ratio. An exceptional feature of this system is its value in the field of coated interlining materials

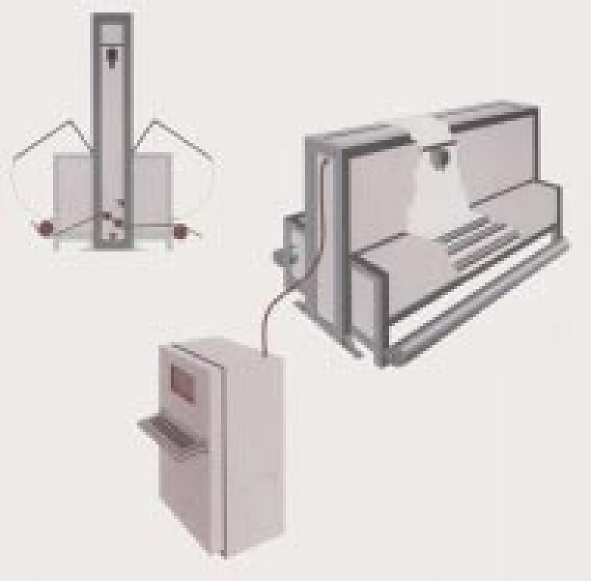

Fig. 10: Typical fabric inspection concept based on image processing with video cameras as in the EVS system.

resp. nonwoven interlinings. It is a prerequisite for these products that the base material contains no optical brightening agent, and that the coating compound (paste or powder) must be enriched with optical brightener and can be used with 11–30 mesh.

sensor type	advantages	disadvantages
laser scanner	● high optical resolution (0.1 mm) ● high line scanning frequency (→ 6 kHz) ● system data rate > 100 MHz possible ● point-synchronous parallel receiving channels possible ● angle of incidence constant (telecentric) ● many years experience with the system	● monochromatic, blind to some coloured faults ● high mechanical complexity (telecentric, up to now) ● limited scanning range (telecentric) ● joining together is problematic ● expensive (up to now) ● photomultipliers used as receivers (up to now)
CCD camera	● no movable mechanics involved ● suitable for colours with white light illumination ● telecentric imaging possible ● simple modular solutions ● long service life of sensor	● high power illumination necessary ● limited scanning rate ● number of pixels limited, i.e. supplementation necessary ● multi-channel reception channels are not point-synchronized (mechanical adjustment problems)
light scanner	● suitable for colours with white light illumination ● simple modular solutions ● long service life of sensor ● high system data rate possible ● suitable for dot-coated nonwovens	● high power illumination necessary ● limited scanning range, i.e. supplementation necessary

Table: Comparison of sensor types used in automatic fabric inspection (source: Schollmeyer).

3. Image processing with video cameras: this system is based on an illuminating unit consisting of a conventional light source and a cylindrical mirror which together produce a sharply defined band of light on the textile surface along the line of inspection. Both the reverse and face sides of the running fabric are monitored by cameras (Fig. 10), in which the illuminated inspection line is imaged by a diode array. Whilst one camera records the image of an illuminated inspection band by transmitted light and therefore detects holes, thin places, etc., among other things, the second camera records the image of the light band by reflection using such a flat angle of observation that all faults projecting above the surface of the fabric such as slubs, stains, creases, etc. are detected by the split beam process. The camera is provided with a diode array of approx. 4000 points so that the smallest recognizable faults of 1 x 1 mm can be detected over an inspection width of 2000 mm. A comparison of different sensor types is given in the table (source: Schollmeyer and Schicktanz).

Fabric length According to DIN: the length between two fully interlaced weft threads measured parallel to the warp at both ends of the fabric in a relaxed condition. The fabric length does not include the zones at the start or end of the piece.

Fabric opening machines →: Tubular fabric slitting machines; Rope opener.

Fabric relaxation → Relaxation.

Fabric slitting device → Cutting of textile fabrics.

Fabric slitting equipment Used for separating running fabric webs in the middle and into strips. Installed on production machines.

Fabric softener (Washing softener) → Washing aftertreating product for preventing boardy handle resulting from washing in a rotary washing machine with a lot of mechanical action and drying in still air. Provides considerable improvement to the handle of washes, provides full softness and makes synthetic fabrics antistatic by using fabric softener in the form of emulsions of mainly quaternary ammonium compounds, (such as distearyl dimethyl ammonium chloride), as a dilute aqueous emulsion, in the final rinse. Fabric softeners can be applied in varying percentages, can be washed out and prevent dye and pigment redeposition. They also have a soil-release effect on fat or pigment/fat soiling and make ironing easier. Practical conditions for fabric softeners: liquor ratio 1:5–1:7, liquor temperature after 5 rinse cycles around 15°C, addition 3–6 g/kg of washload, time 5–10 min.

Fabric softeners Special softening agents (→ softeners) in liquid ready-for-use form, sometimes containing fluorescent brightening agents. Applied in the final rinse after washing in commercial laundries and in household washes in order to achieve a soft handle, antistatic effect, and easier ironing. Since the introduction of drum type washing machines (relatively high mechanical stress) fabric softeners have been used on an increasing scale in order to prevent harshness of handle due to → Drying stiffness. The effect can also be observed visually with e.g. terry fabrics washed under comparable conditions: in the absence of a fabric softener the loop-pile surface appears quite irregular. In the presence of a fabric softener, however, the loop-pile has a much more even appearance.

Fabric speed control Systems to control fabric speed between two processing machines or machine elements in order to achieve a uniform fabric throughput.

Fabric spreading machines Machines used in garment making to unwind rolls of fabric and spread out the material for cutting. The machines are usually combined with measuring and cutting devices.

Fabric stabilisation In controlling the width of fabrics during drying on a stenter frame, a varying extension occurs from the centre to edge of the fabric (Fig. 1), which has a negative effect on the quality and subsequent processing of goods. In the early 1970s, a stretch method was devised by Raduner & Co., under the name ML (micro-expansion) process; this was later developed further in cooperation with Küsters. The principle is as follows: Through the adhesion of the goods on the surface of a roller, the fabric is stretched through the mutual penetration of the two combing rolls (Fig. 2), and after this pre-stretching process it is pulled to the new width (stretch width) by means of spreading devices. This functional principle of many small extensions gives the desired even stretching over the full width of the fabric.

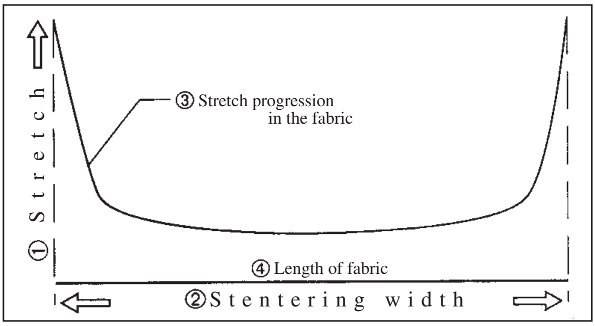

Fig. 1: Stretch progression over the width of the fabric when expanded on a stenter frame.

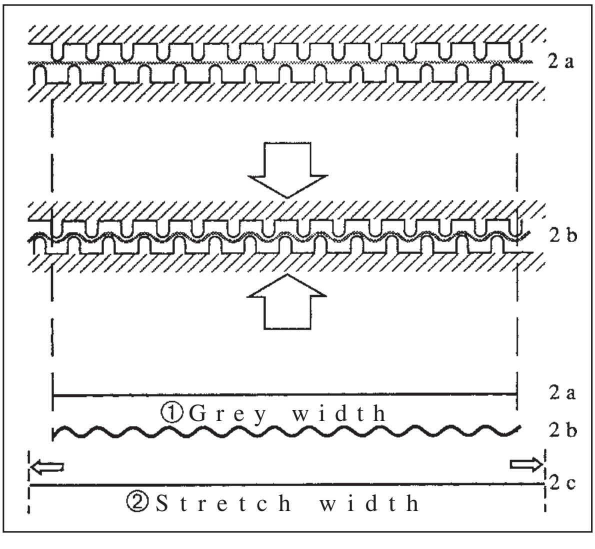

Fig. 2: Functional principle of stretching with two combing rolls.

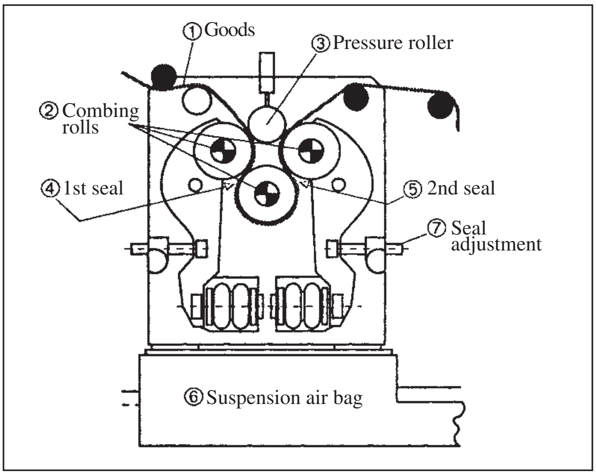

Fig. 3: Running of goods over the combing rolls of the Memotex machine (Küsters).

A uniform effect requires that the fabric is made extensible before processing by means of a swelling process. The macroscopic orientation (parallelisation) of the fibres is further fixed by the swelling process.

Two prerequisites are fulfilled by the Memotex machine concept (Fig. 3):

1. A fabric contact angle of more than 180° on the roller gives fixed cloth guidance.
2. Through a pressure roller, both the warp and weft are held evenly on the combing rolls. The pressure roller is pressed against the combing roll, and thus fixes the length of fabric on the surface of the rollers, which comb into one another.

Fabric straighteners Devices for straightening distorted fabric webs. → Weft straightening.

Fabric straightening machine → Straightening machine.

Fabric tension control A system for tension-free running of woven fabrics in continuous machines. The control functions are designed so that drives (DC motors or geared servomotors) as well as brakes (pneumatic or electric) can be controlled. An additional pneumatic unit is available for use with control systems for pneumatic brakes. Up to 6 brake callipers can be connected to it with a selected logic control (see Fig.).

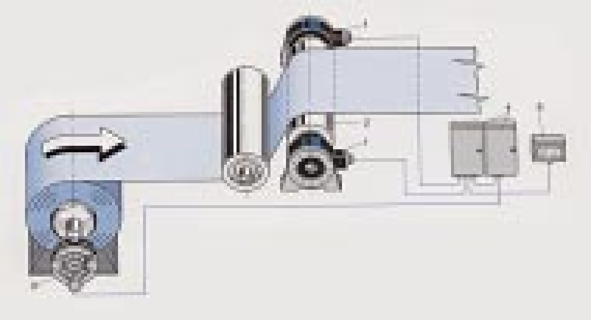

Fig.: Fabric tension plant of Erhard & Leimer.
1 = transducer; 2 = measuring roll; 3 = brake; 4 = control system with pneumatic unit; 5 = digital display.

Fabric tension measurement A system to determine the tractive forces acting on webs of fabric, e.g. by means of the Elmess web tension measuring system with a PD 21 transducer (Fig. 1): this determines the force produced by the tension of the web on a measuring roll where the angle of wrap between the web of fabric and the measuring roll should be 60–180°. The transducers on each side of the roll are connected via four wire cables to an electronic amplifier which evaluates the signals.

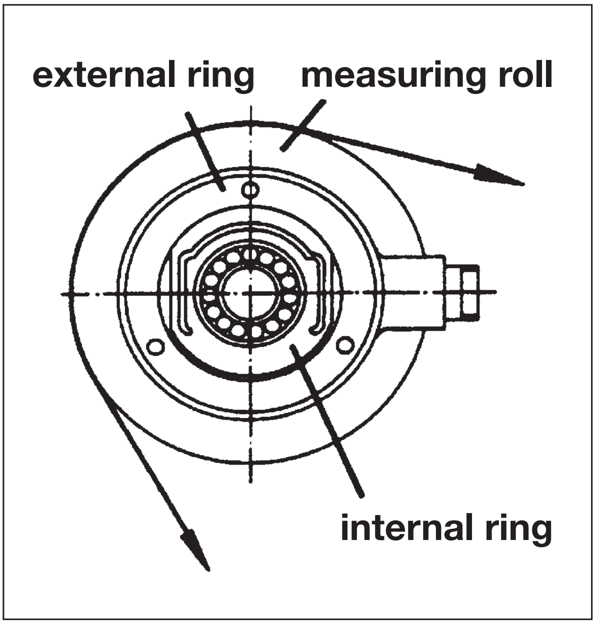

Fig. 1: Structure of the PD 21 for the fabric tension measurement (Erhard & Leimer).

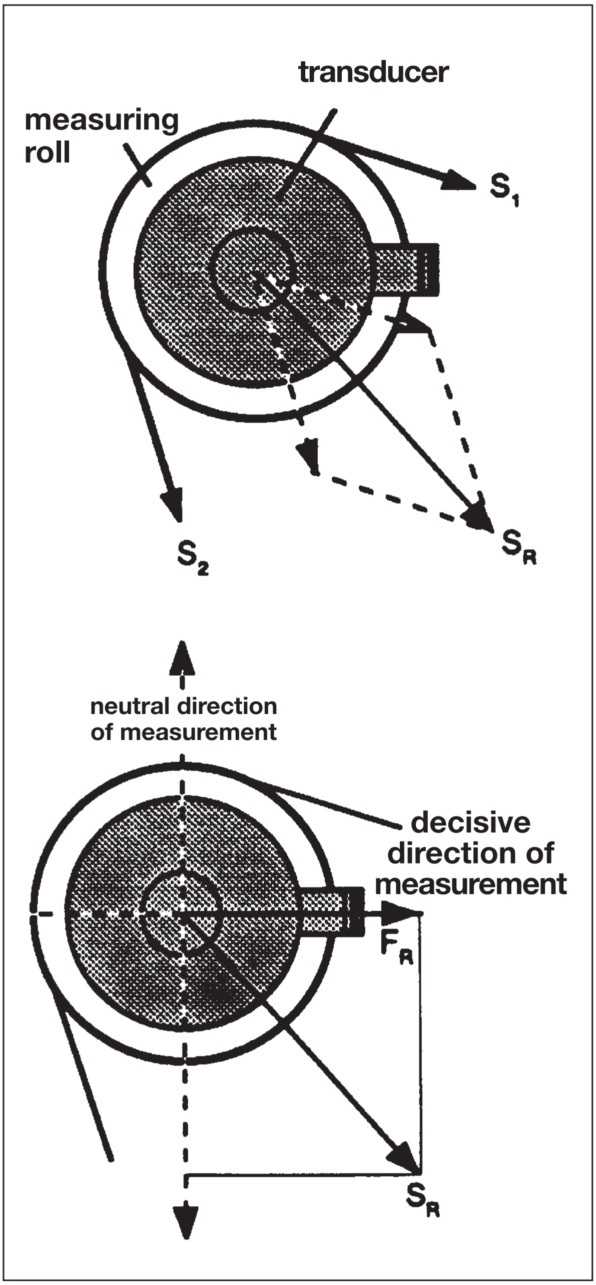

Fig. 2: Principle of measuring of the PD 21 (Erhard & Leimer) for the fabric tension measurement.

The transducer consists of an external and an internal ring and two flanges. Centring rings on both flanges make it possible to install the transducer precisely. The internal ring is designed to function as a measuring instrument; it also supports the ball bearing of the measuring roll. The measuring element itself consists of a double transverse beam assembly to which tension measuring strips in the form of a full electrical bridge are applied. Fixed stops protect the transducers against overloads up to 10 times the nominal measuring range. A stabilised direct current voltage from the electronic amplifier stores the balanced tension measuring strip-full bridge measurements. This bridge is “detuned” by the web tension and its output voltage is altered. The output voltage represents a signal which is proportional to the web tension force.

Both the web tension forces S_1 and S_2 are added together to give the resulting value S_R. Only the force component F_R acting in the direction of measurement is decisive for measuring the web tension (Fig. 2). The direction of measurement corresponds with the direction to the connector. All forces acting at right angles to this direction of measurement are not taken into account for the measurement of web tension (neutral direction of measurement). For example, the weight of the measuring roll itself no longer plays any part if the transducers are installed horizontally. Since the weight of the measuring roll acts in a downward direction, this force lies exactly in the neutral direction of measurement.

Fabric thread-up length The total length of fabric drawn over the rollers and/or suspended on rods in a textile finishing machine (e.g. steamer).

Fabric throughput For open-width processing machines throughput is expressed by the hourly throughput in dry weight per metre fabric width (kg/h/m). Fabric throughput is proportional to the weight/m^2 and the running speed.

Fabric transport

I. In-house: → Transport systems.

II. In processing machines: → Fabric guiding systems.

Fabric weight (cloth weight). Fabric weight may be expressed either as the weight per piece, per running metre, or per unit surface area.

I. Weight per piece or bale weight: the weight of an entire piece.

II. Weight per running metre: quotient of the weight of a full-width cutting of fabric (with or without selvedges) and its length. Since lightweight fabrics are currently of interest from the fashion point of view, efforts are made to reduce the weight per running metre, e.g. of wool fabrics (150 cm width) by suitable means. The use of fine yarns, either as single yarns or ply-yarns, and tighter weave constructions reduce the weight of wool fabrics within the region of 200 g per running metre. Fabric weights below 200 g per running metre are obtained with fine wool fibres of less than 20 µm (see Fig.). Because of the low number of fibres in the yarn cross-section, however, single yarns in the warp must be sized before weaving.

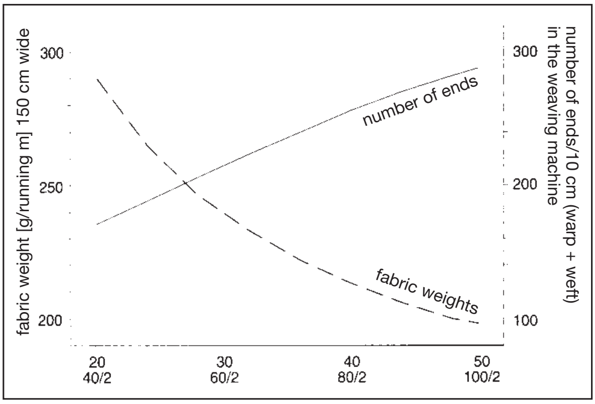

Fig.: Interrelationship between fabric weight and yarn type and number of ends.

III. Weight per square metre: quotient of the weight and length of a single layer of fabric without selvedges. → Fabric weight measurement.

Fabric weight measurement State of the art methods allow the continuous measurement of fabric weight on moving runs of fabric, based on the principle of mass-dependent absorption of a beam from a radioactive isotope passing through the fabric (see Fig.).

Absorption is calculated according to the following formula:

$$J = J_0 \cdot e^{-kF}$$

where

J_0 = radiation capacity of the source
J = residual radiation remaining after absorption by the fabric
F = fabric weight
k = material constant.

The nature of the radiation source, i.e. of the radioactive isotope, depends on the fabric weight that is to be measured. For the range of 500–5000 g/m^2, which is required in the carpet sector, an isotope of strontium (strontium 90) is usually used. This emits beta radiation (electrons) that, after passing through the goods, can be detected by means of an ionisation chamber. The strength of the ionisation current caused by the beta radiation is a measure of the material thickness in the measurement cross-section; thus with corresponding calibration it is also a measure of the fabric weight of the run of fabric passing through. Since with this measurement, the whole fabric is covered, to determine the weight of a coating, a differential measurement must be carried out; in other words, the weight before coating and the weight of the coated goods must be determined. The difference be-

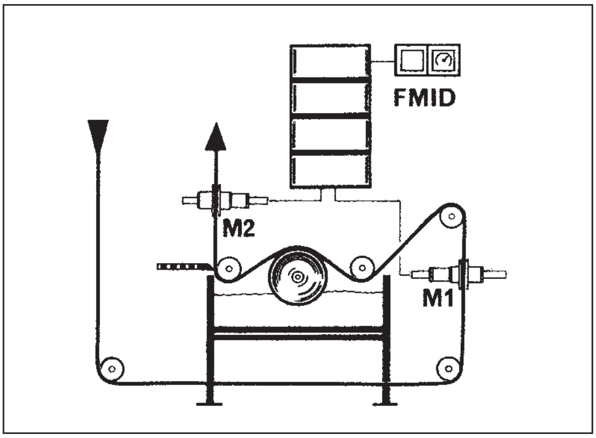

Fig.: Diagram of a fabric weight differential measurement plant, for determining coat weights (Mahlo).

tween the two values yields the coat weight. It is important to note that only comparative values are measured and a system for entering the fabric start weight for the difference calculation is required.

The measuring accuracy of the radiometric fabric weight measurement is better than 1% of the coat weight. In modern equipment, the natural decay of the radiation source, which within the half-life of the isotope leads to a reduction in the radiation intensity to half the initial state (approx. 27 years in the case of strontium 90), is compensated by automatic calibration. Furthermore, both the actual weight of the coat and its deviation from a set target value can be displayed digitally. The digital display of the raw weight and of the total weight is also possible. Devices such as these, which use isotopes, are subject to strict regulatory control and must have their approval continually renewed at regular intervals (source: Schellenberger).

Fabric widths Commercially conventional widths:
130 – 150 cm wool fabrics for outerwear;
80 – 90 cm silk materials;
75 – 200 cm bedding;
40 – 130 cm household linen;
80 – 130 cm tablecloths;
20 – 50 cm handkerchiefs;
80 – 140 cm materials for industrial clothing;
60 – 140 cm velvets;
70 – 80 cm shirtings,
trend toward standardisation of 150 cm.

Face-to-face carpets (double plush carpets). Carpets that are manufactured as a "sandwich" in a single operation, whereby the pile is attached to two substrates, one above the other. The pile weft forms the pile between the two warps, and two cut pile carpets are produced by cutting the pile yarns between the two substrates direct on the loom.

Face-to-face Tournay carpet (double Tournay). A → Face-to-face carpet produced on jacquard looms.

Fachgemeinschaft Textilmaschinen im VDMA → Technical and professional organizations.

Facing in roller printing A defect in roller printing caused by a printing roller with an inadequately polished surface (i.e. unsatisfactory smoothness): in this case the print paste is not entirely removed from the roller surface by the doctor blade leaving a fine film which is transferred to the fabric being printed causing the latter to be lightly stained in the unprinted areas. A similar defect can also be produced if the pressure applied to the doctor blade is not correctly adjusted.

Façonné A fancy material with a small pattern (including velvets and plush fabrics) of varying fibre types for scarves, blouses and ladies' cocktail or evening dresses.

Fade-Ometer Laboratory testing device used to determine the fastness of a coloured textile material to light exposure. → Light fastness.

Fading Loss of colour in dyeings and prints as a result of → Photochemical reactions.

Fagara silk (atlas silk). A → Wild silks produced by the atlas moth (East Asia). Similar to tussah silk, light brown in colour. Used for schappe spinning.

Fahrenheit scale (°F). A temperature scale invented by the German physicist, G. D. Fahrenheit (1686–1736) in which the separation between the freezing point (32°F) and the boiling point of water (212°F) at standard atmospheric pressure is divided into 180 equal parts.

Conversion into °C: $°C = (°F - 32) \cdot {}^{5}/_{9}$.

Faille A fine, cross-ribbed, poplin-like dress and coat fabric (silk, half-silk, viscose filament and staple fibres) in taffeta weave. Faille Français: pure silk, delicate and fine-ribbed. Faille-luisant: iridescent sheen. Luxury faille: fine-ribbed viscose filament with lustrous and matt sides. Faille-mirage: moiré appearance, viscose filament in the warp, metallic yarn in the weft. Faille-reversible, Faille-satin: 2-sided effect lightly ribbed and smooth on the reverse. Failletine: similar to Faille Français, very fine ribbed and delicate.

Fallen wool Wool originating from dead sheep. Is generally removed from the skin using lime before tanning. Its affinity to dyes differs from that of → Virgin wool.

Fallers Protrusions on a drum interior surface which turn and submerge the item being treated during drum rotation, thus increasing the mechanical action. Number of paddles usually 3 equally spaced. Shape of paddles (e.g. trapezoidal or flat) and height should not exceed a certain size, since otherwise the narrowing of the space available for movement would have a detrimental effect. High rotation speeds therefore require lower paddle sizes, which has proved to be more important than increasing the number of paddles. Experience has shown the most efficient paddle height to be ${}^{1}/_{3}$ of the drop height.

Fall height Function of action in application baths, e.g. the washing mechanism in drum washing machines (→ Drum partitions). Fall height = drum diameter in m – liquor level in the drum in m.

Fall-on in printing A partial overprint of a preprinted print paste by another print paste, e.g. a preprinted black outline overprinted with a coloured print paste, or the overprinting of one coloured print paste by a print paste of a different colour = combination shade.

False brocade In contrast to a genuine brocade, this is a woven fabric produced on normal looms where the brocade effect is formed as a rule by a second warp or weft thread system with figuring threads. "False" brocade produced on looms without a swivel embroidery sley can be recognized by its low mechanical resistance: the threads are easily drawn out of the fabric.

False selvedge chain Small support belt (linen warp) for men's ready-to-wear products.

False twist → Texturizing.

False twist yarn (textured) Higher speeds are being accomplished equally via machine and feedstock. Back in the 1970s the machine maker supplied machinery capable of achieving higher speeds whilst feedstock producers provided material that could easily be processed at these higher speeds – or if necessary at even faster speeds. Today the situation is reversed and machines have still greater reserves, being designed to operate at 1500 m/min (Fig. 1).

In order to make full use of the potential the feedstock must be improved. Research is concerned with producing still more uniform yarns by improvements in polymer and spinning process. Spinfinishes are being improved, application rates made more even and thread levelness better in order to attain a more advanced level of speed free from vibration by PC-control (Fig. 2).

→ Textured yarns.

Fan (Air) →: Extractor fans, Compressors, Ventilation systems. Also for steam boilers (forced draught firing, oil firing fan), atomization, pneumatic transportation.

Fancies Examples of fantasy figures plaited from straw.

Fancy A type of coarse flannel, napped on both sides, in linen or twill weave, of cotton or cotton-viscose blend. Double fancy is the name given to goods that are typically two-tone, e.g. with one side pink and the other a mottled blue. Used for cold-weather underwear.

Fancy-ply yarn A collective term for particularly fancy yarns with knots, loops, etc. Special effect yarns are produced on twist frames with additional feeder rolls which supply the main feeder roll at varying speeds.

Fancy print A term used for all types of printed articles which do not fit into the category of traditional Africa print styles. Fancy prints are usually produced with designs having large motifs. They are the cheap mass-produced printed fabrics in West and Central African countries.

Fans Devices for delivering or exhausting large volumes of air or gas with only a low increase in pressure (used in demisting, air conditioning plants and drying systems). Their mode of action is generally based on blowing (suction and blow principle: → Extractor fans; as well as induced-draught fans for steam boiler furnaces). Requirements: → Ventilation systems. Constructional features are determined by their field of use, e.g. centrifugal or airscrew (multi-blade) fans, special fans for acid vapours (exposed parts encased in vulcanite or constructed of stoneware). For industrial applications, belt, electric or steam-driven fans with speed control (variable speed fans) are mainly used.

FAS, abbrev. for: → Fatty alcohol sulphates.

Fashion There has always been a mutual dependency between textile technology and fashion. It is often

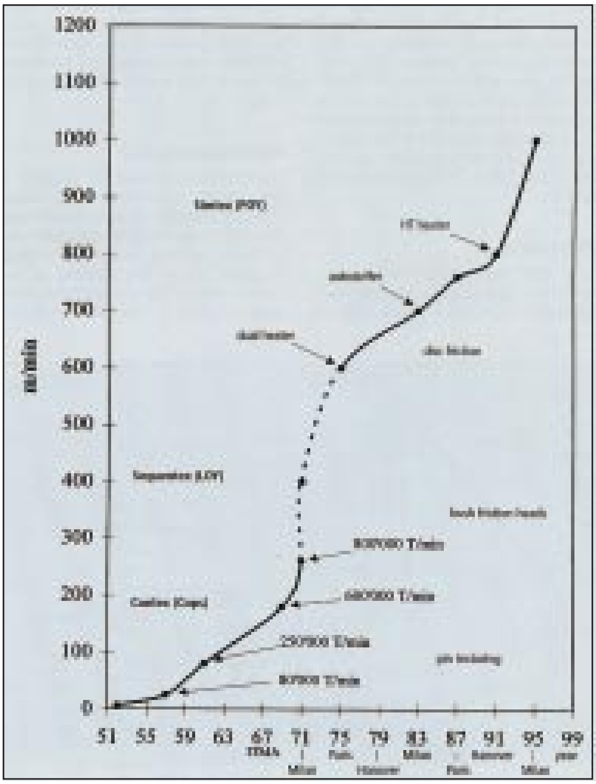

Fig. 1: False-twist texturing: Progression of speeds for texturing PET dtex 167 f 30 (Setila AG).

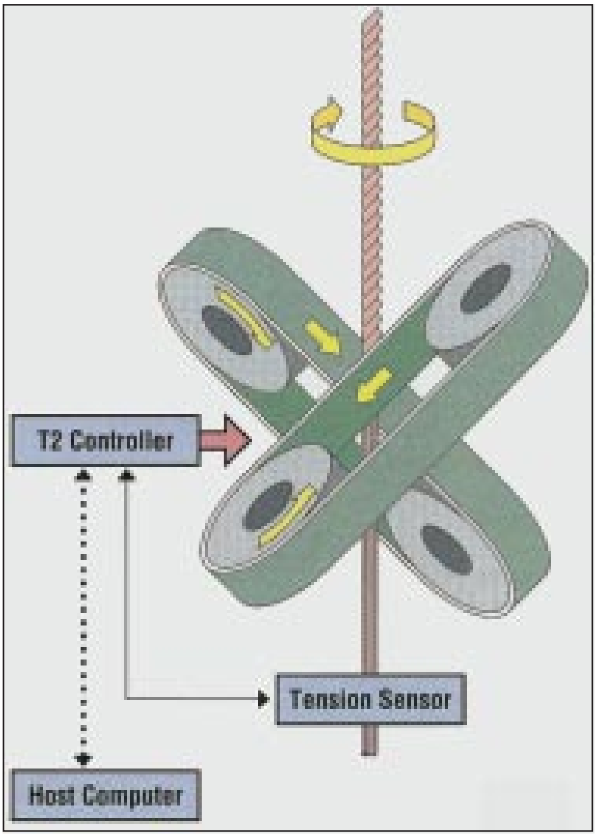

Fig. 2: Muratec NIP Twister with Tension Control System.

difficult to know whether the demand for decoration encourages technical development or whether new technical facilities awaken the demand for fashionable appeal and appreciation. Before the French revolution and the industrial age, it was mainly a question of making people's clothing from natural materials using craftsman's skills. Pictures from centuries past are evidence of how this developed from wearing bear skins to skirts made from bast and straw, linen to woollen doublets and finally to silk robes. Fashion was clothing which leading society figures were wearing and that which was usually unobtainable to the masses because of the scarcity of the valuable materials, and was often even forbidden because of existing clothing regulations. Only after the French revolution were all citizens permitted to dress "à la mode". During the last 150 years, this democratisation has led to increasing equality in clothing, the development in making-up and therefore the demands of the masses for dressing in accordance with fashion. Fashion has therefore become the driving force behind a major branch of industry. In parallel with this, the manufacture of clothing has been transformed from a craft into a technological process. The demand of the masses for standardised clothing encouraged the transformation of the spinning wheel into the spinning machine, and the handloom into the automatic weaving machine. There are many examples showing what textile technology had to do in order to meet increasing demand.

The increase in fibre consumption was initially met by extending cotton plantations, improving sheep breeding and starting to breed silkworms in the Near East. But what would fashion be today without the rapid development of synthetic fibres, without viscose and cupro fibres, and without the manifold uses of polyamide, polyester and polyacrylic fibres. Ladies' stockings, acetate silk dresses, leisure clothing made from textured synthetic yarns and the use of gold and silver thread incorporating metallized synthetic threads are some of the many examples. New fashionable effects have become possible using extremely elastic or shrinkable fibres and bi-component fibres. A comparison of the range of natural dyes more than 100 years ago with the current range of dyes clearly shows where fashion would be today without synthetic dyes. It is not just the brilliant colours of the reactive and cationic dyes that allow shock fashion and brilliant shades of turquoise; the high degree of realism is that which allows the wide range of bright colours to spread, not just in beachwear and leisure wear. Fluorescent dyes and so-called chameleon designs have opened up new avenues. The desire of the masses for fashionable clothing can only be met if the clothing does not require undue care. Textile finishing methods come some way to meeting this demand using new fibres, dyes and auxiliaries. Permanent creases, "Everglaze", non-iron, wash-and-wear, permanent press, "Sanforizing", oilproofing are just a few of the keywords, plus dry-cleaning, waterproof finishing and non-iron clothing. Finishes that were previously impossible from a fashion point of view are being achieved by metallizing, and technological effects using foam coating. In the field of machine technology, spinning machines and automatic weaving machines have been supplemented by hosiery and knitting machines, highly-developed sewing machines and equipment for nonwovens manufacture. Appropriate, continuously operating equipment in dyehouses, printing shops and textile finishing were the prerequisite for faster, better and cheaper processes for these operations. Recent developments are also expected to affect fashion in the future, such as woven and knitted stretch fabrics, nonwovens, sewing and tufting equipment, soil-repellent finishes, differential dyeing fibres and perhaps also with different finishing techniques and solvents. Other textile technology methods are in the pipeline in the form of direct spinning processes and the manufacture of yarn from split film.

Fashion clothing is not worn at the expense of comfort as it was in the days of crinolines and corsets. Manufacturers take clothing comfort into account and attempt to produce clothing that is compatible with the body without having to forego appearance and fashion, not just in the structure of the clothing but also the outward appearance. The sociological aspect of fashion is seen as being the driving force behind economically meaningful mass production in the field of textiles, and also prevents uniformity due to continuous change, and allowing adequate freedom for personal taste. With the aid of advertising and its almost dictatorial power, fashion is "engineered", taste is influenced and the consumer is persuaded to get involved in fashion unless he wants to be a social outcast. Fashion and textile technology therefore help to encourage and further develop an economically important branch of industry.

It is not easy to define the terms "fashion" and "trend". Reduced to a common denominator, one could say that fashion is the continuous further development of peoples' ideas. However, trends could be defined as style directions that run for many years and are continuously perfected. For this reason, curtains, for example, inbetweens, furnishing and upholstery materials and carpets are more difficult to design from a fashion point of view than clothing materials, not least because of the consumer's buying habits. Household textiles are usually only purchased at intervals of 5–10 years in 90% of cases. The reason for this phenomenon of the domestic textiles sector lies in the fact that it is still catching up from a fashion point of view in comparison to clothing. Many household textile manufacturers are constantly trying to become "more fashionable", although consumers counter this initiative with their buying habits. Modified lifestyles can only be sold to the

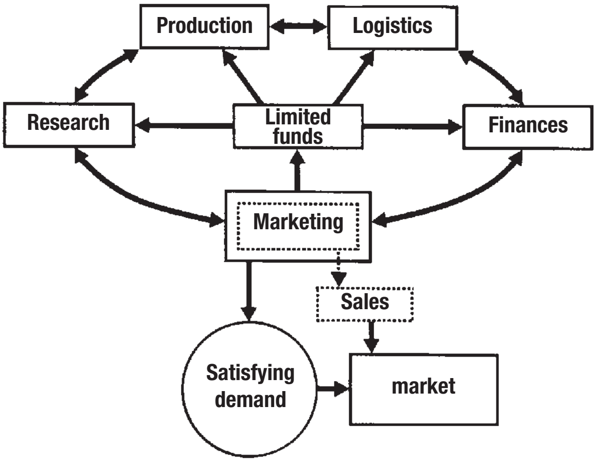

Fig.: Textile developments must meet consumer demand.

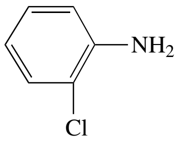
end consumer with the aid of intensive marketing. In order to encourage sales, new markets must be found and new material appearances must be developed using new yarns. The textile industry cannot produce just what it wants to, but has to produce products that meet and satisfy consumer demand. Determining consumer requirements is a marketing task.

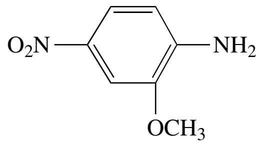
Marketing must formulate market requirements and pass them to research and development. The funds available for research projects should be geared to this. It appears to be natural that research and development can critically assess and differentiate between short and long term requirements and that the correct priorities with potential profit generation will be set in collaboration with marketing (Fig.).

Fashion leaders come into contact with the physiological dimension of their task, since colours have much to do with consumer attitudes. If things are going well, we want to wear red. If we see the future somewhat more pessimistically, the colours become darker and more subdued. There are periods in which warm, burnt colours are in demand. Then brighter colours follow again. Requirements derived from ecological considerations also have a considerable effect on colour selection; they give the fashion world the subtle, soft natural colours. The continuously recurring and accelerating cycle should not be forgotten: it used to take 10 years before a “colour wave” (red shades or green) came back. Now it only takes half as long. In other words: anyone closely involved with fashion can detect certain trends which send them down the correct path. In order to develop the correct sense, as much information as possible must be gathered. Examples of information sources are textile fashion bodies, for example: such groups contain specialists with a feel for fashion and have many years of experience. Additional information can be found in fashion magazines, fashion books and the collections of avant garde designers.

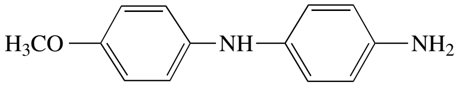
Fast colour bases Coupling products for the development of Naphthol AS dyes (Hoechst). They are not dyes, but soluble intermediate products with a basic character due to the presence of amino groups.Before use, these amino groups must first be diazotized before they can couple, exactly like → Fast colour salts, with Naphthol AS components to form insoluble dyes. Examples:



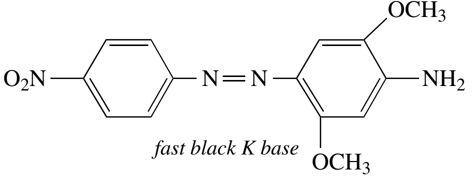
fast yellow G base



fast Bordeaux B base



variamin blue B base



fast black K base

The examples also serve, at the same time, to demonstrate the gradual shift in colour from yellow to black with increasing molecular size.

Fast colour salts These are already diazotized, water-soluble coupling products (so-called stabilized diazo compounds) of the corrresponding → Fast colour bases, used for the development of Naphthol AS dyes (Hoechst). Compared to fast colour bases, the salts offer advantages of better keeping properties, easy solubility, greater reliability, and simpler application.

Fastness Commission The German organisation (EK = Echtheits-Kommission) for colour fastness. Most member countries of the International Organisation for Standardisation → ISO, support its Technical Committee 38 (TC38) which was made responsible for all matters concerning textiles and, within TC38, Sub-Committee 1 (SC1), which became specifically responsible for all colour fastness test methods through the national committees of ECE countries. ISO/TC38/SC1 has continued to this day to encourage the development, international acceptance, and use of agreed methods of test for all the different colour fastness agencies. The two most active groups contributing to this work are the European Colour Fastness Establishment (→ ECE) and the American Association of Textile Chemists and Colourists (→ AATCC). Important technical contributions are also regularly made from countries outside Europe and the USA, including Australia, Canada, China, India, Japan and South Africa. Neither the ECE nor the AATCC are members of ISO – it is the national standards organisations of the respective countries that are ISO members. The national committees of ECE member countries (and others, including the USA) may be contacted through their specific addresses in the respective countries; → Technical organisations.

Fastness Convention European Convention for Fastness Tests of Dyeings and Prints (ECE).

Fastness evaluation of dyeings and prints → Fastness testing.

Fastness improvement → Fastness-improving agents.

Fastness-improving agents Textile auxiliaries or chemicals used to improve the colour fastness of dyeings and prints by means of an aftertreatment. Such products are generally used to improve the colour fastness to light, rubbing, and wet treatments. For this purpose products are used which form virtually insoluble compounds with dyes on the fibre (especially direct and acid dyes, as well as wool/cotton union dyeings). Other products are used to remove unfixed dye from the fibre (e.g. in naphthol dyeing).

Fastness properties →: Fastness standards; Fastness testing.

Fastness ratings of dyeings and prints Comparative numerical ratings obtained by the comparison of textile test specimens against either the → Blue scale or the → Grey scales after an appropriate fastness test.

Fastness requirements in manufacturing This is the sum of all the colour fastness requirements which, due to further processing stages, have to be fulfilled by the dyed or printed textile. For individual fabrics, these fastness requirements differ according to the type of fibre involved. → Fastness testing; → Colour fastness to processing.

Fastness standards (colour fastness standards). The drawing up of international standards for colour fastness determinations is an ongoing activity of → ISO in cooperation with various national standards organizations. It is recommended that guidelines issued by national fastness testing commissions for determining the colour fastness of textiles should only contain slight amendments from the ISO standards.

Fastness testing The purpose of colour fastness testing is to determine the resistance of dyed and printed textiles to various agencies at different stages of the manufacturing process (→ Colour fastness to processing) as well as in subsequent use (→ Colour fastness of textiles in use). Examples of the former category include: colour fastness to kier boiling; chlorination; bleaching (sodium chlorite); bleaching (hypochlorite); bleaching (hydrogen peroxide); decatizing; degumming; carbonizing; mercerizing; vulcanizing; soda boiling; cross-dyeing; stoving; metals in the dyebath; potting; milling; pleating; sublimation; resin finishes, etc., whilst examples of the latter category include colour fastness to light; weathering; washing; water; perspiration; rubbing; burnt gas fumes; chlorinated water (swimming bath water); seawater; ozone in the atmosphere.

The colour fastness testing of dyed and printed textiles has been systematically developed since 1911 by the DEK = Deutsche Echtheitskommission (German Fastness Commission). These tests are among the oldest of all standardized test methods. The Industrial Standards Committee founded in 1917, which was renamed as the DNA in 1926, assumed responsibility for colour fastness testing. In 1975 the name was changed again from the DNA to DIN (i.e. Deutsches Institut für Normung e.V. = German Institute for Industrial Standards). Since the DEK was re-established (after the Second World War) in 1949, the colour fastness test methods have been further supplemented largely as a result of close contact with similar bodies outside Germany (ECE and ISO) which led, in 1978, to the ISO Recommendations being published for the first time as international standards (ISO 105 A to Z) in English and French only. A second edition with a few additions appeared in 1982.

Many colour fastness tests are carried out as so-called “sandwich” tests, i.e. the test specimen is placed between two undyed textile fabrics (→ Adjacent fabrics) made from different fibres (dependent on type of fibre in the test specimen) and sewn together to form a composite for testing. The use of two different adjacent fabrics may, however, be replaced by standard → Multifibre strips in many cases. The composite sandwich is then subjected to the appropriate test procedure after which an assessment of change of colour and staining of adjacent fabric is carried out with the standard → Grey scales. These scales cover 5 full steps arranged in geometrical progression where a rating of 5 represents excellent, and a rating of 1 represents very poor colour fastness. With decreasing fastness, the degree of contrast in the grey scale increases by a factor of 2. The greatest difficulty in using the grey scales is to visually assess the degree of contrast or colour difference between the stained and untreated adjacent fabrics or between the test specimen and the original dyeing or print to coincide with differences in contrast in the grey scales. The degree of uncertainty is naturally higher the greater the colour difference of the test specimen from the grey of the grey scales. For the most reliable assessment, therefore, the average visual judgement of several assessors must be sought, which makes the process more time-consuming and laborious.

Almost all colour fastness assessments, with the exception of light fastness, are carried out with the grey scales. In the case of light fastness, 8 different dyeings which form the → Blue scale are exposed to light at the same time as the test specimen in order to determine and take into account differences between various light fastness testers. After exposure, the degree of fading of the test specimen is compared against that of the blue scale. If the test specimen has faded to the same extent as blue dyeing 5 for example, a light fastness rating of 5 is given. Up to now, there is no standard in existence for the colorimetric evaluation of test specimens against the blue scale so that light fastness ratings must continue to be decided by visual assessment.

Numerical key to assessments:

Evaluation:

Light fastness (Blue scale)		Other types of colour fastness (Grey scale)
very poor	1	poor
poor	2	moderate
moderate	3	quite good
quite good	4	good
good	5	very good
very good	6	
excellent	7	
outstanding	8	

The use of → Standard depths of shade makes it possible to express the depths of shade of the coloured samples being assessed. The problem of establishing standard depth of shade levels is mainly of concern to dye manufacturers since colour fastness testing of their products is extremely important. Colour fastness is, to a greater or lesser extent, highly dependent on the depth of shade. In order for the dyer to be able to compare the colour fastness ratings given in their pattern cards with the corresponding colour fastness ratings of products from other manufacturers, they must be determined under the same conditions worldwide at similar depth of shade levels. The most important depth of shade for testing textile dyes is the so-called 1/1 standard depth. This level has been defined since 1956 by 18 dyeings which have been recognized by the ISO Standards Committee ISO/TC38/SC1. These 18 dyeings are described as standard types. If, for example, it is intended to test the colour fastness of a new dye developed through research, then the dye concentration required to produce the 1/1 standard must be determined as a first step in order that the colour fastness tests can be carried out in accordance with the standards. For this purpose, dyeings are produced at various concentrations and the concentration which gives the same depth of dyeing as the 18 standard types is determined by visual assessment. The assessor has a wide latitude here, especially if the dye being tested differs greatly in shade and/or purity from the nearest standard type which is usually the case with only 18 standard types. Since the opinions of assessors with different levels of experience may vary considerably, a precise result can, once again, only be obtained through painstaking multiple assessments. The already expressed desire for a colorimetric method is therefore understandable.

Over the years, various methods have been proposed and discussed. In 1989, agreement was reached on a colorimetric method, which has been introduced as ISO Standard IS/DP 105-A06 (DIN 6174). By means of the formulae given in this standard, those lightness coordinates for a dyeing based on CIELAB coordinates can be calculated in the CIELAB system which would correspond to a dyeing with the same colour depth as a 1/1 standard depth of shade. By comparing the calculated value with the measured lightness of the dyeing, it can be established whether the dyeing lies within the desired 1/1 standard depth of shade of tolerance or whether it is too light or too dark. It is worthwhile to combine the formulae stipulated in the standard for the determination of 1/1 standard depths of shade with a computer colour matching program. By this means, it is also possible to calculate the concentration required to give a dyeing at 1/1 standard depth in addition to the calculation of lightness (source: Wehlow and Meyer).

Fastness test specimen Used in → Fastness testing often together with → Adjacent fabric. Guidelines: only textile materials in the flat state are suitable for testing. Yarns are knitted or otherwise converted into a flat form for this purpose. Loose fibre is converted into a fleece. Minimum size of test specimen 10 cm x 4 cm. The adjacent fabric specimen and the test specimen, of equal size, are joined together by sewing before the fastness test.

Fastness to cross-dyeing In order to meet the changing demands of the fashion market more quickly, some coloured textiles are produced as follows: yarn is dyed so that it is fast to cross-dyeing (e.g. reactive dyeings on cotton or chrome dyeings on wool); this yarn is then woven with undyed yarn to give a patterned fabric. The fabric is then pretreated and kept in store until a decision has been made on the colour required for the finished article. As soon as this has been decided, the fabric is piece-dyed. During this process, only the undyed yarn component is coloured and the already dyed component is not visible; the latter must not bleed otherwise cross-staining will occur. Colour fastness to cross-dyeing is determined in accordance with DIN 54 049 or BS 1006 X07.

Fastness to degumming This test determines the resistance of dyeings or prints to the effects of soap solutions used for the → Degumming of raw silk. Test specimens, sandwiched between undyed adjacent fabrics, are gently boiled under reflux in a soap solution (7 g/l) for 10 min (liquor ratio 100:1). After this treatment, the test specimens are rinsed in distilled water, followed by rinsing for 10 min in cold tap water, then dried in air (<60°C). Change of colour and staining of adjacent fabrics are assessed with the standard grey scales.

Fastness to hot air vulcanization Fastness of dye to the effects of a typical caoutchouc mixture and its decomposition products during hot air vulcanization. The sample is placed on the non-vulcanized bed of caoutchouc and suspended in the heating cabinet for 30 minutes at 125°C with air circulation. The test piece is allowed to cool and removed from the caoutchouc. The change should be assessed immediately and after conditioning for 4 hours at 20°C and 65% relative humidity.

Fastness to hot water (Fastness to crabbing), resistance to hot water. Test piece is wrapped around a glass rod, treated with 100 ml of acetic acid solution (7 mg/l of pure acetic acid) in a round flask for 30 minutes at 70°C and dried at max. 60°C without rinsing. Assess using grey scale.

Fastness to milling

I. Alkaline: determines the resistance to alkaline milling conditions, a) mild (light): the test specimen is treated in mechanical washing machines with 10 stainless steel balls for 30 min at 40°C with 10 g/l soap (liquor ratio 3:1), after which water at 40°C is added until a liquor ratio of 100:1 is reached, and treatment is continued for a further 10 min followed by rinsing and drying at a temperature up to 60°C; b) strong (severe): treatment as in a) above but with 50 stainless steel balls and 50 g/l soap as well as 10 g/l sodium carbonate (anhydrous) for 2 h at 40°C followed by a further 10 min at 40°C at a liquor ratio of 100:1. Assessment: change of colour and degree of staining are assessed visually by comparison with the standard grey scales.

II. Acidic: determines the resistance to acidic milling conditions, a) mild (light): the test specimen is treated with 1 ml/l conc. sulphuric acid at 60°C for 1 h at a liquor ratio of 40:1; b) strong (severe): treatment with 1 ml/l conc. sulphuric acid and/or 5 ml/l acetic acid 30% at 90°C for 30 min. The test specimen is constantly moved in the liquor and pressed with a glass rod every 2 min to ensure complete penetration during this period. After rinsing, the test specimen is opened on 3 sides and dried at a temperature up to 60°C. Evaluation: as in I above.

Fastness to organic solvents Resistance of dyed and printed textiles to the action of organic solvents, as used in dry cleaning. The guideline for all fibres is: treat test subject for 30 minutes at room temperature (liquor ratio 1:40) separately in each organic solvent. In manual testing, push the test subject to the bottom every 2 minutes using a glass rod. Then squeeze out any excess solvent and dry in warm air at 80°. Assessment: colour change and bleeding using grey scales.

Fastness to processing Fastness properties, i.e. the resistance of effects, dyeings or prints to various agencies fall into two categories: a) fastness performance in use (e.g. colour fastness to light, rubbing and washing) and b) fastness to conditions in processing, i.e. before the goods are finally finished. This latter category is unimportant to the end consumer since it is concerned with the effects of processes carried out after dyeing or printing before final finishing (e.g. carbonizing, decatizing, resin finishing, potting, etc.). Changes in the shade of dyed or printed cotton fabrics after crosslinking with a resin finish may be due to the dyes having poor fastness to the catalyst used. Changes in shade during carbonizing are usually reversible as soon as the accumulated protons, which block the conjugated double bond system of the chromophore, are removed again after neutralization. On the other hand, colour fastness to carbonizing is not given as a typical example of fastness to processing. Dye makers pattern cards contain information on the fastness to processing of their products so that, in the case of colour fastness to carbonizing, for example, care must be taken when establishing dyeing recipes to select dyes with adequate fastness properties.

Fastness to sea water Textile dyeing resistance to sea water. Wet the test piece and accompanying fabric with solution (distilled water containing 30g/l of sodium chloride). Place test piece between two plastic plates in apparatus such as the Hydrotest and expose for 4 hours at 37°. Dry the sample and the accompanying fabric separately in warm air (<60°C). Assessment: colour change and bleeding using the appropriate grey scales. AATCC test 106–1972: 30 g/l of sodium chloride and 5 g/l of anhydrous magnesium chloride, 38°C, 18 hours (DIN 54 007 or ISO 105).

Fastness to soda boiling The resistance of dyeings or prints to the effect of dilute boiling sodium carbonate solution. Test methods are applicable to cellulosic fibres. Two treatments with and without the addition of a reduction inhibitor are used: a) 10 g/l anhydrous sodium carbonate and 4 g/l sodium m-nitrobenzenesulphonate in distilled water; b) 10 g/l anhydrous sodium carbonate, without addition, in distilled water. The test specimen is rolled around a glass rod and boiled for 1 h in the test solution under reflux after which it is unrolled, rinsed for 10 min, squeezed, and dried at 60°C. Assessment: standard grey scale for assessment of change of colour.

Fastness to superheated steam vulcanization Fastness of colour to the effects of a typical caoutchouc mixture and its decomposition products during vulcanisation using open steam that a) is prevented from penetrating the test material, b) penetrates the test material. The sample is placed on a non-vulcanized bed of caoutchouc and wrapped around a steel pipe. Accompanying fabric, cotton and material impermeable to steam and water are placed on top (in condition a) or only accompanying fabric and cotton (in condition b). This assembly is treated for 20 minutes in pre-heated autoclaves at a heating jacket temperature of 141° and vessel temperature of 138°, then air cooled. Assessment: colour change and staining onto accompanying fabric using grey scales.

Fastness to washing In recent years, domestic washing practices have undergone considerable change. In addition to the use of more powerful detergents and the increased mechanical action to which household laundry is now subjected, the trend towards lower washing temperatures must also be mentioned. The textile industry will have to come to terms with these changed conditions by developing appropriate fastness tests on the one hand and by ensuring that the colour fastness of manufactured textiles is suitably adapted to meet these test requirements on the other. Important connections with general validity for the wet fastness of coloured textiles can be demonstrated by reference to the relevant ISO standard proposals. At any time, alternative procedures can be demonstrated for a variety of important substrates which allow new requirements for serviceability fastness to be achieved in practice.

The test conditions for wash fastness tests taken from DIN draft standard 54 017 are presented in condensed form in the Table. These conditions correspond largely with those specified in ISO Standard 105–C06. For each wash temperature indicated by a letter of the alphabet two variants are given: one without and one with the addition of sodium perborate. Particular attention is also drawn to wash test D 3 which is carried out at 70°C with 0.15 g/l available chlorine. If, for example, wash tests C 1 and C 2 are compared with the former ISO Wash Test No. 3 (60°C), the most noticeable differences are the change of washing agent (ECE Reference Detergent instead of soap and sodium carbonate), the inclusion of steel balls to simulate mechanical stresses and, in the case of test C 2, the addition of sodium perborate. Tests for fastness to repeated washing should be simulated by a greater number of steel balls (50 or 100 instead of 25) and a longer treatment time. It is clear that the effect of repeated washing actually carried out in practice is not always achieved with this test and that the dyeings are also subjected to a chemical as well as a mechanical influence instead.

The tendency of dyes to migrate from the dyed material into the wash bath under the given test conditions, as well as the affinity of migrated dye for adjacent materials under the given wash conditions, exercise a decisive influence on the degree of colour fastness of a dyeing or print.

Each test for wet fastness is based on kinetic processes where the same parameters as those involved in actual dyeing processes are applicable: a “dyeing” in the reverse direction, i.e. from the dyed material to the wash liquor takes place in the first stage, and a new dyeing of adjacent materials takes place in the second stage. The extent to which both these processes proceed is chiefly determined by the interactions between dye, fibre and wash liquor. If the first stage is predominant, then the colour of the test specimen becomes considerably lighter accompanied by only a slight staining of the adjacent materials and the migrated dye is retained in the wash liquor. If, however, the second stage predominates (the composition of the wash liquor then encourages a complete absorption of the migrated dyes) a severe staining of the adjacent fabrics occurs with either no difference, or only a slight difference in shade between the latter and the test specimen.

In both process stages, equilibrium reactions are involved which can be represented schematically (see Fig.)

An equilibrium exists between the dyed material and the liquor as well as between the liquor and the adjacent materials. The factors influencing these equilibria which are dependent on the dyed fabric include the type and stability of the dye/fibre bond, the water solubility of the dye and the dye concentration used; the factors dependent on the wash liquor include the presence of additives, the pH, the temperature and the liquor

test no.	temperature (°C)	pH*	liquor (4g/l detergent) (ml)	available chlorine content (%)	sodium perborate (g/l)	number of steel balls single test 30 mins	number of steel balls multiple test 45 mins
A1	40		150	0	0	0	10
A2	40		150	0	1	0	10
B1	50		150	0	0	0	50
B2	50		150	0	1	0	50
C1	60	10.5	50	0	0	25	50
C2	60	10.5	50	0	1	25	50
D1	70	10.5	50	0	0	25	100
D2	70	10.5	50	0	1	25	100
D3	70	10.5	50	0.015	0	25	100
E1	95	10.5	50	0	0	25	100
E2	95	10.5	50	0	1	25	100

Table: Wash tests ISO, 105-C06

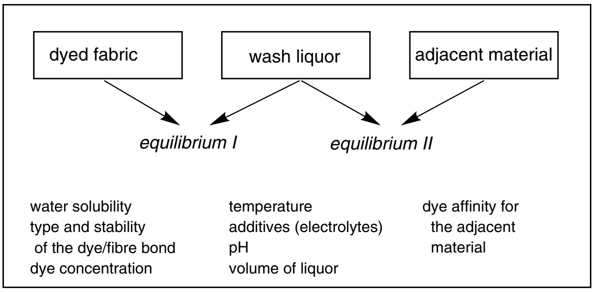


Fig.: Factors which influence wet fastness performance.

ratio, whilst those dependent on the adjacent materials include the types of fibre used and the consequent fibre-dependent affinity of the dyes for these fibres.

Optimum colour fastness is achieved theoretically if equilibrium I is shifted entirely to the side represented by the dyed material and equilibrium II is shifted to the side represented by the wash liquor. To the same extent as the above-mentioned equilibria can be positively influenced in the direction of improved colour fastness by technical manipulations, changes in washing practices can alter these equilibria in the opposite direction with the result that serious colour fastness problems can arise. → Colour fastness to washing considerations for dyeings and prints.

Fastness to wear → Wear fastness properties.

Fastran process

1. Printing: a wet transfer printing process for wool and polyamide in which transfer paper screen printed with water-soluble dyes is brought into contact with prewetted textile material in sandwich form under defined conditions of pressure in a calender and subjected to the action of a high-frequency current. As a result, dye migrates from the paper to the textile material and is fixed thereon in a quasi-steaming process. An aftertreatment is still necessary however.

2. Dyeing: a process for the continuous dyeing of loose wool in which dye fixation is achieved by high-frequency heating.

The Fastran dyeing system for dyeing loose stock and tops (see Fig.) utilizes high frequency current for dye fixation. The electronic fixation unit consists of 50 or 20 kW high frequency generators (each with high tension transformer, rectifier, and oscillator with ancillary equipment and cooling system) with 2 dye fixation chambers connected one behind the other. They are connected to a 3-phase alternating current, 140 kVA, at a voltage between 340 and 600 V.

FAST system of fabric assessment The FAST system (Fabric Assurance by Simple Testing) was developed in Australia by the CSIRO. This system is used to determine the properties of woollen fabrics affecting both the way the fabric performs during cutting and making up, and the visual appearance of clothing fabrics when worn. The system comprises three simple instruments and a testing method and was developed principally for use by fabric manufacturers, finishers and dressmakers.

a) FAST-1 consists of a compression measurement device that measured the thickness of the fabric under two different loads.
b) FAST-2 is a device for measuring flexural rigidity, which measures the bending length of the fabric (the bending length can be used to determine the flexural rigidity).
c) FAST-3 is a device for measuring the elasticity, measuring the elongation of the fabric under two different loads in the warp and weft direction, and diagonally.
d) FAST-4 is a measuring method for the determination of the dimensional stability of the fabric (relaxation shrinkage and hygral expansion).

The parameters measured are entered on to a record card that can then be used to give a good forecast of the properties of the fabric. An important feature of the FAST system is the simplicity of the instruments and the testing procedures. The full evaluation of a fabric can be undertaken in less than 2 hours with a relatively short time requirement for laboratory personnel in operating the equipment.

Fat-free aromatic products Principally derivatives of benzene and naphthalene.

I. Benzene derivatives: products based on → Pyridine C_5H_5N are stable to hard water, acids and alkalis, have outstanding dye solubilizing properties, and are highly effective as levelling agents and dye penetrants in virtually all dyebaths where they are used to some extent in combination with Turkey Red oils and fatty alcohol sulphates, etc., to give additional wetting and softening effects. In the aftertreatment of (direct) dyeings, condensation products improve the colour fastness to water, washing, ironing and perspiration. By sulphonation of e.g. phenol, water-soluble sulphonated phenols or thiophenols are formed, among which condensation products of thiophenols or naphthalene sulphonic acids with formaldehyde or other components may also be included. Such products are useful, on the one hand, as single bath mordants and as valuable resist agents in the dyeing of blends on the other. For the latter application, they are used as dyebath additives in direct dyeing when dyeing at higher temperatures (better dye penetration of seams, etc.) and for the dyeing of two-colour effects where advantages of improved shade purity, higher rub fastness, more favourable dye utilization and better light fastness are obtained.

II. Naphthalene derivatives: as non-fat based products the salts of (alkyl) naphthalene sulphonic acids have taken the place of Turkey Red oils and other fatty products. They are more or less high foaming, stable to hard water, acids and alkalies, and are characterized in the main by outstanding wetting, dye levelling and dye solubilizing properties as well as the promotion of dye penetration. Used as wetting agents in practically all wet processes, and as virtually universal dyeing assistants, and also as emulsifiers to some extent.

Fat-free (synthetic) condensation products (→ Polyglycolether). In 1936 the synthesis of fatty alcohols from low molecular weight products of coal hydrogenation began. By condensation with ethylene oxide (C_2H_4O) products of the type:

$$R–(O–C_2H_4)_x–OH$$

were formed. These compounds, which were the first synthetic detergents and emulsifiers, had excellent wetting properties and protective colloid action with excellent stability to hard water salts, metal salts, acids and alkalis, besides being easily washed out. The → Alkylaryl polyglycolether form a very important group of nonionic surfactants.

Fat liquor Fat-liquoring agent used to treat leather after → Tanning in order to achieve the desired softness, suppleness, fullness, improved tensile strength and resistance to water.

Fat liquoring → Tanning.

FATM (Ger.), abbrev. for: Forschungsstelle für allg. und textile Marktwirtschaft an der Universität Münster (Research Unit for General and Textile Market Economy at the University of Münster). → Technical and professional organizations.

Fats Neutral vegetable or animal products composed of neutral fats and → Fatty acids. Glyceride esters of organic fatty acids, e.g. the glyceride of oleic acid $(C_{17}H_{33}COO)_3C_3H_5$. They are subdivided into → Liquid fats, → Semisolid fats and → Solid fats. Properties: insoluble in water, soluble in ether, white spirit, benzene, chloroform, carbon disulphide, chlorinated hydrocarbons and fat solvents. Fats melt but do not volatilize, they decompose at temperatures of 250–300°C, oxidize in air (become rancid; → Oxidation of oils), and are saponified by alkalis, i.e. split up into fatty acid salts (soaps) and glycerol. Fats also include non-ethereal oils, paraffins, and mineral oils (fats). Chemical characteristics →: Iodine number; Acid value; Saponification value.

Fats, hardening of → Fats, hydrogenation of.

Fats, high-pressure hydrogenation of The hydrogenation of fats under approx. 200 bar pressure at a temperature of approx. 300°C with hydrogen in the presence of a catalyst. Purpose: reduction of the fatty acid carboxyl group (–COOH) to the carbinol group ($–CH_2OH$) with the elimination of water, i.e. substitution of a divalent oxygen atom by two monovalent hydrogen atoms:

$$C_{17}H_{35}COOH \xrightarrow{(+\,4\,H)} C_{17}H_{35}CH_2OH\ \ (+\,H_2O)$$

stearic acid *stearyl alcohol*

By this means, higher fatty alcohols are formed from the corresponding higher fatty acids. The COOH group is destroyed (eliminated). The process is of great technical importance since, with its aid, a large number of fats can be used to make high quality textile auxiliaries.

Fats, hydrogenation of (fats, hardening of). The process involves heating oils or fatty acids to 160–170°C at 6 bar pressure in the presence of a catalyst and hydrogen. Purpose: conversion of cheap → Liquid fats into more valuable → Solid fats, or the conversion of unsaturated liquid fatty acids into the corresponding saturated and solid fatty acids (resp. their glycerides) by the introduction of two hydrogen atoms in place of the double bond: ($R–CH=CH–R$ into $R–CH_2CH_2–R$):

$$C_{17}H_{33}COOH \xrightarrow{(+\,2\,H)} C_{17}H_{35}COOH$$

liquid oleic acid *solid stearic acid*

Fat-solubilizing detergents (fat-solubilizing soaps). Homogeneous mixtures of soap and/or synthetic detergents with fat solvents (approx. 10–95%) and solvent promoters as well if necessary. The considerable variation in composition is responsible for the stability, quality, and utility of these products. Fat-solubilizing detergents generally possess an extraordinarily high wetting, dispersing and solvent action for linseed oil sizes, textile lubricants, dust-binding oils, mineral oils and, in special mixtures, also for particularly resistant impurities. Uses: desizing of linseed oil sizes, desizing washes, removal of textile lubricants, kier boiling assistants, milling assistants, cleaning agents in dyebaths, cleaning of heavily grease-stained textiles, pitch removal, spotting agents (stain removal), etc. (→ Drycleaning detergent).

Fat-solubilizing soaps → Fat-solubilizing detergents.

Fat-soluble dyes → Oil and fat soluble dyes.

Fat solvents Chemicals which are good solvents for fats include: ethanol, methanol, ethyl ether, ethyl acetate, acetone, butanol, carbon disulphide; hydrocarbons such as white spirit, benzene, turpentine, toluene, xylene; hydrated hydrocarbons such as decahydronaphthalene, cyclohexanol, methyl cyclohexanol; chlorinated hydrocarbons such as chloroform, tetrachloroethylene, carbon tetrachloride, trichloroethylene, etc. Uses: either alone or in emulsified mixtures for fat-solubilizing detergents of various composition with soaps, Turkey red oils, etc., fatty alcohol sulphates, fatty acid condensation products, synthetic fats, alkylnaphthalene sulphonates, etc. Also used for desizing (linseed oil sizes), scouring, kier boiling, dyeing, drycleaning (drycleaning detergent), spotting agents (stain removal), etc.

Fats, synthesis of → Fatty acids, synthesis of.

Fatty acid amide polyglycol ethers → Polyglycol ethers.

Fatty acid amides → Fatty acid condensation products.

Fatty acid amide sulphates Formed by the reaction of fatty acids and oxyalkylamines, e.g. monoethanolamine, and subsequent sulphation:

$$R–CO–NH–CH_2–CH_2–O–SO_3Na$$

Fatty acid amide sulphates have good stability and are suitable for use as detergents or for incorporation into mild washing agents.

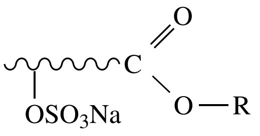
Fatty acid carboxyl group, R–COOH, functional group of all organic acids. → Carboxyl group.

Fatty acid condensation products

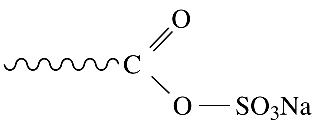
I. Condensed oils: these products are based on the principle of condensation and saponification, e.g. polyricinoleic acid with sulphonic acid groups and a reduced content of free carboxyl groups. By this means, typical wetting oils with good softening properties and good to excellent all-round stability, depending on the degree of sulphonation, are obtained.

II. “Masked” fatty acid (sulphonate) products: these are products in which the carboxyl group is protected by masking, i.e. by blocking the carboxyl group in its former position at the end of the long fatty acid chain.

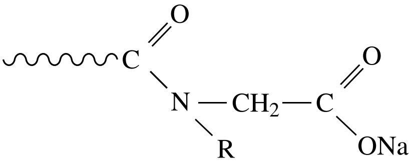
a) (Sulphonated) fatty acid esters: the first products were produced from castor oil by esterification and sulphonation; in general, these were ester oils with excellent wetting and softening properties of good average stability:



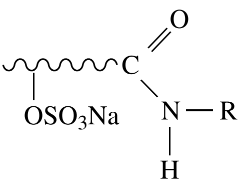
Shortly afterwards, a synthetic detergent, resistant to hard water, with excellent detergency but still limited stability to acids and alkalis was produced by the esterification of oleic acid:



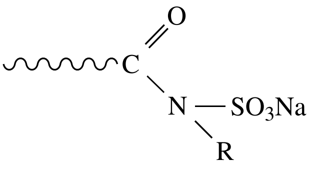
b) fatty acid amides: produced by the successful introduction of nitrogen compounds into the COOH group. Because of the shortage of solubilizing groups, however, the first commercial products of this type were typical water-insoluble emulsifiers. Next followed a surprisingly improved soap with remarkable stability properties due to its end group,



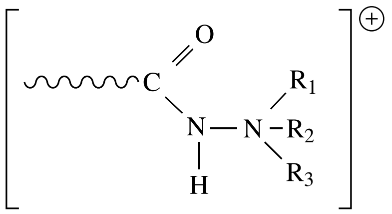
Used as a milling assistant, washing agent and dispersing agent. An example of a sulphonated fatty acid amide without carboxyl groups is:



Used as a non-foaming wetting and levelling agent. A large range of well-known products have been produced on a similar principle. A classic example of a synthetic detergent, stable to hard water, with excellent all-round stability is



Uses: virtually universal application (but not mercerizing and carbonizing). The following (cationic) condensation products of fat residues with amines or polyamines, which are of particular interest in dyeing, should also be mentioned:



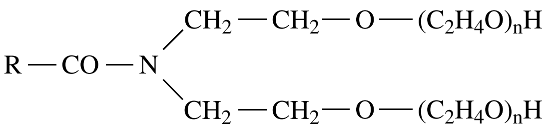
Fatty acid ethanolamides

These partially sulphonated products have high stability, powerful wetting and softening properties, and foam to some extent. Used to improve the fastness properties of direct dyeings.

Fatty acid ethanolamides Formed by the reaction of fatty acids with ethanolamines, e.g. a fatty acid monoethanolamide:

$$R{-}COOH + H_2N{-}C_2H_4OH \rightarrow$$
$$R{-}CO{-}NH{-}C_2H_4OH + H_2O$$

The mono and diethanolamides of higher fatty acids are yellow, wax-like or liquid products. They are used to improve foam stability and as skin-protective components in washing agents and detergents. Ethoxylated fatty acid ethanolamides, e.g.:



$$R{-}CO{-}N\begin{cases} CH_2{-}CH_2{-}O{-}(C_2H_4O)_nH \\ CH_2{-}CH_2{-}O{-}(C_2H_4O)_nH \end{cases}$$

are used as washing agents, softeners and emulsifiers.

Fatty acid ethoxylates, of the type: $C_nH_{2n+1}{-}CO(OCH_2CH_2)_m{-}OH$. Used as additives to spinning preparations.

Fatty acid hydrazides → Hydrazides.

Fatty acid modified synthetic resins → Water-impermeable finishes.

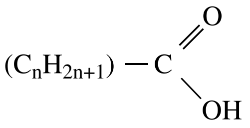
Fatty acid number, the → Acid value is used to measure the amount of fatty acid in the organic solvents used in dry cleaning. The acid number is calculated from the amount of 0.1 N alcoholic potassium hydroxide needed to neutralize 1 ml of the dry cleaning liquor; the amount should not be more than 0.2 ml.

Fatty acid oxyethylamides → Polyglycol ethers.

Fatty acid polyglycol ethers/esters → Polyglycol ethers.

Fatty acid-protein condensation products → Protein-fatty acid condensation products.

Fatty acids, correspond to the general formula



$$(C_nH_{2n+1}){-}C\begin{cases} {=}O \\ {-}OH \end{cases}$$

name	formula	melting point	neutralisation value mg KOH/g
caprylic acid	C_7H_{15}.COOH	16°C	389.1
capric acid	C_9H_{19}.COOH	31°	325.7
lauric acid	$C_{11}H_{23}$.COOH	44°	280.1
myristic acid	$C_{13}H_{27}$.COOH	54°	245.7
palmitic acid	$C_{15}H_{31}$.COOH	63°	218.8
stearic acid	$C_{17}H_{35}$.COOH	70°	197.2
arschic acid	$C_{19}H_{39}$.COOH	77°	179.5
lignoceric acid	$C_{23}H_{47}$.COOH	81°	152.2
melissic acid	$C_{29}H_{59}$.COOH	91°	101.7

Tab. 1: Important higher saturated fatty acids.

Monobasic organic (aliphatic) carboxylic acids (Table 1) derived from or contained in natural → Fats, or produced synthetically (→ Fatty acids, synthesis of). The lowest representative is → Formic acid (H–COOH). Fatty acids with 10–20 carbon atoms are the most important building blocks of naturally occurring neutral fats, fats, and waxes. Modern synthesis is also mainly geared to the production of these fatty acids.

Fatty acids of low and frequently high molecular weight, containing more than 20 carbon atoms, are made use of for particular applications. Fatty acids with 12 and 14 carbon atoms are primarily of interest for synthetic detergents. By contrast, fatty acids with 16 and 18 carbon atoms, although still of interest on account of their detergent-building properties are, however, chiefly used for the production of synthetic softeners, sizes, finishing agents, etc. → Soaps are obtained by treatment of fatty acids with alkaline liquors. Unsaturated higher fatty acids (Table 2) are of special importance as drying oils in linseed oil sizing because of their oxidizable double bonds. Uses: manufacture of soaps, textile auxiliaries, etc.

Fatty acids, alkali salts of → Soaps.

Fatty acids, synthesis of Of great technical importance. The starting product is synthesis gas which is used to produce synthetic paraffin by hydrogenation (Fischer-Tropsch process). The paraffin is then oxidized in the presence of contact substances by the injection of hot air at 80–170°C which brings about the decomposition of 1 molecule paraffin into 2 short-chain molecules of fatty acids with 12–18 carbon atoms (similar to coconut acid). Principle:

name	formula	melting point	neutralisation value mg KOH/g	iodine number
oleic acid	$C_{17}H_{33}$.COOH	14°C	198.6	89.9
elaidic acid	$C_{17}H_{33}$.COOH	44°	198.6	89.9
erucic acid	$C_{21}H_{41}$.COOH	34°	165.7	57.0
ricinoleic acid	$C_{17}H_{32}$(OH).COOH	6°	187.7	85
linoleic acid	$C_{17}H_{31}$.COOH	—18°	200.1	181
linolenic acid	$C_{17}H_{29}$.COOH	—11°	201.5	273.5
elaeostearins	$C_{17}H_{29}$.COOH	48°	201.5	273.5

Tab. 2: Higher unsaturated fatty acids.

Paraffin hydrocarbon $C_{24}H_{50}$ →
2 $C_{11}H_{23}$–COOH (lauric acid)

Raw soap is formed by saponification with caustic soda liquor from which paraffin residues are extracted by distillation. The pure synthetic → Fatty acids are obtained by adding acid to the raw mixture of fatty acids followed by fractional distillation. These acids behave in a similar manner to natural fatty acids, i.e. they form soaps with alkalis or fats with synthetic glycerol.

Approx. 75 t of synthetic raw fatty acids are obtained from 100 t of raw paraffin product.

Fatty alcohol condensation products For the production of highly stable textile auxiliaries it is logical to make use of the extremely useful higher → Fatty alcohols. By condensation of these alcohols with further substances, a lengthening of the fatty chain is achieved which increases the absolute effectiveness of these products still further in comparison to the starting materials. By this means, fatty alcohol sulphonates are obtained which, although stable to hard water salts, are nevertheless only stable to dilute acids etc. (carboxyl group). Products without sulphonic acid and carboxyl groups are obtained by condensation with ethylene oxide (C_2H_4O) which have good all-round stability and are used as levelling agents and dye penetrants in dyeing with cationic, direct, vat, 1:1 metal-complex, and naphthol dyes. These products are excellent stripping agents for the latter class of dye and have a simultaneous cleaning and wetting action. Levelling agents for 1:1 metal-complex dyeings, based on ethoxylated fatty alcohols, permit a 50% reduction in the amount of sulphuric acid required which results in a more gentle treatment of the fibre. Analogous products are also used for the washing of wool under acidic conditions, for levelling/brightening in acidic dyebaths, and as emulsifiers, etc. Sulphated and ethoxylated fatty alcohols are of importance as wetting, washing, and levelling agents.

Fatty alcohol derivatives, e.g. with sulphonic acid groups in the middle position → Fatty alcohol sulphates, fatty alcohol esters, pyrophosphoric acid esters, condensates with sulphonic acids, → Fatty alcohol ethoxylates, etc. Properties: most have high stability with good wetting, levelling, cleaning, and softening properties.

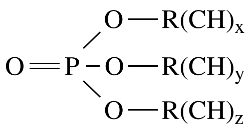
Fatty alcohol esters →: Fatty sulphuric esters; Fatty alcohol mineral acid esters.

Fatty alcohol ethoxylates Type: $C_nH_{2n+1}(OCH_2)_mOH$. → Spinning preparations.

Fatty alcohol ethoxylates and acetates Type: R–O–$(C_2H_4O)_n$–CH_2–COOH. Carboxymethylated fatty alcohol ethoxylates (e.g. sodium salt of C_{12}/C_{14} fatty alcohol-4,5-EO acetate). In contrast to soaps, these compounds possess condensed ethylene oxide units capable of hydration between the hydrophobic and hydrophilic parts of the surfactant molecule. This modification results in improved water-solubility and stability to hard water. Suitable for use as antistatics, dispersing agents, textile auxiliaries and surfactant components for washing agents and detergents. This class of anionic surfactants, produced by the reaction of fatty alcohol ethoxylates with chloroacetic acid, is of technical interest since, despite the anionic character of these products, they are not sensitive to calcium hardness. They also have a good lime-soap dispersing capacity. The detergency of these products is good and their soil-suspending properties are particularly noteworthy.

Fatty alcohol mineral acid esters Apart from the → Fatty alcohol sulphates (sulphuric esters of fats), these are esters of persulphuric acid, phosphoric acid and pyrophosphoric acid used as textile auxiliaries of similar composition. They are of practical significance as wetting agents with detergency properties and oxygen-releasing bleaching auxiliaries. Also used for the aftersoaping of fast dyeings, etc.

Fatty alcohol phosphates Anionic products with low detergency and wetting properties. They are of importance, e.g. as antistatics.



Fatty alcohol polyglycol ethers → Polyglycol ethers.

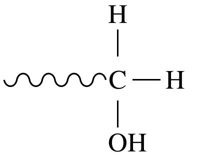
Fatty alcohols These compounds are formed as follows,

$C_{17}H_{35}COOH$ → $C_{17}H_{35}CH_2OH$

stearic acid → stearyl alcohol (octadecanol)

This reaction is accompanied by complete elimination of the problematic fatty acid carboxyl group. In principle, the complex R–COOH is reduced in the high pressure hydrogenation of fats to R–CH_2OH, as a result of which higher fatty alcohols with C_{8-18} are formed from the corresponding fatty acids.

The fatty acid glycerides or fatty acids of natural origin (coconut oil, palm oil, olein, lanolin, sperm oil, etc.) or the synthetic fatty acids obtained from the oxidation of paraffins are used as starting materials. The fatty alcohols thus formed are always primary alcohols in which one solubilizing group is missing.



The production of synthetic fatty alcohols is carried out by the following methods:

I. Oxidation of hydrocarbons in peanut oil with the addition of boron trioxide accompanied by the formation of secondary fatty alcohols (Baschkiroff process).

II. Ziegler process from ethylene (alfols).

III. Oxo process from olefin hydrocarbon vapours passed over cobalt catalysts in the presence of CO and H_2. The oxidation results in the formation of branched-chain primary alcohols (oxo alcohols).

Fatty alcohols are insoluble in water but soluble in many organic solvents. Together with soaps, Turkey Red oils, fatty alcohol sulphates and other solvents, they are used in textile auxiliaries as softeners and finishing agents. With paraffin they are also used for water-repellent finishes, etc. Low molecular weight fatty alcohols are useful as antifoams. The most technically important fatty alcohols are:

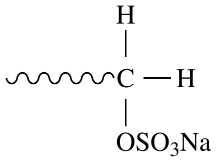
- Lauryl alcohol,
- Dodecyl alcohol,
- Myristyl alcohol,
- Tetradecyl alcohol,
- Palmityl alcohol,
- Cetyl alcohol,
- Stearyl alcohol,
- Octadecyl alcohol,
- Oleyl alcohol.

Fatty alcohols, oxyethylated → Polyethylene glycol ester.

Fatty alcohol sulphates

I. The type of sulphate (→ Sulphation) that contains $-C-O-SO_3Na$ as a fatty ester of sulphuric acid with the sulpho group connected to carbon through an oxygen atom.

II. Fatty alcohol sulphates (primary alkyl sulphates) are formed by the esterification of fatty alcohols with acids, e.g. sulphuric acid (after neutralization). Like Turkey Red oils, they are → Fatty alcohol sulphuric esters but without their carboxyl groups. The desired processing properties may be selectively determined by an appropriate choice of the number of carbon atoms. Sulphated oleyl alcohol and sperm alcohol are predominantly used as washing and wetting agents. A range of properties are obtained from mixtures of fatty alcohol sulphates, e.g. "synthetic detergents" with combined wetting, levelling, washing, softening and dye-penetrating properties. They are also used as brightening agents, delustrants, degumming and lubricating agents, besides oxidative bleach stabilisers, emulsifiers, etc.



$$\sim\!\sim\!\sim C(H)(H)(OSO_3Na)$$

Fatty alcohol sulphonates Sulphonates (→ Sulphonation) of the type $-C-SO_3Na$ exist as salts of fatty sulphonic acids with a direct C–S bond.

Fatty alcohol sulphuric esters Identical with → Fatty alcohol sulphates (→ Fatty sulphuric esters).

Fatty amine polyglycol ethers → Polyglycol ethers.

Fatty amines Higher → Alkylamines of the type: $R-CH_2-NH_2$. Uses: synthesis of surface-active compounds; corrosion inhibitors; as the acetates for emulsifiers and textile auxiliaries. Secondary fatty amines (distearylamine) are used as starting materials for the manufacture of laundry softeners. An interesting class of fatty amines are the hydroxy amines (cationic surfactants).

Fatty aromatic condensation products Obtained by the condensation of → Fatty acids (fats) with aromatic (benzene, naphthalene) derivatives.

Fatty chain ion The ion which, on dissociation of soap-like textile auxiliaries, contains the fatty residue (aliphatic hydrocarbon residue) which may be anionic or cationic.

Fatty sulphuric esters, alkyl sulphates, i.e. → Fatty alcohol sulphonates, sulphonation products (anionic character) of fats or fatty alcohols that are unsaturated or contain hydroxyl groups (→ Fatty alcohol sulphates). Typical groups: $-C-O-SO_3H$ or $-C-SO_4H$. The neutral sodium salts (→ Metal fatty alcohol sulphates) are produced by replacing the hydrogen atom with sodium. In contrast to "real" sulphonic esters, the sulphur atom is connected through an "oxygen bridge" (C–O–S–). This leads to the alternative names of "O-sulphonates", alkyl sulphonates or sulphuric acid alkyl ethers.

Fault detection in fabric inspection When inspecting goods faults may be detected either by visual evaluation or automatically by using appropriate optical systems. In both cases the fault detection is carried out on a moving length of cloth.

Automated fabric inspection makes use of either mobile video cameras or static "eyes" fitted with complicated computer hardware and software for the collection of information (Figs 1, 2 + 3).

Fault marking and recording devices Devices for the mechanical registration of fabric faults on index cards or in connection with fault marking threads on the selvedge of the fabric, during inspection by machine. Certain devices can be used at inspection tables on moving fabric.

Fault registration is carried out using devices that register the type, position and number of faults during fabric inspection and classify them into categories. The identification details of the pieces examined are also noted.

Faults in textiles A fault is a → Characteristic that does not fulfil a prescribed requirement. A fault does not necessarily affect the usefulness of the product. It is

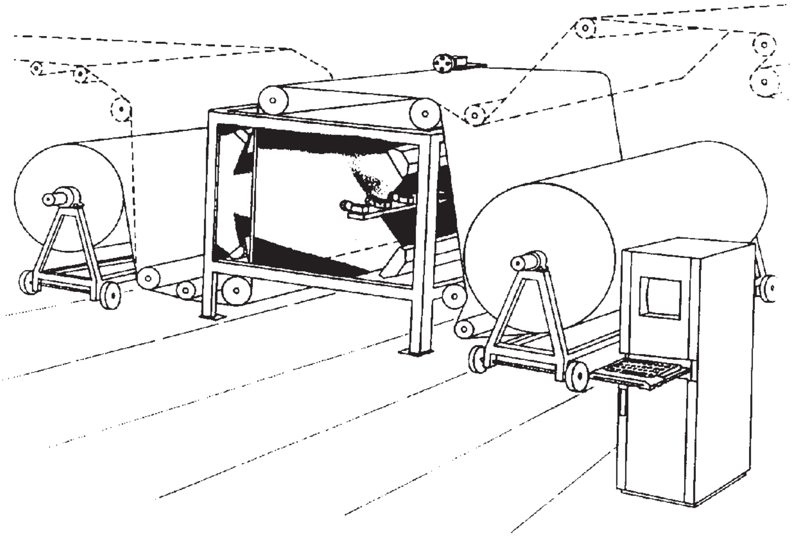


Fig. 2: I-TEX 200 video fault detection system (Israel)

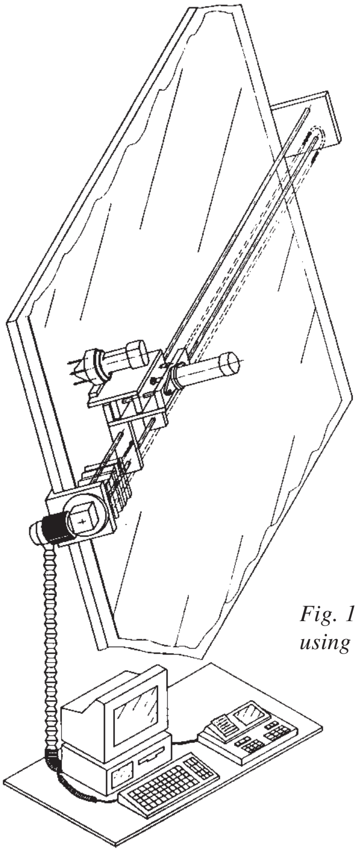

Fig. 1: Trial fault detection during fabric inspection using a mobile video camera

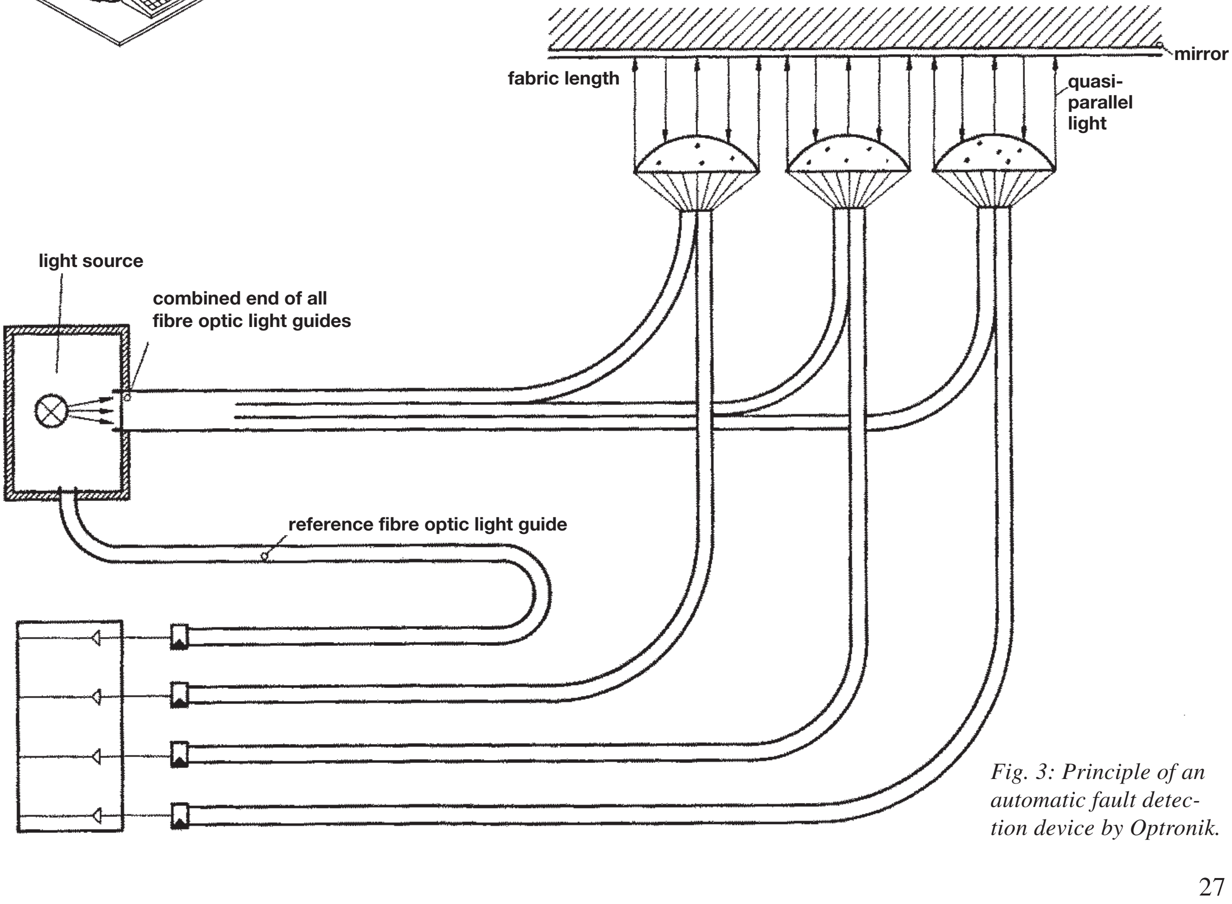

Fig. 3: Principle of an automatic fault detection device by Optronik.

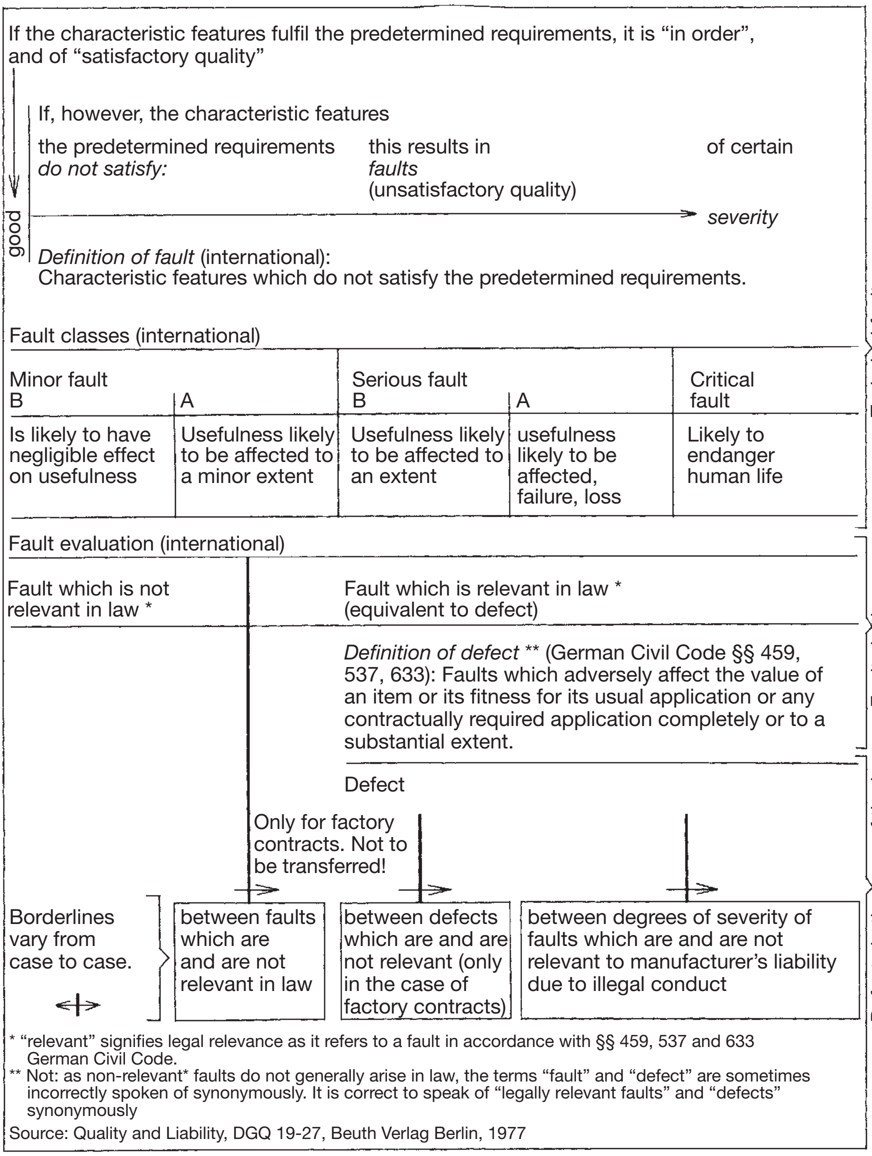


If the characteristic features fulfil the predetermined requirements, it is “in order”, and of “satisfactory quality”

If, however, the characteristic features the predetermined requirements *do not satisfy:* this results in *faults* (unsatisfactory quality) of certain *severity*

Definition of fault (international): Characteristic features which do not satisfy the predetermined requirements.

Fault classes (international)

Minor fault B	Minor fault A	Serious fault B	Serious fault A	Critical fault
Is likely to have negligible effect on usefulness	Usefulness likely to be affected to a minor extent	Usefulness likely to be affected to an extent	usefulness likely to be affected, failure, loss	Likely to endanger human life

Fault evaluation (international)

Fault which is not relevant in law *

Fault which is relevant in law * (equivalent to defect)

Definition of defect ** (German Civil Code §§ 459, 537, 633): Faults which adversely affect the value of an item or its fitness for its usual application or any contractually required application completely or to a substantial extent.

Defect

Only for factory contracts. Not to be transferred!

Borderlines vary from case to case.

between faults which are and are not relevant in law

between defects which are and are not relevant (only in the case of factory contracts)

between degrees of severity of faults which are and are not relevant to manufacturer’s liability due to illegal conduct

* “relevant” signifies legal relevance as it refers to a fault in accordance with §§ 459, 537 and 633 German Civil Code.

** Not: as non-relevant* faults do not generally arise in law, the terms “fault” and “defect” are sometimes incorrectly spoken of synonymously. It is correct to speak of “legally relevant faults” and “defects” synonymously

Source: Quality and Liability, DGQ 19-27, Beuth Verlag Berlin, 1977

Tab.: Overview of the terms fault and defect from a technical and legal viewpoint.

therefore to be differentiated from the term → Defect that always represents an adverse effect on usefulness (Tab.).

Deviations of the actual value from the desired value are permitted within a certain tolerance and therefore not regarded as faults. There is a strong link here with the terms “characteristic” and “limit value”: often in practice limit values of a characteristic are encountered which are dependent on the size of one or more characteristics. These therefore also lead to similarly dependent faults. Apparent faults are immediately recognizable during required detailed inspection or testing procedures which must be carried out, for example in accordance with the standard conditions of the German textile finishing industry a clothing manufacturer must inspect all incoming goods before further processing. In contrast to this type are hidden faults which first become apparent in the course of time (e.g. whilst being worn) or whose presence is only detected as a result of complex tests. These include dye fastness defects, deviations from the blend proportions, chemical damage to the fabric.

Faulty batches Unlevel dyed or otherwise unusable → Dye batch or similar.

FBA, abbrev. for: → Fluorescent brightening agents.

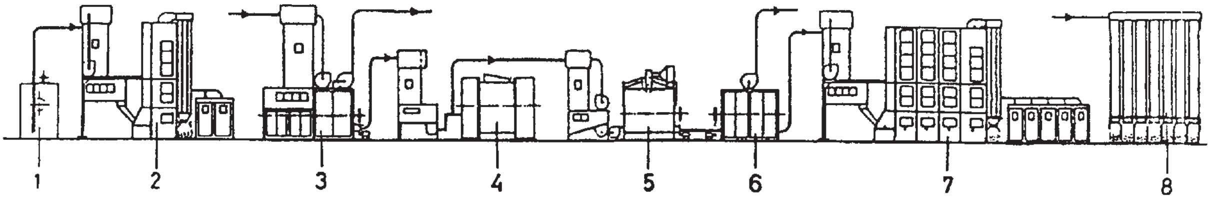
FC, abbrev. for → Fluorocarbons.

FCR (Ger.), abbrev. for: Forschungsstelle Chemischreinigung (Research Unit for Drycleaning); → Professional and technical organizations.

FCT, abbrev. for: → Fog chamber technique.

FdH (Ger.), abbrev. for: Forschungsinstitut der Hutindustrie (Research Institute of the Hat Manufacturing Industry); → Technical and professional organizations.

Fe, chemical symbol for iron (26).



1. **Shaking out machine for untreated feather bundles**
2. **Presorting machine**
3. **Dust extraction machine**
4. **Washing and centrifuge machine**
5. **Drier**
6. **Cooling and de-dusting machine**
7. **Sorting machine**
8. **Filter plant for all machines**

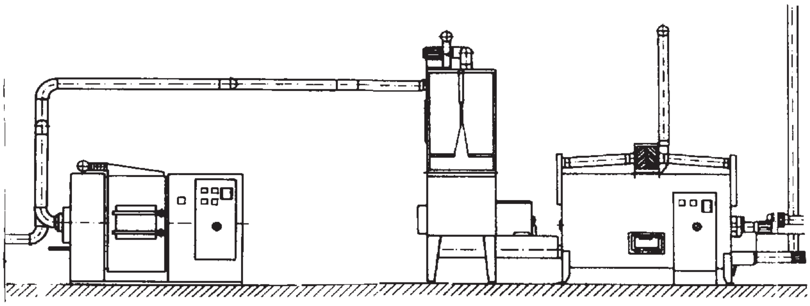


Fig.: Processing line for the automated treatment of feathers and down for bedding.

Feather processing Feathers and down used for the filling of quilts. After initial sorting they require washing in special machines. This is done in 60 kg batches in drum washers that are also capable of centrifuging for water-use minimisation (Fig.). The feathers are loaded and unloaded by air jet into a continuous tumble drier where they are also sprayed with disinfectant (and possibly light bleach) and then dried. The batch sizes are 60 kg/h per machine and this determines the line capacity. Problems may arise with black feathers, when only a small number contaminate a white batch.

Featherproof → Featherproof finishing of duvets, eiderdowns.

Featherproof finishing of duvets, eiderdowns Finishes for this purpose are mainly based on the application of thermoplastic synthetic resins followed by a calender treatment. In order to produce a satisfactory finish, a distinction must be made between bed ticking and downproof fabrics and, in the case of the filling material, between down and feathers.

Feeding addition A finishing term for the regular feeding of finishing liquors during continuous processing.

Feed unit A delivery system for feeding non-batched textile fabrics in open-width, rope or plaited form.

Fehling's solution A solution of copper sulphate, potassium sodium tartrate and NaOH used for estimating and detecting reducing sugars. Textile applications include the detection of hydrocellulose, oxycellulose and photocellulose as well as sugars (analysis of finishes). The Fehling's solution is freshly prepared from 69,278 g of copper (II) sulphate and Rochelle salt solution (173 g potassium sodium tartrate tetrahydrate in 400 ml water + 100 g sodium hydroxide made up to 500 ml). Both solutions must be mixed before use. The test is carried out by heating the material with 10% of a freshly prepared Fehling's solution to the boil on a water bath. An approximately quantitative evaluation is made with the aid of a colorimeter. The colour of the copper (I) oxide which is precipitated onto the affected area of the textile is pink to brick-red.

FEK (Ger.), abbrev. for: Französische Echtheitskommission (French Fastness Commission) Paris. → Technical and professional organizations.

Fellmongered wool → Skin wool.

Felt Textile fabric made of, or with, a random fibrous material. Classification according to type of manufacture:

I. → Needle punched felt.

II. → Milling felt (wool and hair felt): In accordance with DIN 61 205 surface effect or whole fabric made of feltable fibres, possibly mixed with non-felting fibres, includes nonwovens, consolidated through the effects of moisture, temperature, pressure and movement (felting and, if necessary, milling). From hairs = hair felt, from wool = wool felt, from wool and hairs = mixed felt (milled fabrics).

III. Fabric felt made of woven, milled and felted woollen system yarn. May be one-sided with felt and fabric layers or double-sided with 2 felted surfaces and a woven interior. Heavily milled, single or multi-layer fabric with a raised surface is called felt cloth or cloth felt. There are also doubled-sided felts with a carrier fabric made of cotton or jute and a double-sided wool fibre surface.

Wide range of applications. Light piece felt for clothing purposes (traditional costumes), cut as trimming instead of leather, sewed or stuck on (edging, braid, jacket, coat under-collar), similarly also for decorative purposes, in place of carpets, as carpet underlay and, if manufactured differently, as base for hat manufacture. Technical felts are widely used as felt jackets, calender felt, tubular felt, embossing felt etc. for winding around working rollers and heated drying cylinders, as back cloth, damping felt, shock absorbing foundation underlay, cushions, gaskets etc.

Feltability of wool → Felting propensity of wool.

Felt body → Hat body.

Felt calender (→ Calenders). A special type of calender at the delivery end of a stenter (see Fig.) used especially for linings.

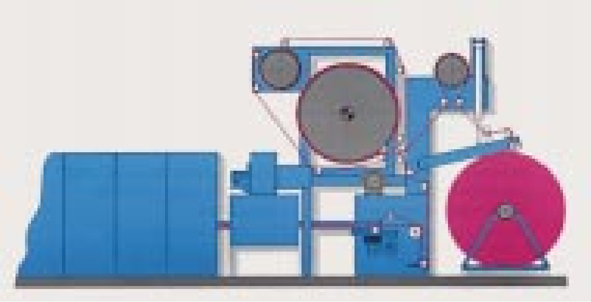

Fig.: Felt calender (Krantz).

Felt chromatogram → Levelling property test.

Felt cloth, woven felt → Felt.

Felt fabric A term used to describe a milled felt of a similar type to → "Feltine" which is not woven, bonded or stitched. It is made, e.g. from wool fleece (with/without man-made fibres) which has been bonded into a web by felting in a plate felting machine followed by subsequent milling.

Felt ground → Needle-punched carpets.

Feltine Proper name of a milled felt which has no woven structure and no chemical bonding, the textile fabric instead being created by the intensive felting of loose virgin wool. Feltine is piece dyed and may be impregnated. The brilliancy of the colours is typical. These materials are produced to defined thickness and handle (stiffness). Their use is traditional in certain types of clothing.

Felting An undesired process of superficial "felting" of woollens or an intentional process. This is used to mean the processing of loose fibres to form a dense and durable fabric, whereby mechanical effects (pressure, impact, friction) aided by moisture and warmth achieve a homogeneous combination of the fibre material. Milling is similar to felting. This is the processing of piece goods to give them a high density and strength. In milled fabrics, individual fibres or individual warp and weft threads are no longer recognisable, because they disappear under a uniformly dense hair cover. This felting process only occurs in animal hairs, particularly wool. In felting or milling the material shrinks in length and breadth, giving the material a completely different appearance and a different (full) handle and higher weight per metre. The shrinkage process is strongly dependent upon the pH of the treatment liquor. For certain applications, e.g. for carpets, the felting of woollen yarns is carried out using a discontinuous and continuous process in water or solvent. → Felting propensity of wool; Anti-felting finish.

Felting, degree of Measure of the tendency to felt according to the → Aachen felting test, expressed in terms of felt density in g/cm^3.

Felting density → Felting, degree of.

Felting propensity of loose wool Measured by means of the → Aachen felting test.

Felting propensity of wool This is a characteristic found in animal fibres, which shrink under certain conditions. The causes of → Felting are not precisely understood. There are many familiar felting theories, and we will only describe the most important theories. We referred earlier to individual characteristics of wool, and these are reflected in the felting theories:

a) Primary (causal) characteristics such as surface structure, frictional behaviour (DFE), lengthways or cross elastic characteristics;

b) Secondary characteristics such as fineness, length, crimp, grease content;

c) External factors, which represent the conditions during felting and milling, such as pH, temperature, milling auxiliaries.

A first theory originates from Short, and was later taken up by Martin. Fig. 1 (a) clarifies the most important phases of this theory.

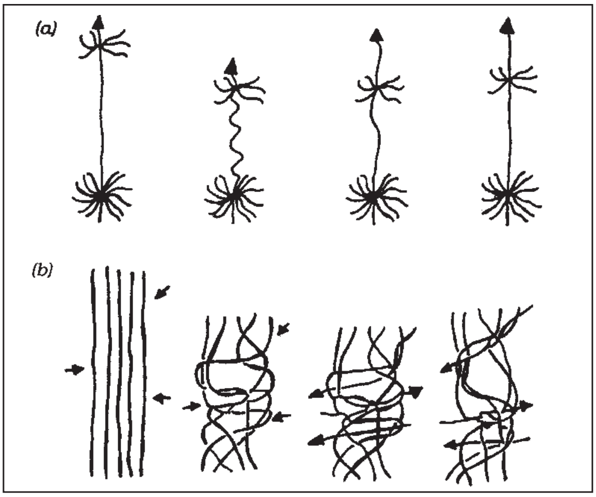

Fig. 1: Theoretical sequence of the felting process according to Shorter and Martin.
(a) = movement of the open knot (above) in direction of the fixed knot (below) by the action of the elastic, operative fibre; (b) = transfer of model (a) to multiple fibres.

In contrast to this theory, Arnold believes that the fibres come into contact due to friction, impact and pressure and wander due to their scale structure (earth worm theory). Another familiar theory is what Martin calls the "Loop Locking" theory (Fig. 1 (b)): The use of mechanical compression causes the fibres in yarn to bend into loops. Loose fibres (arrows) wander about, root end first, and repeated compression gradually makes these into loops. Finally, knots or kinks form, and the yarn can no longer return to its original length. A compressed fibre area of operative fibres with root ends is first penetrated, whereby knotting at the different points in the fibres is not necessary. After the external effect ceases, the fabric can no longer return to its original state.

Common to all theories is the recognition that the felting process is dependent upon many factors. The importance of the DFE (Directional Frictional Effect) is often stressed. According to this theory, a high frictional coefficient in the tip-base direction in comparison to the base-tip direction causes the wool fibre to move towards the base under frictional loading. This effect is dependent upon the scale structure of wool, which means that when wool fibres move in an unorientated, loose fibre compound, the fibres must move in the direction of the base (Fig. 2).

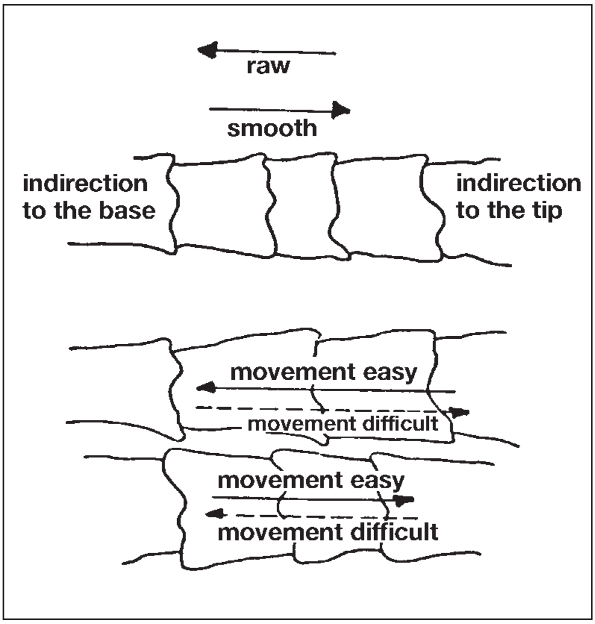

Fig. 2: Directional frictional coefficient and scale structure of wool.

In addition to the felting theories above, in the context of antifelting finishes, Stigter and Meichelbeck and Knitter have discussed the felting behaviour (or flocculation behaviour) of wool fibres in an aqueous medium and in solvent mixtures. They attributed felting behaviour to certain "charge relationships" in the wool and thus deviate significantly from previous theories. It was found that untreated short wools in aqueous solutions combine to form floccular aggregates. The relatively uncharged, hydrophobic nature of the fibre surface causes the fibres to move closer together, thus driving out the water, i.e. keeping the surface between the fibres (hydrophobic) and water (hydrophilic) as small as possible. If the fibres get closer together in a aqueous media, then the water molecules, which are located on the wool fibre are repelled, thus going over into a low energy state (state of lower order). The released energy works as a driving force on the fibres, so that the fibres are brought in close contact allowing them to form hydrophobic interactions. The charge of the groups on the surface of the fibre also influences the felting behaviour of the wool. Meichelbeck and Knittel made the following observation: Positively charged wool shows a strong tendency to felting in a aqueous solution with a high pH, because the charges repel each other (fibre/liquor) and the fibres move closer together. Negatively charged wool, on the other hand, demonstrates almost no tendency to felting in a aqueous liquor with a high pH, because the different charge relationships between wool and liquor counteract each other and thus distance the fibres from each other (= buffering), i.e. the fibres are separated by a liquor film.

The electrostatic interaction between the fibres thus influences the felting behaviour of wool. These findings help to explain the "antifelting" behaviour of wool in hydrophobic solvents such as tetrachloroethane. The wool fibres behave in a hydrophilic manner towards the hydrophobic solvent, forming stable suspensions. This characteristic is a result of the fact that hydrophobic interactions only exist in the presence of water. In contrast, there is a hydrophobic environment in the solvent tetrachloroethane, which prevents hydrophobic interactions occurring between the individual fibres. The absence of such interactions leads to the formation of a "buffering film" (of tetrachloroethane) between the fibres, which means that the fibres cannot get closer together and thus no felting takes place in the wool.

Felting shrinkage In contrast to → Relaxation shrinkage, e.g. this relates to the felting which takes place in woollen fabrics through mechanical movement of the fibres under conditions of moisture, and which can be counteracted by shrinkproof finishing. Adding synthetic fibres to wool counteracts the felting shrinkage. Effective improvement is achieved only with additions from 40–60%.

Felting test for loose wool → Aachen felting test.

Felt jacket Analogous to → Tubular felt, for pulling over working rollers, or as back cloth, etc.

Felt mat Hand-crafted → Flat carpet made of firmly felted natural wool, figured effects are worked-in, natural-coloured felt sections; used as carpet and wall hangings.

Felt press → Pressing.

Felt sleeve → Tubular felt.

Femto- (Danish or Norwegian: *femten* = fifteen). A prefix denoting 10^{-15}, i.e. one quadrillionth (USA and Canada), e.g. 10^{-15} second = 1 femtosecond (fs).

Fents Finished textile piece goods in short lengths (as metre goods) for retail sales. → Cut fabric.

Fermentation A type of chemical decomposition initiated by anaerobic bacteria, enzymes (desmolases, coenzymes), yeasts, moulds, and funghi which mostly involves acidic biochemical reactions without the development of foul-smelling odours (opposite → Putrefaction). As a rule, fermentation results in the cleavage of carbon chains, i.e. the biodegradation of compounds of higher molecular weight to those of lower molecular weight, often accompanied by the development of heat (life support for microorganisms) and waste gases, e.g. carbon dioxide. The fermentation of sugars to alcohols according to the following reaction:

$$C_6H_{12}O_6 \rightarrow 2\ C_2H_5OH + 2\ CO_2$$

is probably the most well-known fermentation process, as well as the fermentation of lactic acid, butyric acid and urea. The course of reaction is, however, considerably more complicated than would appear from the above reaction since a number of further intermediate or side products are formed which are, as a rule, transformed rapidly from one to another. In general, the most favourable temperature for fermentation lies between 30 and 37°C, and the most favourable sugar content between 20–25% (at 30–32% no more fermentation takes place).

Fermentation vats are still used occasionally in Africa and East Asia as a customary method for the dyeing of cotton and wool with indigo. Sugar-containing plants and fruits are used as a fermentation medium, and sodium carbonate (soda), calcium carbonate (lime), wood ash or potassium carbonate (potash) as the alkali.

Ferments (Lat.: *fermentum* = yeast). Any agents or substances, such as bacteria, moulds, yeasts or enzymes, that cause fermentation to take place.

Feronia rubber is a gum from East India → Vegetable gum, similar to → Gum Arabic, the primary constituent of which is arabinic gum, making it very water soluble.

Ferric salts Iron (III) salts; → Iron.

Ferrite A ceramic iron oxide compound having ferromagnetic properties with a general formula MFe_2O_4, where M is generally a metal such as cobalt, nickel or zinc.

Ferrous salts Iron (II) salts; → Iron.

Festoon ager A steaming chamber for short print runs. The fabric is transported in loops suspended on rotating upper rollers so that there is no roller contact with the printed side.

Festoon drier → Short loop drier.

Festoon dwell chamber → Festoon store.

Festoon scouring machine → Mezzera continuous scouring machine. Machine used in silk and artificial silk finishing for creping and shrinking, also used on knitted fabrics.

Festoon steamer (steaming chamber). A chamber type steamer of brickwork or cast-iron construction suitable for long runs (1000 m and above). The fabric is transported through the roof-heated steam zone suspended in loops from support rods attached to an endless moving chain. Disadvantages of this type of steamer are (1) extraordinarily large dimensions (up to 10 m in height), (2) high steam consumption and (3) difficulty in achieving uniform steam circulation.

Manuf.: Ramisch Kleinewefers.

Festoon stitch Identical with the so-called “buttonhole stitch”.

Festoon store Acts as a relaxing unit. Fabric is introduced via an adjustable slit and suspended on supporting rods. Open-width submerged fabric passage, tension-free, does not cause creasing. External direct and indirect heaters, automatic temperature control.

Festoon tape is thin, batiste-like edging and bordering tape with a dog-legged selvedge and decoration resembling eyelet embroidery.

FI, → Fique fibre, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

FIANN (Fr.), abbrev. for: Fédération Internationale des Associations Nationales de Normalisation (International Federation of National Standards Associations); → Technical and professional organizations.

Fiberset process A resin finishing process for cotton and polyester/cotton fabrics in which a reactive prepolymer is applied together with N-methylol compounds. Polymerization and crosslinking of the applied finish is achieved by treatment in the vapour of a low boiling chlorinated hydrocarbon.

Fibre The smallest unit of any textile material. The so-called raw fibre (→ Fibres) is converted by spinning into threads (yarns of various types).

Fibre affinity →: Affinity; Dye affinity; Textile auxiliaries with fibre and dye affinity in wool dyeing.

Fibre attraction Forces acting between soil particles and textile fibres: a) mechanical retention, b) chemical bonding (stains), c) adsorption, e) electrostatic attraction. The attachment of fat-free soil particles (pigment soil) is mainly due to geometrical factors, i.e. dimensional relationships between fibre surface roughness and pigment particles in aqueous dispersion which are not based on energetic bonding (e.g. adsorption, absorption).

Fibre blends, dyeing and finishing of Efforts to extend the ranges of woven and knitted fabrics have been increasingly associated with the use of natural and man-made fibres in fibre blends. The corresponding

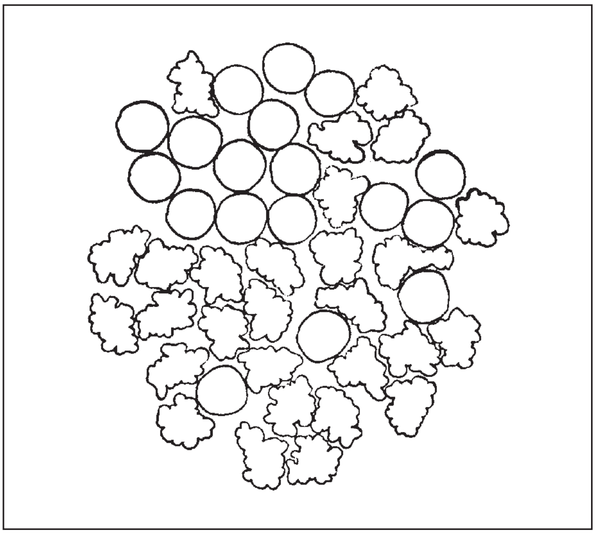

Fig. 1: Projection diagram of a polyamide 6 and viscose filament blended yarn.

dyeing methods	*weight (´000 tonnes)*
exhaust dyeing (warp knitted fabric)	720
exhaust dyeing (woven fabric)	390
exhaust dyeing (yarn)	460
cold dwell dyeing	35
continuous dyeing	1 350
white fabric	750
prints	650
	4 365

Tab.: World consumption of polyester/cellulose blends.

yarns are also described as heteroyarns (Fig. 1). Experience has shown that the use of such blends can significantly reduce the consumption of natural raw materials (such as wool or cotton) both for everyday products as well as technical textiles. At the same time, the quality of the article and its comfort in practical use can also be improved. The growing use of various fibre blends calls for the application of special finishing processes with the properties of each fibre component, as well as its behaviour towards dyes and chemicals, being taken into account. In principle, two types of process are used in practice: i.e. the two-bath method in which each component of the fibre blend is dyed separately, as well as the single bath method with only one process stage for all fibre components present. The single bath method is therefore more complicated since the processing conditions must be adapted to suit the most sensitive of the fibre components and the dyes selected for dyeing often have a different affinity for the fibres present. On the other hand, however, considerable savings of water, energy, chemicals and dyestuffs are achieved with the single bath method in most cases.

The popularity of polyester/cellulose blends has shown continual growth over recent years (see Table and Fig. 2).

A schematic representation of the distribution of disperse and reactive dyes in the dyeing of polyester/cotton blends is given in Fig. 3.

Fibre bonding device → Heat bonding of thermoplastics.

Fibre bundle strength The tensile strength of a cotton fibre bundle at zero gauge length per unit cross-section. It is determined in accordance with the → Pressley Index.

Fibre bundle tensile strength → Pressley Index.

Fibre composites Flexible, porous fabrics (→ Bonded fabrics) consisting partially or entirely of textile fibres formed by the bonding of → Nonwovens.

Fibre crosslinking agents Finishing agents with at least 2 functional groups capable of reacting with the fibre. →: Reactive resin; Cross-linker; Resin finishing agents.

Fibre cross-sections, preparation of → Microscopy fibre cross-sections, preparation of.

Fibre damage (cellulosic fibres), tests for Detection and determination of oxycellulose, hydrocellulose, photocellulose and pyrocellulose.

I. General determination of:
a) Degree of polymerization, e.g. fluidity;
b) Reducing properties (only for hydrocellulose);
c) Dye uptake of basic groups (only for oxycellulose);
d) Alkali solubility;
e) Tensile strength.

II. Qualitative methods of determination:
a) Fehling's solution: brick-red colour;
b) Ammoniacal silver solution: yellow-brown colour;
c) Lead-cochineal reaction: blue colour (oxycellulose);
d) Gold-purple reaction: red-brown colour (hydrocellulose remains unstained);
e) Methylene blue reaction: blue colour;
f) Nessler reagent: yellow colour turning grey later;
g) Schiff's reagent: red colour;
h) Berlin blue reaction: deep blue colour (oxycellulose);
i) Boil in caustic soda solution: yellow to brown colour;
j) "Mushroom" reaction (microscopic examination of fibre swelling in a 15% solution of caustic soda): undamaged cellulose produces a mushroom-like swelling at the ends of the fibres. Damaged cellulose, on the other hand, produces very little or no fibre swelling.

III. Quantitative methods of determination:
a) Copper number: hydrocellulose and other reducing substances;
b) Permanganate number: oxycellulose and hydrocellulose;
c) Methylene blue number: oxycellulose;
d) Alkali solubility: oxycellulose, hydrocellulose, pyrocellulose, photocellulose;
e) Degree of polymerization: oxycellulose and hydrocellulose;
f) Tensile strength.

IV. Detection of acids or alkalis on the fibre:
a) Test an aqueous extract with indicator paper (minimum detectable amount of sulphuric acid is 0,02%) or measure the pH.
b) The specimen is spotted with a 0,02% solution of methyl red in 50% alcohol. A red colour indicates the presence of acid whilst a yellow colour indicates alkali. Limit of detection is 0,005% of acid or alkali.

Fibre damage (regenerated cellulosic fibres), tests for Methods of detection and determination:

I. Presence of acids or alkalis on the fibre, oxycellulose, hydrocellulose, as under → Fibre damage (cellulosic fibres) tests for.

II. Degree of polymerization (→ Caustic soda liquor.

III. Solubility in sodium hydroxide solution.

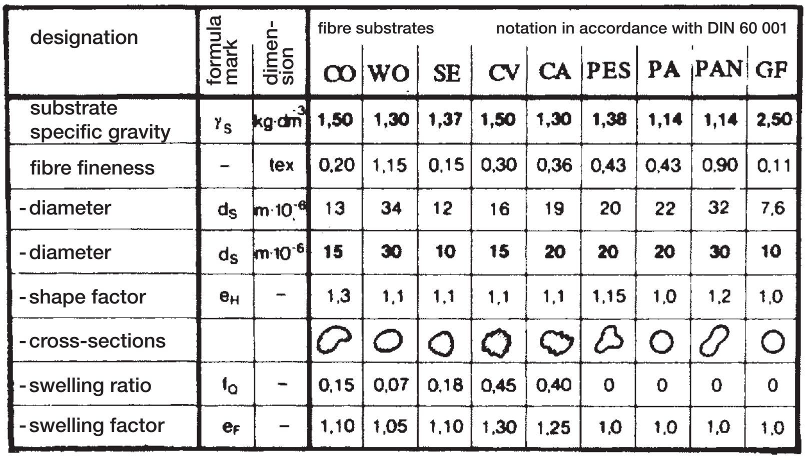
Fibre damage (wool), tests for

I. Qualitative methods: a) fibre microscopy; b) presence of acids or alkalis on the fibre (also including quantitative determination) as under → Fibre damage (cellulosic fibres) tests for; c) chemical tests →: Biuret reaction; Tin salt reaction; Diazo reaction for wool damage; Silver test; Elasticum reaction; Indigo carmine reaction.

II. Quantitative methods: a) alkali solubility; acid solubility; c) urea-bisulphite solubility; d) cystine and tryptophan content.

Fibre differentiation → Fibre identification.

Fibre dimensions and characteristics Dimensions and characteristics of importance in textile processing and finishing, together with typical fibre cross-sections and their corresponding form factors, are listed in the Table.



designation	formula mark	dimension	fibre substrates	notation in accordance with DIN 60 001							
			CO	WO	SE	CV	CA	PES	PA	PAN	GF
substrate specific gravity	γ_S	$kg \cdot dm^{-3}$	1,50	1,30	1,37	1,50	1,30	1,38	1,14	1,14	2,50
fibre fineness	–	tex	0,20	1,15	0,15	0,30	0,36	0,43	0,43	0,90	0,11

Tab.: Dimensions of various fibres.

Fibre dust Small fibre particles dispersed in the atmosphere.

Fibre engineering The production of tailor-made fibres which are structural modifications of basic man-made fibres types to meet specific requirements, i.e. fibre construction tailored to produce special types of fibre with preprogrammed properties in accordance with exact physico-chemical principles (molecular engineering). These modifications can be achieved, e.g. by:

1. Changes in molecular weight (= changes in degree of polymerization = changed fibre-technological properties).

2. → Copolymerization (e.g. for single-bath multicolour effects in dyeing).

3. Use of comonomers (e.g. special softening effects).

4. Aromatization (higher melting temperatures).

5. Modification of side groups (differential dyeing types, flame-retardancy, modified strength, stiffness, shrinkage properties, melting properties, solubility, etc.).

6. Use of polymer mixtures (polyblends, bicomponent fibres).

7. Polymer pigmentation (hydrophilic effects, antistatic effects, flame retardancy, fluorescent brightening effects, etc.).

8. Physical modifications (high-shrinkage fibres).

Fibre identification It is often necessary to make a rapid identification of the fibres present in a fabric. There are various methods, which may be used in combination or to confirm results:

- Burning test;
- Microscopic examination (normal and in cross-section);
- Determine the characteristic features;
- Solubility (solvent separation);
- Special confirmation tests;
- Staining tests for undyed materials.

1. Staining with Neocarmine W (Tab. 1): a small sample of the material, pre-wetted with alcohol, is immersed in the Neocarmine solution for 3–5 min., then removed, rinsed for 2 mins in running water and dried.

Fibre	Microscopic characteristic	Stain	Chemical reactions
Wool	Overlapping outer scales with internal length-wise lines. Coarse fibres may have internal dark blotches or rope-like marks.	yellow	dissolved in 2% potassium hydroxide solution, boil for 15 min.
Recovered wool	Scales more or less pronounced, fibrillated brush-like fibre ends.	yellow-brown	"
Coarse hairs	broad, often opaque, and form a very broad, striated cylinder.	yellow	"
Camel hair	Colour is grey, yellow to brown	"	"
Wool or lint fibre	scaly, unmarked, length-wise stripes		
Bristle	dark brown to black, generally contain blotches or continuous channelled markings with grainy content (natural dyes)		
Cashmere	Colour is white, grey or brown, the outer layer consists of fine, well-defined scales	yellow	"
Wool or lint fibre	display coarse stripes and split fibres		
Bristle	rope-like markings with fine-grained content		
Mohair	coarse stripes, wide, regular splits in the fibres, the scales are thin and often narrow to a point, fine hairs unmarked	"	"
Angora	Scales as with wool, but more pointed, groups of markings arranged like a string of pearls; coarser hairs have several rows of markings.	"	"
Raw silk	Single fibres are stuck together with gum (sericin)	olive green	soluble in formic acid zinc chloride solution, warm or boil for 1 min in conc. nitric acid.
Degummed silk	structureless, smooth, translucent, irregular length-wise.	dull yellow	"
Tussah silk (wild silk)	Individual fibres broad, band-like with fine length-wise stripes and creases, slightly twisted	green	dissolved by boiling for a few minutes in conc. nitric acid.
Raw cotton	thin ribbon-like with length-wise twists in either direction	light blue (red spots)	swells before dissolving in Cuprammonium hydroxide
Mercerized cotton	more cylindrical than ribbon-like structure with very few twists	deep blue (red spots)	dissolves without swelling in Cuprammonium hydroxide.
Viscose	longitudinal stripes, varying in intensity	red – reddish purple	swells before dissolving in Cuprammonium hydroxide
Cupro	structureless, smooth, translucent	deep blue	"
Cellulose Diacetate	1-3 longitudinal stripes, otherwise structureless	yellow (red or green spots)	soluble in acetone, glacial acetic acid and formic acid, not readily soluble in cold dichloromethane
Cellulose Triacetate	"	yellow (green spots)	soluble in cold dichloromethane and glacial acetic acid, practically insoluble in acetone
Kasein	partially smooth, partially striped longitudinally, usually with grained deposits	yellow-orange	
Polyamide	smooth, structureless	green (yellow spots)	soluble in cold 85% formic acid, turbid or precipitation on addition of water
Polyacrylonitrile	weak, longitudinally striped, slight twist	only slightly stained	soluble in cold nitric acid and boiling DMF
Polyester	smooth and structureless		soluble in molten phenol and boiling o-dichlorobenzene
Polyvinylchloride	smooth, fine to thick, some very thick sections	soiled	soluble in boiling dichloromethane and cold DMF

Tab. 1: Microscopic fibre identification after staining with Neocarmine W (plus chemical tests).
[Polyester may only be stained with Neocarmine MS (Merck)]

The staining process requires a white or only pale dyed material. Dyed material is not suited to this test method.

2. Staining with Neocarmine MS: a small sample of the material, pre-wetted with alcohol, is immersed in boiling Neocarmine solution for 5 min., then removed, rinsed for 2 min in running water and dried.

3. Dry distillation: the fibre sample is heated in a dry test tube. The gases released are tested with moistened litmus paper. Acid vapours turn blue litmus paper red, alkaline vapours turn red litmus paper blue. Acid vapours are released by: cellulose fibres (natural and recovered), acetate fibres. Alkaline vapours are released by: protein fibres (wool, silk, synthetic protein fibres), polyamide fibres, polyacrylonitrile fibres. Polyester fibres are initially neutral, then acidic.

4. Polyvinylchloride test: A fibre melted onto a copper wire colours a Bunsen burner flame intense blue-green.

5. Solvent separation (Tab. 2): Starting with dichloromethane, fibres are separated into groups by individual solvents. If the fibre is insoluble, a new sample is tried and then it is moved on to the next solvent. If a blended spun yarn is being tested, the sample must be dried between each stage and used for the next relevant solution test. The fibre materials are thus separated into different groups according to solubility and within each group identified by means of specific tests. To carry out the solution test: the fibre sample is placed in a test tube with approx. 5 ml of the solvent. The test can be carried out cold, but it is normally necessary to use hot solubility. A rule of thumb for the length of treatment is:

- cold: 30 mins, agitated, at room temperature,
- hot: 5 mins at the boiling temperature of the solution being used.

To ensure reliable evaluation of the solubility (esp. in the case of blended fibres) a control reaction is carried out (Tab. 2). After the solution test, approximately twice the volume of a "non-solvent" is added to the cooled solution. The dissolved fibre is precipitated out in the form of cloudiness or a flocculent precipitation. If using solutions which can be mixed with water, water should preferably be used, otherwise methanol. If the precipitated fibre material is to be used for further tests, it should be filtered out and dried.

Fibre identification by dry distillation A sample of fibre material is slowly heated in a dry test tube. The escaping vapours are tested with moistened litmus or pH indicator paper (see Table). Wool, animal hairs and casein (but not silk): blackening of moistened lead acetate paper (by H_2S). In the case of fibre blends, the components should first be separated by teasing them apart, and the fibres tested individually.

Solution/ fibre to be dissolved	control reaction
1. Dichloromethane cold: triacetate hot: PVC after chlorinated	with methanol: precipitation
2. Acetone cold $2^1/_2$ acetate	with water: turbidity
3. Tetrahydrofuran PVC not after chlorinated PVDC (polyvinylidene chloride)	with methanol: precipitation
4. Dimethyl formamide PA6, PUE, PAC	with water: precipitation
5. Formic acid 98% PA 6.6 (mulberry silk decomposes)	with water: precipitation
6. o-dichlorobenzene Polyester (PETP, PBTP)	cool off: turbidity
7. Xylene Polyethylene, Polypropylene	cool off: turbidity
8. Caustic soda 5% Wool, silk	cool off, with hydrochloric acid: turbidity

Tab.: Fibre identification by dry distillation. (Symbols in accordance with DIN 60 001 T4/08.91).

Fibre identification by luminescence Qualitative analysis of native and synthetic fibres by means of secondary luminescence produced by the exposure of fibres pretreated with rhodamine or fuchsin (magenta) to UV radiation. Optimum pretreatment: after 2–3 min prewash in sodium carbonate solution, treat for 10 min at 70°C in a solution having a specific dye concentration at a liquor ratio of 100:1 or 200:1. The pretreated fibre material is then observed under the microscope fitted with a luminescence accessory (mercury vapour lamp and light filter to allow the passage of radiation between 300–400 nm only). Each type of fibre gives a characteristic secondary luminescence colour depending on the indicator dye used, which also remains visible in fibre blends and dyed textiles.

Fibre identification by microscopy Fundamentals of microscopic and cinematographic methods of textile testing:

I. Examination in the magnifying glass range.

II. Methods of textile microscopy (light field, dark field, phase contrast, polarization and fluorescence microscopy).

III. Preparation of test specimens (impressions in Tylose, gelatine, elastomeric resins or by galvanoplasty in polystyrene/gold, microtome sections).

IV. Microscopic measurement and counting.

V. Use of filters and their effects.

VI. Scanning electron microscopy.

VII. Cinematography (HF and ultra short-exposure photography).

Fibre identification, rapid identification of man-made fibres Fibre solubility according to the scheme given below:

Fibre identification reagents →: Acetone solubility test; Aniline sulphate test; Caustic soda solubility test; Zinc chloride solubility test; Diphenylamine-sulphuric acid; Glacial acetic acid solubility test; Iodine-potassium iodide solution; Cuprammonium hydroxide; Methylene blue test; Nickel ammonium hydroxide; Persoz reagent; Phloroglucinol reaction; Nitric acid solubility test; Sulphuric acid solubility test; Zinc chlor-iodide solution; Zarts solution. → Fibre identification; Fibre identification scheme.

Fibre identification scheme (Tucci)

I. Homogeneous man-made fibres (i.e. not blended) are easy to separate and identify by their differing solubilities in organic solvents (Fig. 1).

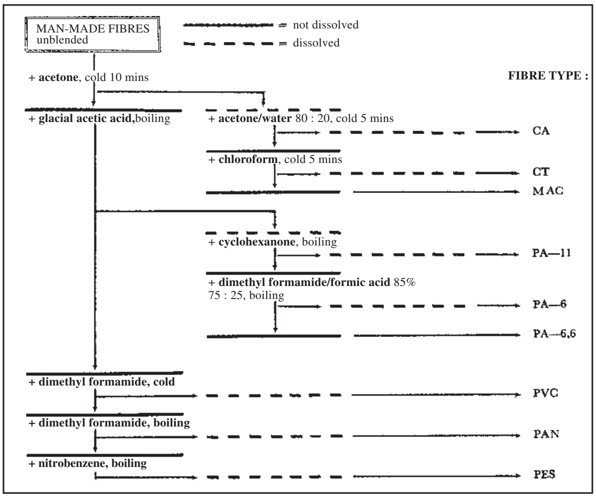

Fig. 1: Tucci's fibre identification chart (symbols in accordance with DIN 60 001 T4/08.91).

II. Fibre blends, especially intimate blends containing only a very small proportion of man-made fibres, are very difficult to identify by means of solubility alone. For this reason, a second test should be carried out to confirm whether the solvent does in fact contain dissolved fibre or not. After decanting the solvent off the fibre specimen it is tested according to the control reactions shown in the identification scheme (Fig. 2).

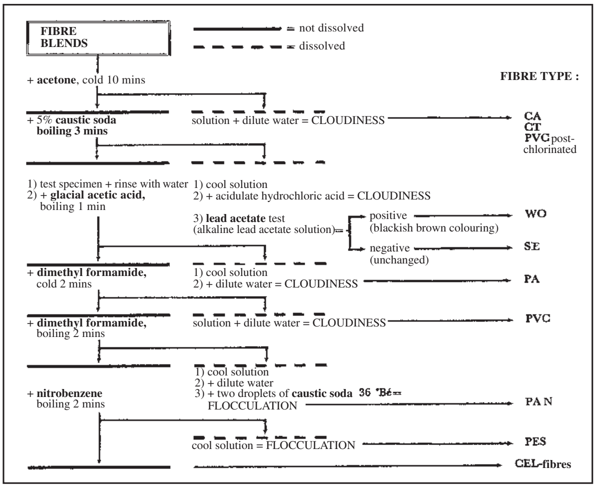

Fig. 2: Identification of fibre blends (according to Tucci). (Symbols in accordance with DIN 60 001 T4/08.91).

Fibre melting point →: Burning properties; Temperature characteristics of textile fibres.

Fibre modification

I. → Weight reduction of polyester fibres.

II. → Acetylated cotton.

III. → Affinity modification.

Fibre moisture content → Moisture absorption of fibres; Moisture regain.

Fibre plant → Natural cellulosic fibres.

Fibre polymers →: Macromolecules; Polymers.

Fibre pores (→: Vacuole; Medulla; Pore size of fibres). Intermicellar regions of fibre structure. In the case of wool, medullated fibres are somewhat more brittle. The abrasion resistance of a mixture containing a high proportion of medullated fibres (above 25%) is somewhat poorer than that of non-medullated fibres. On the other hand, the reproducibility is better.

Fibre pores, determination of Determined by → Mercury porosimetry. Under comparable test conditions the pore volume of the fibres increases as follows:

Polyester < Polyamide < Polypropylene < Cellulose < Polyacrylonitrile.

Within a fibre group the pore volume may vary considerably. It also varies considerably with different production methods. Thus, for example, dry spun fibres are more compact than wet spun.

Fibre protective agents Products of this type are used particularly for the protection of animal fibres in bleaching, dyeing and stripping. Fibre protective agents are also important in the wet processing of fibre blends. Even in the wet processing of cellulosic fibres, fibre protective agents have a role to play, e.g. to provide protective screening against oxidative/reductive changes in vat dyeing, and in oxidative bleaching, etc. Fibre protective agents are based on, e.g. protein degradation products, fatty acid protein condensation products, ammonium salts of alkyl sulphates and alkyl sulphonates as well as lignin sulphonic acid salts.

Fibre proteins (fibrillar proteins, chain proteins, scleroproteins). High molecular weight polypeptides consisting of long threadlike or chain molecules (→: Silk fibroin; Wool keratin). They are formed from → Amino acids.

Fibre quality testing Objective fibre testing is being increasingly automated. The classification of fibre quality using objective measurement methods has not yet penetrated the wool and silk market to the same extent as in the cotton. Specialists classified cotton by a subjective visual evaluation, assessing the fibre length, any impurities, the colour etc. and then gave the material a certain "class". The classifier was not, however, in a position to estimate the fineness, strength, elasticity and microdust content of the fibre etc. by mere visual inspection. During the last 50 years numerous types of test equipment have been developed for assessing the various fibre characteristics that can be measured with a sufficient reproducibility. The majority of these testing devices were, however, time-consuming and e.g. unsuitable for testing cotton in large quantities. They were used in cotton fibre research, by textile machine manufacturers and by some progressive spinning companies. The automation of fibre testing began in 1965 with collaboration between the US Department of Agriculture (USDA) and the Texan plant manufacturer Motion Control. This collaboration led to the first HVI (High Volume Instrument), followed by a further, similar device developed by Spinlab in 1984. Today a considerable proportion of the American cotton yield is tested by machine.

All earlier fibre testing procedures necessitated the preparation of a fibre sample, consisting of several thousand fibres, which were then combined to form a "bundle". As clips held the bundle, it was not possible to determine the proportion of short fibres in a "bundle test". Furthermore a bundle test did not allow fibre to fibre variations to be determined. It was not possible to determine the nep content by means of a bundle test. Neps occur where the fibres have formed lumps and are distinguished as natural (growth neps) and processing neps. The latter arise especially in cotton processing (scutcher, carder). Microscopic inspection will show that a large number of the neps consists of clumps of dead fibres or that they have been formed around the remains of a husk. The AFIS-N nep count and classification system employs evaluation of individual fibres to enable direct assessment of the nep content. The machine divides the sample into individual fibres, neps and trash (dust). The dust particles are separated off by means of a centrifugal process. The individual fibres and neps are caught up in a stream of air and led through an optoelectronic scanner. Here the nep responses are converted into a proportional voltage. The individual neps generate a characteristic pulse voltage, the size and length of which corresponds to the type of nep.

The availability of fibres in the fine yarn count region, from around 20 tex (Nm 50), is crucial to spinning success. The individual fibre count in terms of distribution has a considerable influence on the yarn quality and running properties. The fineness of the fibre therefore increases in importance as the yarn count increases. The fineness of cotton is usually given in micronaires. The micronaire value is a non-dimensional value representing the air permeability of a compressed cotton sample; it is direct relationship to the fibre surface area. This value, however, does not give a definitive value to the actual fineness in dtex, as it is also influenced by the maturity of the fibres. The effective average fibre fineness can be calculated in accordance with a formula devised by E. Lord, if micronaire value and degree of maturity are known.

The figure shows the relationship between the micronaire value, maturity and fibre fineness. It can be

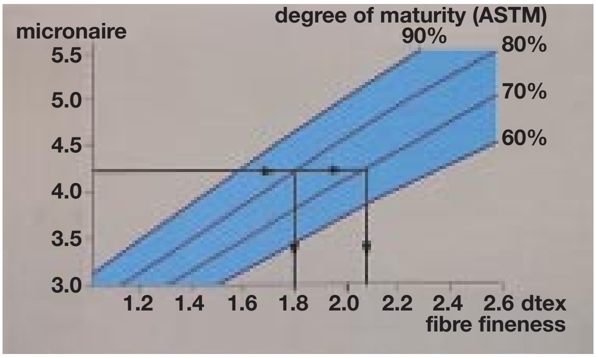

Fig.: Fibre testing: Fibre fineness of cotton in relation to degree of maturity.

seen that, given a constant micronaire value, different degrees of maturity affect the fibre fineness. The possible spin parameters are limited in this way. When spinning cotton there should be around 100–110 fibres in the yarn section in order to achieve stability in spinning and good breaking strength and regularity. Under particularly favourable conditions even yarns with a low average number of fibres may be spun successfully.

Fibre-reactive compounds → Reactant-fixable dyeings; Reactive resin.

Fibres (textile fibres). Linear-shaped raw materials capable of being processed into textiles and characterized by adequate flexibility, fineness and strength with a high ratio of length to thickness (Fig. 1).

They may be subdivided into:

I. Natural fibres:

1. Vegetable fibres: a) vegetable hairs (seed and fruit fibres); b) bast fibres, soft fibres (bast fibre bundles from the stems of dicotyledenous leaf plants); c) hard fibres (sclerenchymatous fibres and vascular bundles from the leaves or fruits of monocotyledonous plants); d) other vegetable fibres.
2. Animal fibres: a) wool and animal hairs; b) silk fibres.
3. Mineral fibres.

II. Man-made fibres:

1. Produced from natural polymers: a) of vegetable origin; b) of animal origin.
2. Produced from synthetic polymers: a) polycondensation fibres; b) polyaddition fibres; c) polymer fibres; d) bicomponent fibres.

III. Other industrially-manufactured fibres of inorganic basis; glass fibres, mineral fibres, metallic fibres, etc.

Fig. 1: Important fibre characteristics of natural fibre materials in comparison to regenerated cellulose fibre materials and synthetic fibre materials.

Depending on their form, fibres are also subdivided into:

- Staple fibres = fibres of predetermined short lengths (approx. 15–500 mm);
- Continuous filaments, of practically unlimited lengths;
- Flock fibres = very short fibres which cannot be spun < 15 mm.

Individual fibres form the basic building blocks of threads in the form of yarns used in the production of textile fabrics by weaving and knitting as well as nonwoven fabrics. Textiles are morphologically-determined structures produced from spinnable fibres of the staple variety and/or continuous fibres. In the spinning process, fibres are bonded together into threads by drafting.

I. Natural fibres:

Cotton: In terms of quantity this is the most important of the natural fibres. In its physical structure it reveals a large number of extremely strong fibrils of high order. These fibrils form an unusual spiral structure which can be easily penetrated by water and which, due to its chemical structure, is capable of forming bonds with a wide variety of chemicals, dyes, crosslinking agents, flame-retardants, water-repellent agents, etc. The same swelling properties make thorough washing treatments possible. Since the cotton fibre is not thermoplastic, it can be washed at the boil. The surface characteristics of cotton are to a large extent responsible for its comfort in wear, its rapid water absorbing properties, and its ability to retain good whiteness throughout its serviceable life. The main weakness of cotton is its lack of easy-care properties insofar as it is unable to satisfy the expectations of today’s consumer. The basic problem is not that cotton cannot be given an easy-care finish, but the fact that this improvement can only be achieved at the expense of significant strength and abrasion losses when cotton is resin finished to obtain improved wrinkle resistance.

Wool: The chemical structure of the wool fibre (even more than that of cotton) makes it possible to form chemical bonds with a great number of chemicals, dyes, etc. Among the many textile properties characteristic of the wool fibre, its three-dimensional, highly stable crimp, which is largely responsible for the bulk and handle of wool fabrics, as well as the reversible changes in crimp intensity due to variations in moisture content, are particularly noteworthy. The different swelling properties of both halves of the bicomponent wool structure cause a flattening of the crimp curvature when wet with a consequent reduction in the pore volume of yarns or finished goods. The wool fibre is a compound system of keratin fibrils in a network of cell membrane complex and matrix proteins. This structure, which is partly responsible for the good wearing comfort of wool, gives the fibre good temperature stability in the dry state and, at temperatures below 100°C, also in the wet state. Its felting propensity is one of those characteristics which, in contrast to cotton and man-made fibres, make the fibre particularly desirable in certain branches of the textile industry on the one hand, such as the manufacture of cloths, felts and hats but which, on the other hand, is a disadvantage in other applications. A further unfavourable property of apparel textiles made from wool fibres is their pilling propensity and (as in the case of cotton) their inadequate easy-care properties by today’s standards although these can be improved by the application of appropriate finishes.

II. 1. Man-made fibres from natural raw materials: The specific properties of viscose and modal fibres may be discussed under this category. The raw material for the manufacture of these fibres is cellulose. Whilst the chemical structure is identical to that of cotton, important differences in the physical structure of both these fibre types can be identified.

Viscose: In contrast to cotton, the average degree of polymerization of viscose fibres is lower. Moreover, the degree of order, which is approx. 30–40%, is likewise lower than that of cotton (50–60%). The major proportion of the fibre is present as an amorphous intermicellar region. Due to these structural deviations in comparison with cotton, viscose reveals certain differences in its range of properties. The conventional viscose fibre thus exhibits lower strength properties, a higher water absorption, a greater creasing propensity and a higher extensibility than cotton. Its easy-care properties are likewise inadequate by today’s standards. Viscose fibres are particularly valued for their high degree of lustre in textile fabrics.

Modal fibres: Developments in the manufacture of regenerated cellulosic fibres have made it possible to control the processes of manufacture in such a way that the morphology, degree of order and orientation of the fibre can be modified as desired. As a result of this knowledge, a group of regenerated cellulosic fibres with properties very similar to those of cotton has been developed. As examples of these modal fibres, the properties of polynosic and HWM (high wet modulus) types will be discussed. The polynosics have good form stability, increased linear strength properties and can be readily mercerized. The HWM types have an approx. 50–70% higher transverse strength; as a result they can also be mercerized under certain conditions, their bending rigidity is lower, and they are not subject to fibrillation. Their water retention capacity of 60–70% lies within the same range as that of cotton. The above properties predestine these fibres for blending with natural and synthetic fibres.

II. 2. Man-made fibres from synthetic polymers: The synthetic man-made fibres include the three important polymer groups of polyester, polyamide and polyacrylonitrile. Although of somewhat lesser importance

FIBRE TYPE	temperatures 1) glass 2) fixation/ ironing 3) melting in°C	density in g/cm^3	Humidity 1) regain 2) up take %	stress-strain curve modulus of elasticity in cN / dtex	Light resistance	dyeability	characteristic properties	textile fields of application

The manufacture of very fine filament yarns is possible	In textile fabrics, which should have a high extensibility and high elastic recovery, in quantities of 2 - 30 % foundation garments, swimwear, underwear, outer clothing

Fig. 2: Characteristic properties of synthetic fibre materials.

in terms of quantity, the polyolefins such as polypropylene, polyvinyl derivatives and elastomers based on polyurethane also deserve to be mentioned here. The introduction of all these fibres into the various textile end-products took place rapidly. During this introductory phase, the textile processing industries quickly learned how to exploit the specific properties of the individual synthetic fibres to the best advantage (Fig. 2).

The various synthetic fibre producers already started to extend their market position further during this introductory phase by exhausting the diverse possibilities offered by the selective formation of polymers, spinning dope modifications, and variations in the manufacturing processes. The development of these chemically and physically-modified types and their subsequent introduction into the market has considerably increased the range of synthetic fibres.

Polyamide: Although in terms of quantity, the polyamide fibre has now fallen back to second place, it is a fact that the polyamides were the first mass-produced synthetic fibres which found rapid acceptance in the textile market. They have a sound raw material basis; the melting points of the polyamide-6 and 6.6 polymers are well-suited to fibre manufacture and application. The specific gravity is low without reaching a minimum value. The most important properties of polyamides are their high strength characteristics, their extensibility which can be adjusted over wide limits, very good abrasion and flexing resistance, good dyeability which is relatively easily modified, good texturing characteristics and satisfactory form stability. In practical terms, these specific fibre properties make polyamide fibres particularly suitable for applications where the durability properties of the end-product need to be increased. The most important fields of application for polyamide fibres therefore include floorcoverings, women's hosiery, women's underwear, leisurewear and hard-wearing clothing. Unfavourable properties of the polyamide fibres are, however, their moderate wet form stability and the limp handle of polyamide fabrics.

Polyester: As one of the earliest synthetic fibres this fibre, which is based on polyethylene terephthalate, has enjoyed an outstanding growth in production volume in recent years which has far outstripped all other fibres. The reason is due to the fact that textiles produced from polyester fibres have good easy-care properties and excellent wear resistance. Moreover, polyester fibres can be readily modified and have good texturing characteristics. The chemical and physical structure is responsible for this range of properties. The melting point of the polymer is sufficiently high for fibre manufacture and application. Its glass transition temperature of between 68–80°C (depending on degree of orientation) and its high degree of order help the polyester fibre to withstand the various industrial processes and care treatments without permanent deformation. In addition to the fibre characteristics which can be varied during manufacture such as fibre fineness, fibre length, tensile strength and extensibility, it is also possible to modify the pilling propensity, dyeability and shrinkage properties of the polyester fibre. The wide diversity of applications of polyester fibres, especially in apparel articles, already gave rise to an early desire to match the pilling propensity of the fibres to the particular article construction. The resultant fibre type developments are today included within the standard fibre type program of the man-made fibre manufacturer.

Polyacrylonitrile: The chemical structure of polyacrylonitrile as well as its physical structure make chemical and/or physical modifications of this fibre possible. Accordingly, fibre manufacturers are able to offer fibre types with different dyeability as well as flame-retardant types. Due to the high bulk and good thermal retention properties, pleasant handle, excellent resistance to light and weathering, as well as the interesting coloration possibilities, articles produced from polyacrylonitrile fibres enjoy an established niche in the textile market. The high glass transition temperature of 95°C (dry) and low swellability are responsible for the easy-care properties of textiles produced from polyacrylonitrile. The thermoplastic properties of these fibres makes it possible to achieve permanent pleating and shaping effects etc. which are also resistant to washing. The physical structure of the polymer allows the production of shrinkable fibres. Also dependent on their structure, polyacrylonitrile fibres can be produced with varying degrees of crimp and crimp stability. These possibilities for fibre variation allow the production of a great number of different fabric characteristics. By appropriate selection of the draw ratio and drawing temperature with subsequent gentle drying in spinning, fibres having different degrees of shrinkage are produced which are used in blends with non-shrinking natural or man-made fibres for the production of high-bulk yarns.

Elastomers: Unaffected by the stormy development of the synthetic fibres, highly-elastic fibres remained the exclusive domain of sulphur-vulcanized rubber threads for a long time. It was only at the beginning of the 1960's that highly-elastic polyurethane elastomers began to find wide application. In the meantime, they have displaced a considerable proportion of rubber threads from their traditional fields of application. Due to their chemical and physical structure, as well as the possibility to spin fine titres of approx. 20 dtex, elastomer filaments based on polyurethane have a very good range of properties which will allow them to find a still wider field of application (partly contributed by von Falkai).

Fibres, abbrev. for → Standard abbrev. for textile fibres.

Fibre saturation value is a measurement of the dye up-take potential of a fibre.

Fibres harmful to health Fibres which can have a harmful effect on the health of humans, e.g. asbestos.

Fibre sheath → Covering layer.

Fibre softening range → Softening range.

Fibre strength Strength of individual fibres. The → Tensile strength of textile fibres can only be considered in relation to their elongation (→: Stress-strain behaviour; Mechanical properties of fibres). Due to the specific morphological structure of textile fibres, both properties are dependent on the moisture content. It is for this reason that the tensile strength and elongation of fibres are given for both the dry as well as the wet state (see Table).

fibre material	strength		elongation

CF	100–170	100	1	1

Tab.: Fibre strength and elongation symbols in accordance with DIN 60 001 T4/08.91).
(1) = elementary fibre; (2) technical fibre; (F) = filament; (S) = staple fibre; (m-) = meta; (p-) = para.

Fibre surface area includes both the external and, predominantly, internal surfaces of the fibre. The latter is dependent on the numerous capillary-like canals and intermicellar spaces. The surface area of 1 g of cotton is approx. 5000 m^2, and the area of wettable surfaces is approx. 100–400 m^2 for 1 kg of fibres. It is accordingly much greater than the surface area of the liquor at the fibre sites where surfactant molecules responsible for the wetting process are located. In practical terms this means that an enormous, newly-formed boundary layer consisting of a micellar structure with surfactant molecules is built up within the shortest possible time from surfactant molecules which must be available in the solution as a reserve supply.

Fibre surface area, calculation of The fibre surface area may be calculated from the fibre surface O, the fibre weight G, the specific gravity of the fibres, and the diameter of individual fibres D:

$$O = \frac{4 \cdot G}{s \cdot D}$$

For the same weight, fibre surface area is greater the thinner and lighter the individual fibres are. This explains, e.g. the excellent warmth retaining properties of angora rabbit hair (∅ = 12 µm) compared to wool (∅ = 20–30 µm).

Fibre swelling →: Swelling; Moisture properties of fibres and yarns.

Fibre texture Fibre texture describes the state of order or orientation of the macromolecules in fibre structure (→ Texture). It can be understood by the presence of crystal aggregates with individual arrangements of crystallites in such a way that all the crystallites possess a definite lattice structure in approx. the same direction, i.e. a symmetry of the fibre axis exists which is detectable by X-ray crystallography. Fibre texture is characterized in other respects by the anisotropy of fibre crystallite orientation, i.e. higher orientation in the direction of the longitudinal axis due to primary valency bonds (which means greater strength, lower extensibility and swellability as well as easier cleavability) and lower orientation in the transverse direction due to secondary valency bonds (which means lower strength and higher swellability). Thus, the strength of regenerated cellulosic fibres in the transverse direction is only approx. 10% of that in the longitudinal direction (which is revealed by lower abrasion resistance and lower flexural strength) and the degree of swelling in the longitudinal direction is only about 10 % of that in the transverse direction. Rubber and related substances only assume a fibre-like texture in the stretched or drawn state, with the fibre axis lying along the direction of applied tension. All variants of fibre texture form spherical and spiral fibre textures.

Fibre tow → Tow.

Fibre wettability → Wettability.

Fibrids Synthetic binding elements with a fine structure resembling that of “wood pulp”, i.e. a netted filamentary or fibrillar structure, produced from polyamide, polyester, polyacrylonitrile, etc. They are used as a binding medium after the extraction of water from synthetic fibres on paper making machines. Fibrids (e.g. copolymers) have lower melting points than the main fibre component so that bonding of the latter is easily achieved by heat treatment. This process has been further developed for the manufacture of nonwoven webs, e.g. wet-laid synthetic papers.

Fibrillar proteins identical with → Fibre proteins.

Fibrillatable Short staple fibres used for the manufacture of nonwovens by the wet blending system used in paper manufacture.

Fibrillated film fibres Staple fibres produced by cutting, chopping or stretch-breaking fibrillated yarn or fibrillated film tow. See → Split fibres.

Fibrillated split yarns Fibrillated → Tape yarns, monoaxially drawn or e.g. split by needle rollers as a continuous material.

Fibrils

I. A very fine cellulosic fibre (∅ = 0,4 µm) formed from lamellar filaments resp. individual filaments (approx. 100 fibrils).

II. Fine fibrils have also been detected in cellulosic fibres under the electron microscope.

III. In → Wool structure the fibrils are spindle-shaped, tightly packed, twisted, fine fibres in the so-called spindle cells. These fibrils are composed of fibril bundles which, themselves are composed of individual fibrils.

IV. By analogy with wool, individual fibrils and fibril bundles are likewise present in the structure of → Silk. In the case of silk, however, fibrils are also understood to include the individual small fibres projecting from the surface of silk fabrics formed by the action of abrasion.

Fibroin Structural component (from → Fibroinogen) of → Silk (comprising 71–82%), in the form of a double fibroin filament which is covered by → Sericin in the form of silk gum. Contains the amino acids alanine, glycine, serine comprising approx. 75% as essential components of high molecular order crystallites, whereas with tyrosine the remaining amino acids which represent the low-molecular portion are the presumed components of the amorphous areas, which may include the “cuticulin”. Composition ($C_{15}H_{23}N_5O_6$): 49% carbon, 25% oxygen, 19% nitrogen, 6% water. Fibroin is insoluble in water, can be hydrolyzed to form amino acids and detectable as a polypeptide in a similar way to wool keratin, but without the cystine content. The length of a fibroin-amino acid residue in the polypeptide chain corresponds to 0.00035 µm and the length of the fibroin approx. 0.046 µm, which is equivalent to approx. 150 amino acids, of which only approx. 84 are glycine residues and 45 are alanine residues. As with wool keratin, elongated fibroin chain molecules (∅ approx. 0.0005 µm) are arranged together parallel to the chain sheet or grid, in which the grid repeats at a spacing of just 0.0005 µm. With the dimensions referred to, the main polypeptide chains of the fibroins

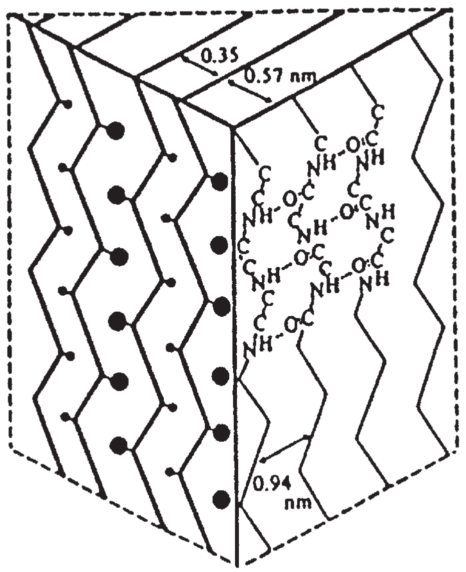

Fig.: Pleated sheet structure of fibroin polymer chains at a spacing which can be detected by radioscopy in a three-dimensional space (unit cell).

are accordingly extended substantially parallel to the fibre axis (similarly to β keratin) and are tightly packed, leaving no space here in the crystalline structure of the crystals or micelles for amino acids with large side groups. Consequently with side chains in fibroin, hydrogen bonds occur which determine the cohesion of the main chains and consequently the strength (Fig.).

Consequently, additional salt linkages are improbable, at least in the tightly packed area of the crystallites. This is another area in which a distinction can be made between fibroin and wool keratin. Another difference is that fibroin contains proportionally far fewer diaminocarboxylic acids with so-called amino extra groups, and therefore has a lower isoelectric neutral range between pH 3.8–4.7 (wool approx. 4–7) and a lower acid equivalent of 0.023 g/100 g (wool, 0.085).

Fibroin fibre A → Man-made protein fibre produced from silk fibroin. A fibroin solution is obtained by the dissolution of silk wastes which can be spun into fibre again. Fibroin fibre has no commercial importance.

Fibroin filaments → Continuous filament of silk composed of → Fibroin.

Fibroinogen soluble, water-extractable protein that is a precursor of silk fibroin. After standing for several hours a fibrous precipitate forms spontaneously as a linear aggregation of individual fibrils (length up to 0.35 µm, diameter 0.01 µm). Can be considered to be analogous to → Prekeratin of wool.

Fibrous webs Textile materials produced from textile fibres laid in a more or less random orientation which are held together by fibre cohesion or adhesion. They are classified in various ways:

I. According to method of manufacture (mechanical, aerodynamic or wet/hydrodynamically formed fibrous webs, → Spunbonded fabrics).

II. According to the bonding process (→: Nonwovens, Wadding, Stitch-bonded nonwovens, Stitch-bonded pile fabric).

III. According to fibre orientation (oriented webs; cross-laid webs; random webs).

Fick's equation, describes the diffusion processes for the quantitative diffusion of dye in terms of rate of transfer per unit area within e.g. a fibre:

$$n = -D\frac{dc}{dx}$$

From this equation, the term

$$\frac{dc}{dx}$$

is a concentration gradient, which represents an important prerequisite for the → Diffusion.

Fick's laws of diffusion In the simplest case when the concentration gradient is maintained in a constant state and the number of particles diffuse through an area with the cross-section q per unit time, the change in concentration with time at this position of surface q and the concentration gradients

$$\frac{dc}{dx}$$

are proportional.
Fick's first law of diffusion:

$$\frac{dc}{dt} = -D \cdot q \cdot \frac{dc}{dx}$$

where D = the diffusion coefficient (cm^2/s).

The change in concentration with time is given by Fick's second law of diffusion:

$$\left(\frac{dc}{dx}\right)_x = D\left(\frac{d^2c}{dx^2}\right)_t$$

The differential equation may be solved by fixing the starting conditions (t = 0, x = 0, c = 0). Finally, D can be calculated with the aid of the Gaussian error integral if the time t and the distance to the origin of diffusion x are known.

FID

I. (Fr.) abbrev. for: “Fédération International de Documentation”, international association for documentation, with headquarters in The Hague, Holland; → Technical and professional organizations.

II. Abbrev. for: → Flame ionization detector.

Fiddlestrings → Shiners.

Field of vision In the resting position, the human field of vision with both eyes extends from an angle of approx. 65° to both sides of the direction of view and can measure approx. 50° in the upper and lower directions. The powers of vision are greatest in the centre of the field of vision and lowest at its periphery. This fact can be explained by the higher image definition in the Fovea centralis where the greatest number of retinal cones are located which, in contrast to the rods (lightness/darkness receptors), are responsible for colour vision. Towards the periphery, the capacity for colour perception decreases greatly, and the sensitivity to lightness/darkness increases due to the higher number of rods. The centre of the field of the vision forms a viewing angle of approx. 20° so that when a sample is viewed at a distance of approx. 50 cm from the eye, an elliptical to circular surface area of approx. 30 cm diameter exists which corresponds to the size of colour matching samples including the original. The part which lies outside this area is known as the surrounding field.

FIFT (Ger.), abbrev. for: Forschungsinstitut für Textiltechnologie (Chemnitz) = Research Institute for Textile Technology, Chemnitz; → Technical and professional organizations.

Filament A fibre of indefinite length. Also used in connection with the now obsolete term “artificial silk”.

Filamentary molecules → Chain molecule.

Filament yarn Yarn which is composed of → Filament. Yarns produced from one or more filaments are preferably referred to as → Monofilament yarn or → Multifilament yarn respectively.

In filament yarn production (Fig.), direct spinning outweighs extruder spinning, the yarn being spun directly from the polymerisation plant. Extruder spinning machines fitted with chips are used, primarily for producing special yarns, as in compact equipment for example.

Particular regard is paid to an optimum melt temperature distribution and dwell time possible. Energy is saved by improved heat insulation and by reducing the areas irradiated. There are various developments for cooling the filaments in the quenching chamber, the use of a perforated tube which draws the cooling air through the movement of the filaments, therefore providing self-regulation, being emphasized in this connection. This process is used at very high spinning speeds.

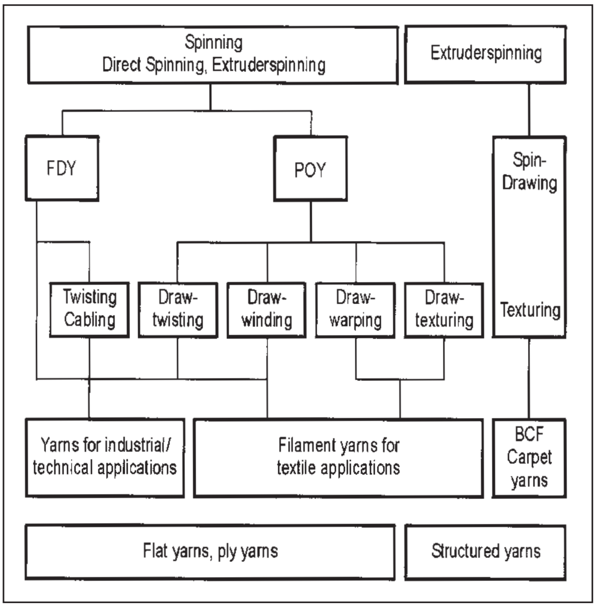

Fig: Filament yarn production.

In primary spinning, partial drawing is achieved, producing LOY/POY yarns (low oriented yarn, preoriented yarn). POY yarns must retain residual stretch in further processing. Fully drawn yarns are described as FOY or FDY yarns (fully oriented yarn, fully drawn yarn). On FDY machines, drawing is effected mainly by godets.

Filled soap Soap without excess electrolyte produced by saponification without salting out and using the calculated quantity of alkali. The glycerol formed is retained in the soap by the inclusion of neutral fat.

Filling doctor Two-bladed doctor in form of a box used as a counter-doctor for introducing dye liquor when using printing paste.

Filling factor, Concerns the ratio between vessel content in litres and material weight in kilograms → Load ratio; Liquor-to-goods-ratio.

Filling fibre Used to fill cushions, duvets, sleeping bags etc. Nowadays mainly consists of synthetic fibres.

Filling finish A type of finish used to increase the weight of a textile fabric by the application of so-called filling agents (which are cheaper than the textile material). The finish also produces a “compacting” effect and a fuller handle which may or may not be resistant to washing. → Weighting.

Filling warp Consists of coarse warp threads which provide fabrics with a coarse fullness and allow less interlacing. Filling warps are supplied for weaving on separate beams.

Film Any thin layer of a substance, e.g. size film, synthetic resin film, paint film, etc., which can also be removed from the surface of the parent substance and is likewise referred to as a film. The term film is, however, associated more with the idea of a non-independent film of a more or less elastic nature. Photographic film is actually a carrier-foil with a coating of light-sensitive film (photographic plate).

Film application The application of finishing liquors to textile fabrics, mainly in concentrated form (liquor pick-up of 40%). By this means, a film of liquid is transferred to the textile which completely saturates the fibres, e.g. kiss-roll application, slop padding (→ Low wet pick-up).

Film-forming agents Polymers which form coherent → Film after evaporation of their solvents or dispersants. The → Minimum film forming temperature is important in textile applications. The main applications are as follows:

a) Hard film-forming agents (glass transition temperature >25°C): Used for stiff finishes, interlinings, bonding of nonwovens, filtration fabrics, bonding of needle-punched felts, tufting precoats, carpet backcoating, glass textiles, selvedge gumming of knitgoods, binders for net curtains, mouldable textiles.
b) Less hard to soft film-forming agents (glass transition temperature –10 to +20°C): Finishes for tickings, linings, mattress tickings, glass textiles, backcoatings for woven carpets, textile coatings, coating of roller blinds.
c) Soft to very soft film-forming agents (glass transition temperature –10 to –30°C): Used for nonwovens, coating of knitted plush, bonding, pigment binders, flock adhesives.
d) Very soft, high tack film-forming agents (glass transition temperature <–30°C): Adhesives.

Film-release transfer printing A → Transfer printing process in which the transfer of dye from the support medium (paper) to the textile substrate does not take place via the gaseous phase as in conventional dry transfer printing, nor via the liquid phase as in wet transfer printing, but from dyes (which can belong to any colorant class) embedded in a film on the support medium which is released mechanically and transferred to the textile. Subsequent fixation of the dyes is carried out by the usual dry heat or steaming treatments depending on the type of fibre and dye class. Pigments can also be used with a soft binder. The transfer printing temperature and the required pressure are variable from room temperature up to 200°C resp. from rotary iron pressure upwards depending on the composition of the film. The dye-containing film is also degradable under the influence of temperature so that no deterioration in handle occurs and afterwashing of the printed goods can be dispensed with.

Filter breakdown The filter is saturated and full and needs cleaning.

Filter cartridge Replaceable cartridge filter for the purification of solvent liquors in particular in small dry cleaning machines. Consisting of metal grains, filter paper, active carbon etc. → Filter auxiliaries.

Filter fibre finish Well proven media for filtering, air conditioning and ventilation technology or liquid filtration made of layers of fibrous material in the form of fabrics, nonwovens or needle felts. Synthetic fibres with relatively smooth surfaces are modified during manufacturing processes and aftertreatments, so that the total available filtering surface of the individual fibres is significantly enhanced. This generates better circulation and radial flows that have a favourable and beneficial effect on the degree of separation of the total system. The fibre surface gives significant flow improvements in the form of eddies near the surface of the fibre. This results in a marked increase in speed. The smooth surface of the synthetic fibre can also be modified by a special finishing process so that the total avail-able filtering surface of the individual fibres is greatly increased. Due to the high degree of distribution of high molecular products and their small size even the finest fibre hollows are then filled. The particle fineness and the extent of the internal surface are increased by 50 times compared to conventional filter media. The media surface is matched to the size of the largest particles of the absorbed product. The external energy required caused by the pressure difference at the filter media is enough to create turbulence in the direct vicinity of the fibres. A further effect of the micro particles is caused by the fact that the so-called detachment effect is achieved in fibre flows by turbulent effect of the boundary layer. Because the filter resistance is made up of a component that is dependent upon the pressure field and fibre compound and a component determined by the friction of gases at the fibre surface, and the pressure resistance usually far exceeds the frictional resistance, the overall filter resistance is not negatively influenced.

Filter for waste water treatment Waste water treatment plants are subject to the requirement of low suspended material and BSB_5 content, whereby the undissolved and suspended substances are generally the BSB_5 carriers and originate from biological or chemical cleaning. The biological and chemical flake residues can be removed from the waste water using various filtration processes. The main methods used in waste water treatment in practice are the microsieve and rapid sand filter.

In microsieving, the waste water is filtered through a very tightly woven steel fabric using the natural pressure difference. Mesh sizes of 23 µm or 35 µm are normally used, with larger particles being filtered out and retained on the grid. This causes a precoated filter layer made up of waste water particles to form during the filtration process. This intrinsic filter layer has significantly smaller pore holes, so that particles of particle size 5–10 µm and even smaller can be retained. Micro sieving is a continuous process, because the sieve fabric is stretched onto a rotating sieve drum. This is always $^2/_3$ immersed and waste water flows through it from inside to outside. The settled suspension layer is continuously washed down the apex line.

A rapid sand filter can be viewed as a pile of sand, for example, forming a filter bed. The suspended material from the waste water is trapped in the pore space of the grain pile as it flows through the filter bed. If the filter capacity has been exhausted, i.e. the filter bed is full, the settled suspended material must be removed. Thus the rapid sand filter is operated discontinuously, alternating between a filtration phase and a backwashing process. The backwashing takes place using water or in combination with air, which requires an intensive turbulence in the filter body to loosen and wash out the suspended material. Continuous operation is possible if several units are connected in parallel. For the filtration of suspensions with a broad particle size spectrum it is advantageous if the water flows through increasingly small pore cross sections, initially trapping the coarse particles, followed by increasingly fine particles. Such a filter medium permits an optimal space filtration over the entire depth of the filter bed. Within certain boundaries the possibility of nitrification exists due to the colonization of micro-organisms on the grain pile in rapid sand filters. This means that two treatment stages can be combined in one unit.

Filtration with microsieves and rapid sand filters is employed where strict discharge conditions regarding filterable substances or BSB_5 make this necessary. These methods are also employed as an intermediate stage before an active carbon unit, to avoid deposits of suspended material, which impair the adsorption process.

The elimination of dissolved, refractory organic substances is a further process step in waste water cleaning, which can be determined by the residual CSB in the waste water treatment plant. A procedure that is suitable for the elimination of these substances is the adsorption on active carbon. This can be used to eliminate organic substances from the waste water. Molecular weight and hydrophility are critical for the adsorption capability of the individual organic molecules. It is generally true that large molecules can be better bound by adsorption than small ones. Furthermore, it is also true that the more hydrophilic side chains a molecule possesses, e.g. $-OH$, $-COOH$, $-NH_2$ and $-SO_3H$, the less well it is adsorbed on active carbon. In the after-cleaning of mechanical-biological discharges primarily homopolar organic substances are eliminated, as are adsorbable organic halogen compounds (AOX); the easily soluble, low molecular organic substances must be broken down microbially beforehand. If the waste water to be cleaned is not cleaned biologically in advance, or is insufficiently biologically cleaned, the adsorption of biologically degradable substances on active carbon leads to microbial growth in the pore area of the carbon grains. The microbial colonization of the adsorption grains this causes must lead to a decrease in the available sorption area, thus limiting the filter potential.

Active carbon as an adsorbing agent is usually used in the form of granules in contact columns. The waste water is passed through filters filled with granular active carbon. As the water passes through the filter layer the organic substances are gradually adsorbed. The cleaning performance of an adsorption stage depends exclusively upon the contact time between active carbon and waste water. All other operating parameters are of lesser importance for the effectiveness of adsorption. A contact time or throughflow time of 20–30 min (in relation to the empty column) can be considered adequate. Adsorption is a process that follows an exponential function until equilibrium and thus must be allowed sufficient time. Active carbon can be charged with organic material of up to 80% of its own weight. If it is fully charged, regeneration must take place. The sorptive capacity can be restored chemically by extraction or physically by thermal processes. Thermal regeneration is generally used, freeing the sorption areas in the pore space at temperatures from 750–950°C. There are two alternative methods of operating contact columns:

1. Discontinuous operation, which requires the connection of several units in parallel to prevent interruptions to operation.

2. Continuous operation of contact columns, which requires that the carbon moves in the column by means of a sliding bed, and can thus be passed through the regeneration cycle and then recirculated.

Sludge is created by various waste water cleaning processes, the further treatment of which depends upon its character and composition. Waste water sludge has a water content of 90–98%. There are two main techniques available to separate out the water: Filtration and gravity separation.

Filtration separates solid and liquid phases using filter material. Common procedures are negative pressure (vacuum) and overpressure (pressing) filtration, sieving devices and sedimentation devices. Gravity separation is based upon the different densities of water and solids. The separating effect is dependent upon the difference in density. Common processes are thickening, flotation thickening, centrifuging (increased gravity field). The remaining solids after sludge dewatering must then be disposed of along with the remaining water (residual water content 30–70%, depending upon water binding ability of the sludge). Several possibilities can be considered for this:

1. In the case of suitable, toxin-free sludges, agricultural reuse or sludge composting.

2. Sludge burning or incineration.

3. Depositing on waste tips or special waste tips depending upon the sludge composition.

Filtering charcoal → Activated carbon.

Filtering powder → Filter auxiliaries.

Filter inserts for dye tubes Dyeing tube inserts made of special paper or filter material, which filter out impurities undissolved dyes etc. Elastic filter inserts help the inner yarn layers resist slipping if the package is mishandled. Application: For tubeless cross-wound yarn packages (muffs) made of continuously prebulked HB yarn, for the dyeing of HB yarn and hank yarns in cross wound package form, in hank dyeable yarns in cross-wound form, for the bulking and dyeing of bulked yarns in cross wound package form. In polyester union yarns the previously necessary autoclaving and rewinding is avoided but the filter tubes become disposable items.

Filters → Filtration plants.

Filter saturation describes the degree of saturation of an adsorption bed.

Filters for dry-cleaning plants →: Sewerage filter; Cartridge filter.

Filters for gas purification Textile filter media for separating out dust, primarily from air, use one or more of three main principles:

1. Dust removal by the adsorption of the smallest particles onto a high surface-area substrate.

2. Mechanical separation mainly of fibre-fly whereby the air passes the fabric but the fibres cannot.

3. Electrostatic forces are exploited by the systematic charging of filter material and/or dust, in order to separate components with opposing charges from each other. The filter material must be chemically treated so that the polarity, the charge intensity and the charge decay rate can be matched to the characteristics of the dust, if an agglomeration of the dust particles is to be achieved (Fig.).

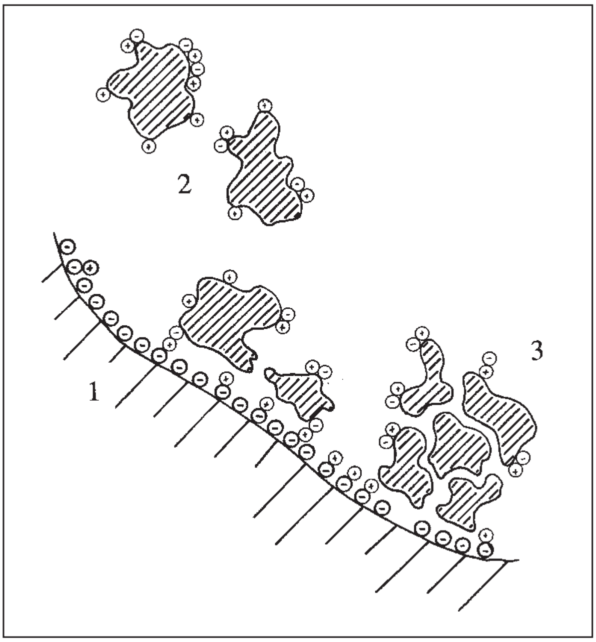

Fig.: Agglomeration by electrostatic in filters.
1 = fibre surface with predominantly negative charged sphere; 2 = predominantly positive charged dust particles; 3 = neutral agglomerated dust particles.

In electrostatically charged dust, which may have a dust resistance of up to 10^{22} Ω, the individual particles, which largely have the same polarity, tend to repel each other. If some of the charge is taken by the fibre surface, the particles can meet together and agglomerate more easily. They form large, and often more dense, dust aggregates than the original finely dispersed particles. This process of charge neutralisation always occurs between charged dust and a filter medium with the opposite charge. Positively charged dust can be made to agglomerate on the fibre by contact with negatively charged polyester fibres.

Filtration The separation of dispersed or dissolved particles by appropriate methods (Fig. 1).

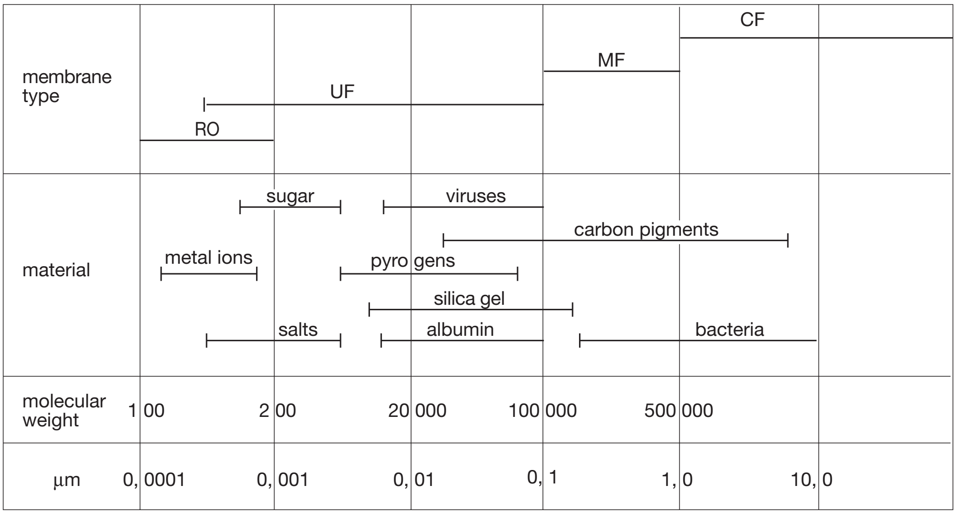

Fig. 1: Application range of different filtration methods.
RO = reverse osmosis; UF = ultrafiltration; MF = microfiltration; CF = conventional filtration.

Filtration auxiliaries (Clarification aids), are used in pressure filtration systems (effluent filters) to assist in the formation of a porous “filtration cake” that serves to remove solids. They also play a large role in dry cleaning. In addition, filtration aids are often used for other filtration processes such as the removal of oil from condensates, chromatographic and analytical tasks etc. In dry cleaning filtration aids must fulfil the following requirements: no adsorption of cleaning intensifiers, no chemical reaction with the solvent, high throughput at maximum clarification, no contamination due to sand etc. (mechanical damage to filters and pumps), no coagulation in the presence of water (applies particularly to kieselguhr).

I. Absorptive or inert filtration aids for the filtration of dye impurities. These should be chemically inactive and form a flushable coating, which resists compaction, be porous to solvents and impervious to particulates. These requirements are best fulfilled by → Kieselguhr, particularly with regard to the uniform pore size structure and plate-form. Metallic salts (aluminium, iron) and clay, sand and organic components must not be present. A wide variety of types of kieselguhr are available on the market. They can reduce in volume with increasing pressure and thus reduce the permeability of the filtration cake. Different types cannot simply be interchanged. High water and moisture volumes work most economically when a small amount of filtration aid is used.

II. In addition to I., adsorptive filtration aids (also called effluent filtration aids) serve primarily to bind molecular dissolved impurities, specifically fatty acids, body fats etc. and dissolved dyestuffs. This includes → Activated carbon, active earths, kieselguhr with alumina, magnesium silicate etc. Such filtration aids work selectively, they therefore do not trap all substances dissolved in the solvent in the same way. This depends upon the type of dissolved substances (e.g. tar, bitumen, resin, mineral oil are difficult to adsorb), and on the temperature and retention time.

Filtration aid dosing equipment is incorporated into the machine – pump – filtration – machine circuit so that the filtration aid need not be added with the filter mass, and to allow the correct amount of additive to enter the system at the correct time (dosing).

Filtration plants Many different types, depending upon application, e.g. mainly for liquids (→ Water filter) and solvents (→ Sewerage filter).

I. Cartridge, rod, pipe filter: Usually porous hollow cylinder (kieselguhr, carbon, quartz/bakelite, quartz/fireclay, earthenware etc.).

II. Air filter.

III. Membrane filter: For fine colloidal liquids and bacteria free water.

IV. Plate filter: Covered with a) cotton, asbestos, polyvinylchloride, PA 6/PA 6.6 etc.) or b) metallic cloth, metal wires.

V. Shock filters: Spring reinforced filter hose with precoating, removal of the filter cake by momentary shock filter cleaning, i.e. pressure over the whole filter element.

VI. Centripetal filter: The tangential entry and exit of liquid causes streamlines parallel to the eddy current, foreign bodies tend towards the central axis of the eddy, sieving filter inserts made of metal, porcelain etc.; also for higher pressures (up to 46 bar and above).

Final finishing

I. All finishing processes after dyeing or certain specific mechanical finishing processes for coloured woven fabrics (dry finishing): rubberizing and proofing, waterproofing, drying, shearing, pressing, decatizing, crease-proofing, calendering, embossing and suchlike.

II. Post-finishing of dry-cleaned garments → Dry finishing of fabrics.

III. By final finishing is meant all the → Chemical finishing treatments applied to a textile fabric after dyeing and/or printing which provide fitness for purpose resp. the desired wear characteristics, e.g. wash-and-wear finishes, easy-care finishes, etc.

Final inspection → Quality control.

Final inspection and make-up of finished goods Comprises fabric inspection, roll cutting, labelling, packaging, storage and despatch (Fig.).

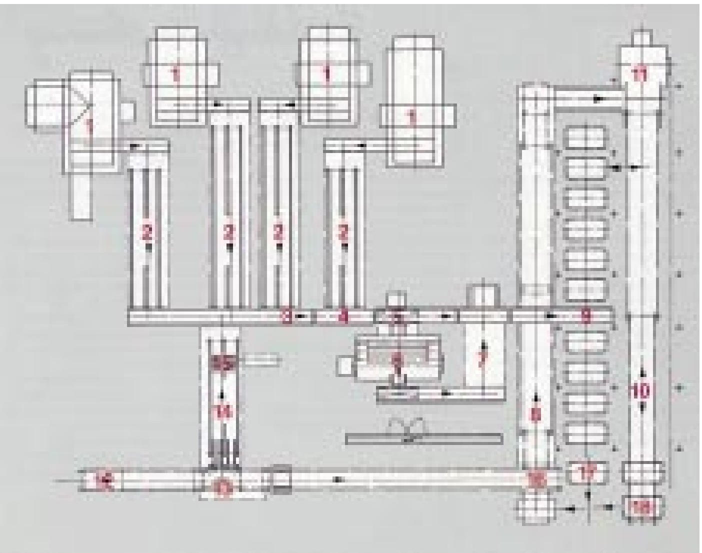

Fig.: Colsman and Kirschner automatic final inspection and make-up of finished goods plant in a cloth mill.
1 = rolling machine; 2 = intermediate storage; 3 = roll transfer; 4 = scales/labelling machine; 5 = automatic input roll feed; 6 = automatic packaging machine; 7 = roll return; 8 = intermediate empty pallet storage; 9 = palletting on 10 different pallets; 10 = lower level: pallet change, upper level: full pallet buffer; 11 = full pallet stacker; 12 = full pallet feed; 13 = pallet emptying; 14 = roll segregation; 15 = sorting by scanner; 16 = empty pallet feed; 17 = urgent pallet removal; 18 = store pallet removal.

Fine chemicals In contrast to → Heavy chemicals, these are chemicals produced in comparatively small quantities of relatively high purity. They are used as e.g. pharmaceutical and biological products, perfumes, photographic chemicals and laboratory reagents.

Fine dispersion → Dispersion, degree of.

Fineness of natural fibres This describes the “thickness” of textile fibres and is usually expressed in dtex as a rule (→ Linear density of fibres and yarns) or, in special cases, in µm (diameter) or, the micronaire value for cotton. The fineness of fibres is an important factor which has a direct influence on yarn properties with regard to strength, spinnability limits, yarn character and uniformity. The usual fineness ranges of the main natural fibres are:

Cotton	1,5– 5	dtex
Flax	10–40	dtex
Wool	2–15	dtex
Silk	1– 4	dtex

The fineness of man-made fibres is controlled by the spinning process.

Various methods are available to determine the fineness of natural fibres:

1. Gravimetric procedure: by determining the weight of spun fibre sections of known length.

2. Determination of the micronaire value: by measurement of the air flow rate for cotton.

3. Measurement of fibre diameter: microprojection of a number of individual fibres.

Fineness of synthetic fibres The man-made fibre industry has been successful in producing finer and finer fibres. In the filament yarn sector, fibres of 1,0–0,3 dtex have been produced by European fibre manufacturers, i.e. the so-called microfibres (see Fig). In the meantime, Japanese developments have been aimed at fibres with a fineness of <0,3 dtex. Such fibres are logically described as so-called super microfibres. In the staple fibre sector, fibre fineness of up to 2,4 dtex for polyester have been available for some time. In mixtures with wool, such fibres have optimum spinnability limits from approx. 12,5 tex (as yarn); the weight of fabrics produced from these mixtures is approx. 230–330 g per running metre depending on the type of weave used. The ever-increasing trend towards finer, softer, and therefore lighter fabrics in the outerwear sector is subject to limits in blend fabrics with regard to the fineness of polyester fibres in polyester/wool blends, since titres finer than 1,3 dtex have a negative influence on fibre distribution in the yarn cross-section. As a result, there is no more agreement between fabric aesthetics and serviceability.

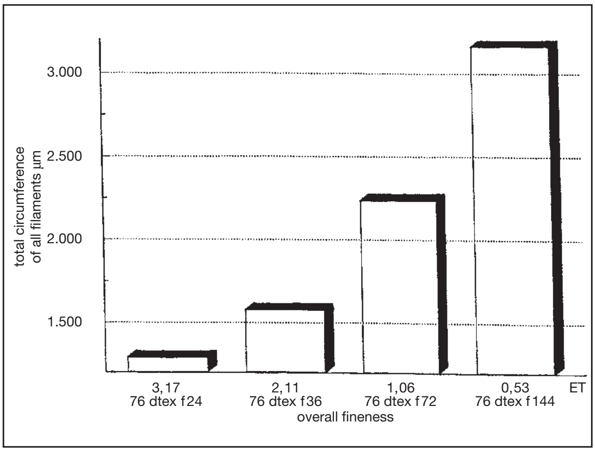

Fig.: Dependency of filament circumference on individual fineness with the same overall fineness (Hoechst).

In the meantime, polyester fine titre fibres with a fineness of 1,3 dtex have been processed with fine wool fibres of approx. 18 µm in order to obtain fabrics with particularly flowing drape and high strength properties and low wrinkle propensity typical of polyester/wool fabrics. In this case, fabric weights of approx. 170 g per running metre (plain-weave) up to 270 g per running metre (twill weave) are achieved with yarns of 9–14 tex fineness. With a decrease in individual titre, the total surface area of fibres with increases the same total titre. Fibre finenesses up to 1 dtex are recorded in the old DIN 60 800 which has now been withdrawn. Up to now it has not been possible to establish an exact definition for the finenesses given below. The following descriptions are used in practice:

Coarse fibres	>7,0	dtex
Fine fibres (Normal fibres)	7,0–2,4	dtex
Very fine fibres	2,4–1,0	dtex
Microfibres	1,0–0,3	dtex
Super Microfibres	<0,3	dtex

Fine ribbed woollen fabric (Drapé = a French term for woollen cloth). A generally high-quality finely-ribbed woollen material. It is woven either with worsted yarns in the warp and weft or with a worsted warp and a fine carded yarn weft in 7, 9, 11 or 13 shaft reinforced satin weave (corkscrew weave) and is given a fine, close-napped finish with the weave structure still largely visible, to achieve a matt shimmering lustre. The three classic business suits of former times were produced from fine-ribbed woollens, foulé and piqué. The two former qualities have, however, lost much of their former importance and are now only produced on a small scale, mainly for black business suitings.

Fine rib fabrics 1 x 1 rib fabrics are double face knit goods. The fabric has a similar appearance on both sides and single wales of face loops alternate with single wales of back loops. Rib fabrics are very elastic widthwise and are therefore used for cuffs, collars and trimmings as well as underwear.

Fine soda (soda, calcined; soda ash), anhydrous → Sodium carbonate available commercially as small or fine crystals.

Fine structure of fibres (Fibre fine structure). The molecular textile technology (according to H. Zahn) seeks to explain the mechanical properties of fibres by the spatial structure (conformation) of the chain molecules of the fibre polymers on which they are based. The fine structure of a fibre denotes the composition of the smallest components such as the chemical constituents (polymer chains), their bonding into crystalline and non-crystalline (amorphous) regions and fibrils. The colloidal structure when spinning a synthetic fibre or during the biosynthesis of a natural fibre affects the fine structure of the fibre and its morphology, i.e. the whole structure is composed of its smallest components.

Synthetic fibres that are manufactured from thermoplastic polymers are forced through spinnerets into the spinning chamber where they are met by a blast of cold air. The rapid cooling in the spinning line does not cause the fibres to crystallise, as the rigid molecules need more time to arrange themselves spatially. The fibres are given textile characteristics and final molecular structure by stretching and thermal treatment. The macromolecules and crystalline structures undergo complex orientation and arrangement processes and transformation of the lamellar structure into a fibrous-fibrillar structure. Filament yarns spun at a moderate speed (1800–3000 m/min) and at high speed (3000–4000 m/min) (POY filament yarns) are stretched as they leave the spinning nozzles due to the high drawing-off speeds and the prevailing conditions in the spinning nozzles. This is the basis of the fibre structure; there is a high degree of crystallization. The resultant crystalline forms are more stable, as the extension and orientation of the macromolecules occurs at the same time as spinning. Filament yarns pre-oriented in this way are initially used in draw texturing; once they have been further stretched they can be used like all other filament yarns. Yarns spun at high speeds, called stretch-spun yarns (4000–6000 m/min and more), effectively obtain a higher degree of ordering and orientation during the spinning process, so that the structural, physical and chemical properties are comparable to those of the classic yarns which are spun and then stretched, with the difference, however, that they have greater regularity. The dyeing properties of the partially crystallized polymers are dependent on their structure, i.e. from the amount of the crystalline and amorphous fractions, their arrangement and the movability of the macromolecules (Fig. 1).

If an attempt is made to describe synthetic fibres by means of a two-phase model, it must ideally be assumed that the material consists of an amorphous and a crystalline phase, whereby the physical properties of each phase can be assumed independent of the presence and quantity of the other phase. An analysis of the central quadratic fluctuations in density shows, however, that, for example, the polyethylene terephthalate structure in polyester cannot be described with precision by means of a two-phase model. Research has led, through the assumption of a transitional area of finite width between the amorphous and crystalline areas, to a three-phase model of crystalline, non-isotropic and non-crystalline areas. In principle the non-crystalline areas are built up of the following types of chains (Fig. 2): chains which bind the crystallite (t_1; t_2), those with a free end (f) and loops (s_{1-4}), the border zones containing sharper folds. The border areas of the crystallite are arranged in parallel to one another.

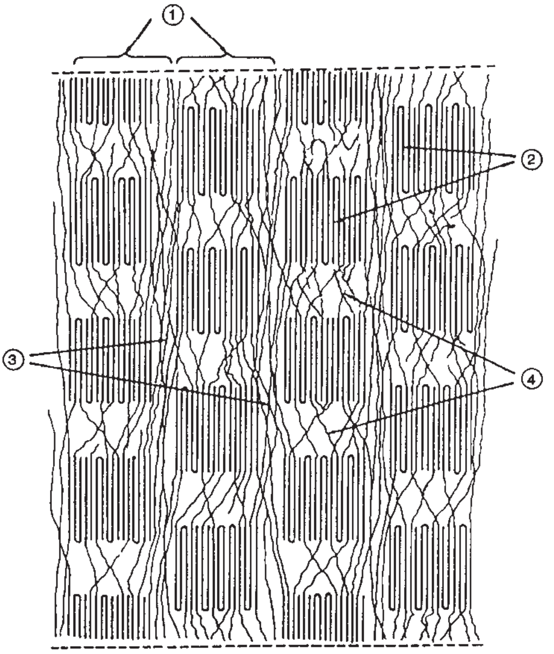

Fig. 1: Fine structure model for synthetic fibres (source: Prevorsec).
1 = microfibrils; 2 = crystallite; 3 = stretched amorphic molecules (anisotropic); 4 = random areas (isotropic).

The fine structure of natural fibres essentially shows more the character of the hierarchy of the structural components (→ Hierarchical fibre structure), which can be reproduced in biosynthesis by the sequence of the basic components (the amino acid sequence in the case of wool), or the growth conditions (for cotton, the vari-

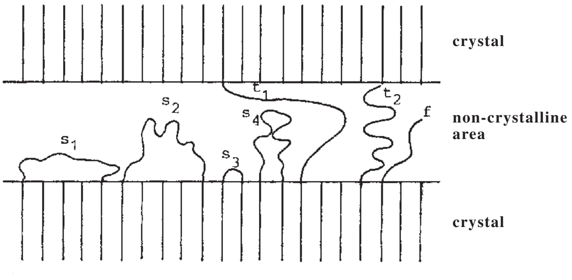

Fig. 2: Diagram of the different chain types of the non-crystalline area in the fine structure of fibres.

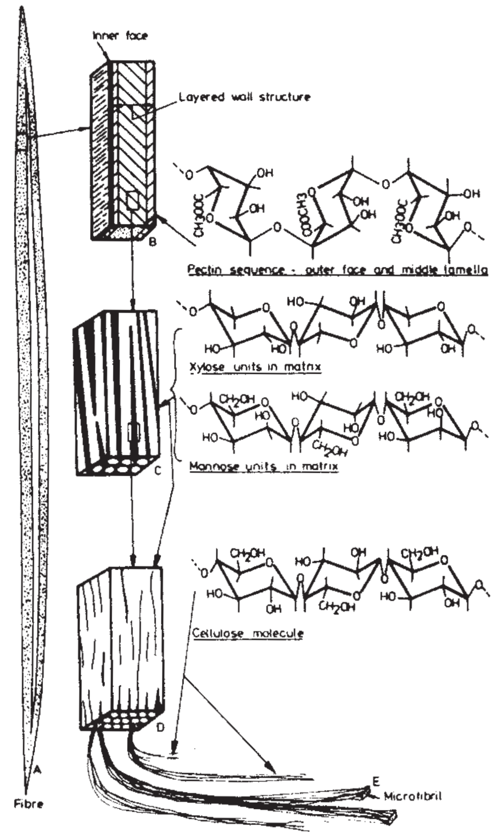

Fig. 3: Fine structure: Cell wall structure of a wood fibre cell. A: the fibre has a layer structure. The main composition of polysaccharides in the different layers is shown in the sections B, C, D (Rees 1977).

ation in cellulose content of the primary and secondary walls and in the growth rings) (Fig. 3).

Fine turbidity meter (Based upon scattered light measurement), for liquids → Photometer. It is used to monitor ground water sources and for treatment process in water works (fine turbidity measuring). Principle: A scattered light is generated by a lamp and passes the in- and out lenses of a measuring cell. The reduction in light returning to the measuring cell represents the turbidity of the water. This is varied in some photometers by a) the choice of cell dimensions, b) black glass located at the exit point of the beam of light, and c) by a double image of the scattered light bundle and a system of screens to keep the stray light away from the measurement cell.

Finger test Used to evaluate dye penetration in transfer-printed textile floorcoverings. The complete back-coated and printed carpet sample is wrapped around the little finger: if no white fibres are visible, penetration is considered to be satisfactory, even for carpet laying on staircases which is one of the most critical carpet applications.

Finish Final treatment, →: Proofing, Dressing; (more generally, also) Improving, Processing; (often also) Ironing, Pressing, etc. (cleaned or dyed clothing). Finisher: proofer, dresser.

Finish decatizing, wet steam decatizing → Decatizing.

Finished goods → Textile finished goods.

Finishing Besides washing, this includes desizing, steaming, setting, and the production of various effects such as calendering, raising, etc., as well as treatments to improve serviceability properties such as water-repellent, shrink-resistant, wrinkle-resistant and soil-release finishes, etc. Finishing is understood to involve all those processes which cannot be classified under dyeing and printing. Bleaching, dyeing and printing are concerned with the production of colour, whilst finishing provides additional characteristics beyond coloration. In the case of textile fabrics, these characteristics are imparted both before coloration (pretreatment) as well as in final finishing after coloration. The major part of finishing takes place at the interface between the textile and garment industries and it is therefore important for the finisher to have a very wide knowledge of the influences of all processing stages. A rapid technological change is taking place both in the textile as well as the garment industry accompanied by increasing specialization. The traditional separation of both branches of industry is becoming less distinct as a result of their closer interdependence.

A distinction is made between wet and dry finishing. Where wet finishing is concerned with the preparation of textiles for subsequent coloration, it is referred to as pretreatment. When bleached, dyed or printed fabrics are treated with chemicals for the achievement of wrinkle-resistant, permanent-press or easy-care properties, in addition to dry finishing processes, this form of finishing is referred to as resin finishing. The development of characteristics in finishing processes may be subdivided into:

- Cleaning processes (including relaxation and the development of bulk),
- Setting, to achieve stabilization of the desired dimensions,
- Surface finishing to achieve certain physical and optical properties such as handle and lustre,
- Resin finishing for the achievement of serviceability and easy-care characteristics in proportion to the basic fibre properties.

Yarns: Sewing threads are lubricated, e.g. by impregnation with waxes, paraffins or silicone auxiliaries to reduce friction during sewing. A finish is applied to synthetic fibres after spinning to prevent the development of electrostatic charges during subsequent processes. This type of yarn finish can be regarded as being at the boundary between spinning and finishing as the process forms part of the actual spinning process and is carried out immediately after the fibres are spun. The treatment of cotton yarns with liquid ammonia in yarn mercerizing is a finishing process aimed at the achievement of specific yarn properties (lustre, bulk, handle, improved dyeability). The raising of yarns to achieve the typical hairiness for certain hand knitting yarns also represents a treatment carried out independently of yarn production which is included under finishing.

Fabrics: The main attention in finishing is devoted to the treatment of fabrics where processes which cause chemical changes to the fibres are mainly used. Other finishing processes also involve mechanical treatments for the achievement of specific effects. Particularly smooth napless fabrics can be produced by singeing or shearing.These treatments are considered as mechanical processes, although chemical processes are also involved (burning process, cutting of fibres on shearing machines with depolymerization of affected polymers. Opposite effects, e.g. for the production of voluminous, soft, rough or uneven surfaces are achieved by emerizing or raising (which are likewise mechanical processes). Also in the case of fabric finishing there are areas which border on other fields. If, e.g. loomstate fabrics are inspected for faults in the mending department of a weaving plant, or floats are removed on corduroy cutting machines in weaving plants, these processes are, in efect, preparatory treatments for finishing. The cut loomstate corduroy fabric is only converted into a real corduroy fabric by the finisher after numerous passages on brushing machines, etc. The anti-felting finishes given to made-up pullovers in paddle machines by the knitgoods manufacturer may likewise be considered as finishing processes.

Finally, in the widest sense, each drycleaning treatment can be regarded as a finishing operation since typical cleaning processes are involved. Moreover, when garment pieces are “re-proofed” with a water-repellent finish after the drycleaning process, this is carried out according to the same principles as any water-repellent treatment applied in fabric finishing.

Finishing agents These are products which give textile materials the desired end-effect, e.g. in the form of more or less fullness, stiffness or even weighting, etc. Such finishes are mainly produced with vegetable or animal glues, starches, starch derivatives, water-soluble plastics and plastic dispersions, cellulose derivatives and preparations, if necessary with the co-application of pigments.

Finishing and decatizing machines → Decatizing.

Finishing mangles In general, the requirements for uniform liquor pick-up on finishing mangles (see Fig.) are not as high as those placed on dye padders.

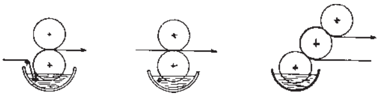

Fig.: Finish padder types: immersion path in a trough (left), slop padder (centre), inclined padder.

Finishing of hat felts

I. Shellac finish (Stork-Morawsky reaction): heat approx. 0.5 g finely shredded hat felt with 10 ml acetic anhydride for 3 min, cool and filter. Transfer the filtrate to a porcelain dish and allow 1 drop conc. sulphuric acid to flow down the inside wall of the dish. When the sulphuric acid mixes with the filtrate, a cherry red colour develops. This test is only suitable for natural resins containing abietic acid (e.g. colophony, beeswax, etc.).

II. Polyvinyl acetate finishes: boil approx. 0.5 g finely shredded hat felt in acetone for 15 min (reflux condenser), cool, filter, and allow the filtrate to dry. Polyvinyl acetate forms a film with the following characteristic reactions:

- iodine test with potassium iodide solution gives a violet-brown colour.
- saponify the dried film to polyvinyl alcohol (resinous mass) by boiling with 1 g caustic alkali in 10 ml methanol. Dissolve the polyvinyl alcohol in distilled water and add 1 ml hydrochloric acid and a pinch of sodium tetraborate. Depending on the quantity present, polyvinyl alcohol gives a blue-green colour, turbidity or precipitation.

III. Water-repellent impregnations with aluminium salts (test for aluminium): extract approx. 0.5 g of finely shredded hat felt with 50 ml 5% sulphuric acid for 10 min at the boil. Neutralize the filtrate with sodium acetate and add a few drops of morin: a yellow-green fluorescence confirms the presence of aluminium.

Finishing of textiles → Textile finishing.

Finishing soaps These products confer soft handle characteristics on textile fabrics and generally increase the wetting and penetrating properties of sizes and finishes. Suitable sizing compositions containing these products are more easily desized. Certain impregnating agents used for water-repellent finishes are also based on finishing soaps.

Finishing wash A treatment carried out after the production of textile fabrics in order to remove substances present in, or applied to, the fibre during previous stages of processing and thereby achieve a further improvement in the properties of the material (e.g. scouring of wool fabrics). In the discontinuous finishing wash, the material remains in a machine and wash/rinse liquors are introduced and exchanged as required by the process. The greatest disadvantage here is the fact that specific tasks are not performed in the individual process stages. In the continuous finishing wash, the fabric passes through several separate machines and sections in which the state of the wash/rinse liquors is more or less constantly maintained. A disadvantage in this case is the relatively low speed of the goods which means that their kinetic energy cannot be utilized to improve the washing effect and further contribute to the improvement of quality. For the continuous finishing wash in particular, the use of wash-active detergents must be suitably adapted to the processing conditions or optimized for the complex system represented by soiled fabric/machine/process.

Finish stains Such stains are usually stiffer than the surrounding material and are mainly round, oval, of matt appearance with a distinct dark ring. They may be removed by: a) a suitable detergent (with glycerol and, if necessary, ammonia); b) 1% ammonia solution. Care is necessary in the case of poor colour fastness. Ring removal: water/acetone. If necessary, matt areas (on wool) can be removed by covering with a piece of damp cloth after drying followed by hot ironing.

Fique fibre (Cabuya) → Mauritius hemp.

Fire A process of → Combustion, accompanied by the development of heat, smoke or flames.

Fire alarms Various types are available to comply with specific standards and regulations, e.g. differential alarms, push-button alarms, electronic alarms, smoke alarms, molten-metal alarms, scattered light detectors, early-warning fire alarms, etc.

Fire behaviour The behaviour of a textile fire is increasingly simulated by burning complete textile arrangements (e.g. net curtains in a living environment) (pilot plant test) rather than by tests alone. The illustration shows the interrelationship of this type of fire behaviour from the outbreak of fire via flash-over to the fully developed fire with temperature.

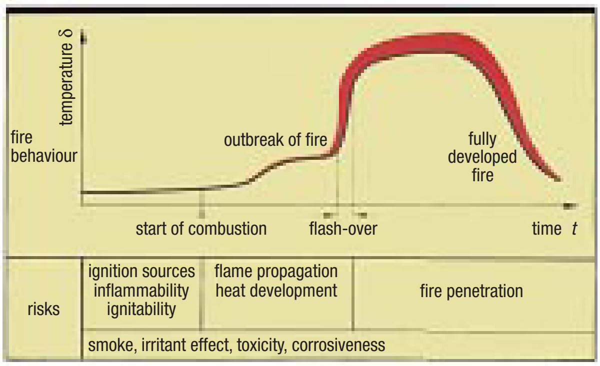

Fig.: Fire behaviour relative to substrate temperature.

Fire extinguisher, dry ice type A fire extinguisher consisting of a pressure cylinder (containing 5–6 kg of compressed liquid carbon dioxide) and a so-called snow-tube in which (during operation) approx. 70% of the carbon dioxide rapidly turns to gas (production of latent heat causing evaporative cooling) and the remainder is cooled to – 80°C in the form of solid dry ice. Fire is immediately extinguished by the dry ice (cooling down effect and dilution of oxygen). The dry ice evaporates without residue thereby causing no damage. This type of fire extinguisher can, therefore, be successfully used for gasoline, oil, paint, factory and motor fires, etc. (Dry ice fire extinguishers must not be kept in rooms at temperatures above 35°C).

Fire extinguishers Include a) ammonia extinguishers, b) halon fire extinguishers, c) dry ice, d) wet fire extinguishers, e) foam extinguishers, f) sprinkler systems and g) powder-type fire extinguishers. Each type of fire extinguisher is only suitable for a specific kind of fire. For this reason, combustible materials are classified under so-called fire hazard classes (DIN EN 2):

A. Combustible solids (capable of supporting flames/incandescence), e.g. wood, paper, textiles, coal.
B. Combustible liquids (flame-forming), e.g. gasoline, oils, fats, varnishes, ether, alcohol.
C. Combustible gases (flame-forming), e.g. propane, hydrogen, town gas, natural gas.
D. Combustible metals, e.g. aluminium, magnesium and their alloys, sodium, potassium.
E. Fires in electrical equipment.

On this basis, powder-type fire extinguishers are used for fires in classes ABC, BC, BCE and ABCDE. In addition, portable fire extinguishers of the dry ice and carbon dioxide mist type are used for category B, carbon dioxide gas extinguishers for category C, halon extinguishers for categories BC and water extinguishers for category A. In addition to the extinguishants mentioned above fire extinguishers also contain propellants for sustained depression extinguishers (air or gas under pressure), gas propellant extinguishers (pressurized gas in propellant containers) and pressurized gas extinguishers (gas produced by chemical action for immediate use). Each type of fire extinguisher is clearly labelled with the permitted applications for which it is suitable.

Fire extinguishers, carbon dioxide type System: distributor and gas supply tube with spray nozzles fitted on the ceiling of the space or room being protected. These are fed from carbon dioxide cylinders stored in another location. In the event of fire risk, metal plugs on the gas supply tubes melt due to the developing heat (at 72°C). The gas supply from the cylinders is then released and carbon dioxide gas flows through the nozzles into the fire zone causing rapid smothering of the fire. Applications: for all departments where a fire risk exists, especially for drycleaning plants which use flammable solvents, e.g. white spirit. Also used as an automatic fire extinguishing system in stenters.

Fire extinguishers for drycleaning plants Water is totally unsuitable for drycleaning plants which employ flammable solvents such as white spirit. In practice, the following types have proved to be the most suitable: ammonia extinguishers, carbon dioxide extinguishers, dry ice extinguishers, foam extinguishers and powder-type extinguishers.

Fire extinguishing powders Used as extinguishants in → Fire extinguishers. Designation according to fire classification:

1. Flame-propagating fires (e.g. for fire classifications BC, BCE): sodium bicarbonate basis. The extin-

guishant action is due to a fire-inhibiting effect (prevention of further combustion processes).

2. Incandescent fires (e.g. for fire classifications ABC and ABCDE): ammonium phosphate, ammonium sulphate, aggregates. The extinguishant action is due to an inhibiting effect in the case of BC and a barrier layer effect in the case of AD.

3. Metal fires (for fire classification D): based on inorganic chlorides and silicates. The extinguishant effect is due to the formation of a molten salt barrier layer on the burning metal.

Fire hazard classification → Fire extinguishers.

Fire load The totality of all combustible materials in the area surrounding the source of a fire which is of decisive importance for the progress of any outbreak of fire. The fact that a very hot updraught of air from an open fire requires an incoming flow of cold air close to floor level has been confirmed by large scale fire tests. This cold air flow is favourable against the spread of fire on floors by counteracting its propagation through floorcoverings to some extent. As a result, textile floorcoverings, for example, generally represent only a small proportion of any fire load. This quantitative ratio between floorcoverings and other fire load components justifies the claim that the former can be disregarded as far as their contribution to the formation of → Combustion gases is concerned.

Fireproof This term relates to the property of remaining unchanged through the action of fire, e.g. as in the case of asbestos. All other textile fibres can be given a → Flame-retardant finish but these are not normally fireproof. Developments in the spinning technology of carbon fibres have resulted in the production of fibres with heat resistance up to 2500°C which therefore qualify as fireproof fibres. Fireproof properties begin at 1500°C; the most common oven temperatures are between 1500–2000°C.

Fire protection The installation of a reliable in-house fire protection system is to be recommended. Localized installations based on connections to water hydrants in the form of portable fire hose reels may be considered here. Although such systems can be installed at relatively low cost, they are not always sufficient. Hand fire extinguishers (→ Fire extinguishers) are particularly effective, as well as halon extinguishers. All installations for fire protection can be made readily identifiable with red paint. For large industrial plants either one or several centralized fire alarm systems are recommended.

Fire protection equipment (→: Fire extinguishers; Fire alarms). Fire protection equipment is particularly important in the textile industry in order to keep the outbreak of fire under control. Electronic smoke, heat, spark and flame alarms are recommended because of the special importance of early warning. It is also most important for all the factors which can influence the outbreak of fire to be thoroughly analyzed by fire protection experts. The integration of fire protection into the entire safety organization of a plant ensures an optimum level of safety in medium to large textile plants.

Fire protection in textiles Organic substances, including the majority of textiles in common use (with the exception of asbestos and glass fibres), are combustible under certain conditions even if they do not appear to be combustible under the usual test conditions. This means that expressions such as "incombustible" and "non-combustible" are to be avoided at all costs for organic substances. Textiles produced from aramid fibres or polyvinyl chloride (PVC) are indeed non-combustible at normal temperatures (and consequently also in the usual small flammability tests) but suddenly become combustible, on the other hand, at higher temperatures, e.g. from 150–200°C. Fabrics declared to be "flame retardant" can likewise become flammable if they have been soiled or roughened during use or as a result of laundering and dry cleaning. In this connection, it should be emphasized that washing instructions attached to "flame retardant" textiles must be strictly observed. Any deposits formed on the fabric during laundering, e.g. lime soaps, can have an adverse effect on its burning properties even if the flame retardant chemicals are still present. In these cases, the original flame retardant properties may be restored again by appropriate washing. Every fire represents the external manifestation of complex chemical and physical processes which can vary greatly from one fire situation to another. It is, therefore, not possible to include all the criteria relating to a particular fire in a single laboratory test method. Consequently, the test principles underlying attempts to reconstruct a particular fire situation in the laboratory are also correspondingly varied. For this reason, different test methods are often resorted to in order to provide reliable information on the burning behaviour of a specific material.

- Textiles made from natural fibres and common blends of natural and synthetic fibres which lie within the range of normal flammability include those produced from cotton, acrylic, acetate, viscose, polyester/cotton, polyester/viscose, and polyamide/cotton.
- Textile raw materials which are less flammable include blends such as polyester/wool (55/45), polyamide/wool, polyester or polyamide alone, as well as modacrylic fibres, flame-retardant viscose, flame-retardant acetate and wool.
- Textiles produced from man-made fibres, which burn less readily on their own than the substrates mentioned above but which nevertheless must be described as combustible, include the aromatic polyamides, specific modacrylics, polyvinyl chloride, specific polyester fibres and the polyamide imides.

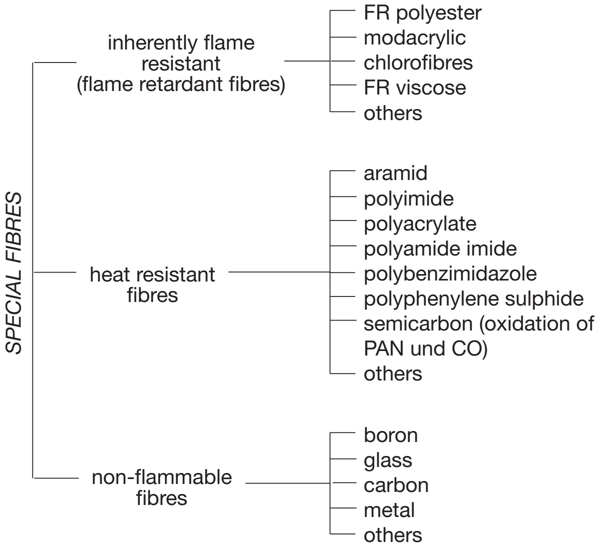

Fig.: Man-made fibres and textiles for fire protection. FR = flame resistant.

- Textiles produced from man-made and other fibres which are practically non-flammable on their own and are capable of withstanding temperatures up to approx. 1000°C, can be produced from boron carbide, carbon, glass or metals (see Fig.).

Workwear capable of protecting the wearer against exposure to high risks of fire but which has to be worn throughout the day is not only expected to offer protection from flames but must also be comfortable to wear, have a normal wear life, and allow cleaning by methods in common use. In addition, intelligently conceived products are needed which are capable of fulfilling the required properties as far as possible throughout their entire working life with the same level of protection. Quality assurance is extremely important here especially since the safety of human lives is at stake. Textiles designated as flame retardant or flame resistant must therefore exhibit these properties even if the wearer is not particularly at risk. Appropriate test methods and classification procedures are required for control purposes.

Since the supply of oxygen is greater in the case of lightweight fabrics with an open structure (e.g. curtains) compared to heavy, tightly-woven materials (e.g. textile floorcoverings and wall hangings), the former burn more rapidly and more intensely than the latter and therefore represent a greater fire hazard. The spatial arrangement of the material represents another criterion here. Textiles which hang vertically (curtaining or drapes) are more hazardous than those which lie on the floor (e.g. textile floor coverings) since the spread of flames takes place primarily in a vertically upwards direction. Decomposition products formed during pyrolysis represent another important criterion here. They are dependent on the chemical composition of the fibre and applied finishing agents. If all the decomposition products are combustible, flammability is obviously greater than in cases where non-combustible gases are released. The latter displace oxygen and inhibit or prevent the combustion process. In principle, all organic natural and man-made fibres are combustible. However, the amount of energy released per unit time and the combustibility of decomposition products varies greatly from one type of fibre to another. The decomposition products can be influenced above all by additives to the fibre polymer or by the application of appropriate finishing agents. Whilst man-made fibres are generally made flame retardant by introducing additives into the fibre polymer, finishing agents have been developed for natural fibres (cotton, wool) which are applied to dyed or printed fabrics. When these materials are burned, non-combustible gases are liberated from the additives and the atmospheric oxygen surrounding the textile is displaced. A large number of finishing agents capable of making textiles flame retardant are now available. In order to select a suitable finish for a particular application it is important to consider both the durability of the finish (especially to laundering) and the quantity which must be applied to the textile in order to achieve an optimum effect. The problem of skin compatibility with such finishes must be checked separately. Requirements for the flame retardant properties of textiles are dependent on their fields of application (clothing, home textiles, technical textiles). Before a specific range of requirements is laid down, however, it must first be ascertained whether an appropriate technology exists which can be expected to produce a fabric with the properties required by the market. These technologies also need to be checked for their environmental compatibility and other possibly harmful consequences. It is pointless to stipulate requirements for materials that can only be produced by methods according to the present state-of-the-art which alone are not above reproach with regard to questions of environmental compatibility or other harmful consequences. A typical example of an undoubtedly hastily introduced government regulation was the Flammability Regulation for Children’s Nightwear at the beginning of the 1970’s in the USA which ended in the notorious TRIS debacle: tris(dibromopropyl) phosphate, a flame retardant which was primarily used as a finish for children’s nightwear made of polyester so that these garments could satisfy the test requirements demanded by the fire protection legislation at that time, turned out to be a suspected mutagen and carcinogen some years after its use in the trade and therefore had to be withdrawn from the market overnight.

Fire-resistant cover → Pressing.

Fire-resistant fibres Fibres based on inorganic materials (mineral fibres) take first place here, e.g. glass, ceramic or asbestos. → High temperature fibres.

First strike A term used for the concentration gradient at the beginning of a pad dyeing, e.g. with direct dyes on cotton.

Fischer-Tropsch waxes Synthetic → Wax obtained as the products of coke hydrogenation (Fischer-Tropsch process). These include the kogasin waxes (boiling limits 160–320°C) and soft wax at 320–450°C which are used as the basis for fatty acid synthesis and degradation products such as fatty alcohols, esters, etc. and hard wax or hard paraffin at 450°C. Further processing results in oxidized and partly-saponified waxes which are dispersible or emulsifiable in water with emulsifiers. Fischer-Tropsch waxes have a comparatively low molecular weight (approx. 600–700). Because of their narrow molecular weight distribution, they are nevertheless relatively hard and high melting. Compared to polyethylene waxes, they are characterized particularly by their lubricity.

"Fished" wool Short-fibre wool which has been "fished out" of the wool washing plant. It is usually returned for process in the woollen yarn spinning system.

Fish glue → Glue.

Fish test Procedure for monitoring the contamination of bodies of water. The average lifespan of certain species of fish under such conditions is used as a measure of the contamination of the water. Specially bred fish are released at given intervals of time into a section of water (or tributary) which is isolated by wire netting. The occurrence of dead fish is counted, and from the mean lifespan the degree of contamination is derived. →: Lethal limit; Toxicology.

Fish toxicity → Fish toxicity of textile waste water.

Fish toxicity of cationic surfactants The acute toxicity of cationic surfactants lies within the range 1,5–4 mg/l or lower in the case of cationic surfactants with specific disinfectant properties. At concentrations between 5 and 30 ppb found in water courses, no harmful effects on fish and other aquatic organisms are to be expected. (→ Fish toxicity of waste waters; Fish test).

Fish toxicity of textile waste water Increased attention must now be paid to the waste water problems of dyehouses and textile finishing plants situated near water courses. From tests, e.g. the following effects have been found (various sources): Up to 5 mg/l chlorine at 12°C led to fish lying on their sides after 76 min and death after 6 h (tench); the toxicity threshold of 0,3–0,4 mg/l for many kinds of fish to this pollutant is, however, considerably lower. Quicklime (waste water treatment process): amounts of quicklime up to 70°C at 16°C caused death after 26 min (trout): the critical upper pH levels are 9,2 for trout, 9,2 for perch, 10,7 for pike, and 10,8 for carp. Amounts of chrome alum up to 200 mg/l at 9°C had no harmful effects after 75 min (trout). Soap in amounts up to 1000 mg/l at 14°C caused fish to lie on their sides after 2 hours (trout), but they recovered again after 67 min in pure water. The → Lethal limit of anionic surfactants for fish is 5–10 mg/l. Cationic compounds are, in some cases, even more toxic (1–5 mg/l). As far as fish toxicity is concerned, additional synergistic effects of various components also need to be considered, as well as the chemistry of the receiving water course (e.g. water hardness) which can greatly alter the toxicity of individual substances. For receiving water courses with a low flow rate, the high → BOD of textile waste waters (e.g. due to carbohydrates) can also be hazardous to fish if oxygen depletion occurs. The frequency distribution of different kinds of fish in water courses is dependent on the degree of eutrophication.

Fishy odour (amine odour). A defect in finished textiles which manifests itself as the development of an unpleasant odour in fabrics with urea or melamine-formaldehyde crease-resist finishes due mainly to trimethylamine $N(CH_3)_3$. It is prevented by a thorough alkaline afterwash with sodium carbonate, and in the USA also by means of an ozone treatment. A preliminary examination of resin-finished fabrics can be carried out by odour analysis (fabric specimen 2 x 4 cm in size + hot 5% sodium carbonate solution in a test tube. The tube is immediately closed and tested for the development of odour after 5 min: a fishy odour indicates with certainty that problems can be expected during storage, a negative test is an indication that the finished goods can be stored without risk). A more reliable test is to boil a 3 g fabric specimen in water and distil over an iodine potassium iodide solution when quantities as low as 0,5 mg trimethylamine are still detectable. Findings: a brownish-black to black precipitate indicates large quantities of trimethylamine which will definitely result in claims for defective goods. Brownish-black stains or rings at the bottom of the sample are an indication of borderline goods. Where neither precipitation nor cloudiness, stains or rings at the bottom of the sample are present, experience up to now indicates that subsequent development of fishy odour is not to be expected. Tests based on gas chromatography can also be included in the series of tests.

Fitted carpets Carpets as floor coverings, in roll form, for wall-to-wall fitting. → Contract carpet.

Fittings Mountings or fittings for the installation of pipework (bushings, flanges, T-pieces, junctions, etc.).

Fittings for high-pressure steam boilers (→ Fittings), these include, e.g. steam traps; steam trap regulators; pumps; gilled pipes; pipework; dampers; safety systems; valves.

Fixanal, exactly weighed amounts of pure chemicals in ampoules for preparing normal solutions. The contents of the ampoule are dissolved in 1 l of distilled water (volumetric flask) to give a solution of the stated normality. An accuracy of ±2% is guaranteed. Handling is very straightforward.

Fixation (→ Heat setting). In the course of the manufacturing process for a textile, from the yarn to the finished fabric, heat treatment may be necessary at various stages. When the process is used to facilitate the next process it is called intermediate fixation; if it is a final operation for establishing the characteristics of the finished article, it can be called final set or final fixation.

Intermediate fixation operations mainly serve the following purposes:

1. Preshrinking of yarn (amongst other things) for removing the potential for shrinkage from subsequent piece goods processing and to reduce the shrinkage in a subsequent yarn dyeing process.
2. Equalisation of tension differences from the spinning process.
3. Stabilisation of a yarn twist, for better subsequent processing capability.
4. Fixation of dyes.
5. Development and fixation of yarn crimp or fibre crimp, which in respect of the crimp is a final setting, but which in respect of the piece goods is an intermediate fixation.

Final fixation is above all for the purpose of:

- shaping,
- stabilising a fabric against subsequent stress in wear and laundering,
- establishing the desired material appearance,
- reducing creasing,
- Influencing the handle of the goods.

First and foremost, fixation is a temperature treatment. Air, water or steams are used to transfer the thermal energy. The choice of fixation medium depends on the purpose and the fibre type, amongst other things. The following essential differences between hot air and (water) vapour should be noted:

- Steam has a greater capacity for heat transfer than air;
- Water (including steam) acts as a swelling agent and thus supports the temperature effect, particularly in the case of polyamide;
- Steam has the ability to act as a protective medium and prevents oxidation.
- At high temperatures, steam can lead to hydrolysis (e.g. polyester);
- Steam and water can promote the separation of monomers and oligomers.

The macro-molecular synthetic fibres have a mixed amorphous-crystalline structure. The macromolecules, which are oriented in the fibre axis, are bound in the amorphous areas by means of hydrogen bonds. If a yarn (fibre) is mechanically deformed during subsequent processing (through elongation, flexing, twisting), amongst other things, the distance between the bonding points becomes greater, and stresses develop. These have the effect of making the yarn tend to return to its original form, when the processing tensions are removed. In the fixation process, these structures are affected according to the temperature of exposure, the duration of treatment, and the yarn tension. The crystalline state is altered, the cross-linkages are broken. During steam setting, the latter is supported by the addition of water molecules at the junctures (swelling). During the cooling process, and depending on the speed of cooling, a mixture of amorphous and crystalline zones forms once again. Here, the cross-linkages adopt the new mechanical form of the yarn, and fixation takes place. Through renewed temperature treatment, the process outlined above can be repeated. Here, the state after the first fixation is overcome only by applying a higher temperature. If the permitted conditions are exceeded during fixation, additional degradative reactions occur, which lead to irreversible changes (damage). Various physical and chemical characteristics of the yarn are heavily dependent on this inner structure (source: Kaufmann and Häussler).

Fixation accelerator A fixation accelerator increases the diffusion of a disperse dye in a print thickener to such an extent that it is no longer a rate-determining step in the rate of reaction during the fixation of prints on polyester.A fixation accelerator thus speeds up, or lowers the temperature required for reaction. Moreover, the fibre structure is changed by a fixation accelerator in such a way that diffusion of dye into the substrate is improved without the accelerator itself remaining behind. Fixation accelerators also have wetting and dye-dissolving properties.

Fixation bath Used in all two-phase printing processes. The liquor contains all the necessary chemicals and additions to bring about the fixation of dyes printed without fixation auxiliaries and prevent the dyes from dissolving out during passage of the printed fabric through the fixation bath. Thus, in the continuous dyeing of e.g. polyester/cotton blend fabrics with combinations of disperse and reactive dyes, the disperse dye is first “dissolved” in the polyester fibre by a thermosol treatment before caustic soda solution (as a fixation bath) is applied prior to steaming in order to fix the reactive dye. The thermosol treatment also protects the disperse dye from alkali saponification due to the subsequent application of caustic soda.

Fixation goods Expression used to describe the fixation of interlinings, used for interlining and the outer fabric.

Fixation of reactive dyes in direct printing by hanging The fixation of prints produced on cotton with highly reactive dyes may also be achieved by hanging (similar to the print and lay process). The textile material, printed with a paste containing alkali and dye is allowed to hang, without intermediate drying, in a warm, humid atmosphere for 3–4 hours until fixation is complete. This process is particularly attractive for small scale production (no energy required), e.g. colleges of art, handicraft industries, etc.

Fixation press → Ironing machines.

Fixation ratio, proportion of fixed dyestuff to dyestuff used.

Fixation temperature The temperature range in which dyes become firmly anchored (fixed) to an appropriate textile material.

Fixation time The time span required for a dye to become firmly anchored (fixed) to a textile substrate at a specific → Fixation temperature.

Fixing (Lat.: fixus = fix, durable)

I. Of textiles in the sense of fixing the size or form →: Alkaline scouring, Crabbing, Decatizing, Potting, Hose setting, Heat setting (→ Fixation). The degree of fixation, i.e. the structural alteration which arises through the effect of heat, can be determined in polyester by solubility determination in phenol/tetrachloroethane; similarly through differential thermal analysis (DTA), which can also be used for polyamide.

II. Of dyeings, takes place e.g. through auxiliaries for increasing the fastness, and → Developers.

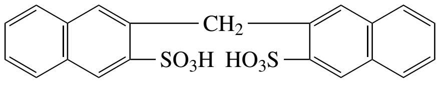
III. Of prints: fixative development. Takes place normally on the steamer.

IV. Of dyestuffs, mostly through hot air (→ Thermosol process), direct contact (hot-roll fixation machines) or steaming.

Fixing joint When fixing interlining fabrics to an outer fabric, the position of the adhesive mass where the (hot) sealing temperature must be reached.

Fixotest apparatus A test apparatus used to determine the colour fastness of dyeings and prints to contact heat (colour fastness to dry heat pleating and dry heat setting according to DIN 54 060, colour fastness to hot pressing according to DIN 54 022). The test is carried out on three plate pairs, each in a single operation at 150, 180 and 210°C. Manuf.: Original Hanau.

Fixtanes, organic compounds consisting of two aromatic ring systems connected by aliphatic chains, as e.g. fixtane acid,



the mercury salt of which is used as a fungicide. Fixtanes have no affinity for fibres but become insoluble after drying. Solutions of the mercury salt can only be made at up to 0.25%; however concentrations of up to 2.5% (density 1.53 to 1.94) can be made by adding free acid.

FL

I. abbrev. for: Finnish Patent.

II. → Polyfluoroethylene fibres, standard abbrev. after the → EDP Code (→ Textile fibre symbols).

Fl → Flax, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988; from 1991 → LI.

Flaking off Certain thickeners with a high solids content used in textile printing produce hard and brittle films on textile fabrics after printing and drying. Such films may have a tendency to → Split off or flake off the material. In the latter case, there is no addition of the second colour in → Fall-on in printing.

Flame A region in which combustion occurs in the gas phase accompanied by the evolution of heat and visible light.

Flame a fabric, to → Singeing.

Flame backcoating A gas flame is used for back coating. The fabric/foam sandwich is led over a burner strip across the entire width (see Fig.). The gas flame melts the surface of the foam, and a solid connection is provided by subsequently applying pressure. This form of backcoating produces exhaust gas.

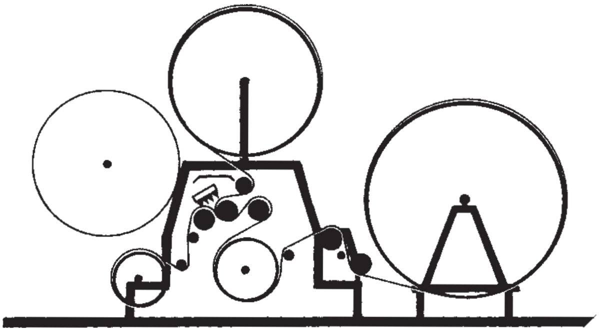


Fig.: Flame backcoating system (Mohr).

Flame drying → Remaflam process.

Flame emission spectroscopy Like → Atomic absorption spectroscopy, flame emission spectroscopy is a method used for detecting traces of heavy metals.

Flame ionization detector (FID). A technique used for the monitoring of toxic atmospheric pollutants, e.g. to determine the content of organically-bound carbon in exhaust air streams. Part of the exhaust air flow is withdrawn as required by a heatable probe. The analyzer compares the unknown concentration of the measured gas with the known concentration of a calibration gas. An electrical field is applied to a pure hydrogen flame which burns in a supply of hydrocarbon-free air. If organic compounds are introduced into the flame by the gas being measured, a measurable ion current develops during combustion. The resultant signal is proportional to the number of non-preoxidized carbon atoms introduced by the gas. Preoxidized and halogenated carbon atoms are only partially detected by this means whilst carbon monoxide and carbon dioxide are not detected at all.

The substance-dependent response factor r describes the signal/concentration ratio in gas chromatography detection. Propane is indicated by a factor of r = 1 per definition, whilst formaldehyde has a factor of r = 0,3. Moreover, the proportion of carbon in formaldehyde is only 40% so that, in comparison to propane, the sensitivity is 13,4 times poorer. For this reason, formaldehyde is difficult, if not impossible, to detect with an FID.

Flame laminating A process used for bonding woven or knitted textiles to a layer of foam which is melted by application of a flame.

Flame-lamination → Laminating.

Flame-proof finishes → Flame-retardant finishing.

Flame retardance The property of a textile material, either inherent or by virtue of an applied finish, to inhibit or suppress the propagation of flame (ISO).

Flame retardancy theories Examination of the burning behaviour of organic fibres or the course of → Pyrolysis reveals various mechanisms for the action of flame-retardant finishes, i.e. possibilities for bringing influence to bear (→ Flame-retardant finishing).

I. Endothermic reaction: under the action of heat at comparable temperatures the flame-retardant chemical and the fibre are decomposed. Thermal breakdown of the flame-retardant chemical extracts energy from the combustion process which has an endothermic effect.

II. Development of non-combustible gases: during fibre pyrolysis, flame-retardant chemicals form gases which are either non-combustible or only slightly combustible. As a result, the local oxygen content is reduced and combustion is consequently made more difficult.

III. Melt theory: under the action of heat and the expenditure of energy, flame-retardant chemicals are converted into a melted state which impedes the access of air and inhibits the evolution of combustible gases.

IV. Formation of radicals: with the provision of energy, flame-retardant chemicals form gases capable of intercepting the reactive radicals of the combustion process so that less energy is released during combustion.

V. Dehydration: flame-retardant chemicals intervene in the pyrolysis reaction with a dehydrating effect. This promotes the formation of carbonization residues and, at the same time, reduces the production of combustible gases.

The optimum flame-retardant action exists when as many of the described mechanisms as possible act in combination so that synergistic effects often occur.

Flame-retardant chemicals Most of the processes developed for cellulose are all based on achieving a permanent reduction of combustibility through the *in situ* insolubilization on the fibre (covalent reactions with the hydroxyl groups of cellulose and/or polymerization) of organic phosphorus compounds in the presence of nitrogen. It has been recognized that nitrogen contributes to the efficacy of organic compounds. The high nucleophilic character of nitrogen and the high electrophilic character of phosphorus in flame-retardant chemicals are important conditions for the achievement of an effective nitrogen/phosphorus synergy. An exceptionally good source of nitrogen to provide the desired synergistic contribution is trimethylmelamine because of its high nitrogen content as well as its adequate nucleophilic character.

Classification:

I. According to washing fastness:

1. Not fast to washing (mostly inorganic salts) or with limited fastness to washing (reduced solubility through heating or condensation, e.g. urea-phosphoric acid).

2. Fast to washing as in a) the single-bath process (e.g. inorganic salts with synthetic resins or chlorinated paraffins) and in b) the two-bath process (mainly with inorganic titanium, antimony and tin salts).

II. According to chemical characteristics:

1. Inorganic compounds: a) Halogenides and also fluorides and bromides to some extent. Improved fastness to washing is achieved by combinations with chlorinated paraffins, synthetic resins, etc.; b) Metal oxides, especially those of titanium and antimony (with afterglow; antimony oxychloride prevents afterglow), also used in plastic dispersions; c) Salts of sulphamic acid, e.g. 85% ammonium sulphamate (afterglow when used alone) and 15% ammonium phosphate. Improved fastness to washing following e.g. an aftertreatment with aminoplasts and condensation; d) Inorganic phosphates, chiefly ammonium phosphates; e) Other inorganic compounds: sodium silicate (20% solution) and sodium tetraborate (alone or in combination with boric acid, ammonium phosphate, etc.), also zinc borate, zinc carbonate and aluminium silicate.

2. Organic compounds: a) Organophosphorus compounds, e.g. THPC; b) The aminated and alkoxylated derivatives of the polymer dichlorophosphornitrilechloride or chlorinated paraffins (excellent fastness to washing) are of great importance in combination with antimony salts for military fabrics and workwear; c) Organosilicon compounds such as the water-soluble sodium methylsiliconate produce effects with high resistance to washing; d) Other organic compounds, e.g. polyvinyl chloride (for flame-retardant coatings), organic esters of titanic acid, phosphates with alkyl substitution.

Flame-retardant fibres

I. The fact that many products recommended and applied as flame-retardant finishes are suspected of being carcinogenic has, above all, induced fibre producers to increase their efforts to produce intrinsically flame-retardant fibres. In the case of synthetic fibres this can be achieved by e.g. grafting, or by making suitable additions to the spinning mass. Native cellulosic fibres can be made flame-retardant by modification (phosphorylation), and regenerated cellulosic fibres by the deposition of flame-retardant products (e.g. organophosphorus derivatives).

II. The burning properties of textiles are influenced by a wide variety of factors (→ Flame-retardant finishing; High-temperature resistant fibres). In addition to substrate-specific properties, the presence of foreign substances in particular, are responsible for initiating synergistic as well as catalytic effects. It is therefore very difficult to predict the behaviour of the end product from the burning properties of individual components due to the influence of many diverse factors (Fig. 1).

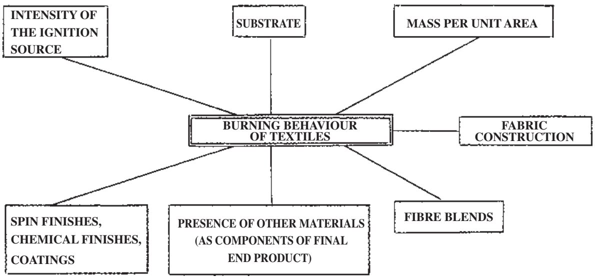

Fig. 1: Factors influencing the burning behaviour of textiles.

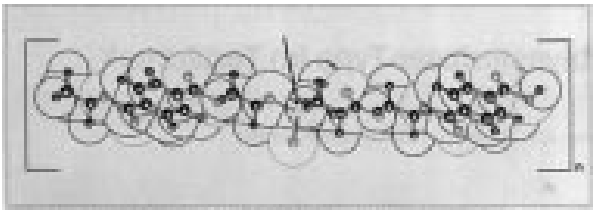

Fig. 2: Flame-retardant action produced by organophosphorus compounds (source: Hoechst).

A flame-retardant polyester fibre contains, e.g. 0.6% of phosphorus as a co-monomer which is polymerized in the spinning mass. The essential difference of a fibre modified in this way (Fig. 2), in comparison to a conventional polyester fibre, is its self-extinguishing property. A test carried out in accordance with DIN 4102, B2 demonstrates its typical burning behaviour. Although exposed to a flame for 15 s, the test specimen only burns for approx. 1–2 s before burning is extinguished and the fibre melts a little without burning. In order to maintain the flame retardant properties of the fibre starting product right up to the textile fabric end product, all the finishing processes such as dyeing, printing, finishing (including coating, where applicable), must be appropriately adapted to prevent any impairment of the flame retardant properties.

Flame-retardant finishing The oft-quoted expression “flameproof” is incorrect, since only certain fibre materials can be said to be flameproof or inflammable, mainly those of inorganic origin. Polyacryl nitrile fibres and cellulose fibres are the easiest to ignite and burn. The flameproofing procedure therefore mainly concentrates on these textiles. For decades, the cotton materials used for interior decoration in public buildings, for example, have been given flame-retardant finishing with relatively few problems. However, problems started when certain countries (initially the USA) started to issue legal regulations for clothing materials and ban the sale of easily flammable articles. The processes that had been previously used were no longer viable, since there was inadequate wash-fastness and the handle had been too greatly affected. It soon emerged that state regulations had exceeded technical feasibility. It was difficult to find a flame-retardant finish of adequate wash-fastness that did not irritate the skin and did not adversely affect the handle of the material. Countless test methods and testing devices were developed, and it was discovered that there were discrepancies between the results of such tests and the actual behaviour of the material during use.

The combustion behaviour of a fibre in textile products cannot be characterised by a single parameter. The tests mainly relate to flammability, flame spread and smoke production. Another test that has been introduced is the test for oxygen demand. This LOI (Limiting Oxygen Index) specifies the minimum oxygen concentration in the mixture with nitrogen that is just about adequate for continued burning; it is also known as the VTO2 index (Fig. 1).

Ignition temperatures:	
Cotton	400°C
Wool	600°C
Acetate	525°C
Triacetate	540°C
Polyester	510°C
Polyacryl nitrile	560°C
Polypropylene	570°C

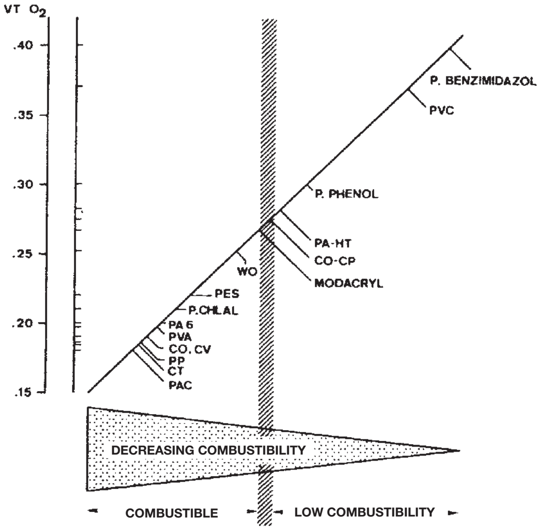

Fig. 1: Limiting oxygen index (VTO_2) for several fibre materials [-CP = Pyrovatex CP finish (Pfersee); -HT = High temperature resistant; P - Poly-].

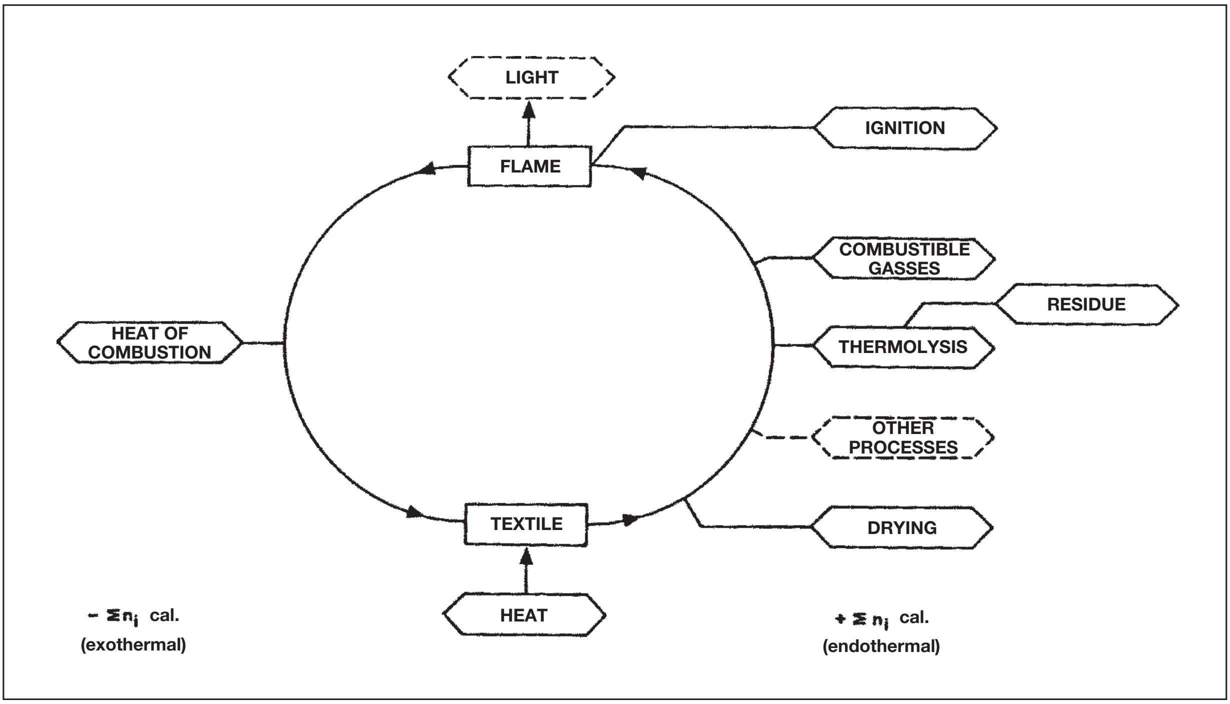

Fig. 2: Schematic diagram of the ignition and combustion of textiles in the form of an energy audit. Σn_j *cal. signifies the sum total of all thermal energy that is absorbed or emitted during the individual phases.*

Synthetic fibres present a particular problem in that they melt and drip when heated. It has emerged that dyes can even increase combustibility (e.g. in polyamide).

When a fibre burns, a state of equilibrium is reached between oxidative flame burning and pyrolysis inside the fibres (Fig. 2). The exothermic combustion feeds the endothermic pyrolysis with energy, whereas the pyrolysis produces gases that diffuse within the flame if oxygen is excluded and therefore feed the flame. A thermal balance is reached in this system by the sum total of the thermal energy that is absorbed or emitted in the individual phases (textile combustion process). Several theories concerning flame-retarding finishing can be derived from this knowledge:

– Gas theory: dilution of the easily combustible gases with gases of low combustibility (N_2, Br_2).
– Coating theory: creation of an inert atmosphere over the substrate surface with CO_2, H_2O, HCl (from PVC coatings).
– Thermal theory: reduction of substrate temperature below the ignition temperature by adding heat-absorbent substances that do not degrade (Na_2MoO_4, $NaVO_3$).
– Chemical theory: catalysis of pyrolysis by producing of gases of low combustibility and carbon. Reduction of the tendency to depolymerize. Promotion of water removal (P-N synergism).

Known flame-retardant concepts can be grouped as follows:

1. Dense material structure.

2. Fibre spinning mass modification: a) copolymerization of modacrylics (instead of polyacryl nitrile); b) additives (viscose, acetate, polyacryl nitrile); c) aramids, polyvinylchloride.

3. Chemical modification: a) Grafting (vinyl chloride to polyacryl nitrile); b) reaction between cellulose and phosphor-nitrogen compounds.

4. Finishing: a) low molecular compounds (tris-(2,3 dibromopropyl) nitrile chloride); b) polymers (polyvinylchloride Sb_2O_3 mixture); c) in situ polymerisation (tetrakis (hydroxymethyl) phosphonium chloride; d) salts.

In order to have the desired effect, the fibres must be charged with large quantities of these products (10–20%). The finishes that are not washproof are only used in exceptional cases. The same applies to the metal oxide deposit process, e.g. the “Erifon” process (DuPont) that is used to impregnate a titanyl chloride and antimony trichloride solution with subsequent passage through a sodium carbonate bath, and similar processes. Finishes containing antimony have a tendency to after-glow. This process also causes the handle of the material to be adversely affected. The permanently flame-retardant finishes are therefore of primary interest, some of which can be used for synthetic fibres.

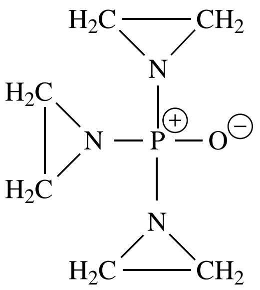
The products that are used must not be toxic or carcinogenic, which also applies to the vapours and gases that are produced during pyrolysis. They must also be skin-compatible. Flame-retardant finishes free from antimony and chlorine are therefore required for environmental reasons. There is also the additional problem of effluent, since most phosphor nitrogen compounds are not biodegradable.

The most important phosphorus-based product groups are structured as follows:

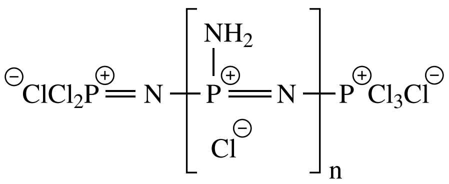
- tetrakis hydroxy methyl phosphonium chloride (THPC):

$$(HOCH_2)_4P^+Cl^-$$

- Tris-aziridinyl phosphin oxide (APO):

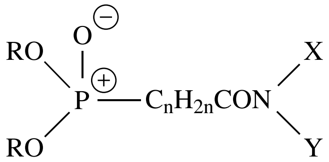


- Phosphor nitrile chloride polymers (PNC):



$$^{\ominus}ClCl_2\overset{\oplus}{P}{=}N-\left[\overset{\oplus}{P}(NH_2)(Cl^{\ominus}){=}N\right]_n-\overset{\oplus}{P}Cl_3Cl^{\ominus}$$

- N-methylol dialkyl phosphonium carbonic acid amide:



R = alkyl
X = hydroxymethyl
Y = H or hydroxymethyl

The individual working stages of a typical flameproofing finishing are:

1. Impregnation on a two or three roller padder with adequate depth of submersion.
2. Drying on the stenter frame, loop drier or hot flue, whereby shock drying must be avoided at all costs.
3. Heat setting in a condensing oven with good air circulation and a working temperature of at least 160°C.
4. Washing on a full-width washing machine with four or more washing compartments.
5. Final drying.

Although wool is naturally difficult to ignite and burn, flame-retardant finishing has been sought for wool carpets. The IWS "Zirpro" process uses potassium hexafluoro titanate and zirconate for this purpose. These products can be applied in exhaust and pad processes (even in a dye liquor in some cases). Other flame-retardant agents for wool are zircon wolfram complexes and tetra bromphthalic acid.

Flame-retardant finishing of carpets Flame-retardant finishing of carpets is becoming increasingly important because of the constant increase in the use of fitted carpeting. The combustion behaviour of the floor coverings is influenced by the substrate and pile materials, the carpet structure and the backing system. It is complicated by the fact that different materials interact. Cotton carpets can be given a flame-retardant finish using THP derivatives whilst titanium or zirconium salts are used for wool carpets. Aluminium hydrate is added to the back coatings in order to increase flame retardancy. The finish is applied by slop padding or spraying carpet materials with solutions or dispersions containing flame-retardant materials (→ Flame-retardant finishing). It is possible to subdivide textile floor coverings into different combustion classes as per the test methods of DIN 54 332. DIN 66 081 describes division into three classes. Flame-retardant finishing increases the static charging of the coverings.

Flame retardant reactive finishing of cotton Fixation of flame-retardant agents via reactions with cellulose. In this process the methylol group reacts with the cellulose hydroxyl group. With → THPC a reaction with ammonia also takes place due to condensation and soluble polymers are formed. The advantages of this process lie in the good washing and dry-cleaning fastness of the finish produced. However, the often unavoidable disadvantages are: some complicated processes requiring special equipment; loss of tensile strength; harsh handle; detrimental effect on dyeing; ineffective on cotton/synthetic fibre mixtures.

Flame retardants and COD The → COD of flame-retardant finishing liquors arises not only from the flame-retardant product itself but also from additional auxiliaries. For example, the COD values of various commercial flame-retardant products examined were between 0–900 mg O_2/l, i.e. still relatively low in comparison to the other auxiliaries investigated with up to 2200 mg O_2/l. In the cases investigated here, a COD of 200 000–300 000 mg O_2/l per litre of discharged residual finishing liquor was determined.

Flame shearing machine Piece of singeing equipment for producing a non-pile finish to textile fabrics affecting the textile ground. The material is introduced to the singeing flame at an acute angle via a water-cooled singeing bed. More economical when the material is presented twice for singeing. Burners work in dual-jet system. Carpet singeing machine in which the material is passed over the flame at an acute angle via a water cooled bed. This produces in-depth singeing for a non-pile finish.

Flame spread The extent of propagation of a → Flame on the surface of a material.

Flame spread rate The rate of propagation of a flame front on the surface of a material under specified test conditions.

Flammability

I. → Flame-retardant finishing.

II. Flammability and → Burning properties are influenced not only by the type of textile fibre, but also by the weight, weave and degree of yarn twist. Flame retardant finishes as well as the type of binders used in laminates also influence the flammability of textiles. → Burning behaviour of textiles.

Flammability directives A number of EC directives which deal, among other things, with the flammability of textiles and products containing textile materials include the following:

- Construction Products Directive (CPD)
  Council Directive 89/106/EEC, 21.12.1989.
- Personal Protective Equipment Directive (PPE)
  Council Directive 89/686/EEC, 21.12.1989.
- Safety of Toys Directive
  Council Directive 88/378/EEC, 3.5.1988.

I. The EC directive on construction products (CPD = Construction Products Directive): this directive describes the essential requirements for materials to be used for construction purposes. These requirements are mainly concerned with various aspects relating to the safety of persons and goods, which also includes safety in the event of fire. Textile products affected by this directive consist exclusively of materials used for interior decoration firmly bonded to various supporting materials which cannot be removed under normal conditions of use and can therefore be compared with actual construction materials. This applies particularly to:

- wall and ceiling coverings as well as
- floorcoverings.

II. The directive on protective equipment for persons (PPE = Personal Protective Equipment Directive): this directive stipulates the requirements placed on protective clothing for persons exposed to physical risks by the nature of their work (mechanical, electrical, radioactivity, noise, rigours of the weather) or chemical risks (chemicals hazardous to health) or those persons who come into contact with fire, heat and molten materials at high temperatures.

III. The directive on the safety of toys (Safety of Toys Directive): this directive specifies the essential requirements for the safety of toys with regard to physical, mechanical, chemical and electronic risks where particular attention is given to burning behaviour. Tests specifically designed for toys are carried out in accordance with Standard EN 71 which is one of the few standards harmonized throughout the European Community. Additional directives:

1. Draft directive on the burning behaviour of upholstered furniture, related articles and sub-products (8.2.1991). Articles affected by this directive include:

- upholstered furniture, i.e. upholstered chairs, seats, seat cushions etc.;
- related articles, i.e. mattresses, moveable cushions, bed-settees and similar articles;
- sub-products, i.e. filling materials (e.g. polyurethane or latex foams), sandwich inserts and upholstery fabrics.

Requirements:

- primary ignition level,
- heat and smoke development and their influence on the time of escape,
- labelling information.

Fields of application:

- private sector,
- public sector,
- high risk sectors.

2. The directive on the contents of buildings (Buildings Contents Directive): this applies to, e.g. textiles such as curtains and furnishing fabrics as well as bed linen.

3. Apparel: no official EC draft directive exists at present for apparel.

4. Industrial and technical applications.

(source: Horak).

Flammability guidelines → Flammability directives.

Flammability test Flammability test should be capable of providing information on a wide range of burning criteria. Such variable criteria can only be determined by different kinds of test methods. It is particularly important here to distinguish between burning behaviour at room temperature (i.e. at the start of a fire) and burning behaviour at high temperatures. Criteria for flammability tests include:

1. Ignition properties: a) energy requirement; b) ignition time.

2. Burning behaviour (at room temperature): the test specimen, a) does not burn independently; b) burns slowly and is self-extinguishing; c) burns slowly and is not self-extinguishing; d) burns rapidly.

3. Secondary effects: smoke development (density, toxicity).

4. Burning behaviour (at elevated temperatures (e.g. third-degree fires): the test specimen, a) remains unaffected (e.g. ceramics); b) decomposes (smouldering fire); c) continues to burn up to a critical heat flux density; d) ignites and causes the fire to spread to non-burning areas (fire propagating).

Tests are necessary in order to be able to estimate the complexity and risks of fires by their most important parameters. To facilitate reproducible results, therefore, standards have been developed which make it possible to describe and evaluate the burning process by means of standardized tests with the aid of unambiguous questions. The following procedure is therefore appropriate:

- determine the specific requirements;
- specify tests capable of controlling and matching these requirements, then
- stipulate the appropriate standards, and finally
- establish, and under certain circumstances, classify the properties of the article which are commensurate with its expected performance.

Since a permanent and maximum flame retardant effect is not necessary in all cases and is dependent on the intended purpose, the standard tests should indicate the classes in which the respective article belongs. During standardization, the present state-of-the-art, the market situation which may possibly include considerations of fashion, the appearance, the serviceability properties and finally the price of representative functional textiles must be taken into consideration in all cases. Test procedures to determine the burning behaviour of textiles, as well as any observed secondary manifestations, may be divided into two groups:

- methods for scientific investigations (Fig. 1),
- methods for practical situations (Fig. 2).

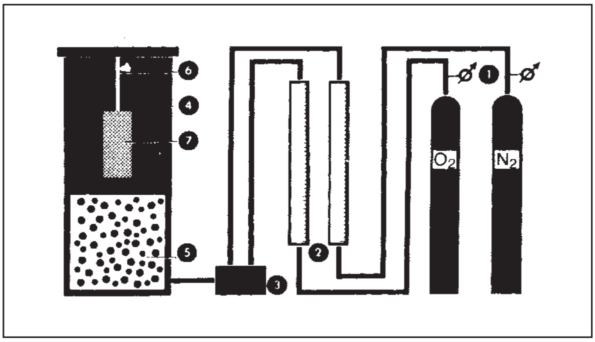


Fig. 1: Limiting Oxygen Index test (LOI test), schematic representation of a more scientifically based flammability test.
1 = manometer with fine regulation; 2 = gas flow meter; 3 = glass mixing chamber; 4 = Pyrex glass cylinder; 5 = bed of 5 mm size glass balls; 6 = specimen holder; 7 = test specimen.

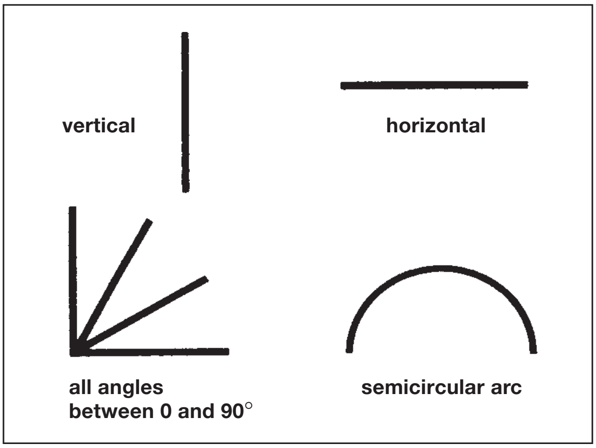

Fig. 2: Diagram illustrating test procedures for practice-relevant flammability testing.

Standardized test methods:

I. The vertical test is one of the most stringent tests of all. This test measures the resistance of the material to flames although the degree of flammability is not determined. It is suitable for non-flammable textiles or those which burn with difficulty. The test can also be used to evaluate the effects of flame retardant finishes.

II. The 45° test is used for readily flammable textiles and represents a compromise between I and III. This test has been the subject of extensive criticism.

III. The horizontal test. In this case, the test specimen is secured horizontally so that no chimney effect can occur. For this reason, it is only used for special articles and/or for the determination of flammability.

IV. Arch tester to determine burning and smouldering behaviour with the aid of an arch test assembly. The effect of exposing test specimens stretched in a semicircle to a flame for a specified length of time is determined.

(source: in part by Carl).

Flammability testing (→ Burning properties, → Flammability, → Burning tests for fibre identification). Various (defined) ignition sources are used in this test. The textiles to be tested are subjected to these sources for a specific time. The textile finisher's problem is that each country has its own testing methods that stipulate different test subject positions and ignition sources, e.g. glowing cigarettes, different kinds of gas flame, even alcohol flames, waste paper baskets filled with wood shavings, electrical radiators, wooden cribs, hot metal nuts, cigarette lighters and matches.

In principle, the combustion time after the source has been removed or burned off is used as a criterion for measuring and evaluation, as is the after-glow, and above all the size of the destroyed area of the test subject. However, even if the regulations are strictly adhered to within a test method, it is often difficult to reproduce the test results. In order to make a scientific analysis of the combustion behaviour, thermal gravimetry, differential thermal analysis, differential scanning calorimetry and thermo-mechanical thermal evolution analysis are used. The combustion behaviour and the pyrolysis products of fabrics finished with flameproofing agents containing chromium or phosphorus can be analysed by gas chromatography and mass spectography. Many test procedures and pieces of equipment have been developed in the various countries, some of which have been declared obligatory, although experts consider the results thereof to be inconclusive. A test that meets all requirements must include the fol-

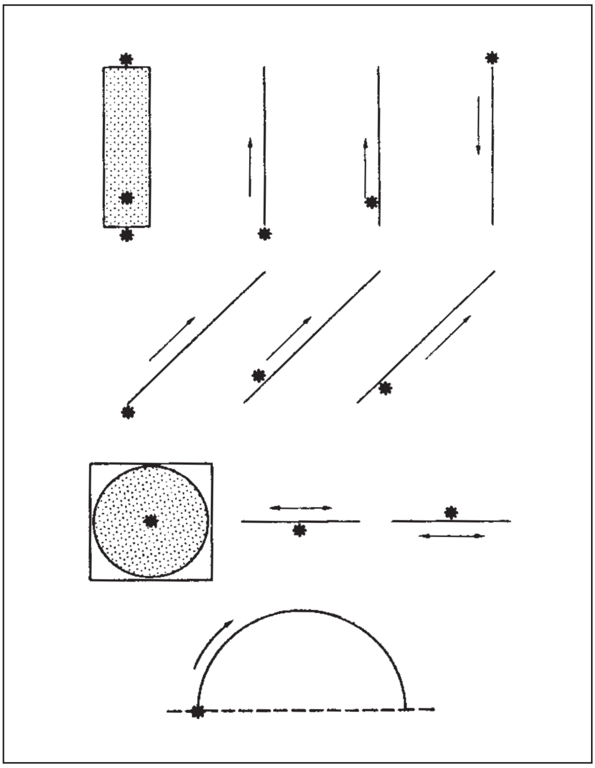

Fig.: Possible ignition points on samples in the flammability test.
** = ignition point; → = main direction of flame spread.*

lowing: residual ignitability, combustion time, extinguishability, shrinkage, melting, smoke emission and toxic gas build-up. Special test regulations and different equipment must be used for some textiles. A distinction is made between the test subject's position in relation to the vertical, horizontal, angle and arc tester. The vertical test (DIN 53 506) is for testing low combustibility, the horizontal test (DIN 54 333) is for testing the flame spread (see Fig.) and other criteria can be measured using the angle and arc test (DIN 54 331). → Flammability test.

Flammability – test method requirements The following demands have been placed on test methods for flammability:

a) Determination of flammability (from a small flame to independent ignition with flames);
b) Fire propagation speed (flame spread rate, burning rate);
c) Determination of the heat of combustion generated;
d) Tendency to form burning melt droplets;
e) Flammability of home textiles at high ambient temperatures and high ventilation;
f) Determination of smoke and/or (toxic) gas development;
g) Determination of heat shock behaviour.

From the numerous test methods for the determination of flammability, only those which correspond to the particular requirements of the article must be selected. An important criterion is the form of the test specimen; for example, this can be vertical, horizontal, inclined at an angle or in the form of an arch. → Flammability testing.

Flammable liquids Flashpoint and ignition point: the burning point of a liquid lies mostly approx. 20–60 °C above the → Flashpoint. With certain liquids, however, e.g. ethyl ether or gasoline, it falls almost to the same level as their flashpoints. Attention is drawn to the low ignition temperatures (auto-ignition temperatures) of ether and carbon disulphide (see Table). → Hazard classification of flammable solvents.

combustible	flash point (˚C)	ignition point (˚C)
acetone	–19	540
ethanol	12	425
i-amyl alcohol primary	43	340
benzene	–20 bis +10	250
benzol	–11	555
diesel oil	55	220
dioxane	11	375
acetic ether	–4	460
ether	–40	170
hexane	–26	240
machine oil	135/300	400/610
methanol	11	455
paraffin	158 bis 195	220 bis 250
pentane	–20	285
petroleum ether	–20	280
carbon disulphide	–20	102
toluene	6	535
xylol	25	525

Tab.: Flash point and ignition point of different combustible liquids.

Flammé effect on hank yarn → Dyeing of flammé effects.

Flammé yarn

I. Hank-printed yarn, e.g. for shirt flannel.

II. Dyeing → Dyeing of ombré or shaded effects.

III. Spinning; a yarn spun with irregular thicknesses (slubs, nepps, etc.).

Flanged bobbin → Cylindrical package, cheese.

Flannel Collective term for single-sided or two-sided napped fabric made from wool, cotton, union fabric or viscose filament; usually with plain or twill weave. The soft, supple handle is characteristic and is created by milling, with the clear nap still allowing the weave pattern to be clearly seen. The napping process causes the colours to merge gently into each other; the fibre nap is fairly short in these materials, and is sometimes evened out by emerizing. Wool flannels are either made from worsted or woollen yarn, usually soft-spun from fine merino, i.e. easily milled wools. Flannels are mainly light mixture shades (grey and beige shades), light weight (approx. 240–440 g/m^2) materials. Variously named according to fibre type, weave or end-use (wool, twill, crepe, dress, blouse or shirt flannel). Type of finish: light to medium melton finish. Used for dress, costume, suit and coat materials (wool) and sports shirts or pyjamas (cotton).

Flash ageing A modern form of the → Two-phase printing process. The flash ageing process is characterized by the use of short steaming times at high temperatures. Principle: thickened vat dyes are printed without fixation chemicals, dried, padded with an alkaline solution of a reducing agent (caustic soda liquor and sodium dithionite), then steamed immediately without intermediate drying for 20–60 s at 120–140°C in a special rapid steamer (e.g. flash ager as in Figs. 1 and 2, rainbow or arch steamer, tower steamer). There is no contact with the face side of the printed fabric during its passage through the steamer in order to prevent marking off. Thickener combinations which coagulate in the alkaline fixation liquor are employed. Fixation is completed by subsequent oxidation and soaping at the boil.

In order to avoid the use of urea, reactive dyes can also be printed by the two-phase method as follows: Stage 1: the reactive dyes are printed without fixation chemicals and dried. Stage 2: the printed fabric is padded with an alkali solution containing an addition of electrolyte and steamed.

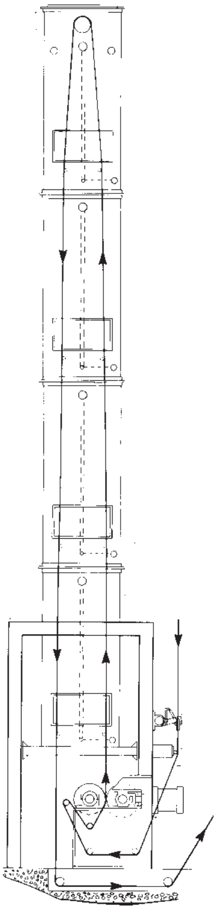

Fig. 1: Flash-ager by Dinting.

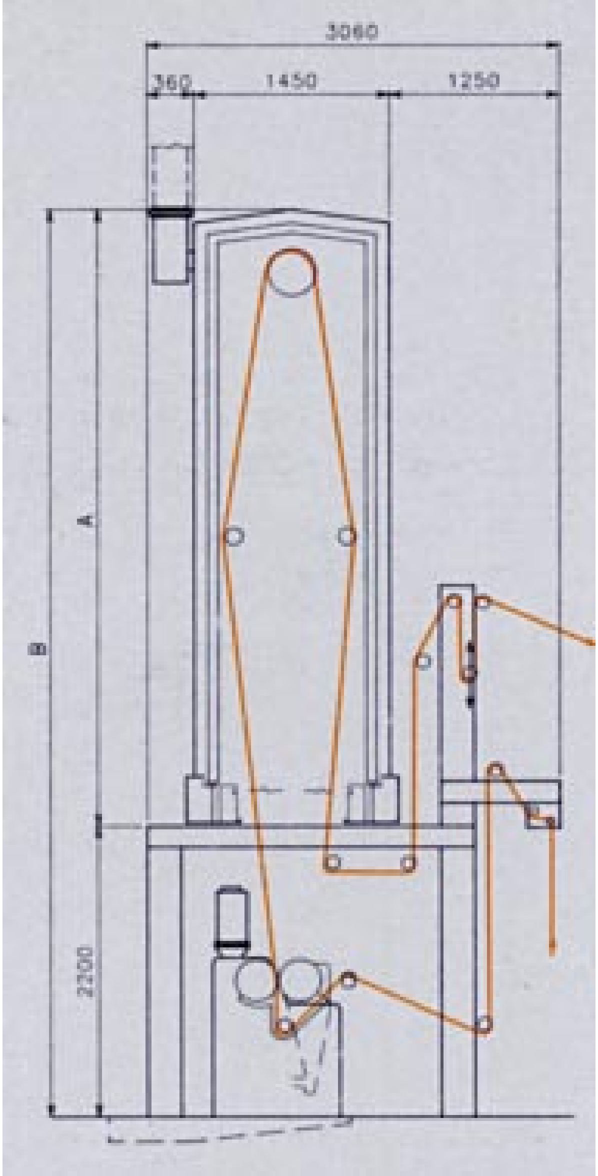

Fig. 2: Flash-ager by Arioli.

This method of fixation has the advantage of simplified print paste formulation and less hydrolysis of the reactive dyes.

Flash ager Energy and room economized → Rapid ager.

Flash point (FP). The temperature at which sufficient vapour builds up over a flammable liquid to form a combustible mixture with air near the surface of the liquid. The application of a small naked flame at the flash point temperature produces a momentary flash only since the temperature is still too low for sustained combustion. The latter only takes place at a somewhat higher temperature (the so-called auto-ignition temperature). General principles: a low → Boiling point means a low flash point, high volatility and higher risk of fire. The flash point is therefore an important measure for comparing the flammability of → Flammable liquids.

Flatbed laminating machine The goods to be laminated are heated by feeding between two Teflon-coated continuous belts. The belts hold the goods flat and even whilst the melt adhesive is heated by contact heat (Fig. 1). This allows treatment of a wide variety of flexible or rigid sandwich constructions.

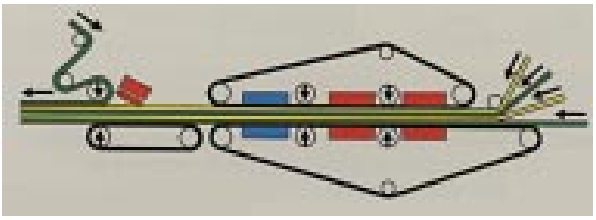

Fig. 1: Meyer flatbed laminating machine with down-stream laminating roller station and IR heater, e.g. for thermo-sensitive substrates, or ones which are heavily insulating, or for the production of multiple laminates in one work cycle.

The concept of laminating in an open width passage makes it possible to vary the gap height by raising or lowering the upper heating zone. A single machine can be used to laminate materials of the most diverse thickness. The height is adjusted mechanically, or by means of servomotors. Whilst the goods to be laminated pass, flat, between the heating zones, a slight pressure is exerted via the upper and lower belts. In order to reach the necessary bonding values, additional pre-setting takes place by means of a pair of pressing rollers in the middle of the system; at the end (before the outlet and cooling), a second pair of pressing rollers creates the end pressure. The pressing force is adjustable. The lamination speed depends on the density and thickness of the material (thermal transfer coefficient), the processing temperature of the thermoplastic adhesive and the length of the heating section. In standard machines, it moves between 2–15 metres per minute; in the case of types with a heating section of double the length, up to 30 metres per minute are possible.

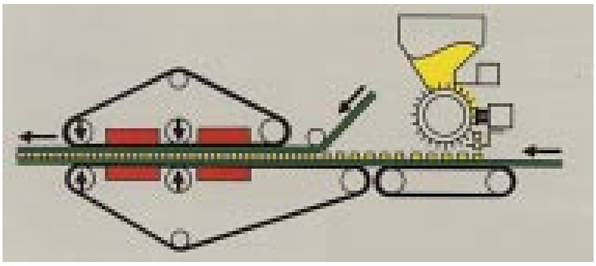

Fig. 2: Meyer flatbed laminating machine with up-stream powder dispersion system.

In the last few years, there has been a marked development in the area of thermoplastic adhesive polymers and their blends. Depending on the application, from the variety of compatibilities, processing temperatures, thermal stabilities, chemical fastnesses and the like, the correct adhesive can be determined. Ecologically safe adhesive systems include e.g. thermoplastic adhesive films, bonded nets, powder, powder spot, paste spot, hot-melt glues, self-adhesive films (Fig. 2).

Flat carpet

I. (→ Smooth carpet), carpet without pile or napped surface as per DIN 61151. Examples: coir and sisal mats, → Gobelin tapestry.

II. Carpets without pile or nap such as hand-woven carpets → Kilim carpets, and carpets with extraneous decorative effects →: Allgaeu carpets, Applique carpets, Skin rugs, Felt mats with and without decorative materials incorporated, or mechanically woven carpets in plain weave made from hair yarn, wool, coir, sisal, cotton. Opposite: → Pile carpets.

Flat conical cheese A precision-wound conical yarn package in the form of a narrow wound (short traverse) large diameter cheese (→ Crosswound yarn package).

Flat foam → Smooth foam backing.

Flat iron A pressing iron used for the manual → Ironing of garments.

Flat iron with interchangeable base plates A type of flat iron, formerly in common use, with interchangeable sole plates which can be heated up individually and placed in the iron again when hot.

Flat packings → Seals, mostly cut from discs, are placed or clamped between the metal surfaces that are to be joined, or held fast in a groove.

Flat press A hydraulic press used for → Pressing (see Fig. 3) in which transverse-folded layers of woven fabric (or, more rarely, knitgoods) are interleaved in the open-width state with heated or cold press papers and the pile so formed is subjected to pressure. Heating is achieved by inserting pressboards heated by electrical resistance wires at intervals throughout the batch.

Flat screen printing A discontinuous form of → Screen printing in contrast to continuous → Rotary screen printing. In screen printing a print paste is applied to a textile fabric through a screen engraved with a design in the form of a "negative" by means of a squeegee. The term "screen printing" is derived from the process of making printing screens which are coated with a light-sensitive film and dried. The coated screen is then exposed to light only in those areas where the coating is to be made insoluble, i.e. where no print paste is required to pass through the screen mesh on to the fabric being printed. Flat screen printing on long tables (hand screen printing) is the original form of screen printing and is still used for printing short runs of high quality prints. In this method the length of textile fabric is glued or pinned on to the printing table and then printed by hand with flat

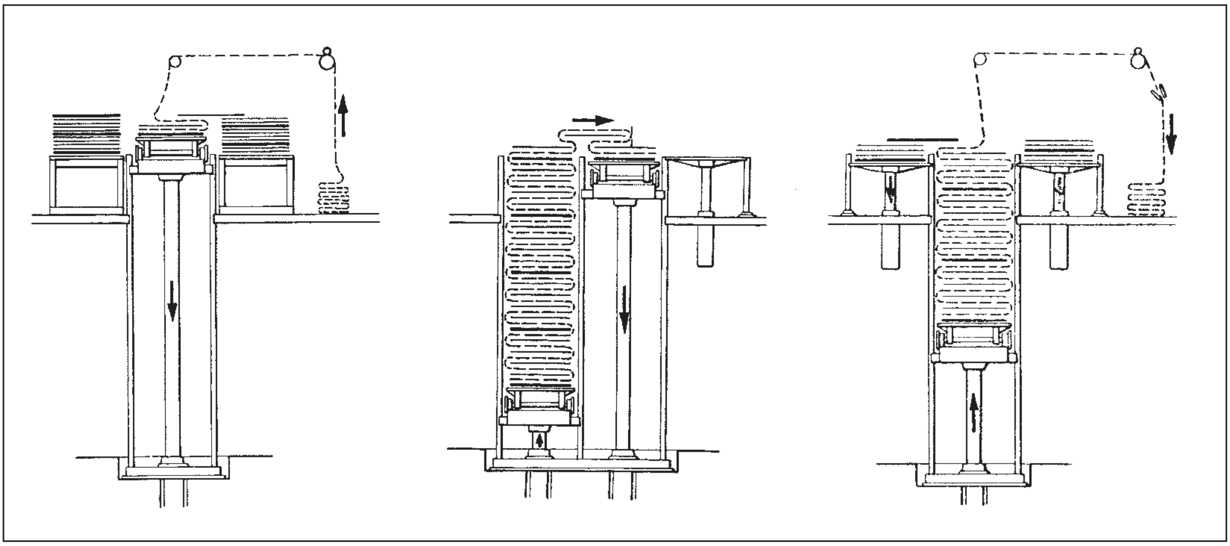

Fig. 3: Pressboard press by Krantz.
left = insertion of press boards; centre = reversal of press batch; right = removal of press boards (thick black line = electrically heated press boards).

screens using squeegees. The procedure has been simplified by the use of a screen printing carriage which moves on rails from repeat to repeat along the table and is lowered into the printing position at each repeat stop. Fully-automatic screen printing carriages take care of screen transport, stopping at the repeat point, and electrically-driven squeegee operation. Mechanized screen printing involves the use of stationary screens supported in frames. The screen frame serves the purpose of raising the screen whilst the textile fabric which is glued to an endless rubber blanket is transported the length of one repeat after which the screen is lowered into the printing position once again. Printing is carried out by applying print paste through the stationary screen by means of a squeegee, i.e. in contrast to roller printing the process is intermittent.

A flat-bed screen printing machine consists essentially of a fabric feed unit, a glueing system and the printing unit itself. A liquid adhesive is applied to the printing blanket by the glueing system; in the case of printing blankets precoated with a thermoplast adhesive, however, a heated plate is used instead of the glueing system so that the heated fabric is attached to the thermoplast layer by pressure. After the fabric has been printed it is detached from the printing blanket and dried in the drying chamber. The rubber printing blanket returns under the printing machine where it passes though a washing zone before receiving a new coating of glue.

Various squeegee systems are employed in flat screen printing:

1. Blade squeegees: single and double squeegees or tilting squeegees (Fig. 1).
2. Roller squeegees.
3. Magnet-roll squeegees.

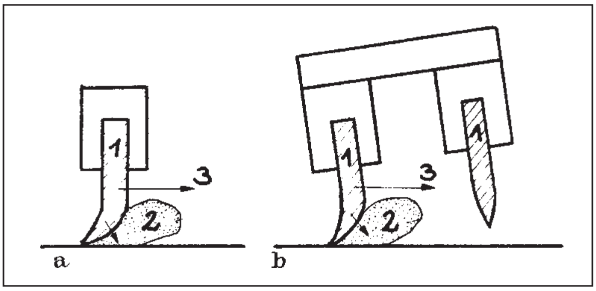

Fig. 1: Method of operation of the single doctor blade (a) and double doctor blade (b).
1 = Doctor blade; 2 = printing paste; 3 = doctor blade direction.

In the case of blade squeegees the application of print paste and print paste penetration are controlled by the squeegee angle and the pressure (Fig. 2).

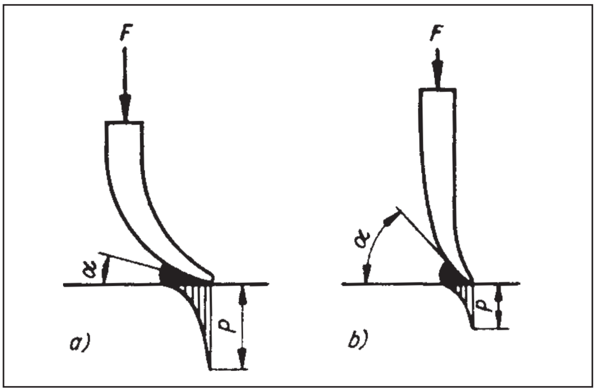

Fig. 2: Through print dimension p relative to doctor blade angle α and doctor blade pressure F.

Previous Page

Flat screens → Screens for screen printing.

Flat sheets for fibre manufacture Initial raw materials are flat sheets of polyethylene or polypropylene, with additives such as stabilisers for increasing the resistance to heat, oxidation and UV radiation, as well as antistatic agents, possibly dyestuff pigments, adhesion agents etc. Extruded, (tubular film / blown film, then split and laid open to form flat sheets), subsequent processing into → Tape yarns.

Flat spotting Flat spot formation, a reversible indentation in a vehicle tyre in the region of the ground contact area, caused by stress whilst stationary caused by differential stretching of the cord fabric inlay → Non-flat spotting.

Flat-table pantograph → Engraving.

Flattening and glazing calender → Glazing and flattening calender.

Flat yarns By slitting a polyolefin flat sheet, flat yarns of a rectangular cross-section are formed. These can be spool wound for weaving and knitting; they may be processed directly onto weaving or knitting machines. Mono- and multifilament forms can also be combined with conventional yarns. Twisted/ doubled flat yarns have the character of round yarns or round twist yarns. Using another method, by means of fibrillation or capillarization → Split film yarns can be used to create flat yarns as pseudo-multifilaments, or similar connected in a net-like manner, with further processing via twisting/ doubling (split round yarns, split twist) or crimp texturing and twisting (split crimp yarn, e.g. for carpet pile). Similarly also from tape yarns a) directly into flat yarns (for warp beams or cross-wound bobbins) or b) likewise via splitting fibrillation (split or fibrillated yarns) and crimp-textured and twisted (split crimp yarn). A further process involves passing the yarns through a subsequent processing of tape yarns, is through splitting through fibrillation, crimping or fibre cutting into → Split fibres (Split non-wovens), and by twisting into split fibre yarn. Used for bast fibre substitutes, binder warp / backing fabric for tufted carpets, needle-felt carpets, coating fabric, pile for outdoor carpets, furnishing fabrics, automobile / furniture upholstery fabric, wall coverings, the packaging sector (for textiles and sacks, slip-proof/stackable through the application of wax), workwear, rainwear, high-visibility clothing, tablecloths, awnings, tarpaulins, tent materials, filter fabrics, technical purposes.

Flax (linum, linen) → Bast fibres belonging among the → Natural cellulosic fibres (up to 120 cm long) with a smooth surface structure and increased natural lustre. Preformed in the stem of the flax plant (small seed form = fibre flax, large seed form = oil flax; also hybrids; different fibre content) as described under → Flax long fibre structure. Microscopic: cylindrical, smooth, narrow lumen, transverse fracture is typical, wall displacement, knotty. Fibre production:

1. Mechanical fibre separation of woody core and bark stems.

2. Retting and then mechanical processing (: → Scutching, hackling. Byproducts: woody pieces or shavings, short fibres and →: Oakum and flax oil).

3. → Cottonising (→ Flax cell structure).

Raw flax contains celse, water, fat, wax, dyestuff, up to 25% incrustation (impurities) (→ Flax composition). Pure flax (linen): like cotton, almost pure cellulose, but thicker cell walls (greater resistance to alkalis and oxidizing agents). Raw flax requires to be scoured and bleached before dyeing (10–20% weight loss).

Flax cell structure In retted and raw (green) flax the individual fibre cells are separated by middle lamellae (→ Flax long-fibre structure). Each individual lamella forms an elongated polyhedral prism which is spindle-shaped with extremely fine points at the top and the bottom. Due to the growth in thickness of the individual cells, a clear layer structure can be seen in the cross-section of the entire wall substance. The structure is built up as follows from the outside to the inside:

1. The middle lamellae as the external membrane, which has a high proportion of pectins.

2. The primary wall (primary membrane, external cell wall), which is very thin and smooth with hardly any pectin content.

3. The secondary wall which is of greater thickness and very solid; it contains hemicelluloses as well as protein substances and increasing amounts of pectins up to the fibre cell core.

4. The tertiary wall forms the boundary to the

5. Lumen or cell canal which, after maturity, is mainly linear in shape or fissured and contains approx. 4% protein residues.

Flax, composition of (chemical). The composition of flax can vary considerably depending on the state of the fibre (see Table).

% content	Raw flax	Retted flax	Hackled flax
Cellulose	56,5	64,1	65–89
Hemicellulose	15,4	16,7	–
Epidermis/wood residue	–	–	5,0
Pectin	3,8	1,8	2–7
Protein	–	–	2–5
Lignin	2,5	2,0	1–5
Soluble	10,5	3,9	–
Fats/waxes	1,3	1,5	1,8–5
Water	10,0	10,0	9–10
Ash	–	–	0,5–1,3

Tab.: Percentage composition of flax in different processing stages (pectin content can be up to 25% in the event of poor retting).

Flax (linen)-cotton, tests to distinguish between
I. → Methylene blue test.

II. After removal of any finish etc., allow the test specimen to lie for 15 min in a 1:10 copper sulphate solution, rinse thoroughly under a stream of water, then allow to lie for 15 min in a 1:10 solution of potassium hexacyanoferrate (II) solution, rinse thoroughly: flax = copper red, cotton = uncoloured.

III. Quinoline test: allow the test specimen to lie for some minutes in a lukewarm quinoline solution, rinse and treat with dilute sulphuric acid: flax = blue colour, cotton remains uncoloured (reagent: alcoholic quinoline solution diluted with water and glycerol).

Flax long-fibre structure The so-called bast layer forms a layered ring of adjacent bast fibre bundles in the → Flax stem structure. Each bundle tightly joins a group of individual fibres together and itself becomes entwined in the cortical layer. Two types of compound, which are caused by the different type of the so-called centre lamella functioning as a binding membrane layer, are distinguished in the fibre structure according to the following:

1. The woody centre lamella seals the elementary fibres or individual bast cells (→ Flax cell structure), which are 20–25 mm long and 20–25 µm thick and offset spirally side by side and on top of each other into a self-contained bundle in parallel. Calcium-containing pectin with lignin inlays appear here in particular as a binding membrane layer. This centre lamella is extremely resistant to chemical and enzyme attack. It is not damaged by normal types of rotting (so-called wood or woody fibres), but it is intentionally destroyed in cottonizing. The latter results in fibre foreshortening, in extreme cases up to single-cell elementary fibre length, and simultaneous refining (→ Cottonized flax).

2. The parenchyma centre lamella surrounds each of the fibre cell bundles (300–1300 mm long) as a membrane made of pectin and seals it with the cortical cells. These centre lamellas are destroyed by rotting caused by gradual pectin degradation so that the now loosened fibre bundles can be isolated from the remaining stem layers by breaking, scutching and hackling. This is how, besides the shives from the wood strands, the 100–600 mm long multicellular flax long fibres arise and become shorter random fibres of → Bast fibre tow, both now spinnable.

In the past, numerous experiments using morphological tests were carried out with the aim of obtaining information about the quality of the flax, e.g. via light microscopy. The anatomy of the fibres and fibre bundles depends on the type of linen, growth conditions and position within the stem and influences the fibre yield and fibre quality (Figs. 1 + 2). The fibre quality is calculated from the percentage share of fibre bundles over the total stem cross-sectional area in the microscopic display. It is also characterised by the type of fibre cell bonds (fibre bundles) from the closed oval to kidney-shaped contour. Irregularly shaped bundles are characteristic of a poor quality flax. Besides the shape of the fibre bundles, the shape of the individual fibre cells is also important. A qualitatively high-grade flax has a quadrilateral shape with 3–7 edges in its elementary fibres. Poor fibres are oval. The fibre strength is influenced by the thickness of the cell wall, which, amongst other things, depends on the degree of ripeness. High-grade fibres have extremely thick cell walls, which can cover more than 98% of the fibre cross-sectional area (according to Kessler).

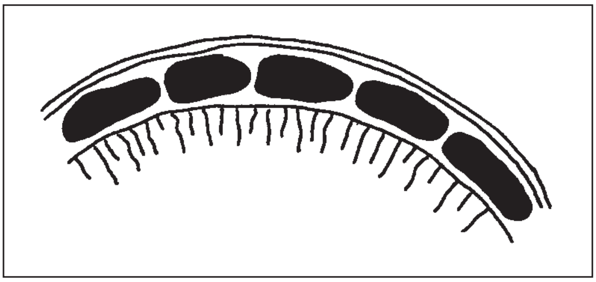

Fig. 1: Fibre bundle of qualitatively high-grade flax.

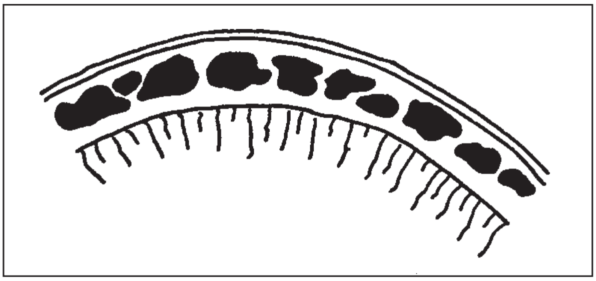

Fig. 2: Fibre bundle of low-grade flax.

Degree of resolution: The term should be explained more clearly with Fig. 3. This concerns a schematically

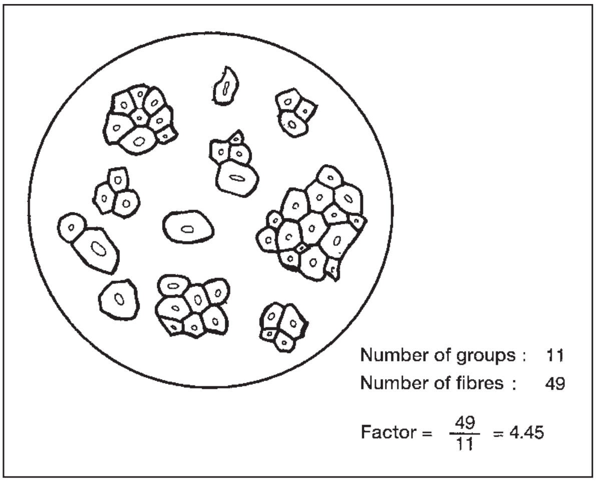

Fig. 3: Degree of resolution of flax fibres.

represented cross-section of flax fibres. In order to calculate the degree of resolution, the total fibres per cross-section and the number of connected fibre groups G is counted. The number of groups is divided by the total number of fibres F and this then gives a metric measurement for the degree of resolution A.

$$A = \frac{F}{G}$$

The larger this metric measurement, the lower the number of fibre groups is and the lower the degree of resolution. An image analysis system can in future take over this counting and calculation process. Another important variable is the dispersion of the degree of resolution. A large dispersion means that a batch contains both individual fibres and a multitude of fibre bundles. But the more irregular a fibre sample is the worse the spinning properties and later also the thread uniformity are. The degree of resolution is also a measurement of the quality of the fibre degradation. The worse the degradation (from rotting and similar), the larger fibre bundles the fibre sample contains. Coarse and short fibres, so-called stick fibres, always lead to processing difficulties in spinning.

Divisibility: As the degree of resolution varies with increasing mechanical treatment, another parameter is important. This is the divisibility, i.e. the propensity of a fibre sample to be refined in the ongoing processing stage. The better the divisibility the more regular the fibre sample is with increasing processing and the less problematic the spinning is. The divisibility T is calculated via the change in the degree of resolution, which is measured before (Av) and after (An) a mechanical process. The higher the divisibility the better the ability is to process in the spinning later.

$$T = \frac{An}{Av}$$

Flax processing Flax is a typical example of a renewable raw material. There are few plants which can be employed and used so completely, and in such diverse areas. In the preparation of the flax straw, long fibres and short fibres occur, with the long fibres being useable in all textile areas, depending on their quality. Besides clothing purposes, they can also be used for geotextiles, insulation materials and (in conjunction with synthetics) preforms for vehicles.

Approximately 100 days after the seed has been collected, the flax straw is harvested at the point of yellow-green ripeness. In order to harvest the bast fibre bundle in its full length, the flax is not mown, but pulled out with the roots. Harvesting takes place with specially constructed flax-pulling machines. Separating the bast fibre strands located in the flax stem requires extensive processing (Fig. 1). Here, the fibre bundles have to be separated from the other constituents of the stem. Since flax – unlike other natural fibres – does not have an inherent length and fineness to start with, the way in which the bast fibre bundle is exposed or split is decisive for the subsequent appearance of the fibre and for the running characteristics during spinning.

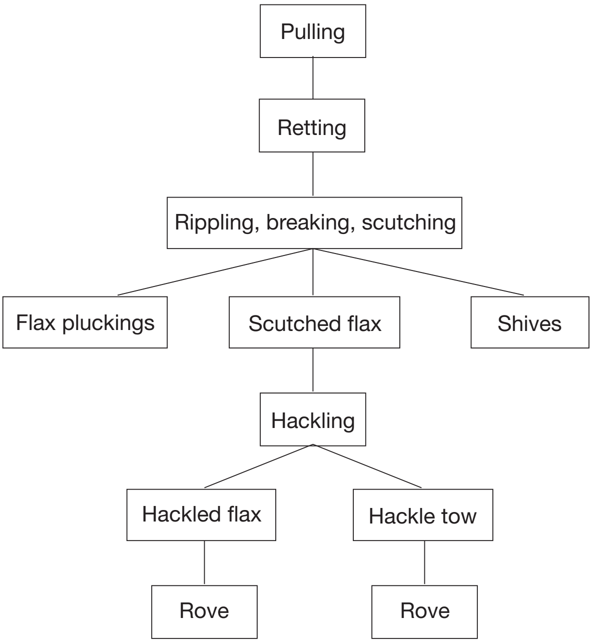

Fig. 1: From flax straw to linen fibre.

From time immemorial, the mechanical preparation has been preceded by a biological or chemical process that decomposes the pectin-containing lamellae of the plant layer surrounding the fibre, so that after this cement substance has been dissolved or partially dissolved, the subsequent separation of the fibre bundle can be carried out carefully. The technical extraction of the flax fibres is divided into several sections, from the preparation of the flax straw, the so-called flax retting, to the partial solution of the middle lamellae (vegetable glue), to the mechanical preparation for exposing and dividing the loosened fibre strands, and for removing the remaining stem parts. The following degradation methods are distinguished:

- dew retting,
- water retting,
- microbial degradation methods,
- enzymatic degradation methods,
- steam pressure methods,
- chemical degradation methods,
- tenside degradation.

Lignin has a considerable influence on the quality of cellulose fibre substances. The view is that the role of lignin in ligno-containing plants consists in the formation of cellulose fibres: lignin as a cementing material lends the plant parts a mechanical stability. The lignin content in plant parts that are compressed during growth is considerably higher than in areas that are stretched. However, the role of lignin in the resistance to tearing is not sufficiently convincing, since in the dew retting of flax, a partial decortication takes place, which does not affect the strength of the dry technical fibre, but results in improved spinning performance in the wet spinning process.

The main glue substances of the bast fibres are pectins. They are contained in the composition of all bast connective tissue, and even impregnate the walls of the elementary fibre. During the flax preparation, the pectic substances are subjected to decomposition. The processing properties of the retted flax can be deduced from the degree of decomposition. An increased pectic substance content results in brittleness of the fibre, hardness, and poorer separation properties. This applies both to the dressed bast as well as to the industrially prepared, steam-retted flax fibre. On the other hand, excessive removal of the pectic substances can lead to a breakdown of the technical fibre. Since the pectic substances are highly moisture absorbent, and serve as moisture regulators in the living plant tissue, one can assume that it is expedient to leave a certain amount of pectic substance on the fibre (Table 1), in order to intensify the relaxation processes during softening through storage in water.

Fibre	Component content to absolutely dry material, %						
	Cellulose	Lignin	Wax-like substances	Pectic substances	Nitrogen	Ash	Pectose
Flax	72.9	4.6	2.1	3.7	0.35	0.86	3.3
Cotton	84.3	1.87	1.12	1.21	0.26	1.0	1.73

Tab. 1: Composition of dew-retted flax fibres compared with cotton fibre.

During dew retting and water retting, the fermentation action is specific and leads to elimination of the polyuronic acids from the fibre. In respect of the lignin content, the water-retted fibre is similar to the dew-retted fibre, although more acid-insoluble lignin is contained in the water-retted fibre (Table 2). The steam-retted fibre differs considerably from the dew-retted and the water-retted fibres. The thermal treatment leads, just like the fermenting treatment, to the elimination of the non-cellulose polysaccharides from the bast. However, in the case of the steam-retted fibre, the reduction in the total content of polysaccharides results from the elimination of the pectic substances and hemicelluloses. This treatment does not cause any other significant changes in the ratio of the carbohydrate components in the remaining pectic substances and hemicelluloses; the component composition of the polysaccharides in the steam-retted fibre is similar to that of the initial bast. These two circumstances are evidence of the fact that during the thermo-chemical treatment, a random hydrolysis of the polysaccharides takes place. Compared with the better quality dew- and water-retted fibres, the steam-retted fibre has the highest pectic substance content and polyuronic acid content and a lower amount of hemicellulose. The raised content of polyuronic acid that is present evidently worsens the quality of the linen fibre, since the polyuronic acids are responsible for the formation of cross-linkages between the components of the plant tissue. However, more cross-linking means poorer spinning properties. On the other hand, leaving the hemicelluloses in the linen fibre is evidently desirable, since they contribute towards raising the mechanical strength. The steam-retted fibre is also characterised by an increased content of acid-resistant lignin faction, which because of the brittleness and greater difficulty in bleaching thus caused means a reduction in quality.

Hackled fibre	Bast	Dew-retted	Water-retted	Steam-retted
Ash content, %		1.37	1.01	
Lignin, %	8.4	5.71	5.96	6.3
of which:				
acid-insoluble	–	4.32	4.98	–
acid-soluble	–	1.39	0.98	–
Pectic substances (PS), % of the originally weighed-in amount	6.88	3.03	2.28	4.7
of which in % to PS				
Polyuronic acids	49.42	40.8	50.3	52.4
Hexosans	33.14	43.8	34.2	31.0
Pentosans	17.44	15.4	15.5	14.5
Hemicelluloses (HC), % of the originally weighed-in amount	8.3	7.41	7.14	6.10
of which in % to HC				
Polyuronic acids	18.7	9.4	13.3	17.2
Hexosans	56.3	71.8	69.2	62.4
Pentosans	25.0	18.8	18.4	20.4
Sum total of carbohydrates, % of the originally weighed-in amount	13.4	10.7	9.4	10.8
of which in % to total carbohydrates				
Polyuronic acids	29.69	18.87	21.6	32.6
Hexosans	49.03	64.9	62.1	49.88
Pentosans	21.28	16.5	16.3	17.59

Tab. 2: Analysis results of the chemical composition of flax fibres produced from a uniform section of straw.

Following the conventional treatment (Fig. 2), the dried retted flax is brought in and de-seeded through rippling. Subsequently, the wood layer of the stem is disintegrated by means of a mechanical breaking process, in the course of which it emerges partly as shives, without the pliable fibre bast being damaged. This breaking process is followed by scutching. Here, the broken flax straw is freed of short fibres and any wood parts that may still be attached, so that the bast fibre bundles are exposed. Here, rapidly circulating rails which sit on a shaft, the so-called fly cutters, beat out

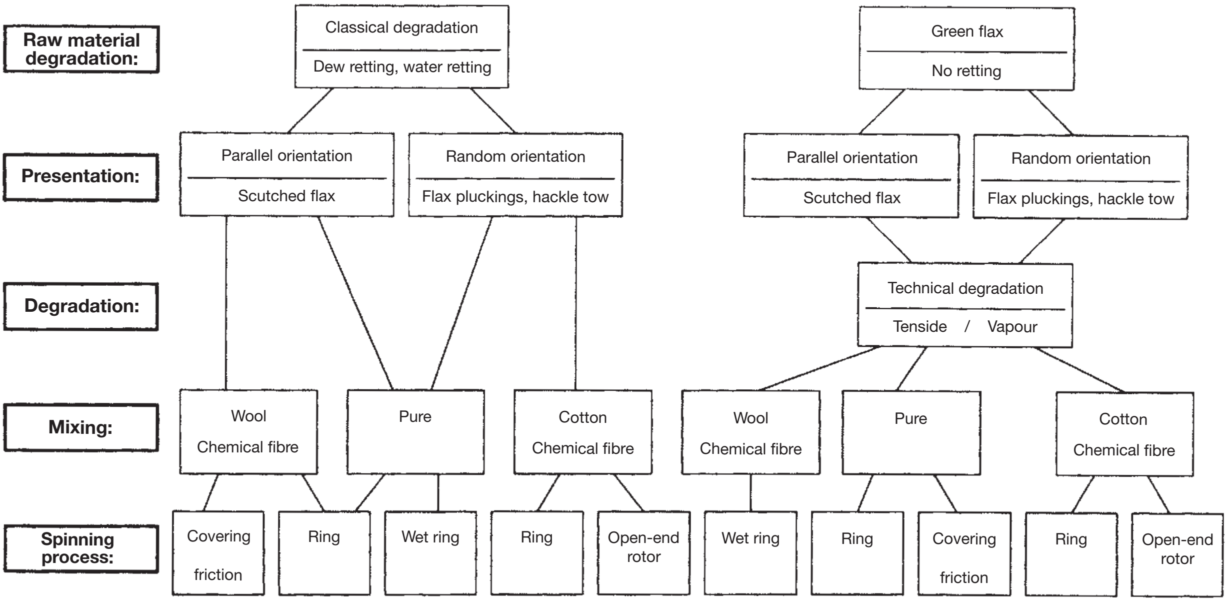

Fig. 2: Examples of types of degradation and processing technology for flax (source: Fischer & Topf).

the shives and the short fibre material (flax pluckings) from the jammed and dangling material. What is obtained is the scutched flax, which is largely free of wood constituents. The preparation processes that have been described can be classified as agriculture, whereas the further processing of the fibre material takes place in the spinning mill.

Refining the still straggly, coarse and unseparated fibres still further, and separating out fibre parts that are too short and weak, is the aim of hackling. This is a type of combing process with faller gills that run perpendicularly downwards on continuous belts, the so-called hackling areas. These have a needle density that increases in the direction of passage, so that as the material passes through, an increasing fineness is achieved. During hackling, high-quality hackled flax is produced, as well as the shorter hackle tow that is once again in random orientation. (source: Wurster, Chodyrew).

Flax stem structure The outermost single-layer cell wall of the stem forms the epidermis. It supports a resistant wax layer, the cuticle. Further in is the cortical layer, in which ca. 20–50 bast fibre bundles are located arranged in rings. Each of these bundles contains ca. 10–30 elementary fibres, which are stuck together within the bundles using pectins. The cortical layer is surrounded by the cambium. After the cambium comes the woody layer, which consists of concentrated wood cells. The innermost fabric layer forms the medulla. In the centre of the stem is a dried out pore, the medullary canal. Only the bast fibre bundles stored in the cortical layer are important for textile processing.

Differences in the form of layers from outer to inner (see Fig.):

1. Cuticle, small thin outer skin with wax coating.

2. Epidermis, outermost layer of water-rich cells with numerous slot openings as breathable pores (30–40/mm^2).

3. Cortical layer made of parenchyma cells, bonded with the so-called starch border as the innermost cell layer.

4. Bast layer made of numerous concentrically arranged bast fibre bundles, in which both the individual fibres mutually and each bundle are bonded with the cortical layer by centre lamellas (→ Flax long-fibre structure). Each bundle is separated from the subsequent one by the medullary ray. The soft bast (phloem) forms the transition to the perforated layer.

5. Perforated part made of transverse walls pierced like a sieve, forms a joint laminated area with the first arising bast fibres as the bast part in the immature stem state (procambium), but lies under the bast layer in the

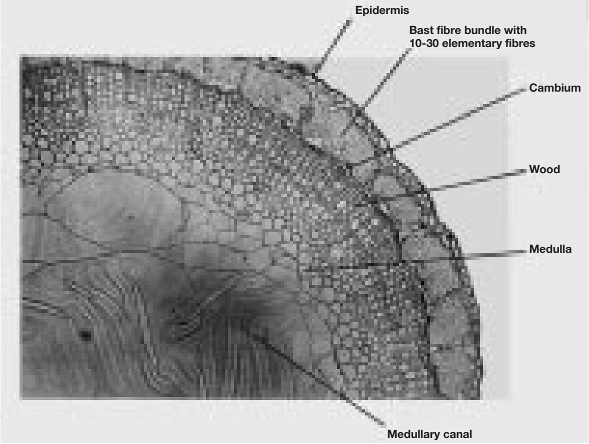

Fig.: Cross-section through a flax stem.

mature state. The part between the cortical layer and perforated part is also described as the vascular bundle or differentiated as the primary and secondary cortex.

6. Cambium (split pin layer), thin growth layer, which continually forms new perforated and wood cells.

7. Wood layer, made of already thicker walled, strongly lignified cells.

8. Medulla layer.

9. Air-filled hollow canal, pushes through a large part of the stem length.

Fibre exposure by (rotting), breaking, scutching and hackling. Extract 730 g of flax straw, 584 g of rotted flax, 184 g of scutched flax and 74 g of hackled flax from 1 kg of flax stems. Other bast fibre stems are similarly constructed in principle. The jute stem contains ordered fibre bundles in medium strength bands made of individual fibres stored closely together in groups, almost always permeated with lignin. In the hemp stalk, bast fibre bundles of varying fineness are formed in succession from different growth periods; fibre wall greatly thickened. On the other hand, the ramie stalk only contains smaller groups of less stripe-formed bundled individual fibres and some isolated embedded individual fibres.

Flax straw The → Flax stem structure is composed of approx. 73% flax straw. The term is also used to describe air-dried flax stems harvested by plucking.

Fleawort Seeds of a Eurasian plantain (*Plantago psyllium* or *Plantago indica*) which, after aqueous swelling, are still used from time to time as a finishing agent for lustre finishes on plush, silk etc.

Fleece The still coherent wool mass obtained after sheep shearing which is of variable length, fineness and quality. It is divided up into various qualities by wool sorting, e.g. back wool, skirtings, bellies and crutchings (DIN 60 004). The average fleece weighs 7 kg, special breeds yield 10 kg per sheep per shearing.

Fleece wash → Backwash.

Flexibility → Suppleness.

Flexible dye tubes Elastic radial or axial → Dye tubes which are capable of absorbing fibre shrinkage in yarn packages during dyeing.

Flexible roller A flexible pressure roller consists essentially of a special steel outer tube covered with vulcanized rubber and a concentric steel core firmly attached to the roller tube in the centre. Flexible rollers of this type are always paired with a counter roller of conventional construction. The conventional roller deflects under pressure to a known extent. In the case of the flexible roller (see Fig.), which is always installed as a pressure roller, the applied pressure causes a corresponding deflection of the core whilst the roller tube, on the other hand, conforms to the elastic line of the conventional roller. The hardness of both rollers are matched to each other in such a way that they produce the same elastic line across the entire pressure zone. By this means, a uniform nip is achieved across the full width of the rollers without the assistance of compensating forces. The nips of padders with flexible rollers therefore always have a clean cut zero position without the application of compensating forces.

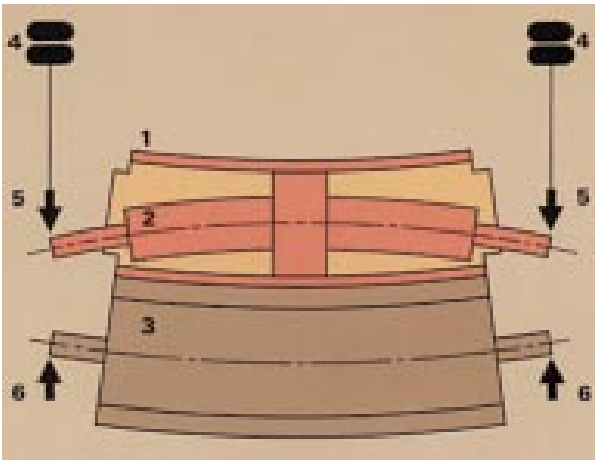

Fig.: Functional principle of a flexible roller.
1 = roller shell; 2 = roller core; 3 = counter roller;
4 = pneumatic pressure loading; 5 = pressure application;
6 = roller bearing.

Flexing abrasion resistance → Abrasion resistance test carried out with the specimen flexed by 90° (→ Flexing fatigue limit).

Results for individual fibres:

Polyamide	100
Polyester, cotton-type	60
Polyester, wool-type (pilling resistant)	15
Cotton	10
Viscose	5
Wool	1

Flexing fatigue limit (Bending fatigue resistance). Fibres, yarns or fabrics are tested by subjecting them to an alternating backwards and forwards bending action at a specific bending or flexing angle (as a rule ±180°) until breaking point under a simultaneous pretensioning load. The result of the test is the so-called flexing fatigue factor or bending resistance factor for which Böhringer has provided the following rounded values:

flax	880
jute	1050
acetate filament	300
viscose filament	2500–7000
viscose spun fibre	800–1400
cuprammonium filament	20 000
cotton	65 000
silk	75 000
wool	156 000
polyamide 6.6	45 000
polyamide 6	500 000

Attention is drawn to the fact that even small variations in the clamping pressure and state of the clamps can produce highly variable measurements. Furthermore, the degree of flexing fatigue is, in principle, dependent on the raw material, yarn type, fabric construction and also the effect of finishes. Low values in this test are indicative of a high degree of brittleness and poor abrasion resistance (especially at the edges of fabrics and in fold areas). Flexing fatigue testing instruments are therefore not only used to evaluate the so-called wear resistance of textiles, i.e. the strength and wear resistance under practical conditions, but also to test the effects of all kinds of finishes.

Flexnip The first high wet pick-up liquor application system developed by Küsters in 1987 (see Fig.). Mainly used for addition pick-up in the pretreatment of cotton fabrics.

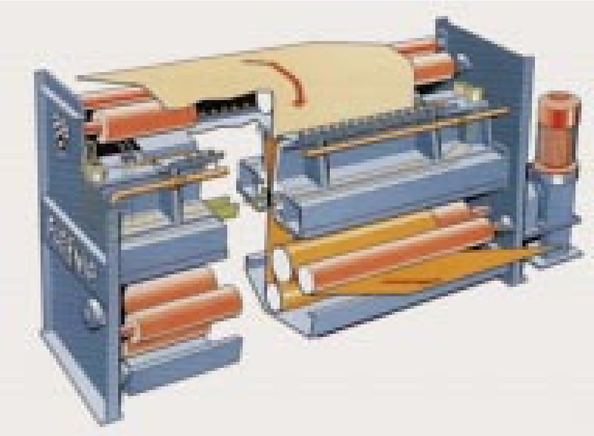

Fig.: Flexnip (Küsters).

Due to the high quantity of liquor retained in the free volume of the fabric after Flexnip application, good levels of whiteness, high absorbency and removal of seed husks can be achieved with a single-stage peroxide bleach.

Flexographic printing A form of → Letterpress printing for the printing of paper or foil, in which the relief rubber or plastic printing plates are attached to a rotary printing cylinder. Mainly spirit-soluble thin printing inks are used to transfer printed images to the substrate which dry rapidly by evaporation of solvent. The process is important for the production of transfer printing papers.

Flexography → Flexographic printing.

Flexometer American NBS testing device for determining bending resistance and evaluating crease-resistant finishes. The torque and the angle of the folded test subject are used to determine the amount of work that is required for folding and unfolding the subject. The bending resistance level during unfolding is used as a measure of crease resistance.

Flexural strength or resistance The force of bending together a single or multi-folded strip of fabric to a specified bending angle, or the permanent and elastic bending together under a specific load (→ Flexing fatigue limit).

Flinserl → Frosting.

Flip-flop mechanism → Dual action.

Flipper Name given to tension-free open-width washing and relaxing machine for woven and knitted fabrics. Control by free-floating rollers with no mechanical drive, super-light rotation due to hydrostatic buoyancy. Almost tension-free cloth passage produces relaxing action due to positive control by floating hollow rollers, whose hydrostatic drive produces extremely light rotation and therefore low-tension material movement. Gravity driven by the downwards path of the liquor-saturated cloth. – Machine maker: Küsters.

Float A control valve used in → Steam traps.

Floating A term used to describe a length of yarn or thread usually on the surface of a fabric lying in any direction between adjacent intersections in the woven or knitted structure.

Floating bell Alternatively bell float. Controller for → Steam trap.

Floating bell steam trap → Steam trap with a mechanical operating mechanism similar to the ball float, but with the advantage that the outlet valve is in the upper area, i.e. outside the contamination zone. Also, steam never reaches the valve because the steam is always beneath the bell (Fig. 1).

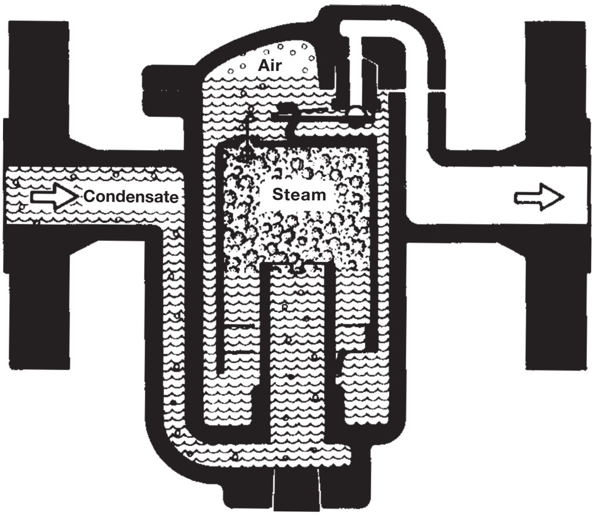

Fig. 1: Method of operation of a floating bell steam trap.

The bell is an open float and cannot be destroyed by water impact like the ball. Furthermore: automatic venting, unaffected by contamination, no loss of fresh steam, easy to check, trouble-free operation with 99% counterpressure. Can be connected in any location, maintenance-free.

Floating of textile materials An undesirable occurrence in dyeing processes due to the use of high foaming textile auxiliaries (wetting, dispersing and levelling agents) and inclusions of air as a result of which textile materials show an increased tendency to float on the surface of the dyebath. The consequences are unlevel dyeings, dye stains and tangling of the textile material.

Prevention: use of antifoams, low-foaming textile auxiliaries, periodic interruption of the seams in the dyeing of tubular knitted fabrics. → floating.

Floating of textile materials in wet processing A problem in which yarn or piece goods float on the surface of the liquor, e.g. at the beginning of dyeing, or do not sink uniformly. The problem is caused by inclusions of air which are slow to escape due to the inadequate wetting out of the textile material.

Floating threads Threads or yarns present in a fabric structure in → Floating.

Float valve A type of → Valve used to control the level of liquid in a vessel.

Flocculation → Coagulation.

Flocculation and precipitation Flocculation and → Precipitation are coupled processes of effluent treatment. Here emphasis is on the colloidal chemistry of flocculation. The poor sedimentation of solid particles formed by precipitation mainly has the following causes:

1. The small mass and the resulting lower precipitation speed of the contaminants.

2. The Brownian motion, which moves the very fine, solid particles in all directions, also against the force of gravity, thereby keeping them in suspension.

3. The analogous charging of the solid particles and colloids in the water causes mutual repulsion, thus preventing their meeting.

The purpose of using precipitation and flocculation chemicals is to overcome these difficulties. Colloids or finely dispersed impurities in the water are usually negatively charged with 15–25 mV. The precipitant cations destabilise the suspended particles by partial neutralisation of their negative surface charge, the effect of the ions increasing with their specific charge. Thus bivalent ions (Ca^{2+}, Fe^{2+}, Zn^{2+}) are better than monovalent, and trivalent ions (Fe^{3+}, Al^{3+}) are better than bivalent. These processes are simply illustrated in Figs. 1–3, in this case with iron ions.

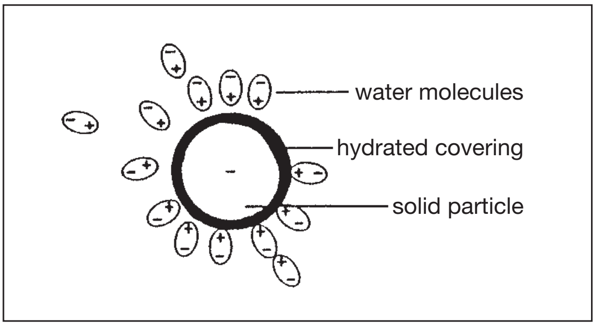

Fig. 1: Hydrated covering of a solid particle in water.

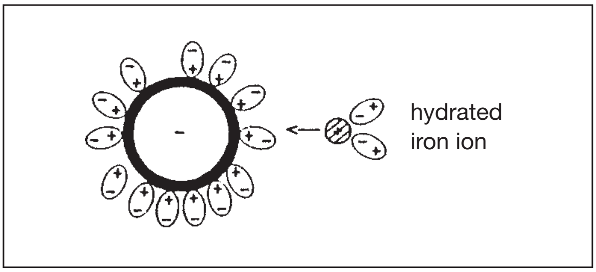

Fig. 2: Admission of iron ions.

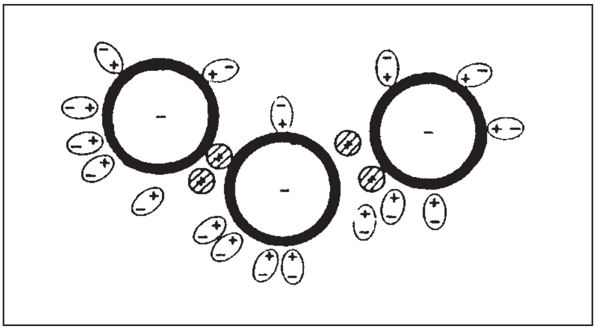

Fig. 3: Flocculation by coagulation.

The electro-negatively acting hydrated solid particles and the electro-positively acting hydrated iron ions collide due to high turbulence (important at this stage), causing partial or complete outward discharging. Thanks to the equalisation of solid particle and colloid charges, these no longer repel each other but adhere on collision, due to electrostatic proximity forces, i.e. they coagulate. This causes the formation of “floccules” with a greater mass and better sedimentation characteristics. At this point, the turbulence is largely undesirable and should be compensated by slowly stirring. Moreover, during dissolution of the metallic salts in the water as precipitant and flocculent, the flocculating metal hydroxide forms as absorbent in a counterreaction to precipitation and coagulation. To promote the formation of the hydroxide floccules, during which the acid components of the salt are released, the alkalinity of the effluent is taken advantage of. In some cases, the addition of a base substance, such as caustic soda or milk of lime, is necessary. The addition of alkali is necessary when ferrous sulphate is used as flocculent, in order to accelerate oxidation of the bivalent iron to trivalent with oxygen (by stirring or aerating).

In their amorphous formation covering a large surface, the hydroxide floccules, which precipitate as jelly-like deposits, absorb the destabilised and flocculated

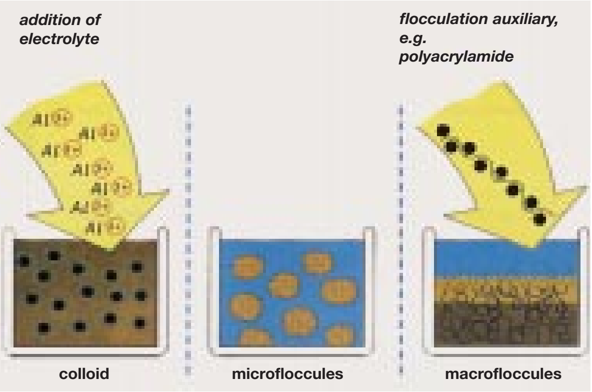

Fig. 4: The chemocolloidal processes during precipitation with aluminium sulphate and polyacrylamide, by courtesy of Röhm GmbH.

contaminants such as polyphosphates and, above all, dyestuffs. In general, it is usual for the reaction to be effected at the so-called isoelectric point, i.e. at the pH at which charging of the colloidal particles disappears, and the colloidal solution is especially unstable and thus flocculates easily. However, effluent purification does not merely consist of coagulation processes, but is governed by absorption effects for which it can be to advantage for the suspended particles to be charged.

The application of ferrous chloride together with calcium hydroxide has a synergetic effect. Whether this effect is due to the improved absorption properties of the floccules, the formation of associates, the formation of salts of low solubility, or for other reasons, is not certain. The process of flocculation of colloidally dissolved and suspended substances in the effluent is called primary flocculation. If the floccules thereby formed do not have an adequate sedimentation ability, a flocculent can be added. These secondary flocculents are high-molecular compounds which, besides absorption of the primary floccules, cause a further increase in the size of the floccules and thus have a weighting effect, resulting in improved sedimentation properties. Such synergetic flocculents are, for example, compounds on the basis of polyacrylamide (Fig. 4). Depending on the type of effluent, ionic or non-ionic flocculents are used.

polyacrylamide

Polyacrylamide with the carbon amide group ($-CONH_2$) is electrically neutral in an aqueous solution, i.e. is "non-ionic". The carbonic acid groups in polyacrylic acid, which are reduced to sodium salt, dissociate in water, so that a negatively charged oxygen atom remains in the carboxyl group. This results in an "anion-active" flocculent. An important characteristic of such a flocculent is the chain length and, therefore, the number of active groups per molecular unit. A polyacrylamide with a molecular weight of approx. 7 mill. is made up of around 100 000 elements. It therefore contains up to 100 000 active groups. The chemical industry supplies such flocculents with molecular weights of over 10 mill. Their application quantities are very low, being around 1 g/m^3, which is why they are always used in highly diluted solutions. It should not be forgotten, however, that flocculents increase the volume of sludge in the precipitated substances in effluents.

Traditional flocculation plants comprise three separate plant sections for the process stages.

1. Mixing of the effluent with the flocculents and flocculation auxiliaries (comparatively high turbulence and short dwell time).
2. Flocculation (during which there is merely a slow stirring action).
3. Sludge separation by sedimentation.

In the so-called sludge contact process (Fig. 5), either the process stages 1–3 or 2 + 3 are combined, or a specific quantity of sludge is recycled to the flocculation reactor, thus achieving an improvement in the flocculation process and reduction in the amount of sludge.

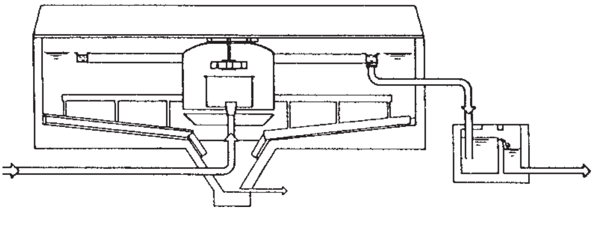

Fig. 5: Reactor, operating by the sludge contact method.

Flock To → Flock; short pieces of monofilament fibre, i.e. short fibre material made of viscose, polyamide, polyester, polyacryl nitrile, acetate or natural fibres (wool, cotton) and frequently also so-called metal flock made from aluminium, brass or bronze powder (see Table) prepared for flocking and flock-printing. The most frequently-used fibre titres are in the range of 0.9–22 dtex, and the usual fibre lengths are between 0.5 and 2 mm. "Glow" or reflective flock is always prepared by static electrical means using electrolytes, and therefore conducts electricity to a certain extent.

Fibre material	Benefits	Disadvantages
Viscose	- Soft, silky surface - Possibility of achieving crush effects	- Moderate resistance to wear and tear, particularly when wet
Polyamide	- High resistance to wear, even when wet - High crush resistance	- Perceptible harder compared to viscose with the same length-to-titre ratio
Polyester	- Very high abrasion resistance, particularly when wet - Easy to dye using disperse dyes, e.g. by sublistatic process	- Very low water absorption property - Harsher handle than viscose
Polyacrylic	- Soft, silk-like surface - Possibility of achieving high colour brightness and colour fastness - Possibility of achieving crush effects - Better abrasion resistance than viscose, particularly when wet	- Susceptible to crushing - More susceptible to abrasion than polyamide and polyester
Modal	- Flock of modal fibre is comparable with polyacryl nitrile flock, with the additional advantage of having low flammability	

Tab.: Raw materials for flock production

Manufacture:

1. By grinding in the ball mill, cotton and wool, occasionally viscose, in average lengths of approx. 0.2 to 0.3 mm.

2. By precision cutting with a precision of 0.1 mm. Usually standard lengths of 0.3, 0.5, 1.0, 1.5, 2.0, 3.0 mm etc. The cut edges should be right-angled and clean-cut. As well as synthetic fibres, viscose filaments are used. In fine filament capillaries and lustrous, e.g.: 0.3 to 0.5 mm for simulated suede, 0.8 to 1.0 mm for simulated velours, 1.2 to 1.5 mm for simulated velvet.

This kind of flock is available in many different shades with customized dyeing and finishing, including water repellent etc. to meet all specifications. Defective short fibres create potential sources of faults, e.g. overheating in milling (creating a grey shimmer, as though it was dusty), blunt cut ends, fused cut edges (because of knife being too high), kinked or bent flock. For this reason a perfect cut and careful screening is required.

Flock prepared by a special process is almost always applied in the textile sector by electrostatic or electrostatic/mechanical means. The main tasks of the flock adhesive are to retain the flock fibres during flocking in order to achieve a high flock density and provide the required anchorage once the adhesive has been applied (Fig.). The variety of effects that can be produced by flocking extends from fine velour, e.g. for clothing, to velvet or suede-like decorative fabrics and simulated fur and floor coverings.

Flock adhesive From a chemical point of view, flock adhesive may be categorized as follows:

I. Thermoplastics:

a) Polyvinyl acetate

b) Polyacrylic acid ester

c) Polyvinylchloride

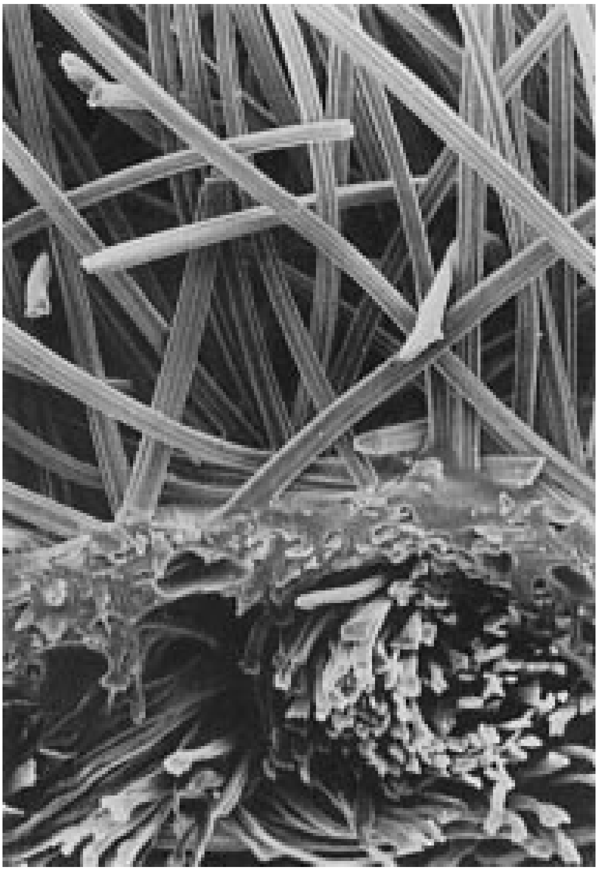

Fig.: Scanning electron micrograph of the fibres anchored in adhesive by flocking.

d) Copolymerisates such as ethene vinyl acetate, vinyl acetate acrylic acid ester, acrylic acid ester-acrylic nitrile

II. Duroplastics:

a) Phenolic resins

b) Formaldehyde/urea resins
c) Melamine resins
d) Epoxy resins
III. Elastomers:
a) Polyurethane
b) Polybutadene styrol
c) Polybutadene acryl nitrile
d) Polyisoprene
e) Polychlorophene
f) Polysiloxane.

Curing by solvent evaporation: In the case of polyacrylic acid ester, the acrylic acid must be esterified with alcohols of longer chain length if the side chains resulting in the polymer are to act as spacers, keeping the main chains apart in the sense that solvents (as a constituent of the adhesive) can easily diffuse between the chains and swell the polymer. When the adhesive sets, the solvent evaporates.

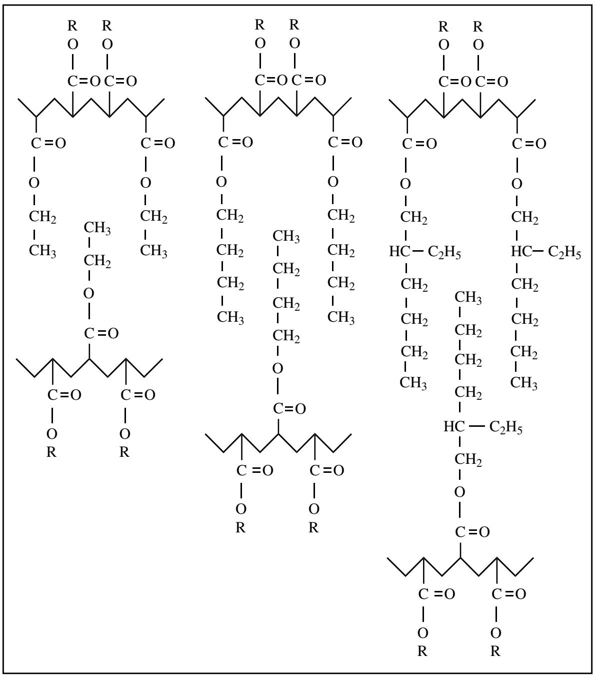

Fig. 1: Acrylic acid ester adhesive.

Condensation curing: if cross-linking or self cross-linking acrylic acid esters are used, these contain, as well as the ester, N-methylol acrylamide in the chain, a compound that has terminal hydroxyl groups that react with each other to separate water when heated and form a covalent bond (ether crosslinking), provided that two such hydroxyl groups are close enough to each other from a purely spatial point of view (Fig. 2). It is natural that such cross-linking occurs more easily with short side chains and greater molecule chain packing density, and it therefore becomes clear that a cross-linked acrylic acid and methacrylic acid methyl ester has the best solvent fastness but at the same time also has the harshest handle of the acrylic acid esters. This example shows that there can be no dry-cleaning resistant acrylic acid 2 ethyl hexyl ester, since the main chains are far apart and cross-linking is almost impossible. This means that a compromise always has to be made between softness and handle on the one hand and solvent fastness on the other.

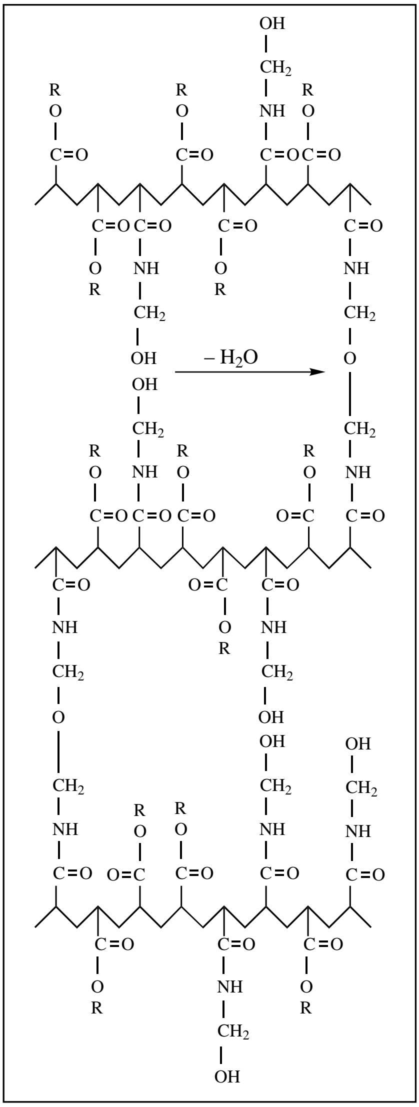

Fig. 2: Condensation

Polyaddition curing: Polyaddition, shown in Fig. 3, between an epoxy resin and an amine, progresses in such a the way that the terminal ethene oxide group in the resin reacts with the amino group of the hardener (polyamine, diamine etc.). This in turn creates a network of covalent links that give the resin formed more strength and resistance to modification, since the mobility of the segments in relation to each other declines and the entire system becomes more rigid.

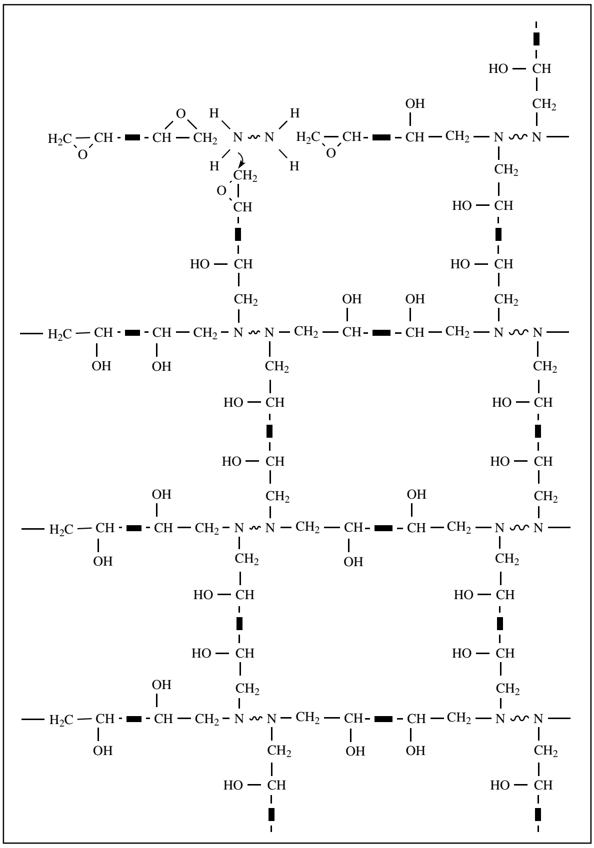

Fig. 3: Epoxidic cold cross-linking.

A typical addition process is the creation of polyurethanes from isocyanates and bivalent or polyvalent alcohols (Fig. 4). The link between various molecules in a diisocyanate with a trialcohol is evident between terminal –N=C=O and OH groups that react with each other as shown in the previous example by means of polyaddition and form covalent bonds. Here too a three-dimensional network with good chemical resistance is formed (source: Stukenbrock).

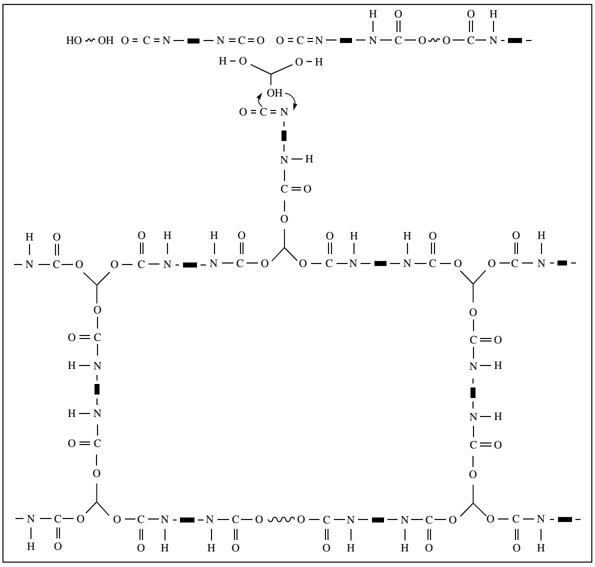

Fig. 4: Creation of polyurethane.

Flock coating → Flocking.

Flocked carpet → Contract carpet produced by → Flocking on to a substrate consisting of a ground fabric, nonwoven, or rubber sheeting. The applied flock is in the form of, e.g. short cut polyamide fibres.

Flocked fabrics → Flocked textiles or textiles with → Flock yarn.

Flocked textiles These are defined by the German standard DIN 60 000 as fabrics in which textile fibres are bonded at one of their ends to a textile or non-textile base material by means of an adhesive. → Flocking, flock coating.

Flocking On the market there is a variety of aqueous-based acrylic emulsions, which meet the demands of adhesives for the textile flocking industry. Films of these emulsions range from the very soft and elastic to firm. All have excellent adhesion to a wide variety of substrates. Durability, including excellent solvent resistance, along with the softness of hand, can be had by proper selection of grades. Simple formulation and subsequent ease of clean up are additional advantages of these products.

The beater-bar flocking machine was patented in 1938 by F. L. Foster (U.S. Patent 2,128,811). It was discovered that if freshly flocked fabric were beaten on the underside, the fibres would become more deeply embedded in the adhesive and would acquire a more vertical orientation. In beater-bar machines, adhesive-coated fabric passes over a series of polygonal bars that spin at high speed, spanking the underside of the fabric as they rotate, making it vibrate up and down very rapidly. Flock is sifted down onto the adhesive-coated surface and moved into an erect postion by a slight electrostatic field. Continued beating works the fibres well into the adhesive. Although the fibres are embedded deeply in the adhesive, many of them are oblique rather than perpendicular to the surface. Flock density is usually restricted to about 4650 fibres per cm^2. The basic elements of a beater-bar flocking machine are shown in Fig. 1.

In machines designed for electrodeposition of flock, the adhesive-coated fabric passes between two oppositely charged grids, impelling the fibres to become embedded into the adhesive. Fibres that are blocked from attaching themselves the the adhesive fly back to the pole from which they originated. See Fig. 2 for a diagram of electrostatic flocking equipment.

There are two types of flocking equipment in use: Alternating Current and Direct Current. In the alternating current machine one of the two grids is connected to an alternating current generator while the second grid is grounded. The flock particles travel through the

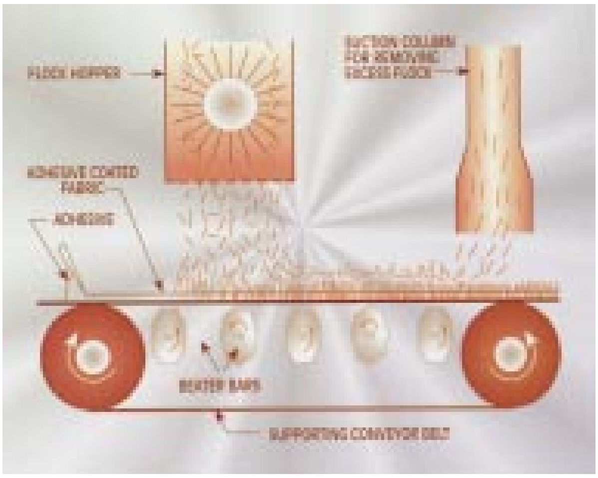

Fig. 1: Beater-bar flocking.

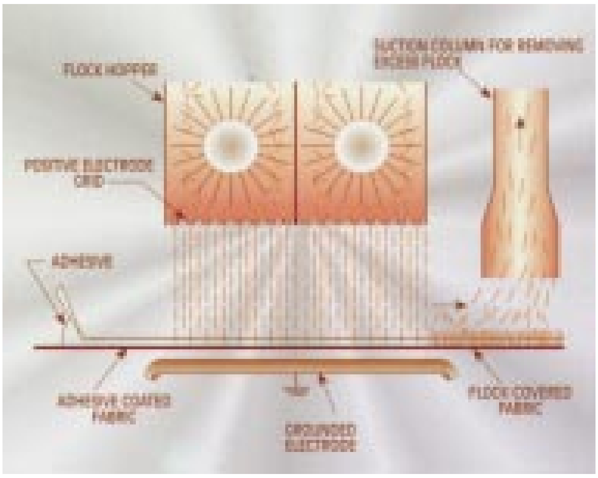

Fig. 2: Electrostatic flocking.

magnetic field oscillating toward the adhesive coating, trying to adjust to the varying field being created. These machines can operate at very high speeds. In the second type of machine, using direct current, the two poles are oppositely charged and the flock particles tend to travel and embed themselves perpendicular to the adhesive layer. Greater flock density can be achieved with this method than with the alternating current equipment. In practice very often both the mechanical and the electrostatic methods are combined.

For applying adhesive knife coating is the most common method employed. Speciality fabrics with a continuous repeated pattern are usually produced by printing the adhesive on the substrate. The level of adhesive applied depends on the length of the flock used as well as on the end-use of the fabric itself. Suede and velvet-type flocked fabrics are ususally prepared with precision-cut rayon or nylon flock which ranges in length from 10 to 20 mm. Closely woven fabric such as cotton sheeting is usually used as a sustrate. Wet adhesive thicknesses of 0.15 to 0.3 mm have provided a durable bond for fibres in this range. This thickness is equivalent to 40 to 80 gms of resin solids/m^2.

When the substrate for flocked fabric is jute or some other open material, conventional thickening alone may not be sufficient to provide an even adhesive layer. In such cases, a two-coat adhesive system is required. A base coat or scrape coat is applied and dried, but not cured, which will fill in the interstices of the weave and give a level base for the application of the flock coat. The base fabric can also be calendered to make it smoother. Producers of flocked carpet commonly use a base coat of about 0.25 mm. For this application, flock fibre is usually nylon from 30–50 mm long. Total film thickness (including the base coat) should range from 0.5–10 mm.

To improve hand Rohm and Haas has developed a crushed foam basecoat. This type of basecoat is capable of producing a superior hand and can be used with virtually any substrate. A Primal TR-934TK based adhesive can be used in conjunction with a crushed foam basecoat to produce a durable flocked fabric with superior hand – a hand that will remain unaltered after drycleaning and flexible during exposure to cold weather. In the past, a typical – though not totally adequate solution to this problem has been the addition of plasticiser. Although this results in a softer hand at virtually all temperatures, the most efficient plasticisers are completely removed in a single dryclean cycle. There is also a limit on the amount of plasticiser that can be used. Excessive amounts will cause a reduction of the internal cohesion of the adhesive, resulting in a reduction of dry and wet abrasion resistance.

Crushed foam can be used on low-yield nylon, low-yield acetate and tricot knits, all fabrics that were formerly considered either too open or too irregular to be used for flocking. The soft flexible foam fills in all irregularities in the substrate with virtually no strike through. A crushed foam formulation based on Primax 210 is recommended for the basecoat. Primax 210 was designed specifically to withstand the higher shear encountered in foaming devices. It provides a good balance of properties including a soft, non-blocking coating which is durable to laundering and drycleaning and good low temperature flexibility without the need for external plasticiser. Because Primax 210 is not self-reactive, a crosslinking agent is used. Thickening is achieved by neutralisation with ammonia.

Foam flocking adhesive technology is an expansion of the crushed foam technique except that when the foam is applied to the fabric and flocked, the dried foam is not crushed. The advantages gained by foaming the adhesive are that it limits the penetration of the foam into the fabric substrate, yielding a soft, aesthetic hand and tends to "bridge over" the interstices in loosely woven fabrics minimising strike through. It also retains a degree of air permeability which is important in upholstery and apparel applications as the foam is usually blown to a density of 1.5 gm/cc (a 2 to 1 blow-up) and not crushed.

Before application to the fabric, the foam should have a consistency similar to that of aerosol shaving cream. Over the fabric, the gap setting of the metering knife (or stationary roll which is frequently employed for the same purpose) should be approx. 0.4 mm to give a dry add-on of approx. 20 to 25 dry g/m^2.

Immediately after coating, the fabric should be put into a tenter frame. The tenter frame carries the fabric through an oven at a temperature of 120°C for 60 seconds. An accurate schedule must be maintained since overdrying will cause problems in crushing. The foam will crush best with a moisture content of 5 to 10 percent. High temperatures should be avoided in the initial stages of drying to prevent "mud-cracking". High air turbulence in the oven should also be avoided, particularly when open fabrics are being coated. In cases of extreme turbulence, it is possible to flow the foam coating right off these fabrics.

After the foam is dried, it can be crushed. The best method of determining proper conditions for crushing is to squeeze the coated surface between the fingers. If the foam is overdried, it will spring back; if under-dried the foam can be pushed off and a wet layer will be obvious at the bottom of the coating; if properly dried, the foam will crush readily and stay crushed when the pressure is removed. The crush rolls are similar to a pad mangle configuration, although the top roll, which crushes against the coating, is frequently metal. A cleaning doctor may be mounted on the top metal roll. The total pressure applied for crushing will vary depending upon the width of the goods (which can vary from 1 m to 2 m) and the type of foam coating being employed. Crush roll pressures generally range anywhere from 50 to 70 Kg/Linear cm total pressure on the full width of the goods. The flockcoat formulation based on Primal TR-934TK can then be applied to the crushed foam basecoat by any of the standard application methods.

The resistance of flocked fabrics to drycleaning is often evaluated by AATCC Test Method – 1963T, "Durability of Applied Designs and Finishes". In this test, samples are subjected to 30 minutes of tumbling in the Launder-Ometer at room temperature in a stainless steel container with perchloroethylene and 100 stainless steel balls to simulate the kind of mechanical action that occurs in a drycleaning machine. The samples can then be examined visually or weighed to determine the extent of flock lost. Commercial coin-operated drycleaning machines are often used where a Launder-Ometer is not available.

The cold temperature flexibility of a flocked fabric is determined by measuring its drape flex at a specified temperature in a cold box. A wide variety of factors affect cold flex, including substrate used, direction (warp or fill) in which the measurement is made, the nature and amount of basecoat and flockcoat adhesive applied and the presence of a plasticiser in the system. Cold flex is measured by the Cantilever Bending Method as described in U.S. Government Test Method No. 506. In this test, a 2.5 to 15 mm specimen is mounted flockside up on a Drape-Flex Stiffness Tester set in a cold box at a controlled temperature. The sample is pushed slowly off the edge of the stiffness tester until it bends under its own weight to an end point angle of about 45°. The length in inches which the sample must be pushed before meeting the 45° angle is defined as its cold flex at a given temperature. (The test should be done on both the warp and fill directions and the average of the two measurements taken as the fabric's cold flexibility). Just what constitutes an acceptable cold flex is debatable. However, all flocked fabrics will feel considerably stiffer to the touch at –30°C than they do at room temperature. In research done at Rohm and Haas, a cold flex value of 3.5 at –30°C is considered to be the maximum acceptable value.

A specified number of cycles in an automatic washer (drying between cycles) at 60°C are used to test the durability of flocked fabrics to home laundering. A half cup of detergent and a ballast of eight terry cloth towels should be added to the load. As with the durability to drycleaning test, the samples can be examined visually or weighed to determine the extent of flock lost.

The abrasion resistance of flocked fabric depends on the abrasion resistance of the flock and the ability of the adhesive to retain the flock during abrading action. The sample fabrics are conditioned for 24 hours at 20°C and 65 percent relative humidity and then tested on a Taber Abraser. The abraser should be fitted with H-10 wheels and 500 gram weights and run for 500 cycles. Although these are severe conditions, they can serve to differentiate between the different variables present. The test can also be run on fabrics which are still wet after washing or drycleaning.

Flocking adhesive → Flock adhesive.

Flocking, flock coating Also known as flock pile process and → Flock printing. These are surface finishing techniques for the comparatively inexpensive production of high quality suede, velvet, velour or imitation fur effects (→ Bonded fabrics) as well as floorcoverings (see Fig.). Flocking methods include several process variants.

(Prerequisites for the base fabric are: well desized material if, e.g. woven cotton; surfaces to be as smooth and compact as possible: unlevelness results in unsatisfactory flock effects). The main processes in flocking are as follows:

1. Application of adhesive: e.g. by squeegees, rollers, screens or spray methods. The adhesive (bonding

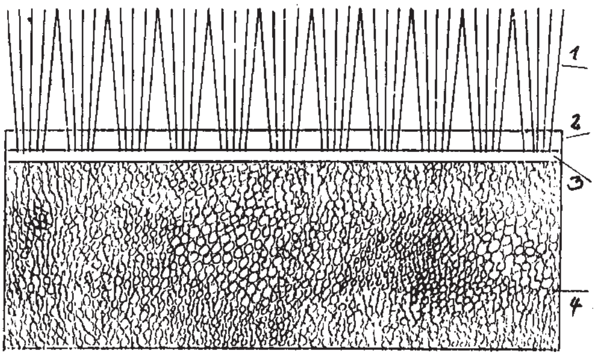

Fig.: Structural diagram of a flocked textile floor covering.
1 = pile layer; 2 = adhesive; 3 = textile substrate; 4 = foam back.

agent, binder) must make good contact with the textile surface without penetrating too far into the material (to maintain flexibility). Consumption of bonding agent is approx. 130g/m^2.

2. Flock application: the flock is applied from above the material or, against the force of gravity, from below the material (for moulded articles). Flocks of precise staple length and titre, a flock moisture content of approx. 13% and dyeings fast to boiling (spun-dyed flocks) are essential prerequisites for optimum results in flocking.

3. Drying: the drying conditions are dependent on the requirements of the particular bonding agent used. Drying is generally carried out at approx. 70°C (solvent-based adhesives) for 3–8 min. Suitable drying units include steam-heated warm or hot air tunnel driers, air jet driers, chamber driers or loop driers, as well as cylinder or plate-contact driers and infra-red radiation in combination with hot air.

4. Final treatment: removal of excess flocks by brushing with brush rollers together with a mechanical suction unit.

→ Flocking processes.

Flocking processes According to the present state-of-the-art, the following methods are used for flocking:

- mechanical,
- pneumatic,
- electrostatic,
- combination of mechanical/electrostatic,
- combination of pneumatic/electrostatic.

According to the principle of mechanical flocking, the flocks are, as a rule, supplied from a dosing device by a brush system and their anchoring in the bed of adhesive is improved by the use of rotating polygonal metal rods (beater rolls) underneath the substrate. The metal rods, which rotate at high speed, cause the material to vibrate continuously within the flocking zone. Purely mechanical flocking processes are, for the most part, hardly ever used in practice nowadays. In pneumatic flocking, the flock is supplied from a dosing device and blown on to the layer of adhesive with the aid of an air current. Alignment of the flocks on the substrate is not achieved with either of these methods and they are therefore only suitable for the application of ground flock.

Electrostatic flocking is entirely different from mechanical or pneumatic methods. The physical principles of electrostatic flocking are based on the attraction of unlike, and the repulsion of like charges. Electrostatic forces are therefore produced on long-shaped particles, e.g. flocks, which are capable of carrying electrical charges (Fig. 1). The fibres, which have become charged by contact or ionization, are subjected to a force in the strong electrical field which causes the fibres to move in the direction of the oppositely-charged electrode. During this movement, the fibres are oriented in the direction of the force line and are separated from each other due to the repulsion of their like charges. The fibres are shot into the adhesive film previously applied to the substrate surface being coated, which functions as the opposite electrode, where they are anchored in the aligned state. The electrical charges are discharged over the adhesive film. Those fibres which have not been able to penetrate into the bonding agent fly back to the other electrode after charge reversal has taken place and participate in the flocking process once more. The purely electrostatic process is mainly used for the flocking of made-up garments or moulded articles.

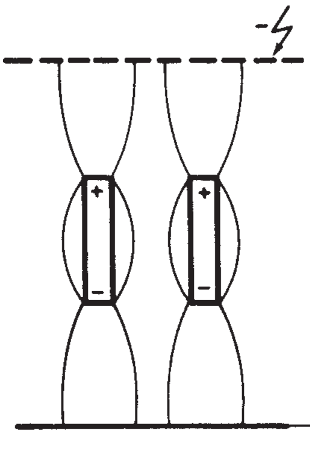

Fig. 1: Orientation of flock fibres in an electrical field.

In combination processes, i.e. electrostatic/mechanical resp. electrostatic/pneumatic, the characteristic features of both techniques are combined. In the first case, the electrostatic process is assisted by dosing the flocks with a brush system (Fig. 2) and vibration of the substrate (using beater rolls or vibrators). In the 2nd process, the transport of flocks in the electrical field is supported by a current of air. The electrostatic/mechan-

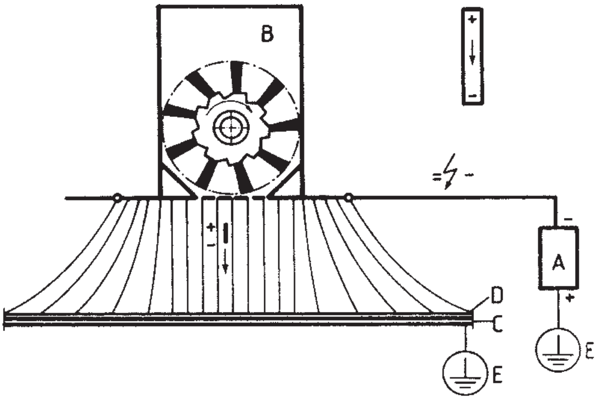

Fig. 2: Flocking plant with high-voltage source (A) and metering system (B).
C = goods; D = adhesive; E = earth electrode.

ical combination is the standard flocking process for continuous webs of fabric. Because of their geometry, the electrostatic/pneumatic process is often used for flocking hollow articles where the use of purely electrostatic flocking would result in unsatisfactory flock densities (source: Brenner and Römpp).

Flock printing Once the adhesive has been applied to the entire surface of the substrate, i.e. including the motif, and this has been produced in the flocking zone using templates, sharpness and resolution power are established by flocking. Flocking may be performed in a downward or upward direction with the parameters of the flocking process determining the sharpness of the contours of the flocked motif. When the flock motif is produced by downward flocking (Fig.) flock 1 is on the upper electrode 2, which is in the form of a screen. During flocking the screen makes oscillating movements on a horizontal plane. The substrate with the adhesive 4 is on the lower electrode 3. The template 5 with the openings 6 for the flock is between the substrate and the high voltage electrode.

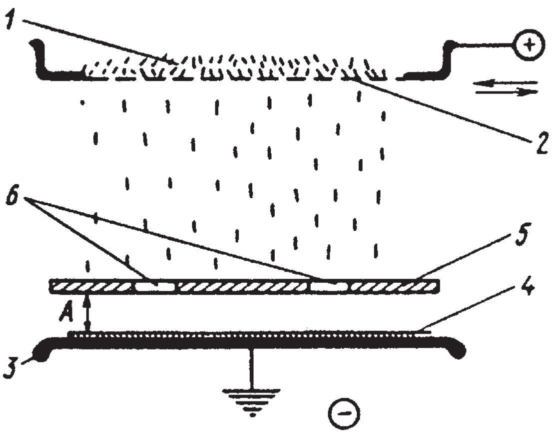

Fig.: Schematic diagram of a laboratory apparatus for flocking using the downward method (explained in text) for flock printing.

In upward flocking the substrate with the adhesive on it is attached to the earthed upper electrode. The flock is on the lower electrode which is connected to the high voltage source. Between the electrodes there is a template containing slits or openings in the shape of the motive. The force of the electrostatic field causes a flock particle that has become charged by contact with the high voltage electrode to be attracted to the earthed electrode. On the substrate these particles can only reach the electrode through the openings in the template. The flock fibres form the motif by being anchored to the adhesive coating. Subsequently they become fixed by the condensation of the adhesive. The sharpness of the flock motif mainly depends on distance A between the substrate and the template. → Flocking.

Flock radiator → Flocking.

Flock silk Less valuable natural silk such as silk waste →: Bourette; Frisons.

Flock transfer printing A process for the individual application of flock patterns to e.g. ready-made garments such as T-shirts. No after-cleaning is required although the preparation is laborious as far as the printing technique is concerned: a flocked release paper is screen printed with a single or multicolour design first of all (Figs. 1 + 2).

Fig. 1: Printing of flock paper with dye paste based on a special printing recipe (Tubi trans. CHT).

Fig. 2: Completed print in three colours on the flocked ground (Tubi trans. CHT).

Fig. 3: Adhesive printing (Tubi trans. CHT).

Fig. 4: Application of hot-melt granulate (and intermediate drying of the adhesive print) (CHT).

Next, a cover adhesive is then also applied by screen printing (Fig. 3). It is most important here to ensure that the flock is only surface printed with adhesive in this operation, i.e. the adhesive layer must not penetrate through the flock. Immediately afterwards, a hot-melt granulate is strewn on to the adhesive layer whilst still wet (Fig. 4) before intermediate drying. Excess granulate is removed by brushing after the material has been dried (Fig. 5).

Fig. 5: Intermediate cleaning (dry) to remove the excess granulate (source: CHT).

Fig. 6: Final flock transfer print (source: CHT).

The print paste/s and dye/s must then be fixed by condensation since the fastness achieved after subsequent transfer to the garment by hot ironing is dependent on this stage. The final transfer is obtained by placing the flock print (paper side upwards) on the substrate and subjecting it to heat in an ironing press (120°C for at least 10 s). The spent paper is then peeled off leaving the flock transfer behind (Fig. 6).

Flock yarn Velvet-like polyamide-based compound yarn, manufactured using a carrier thread with a firmly bonded adhesive sheath consisting of almost right-angled radial flocking. The flock cannot be removed without damaging the core thread = high abrasion resistance, resistance to shedding, resistant of high-frequency fusion, easy to clean, tetrachloroethane resistant. Used to add texture to woven fabric, warp-knitted fabric and knitwear with high-bulk yarns, as an appearance, to impart visual, handle and abrasion-resist properties for raised and velvet-like areas, particularly car upholstery, upholstered furniture and decorative materials.

Floconné (Fr. flocon = flock). A term used for thick, soft double fabrics (900–1000 g/m^2) made from carded yarns produced mainly with high-grade merino wools. The characteristic appearance is achieved by means of a separately picked 3rd weft yarn, the flock weft, which floats lengthways, and is subsequently raised (it is therefore also referred to as “napped cloth”) which gives rise to flock-like fibre tufts on the surface of the fabric. Depending on the weave, it is produced with rib, diagonal or herringbone effects; wool or piece-dyed. Used for high quality men’s coats.

Floorcoverings → Textile floorcoverings.

Floorcoverings, textile → Textile floorcoverings.

Floret silk → Schappe (silk).

Florida earth A → Bleaching earth originating in Florida.

Floss (Duvet, Fiochetti, Pelosität). Partially fluffy silk, caused by stray drops of secretion from the silk worm or as a result of aberrant spinning process, localized fluffing during the degumming process, effects of wear etc.)

Flotation (French: flotage = floating on top), term derived from ore preparation where flotation is used for concentrating slurries and flotation agents increase the water-repelling character of metals, so that they escape to the surface of the water, so to speak, in air bubbles when air is blown through the water and lighter fractions are separated from heavier fractions (Fig.). Fibre mixtures can also be separated in a quantitatively viable way using this method (margin of error only ± 1%), provided that the relative density of the individual components differs by at least 0.08 g/ml. Separation takes place using inert solvent with a relative density between that of the fibre components. For example, 100 g of fine, cut fibre pieces no longer than 0.5 mm and dried at 105°C is mixed with the solvent. After a settling period, the heavy fibres sink, and the floating, lighter fibres collect on the surface. The two fractions can now be determined separately after removing the solvent by weighing. Test apparatus has been designed to accomplish this (glass tube with outflow on the side at the top). A mixture of tetrachlorocarbonate (density 1.6) and alcohol (density 0.79) or xylol (density 0.86) for example is suitable as a separating fluid.

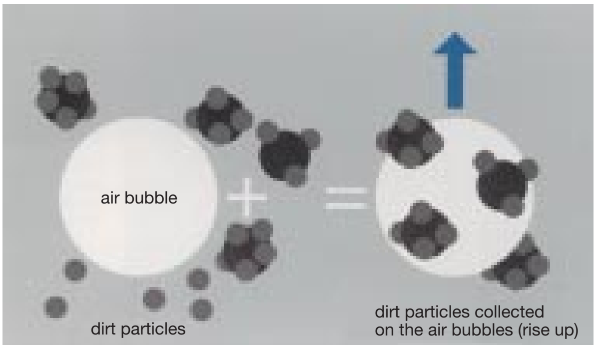

Fig.: Basic principle of flotation: fine particles collect on air bubbles, and are carried by them to the surface, where they are skimmed off.

Fibre group classification:

I. Synthetics (density 1.16–1.20) polyamide, polyacryl nitrile, without polyester.

II. Protein fibres and acetate fibres (density 1.27–1.32) with wool, silk, protein man-made fibres, acetate fibres.

III. Cellulose and polyester fibres (density 1.40–1.53) with natural fibres (wool, flax, jute, hemp, ramie), regenerate fibres (viscose and cupro fibres) and polyester fibres.

IV. Mineral fibres (density 1.90 and above).

Flour → Locust bean flour.

Flow characteristics of printing thickeners and print pastes The tack of printing thickenings and other viscous pastes is a measure of their thread-forming properties (see Fig. 1).

Fig. 1: Flow characteristics of print pastes demonstrated on an ACS datacolor metering valve.

Such pastes are correspondingly described as having short or long flow characteristics. The longer a thread can be pulled from a paste, the higher the tack value of the thickener. The tack value is dependent on the viscosity but is not identical to it since although viscosity rises with increasing concentration, the tack value reaches a maximum at a specific concentration. A practical test can be made with the fingers: by placing a small quantity of the thickener between the thumb and the index finger and slowly drawing them apart, the respective tack value can be estimated by the length of the thread formed. Tests on thickening agents and print pastes have shown that the optimum concentration almost coincides with the maximum tack value. To this extent, the determination of maximum tack value provides an ideal and simple measure for establishing the optimum concentration for good → Print definition (not print penetration). For example, the tack value of starch and gum arabic at first increases with the concentration, reaches a maximum, then decreases again. However, the absolute value of the maximum is quite different for both these thickenings, and is due to the fact that starch produces short flow, and gum arabic long flow thickeners. Made up print pastes often exhibit different flow properties than the pure thickeners they have been prepared from due to the chemicals and dyes which have been added.

Flow dyeing Obsolete procedure for achieving cheaper dyeing. The warp or weft yarn is immersed in a strong dye, dried without rinsing and woven with non-dyed weft or warp yarn. The fabric is simply passed through hot water on the padder, whereby dye is transferred to the non-dyed material.

Flow limit → Rheological behaviour of solutions.

Flow measurement Measuring the flow of materials in pipelines is not an easy task, since per definition flow is a quotient that has to be calculated by volume over time. This means the quantity of a material flowing through a certain pipe cross-section within a certain unit of time (e.g. m^3/hr. or l/s.). Devices that primarily determine the quantity are called volume flow measuring devices or meters. The quantity can be calculated as mass m or volume V. Adding a differential time element to a counter produces a flow meter that calculates either mass flow (q_m) or volume flow (q_v) (Fig. 1).

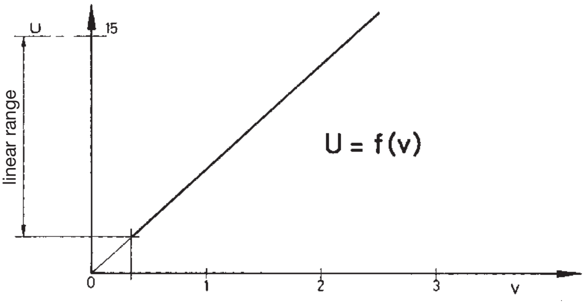

Fig. 1: Optimum relationship between solution flow speed v [m/s.] and voltage U.

Some of the many demands that textile processors make of the use of flow measuring devices are:

1. The measuring device should be independent of the Reynolds number over as wide a range as possible, and the transition from laminar to turbulent flow should not affect the measurement. The measuring range should be as wide as possible. The display should not be affected by the viscosity or viscosity changes caused by temperature fluctuations.

The Reynolds number ($Re = v \cdot d/\nu$) is calculated from the flow speed v, the pipeline diameter d and the kinematic viscosity of the material ν. It determines whether the flow in a pipeline is laminar or turbulent flow. Since some measuring systems cannot be used in the laminar range and measuring errors could occur in the laminar/turbulent transition area, the Reynolds number is extremely important. Considerable attention should therefore be paid to the Reynolds number range within which a measuring device can operate.

2. The flow measurement systems should be as independent as possible of the flow profile and the flow form. Measuring devices intended for use in the field should have straight entry and exit sections upstream and downstream of the device which are as short as possible.

3. The considerable demands made of measuring equipment in dyehouse systems with regard to corrosion, temperature and pressure resistance make it important to use measuring systems without moving mechanical parts wherever possible.

4. Measuring the flow of liquids that are dirty or contain solids is often extremely important when dealing with water and effluent. The measurement should not be affected by the inclusion of gas or air. The pipe cross-section of the measuring device should be as unobstructed as possible in order to minimise pressure loss. This requirement applies to both gas and liquid measurement. Since there is no linear relationship between flow and/or volume and the displayed value in many measuring systems, linearisation is desirable.

5. The dynamic characteristics of the measuring devices may also be important regarding device selection. For example, this applies to pulsating flows and/or the use of the devices in control applications.

Flow forms and flow profiles, i.e. the distribution of the speed component v over the cross section, take many different forms in pipelines. This particularly applies if the pipeline is not straight, or if there are deviations such as bends, elbows and sudden cross-section changes such as valves, flaps etc. upstream or downstream of the measuring devices (Fig. 2). The flow is usually laminar if the Reynolds number is <2300. If the Reynolds number is greater than 4000, the flow is turbulent. Ideal uninterrupted flow should only have v_z speed components in the direction of the pipe axis z. However, in practice other flows occur which contain flow components that go in all three directions v_x, v_y and v_z (turbulence). The optimum flow and quantity measuring device that is required should be completely independent of the flow profile. This means that the same measuring result must be achieved irrespective of whether the flow is laminar or turbulent, symmetrical or asymmetrical. Furthermore, turbulence and any other flow interference factors should not affect the measurement. Only volume meters have been able to meet these requirements up to now. This does not apply to all measuring systems operating on hydrodynamic principles. Differential pressure systems are extremely sensitive with regard to flow conditions and need particularly well designed entry and exit routes.

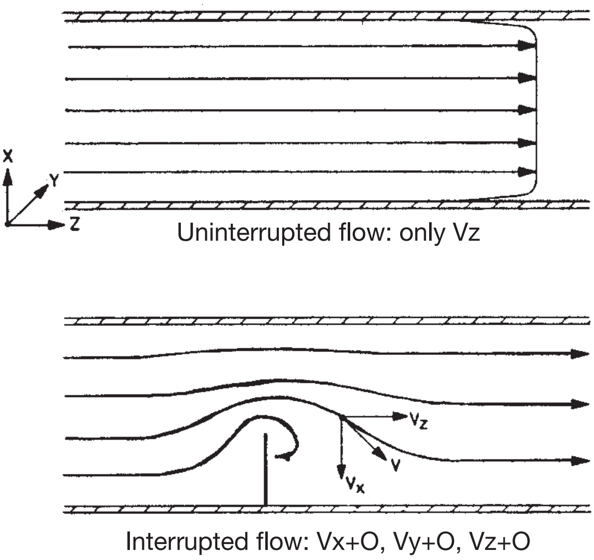

Fig. 2: Installation interference in flow measurement. Top: Laminar flow; bottom: turbulent flow.

This also applies to the same or a slightly lesser extent to other measuring systems such as axial-flow meters, vortex measuring devices, ultrasonic devices etc. Magnetically inductive flow meters are relatively insensitive in terms of flow profiles. Differential pressure measuring devices utilise the presence of differential pressures in the measuring section and therefore also belong to the classical group of mechanically or pneumatically operating processes such as suspended solid particle flow meters, positive-displacement meters (baffle plate meters) and axial-flow meters. On the other hand, vortex, ultrasonic, gyrostatic (coriolis force principle) and magnetically inductive flow measuring devices work on the principle of magnetic induction. One example from each group of devices is described in the following:

1. Hydrodynamic principle (Fig. 3):

The continuous measurement propeller is a hydrometric measuring device for determining flow speeds.

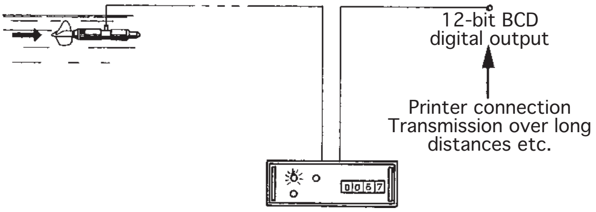

Fig. 3: Hydrodynamic flow measurement principle with stationary propeller.

Unlike the use of the metering process that is normally used for outflow measurements, this propeller allows direct flow speed calculations to be made. It outputs a signal voltage that is proportional to the water speed, The water speed can be read off in m./sec. using a display instrument. The device is maintenance free and is therefore mainly used in applications that require continuous measurement. The measurements can be transmitted elsewhere. A precision direct current signal generator is built into the propeller, which produces a direct current proportional to the propeller speed. Correspondence between the propeller rotation speed, the signal that is produced and the water speed is controlled by the conversion constant. The conversion constant in (V[m/s.]) is calculated for each propeller with a moving load of 50 000 Ω by calibrating in a standard measuring channel.

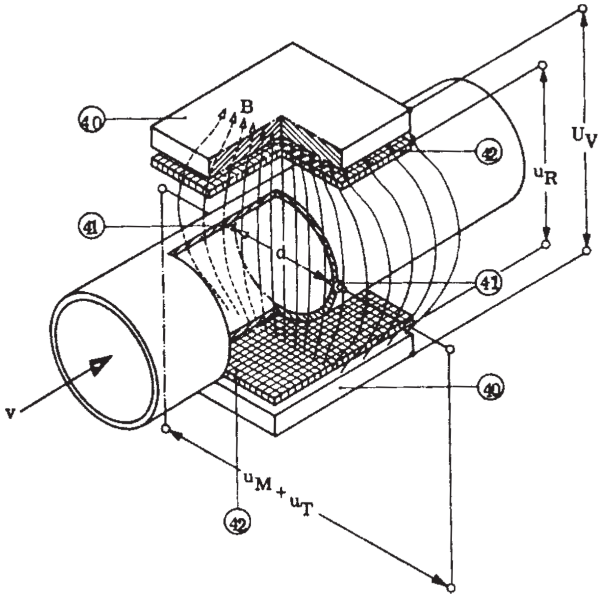

Fig. 4: Magnetic induction flow measurement.

2. Principle of magnetic induction:

The magnetic flow meter (Fig. 4) consists of a transmitter and a converter. It is suitable for measuring flow in all electrically conductive liquids whose conductivity does not exceed 10–1 µS/cm depending on the nominal range of the transmitter. The transmitter and the converter convert a volume flow of zero upward linearly into an electrical signal of 0–220 mA or 4–20 mA. Since measurement is possible in both directions of flow, measurement converters are also available with an output signal ranging from – 20 mA to 0 to + 20 mA. The device can also be calibrated to measure mass flow if the measured material has a constant density. The measurement is essentially independent of pressure, viscosity and conductivity, and is also independent of temperature and density when calibrated for volume flow. It is also largely unaffected by the flow valve. If a liquid flows at speed v through an alternating magnetic field generated by electromagnets with an induction value of B, an AC current of $u_M = B \cdot d \cdot v$ is induced vertically to the magnetic field and the direction of flow. It is picked up at two electrodes that have a distance d between them and is a measure of flow. At the electrodes there is also a transformational voltage of

$$u_T \sim \frac{dB}{dt}$$

The reference voltage of

$$u_R \sim \frac{dB}{dt}$$

is induced in the reference coils by magnetic field B (source (partial): Engelhardt).

Flow mechanism in dyeing → Mass transfer kinetics. The flow of liquor through a randomly oriented mass of textile fibres in dyeing is quite turbulent since it has to pass through numerous differently sized interstices and cross-sections. It has been calculated that the cross-sectional flow narrows and widens 18 times during the passage of liquor through a single layer of woven fabric of thickness $S_T = 0.399$ mm. If the batch roller of a beam dyeing machine is wrapped with this woven cotton fabric to produce a batch of 200 mm in depth, there would be $n = 18 \cdot 200 \div 0.399 = 9000$ constrictions and openings in which the liquor flow is subjected to turbulence during its passage through the batch. It can therefore be assumed with reasonable approximation that during the transport of dye in a liquor flowing through the randomly oriented fibre mass, an integrally uniform turbulent flow of material occurs in which the transport speed in the same direction as the main flow, as well as that at right angles to it, is equally great. For a semi-quantitative and trendwise consideration of dye flow behaviour, the flow rate and quantity of dye liquor, the surface area of the fibre mass and the weight of textile material, as well as the quantity of dye and the chemistry throughout the entire time of dyeing, is the same. Changes in liquor temperature, quantities of auxiliaries, distribution equilibria, etc. dependent on dyeing time are considered as overlapping activities as far as their influence, or their ability to be influenced, is concerned so that the action and interaction of the dye flows remain easily comprehensible. Because of the different dye transport mechanisms in the liquor-related and substrate-related region of the fibre mass through which the dye liquor flows, a separate study of liquor and substrate dye flows is recommended. For this purpose, and based on functional conformity, it is assumed that the dye is transported by the adsorption flow to the surface of the fibres in the fibre mass where it is deposited or stored temporarily. It is further assumed that the dye which has diffused into the volume of the substrate is abstracted from the deposited or temporarily stored layer of dye and adsorbed on the surface of the fibre mass independent of the liquor flow. An S-shaped curve progression is characteristic for the dependence of dye concentration c_{PFx} on the dyeing time z_x resulting from the interaction of flow and adsorption transport during a convective (circulating liquor) dyeing.

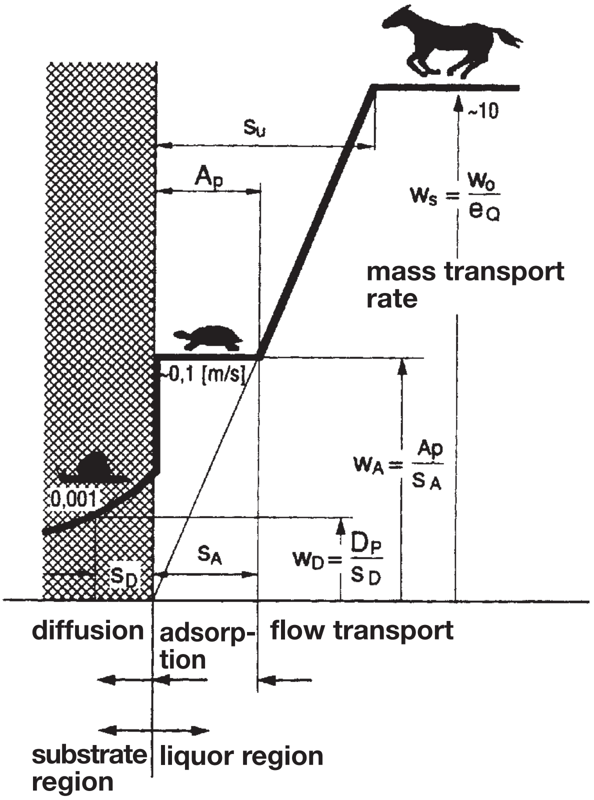

Fig.: Schematic representation for a quantitative examination of dye flow regions in the fibre mass through which dye liquor is circulated (Kretschmer).

The local mass transport rate is the same as the locally identical flow rate of the liquor; the flow rate of the liquor and consequently the mass transport rate across the boundary layer thickness s_U also decreases linearly to a value of zero at the surface of the fibrous mass. The dye transport speed w_A which determines the liquor-related dye flow is available at distance s_A from the surface of the fibre mass in which the dye transport speed of the flow and adsorption regions is exactly the same. The available dye transport speed w_A is considerably smaller than that of the liquor flow w_S in the fibre mass through which the liquor circulates. This is emphasized by the animal symbols depicted in the figure (reduced in size for didactic reasons). From this it can be seen that the relationship between dye transport speed w_S in the flow region and that in the adsorption region in close proximity to the fibre surface w_A is comparable to that between a horse and a tortoise. With the aid of a further analogy, it may be concluded that the flow speed represented by the horse can only be taken advantage of if the speed of the (adsorption) tortoise is high or when it can be raised above the adsorption coefficient A_P. The dye transport in the adsorption region, i.e. the region represented by the tortoise in the figure, is determined to a decisive extent by the substrate-dependent chemistry of the dyes and auxiliaries as far as the supply of dye for the textile fibre mass up to the surface of the fibrous mass is concerned. In order to describe the dye transport processes taking place in the adsorption region, the adsorption coefficient A_P m^2/s has been introduced which, as a material-related integral parameter, includes the adsorption-influencing factors determined by the substrate-dye and auxiliary chemistry as well as the adsorption influences dependent on the process, concentrations, temperatures, times, etc. Since the adsorption coefficient A_P integrally includes both the decisive influences of substrate and dye/auxiliary chemistry as well as the process technology, it can be used to advantage for the characterization and/or evaluation of process-dependent chemistry, process physics and machine technology, especially in the field of computer-assisted process control. For this purpose, it is advantageous if the adsorption coefficient

A_P can be derived from the liquor-related measurements with sensor technology currently available in the market as well as online in computer-controlled dyeing, pretreatment, washing and wet finishing processes (source: Kretschmer).

Flow properties →: Rheology in printing and coating; Rheological behaviour of solutions; Rheopexy; Thixotropy.

Flow resistance in yarn packages → Mass transfer kinetics.

Flow washing process A continuous washing and rinsing process in a flowing current of liquor (constant water inflow and drain-off), in which only the temperature and concentration of the wash liquor flowing through the machine are controlled. The throughput of laundry may be cyclic or continuous. Two alternatives are available, i.e. the → Clear flow laundry wash process and the → Counter current washing process. The opposite principle is represented by the → Multi-bath washing for laundry.

Flue gas analyzer (electrical). An instrument for checking the levels of CO_2, CO, $(NO)_x$, SO_2 and H_2 exhaust gases produced in boiler furnaces in order to achieve more reliable, economic and environmentally friendly combustion of the fuel used. It is based on determining the thermal conductivity of the exhaust gas mixture. For this purpose, the exhaust gases are brought into contact with a platinum wire heated electrically to 100°C from which their composition is determined by thermal conductivity. This provides a measure of the gas mixture from which it can be seen whether the composition lies within acceptable parameters or not.

Flue gas neutralization A process for the neutralization of alkaline waste waters by the carbon dioxide (CO_2) contained in flue gases. A large quantity of CO_2 is produced in boiler furnaces. Even if only 10% of the hot gases at 100–200°C are used for the neutralization of alkaline waste water, the procedure is still ecologically sound. More CO_2 cannot be utilized because of its great excess by stoichiometric comparison with the alkali content of the waste water. For this purpose, a system is used without a storage reservoir (see Fig.), based on the principle of the loop-type bubble column reactor which is already well-proven in the textile finishing industry, or the introduction of flue gas by "submersed circulation". This latter method requires an additional treatment reservoir but results in a simultaneous thorough mixing and a degree of ventilation via surface movement. The introduction of air into the neutralization tanks may be necessary to prevent putrefaction.

Fluff → Down.

Fluff formation → Pile formation.

Fluid Liquid or liquid product.

Fluid-bed process (hot sand dry fixation process). In this process sand or glass pearls of 100–200 µm diameter are used as a heat transfer medium from the heat source to the material being treated. In the case of materials produced from synthetic fibres, the fluid-bed process is used for heat-setting, thermosol dyeing, the curing of pigment dyeings and prints, the curing of synthetic resins and drying operations. The material being treated passes through the mass of hot sand/glass pearls in a V-shaped chute. Manuf.: British Tufting Machinery Ltd., Blackburn (GB).

A system based on the same principle for the heating of laboratory dyeing equipment is also manufactured by Roaches (GB).

Fluidic oscillator Name given to acoustic measuring device for controlling the moisture in exhaust air

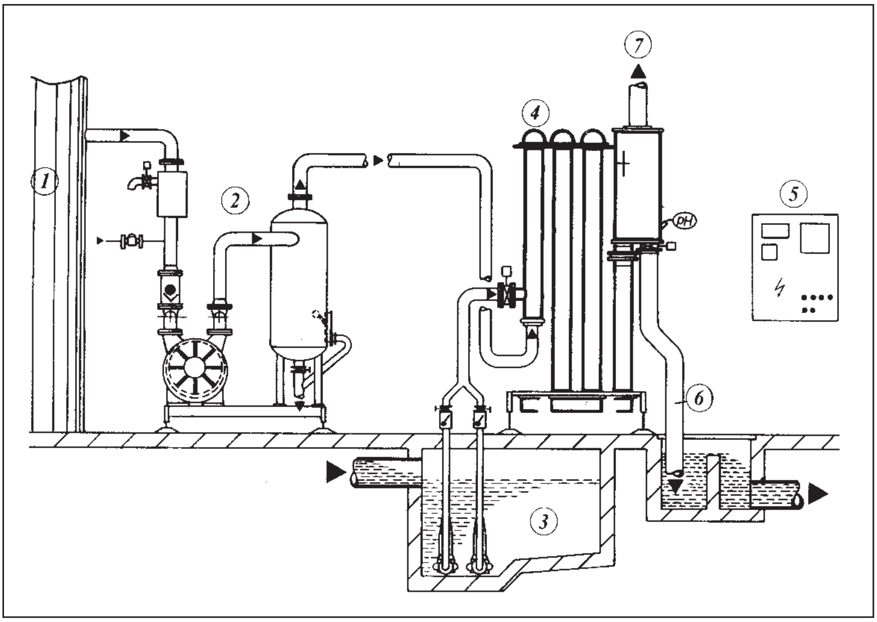

Fig.: Typical layout of Göttsche and Schwarzlmüller flue gas neutralization system.

Fig.: Fluidic oscillator (Mahlo) for exhaust air moisture control.

(Fig.). Uses speed of sound U as the measuring parameter, which changes with the amount of water vapour in the air. In water vapour U is approx. 25% greater than in dry air; mix ratios therefore provide easily measurable intermediate values. The effect of temperature can be included in the electronic analysis of the moisture measurement by measuring the temperature at the same time. The acoustic radiation produced by an oscillator of constant frequency, penetrates the medium (exhaust air) and is then converted into electrical vibration by a microphone. The water vapour content is immediately read off on an instrument that is calibrated in % volume. The main advantage of this measuring method is that a probe can be installed directly in the exhaust air channel or the dryer, so that different flow speeds and gaseous or solid components in the exhaust air cannot falsify the measuring result. Switched on/off using pushbuttons in the scale section. – Machine maker: Mahlo.

Fluidimeter

I. Flowmeter, various systems such as flow-measuring devices, choke systems, floats, damming devices etc.

II. Liquid level meter, mechanical, hydraulic, pneumatic and electrical.

III. Volumeters, volume recording by piston, dial, float, etc.

Fluidyer Name given to dye liquor application mechanism with foam distribution system for plain and differential carpet dyeing. – Machine maker: Küsters.

Fluorescence A type of → Luminescence in which substances exposed to a light source emit light of another wavelength or colour. In contrast to → Phosphorescence, the phenomenon ceases immediately the source of light is cut off. It is explained by the fact that fluorescence-exciting molecules reflect the absorbed light energy again at two different wavelengths of light visible to the eye so that a mixture of reflected colours is unavoidably formed. Thus fluorescein for example, in dilute solution, has the property of appearing in its complementary colour, i.e. since in this case the blue portion is absorbed from the sun's spectrum, the reflected colour appears yellow. In addition, a further portion of the absorbed blue light is converted into light of higher wavelength which is always reflected as green so that the solution appears yellow and green at the same time which is recognized as fluorescence. In general, fluorescence is concentration-dependent and is the more pronounced, the lower the concentration of the fluorescent substance.

Fluorescence colorimeter → Fluorimetry.

Fluorescence quenching The intensity of fluorescence of solutions of fluorescent substances is reduced by the addition of certain inorganic salts or organic substances. The fluorescence may be completely quenched (→ Extinction). The quenching varies with different fluorescent substances, e.g. with the same quenching agents, the fluorescence of acridine is strongly quenched, the quenching is somewhat less with quinine and even less with fluorescein. Inorganic salts that act as quenchers can be put into a series of decreasing quenching power, iodides being the strongest quenchers. This is in the same order as the refraction of the anion, which is related to the number of free electrons in the quencher. On the other hand, the cation is not very important in the quenching effect of salts. Organic quenchers are in particular substances that contain iodine or sulphur as a hetero atom and conjugated unsaturated systems (e.g. diphenyl butadiene, furan, thiophene), benzene derivatives with continuous conjugated systems (substituted with OH-, OCH_3-, CH_3-), acids and esters, especially disubstituted ones, other aliphatic compounds, many substances with a double bond, saturated ring systems and conjugated systems (benzene, pyridine). Although the quenching is somewhat greater in methanolic solutions than in water because of the lower viscosities, the not very large differences cannot be used reliably to compare the quenching effects of salts with those of organic substances.

The equation for quenching is:

$$F = F_0 \cdot \frac{1}{1 + b + c}$$

where c is the concentration in mol/l and b is a quenching constant that is characteristic for each substance, h values from $^1/_c \cdot b$ are given in Tables 1 and 2.

Fluorescent bleaching agent → Fluorescent brightening agents.

Fluorescent brighteners – application to textiles The treatment of textiles with → Fluorescent brightening agents is carried out to improve the quality of the white. To the textile finisher, white is not a specific colour since he is concerned with many different "whites" in practice, e.g. whites with a neutral, greenish, violet,

reddish and bluish cast. As a rule, the finisher will be given a standard pattern from the customer which he is expected to match in bulk. He must therefore “colour” white goods like dye batches and, in the past, this had been accomplished with small amounts of blue and violet dyes. In the finishing of cotton and linen, these dyes were added to the final finish bath (“blueing”). A radical change in the tinting of whites came about after the discovery of optical brighteners or fluorescent brightening agents which dates back to an observation of Krais in 1929 who noticed that when linen yarn was treated with a solution of aesculine (a glucoside from horse chestnuts) it became whiter in appearance.

Commercial fluorescent brightening agents are mainly derivatives of stilbene and coumarin. They are colourless or only slightly self-coloured substances with fluorescent properties. These substances have the ability to absorb the UV wavelengths of daylight which are actually invisible to the human eye and transform them into rays of longer wavelength which now lie in the visible spectrum. As a result, blue rays are formed which supplement the natural yellowish self-colour of the fibre so that it appears white. A bluish, reddish or greenish fluorescence is produced depending on the chemical constitution of the fluorescent brightening agent. Since the fluorescence is only produced by UV rays, the effect of fluorescent brighteners depends on the UV content of the light source.

As far as their behaviour towards the fibre is concerned and their application properties, fluorescent brightening agents are similar to dyestuffs. Some products are therefore available with reactive groups for example. The same standards of fastness have to be met by white goods which have been treated with fluorescent brighteners as coloured dyeings. Manufacturer’s recommendations for the achievement of maximum fastness ratings with fluorescent brighteners must be strictly adhered to. Suitable brighteners are now available for almost any fibre and any method of application. The weak self-colour of fluorescent brighteners is masked by the fluorescence up to certain concentrations, but becomes noticeable if these concentrations are exceeded.

It is incorrect to assume that the application of higher quantities of fluorescent brightening agents can compensate for poor bleaching. The higher the base white of the bleached material, the better the effect of the fluorescent brightening agent. Its effect can, however, be further improved by the co-application of small amounts of toning dyes (mainly blue or violet). The toning dye compensates for the yellowish cast by producing a neutral grey which is perceived to be “whiter”. However, if the base white is deficient, the grey cast will be too pronounced. As toning dyes, those selected from product ranges appropriate for dyeing the fibre in question are not necessarily the most suitable here. Dyes having the least possible affinity for the fibre are preferred for this application. For example, acid or disperse dyes are the preferred choice for cellulosic fibres.

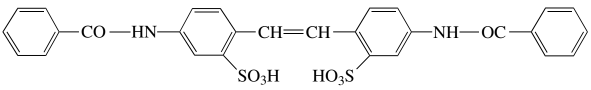
Wherever possible, the finisher will avoid applying fluorescent brighteners by a separate process, especially when continuous processing is involved. These products can already be incorporated in scouring or bleaching baths since many of them are stable to bleaching chemicals. As in the case of dyes, fluorescent brighteners can be classified in terms of their affinity. Exhaustion on to the fibre may be controlled by the addition of salt and the application temperature. If the affinity is too high, levelling problems are likely to occur under certain circumstances. Fluorescent brighteners also have different fastness properties. For this reason, consideration must be given to subsequent finishing processes when selecting the most suitable fluorescent brightener. Certain products are suitable for application in the final stages of finishing, e.g. along with resin finishes or flame retardant (FR) finishes. For the application of fluorescent brighteners to polyolefin fibres, attention must be paid to the fact that certain products have a tendency to exude from the textiles during storage which can lead to yellowing.

For the application of fluorescent brighteners to fibre blends, it is very seldom that the same product can be applied to all the fibres and the most suitable product for each fibre must be used. In these cases "cross-staining" cannot be avoided and, for this reason, additional clearing treatments are necessary to achieve optimum white effects. This applies, for example, to polyester/cotton blends where, under certain circumstances, the disperse-type fluorescent brightener used for the polyester component must be removed from the cotton component by treatment in a sodium dithionite bath. In the case of polyester/wool blends, a fluorescent brightener is applied to the polyester component first, then the wool is bleached in a bath containing a different fluorescent brightener suitable for the wool.

When the results of fluorescent brightener application are "off-shade" or otherwise defective, the product can be stripped from the goods in a similar manner to dyes. Depending on the fibre and the particular fluorescent brightener used, certain precautions are necessary. For example, when fluorescent brighteners based on stilbene are applied to polyamide fibres, they must not be stripped with chlorite since the decomposition products subsequently turn yellow.

Fluorescent brighteners are not only used for white goods but also to enhance pale blue, red, violet and green pastel shades. However, in the case of subdued pastel shades, e.g. beige, the application of a fluorescent brightener causes alterations in the shade. Since practically all household detergents contain fluorescent brightening agents, these products exhaust on to the textiles in the first wash. It is for this reason, therefore, that dyers are recommended to dye pastel shades in the presence of fluorescent brighteners in order to avoid complaints or claims from customers. Fluorescent brighteners may also be applied to synthetic fibres by heat transfer printing and suitable transfer papers are commercially available. Some fluorescent brighteners are sensitive to ferric ions. Deterioration of the white effects (yellowing, greening or greying) occurs when excessive concentrations of fluorescent brighteners are used. The maximum recommended concentration is product-dependent. Where thermofixation methods are employed, e.g. on synthetic fibres, incomplete development of the fluorescent brightener will result if the thermofixation temperature is too low. When fluorescent brighteners with inadequate stability to subsequent resin finishes are used, e.g. on cellulosic fibres, shade changes can occur after finishing.

Fluorescent brightening agents (optical brightening agents, brighteners, white dyes), organic compounds that fluoresce in a colour that is complementary to that of the textiles and can be used to compensate the natural colour. The brightening effect comes from fluorescence, which depends on the property of certain organic compounds to convert short wavelength light, in the 300–400 nm range, into longer, 400–500 nm, wavelengths. An example of a typical brightener is dibenzoyl diaminostilbene disulphonic acid:



Such chemical substances can be considered as light transformers, substances that "transform" the light energy; as the transformed blue component is added to the incident visible light, the total of all the colours of reflected light (additive colour mixture) is greater. Consequently, fluorescent brightened textile materials appear not only whiter (depending on the light source) but in fact also brighter, i.e. without chemical bleaching, there is an increase in the light reflected.

Light is one of the energy forms carried by photons. When a photon meets a molecule its energy is transformed into chemically bound energy, i.e. it is completely absorbed into the chemical substance. The energy absorbed converts the chemical molecule from its original ground state into an excited state (singlet state). From this excited state the molecule can return to the ground state in various ways:

1. Immediate return by converting the absorbed energy into a photon; the molecule radiates in a new colour. When the original absorption is of invisible u.v. light, this radiation is visible and is called fluorescence.

2. A radiationless transition from the excited state back to the ground state takes place if the absorbed energy is given up piecemeal and hardly affects the environment. Absorbers of u.v. light, such as protecting substances for human skin (sun protection creams), automotive paints or dyed fibres, convert the absorbed energy into heat in this way.

3. Delayed radiation arises from conversion of the first excited state into a second excited but stable state, which much later gives up a quantum of light (when visible light has been taken up, e.g. with fireflies or glow-worms in the night, this is called phosphorescence).

4. The molecule can come down to a lower energy level from the second excited state, by a chemical reaction (e.g. with other molecules), the absorbed energy being stored in the new chemical compound.

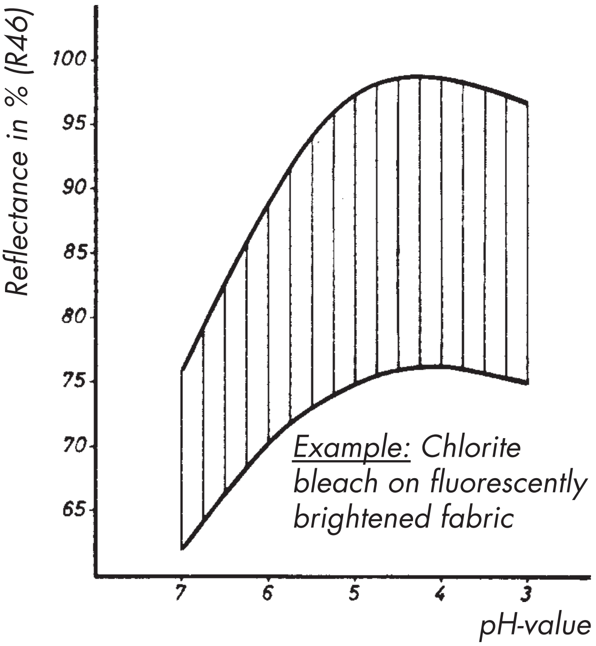


Fig. 1: Increase in fluorescence as a function of the degree of whiteness of the substrate.

The lower line in Fig. 1 shows the chemical white from chlorite bleaching at various pH values. This curve is significant for the fluorescence. Although the same amounts of brightener were applied to all the samples, the fluorescence of the brightener increases sharply with an increasing degree of chemical whiteness. This clearly shows that part of the fluorescence is quenched by the yellow component of the cotton/polyester fabric and only returns when the degree of chemical whiteness is improved. The conclusions from this are clear: if the chemical bleaching is neglected, the degree of whiteness will be reduced (Fig. 2); however, even a small reduction in the degree of whiteness of the substrate will block a considerable part of the brightening effect. This double effect is not the least of the reasons for the large variations in whiteness that can appear during production of cotton/polyester fabrics.

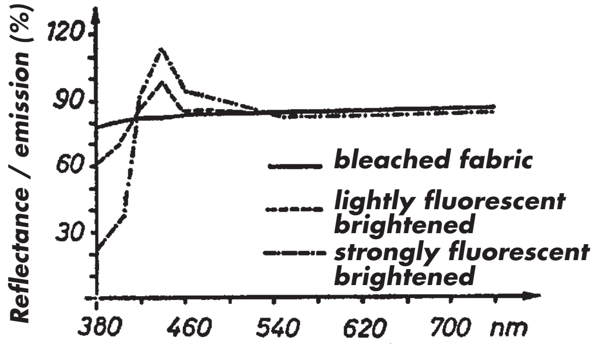

Fig. 2: Spectral reflectance curves of an unbrightened and two different fluorescently brightened fabrics.

The presence of conjugated double bonds is essential in the constitution of fluorescent molecules (substantivity), e.g.:

–C=C–C=C–C=C– (stilbene type)

–N=C–C=C–C=C– (imidazole type)

A large number of the fluorescent brightening agents used in the textile, paper and detergent industries are based on diaminostilbene disulphonic acid. Besides these, there are also products based on coumarin and benzimidazole. A fluorescent brightening agent may be anionic, cationic or a dispersion, depending on its structure. Care has to be taken with applications in combination with other compounds (detergents, finishing agents). Fluorescent brightening agents are available for all types of fibre. When they are chosen correctly, they fulfil the requirements for good fastness to water, washing and light and also for skin contact. The affinity of individual types varies, so the best product has to be selected for each fibre.

Fluorescent brightening agents – affinity for cotton/polyester High, medium and low affinity types are used for brightening cotton. Products with high affinity have lower average diffusion coefficients in the fibre than medium or low affinity compounds. However, under comparable conditions, the mass transport/unit time is greater with high affinity products and hence the exhaustion and rates of build-up are higher than with the lower affinity products. The consequences are increased concentration at the fibre surfaces and better exhaustion of the bath. For cotton brighteners addition of electrolyte (with low, medium and even high affinity leads to a significantly higher degree of exhaustion and better reproducibility, but also to significant differences in products with different affinities) and bath temperature are significant. The Figure shows

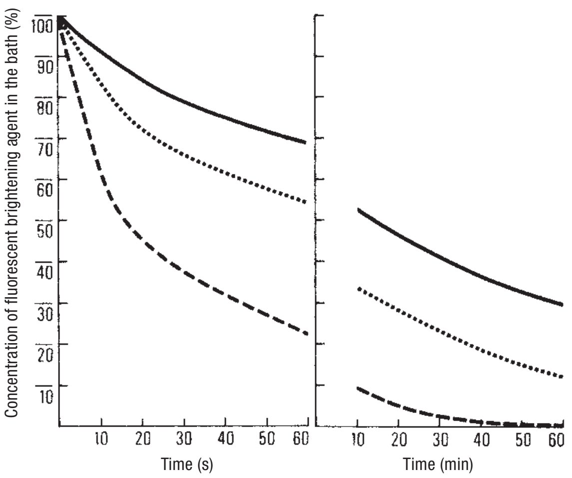

Fig.: Exhaustion curves for various fluorescent brighteners on bleached cotton at 40°C.
— low affinity product; – – low to medium affinity product; · · · high affinity product.
Liquor ratio 30:1; 5 g/l sodium sulphate.

typical exhaustion curves for application to bleached cotton, where even at 40°C there is a difference in the rates of exhaustion of high, medium and low affinity types of brightener.

Similar curves are also produced from applications at 90°C. Here it can be seen that the degrees of exhaustion of low and medium affinity types are significantly reduced, while those of the high affinity types remain relatively constant. Because of this, high affinity types of cotton brighteners are used especially for batchwise exhaustion processes with good bath circulation or movement of the material, preferably in the higher temperature range of > 60°C, and bleaching processes with high wash off temperatures, but only used with reservation for semi and fully continuous bleaching processes. Generally they provide good build up and high yield, but they can also lead to levelling problems; for effective development on the substrate, higher temperatures are required than with the lower affinity products. On the other hand medium to low affinity types (types of decreased affinity) are especially suitable for all types of padding processes, and also for semi and fully continuous bleaching systems. Their rapid diffusion ensures good levelness in exhaust processes, even under unsuitable working conditions and in processes with immediate drying they are developed quickly on the substrate; care must be taken that with these types of brightener the fastnesses to washing and water can be poor because of their low affinities. On the other hand, with the water-insoluble brighteners for polyester, differences in affinity in the temperature range of 40–90°C are not very significant.

Fluorescent brightening agents (FBA's), application in spinning This application of fluorescent brightening agents (FBA's) serves to improve the appearance of the raw white shade of regenerated cellulosic and other man-made fibres as well as to achieve a high degree of whiteness in yarns and fabrics produced from these fibres. For this purpose, special fluorescent brightening agents are mixed, in the form of aqueous dispersions, with the fibre starting products for the polymerization or condensation reaction or, they are mixed in the dry state with fibre polymer granules in tumbling mixers.

Fluorescent brightening agents in the preparation of print screens Fashion materials which are only to be printed in relatively small yardages are often printed by screen printing processes. Screens of nylon or polyester gauze are used, with the pattern in the form of permeable and impermeable, lacquer coated areas. The emulsions used for this are made with light sensitive sensitizers. On exposure to light, the emulsion hardens to form the pattern. Finishing a polyester screen gauze with a brightening agent produces an increase in the total light reflected to more than 100% because of the fluorescent emission in the blue part of the spectrum. This additional energy in the light sensitive region of the emulsion (390–450 nm) accelerates the hardening of the lacquer and consequently saves time.

Fluorescent brightening agents / quantitative determination on cellulosic materials

1. Cadoxen method: 20 mg of the cellulose fibre with the fluorescent brightening agent is dissolved by shaking in 10 ml of cadoxen (cadmium-ethylene diamine) over 2 hours at room temperature (protected from light). The u.v. absorption of the solution is measured at the wavelength of the absorption maximum in the u.v. region (optical density). From the measured optical density, the amount of the fluorescent brightening agent in the dissolved sample is determined (with a calibration curve) and from that, the content of the fluorescent brightener in the fibre is calculated. The values obtained are higher than those determined by the pyridine method.

2. Pyridine method: 20mg of fibre is extracted by leaving overnight in 10 ml of 25% aqueous pyridine solution. The extraction solution is analysed in the same way as in the cadoxen method and the concentration of brightener determined.

Fluorescent brightening agents, spectroscopic conditions, a) the absorption should be as strong as possible as close as possible to 400 nm; b) there should be practically no absorption above 400 nm; c) the fluorescence should be in the required region of the spectrum; d) the fluorescent light should have the strongest possible intensity. These properties are best calculated by the PPP (Pariser, Parr and Pople) method. Fluorescent brightening agents can have a violet or a blue-green tint or be toned down with shading colours. Polyester brighteners are often sold as mixtures of several components. The supplier seeks to get the required fastness, stability and tone and to meet his commercial requirements in this way. A brightener with a strongly violet tone, e.g. with a reflection maximum at 430 nm, can be modified by mixing it with a component with a blue-green tone (λ max. 440 nm) so that a visually and colorimetrically neutral white is produced (Fig. 1).

There is also a synergy from a mixture of two different brightener species (Fig. 2). This means that the overall effect of the combination of substances is greater than that of the same amounts of the individual components. For example, for polyester brighteners at a definite proportion of two components, A and B, in a mixture the whitening effect is better than that of either of the components. A ratio of 65 parts of component A and 35 parts of component B produces an increase in the whiteness of 14 units in the whiteness (total whiteness calculated by a whiteness and colour formula) and a shift in the tone. The technical and economic advantages (brilliance and the difference in the production costs) need no further explanation.

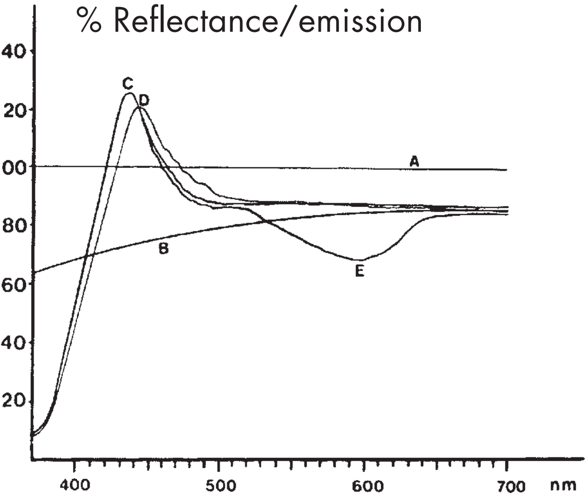

Fig. 1: Reflection/emission curves of fluorescent brightening agents.
A = 100% reflection (MgO); B = ground white of the substrate; C = brightener with a violet tone; D = brightener with blue-green tone; E = brightener with a violet tone with a toning dye.

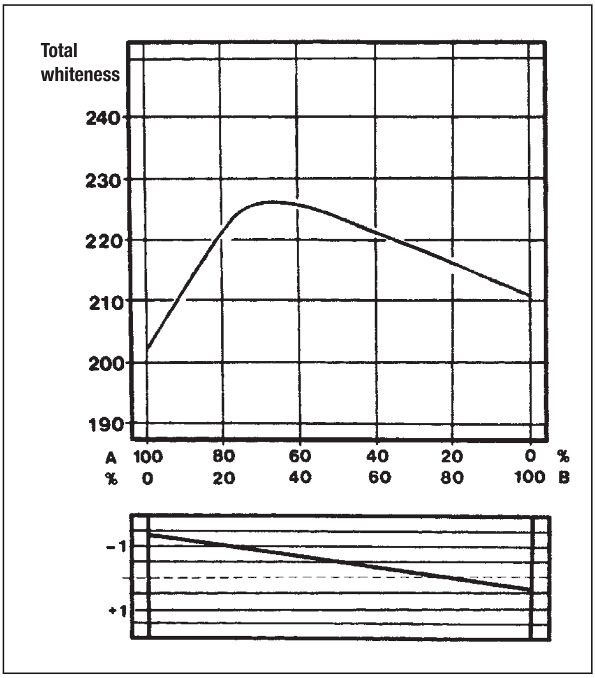

Fig. 2: Synergistic effect and colour shift of a mixture of brighteners.
A = Stilbene benzoxazolyl derivative; B = Pyrenyl derivative.

Fluorescent brightening of textiles Treatment of textiles with optical brighteners or, more correctly, → Fluorescent brightening agents. If possible, the application of fluorescent brightener is combined with other processes (combination processes) and not given as a separate treatment, e.g. the fluorescent brightening agent is applied in the scouring, bleaching or finishing bath. Fluorescent brightening agents are also frequently applied together with very small quantities of "blueing" dyes (→ Tinting of bleached goods). For certain fabrics, application by heat transfer processes represents an elegant method. Attention should be paid to the fact that the presence of iron and copper ions can have a negative influence on the whiteness of cotton treated with fluorescent brightening agents.

Fluorescent dyes

I. A group of organic dyestuffs which, when applied to a textile material, give rise to → Fluorescence under UV radiation (some also fluoresce in daylight; → Dayglow colours). The practically colourless → Fluorescent brightening agents and many individual dyes from various dye classes which produce very intense effects are also included in this category. These products and other types with different constitutions, with and without solubilizing groups, have been introduced by various dye makers in special ranges of fluorescent dyes, most of which can be applied together with curable plastic dispersions to textiles by padding, spraying, screen printing, etc. Since the fluorescent effect can often be invisible at high dyestuff concentrations (e.g. in the region of 3%) optimum percentage concentrations must be established in each case. Uses: evening wear, theatre props, protective clothing for emergency services, marine applications, etc.

II. Range of so-called → Luminous dyes that are highly fluorescent in daylight and under UV light. Suitable for coloration of plastic mass (polyvinyl chloride, celluloid, urea formaldehyde resins, lacquers), used in a similar way in pigment printing.

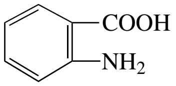
Fluorescent lighting → Fluorescent tube lighting.

Fluorescent salts A collection of soluble salts that may be applied to all textile substrates to give fluorescent effects typically in (yellow-) green, blue and blue-violet colours. Certain types show a similar affinity for wool to acid dyestuffs and will resist washing-out. Other fluorescent salts, without fibre affinity, may be applied without an end-rinse and are directly dried onto the fibre. On cotton the effects are notably fugitive. The combination of dyestuffs and fluorescent salts allows the production of brilliant colours that cannot be achieved with normal daylight colours. Similarly, print pastes with suitable thickening systems allow the development of colours of otherwise unachievable brilliance on dark grounds. A further use of fluorescent salts in print systems is as an indicator for print faults.

Fluorescent tube lighting Also mistakenly known as neon lights or fluorescent tubes. Gas discharge lamps with either glowing electrodes as high voltage fluorescent lights (mainly for advertising purposes) or with glow electrodes as low voltage fluorescent lights. Preferred lighting source for lighting work rooms, workshops, offices, shops etc. Much longer service life than light bulbs and 3–4 times the illumination, allows more economic use, particularly as a strip light in two or more levels, with special reflective coating for high work rooms, also with two different coatings, in various colours and dimensions and bar, ring and U shape etc. Multipurpose model; dust, moisture, acid, explosion-proof fluorescent lighting groups; a) with extremely high illumination for lighting systems with maximum economy; b) with even better illumination and good colour reproduction for general use; c) with particularly good colour representation, also as dual level lamp with colour rendering of incandescent and “white light”. High frequency fields excite fluorescent lights in their effective range to light without contact, meaning that these lamps can be used as indicators for HF fields.

Fluorescent whitening agents (fluorescent brightening agents). A fluorescent brightening agent is a compound which, when applied to a textile material, absorbs the short wavelength electromagnetic radiation (UV light) which is invisible to the human eye and converts it into visible light of longer wavelength which is emitted either as violet, pure blue or greenish blue. When this radiation is combined with the more yellowish self-colour of a bleached textile material, a brilliant white is produced. Thus, a bleached fabric does not appear pure white but somewhat yellowish since a certain amount of blue radiation is absorbed from the incident white light so that the re-emitted light is deficient in blue and the proportion of red-yellow-green predominates to some extent. This blue deficiency is therefore supplemented by a fluorescent brightening agent in an additive manner, unlike the use of “blueing” dyes where the “whiteness equilibrium” is restored by the absorption of excess yellow radiation. Although a neutral white is also achieved by this means, it is greyer in this case which results in a lower level of whiteness, i.e. the effect is subtractive (Fig. 1).

Fluorescence is produced by the molecule absorbing high energy radiation and re-emitting it as lower energy radiation, i.e. as radiation at longer wavelengths; the energy difference is lost as kinetic energy. For a molecule to be capable of fulfilling this function, certain constructional principles are an essential prerequisite and these may be determined empirically. Hence, fluorescence is associated, above all, with the aromatic character of a molecule although the presence of an aromatic ring by itself is still not sufficient to provide the molecule with the characteristics of a fluorescent brightening agent. Anthranilic acid, for example, produces an intense blue-violet fluorescence in aqueous solution but, despite this, it is not suitable for use as a fluorescent brightening agent.



Anthranilic acid

Most fluorescent brightening agents do not fluoresce in powder form but only in solution. Some types are also known which do not even fluoresce in solution but only after application on the fibre. Fluorescence is therefore not only dependent on the structure of the molecule, but also on its actual condition. Whether or not a fluorescent compound is suitable for use as a fluorescent brightening agent can only be assessed after its application on a textile fibre. Apart from the fact that the molecule must satisfy certain coloristic requirements and, e.g. possess satisfactory fastness to light and washing, it is the fluorescent effect which must compensate for the yellowish cast of the fibre that is of decisive importance as far as its suitability for use as a fluorescent brightening agent is concerned.

A fluorescent brightening agent is actually a dyestuff which, instead of the typical chromophore system of a dye, contains a fluorescing system and, exactly like a coloured dye, contains certain substituents which favour affinity for the particular type of fibre it will be applied to. In the case of cotton, for example, suitable fluorescent brightening agents are more or less substantive derivatives of diaminostilbenedisulphonic acid (Fig. 2, example I) like the compounds with the basic

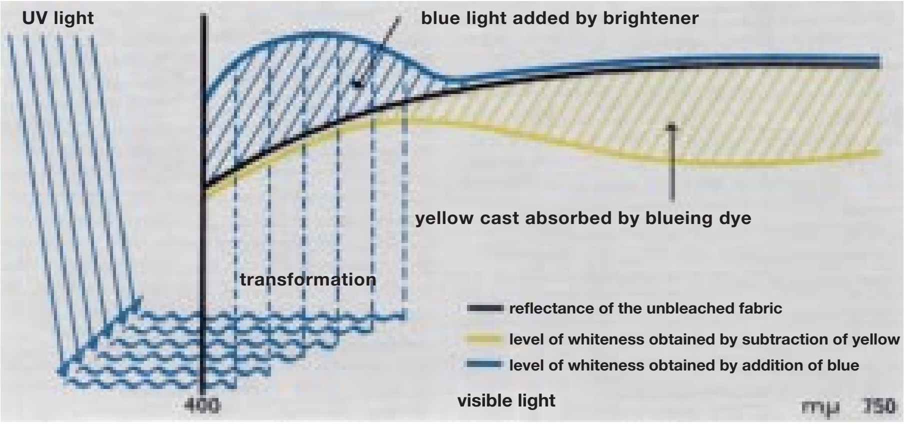


Fig. 1: Influence of a fluorescent brightening agent on a “neutral” white.

III derivative of diaminostilbenedisulphonic acid

IV glucoside of 6,7-dihydroxycoumarin

V 7-aminocoumarin

VI 3-phenylcoumarin

VII diphenylpyrazoline

VIII bis-benzazole

Fig. 2: Structural formulae of a few compounds from which fluorescent brightening agents are derived.

skeleton represented in formulae II and III. However, compounds derived from formula II are not stable to chlorine in solution although, by contrast, they generally have excellent chlorine fastness on the fibre. Compounds based on formula III are also stable to chlorine in solution.

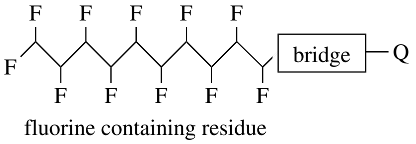
Stilbene derivatives may also be present in isomeric forms, i.e. in the cis and trans configurations. As powder brands and typical commercial liquid brands these fluorescent brightening agents are present in the trans form. The cis form, which is rapidly formed by the action of light on the trans form, does not exhaust on cotton and, for this reason, solutions of this type of fluorescent brightening agent should be protected against the action of light.

Aesculine is the glucoside of 6,7-dihydroxycoumarin (formula IV). Although this particular coumarin derivative is of no commercial significance, a large number of useful products have been derived from 7-aminocoumarin (formula V). Interesting products are likewise found among the 3-phenylcoumarins (formula VI). Many fluorescent brightening agents are derived from heterocyclic compounds containing nitrogen such as those represented by formulae VII and VIII (source: Wagner).

Fluorides Salts of hydrofluoric acid $HF \cdot H_2O$, some of which are neutral (type: sodium fluoride) but most are acidic (type: potassium hydrogen fluoride KHF_2) as well as complex salts.

Fluorimetry An analytical technique concerned with measuring the fluorescence of liquids or solutions induced by UV light or X-rays, either by comparative visual assessment, dilution, fluorescence quenching or with the greatest reliability using photoelectric measuring instruments in a similar manner to → Colorimetry.

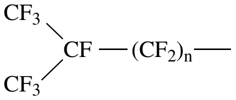
Fluorinated surfactants, fluorine containing surface active substances. The hydrophobic part of the molecule contains a perfluoroalkyl chain on the following principle:



Q = hydrophilic residue (anionic, cationic, non-ionic).

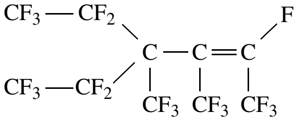
Suitable fluorine containing residues are e.g.:

$CF_3(CF_2)_n$— straight chain, unbranched



$$(CF_3)_2CF{-}(CF_2)_n{-}$$

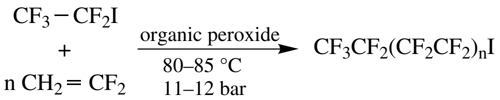
terminal branching



$$(CF_3{-}CF_2)_2C(CF_3){-}C(CF_3){=}C(CF_3)F$$

heavily branched

Amongst others methods, they can be produced by telomerization of tetrafluoroethylene to perfluoroalkyl iodides according to the reaction:



$$CF_3{-}CF_2I + n\,CH_2{=}CF_2 \xrightarrow[\text{80–85 °C, 11–12 bar}]{\text{organic peroxide}} CF_3CF_2(CF_2CF_2)_nI$$

The products with chains of 1–10 carbon atoms are valuable raw materials that can be used to produce a wide range of interesting fluorinated surfactants by replacement of the iodine, e.g. by addition of ethylene, esterification with nitric acid and hydrolysis to fluorine containing alcohols, or oxidation to fluorine containing carboxylic acids, or by reaction with thiourea to fluorine containing sulphonic acids etc., giving a large number of possible fluorinated surfactants with perfluoroalkylene groups and normally hydrophilic end groups. The surface tensions of the surfactants in water vary. Fluorinated surfactants can affect the foaming properties of normal surfactants, acting as defoamers or foam suppressers, and also bring hitherto unknown advantages with their stability to heat, acids and oxidizing conditions and e.g. can reduce the danger of dye spots during dyeing and printing.

Fluorine (F). A nonmetallic → Halogen element in group VIIA of the periodic classification. Atomic weight 19, the most electronegative element and powerful oxidizing agent known. Fluorine is a pale yellowish-green toxic gas with a pungent odour. It reacts vigorously with water (formation of hydrogen fluoride HF, salts → Fluorides). It also reacts vigorously with virtually all elements, frequently with ignition (except *inter alia* lead, and only attacks the surface of copper).

Fluorine based water- and oil-proofing agents, apart from fluorinated surfactants, fluorine-containing finishing agents for textiles, leather and paper are important members of the series of perfluoroalkyl products that are produced by electrofluorination, telomerization or oligomerization of perfluoroolefines. The technically significant intermediates for producing these types are OH-functional compounds, e.g.:

C_8F_{17}-$SO_2N(R)CH_2CH_2OH$ (R = e.g. CH_3, C_2H_5)
C_8F_{17}-$SO_2N(CH_2CH_2OH)_2$
$R_FCH_2CH_2OH$ (R_F = e.g. perfluorinated C_6-C_{12})

Fluorinated alcohols serve for the production of water- and oil-proofing agents (based on acrylates, methacrylates or urethanes) as well as components of polymer systems such as polyurethanes and polyesters. In particular water- and oil-repellant products for fibrous substrates are very important commercially. Fluorinated alcohols are produced by hydroxyalkylation of primary or secondary perfluorooctyl sulphonamides with e.g. ethylene carbonate. The largest group of textile impregnating agents are usually perfluorocarbon resins produced from the copolymerization of fluorine-containing esters of acrylic/methacrylic acid with fluorine-free monomers or mixtures of different polymers. They can be used either as aqueous, cationic or non-ionic emulsions or in solvents such as 1,1,1-trichloroethane, thermal fixation being carried out after the application. Combinations of perfluoroalkyl compounds with silicones are also used and are not only water- and oil-repellent but also impart a soft handle to textile goods that is fast to washing and dry cleaning, e.g. based on the reaction of Si-H containing organopolysiloxanes with N-allyl-N-perfluoroalkyl sulphonamide.

Fluorine chemicals These are mainly products of the → Perfluoro compounds.

Fluorocarbon chemicals → Perfluoro compounds.

Fluorocarbon fibres → Polyfluoroethylene fibres.

Fluorocarbon finishing Fluoropolymers that are correctly applied to textiles modify the surface properties of these textiles with regard to staining and dirt repellency. Whereas paraffin or silicone-based water repelling only has a water-repelling effect on the textile fibres, fluoric chemicals repel both water and oil. Compared to conventional waterproofing, fluoric chemicals have the advantage of being resistant to washing and dry-cleaning. The “breathability” and therefore wearer comfort is not affected. The same also applies to the handle of the treated textile. Fluoropolymers do not have the same conventional property of silicones for attracting fatty dirt because they are naturally oil-repellent. In physical terms fluoric chemicals reduce the surface energy of the treated fibres. This energy is brought to such a low level that neither aqueous nor oily substances impregnate the surface of the material.

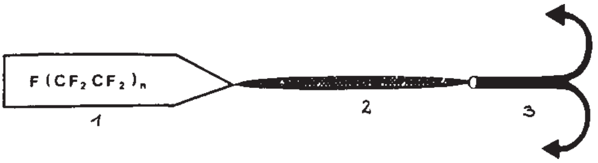


Fig. 1: Model of the mechanism of monomer fluorocarbon agents.
1 = Perfluoroalkyl group: 2 = Spacer; 3 = Anchoring or holding group.

Fluoric chemicals can be divided into three molecular areas (Fig. 1); the perfluoralkyl groups are responsible for waterproofing, oilproofing and dirt repellency. A spacer provides the required molecular mobility so that the substance is soluble or emulsifiable.

An anchoring (holding) group is extremely important, since this guarantees permanence by means of chemical, physical or cross-linked bonding. Polymer fluorocarbon agents (Fig. 2) usually consist of various constituents. As well as long-chain components containing fluorine that are responsible for the finish produced, fluorine-free monomers for improving film formation and/or reactive components for increasing permanence are copolymerized. Areas with components containing fluorine can be alternated with zones

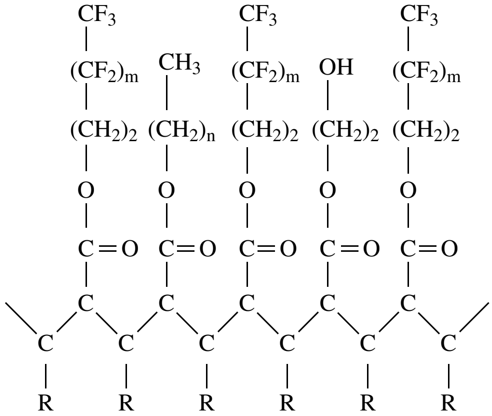

Fig. 2: Fluorocarbon polymer.

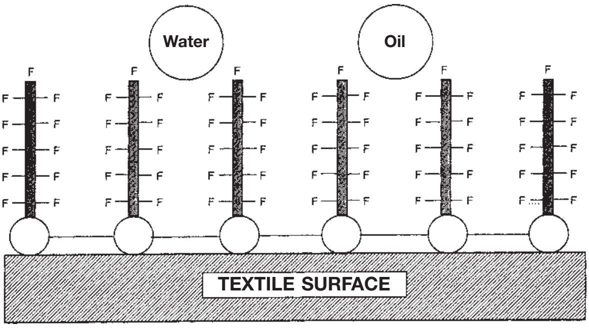

Fig. 3: Water and oil repellency by fluoric chemicals.

containing fluorine-free components. The reactive components are statistically distributed between these areas.

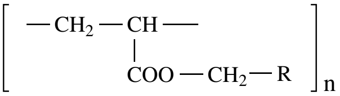
With increasing length of the perfluorinated groupings arranged vertically to the surface of the textile, other components have the effect of increasing the distance between the oil and/or water drops and the textile, thus producing better repellency (Fig. 3).

Perfluoric alkyl alcohol can be converted to monomer urethane-based agents by adding multifunctional isocyanates or converted to acrylates with polymerisation capability by means of transesterification. After polymerisation you have long-chain agents with perfluoric alkyl side chains; the polyurethane or polyacrylate components provide good fixation by direct bonding or polymer dissemination. Extenders are used in the form of fat-modified melamine derivatives in order to "extend" the requirement profile at low cost by reducing the quantities of fluorocarbon (therefore extenders in the form of waterproofing agents), particularly with regard to the water-repellency. The surface of the textile must be completely tenside-free before the fluorocarbons are applied.

Fluorocarbon plastics → Fluorocarbon resins.

Fluorocarbon polymers These include → Polytetrafluoroethylene as synthetic resins. Both are characterized by extraordinarily high chemical resistance and are stable within the temperature range from – 180 to +280°C. Nonstick surfaces are obtained by spraying these synthetic resins on to metal rollers which are used e.g. in sizing and finishing machines. Of greater interest for textile applications are the polymers of fluoroalkyl esters of acrylic acid, e.g.:

(R = perfluoroalkyl residue)



$$\left[-CH_2-\underset{\substack{|\\ COO-CH_2-R}}{CH}- \right]_n$$

These compounds are used in soil-release and stain-release finishes.

Fluorocarbon resins Polymers of → Fluorocarbons. →: Polytetrafluoroethylene; Polytrifluorochloroethylene.

Fluorocarbons These are hydrocarbons in which the hydrogen atoms have been substituted by fluorine atoms. Mixed fluorocarbons contain other halogens in addition to fluorine, e.g. chlorine → Chlorofluorocarbon. Fluorocarbon polymers are thermoplastic → Fluorocarbon resins.

Fluorochrome, fluorescent dyestuff; used as a stain in fluorescence microscopy.

Fluorofibres According to textile labelling regulations and the EDP code system, fluorocarbon fibres are classified as → Polyfluoroethylene fibres.

Fluorosilicates Salts of hydrosilicofluoric acid.

Fluorozirconate process A flame-retardant finish for wool based on → Titanium potassium fluoride or → Potassium hexafluorozirconate.

Flushed printing Overprint with extremely fine colour transitions and colour mixtures, usually on silk, viscose, or triacetate; e.g. on viscose, triacetate with azo print or print with cationic dye. Dry the print, steam for 30 minutes using wet steam, treat with hydrophilic polymers (e.g. polyacrylate) for 5–10 minutes. Rinse and dry.

Flushing of prints in roller printing A defect caused by print paste being pressed out of the engraved areas of a printing roller. It can be due to the lapping of the printing cylinder and the back grey being too hard, i.e. lack of a resilient printing surface, or when the depth of engraving and scale of engraving are not suitable for the particular fabric being printed.

Fly Unwanted loose fibres on a textile material. It is caused by the attraction of fibre dust (mainly as a result of electrostatic attraction).

Fly catchers Devices used to clean fibre dust, fly, loose pieces of yarn, etc. from machinery in order to prevent possible malfunctions due to their accumulation which could impair machine functional performance. Manual or electrically-operated fly catchers are available.

Fly dropping spots Typical round, dark grey to black spots. Removal: a) fatty alcohol sulphate solution with 5% ammonia (warm), with 20% sodium tetraborate for silk; b) petrol or concentrated solvent soap (with alcohol) possibly warm, repeated application; c) alcohol/ammonia 10–15:1 (warm) or 20% alcohol/sodium tetraborate solution (particularly for coloured silks); d) fatty alcohol sulphate/detergent (neutral) warm. Any residue, 5% ammonia.

Fly spotting → Fly dropping spots

Fm, chemical symbol for fermium (100).

FNA (Ger.), abbrev. for: Fachnormenausschuß (Technical Standards Committee) in the → Technical and professional organizations.

FNM (Ger.), abbrev. for: Fachnormenausschuß

Materialprüfung (Technical Standards Committee for Material Testing) in the → Technical and professional organizations.

Foam Foams are microheterogeneous colloidal systems in which gases are distributed within a liquid or solid dispersing agent. When air is passed through a surfactant solution the surfactant is adsorbed on the surface of the bubbles to form a film. As the bubbles break through the liquid/air interface, a double film is formed, i.e. a foam lamella consisting of two monomolecular films of surfactant and the interlamellar liquid. The accumulation and reciprocal contact of the bubbles in the liquid also plays a part in this film formation process. When solutions of substances with low surface activity are used for the generation of foam, e.g. short-chain alcohols or acids (e.g. humic acids in waste waters as direct pollutants in biological waste water treatment plants) foams are formed which are often only stable for a few seconds. Foams with considerably longer stability are produced with substances which cause a considerable decrease in the surface tension of water (e.g. soaps, non-ionic, cationic and amphoteric surfactants). Thermodynamically, foams are unstable systems as they have a higher free surface-energy potential than the starting materials (liquid and air) from which they are formed. Consequently, all foams have a tendency to decompose and are therefore unstable or, at best, metastable.

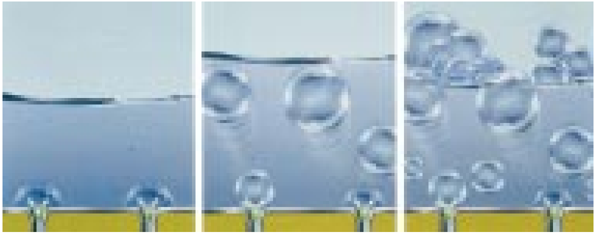


Fig.: Foam.

At the air/water interface of air bubbles in water produced by mechanical action the surfactant molecules accumulate in such a way that, depending on their structure, the hydrophilic part is aligned in the water phase and the hydrophobic part in the air phase. When a concentrated assembly or accumulation of such discrete bubbles are present in a liquid a spherical foam exists. By contrast, a polyhedron foam is an aggregation of polyhedron-shaped bubbles which have lost autonomous existence. Polyhedron foam may be formed through drainage of the interlamellar liquid from a spheroid foam. The thickness of the liquid lamellae is approx. 500 nm, and the “isolated” spherical foam is considerably less stable than the connected polyhedron foam. Metastable foams are characterized by the fact that, after a certain time, the liquid ceases to drain and a metastable structure comes into being. This state is achieved by retarding the thinning of the lamellae so that bursting of the bubbles is delayed. In many cases foam formation causes problems in dyeing and finishing processes and the foam must be destroyed or prevented from forming. On the positive side, dyeing and finishing baths can be foamed in order to achieve a low wet pick-up of dyes, auxiliaries and finishing agents. → Foam application.

Foam application Processes used for the → Low wet pick-up of concentrated foamed finishing liquors, especially for wash and wear finishes on textile fabrics with a possible pick-up of 40% and mainly between 10–20%. Foamed liquors are applied to the textile directly then brought to the desired thickness by means of squeeze rollers or a knife coater, e.g. two-sided foam application in a horizontal 2-bowl padder, one-sided application to carpets, foam application with an air-roll squeegee.

The foamed liquors must be stable for a limited time appropriate to the application method selected. From this it follows that metastable polyhedron foam must be tailor-made for the selected application method. The following foam properties are required for continuous finishing:

- uniformly homogeneous foam,
- variable blow ratio,
- low foam stability (foam decay half-life period),
- rapid breakdown of foam on contact with the textile substrate.

The two media water and foam differ greatly from each other as far as handling is concerned so that new application techniques are necessary for finishing with foamed liquors. Compared to conventional finishing with aqueous solutions it has been found that, despite its different nature, the application technique involving foamed liquors can be smoothly integrated into existing processing operations.

Foam application is characterized as follows:

1. Foaming agent: surfactants developed for the production of foamed liquors allow the generation of tailor-made foams suited to the application method and the substrate.

2. Continuous generation of foam by mechanical means: mechanical foaming of the finishing liquor (resin finishing agent and foaming agent) is achieved continuously by means of typical commercially available mixer. The actual foam is generated in a so-called mixing head by mixing liquor and air. In order to ensure a constant blow ratio, the mixer is designed in such a way that the quantity of air is synchronized with the output of foamed liquor. The generated foam is then delivered to the foam application system.

3. Application methods: in principle, two methods are possible for the application of foamed liquor to a textile material, i.e. direct and indirect foam applica-

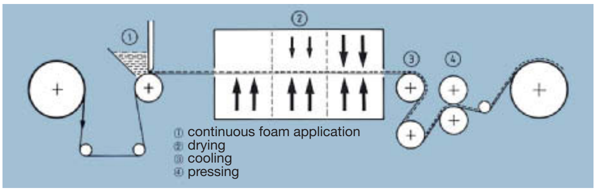

Fig. 1: Doctor knife on roller foam application; subsequent drying.

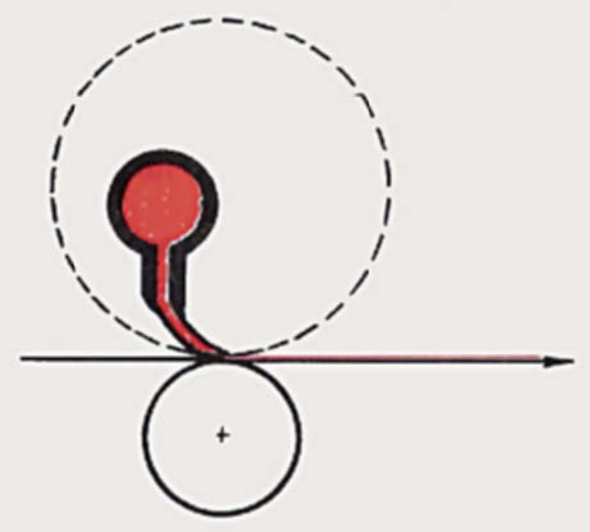

Fig. 2: Foam application by means of rotary screen and internal nip squeegee.

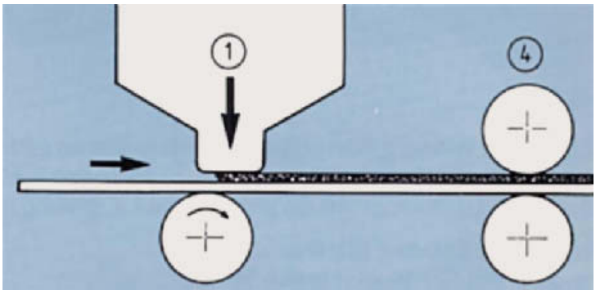

Fig. 3: Foam application by pouring (slot squeegee 1) followed by nip padder (4).

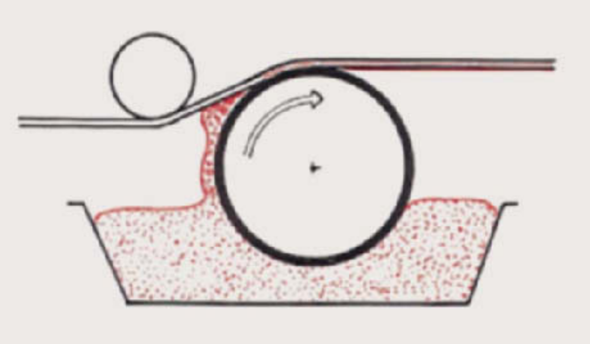

Fig. 4: Foam application by slop padding technology.

tion. With direct application, the total amount of generated foam is brought into contact with the textile material so that reproducibility of the finish is only guaranteed for a specific running speed, a constant blow ratio and a constant quantity of foam since the metastable foam applied is drained by release of the interlamellar liquid. This release of liquid is accelerated by contact with the textile material so that any change in fabric running speed and/or the quantity of foam supplied to the textile results in a different liquor pick-up. In the case of indirect foam application, i.e. the supply of a specific quantity of foam to the textile material, liquor pick-up is independent of the production speed. The following methods are available for the application of foamed liquors to textile fabrics:

- The fabric to be foam finished is guided over a roller in such a way that a blade or knife is positioned over the upper crown of the roller and out of contact with the fabric. By this means foamed liquor is fed to the fabric in amounts determined by the height of the gap between the knife edge and the fabric surface (Fig. 1).
- This method can be modified by applying the foamed liquor from a rotary screen in which all the perforations are open using a double squeegee (Fig. 2).
- Foam can also be applied to carpets through a slotted hopper across the entire width. The foam height is precisely defined by passage through a padder with a pre-set gap between the rollers (Fig. 3).
- Slop padding is also employed as a foam application technique (Fig. 4).
- Finally, foam may be applied between the nip of a horizontal padder (Fig. 5).

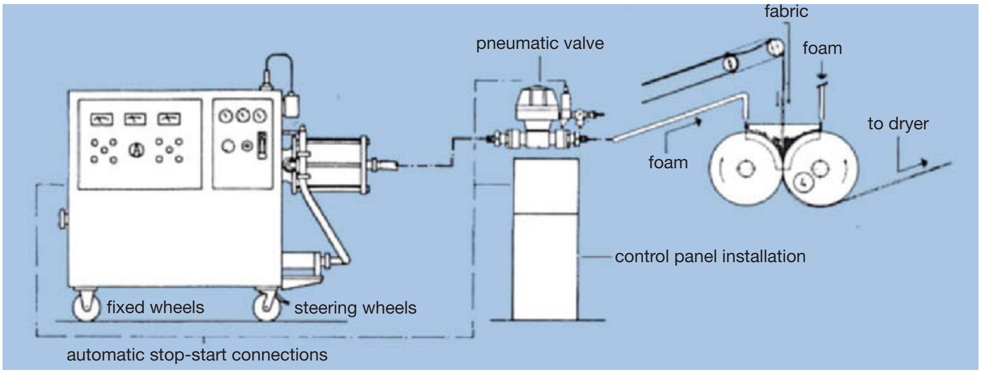

Fig. 5: Foam dosing on a nip padder.

Foam as a source of problems in textile wet processing The following problems can arise in textile wet processing:
- insufficient liquor uptake in padding processes,
- uneven liquor distribution in the textile material,
- formation of stains (inadequate processing treatment, deposition of "dye foam"),
- liquor channeling in yarn packages,
- bursting of yarn packages,
- blockage of machine functions (pumps, rollers),
- malfunction of metering and measuring devices.

The formation of unwanted foam in aqueous solutions is always dependent on two prerequisites:

1. The surface tension between air and water must be lowered (by surfactant action).

2. Air must be entrained in the liquor by mechanical action, i.e. below the surface of the liquor.

Foam does not result from the surfactant alone and is only formed in combination with mechanical influences. The following factors can be responsible for the formation of unwanted foam:
- high production machines (e.g. continuous plants),
- inappropriate impregnation baths (e.g. with a high degree of air contact),
- pumps and liquor circulation systems (e.g. jet dyeing machines),
- "open" fabrics with a high content of air,
- textile contaminants containing emulsifiers (e.g. spinning preparations),
- saponification of natural impurities (e.g. fats, waxes),
- dispersing agents released in wet processing (e.g. from dyestuffs),
- incorrect or excessive amounts of surfactants,
- foam-stabilizing substances.

A high degree of mechanical action is also co-responsible for unwanted foam, i.e.:
- high fabric running speeds,
- high liquor throughput,
- high package densities in yarn package preparation,
- reduced treatment times,
- savings in water consumption (use of short liquor ratios).

It is for these reasons that highly efficient surfactants are required which do not lead to the production of unwanted foam (low-foaming surfactants). A higher degree of activity is thus expected at the textile/liquor resp. soil/liquor interfaces, i.e. the surfactant should be ineffective at the "critical point" of the air/liquor interface.

Foam backing → Back coating of carpets.

Foam breaker →: Defoamer; Antifoams; Drycleaning antifoams.

Foam cleaning Process for cleaning carpets and upholstery materials without complete wetting (so-called shampooing method). The open-structured foam applied to these materials by shampooing emulsifies and disperses the particles of soil adhering to the surface so that they may be easily wiped, brushed or suctioned off again. → Shampoos.

Foam coating The process can be carried out on certain foam application machines. A foam coating system (see Fig.) consists of the following elements: mixer for mixing the compound with the required volume of air, roll-coater, drying unit, pressing cylinder, kiss-roll or padder, and curing oven.

Foam decay Occurs by self-drainage of a foamed liquid. The self-drainage rate (collapse rate) of a foam can be established by determination of the → Foam decay half-life period.

Foam decay half-life period The most widely used and technically simplest method of determining the stability of a foam is measurement of the half-life

Fig.: Stork foam coating.
1 = air inlet; 2 = foam generator; 3 = pump; 4 = microprocessor; 5 = doctor roll; 6 = screen; 7 = operating panel; 8 = bypass.

period of the foam. The time recorded is that required for one half of the liquid in the initial foam to separate from the foam by self-drainage. → Foam evaluation criteria.

Foam degumming A process for the → Degumming of natural silk under mild conditions. Instead of immersing hanks of yarn in the soap bath they are suspended in the soap foam produced by the introduction of live steam into the bath.

Foam density The foam density is calculated according to the formula:

$$\frac{\text{volume of solution consumed foam density}}{\text{volume of foam}}$$

Foam drainage on textile contact This property of a foamed liquid is influenced by several factors, e.g. the → Blow ratio, → Foam decay half-life period (→ Foam performance evaluation), the surfactant combination used to produce the foam and the state of the textile material. In order to evaluate this property of foam a specified quantity of foam is placed on an absorbent cotton test fabric in a tray of defined diameter. The percentual surface enlargement serves as a measure according to the formula:

$$\text{increase in area } [\%] = \frac{D^2 \cdot 100}{d^2}$$

D = diameter of the wetted area after x seconds,
d = diameter of the area of applied foam.

The "wetting power" of the foam must be different depending on the particular application of the foam (dyeing, printing, finishing).

Foam dyeing Dyeing processes based on the use of finely porous foam either as a dyeing medium itself or as a dye carrier. Foam dyeing can be carried out by exhaust and continuous methods. Foaming of the dye liquor serves to increase the liquor volume and is hindered by the presence of electrolytes.

Foam dyeing and finishing units These consist of a foam generator with a foam delivery system, foam applicator, and monitoring device for automatic process control. Advantages: up to 80% savings in water and chemicals, no migration problems (the fabric is almost dry immediately after application), wet-on-wet treatments saving an intermediate drying process are possible. Because of the very low tension and pressure involved, sensitive fabrics can be processed without distortion.

Foamed nonwoven These are three-dimensionally-oriented → Nonwovens based on a synthetic foam with an approx. 50% microcell structure. They are produced in several strengths mainly by synthetic resin impregnation (insensitive to water/moisture). Foam-sandwich nonwovens have been developed to replace the least stressed part of glass fibre reinforced polyester sandwich constructions (higher flexing resistance with greater strength; lower costs compared to full glass laminates with the same flexing resistance; lower specific gravity of the sandwich construction; higher compressive strength). This kind of nonwoven bonded fabric is chiefly used as a composite material for containers, large pipes, flanges, etc. These materials have good resistance to chemicals such as acids, alkalis and nonpolar solvents; they are less resistant to polar solvents, esters, ketones and halogenated hydrocarbons.

Foam evaluation criteria → Foam performance evaluation.

Foam extinguishers Fire extinguishers which mostly contain two separate solutions: a) sodium hydroxide solution and foam-generating additives such as saponine, sulphonated oils and b) mostly acidic-reacting aluminium sulphate solution. When required for use, both solutions are mixed by inverting the fire extinguisher which causes the immediate formation of a light foam with fine bubbles (large quantities of foam from a few litres of liquid). This foam is then directed on to the fire through a connecting tube or hose. Applications: widely used for factory, laboratory, gasoline and garage fires, etc.

Foam finishing technology (FFT technology). A foam application process developed by Union Carbide Corp. and propagated (machine-wise) by Gaston County in which precisely metered quantities of foamed chemicals, etc., are applied to a textile substrate. Penetration of the porous textile fabric by foam results in a uniform distribution of the conc. solution of chemicals at a minimum liquor pick-up of approx. 10%. Migration problems are also eliminated at the same time. The applied foam breaks immediately on contact with the fabric. Foam density is below 0,2 g/cm^3. In contrast to padder applications, the liquor pick-up can be considerably reduced to 10–25% of the fabric weight with this process. Since the greatest part of the water required in conventional padder applications is substituted by air in this process, energy consumption in subsequent drying is also reduced. The precise, independent and automatically controlled volumes of air and highly conc. liquor applied directly to the fabric are the distinctive features of the FFT process in comparison with other foam application systems. The FFT process is particularly suitable for the application of wash and wear finishes. →: Minimum pick-up; Foam application.

Foam formation

I. Unwanted formation of → Foam during wet processing operations. Causes problems in dyeing and printing, etc. and should be prevented. See → Foam as a source of problems in textile wet processing.

II. Foam formation as a desired effect for applications in dyeing and finishing. When solutions of substances with low surface activity are used for foam generation (e.g. short-chain alcohols or acids), the resultant foam is often only stable for a few seconds. Foams with considerably greater stability are produced with substances capable of causing a considerable reduction in the surface tension of water (e.g. soaps, non-ionic, cationic and amphoteric surfactants). → Foam application.

Foam generators Since the end of the 1960's, foam technology has been adopted by the carpet industry for the application of latex compounds in foam backing. Nowadays, foam technology represents an important technique in the carpet and textile industries for various stages of finishing. Compared to liquid compounds, processes based on foam technology allow the volume of application to be increased for the same weight of compound. These conditions ensure high accuracy of application and facilitate e.g. the precise adjustment of product penetration into the carpet backing. The high and varied demands placed on these foams, which are not only used in the carpet industry, call for mixer concepts which can be adapted to the actual operating conditions as far as performance and control are concerned.

The quality of the foamed compounds stands or falls on the quality of air dosing. The smallest fluctuations in air content will change the litre weight of the foam and consequently reduce the quality of the end product. It is therefore necessary to apply a very rapid air measurement with a high degree of linearity. A block diagram illustrating the principle of air control is presented in Fig. 1. Measurement of the flow rate of the compound is of great importance for the control system of a high quality foam mixing system since the actual values detected for the product form the basis for the air quantity control system which further processes this value into the control target value. In Fig. 2, the combined action of both control systems is explained. With the aid of such combined control systems, a predetermined foam litre weight is constantly maintained under different production conditions.

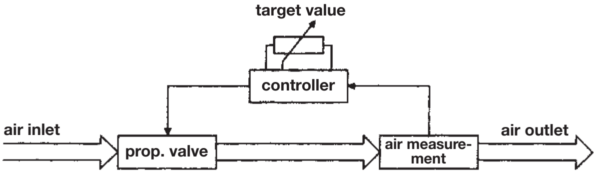

Fig. 1: Block diagram illustrating the principle of an air control system (Wolfgang Groth).

Very exacting requirements are placed on the seals of a foam mixing system. Double-action axial face seals have become established for handling aggressive materials. Individual adaptation to the medium being sealed is achieved by an appropriate pairing of the axial face surfaces. In the carpet industry, hard axial surfaces are used mostly on the product side, e.g. tungsten carbide/tungsten carbide, which have given the best results with highly filled materials. On the atmosphere side, soft seal surfaces are used, e.g. silicon carbide/carbon. Double-action axial face seals provided with a pressure retaining cooling system represent the optimum in the field of shaft seals for foam generating systems.

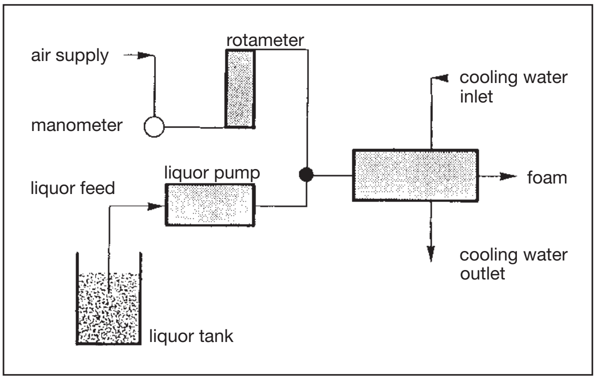

Fig. 2: Foam generator (flow diagram).

Apart from simple operating features, foam generators should be designed for easy cleaning and maintenance since problem-free production can, of course, only proceed if the necessary cleaning and maintenance work is executed quickly and easily. Modern foam generating systems are accommodated in a glass-blasted stainless steel housing, the extremely fine-pored surface of which is effective in preventing deep penetration and adhesion of soil particles. Environmentally-friendly cleaning may be carried out with conventional detergents. The short cleaning process reduces the consumption of water and detergents. The maintenance of foam generating systems has been reduced to a minimum and is limited mainly to topping up the pressure retaining tank and the routine checking of connections (source: Conrad).

Foam generators are of two types, static and dynamic. In static mixers (Fig. 3), air and liquor are brought into contact with each other in a mixing head containing glass beads or Raschig rings. In order to produce a homogeneous foam, the surfactant solution is distributed over the largest possible surface area so that the interface with the incoming air is increased. In this way, the entire surfactant solution is foamed over a selected unit of time to give the desired degree of foaming by the injection of an appropriate amount of air.

The mixing of air and surfactant solution may also be carried out in a dispersion turbine (Fig. 4), which is still based on the same physical principles, although the

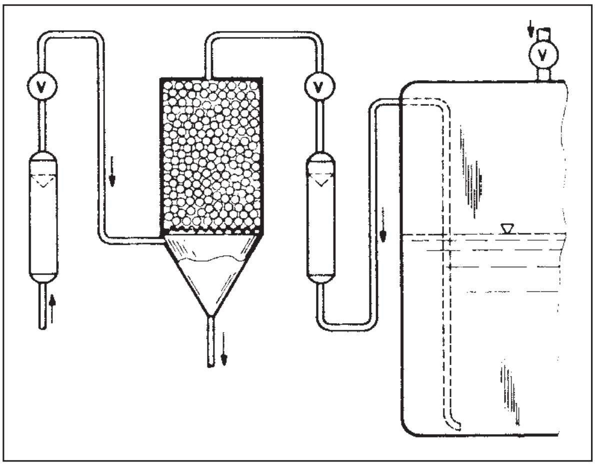

Fig. 3: Schematic representation of foam generation based on the principle of a static mixer.

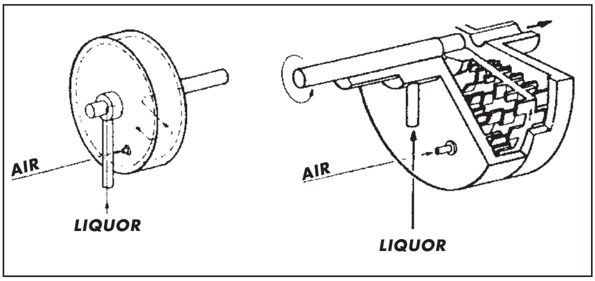

Fig. 4: Schematic representation of a dispersion turbine for foam generation.

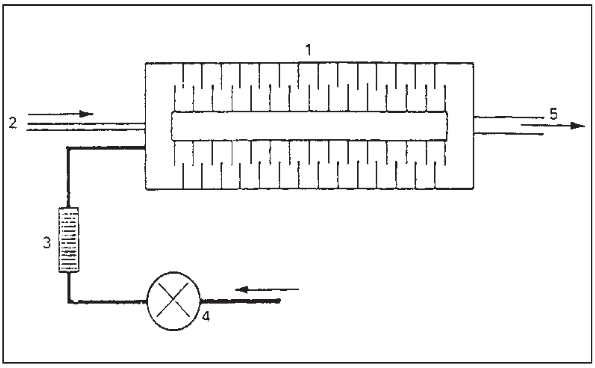

Fig. 5: Dynamic mixer.
1 = rotor/stator in mixing head; 2 = compound; 3 = air flow meter; 4 = air pressure meter; 5 = ready made foam.

size of the unit is somewhat reduced, the ease of cleaning is improved and the system possibly offers more constant conditions.

A dynamic mixer consists of a stator and a rotor (Fig. 5). This system provides control of foam supply quantity, air dosing and gelling agent quantities according to the speeds of the coating plant. These computer-assisted systems represent the present state-of-the-art.

Measuring and control equipment for foam generation is also available. For the supply of coating compound in front of the squeegee, a measuring and control system is available (Fig. 6) which is designed for installation at the coating plant. This system offers the possibility to measure the quantity of coating compound supplied to the squeegee continuously and to control the height of the squeegee by means of a geared motor and/or the supply of coating compound via a standard signal at the mixer. The effects achieved with this measurement and control unit are revealed by the more constant and uniform feed quantity and, above all, by a greater uniformity of the coating thickness.

Foaming The foaming of surfactants is always associated with their desirable properties such as wetting, dispersing or emulsifying. → Foam.

Foaming backing The application of foamed compositions to textile fabrics by bonding or laminating. → Carpet back coating.

Foaming capacity The ability to form an air bubble enveloped by a double film of surfactant. → Foaming power.

Foaming power The capacity of a product to form → Foam. Calculation:

$$\frac{\text{volume of foam}}{\text{volume of solution used}}$$

The ratio of the volume of foam of a sample to the volume of foam of a sodium oleate solution which has been allowed to stand for 1 min is used as a comparative measure of foaming power.

Foaming power of surfactants In the case of non-ionic surfactants the foaming propensity increases with rising ethylene oxide content. Foaming is most pronounced with anionic surfactants having good water solubility. Mixed surfactants have a medium foaming propensity. The foam formation of most non-ionic surfactants foam varies only a little over a wide concentration range compared to the enormous changes in their wetting, dispersing and emulsifying power. With non-ionic surfactants the influence of temperature on the foaming of surfactant solutions at elevated temperatures can be seen. The addition of an electrolyte to a surfactant liquor, e.g. 5 g/l sodium sulphate, causes a distinct lowering of the foaming propensity only in the case of alkylphenol ethoxylates and not with the corresponding oxo alcohol derivatives. With anionic surfactants the influence is non-uniform: the addition of electrolyte appears to exercise more of a foam intensifying influence, whilst the dependence of foaming propensity on temperature is only slight. Non-ionic surfactants with a low degree of ethoxylation produce an even lower amount of foam with addition of electrolytes and temperature changes. Pure anionic surfactants, on the other hand, are among the most highly foaming and difficuluence products. From the foaming point of view, therefore, non-ionic surfactants with a low degree of ethoxylation are to be recommended. Their use is also well-established in practice but only in cases where their electrolyte stability is sufficient to meet requirements. Unfortunately, however, their efficacy or stability is inadequate for the majority of textile wet processing applications so that surfactants with a higher foaming propensity have to be used.

Foam problems and consequent disruptions in processing are only caused by surfactant liquors with foam half-life decay periods which are (significantly) lower than their foam build-up rates. For this reason, a surfactant which foams readily, the foam from which quickly collapses again outside the turbulence zone, can present less problems in practice than a less highly foaming surfactant which produces a stable (tenacious) foam. The foam may indeed build-up slowly but keeps on doing so (until it reaches a level at which it causes disruptions in processing). In order to investigate this problem as well, e.g. in continuous pretreatment, it is necessary to observe not only the absolute level of foam but also the extent of foam collapse which takes place after foam formation. Thus measurements are taken not only of the foam level directly at the end of mechanical actions but also after 30, 60 and 120 s, and even after 3–5 min. → Foam performance evaluation.

Foam inhibitors Substances capable of preventing excessive foaming of wash liquors in washing machines which would otherwise reduce the mechanical washing action and consequently impair washing efficiency. Suitable compounds include, in particular, long-chain soaps (behenates) as well as amine oxides and silicones. An essential prerequisite for the foam regulating action of a substance is a high degree of water insolubility and a high surface spreading pressure. Displacement of surfactant molecules from the liquid/air interface or penetration of the liquid/air interface occupied by surfactant molecules thereby producing disruptions which weaken the mechanical strength of → Foam lamellae causing breakdown of the latter may explain the action of foam regulators. Soaps with a wide chain-length spectrum and silicone oil systems have largely established themselves for these applications. → Foam regulators for wash liquors.

Foam intensifier A substance used to increase the → Foaming power of surfactants.

Foam lamellae Liquid interfaces between individual bubbles of → Foam. Foam is therefore said to possess a “lamellar structure”. Due to capillary action in foam lamellae strong attraction forces for soil particles are released, as a result of which the latter are loosened (by mechanical action such as liquor movement, friction, pressure and squeezing) and removed from the fibre surface. The foam lamellae contain a film of liquid between the surface pellicule layers which consist of a monomolecular surfactant film, i.e. so-called interlamellar liquid.

Foam laminated textiles These are defined in DIN 60 000 as laminates of textile fabrics and sheets of foam. Garments produced from such materials offer increased protection against weather and cold, and are particularly suitable for fashionwear, sportswear and workwear. Such garments are lighter in weight than fur garments. An essential requirement is resistance to washing and drycleaning.

Foam laminates → Foam laminated textiles.

Foam latex Alternative term for → Foam rubber.

Foam latex coating of tufted carpets → Backcoating of carpets.

Foam mixing units Used for foaming latex, polyvinyl chloride, acrylic and polyurethane dispersions for coating and laminating. Foam mixing units capable of faultless operation are a prerequisite for optimum quality and cost-effective latex foam coatings. High performance foam mixing units provide continuous adjustment (variance comparison) of foam weight per litre, compound density, mixing capacity and gelling agent quantities in relation to changes such as the machine running speed. The weight per litre of the foam is also displayed continuously.

Foam padder The Fig. illustrates a foam dyeing unit for carpets which does not require a foam generator. A dye liquor is applied to the carpet pile with the aid of a kiss-roll and subsequently foamed *in situ* by

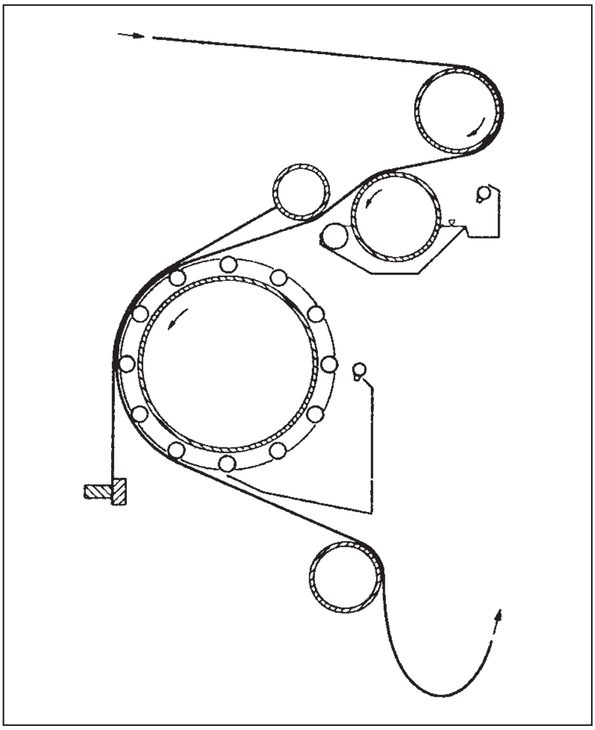

Fig.: Foam production on the fabric by bar rotor in a carpet foam dyeing unit (Fleissner).

mechanical action on passing between a rotating cylinder of rods and a pressure plate at the back of the carpet.

Foam performance evaluation Test methods for the evaluation of foam properties are important in terms of their application in the textile sector. The requirements placed on foam properties in textile finishing processes are given in the Table.

	Field of application	
Criteria	Finishing/dyeing	direct print
Homogeneity of the foam	regular	regular
Degree of foaming	variable	high
Foam stability (foam disintegration half-life)	slight	great
Dehydration of the foam upon contact with the textile	fast	fast

Table: Profile of requirements for foams used in textile applications.

The degree of foaming is the ratio of the starting liquor to the dispersed air in the foam. It plays an important part in foam application since it helps to determine the liquor uptake. The following parameters are possible:

$$\text{Volume ratio} = \frac{\text{Volume of liquor}}{\text{Volume of foam}}$$

$$\begin{array}{l}\text{Ratio of weight}\\ \text{with constant volumes}\end{array} = \frac{\text{Weight of liquor}}{\text{Weight of foam}}$$

$$\text{Foam density} = \frac{\text{g foam}}{\text{cm}^3}$$

$$\text{Foam litre weight} = \frac{\text{g foam}}{\text{l}}$$

The foam weight per litre is determined by calibrating a beaker at 1 litre volume, taring the beaker, filling it to the mark with foam and weighing. For the liquid/air mix ratio, the density of the foam must also be taken into account. If this is $\neq 1$, a correction must be made to the liquor or air supply in order to achieve the desired degree of foaming.

The rate of self-drainage of a foam is determined by the half-life period of decay. The time recorded is that required for one half of the liquid in the initial foam to separate from the foam by self-drainage. For a given foam volume and foam density (S_s), the half quantity of liquid may be calculated as follows where the density of the liquid is $S_F = 1$.

$$V_f = \frac{V_s \cdot S_s}{2\,S_f}$$

V_s = foam volume; S_s = foam density;
S_f = liquid density; V_f = liquid volume.

The more quickly the syneresis (self-drainage) of a foam is completed, the shorter the half-life period of decay (HPD). The drop emergence time (DET) test method is of particular interest in cases where small quantities of liquid have a disruptive effect in foam application. With this method, the point at which drainage of the foam begins can be determined. The drop emergence time provides an indication of the time at which the first drop of liquid flows out of the foam. This determination can be carried out at the same time as the test for HPD in an Imhoff funnel. The more quickly the formation of the first drop occurs, the more unstable the foam.

Another method of characterizing foam collapse measures the time-related re-formation of liquid (kinetics of foam collapse). In this test, a constant foam volume is placed in a funnel which is then covered with a plane glass sheet, and the emerging liquid is measured at discrete intervals of time. The increase in weight is recorded and a graph illustrating the dependence of weight increase on time is plotted. The resultant curves are evaluated as follows: the steeper the gradient, the more unstable the foam (Fig. 1).

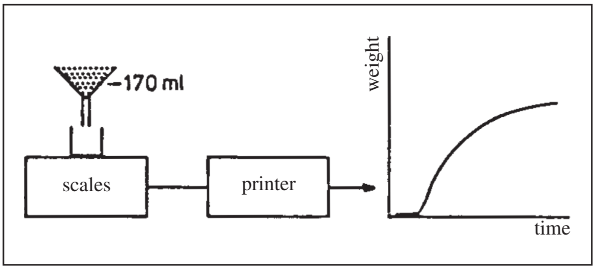

Fig. 1: Method for the determination of foam drainage kinetics.

The drainage of a foam on contact with a textile substrate is dependent on the type of fabric (nature of fibre, fabric construction) in addition to the properties of the foam itself (e.g. degree of foaming, drainage characteristics). This foam characteristic is tested by placing a beaker with a specified diameter filled with foam upside down on the test fabric (ideally this should be the same as the material to be used). The wetted area of the material is determined after a specified time. The measurement parameter here is the percentual growth in wetted surface area which may be calculated as follows (Fig. 2):

$$\text{surface increase [\%]} = \frac{D^2 \cdot 100}{d^2}$$

D = ∅ of the wetted surface after x seconds
d = ∅ of the beaker

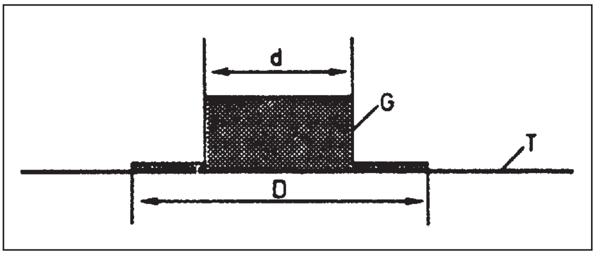

Fig. 2: Method for the determination of foam drainage on contact with the substrate.
d = diameter of the glass beaker; D = diameter of the wetted surface; G = glass beaker with foam; T = textile.

The rheological behaviour of metastable foams is characterized by their pseudoplastic flow, whereby apparent thixotropy or rheopexy can also occur. For the measurement of viscosity, rotary viscometers are used and the following three measurement procedures are recommended:

1. Viscosity measurement with a constant shear gradient D as a function of time t.

2. Viscosity measurement with several specific shear gradients. For this purpose, the speed of the rotating device is increased by degrees, in the process of which the reaction times of the individual shear gradients should be identical.

3. Viscosity measurement with a continuously increasing speed of the rotating device. Both the influence of the increasing shear gradient as well as the time are determined by this means.

The determination of this foam property is of particular interest in foam printing. Evaluation is based on the flow or viscosity curves obtained.

The bubble size provides information on the homogeneity and stability of foams. Fine foams are more stable than coarse. For textile applications, the foam bubbles should be small and uniform (optimum size range 50–100 µm). The bubble size is determined objectively by microphotography. It can also be carried out subjectively by visual evaluation.

Besides the characterization of an existing foam, foaming kinetics can also be of interest to the textile finisher. To this end, the methods of foam formation as well as the measurement procedures of foaming kinetics are subdivided into static and dynamic procedures.

a) Static procedures include those in which
– the air supply is introduced at the bottom of the solution,
– the air supply is produced by manual or mechanical agitation or,
– the air supply is discharged through the solution.

The modified Ross-Miles method (Fig. 3) as specified in DIN 53 902, Part 2 is an example of such a procedure. With this method, the discharge time and foam height of a surfactant solution are measured 30 s, 3 and 5 min after the free outflow of 500 ml water with a hardness corresponding to a calcium carbonate content of 300 mg/kg from a specified height above the liquid surface of the same solution.

Another method is the perforated disc beating procedure in accordance with DIN 53 902, Part 1: in this case, the foam is produced by beating the surfactant liquor in a glass cylinder for 30 s with the aid of a perforated plate attached to a pillar (Fig. 4).

b) Dynamic methods include those in which the air supply is provided by continuous pumping (Fig. 5) or by a stream of the solution. The advantage of these methods is that the speed of circulation, fall height and temperature of the liquors can be varied

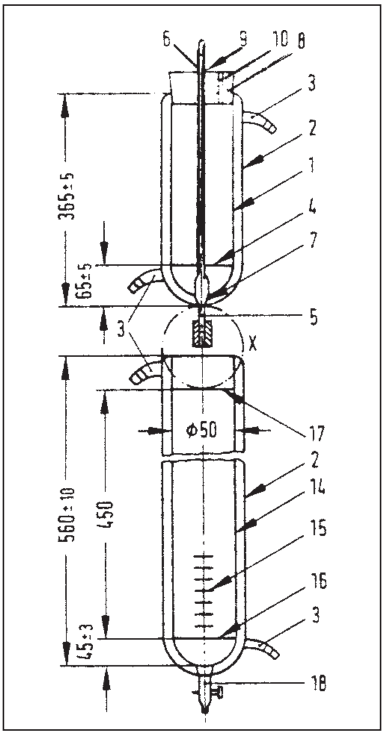

Fig. 3: Modified Ross-Miles apparatus.

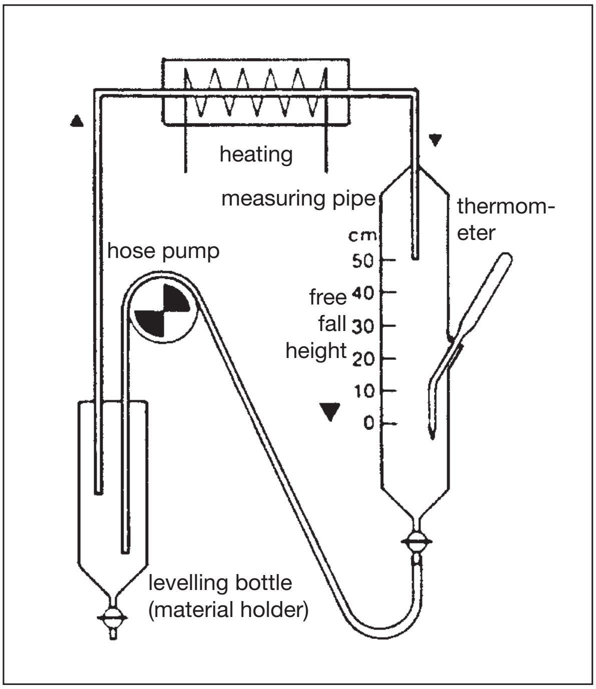

Fig. 5: Foam apparatus for dynamic foam measurement.

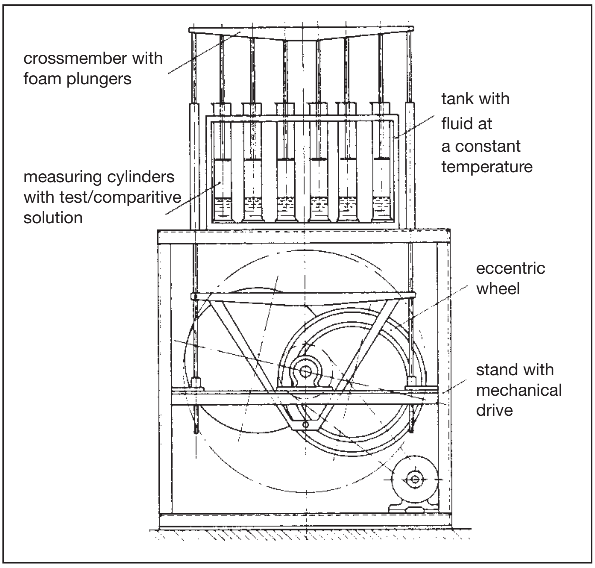

Fig. 4: Schematic representation of an apparatus for the uniform production of foam in several measuring cylinders (DIN 53 902, Part 1).

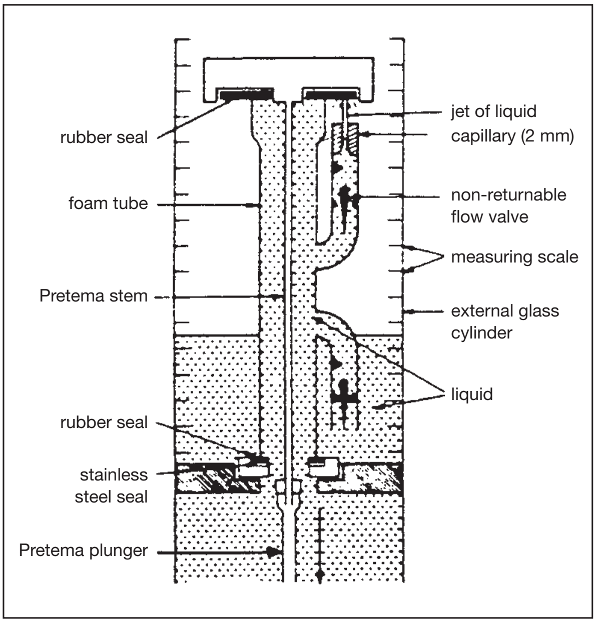

Fig. 6: Schematic representation of the glass foam tube.

and therefore adapted to the conditions encountered in practice.

In the case of one dynamic foam test method of Derbyshire and Leaver (Imperial Chemical Industries Ltd., Manchester), a development based on the use of a modified Pretema Multicolor dyeing machine, Ellner system, manufactured by Pretema AG, is involved. The usual material carriers for dyeing in this machine have been replaced by a glass tube with two valves (Fig. 6). As a result of the up and down movement of the glass tube in the liquor, turbulence is created in the liquor which allows the introduction of air. By this means, information on the kinetics of foam development which are dependent on the concentration of surfactant (Fig. 7) or the temperature is obtained (Fig. 8).

The VSI foam testing apparatus is a joint development of the firm “Haake-Meß-Technik” in Karlsruhe, Germany, and the German Verband Schmierfett-Indu-

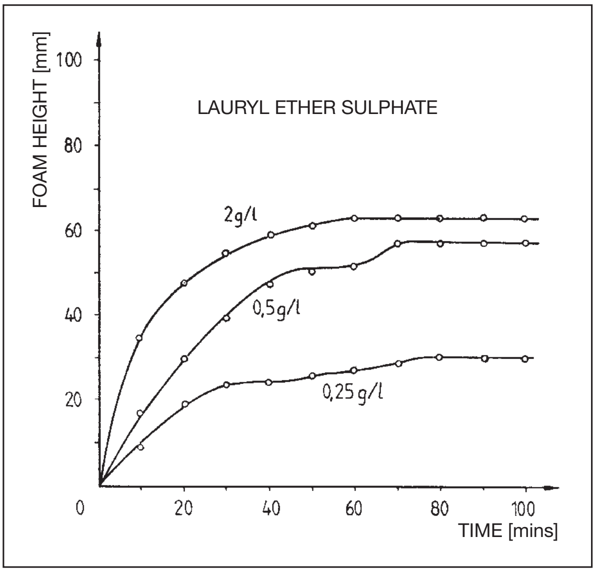

Fig. 7: Dynamic foam test on lauryl ether sulphate (dependence on time and influence of surfactant concentration).

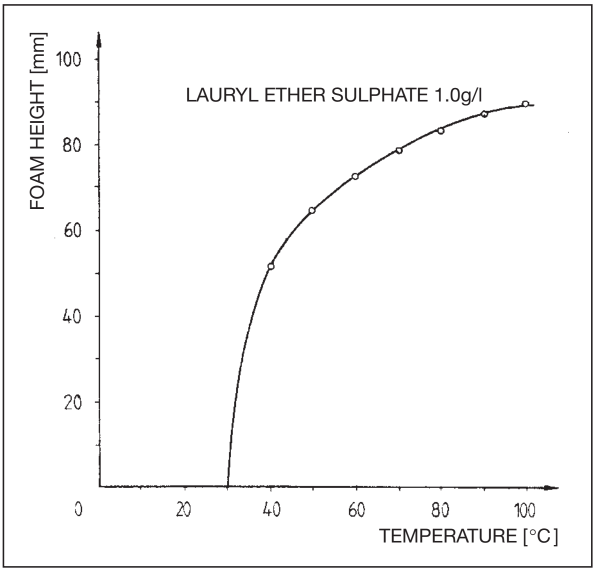

Fig. 8: Dynamic foam test on lauryl ether sulphate (dependence on temperature).

strie e.V. (German Association of the Lubricants Industry). It was developed for controlling the foam resp. foaming behaviour of water-miscible coolants and cutting fluids used in the engineering industry. With this method, the test substance is subjected to specified mixing and showering phases whereby the speed of foam formation as well as the rate of foam collapse are determined. The apparatus (Fig. 9) measures the volume of foam as well as the speed of foam formation and collapse in a vertical cylindrical glass tube in which the test liquid is sprayed perpendicularly downwards under pressure from a shower head on to a baffle plate which causes air to be carried along with it thereby producing foam. The foam rising in the cylindrical tube makes contact with three sensors positioned at different predetermined heights, one after the other, which transmit a measurement signal on foam contact. These signals are recorded dependent on time. Adjustable test parameters of the foam testing apparatus include: the feed pressure (0.5–1.5 bar), the positions of the individual three sensors above the level of the liquid and the target temperature of the test liquid within the limits of 10–60°C by means of a low-temperature thermostat.

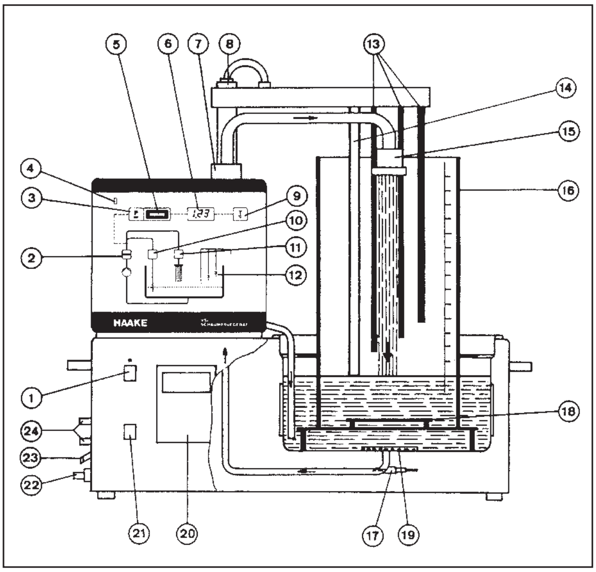

Fig. 9: VSI foam test apparatus (Haake).

14 = liquid level marker; 15 = shower head unit; 16 = glass cylinder; 17 = temperature sensor; 18 = baffle plate;
19 = outflow sieve; 20 = printer; 21 = printer switch;
22 = drain nozzle; 23 = drain valve tumbler switch;
24 = temperature equalizing connections.

Test procedure:

- the stainless steel tank is filled with 5 l of test liquid;
- the test liquid is conditioned, i.e. the test liquid is thoroughly mixed by recirculation and the liquid temperature is brought into line with the required test temperature at the same time;
- measurement of foam formation (showering) and foam collapse.

The measurement values are detected by the 3 sensors positioned in the shower zone. When an electroconductive foam forms during the showering stage and contact is made with sensors 1–3 one after the other, an electric circuit (sensor – apparatus housing – test liquid – foam) is closed on each occasion. By this means, a gradually rising voltage level measurement signal is generated. In addition, the measuring times t_{01} to t_{23} are determined. During foam collapse, the foam detaches itself from the sensors one after the other thereby disconnecting the corresponding electrical circuits in turn. The times t_{43} to t_{21} are measured and the voltage level measurement signal is reduced by stages.

Test results:

a) foam formation:
  - t_{01} = time taken for the foam to rise to the 1st sensor.
  - t_{12} = time taken for the foam to rise from the 1st to the 2nd sensor.
  - t_{23} = time taken for the foam to rise from the 2nd to the 3rd sensor.

b) foam collapse:
  - t_{43} = time taken for the foam to lose contact with the 3rd sensor after switching off the feed pump.
  - t_{32} = time taken for the foam to lose contact with the 2nd sensor (O_S = loss of contact with 3rd sensor).
  - t_{21} = time taken for the foam to lose contact with the 1st sensor (O_S = loss of contact with 2nd sensor).

Another type of foam testing apparatus analyzes the foam height at 3 points with the aid of sensors. The essential feature of this apparatus is the continuous foam test both during foam formation and foam decay. This is accomplished by means of a light metal plate which is supported by the foam and a polyamide thread connected to a counterweight via a gauge for measuring the angle of rotation (Fig. 10).

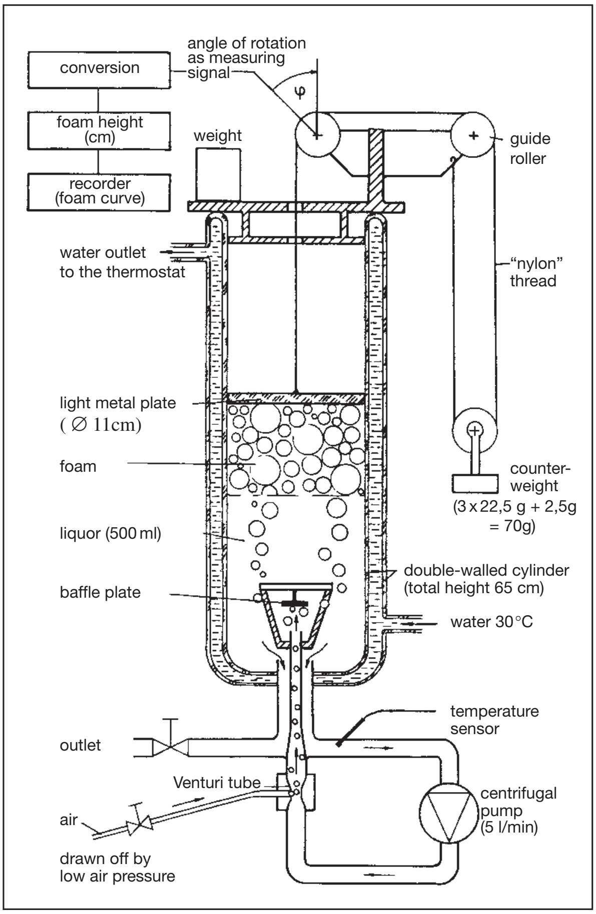

Fig. 10: Schematic representation of the Herrig + Rüttiger foam testing apparatus, developed by Schramm.

500 ml of the liquor under test is introduced into the double-walled cylinder, taking care to keep the liquor as free of foam as possible, and heated to 30°C. During this heating stage, the centrifugal pump is switched on to ensure thorough mixing of the liquor. After reaching the set temperature, the air valve is opened whereupon air flows into the liquor due to the partial vacuum created by the flow of liquor through a constriction in the tube underneath the cylinder (analogous to a venturi nozzle). The air/water mixture is pumped against the baffle plate and the liquor begins to foam as a result of which the light metal plate moves upwards due to the build up of foam beneath it. The counterweight to the metal plate now causes the polyamide thread attached to the metal plate to actuate the wheel of the gauge measuring the angle of rotation. This determines the length travelled by the polyamide thread via the angle of rotation which provides an indirect measure of the foam height.

As soon as the foam reaches a height of 25 cm, the air valve is closed and the centrifugal pump switched off. The maximum foam height of 25 cm is fixed by the ability of the integrated plotter to indicate the height reached. Furthermore, the centrifugal pump must be switched off during collapse of the foam which now begins since, otherwise, the liquor would become too hot due to the relatively high pump capacity (5 l/min) and the resultant heat of friction. The foam collapse is measured by the angle of rotation in a similar manner to the foam formation. The signals from the gauge measuring the angle of rotation are converted into recording signals and plotted as foam curves by an integrated printer (paper transport 1 cm/min). The test is carried out three times on each liquor.

In order to obtain a decisive value from the foam curves for the foaming characteristics of wash liquors and consequently the washing activity, the curves are evaluated by reference to the following points (Fig. 11):

1. Angle of ascent (α).
2. Angle of descent (β).
3. Time of ascent until the max. foam height is reached (a).
4. Distance covered for different foam heights (b).
5. Total distance covered in foam collapse (c).
6. Integration of the foam curve by weighing the area of printer paper enclosed by the curve. Conversion

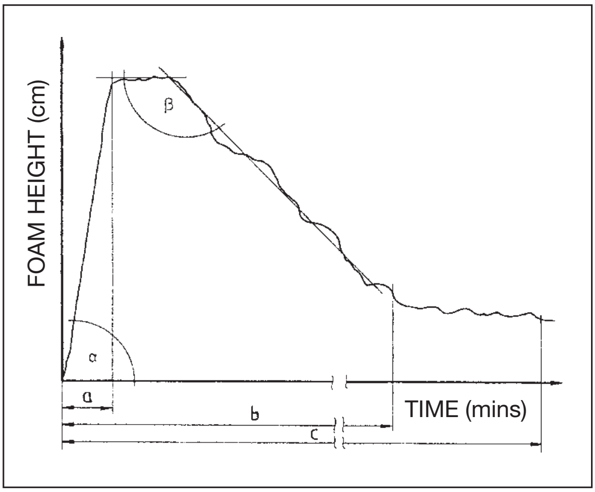

Fig. 11: Values for foam formation/collapse (foam measurement apparatus according to Herrig + Rüttiger).

to give the corresponding surface content is made by reference to a weighed surface area of 1000 cm^2.

Foam preventing agents →: Antifoams; Foam inhibitors.

Foam printing A textile printing variant of low wet pick-up in which a large proportion of the water in print pastes is substituted by air; thickening agents are superfluous and therefore do not need to be washed out. The advantages are reduced soiling of water during afterwashing and lower energy requirements in drying and steaming. The main disadvantage is the need for a separate foam generator for each print paste in the design and the resultant increase in costs. Printing of outlines is also difficult with foam print pastes. A typical foam printing system for rotary screen printing is illustrated in the Fig.

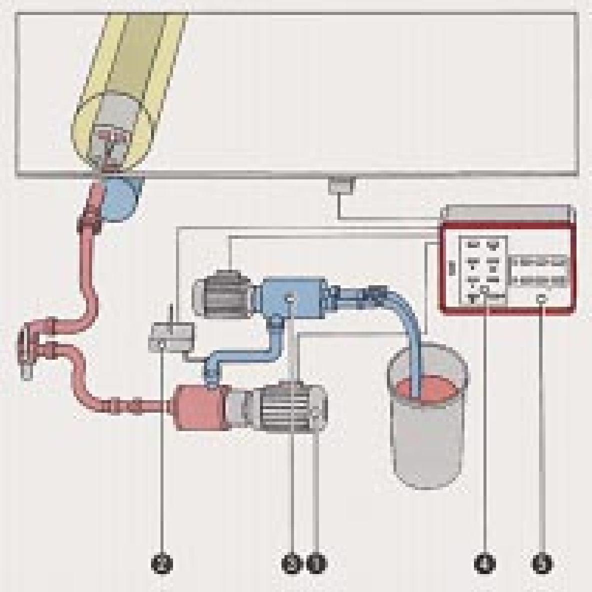

Fig.: Stork closed foam printing system.
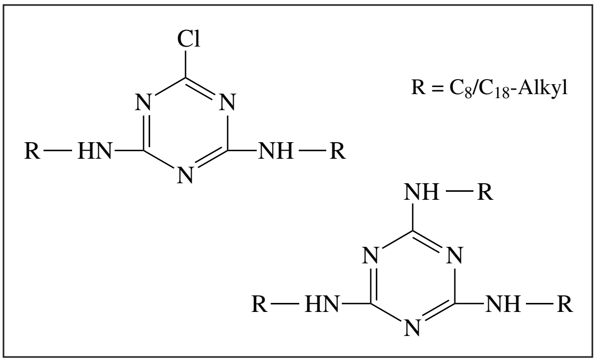
1 = mixing head; 2 = air regulating valve; 3 = paste pump; 4 = microprocessor; 5 = operating panel.

Foam regulators for wash liquors (→ Foam inhibitors). Products designed to prevent excessive foaming of wash liquors which is essential for the drum type washing machines widely used throughout Europe (foaming is an unwanted occurrence). New foam regulators are required for new surfactants (e.g. alkane sulphonates, sulphonated olefins, α-sulphonated fatty acid esters, fatty alcohol sulphates and non-ionic surfactants as well as phosphate substituents) for which, besides the sodium salt of behenic acid, monochlorodialkylaminotriazine and trialkylmelamine (as well as combinations) are recommended as suitable foam regulators for all types of surfactants:



Foam rubber (latex foam). An → Expanded foam produced from → Rubber or synthetic rubber. It consists of approx. 15% rubber and 85% entrapped air or gas cells. Foam rubber is of low weight, odourless, elastic, dimensionally stable, absorbs body transpirations and conducts them away, prevents heat accumulations, provides noise insulation, is resistant to parasites, washable and has a long service life (especially synthetic foam rubber, as well as natural foam rubber which is protected against the action of sun and air). Used in garments (only suitable provided the stability to solvents and drycleaning is adequate); special paddings (incorporation of textile fibres, horsehair glass fibres, etc. provide increased strength) for mattresses, seat upholstery, cushions, carpet underlays; fracture-proof packing; automobiles; shoulder paddings (resistance to drycleaning); trouser webbings (resistance to drycleaning); underarm pads; sponges, etc.

Foam-sandwich nonwovens → Foamed nonwoven.

Foam sizing The process of foam sizing calls for a change in the auxiliaries by which the “add on” to the yarns is applied. An emulsion which typically contains 20% solids or “additives” and 80% water is converted into a foam by the careful introduction of air, the viscosity of which is adjusted empirically in such a way that a good wet add-on is achieved. An appropriate mixture consists of a 4:1 ratio of water to solids with air making up the remainder. This is in contrast to classical size mixtures which can consist of a 9:1 ratio. The resultant properties of both emulsions are approximately the same so that, in each case, the yarn fibres are enveloped and to some extent penetrated with the same add-on quantities. In foam sizing, only 4 parts of water (and not 9 parts) need to be subsequently evaporated so that an energy saving of around 56% is achieved.

Since less water must be used in foam sizing, considerably less mechanical change occurs during application and drying. A lower water content means lower wet elongation stresses are involved so that the original strength of the yarn is maintained. During drying, there is considerably less separation of the filaments from one another as they are already in a much drier state. The separation of sized yarns by the splitting rods is noticeably a more gentle operation so that a stronger and more uniform yarn is obtained free from loose fibres and lumps of size. The composition of the size recipe must nevertheless be modified in order to adapt the process to sizing with foam mixtures.

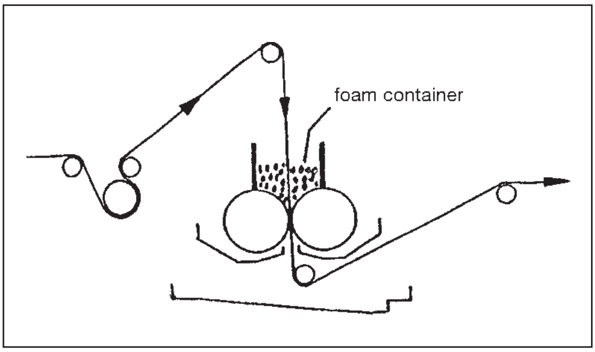


Fig.: Foamed size application.

The size solution is pumped into the foam generator from a size kettle or container where air and water in precisely metered quantities are introduced into the mixture. The generated foam is monitored constantly in order to ensure a uniform consistency which is independent of the processing speed. The composition of the size solution is formulated so that it has a viscosity which ensures a complete covering of the yarn and its stability is also good enough to cope with extended downtimes. The foamed size solution is supplied to the foam container of the size trough or the foam applicator (see Fig.) through a distributor which distributes it uniformly. The container is also sufficiently large to deal with different rates of size consumption. The level of size is controlled to within ± 4 mm by a sonar probe. The set-value can be easily adjusted to adapt the size levels in the container to the types of yarn and production speeds of the sizing machine.

The warp sheet is threaded through a series of rollers into the foam applicator. It passes over a running roller then vertically in a downwards direction through the foam bath. The foamed size liquor is retained at the bottom by two rubber-coated rolls forming a closed nip and by guide plates at the sides and frontal zone shaped to provide a close fit to the rolls. The warp sheet passes downwards through the foamed size liquor and the nip between the rubber-coated rolls then out of the applicator unit via a deflection roller into the drier. During passage of the warp sheet through the container bubbles of size emulsion are taken up by the yarns and transported as far as the nip between the rolls. The rate of size uptake is proportional to the contact time of the yarn sheet in the foamed size liquor. The bubbles burst as soon as the yarn enters the nip; the sun is raised, and the solution of water and size is spread uniformly across the warp sheet. The semi-wet warp then continues its passage into the drier.

Foam stability The ability of a → Foam to remain in a stable condition. Calculation:

$$\frac{\text{foam volume after x min}}{\text{foam volume immediately after preparation}}$$

The rate of self-drainage of a foamed liquid can be established by determination of the foam decay half-life period. The more rapid the foam drainage, the smaller its half-life period of decay.

The foam decay half-life period is the time required for half of the liquid in the initial foam to separate from the foam by self-drainage. In order to determine the half-life period of decay of a foamed liquid, the quantity of liquid present in a specific volume of the foam must first be calculated. For calculation purposes the density of the initial solution S_f is assumed to be 1 g/ml.

For a foam volume V_s and the density of the foam S_s, the half quantity of liquid V_f contained in it may be calculated by means of the following formula:

$$V_f = \frac{V_s \cdot S_s}{2\,S_f}$$

In determining the half-life period of decay, the time taken for the quantity of liquid V_f to drain from the foam volume V_s is measured.

Foam stabilizers Special products used to increase → Foam stability.

Foam structures Foam structures can be regarded as fundamental characteristics for the visual distinction of unstable and metastable liquid foams. With a sufficiently high stability of the surfactant adsorption film, a continuous transition from unstable foams, due to drainage between → Foam lamellae, into metastable foams takes place. With unstable foams an accumulation of only slightly deformed spherical air bubbles is built up. Provided these foam bubbles are distributed as discrete bubbles in the liquid medium a spherical foam exists (→ Foam). In the case of metastable foams, liquid drains between the individual foam bubbles; their autonomy is lost and an aggregation of polyhedron-shaped bubbles is formed, a so-called → Polyhedron foam consisting of an air-filled honeycomb-like structure of liquid lamellae. Due to gravitational forces the interlamellar liquid has a tendency to drain off the lamellae. It is possible to produce metastable polyhedron foams with stabilities tailor-made to meet specific requirements, e.g. by addition of thickeners or the use of appropriate surfactant mixtures. As far as stability is concerned, attention must be paid to external influences (e.g. evaporation of liquid, action of heat, pressure, mechanical shock, antifoaming agents). Foam stability is also affected by textile auxiliaries, dyes, and chemicals which, from time to time, however, may even contribute to better foaming.

Foam suppressants (defoamers, → Antifoams). Products used to prevent the formation of → Foam or considerably reduce foam stability. In general, a foam suppressant should (a) be sparingly soluble in water, so that it is already present at low concentration on the lamella surface, (b) have a positive spreading coefficient relative to the surfactant solution and (c) should form quasi-gaseous interfacial films. These requirements are fulfilled by, e.g. the following products: straight or branched-chain and hydroaromatic alcohols (with 5–18 carbon atoms in the hydrophobic part of the molecule, such as isooctanol), pine oil (main component is terpineol), phosphoric acid alkyl esters (such as tributyl phosphate), alkyl polysiloxanes, as well as lower alcohols. A distinction is made between a “defoamer” which destroys already existing foam and an “antifoam” which prevents the formation of foam.

Foam suppressants in washing detergents → Foam inhibitors.

Foam suppression in dyeing The following procedure has proved beneficial in practice: pretreatment of the material in a liquor containing a → Defoamer only at below 50°C for 15–20 min. Subsequent addition of surfactant (wetting agent, dyeing auxiliaries) and processing as usual. In cases where extensive formation of air bubbles is observed initially, the material is “deaerated” by this means. The effect of defoamers is more economical and longer lasting with this procedure (a single pretreatment is generally sufficient). This method has proved particularly worthwhile for fine cotton yarns, wool hanks which have a tendency to “float” in dyeing machines, wool piece goods which have to be dyed in the winch with high foaming levelling agents as well as for materials made from synthetic fibres.

Foam test methods These are subdivided into two groups:

1. Static methods: in this case, the foam is determined in accordance with DIN standards, i.e. the perforated disc beating procedure and the modified Ross-Miles procedure, in which the surfactant liquor under test is foamed once (by beating with a perforated disc or the surfactant liquor is allowed to run out into a container). A measure of the foaming properties of surfactants is the foaming capacity in ml or the foam height in cm.

2. Dynamic method: a continuous procedure according to the Ross-Miles method. With this procedure, the speed of circulation, fall height and temperature of the surfactant liquor can be varied so that they can be adapted to conditions encountered in practice.

→ Foam; Foam performance evaluation.

Foam viscosity Metastable → Foams exhibit pseudoplastic flow properties similar to non-Newtonian liquids, i.e. the higher the shear stress the lower the viscosity. The viscosity of foams is influenced by the → Blow ratio and the viscosity of the initial solution. Flow properties play an important role in the application of foamed print pastes.

Fog Air which is heavily laden with fine water droplets (fog) encountered in some dyehouses and similar textile finishing operations (→ Fog dissipation plant). Amongst other applications, mist is used in shrinkage (relaxation) machines for the anti-shrink treatment of wool fabrics, e.g. as in the → London shrinking process.

Fog and its consequences in textile finishing plants As air becomes increasingly cooler, its capacity to absorb moisture naturally decreases – a condition which can develop rapidly in bleaching, dyeing, printing and washing departments, especially during the colder months of the year. Air with a high moisture content accompanied by cooling leads to increasing precipitation of water droplets and their condensation in the form of mist or fog. Air with a fog content of 1 g still allows a visibility up to approx. 40 m whereas a fog content of 9 g, on the other hand, reduces the visibility to 1 m maximum. The consequences are: lower efficiency, nuisance, damage to health, possible danger to life (e.g. machine drive transmissions, centrifuges), damage to textile materials caused by drops of condensed water, as well as premature destruction of machinery, plant and equipment, roofings, walls, etc. Simple extraction of the surrounding air to eliminate fog is completely inappropriate (frequently this only leads to an even higher build up of fog), just as the use of fans and downstream heater units alone are not enough to produce a satisfactory distribution of warm air. → Fog dissipation plant.

Fog chamber technique (FCT). A method for the application of → Formaldehyde scavengers to textile fabrics in the form of a mist.

Fog dissipating plant This type of plant is based on the principle of a constant exchange of air adapted to suit local requirements and weather conditions with a) induction of warm air by means of a fan blower (installed approx. 50 cm below ceiling height), and b) the simultaneous extraction of moisture-laden air from the inside to the outside of the building (by means of a suction hood or extractor fan installed as deep as possible within the building space). Control of the air supply and necessary air extraction is absolutely essential in order to eliminate the build up of excess temperature and pressure in the workplace. Typical plants designed for industrial applications already incorporate these constructional features. Centralized fog dissipation plants are preferable for dyehouses with uneven free air space and individual units are only suitable for individually enclosed machines, etc. In all cases, however, the volume of the fresh air supply is greater than the volume of exhaust air (up to 80% for the latter).

Fogging Ever since textiles started to be widely used in car interiors, as well as the odour problem in new cars there has also been the problem of fogging on the inside of the cold front windscreen with milky-opaque substances, which obstructs the driver's view and presents a safety hazard. By definition, the term fogging is not considered to be fogging of the windscreen caused by fresh air from the outside, but the condensation of volatile substances evaporating from interior trim and therefore changing the refractive index of the windscreen. The fogging problem can last for quite a long time in new vehicles, because the evaporation of the substances responsible (spin finishes, additives, polyvinyl chloride plasticizers, synthetic fibre oligomers, stabilizers, emulsifiers, substances in the phenol resin-reinforced non-woven materials that have not been fully cured, dyeing auxiliaries, flame-retardant finish chemicals, fungistats, antisoiling substances, sewability aids) may be a relatively slow chemical cleavage process (age-induced cracking) and prolonged diffusion into the textile material ensues. Fogging, which can also be reaction or diffusion controlled, may be promoted by air convection from the interior air circulation system.

A fogging test takes the temperature situation in the passenger compartment that is fitted with textiles into consideration: there is a negative temperature difference between the location of the textiles (e.g. as thermal insulation) and the very cold windscreen. The vapour pressure of potentially volatile substances is brought about in the test (Candea method) by heating the textile (in the extended Volvo method, DIN draft 75 201, this takes place in beakers on thermostatically controlled heating baths) and substances can condense on the cooled covering plates (Fig. 1). The opacity (Candea) or optical transmission ratio is measured using a reflectometer, but the amount of precipitation is measured gravimetrically; the exact composition can also be analysed using gas chromatography and coupled mass spectrometry and the cause thereof determined.

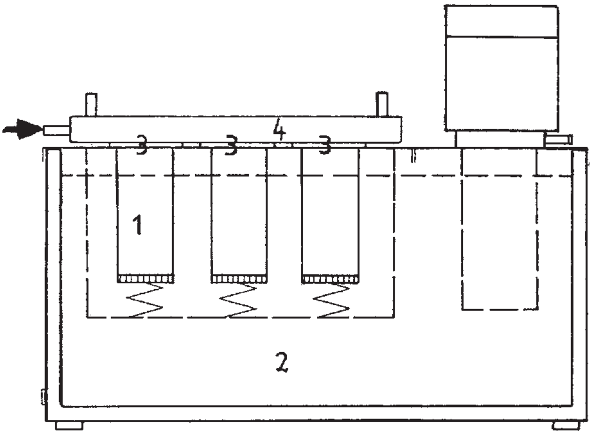

Fig. 1: Fogging device diagram, DIN 75 201 E.
1 = Beaker with sample; 2 = Temperature-controlled bath (100°C); 3 = Glass plate; 4 = Cooling plate.

Measuring method	60° reflectometer	Gravimetry
Test duration	3 h ± 5 min.	16 h ± 10 min.
Temperature		
Heating bath	100 ± 0,3 °C	100 ± 0,3 °C
Cooling water	21 ± 1 °C	21 ± 1 °C
Condensor material	Pane of glass	Aluminium foil

Tab.: Fogging test to DIN 75 201, Draft March 1989.

The DIN 75 201 fogging test, March 1989 draft, was drawn up by the "Fogging" Working Group of the "Commercial Vehicle" and "Plastics" standards committees starting in 1980 and includes both a reflection measurement with a 60° reflectometer and a gravimetric measurement. A test device manufactured by Haake (Fig. 2) meets the criteria of the DIN draft and has prov-

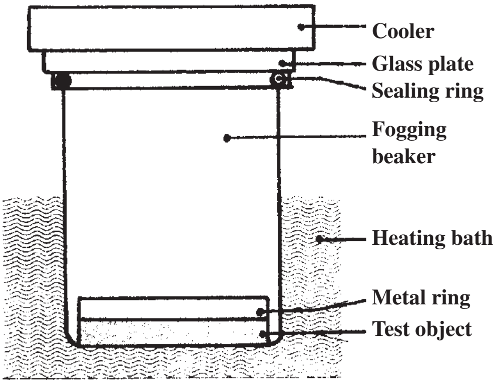

Fig. 2: Diagram of Haake fogging apparatus.

en itself in practice. The temperature of the heating bath and the cooling water is defined in the test procedure.

The cleanliness and the wettability of the glass plates play an important part in the fogging measurement using the reflectometer method. Coating the plate with a test ink with a defined surface tension has proved to be a good control method. An automatic cleaning program developed for cleaning the glass plates and the components in the fogging chamber makes it possible to use the glass plates up to 50 times.

Materials with a high water content, e.g. leather, and also textile materials must be dried before testing. The DIN draft specifies a 7-day drying period over phosphorus pentoxide. However, the results are frequently required within a shorter time. The temperatures that actually occur and how they vary over the course of time are shown in Fig. 3. The dependency of the surface temperature of the test object on its layer thickness and thermal conductivity is of particular interest.

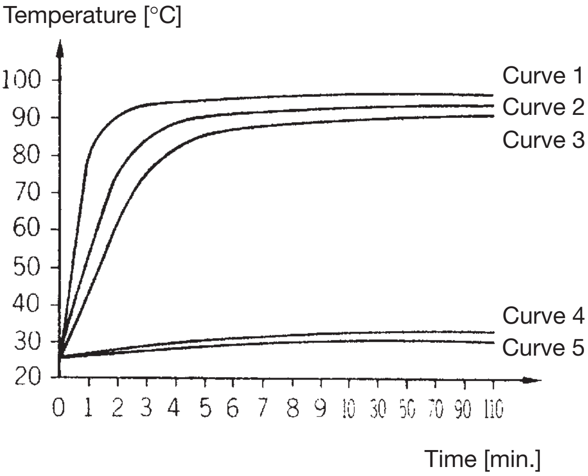

Fig. 3: Temperatures during the fogging test.
1 = Inside of floor; 2 = Car upholstery (approx. 8 mm top side); 3 = Car upholstery (approx. 1.2 mm top side); 4 = Aluminium foil (underside); 5 = Glass plates (underside).

Foil A term in general use for materials in thin, sheet-like form, e.g. aluminium, plastic foil, etc. In this context, therefore, a plastic foil is a flat, autonomous, and more or less elastic material with a thickness of approx. 0,01–0,1 mm, whilst the still thicker forms are described as plates largely because of their stiffness. The term foil should not be confused with → Film.

Foil colorimeter Used for self-determination of pH by submerging paper foil (as an indicator) and comparing with a supplied colour scale. It is advisable to work quickly because of the fast colour change, which is time dependent. Measuring accuracy approx. pH ± 0.1.

Foil wrapping and packing machines Machines for the automated packing of finished textile fabrics in foil which is cut from rolls. The final packing unit is usually heat-sealed.

Fold creases Formed by the compression of tubular (knit) goods through squeeze rolls, padders, etc. Differences in thickness arise between the crease folds at the edges and the rest of the double-layer fabric (Fig. 1) which can result in the non-uniform impregnation or penetration of liquor into the fabric thereby forming crease marks.

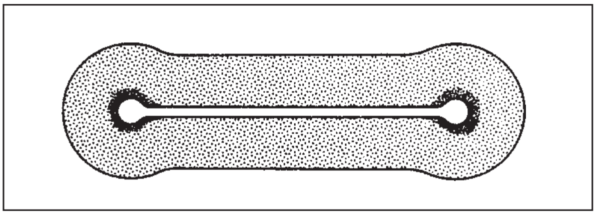

Fig. 1: Material density differences in tubular knitted fabric as a result of fold creases.

Crease marks formed in this way can be prevented by the following measures:
- Application of low nip pressure on the padder.
- Use of soft rubber coatings on the padder bowls.
- Good aeration in the padder trough.
- Vacuum impregnation.
- All-round spraying.
- Ballooning of the tubular fabric (Fig. 2).

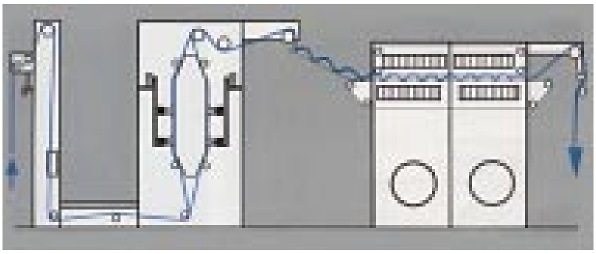

Fig. 2: Inflating unit for tubular knitted fabric for preventing fold crease setting during drying.

Folding machines Used a) for make-up of piece-goods on completion of finishing or b) for individual laundry items. Can be directly connected to a packaging machine → Fabric folding machine.

Folding number With folded, doubled or plied yarns, the folding number represents the total number of individual threads that have been twisted together to form the yarn.

a) In the case of length counts, it is denoted by a number separated from the yarn count by a forward slash (e.g. Nm 30/2),
b) In the case of weight counts, it is denoted by a number separated from the yarn count by a multiplication sign (e.g. 150 tex x 2).

Folding of yarns The doubling of single yarns as a partial stage in the process of → Twisting. The folding process represents a stage in the production of ply yarns. Starting from single yarns, ply yarns are produced in two stages, i.e. firstly by combining the threads on the doubling machine, and secondly by imparting twist in the yarn on the twisting frame. Folding is an essential process for the production of three-fold or multi-folded yarns by the now popular two-for-one twisting or pot spinning methods. Two processing methods for the production of two-fold yarns in two-for-one twisting have established themselves in practice: in the first case by the classic method which involves feeding from doubling bobbins and, in the second case, by means of the so-called direct feed technique in which two bobbins of single yarns are placed side by side (Fig. 1).

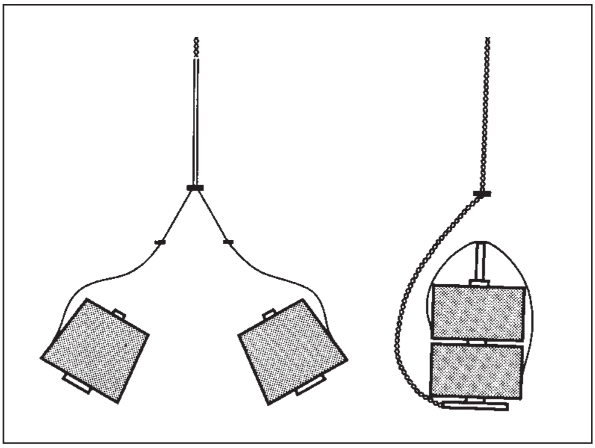

Fig. 1: Twisting by feeding from doubling bobbins (left), and twisting by the direct feed technique (right).

At first sight, the avoidance of the folding stage appears to offer a desirable saving since, in direct twisting, the packages of single yarns are fed directly into the (two-for-one) twister. However, all the influencing parameters must be taken into account in order to be able to decide when it is better to use doubling bobbins or the direct feed technique. In principle, it is true that efforts should be made to use the shortest possible path in yarn production. However, as soon as quality begins to suffer, savings in process costs should not be the only factor to take into consideration.

A perfectly twisted yarn is characterized by having its two component threads twisted together symmetrically (Fig. 2). By contrast, a covered yarn consists simply of one thread with a second thread wrapped around it. The quality enhancing effect is lost in this case since one thread can slip in relation to the other. Yarn covering takes place, e.g. when a very high tension is applied to one thread and virtually no tension is applied to the other. In this case, the taut yarn has no opportunity to become deformed during twisting and the loose yarn wraps around the taut one. A yarn covering effect can occur with direct feed when no uniform thread tension exists and the feed of the respective threads is unbalanced.

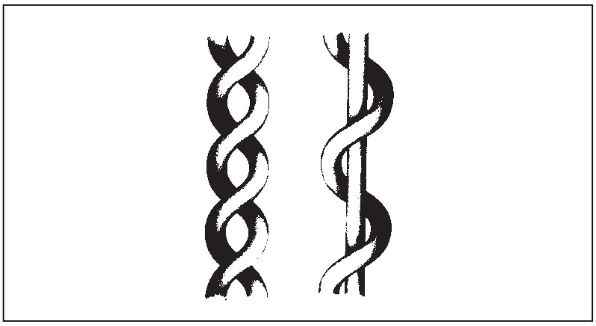

Fig. 2: left: uniformly twisted yarn; right: covered yarn.

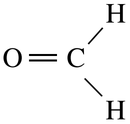
Fold marks These are usually seen as length-wise creases that can cause considerable problems, e.g. in the case of dyeing sensitive polyester fabrics that are thermo-plastic, or alkaline treatment in cellulose processing. For cellulose, similar conditions may be found during bleaching processes but, due to the lower quantities of alkali, heavy creasing is rare and is easier to remove. Alkaline fabric treatments used in boiling off, mercerization and caustic treatment generally involve an initial cold treatment and progress to the alkaline treatment at increased temperatures. All alkaline treatments cause cellulose fibres to swell with the consequent contraction in fibre length and, dependent on time and temperature, this will have a fundamental influence on the formation of fold marks.

Food packaging dyes These are exceptionally pure textile dyes and must conform to the specific purity requirements demanded for food packaging purposes, e.g. coloured nets for oranges, black-dyed net coverings for smoked ham, etc.

For → Cotton maturity index.

Foreign solvents, e.g. in the distillation process in normal dry cleaning, substances apart from tetrachloroethylene and water are distilled over and, depending on their solubility, may be dissolved as “contaminants” in the tetrachloroethylene or run off with the water from the water splitter. They may also make the separation of the water and tetrachloroethylene more difficult; e.g. alcohols used as cleaning auxiliaries.

Formaldehyde (methanal), MW 30, density 0,81. A readily polymerizable colourless gas. It is commercially available as an aqueous solution with a pungent and characteristic odour; 30–40% solution (formalin)



$O=CH_2$

which usually contains 10% methanol to inhibit polymerization. Properties: powerful reducing action; causes proteins to coagulate (principle of tanning) and the hardening of casein fibres; it is a powerful germicide either in solution or vapour form.

Formaldehyde has been classified as an allergen and a suspected carcinogen. The German DFG Commission with responsibility in this area has stated that formaldehyde, which is widely used in laboratories and as an industrial product, also belongs in the category of substances for which a clear carcinogenic potential exists. In this regard, the great number of inhalation tests carried out on test animals in the USA have shown that concentrations of formaldehyde up to 15 times the valid MAK value produced a high rate of cancer development in the nasal mucous membranes of rats, and to a lesser extent with even 6 times the MAK value.

Uses: aftertreatment of substantive dyeings (improved wash fastness); wool protection agent; hardening of casein fibres (during wet finishing); crosslinking agent in resin finishing (formaldehyde finishing); manufacture of resin finishing agents (methylolation); addition to naphthol dyeings; preservative; component in disinfectant solutions; component in numerous fillers, adhesives, etc.

Formaldehyde aftertreatment of direct dyeings Improves the colour fastness of suitable direct dyes to water, washing and perspiration. Suitable direct dyes contain free amino or oxy groups; mainly black dyes.

Formaldehyde/ammonium salt reactions Many dyes which exhibit no changes in the absence of ammonium ions are unstable in the HT-dyeing of polyester/wool blends at 120°C in the presence of formaldehyde, as a wool protection agent, and ammonium salts as buffers or acid donors. With an extended range of dyes it is possible to use buffer mixtures which are free of ammonium salts. The reasons for the unsatisfactory stability of many dyes in a dye/formaldehyde/ammonium salt system are the numerous possibilities for reactions with different reaction products and their intermediate stages as well as their reaction equilibria (see Fig.).

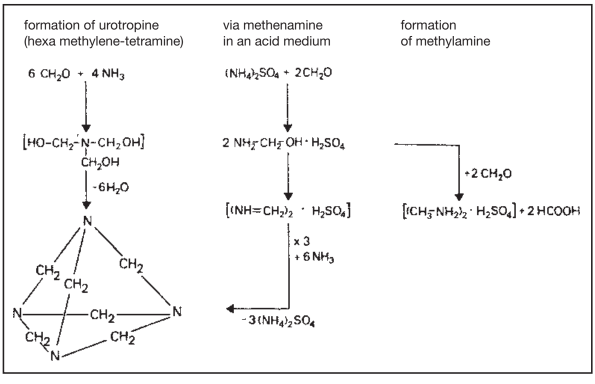


Fig.: Formaldehyde/ammonium salt reactions.

Formaldehyde contamination of waste water, treatment of Waste waters containing formaldehyde cannot be discharged into receiving waters or biological water treatment plants due to the toxicity of formaldehyde towards microorganisms and fish. A new process developed by Degussa for this purpose involves the treatment of waste water with hydrogen peroxide and milk of lime (aqueous suspension of calcium hydroxide) which easily and quickly breaks down formaldehyde. The reaction products are non-toxic and have no disadvantageous effects on receiving waters or biological waste water treatment plants.

Formaldehyde content in resin finishing agents The free formaldehyde content results from the state of equilibrium which is dependent on the chemical constitution, concentration and temperature.

Formaldehyde determination A range of analytical methods is available for the determination of formaldehyde in resin finishing, especially the different types of formaldehyde in crosslinking agents based on N-methylol and N-alkoxymethyl compounds, finishing liquors, as well as finished fabrics. Relatively precise methods are available for the determination of total formaldehyde, free formaldehyde, and the content of N-methylol groups. The formaldehyde released by hydrolysis is extraordinarily dependent on the test conditions. Total formaldehyde is understood to be the total amount of formaldehyde detectable in finishing agents, finishing liquors, and on textile fabrics. It represents the sum of free and combined formaldehyde. The combined formaldehyde is subdivided, in turn, in methylol and methene compounds. The determination of formaldehyde released from textiles by hydrolysis is also important. After hydrolysis in the distillate, the total formaldehyde can be determined iodometrically. The determination of free formaldehyde is mainly carried out by the sulphite method and, in a different manner, by the hydroxylamine method. Methylolformaldehyde can be determined together with the free formaldehyde. The determination of free and hydrolytically-released formaldehyde on textiles can be carried out according to various methods. However, these test methods determine not only the actually available free formaldehyde but also the formaldehyde released by partial hydrolysis in the preparation of the sample.

Formaldehyde donors → Formaldehyde-liberating compounds.

Formaldehyde emission Examinations of people exposed to formaldehyde at work showed that low formaldehyde concentrations can trigger nasal mucous membrane changes in humans that are predisposed to carcinomatous degeneration. In 1989 this led to a situation where formaldehyde was categorized as a potential carcinogen for human beings in the USA. Formaldehyde's ability to trigger allergies is less controversial. Inflammation and eczema can occur if formaldehyde comes into contact with the skin. People who encounter relatively high concentrations of formaldehyde at work are worst affected, e.g. people working in the fields of medicine or textiles. Dermatological investigations have shown that textiles containing formaldehyde can cause skin allergies when worn. Formaldehyde concentrations of 750 ppm are enough to trigger and maintain corresponding reactions in sensitized individuals. Highly sensitized persons can even be affected by concentrations as low as 300 ppm. According to the current state of knowledge, it is assumed that products with a formaldehyde content of less than 0.03% do not usually lead to allergic reactions even on sensitized persons. In various countries, this kind of medical knowledge has led to the introduction of legislation and tolerance limits (e.g. Japan, Finland, Austria). These kinds of restrictions also exist in Germany. According to the hazardous substances legislation that came into force in 1986, in § 9, paragraph 3 for timber products, it was stipulated that these materials may not be brought into public use if the concentration of formaldehyde caused by the timber product that is released into the air of a test room exceeds 0.1 ml/m^3 (ppm). According to paragraph 4, furniture may not be brought into public use if it contains timber products materials that do not meet the requirements in paragraph 3. According to the legislation, clothing textiles with a mass content of 0.15% of free formaldehyde must be marked as such if they contain a finishing agent and come into contact with the skin during normal use.

Area	Law	Tolerance limit
Textile	Hazardous materials legislation (Appendix I) (Chemicals act)	> 150 ppm (must be marked)
Product	Hazardous materials legislation (Appendix VI) (Chemicals act)	> 1 % (must be marked)
Workplace	TRGS 900 (Hazardous materials legislation)	< 0.5 ppm (workplace threshold limit)
Emitted air	Technical directive on air pollution control (BIMSchG 1, VwBV)	< 20 mg/m^3 (Mass flow > 100 g/hr.)

Tab.: Legal regulations for formaldehyde emission.

Whereas timber products and furniture have to observe emission limits (Tab.), domestic textiles have not been included. A regulation for domestic textiles and wallcoverings (among other things) was also discussed in the draft of the hazardous materials legislation but was not initially included. Based on the Ministry of Health recommendation of a maximum formaldehyde concentration of 0.1 ppm for interior rooms and because of the stipulation of this limit for timber products in the hazardous materials legislation it would make sense to use the same value for domestic textiles.

Formaldehyde fastness A form of → Colour fastness to storage conditions test for finished and packed coloured textiles to possible formaldehyde-containing adhesives in packing paper, pleating paper, etc. Test procedure: a dyed or printed textile specimen is exposed in the dry state for 24 h to rising formaldehyde vapours (contained in a small open bowl under a glass bell jar or in closed boxes). The grey scale is used to evaluate change of shade.

Formaldehyde finishes Crosslinking processes for cellulose with formaldehyde or so-called → Formaldehyde-liberating compounds in the presence of acid catalysts. The formaldehyde is mainly applied from aqueous solution by the wet crosslinking process. Such finishes were originally applied to textiles composed of regenerated cellulose to reduce fibre swelling, increase wet tensile strength and improve shrink resistance; also used for the wash-and-wear finishing of cotton. Disadvantages: severe losses in tensile strength and abrasion resistance.

Formaldehyde finishes on cotton in the swollen and partially-swollen state were also of importance (wet and moist crosslinking processes): →: Form D process; Form V process; Form W process.

Formaldehyde-free finishes These finishes are based on the use of compounds which do not contain formaldehyde (Fig. 1) or do not release formaldehyde due to the action of heat or during the storage of finished fabrics (→ Low-formaldehyde resin finishing) such as 4,5-dihydroxy-1,3-dimethylurea and 4,5-dihydroxy-1,3-bisethyleneurea. A finish with reaction products of acrylamide and glyoxal or glutaraldehyde gives poorer effects than usual. A comparison of both basic structures of a low-formaldehyde type finish and a formaldehyde-free finish clearly shows that the number of reactive hydroxyl groups for crosslinking with cellu-

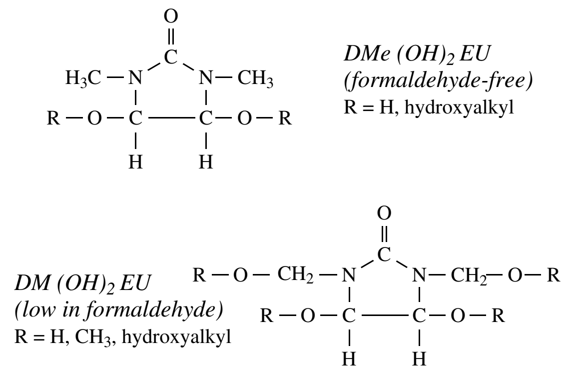

Fig. 1: Comparison of DMe(OH)$_2$EU and DM(OH)$_2$EU by formula.

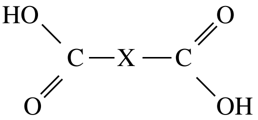
lose in low-formaldehyde glyoxal monoureins is approx. double that in the formaldehyde-free dimethyldihydroxyethyleneurea. Amongst other things, this is the reason why formaldehyde-free crosslinking agents must be applied in at least double the usual crosslinker concentration in order to achieve roughly comparable finishing effects.

In order to achieve the required quality standards in practice, it is frequently necessary to increase the application concentrations of such products by two to four times the concentrations normally used; despite this, however, the level of effects obtainable with the low-formaldehyde glyoxal monoureins (especially in the finishing of regenerated cellulose) is not achieved in many cases. The main problem here is dimensional stability. On considering the fact that approx. double the usual price level must be estimated for dimethyldihydroxyethyleneurea, the great importance of the economic aspect becomes obvious, which translates into a noticeable increase in the price of the end-product. Since both reactivity and stability to hydrolysis are positively influenced by the higher electron density at the nitrogen atom, theoretical disadvantages for fromaldehyde-free crosslinking agents can already be derived, i.e. the need for stronger concentration conditions for bonding to the cellulose fibre and, in addition, the lower stability to hydrolysis. The application of formaldehyde-free crosslinking agents by moist and wet crosslinking methods is not possible.

In comparing both product groups, differences in the quality of crosslinking also exist; bonding to the cellulose via a N-methylol group is accordingly more stable than a crosslink via a hydroxyethylene group, and is produced under milder curing conditions. The well-known structure-related disadvantages of dimethyldihydroxyethyleneurea can, however, be compensated to some extent by suitable pretreatment and the use of appropriate additives.

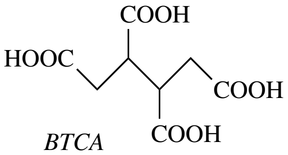
Polycarboxylic acids, e.g.



are also known as cellulose crosslinking agents.

Besides technological parameters, other factors such as availability, ease of production (Fig. 2) and price play a decisive role in the successful marketing of formaldehyde-free crosslinking agents.

Up to now, only butane tetracarboxylic acid BTCA (white solid in powder form; empirical formula $C_8H_{10}O_8$; MW 234,2; mp 192°C; pH approx. 2; solubility in water 130 g/l) can fulfil all these criteria to a large extent.



BTCA

As catalysts for the crosslinking of cellulosic materials with polycarboxylic acids, completely different systems are required compared to the amines, ammonium salts, metal salts and inorganic or organic acids formerly used as catalysts for formaldehyde-based crosslinking agents. Suitable catalysts for this process are mainly the alkali metal salts of phosphorus-containing acids. The majority of these catalysts are weak bases. Catalysis with hypophosphites has proved to be particularly effective; phosphites are somewhat less reactive. In both cases, substances with a high reduction potential are used. They are especially suitable for use on white goods. Phosphates or polyphosphates are also capable of bringing about satisfactory crosslinking. Because of their minimum influence on changes in shade they are preferred in the finishing of coloured goods. The catalysis mechanism is still not understood. Purely as a hypothesis, a three-stage mechanism has been postulated (Fig. 3).

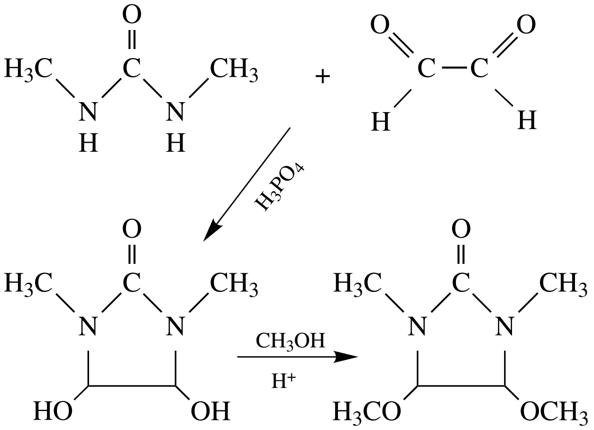


Fig. 2: Production of formaldehyde-free cross-linkers.

Under the action of heat during the curing stage, cyclic anhydrides can be formed from suitable polycarboxylic acid structures. Thermogravimetric and mass spectroscopy investigations have shown that a rapid loss of water takes place which may be taken as further evidence of a possible anhydride formation. In the second stage, the more reactive anhydride is in a position to react with corresponding catalysts to form acyl phosphinates, acyl phosphonates or mixed anhydrides. This hypothetical intermediate stage can finally result in crosslinking of the cellulose by esterification and liberation of the catalyst.

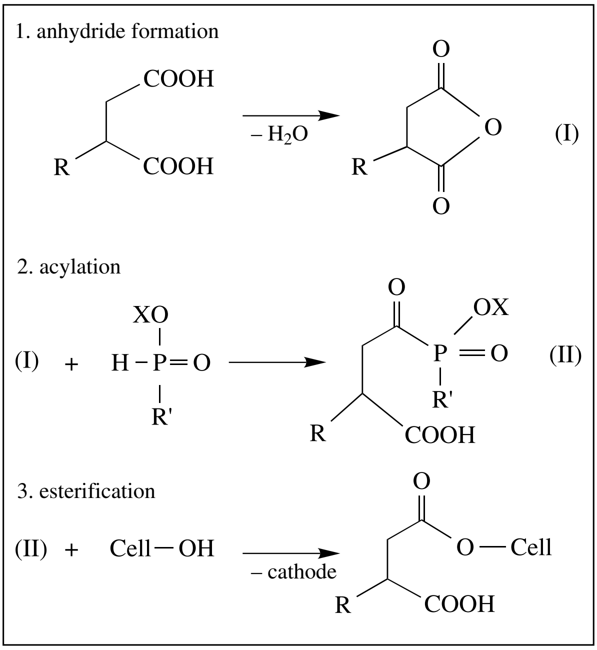

Fig. 3: 3-stage catalysis mechanism.

Formaldehyde-free finishing agents These are, more precisely, formaldehyde-free resin finishing agents used to produce → Formaldehyde-free finishes on cellulosic materials. Crosslinking agents are available for the resin finishing of cellulose which contain no formaldehyde and do not release formaldehyde in the finishing process or during storage of the finished goods.

These products stand in contrast to the resin finishing agents based mainly on N-methylol compounds formerly used. A range of compounds containing reactive groups, but which are formaldehyde-free, have been examined in the development of formaldehyde-free finishing agents. Suitable reactive groups include the aziridine, carboxy, epoxy and chlorohydroxy groups as well as carbon double bonds. Apart from commercial considerations, these compounds suffer from other disadvantageous problems including toxicity. Suitable alternative cost-effective and non-toxic products capable of meeting acceptable finishing standards are difficult to find. Special products based on polyurethane as well as → Silicone elastomers only represent a partial solution. Polycarboxylic acids are also of interest here.

Knowledge of the relationships between chemical constitution and the properties of crosslinking agents based on N-alkoxymethyl compounds has led to the development of extremely low-formaldehyde crosslinking agents for cellulose. This fundamental knowledge has led directly to the practical development of the most important reactant crosslinking agents at the present time based on the low-formaldehyde → Dimethyloldihydroxyethyleneurea with excellent stability to hydrolysis (already marketed since 1975). These partially or fully etherified types of crosslinking agents ensure full compliance with current legislative regulations regarding MAK values in processing as well as the formaldehyde content of substrates which have been resin-finished with these products. Moreover, these products leave nothing to be desired from the ecological, toxicological and dermatological points of view and ensure the production of maximum resin-finishing effects with regard to the easy-care properties of the end-product. Despite this, in all respects, entirely satisfactory situation by today's standards, there is a growing body of opinion calling for still further optimization and absolutely formaldehyde-free finishing variants. These changed quality standards have, in the meantime, been taken into account with the development of formaldehyde-free crosslinking agents for cellulose.

The concept of formaldehyde-free alternative products begs the question as to which basic chemical structures are still available, besides the long established N-methylol or N-alkoxymethyl compounds which are suitable for application by the usual process machines and processing conditions. In principle, possibilities exist for crosslinking between the following basic chemical structures and the hydroxyl groups of cellulose (see Fig.):

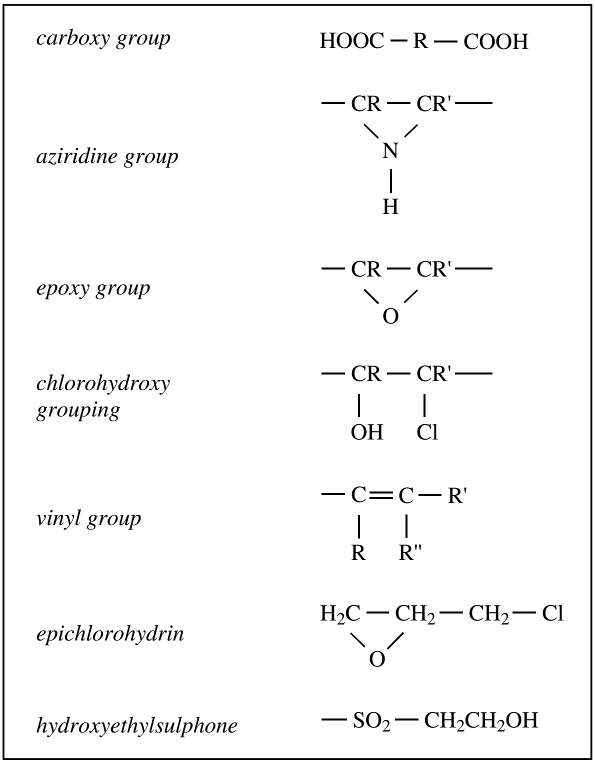

Fig.: Crosslinkings between hydroxyl groups of cellulose and formaldehyde-free basic chemical structures (Pfersee).

- aziridine group,
- epoxy group,
- chlorohydroxy grouping,
- vinyl group,
- epichlorohydrin,
- hydroxyethylsulphone.

On closer examination from the technical point of view, it has been established that in many cases such products result in pronounced yellowing or brown discoloration or an unacceptable effect-strength loss relationship as well as unsatisfactory resin-finishing effects. In addition, the application of such compounds would, in many cases, result in an unacceptable increase in the cost of resin-finishing.

Formaldehyde in HT wool dyeing A variety of technical and ecological disadvantages are associated with the use of formaldehyde as a wool protection agent at 120°C as a short-term stopgap measure:

1. Variations in the concentration of commercial formaldehyde qualities: these differences can be considerable, which makes reliable dosing difficult without previous analysis.

2. Transport and storage shelf-life: limited due to high volatility; formaldehyde is also subject to different import, packing and safety regulations in various countries.

3. Reactivity: the high reactivity of formaldehyde is a safety risk in transport, storage and application: The very rapid reaction with wool (wool keratin/formaldehyde reactions) makes it necessary, in HT dyeing, to add formaldehyde to the dyebath at 40°C in order to eliminate irregular reactions and uneven wool protection.

4. Volatility during dyeing: the addition of formaldehyde at too high a temperature can already result in partial evaporation losses before the wool reaction takes place (temperature-dependent, only completed in the HT range) = risk of possible under-dosage.

5. Impairment of fabric handle: this problem occurs especially with dyed piece goods in blends with cotton.

6. Development of disagreeable smell: this problem is unavoidable especially when the dyeing machine is opened; samples during dyeing must always be taken from a sampling lock.

Formaldehyde in textiles Textile fabrics which have been resin finished with N-methylol or N-alkoxymethyl compounds contain both bound and free formaldehyde. The free formaldehyde is formed during the finishing or storage of resin-finished textiles and can cause skin irritations. The proportions of free formaldehyde are variable and are dependent on the crosslinking conditions (→ Low formaldehyde resin finishing). The free formaldehyde content in textiles is subject to specific ppm limits. Methods for the determination of free formaldehyde → Free formaldehyde, determination of.

Formaldehyde-liberating compounds These are compounds which break down with the release of formaldehyde, e.g. polyoxymethylene (→ POM derivatives). Used as resin-finishing agents. Formaldehyde in the labile form is more or less firmly bound and is released gradually during the finishing process. The result is a much more uniform crosslinking of the cellulose (in comparison with aqueous formaldehyde solutions).

Formaldehyde limits in air At high concentrations free formaldehyde attacks the mucous membranes in humans. The permissible concentrations of formaldehyde are therefore subject to maximum limits in room air (MAK value = 1,2 mg/m^3 air) and in exhaust air (TA-Luft emission limit concentration of 20 mg/m^3 at a flow rate >0,1 kg/h).

Formaldehyde release during ironing When textiles finished with N-methylol compounds are ironed in the moist state formaldehyde may be released which can be very aggravating. In principle, the following ironing procedure is used to determine the released formaldehyde. During the ironing of a fabric sample under specified conditions 10 l of air next to the iron is withdrawn by suction and passed through an alkaline iodine solution. The formaldehyde content is then determined by titration with a 0,02 n thiosulphate solution as the difference compared to a blank test. The result is expressed as the “ironing value” and runs parallel to the sensation response during ironing. The formaldehyde release is influenced considerably by the pH of the fabric and its control with buffering agents or the application of → Formaldehyde scavengers.

Formaldehyde resins A collective term for organic compounds which contain formaldehyde mainly in the form of methylol compounds which may also be etherified, and which are capable of crosslinking reactions (→: Self-crosslinking resins; Reactive resins). The term “formaldehyde resin” is mainly understood to refer only to the self-crosslinking resins such as aminoplasts and phenoplasts.

Formaldehyde scavengers These are substances which are capable of binding formaldehyde. They are used variously in resin finishing, especially in low formaldehyde finishes, e.g. urea, ethylene urea. A reduction in the release of formaldehyde is achieved through the addition of formaldehyde scavengers to resin-finishing baths both in finishing with N-alkoxymethyl compounds as well as during the storage of resin-finished fabrics. In general, however, the desired effect is not satisfactory. Hydrazides and carbohydrazides are also recommended, among other products, to reduce the content of free formaldehyde from glyoxal crosslinking agents. Ethylene glycol and diethylene glycol also reduce the release of formaldehyde and do not cause chlorine retention. In the case of formaldehyde scavengers such as urea, ethylene urea, dicyandiamide and hexamethylene tetramine, adjustment of the pH at the same time is of considerable importance.

Formaldehyde sulphoxylates → Sulphoxylates.

Formaldehyde, tests for Simple preliminary test (e.g. on fabrics containing formaldehyde-based finishes): briefly boil a 3–4 cm^2 fabric specimen in a test tube with 5 ml approx. 2% sulphuric acid: in the presence of formaldehyde, formaldehyde vapour escapes during this test and can be easily recognized by its odour. Other preliminary tests can also be carried out with Nessler's solution or Fehling's solution. More precise methods of formaldehyde detection are based on, e.g. chromotropic acid, Schiff's reagent, carbazole-sulphuric acid and xanthydrol.

Formaldehyde test for Japanese exports: according to Japanese regulations and laws, certain textiles for export must be checked for their content of free or readily releasable formaldehyde.

Formate of alumina → Aluminium formate.

Formates Salts of → Formic acid.

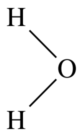
Formatted piece method Used to determine edge/centre evenness (→: Tailing; Ending) in rotary screen printing. A specified quantity of material is mechanically cut into pieces of exactly the same format. The pieces are weighed, printed on the right or left side or centre of the backing cloth using a non-patterned rotary screen and then re-weighed. The dye paste quantity differences that are measured provide a way of gauging whether the printing mechanism and the screen produce level results.

Form D process A formaldehyde finish for cotton in the partially-swollen state (moist crosslinking process) with formaldehyde dissolved in organic solvents in the presence of water.

Formic acid (methanoic acid), HCOOH. A colourless pungent liquid of MW 46, miscible with water, alcohol and ether. Salts: formates. The 98–100% acid has a density of 1,22. It is mostly available as a very pure product. Undesirable impurities include acetic, oxalic, hydrochloric and sulphuric acids, as well as lead, iron and copper. Formic acid is a medium strength acid and has practically no action on cellulose. In use, formic acid is cheaper, more volatile and 12 times stronger in comparison with acetic acid. It is a strong reducing agent and brings about the complete reduction of chrome mordants. Formic acid is corrosive to skin and tissue with the formation of blisters. It is stable to hard water, alkalis and salts. Used as a substitute for sulphuric acid (for wool dyeing under strongly acidic conditions) and acetic acid (wool/cotton union dyeing); dyeing of silk (for slow dye exhaustion); neutralization in wool/cotton dyeing; spotting agent (for grass, fruit and ink stains) etc.

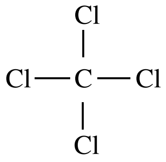
Forming time Within the context of total → Handling time factor, the forming time is the proportion → Processing time and → Transportation time.

Formula, chemical A means of representing a chemical compound by using symbols (as a rule, in the form of the initial letter of the respective element) to indicate the elements or atoms present (either metals or non-metals). Subscripts are used for the numbers of participating atoms (water = H_2O). The same system also applies to molecular groups in brackets, e.g. $Fe(OH)_2$. Since matter cannot be lost, all chemical reactions can be expressed by equations using chemical formulae where the number of atoms in both sides of the equation must be equal. The same applies to molecular weights:



water
H_2O

If the elementary composition and the molecular weight of a compound is known, the chemical formula is first represented by the molecular formula (empirical formula or total molecular formula) which only expresses, in the simplest form, the relative number and the kind of atoms participating in the structure of a molecule, e.g. water = H_2O. In order to illustrate the arrangement of the individual atoms pictorially with their valencies, structural or constitutional formulae are used, e.g.:



$$\begin{array}{c} Cl \\ | \\ Cl-C-Cl \\ | \\ Cl \end{array}$$

carbon tetrachloride
CCl_4

In addition, electronic formulae (→ Atomic bond), →: Configurational formulae are also used.

Formulations Mixtures and solutions of two or more substances.

Form V process (formaldehyde vapour process). A formaldehyde finish for cotton in the gas phase which takes advantage of the fact that pure formaldehyde is a gaseous compound. Formerly, gaseous hydrochloric acid was used as a catalyst.

Form W process (formaldehyde wet process). A formaldehyde finish for cotton in the swollen state (wet crosslinking process). Formaldehyde dissolved in water is allowed to react with cotton in the presence of aqueous hydrochloric acid.

Forschungskuratorium Gesamttextil Headquarters: Frankfurt. Permanent committee of → Gesamtverband der Deutschen Textilindustrie-Gesamttextil e.V. =

Confederation of the German Textile Industry: established in 1951. Members are expert representatives from all areas of the textile industry in matters of research. Task: to promote cooperative textile research and act as mediators to encourage co-operation between the textile industry and research institutes in the mutual interest of both parties. As well as processing research project proposals from industry to the research institutes, the main focus is on evaluating the results of research for industrial use and appropriate publicity. As part of this task the Gesamttextil Research Council has set up a comprehensive consultancy service with the institutes, and produces annual research reports on the work carried out in the research institutes. As well as co-ordinating the activities of the textile research institutes in Germany, the Gesamttextil Research Council strives to obtain financial resources for the ever increasing number of activities of the research institutes by providing funds from industry or obtaining public funds.

Forschungsvereinigungen e.V. Working Group of Industrial Research Associations (AIF); Headquarters; Cologne. Actively promotes exchange of experience and co-ordination of research work. Members are German industry representatives, including the → Gesamttextil Research Council.

Fossil meal → Kieselguhr.

Foulard A soft, lightweight fabric of silk or man-made filament fibre, either plain-dyed or printed, in twill, satin or plain-weave construction (similar to → Pongee). Uses: blouses, dress fabrics, skirts, scarves and ties.

Foulardtherm process A process developed by Ciba-Geigy for the application of fluorescent brightening agents to polyester; also applicable to polyamide, polyvinyl chloride, acetate and triacetate. Fixation of the fluorescent brightening agent is achieved with hot air (150°C) in the heat-setting zone of stenter driers.

Foulé (Fr.: fouler = milled). A soft, serge-like worsted fabric with a rough, fibrous melton-like surface. Its characteristic appearance is produced by prewashing and subsequent raising and milling of the face side; the weave (usually a 2 up, 2 down twill) can still be easily recognized on the back side of the fabric. Used as a ladies dress fabric either plain-dyed or as coloured checks. Also used for men's outerwear, mostly piece-dyed in black.

Fouling, irreversible adsorption of dyestuffs.

Foundation garments The requirements for these materials involve consideration of the following four factors:

- easy-care properties,
- fashion,
- wearing comfort,
- functionality.

The nature of the chosen finishing route and the selection of finishing products are very much dependent on the above quality standards as well as on the respective substrate (the parameters include, e.g. fabric weight, weave, type of fibre blend). In the case of knitgoods for so-called "elastic articles" in the swimwear and sportswear sectors, as well as foundation garments, blends of polyamide filament yarns and polyurethane filaments have established themselves. The proportion of polyurethane in such materials generally varies between 15–20%. These qualities can be dyed either in rope form in winches and overflow machines or in the open-width state in tensionless jiggers and beam dyeing machines. The following dye classes are suitable:

- anionic (acid) dyes,
- disperse dyes,
- 1:2 metal-complex dyes,
- reactive disperse dyes,
- afterchrome dyes.

Four-colour printing A subtractive printing technique based on the half-tone process with the three primary colours of yellow, magenta and cyan. A fourth printing in black or grey is added to enhance the final result (→ Trichromatic printing).

FP (fp), abbrev. for → Freezing point.

FPT textiles American term signifying Fire Proof Textiles. Textile meeting the legal fire prevention regulations in the USA.

Fr, chemical symbol for francium (87).

Fractional solubility of dyes A method used to investigate the homogeneity of dyes which is based on the different solubilities of individual dyes in various solvent mixtures. The solvents mainly used are water, ethanol, ether, benzene, methanol, carbon tetrachloride, etc., or mixtures such as aniline and amyl alcohol (pentanol) 1:1; ethanol and chloroform 3:2; dichlorohydrin and carbon tetrachloride 1:3.

Fractionated dyeing Dye uniformity investigation, based on the fact that dye mixtures can be identified by the different rates at which the individual dyes are absorbed. For example, fresh pieces of material are dyed in succession in a normal dye bath (extremely inaccurate method) for instance for about 1–2 or 15 minutes. After the dye having a quick absorption rate has been fully exhausted, the dye with a slow absorption rate remains and can now also be dyed out separately. The conditions can be varied with regard to temperature, liquor pH, fibre material etc.

Fractionation A process of gradual stepwise separation; e.g. fibre cell layers by stepwise dissolution or "peeling" in order to isolate a specific inner cell layer (fraction). Fractional distillation: the process of separating a mixture of liquids into a series of fractions of different volatilities by distillation. It begins with the liquid of lowest boiling point, follwed by the next higher and so on.

FR additive Abbrev. for flame-retardant additive.

Fragrant finishes Prepared fragrance complexes.

Each fragrant finish is a conglomerate in which each individual component has a purpose that can cause completely different odours and even discoloration, staining and fibre damage if the wrong substance is selected or there is the slightest amount of overdosing or underdosing. The basic materials are natural or synthetic odours with a characteristic smell of their own (for example, phenyl acetaldehyde and cinnamon alcohol are the odours in hyacinths and cinnamon alcohol or geraniol or nerol are the odours in roses). Additional substances for rounding off a more delicate fragrance are esters, aldehydes and alcohols. Fixing agents reinforce the uniform overall effect, reduce the vaporization pressure of the easily volatile components, slow down evaporation and increase permanence. A distinction is made between vegetable fixatives (cedarwood oil, benzoin, gum mastic, styrax, etc.), organic fixatives (ambergris) and synthetic fixatives (benzoic acid, benzyl benzoate, piperonal, etc.).

Framework Administration Regulation of Waste Water (Ger.), Rahmen-Abwasser-Verwaltungsvorschrift (VwV). The base of the german Framework Administration Regulation of Waste Water is the → Water Resources Law.

Franchise system Authorization granted by a manufacturing enterprise to a suitable individual or company for, e.g. the exclusive production of a particular product, range of products, or the use of a particular process or processes. Often takes the form of an association between a central organization and concessionary companies bound to the former by contract.

Francium → Alkali metals.

Free formaldehyde, determination of on textile materials Various methods are available for the determination of free formaldehyde on textile materials (e.g. the Japanese MITI recommendation). Formaldehyde is determined mainly by colorimetric methods according to the respective test procedures (→ Formaldehyde, tests for). Formaldehyde determination by titration with cold sodium sulphite solution is one of the most frequently employed methods.

Free interfacial energy Amount of work required to create or enlarge an isothermal or reversible interface separating 2 phases. Manifests itself as an increase in free energy (free interfacial energy) in the system, expressed in joules.

Free liquor The state of a → Liquor which is difficult to control under practical conditions since the "free" volume is always dependent on the type of material/quantity of material. On the other hand, terms such as "short or long liquor" represent definite relationships between liquor volume: weight of material, i.e. the → Liquor-to-goods-ratio.

Free liquor space The space located between the inner and outer drums in dual drum type machines for the uptake of liquor.

Freezing point (FP). The temperature of transition between the liquid state of a substance to the solid state. The terms "solidification point", "freezing point" and "melting point" are the same. The opposite of freezing is → Melting.

French chalk → Talc.

Fresco (Ital.: fresco = fresh, new)

I. Fresco twist yarn: high-twist 2 to 6-fold yarn composed of relatively fine individual yarns, produced by multiple twisting stages.

II. Fresco fabric: light-weight worsted or woollen fabrics in plain weave woven with the twist yarn of the same name; relatively harsh, slippery handle (due to the high twist), open set; usually yarn dyed but also piece dyed. The special attribute is the high air permeability and considerable resistance to creasing. A distinction is made between:

a) Fine worsted frescos ("Tropicals"), 220–330 g/m^2; all-wool or mixed with polyester (55%); smooth finish.
b) Woollen frescos ("Fresco imitations"), not as fine, approx. 500 g/m^2, usually only made from 2-fold yarn in crossbred wool; clear finish.
Used for summer suits and dresses.

FR fibres → Flame-retardant fibres.

FR finishes → Flame-retardant finishing.

Friction In all fields of textile manufacture, frictional forces and efforts to overcome them play a major role. Thus, softeners are used to improve the sewability of textile fabrics in garment manufacture. Spin finishes are applied to fibres in order to optimize their running properties in spinning and weaving. A few examples of textile technology where friction is an important consideration are given below in order to provide a better understanding of the laws of friction.

I. Spinning: friction occurs in spinning on the ring spinning frames as well as between the yarn and ring traveller and also between the ring traveller and the ring (Fig. 1). The production speed is limited by friction. At unacceptably high speeds, for example, the ring travellers would be spoiled by high temperatures due to the high heat of friction. In the case of OE rotor spinning machines, the tensile strength of the yarns after the rotor and other factors is influenced by the frictional forces between the yarn and the base of the

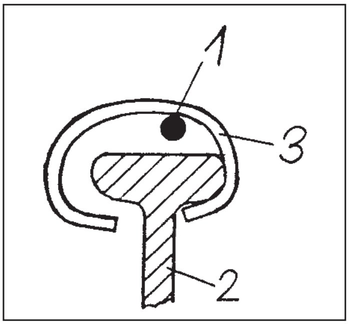


Fig. 1: Schematic representation of yarn (1), ring (2) and ring traveller (3) in ring spinning.

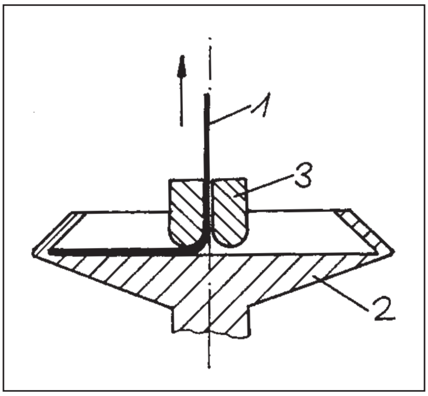

Fig. 2: Schematic representation of yarn (1), rotor (2) and doffing tube (3) on the OE rotor spinning machine.

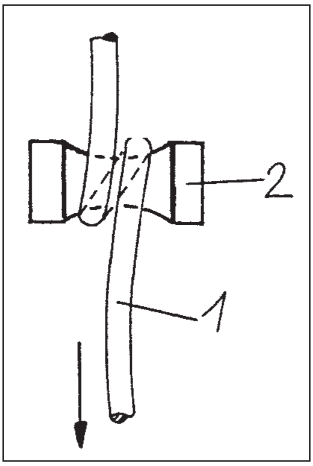

Fig. 3: Schematic representation of yarn (1) and aggregate (2) in false-twist texturing.

rotor as well as between the yarn and the doffing tube (Fig. 2).

II. Texturing: in the false-twist texturing process (Fig. 3) with twisting tubes, certain frictional forces must develop between the yarn and the aggregate of rotating discs for the insertion of twist to occur.

III. Weaving: in the projectile shuttle loom (Fig. 4), the desired tensile force for the weft yarns is regulated by the weft brake (friction brake). In the case of an air-jet loom, weft insertion is only possible as a result of the frictional forces between the weft yarns and the air jet (Fig. 5).

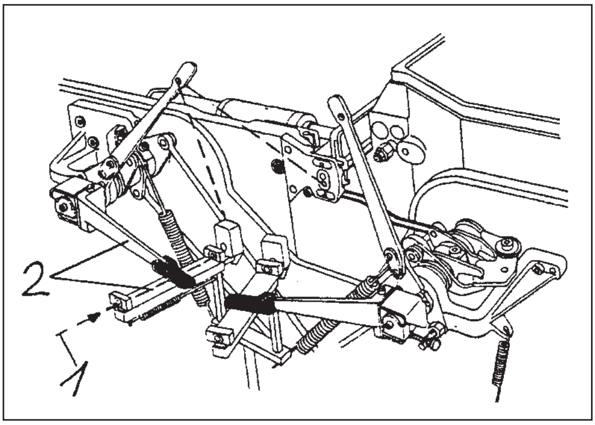

Fig. 4: Projectile shuttle loom with weft yarn (1) and weft brake (2).

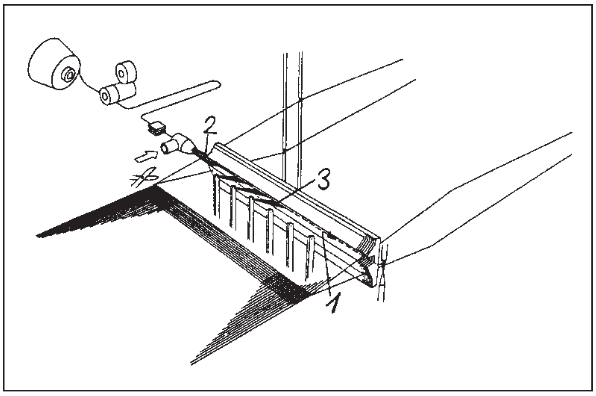

Fig. 5: Principle of the air-jet loom with weft yarn (1), air stream of main jet (2) and air stream of supplementary jets (3).

IV. Finishing: among all the fibre raw materials used in the manufacture of textiles, only wool and a few fine animal hairs have scales on their surface and, consequently, a propensity for felting. This characteristic of the wool fibre is exploited industrially in the manufacture of all milled fabrics produced from carded yarns as well as to achieve a particular fabric appearance with worsted materials and knitted articles and also in the production of felted garments. On the other hand, this property can also have negative effects with other articles that are subjected to frequent washing since the very conditions under which felting can easily occur are present during wet washing treatments.

Since the scales on the surface of wool and other animal hairs project towards the tip of the fibre, they oppose motion in that direction. Consequently, friction is less from root to tip than from tip to root. In the movement of wool fibres against each other, therefore, there is higher resistance in the tip to root direction than vice versa. The so-called directional frictional effect (DFE) according to Mercer, is used as a measure for the different frictional forces here and may be defined as the ratio of the difference of the coefficients of friction to their sum (Table 1). Other formulae for the calculation of DFE found in the literature may give values that are not comparable with each other (see also Fig. 11).

Apart from differences in frictional resistance in both directions of the scales, Table 1 also shows that, as a result of wetting the fibre and consequent swelling, the absolute values of frictional resistance in each direction have increased almost twofold and the differences in frictional resistance in both directions are even 3–4 times higher so that the felting propensity now appears much greater. It is also clear that, in the case of the antifelting finish, the coefficient in the direction against the scales is not reduced by simple smoothen-

	Central stat. coefficients of friction (before start of slippage)			Central dyn. coefficients of friction (after start of slippage)		
	in .. against direction of scaling		DFE	in .. against direction of scaling		DFE
untreated fibre	0,24	0,37	0,21	0,17	0,30	0,28
chlorinated fibre	0,91	0,92	0,01	0,82	0,78	0,02

$$\text{DFE} = \frac{\text{difference in the coefficients of friction}}{\text{sum of the coefficients of friction}}$$

Tab. 1: Coefficients of friction for different wool fibres.

ing of the scale edges to approximately the value of the coefficient in the direction of the scales, but that both coefficients are increased significantly, and to a different extent, with the result that they are almost the same.

As an intrinsically unstable fabric construction, knitted material is often over-stretched in the lengthwise direction after a wet treatment. These tensions are more or less highly blocked depending on the intensity of the frictional forces between the threads of neighbouring loops. In the compressive shrinking process, knitted fabric is compressed, i.e. the frictional forces within the stretched loops are raised; as a result, the loops can be brought back intentionally into their energetically most favourable round form. In compressive shrinking, the contact pressure, i.e. the normal force, should be chosen in such a way that, on the one hand, the fabric is bound to the rubber blanket of the shrinking machine and can be reconstructed by the change in length of the rubber blanket. On the other hand, the frictional force between the shrinking cylinder and the knitted fabric must be overcome. During the compression process, the frictional forces within the binding points of the loops between the fibres have to be overcome. Polysiloxanes, especially silicone elastomers, are used to reduce the friction. These products provide the textile material with excellent recovery characteristics.

The influence of softeners on the shrinkage process may be explained as follows:

a) When a knitted cotton fabric is finished with softeners before mechanical shrinking, the cotton fibre is enveloped with a smooth hydrophobic film. This lubricant reduces the frictional forces between fabric and metal, as well as between fibre and fibre; as a result, the fabric can now be compressed more easily.

b) For the compressive shrinking process, a rubber blanket is provided as a further component in addition to the textile material and metal cylinder. Adherence of the knitted fabric to the rubber blanket is absolutely essential for the success of the shrinking process.

V. Test procedures: in the KES-F-4 procedure of the Kawabata system for the measurement of fabric handle, which is used to determine the friction of fabric surfaces, the friction sensor employed has been adapted from the grooves on the finger tips of the human hand. It consists of 10 wires arranged one behind the other which, together, occupy a surface area of 0.5 cm^2 (Fig. 6).

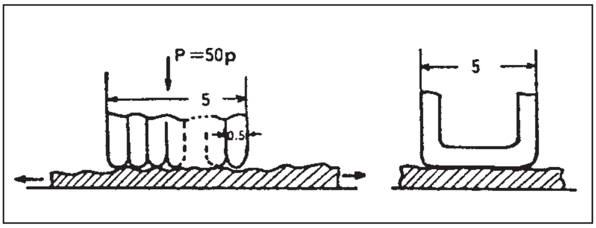

Fig. 6: Friction sensor used to determine surface characteristics.

The friction sensor is loaded with a weight of 0.5 N and firmly anchored in the measuring cell. The test specimen is secured at one end by means of a clamp. This clamp is suspended from a movable lever arm which is loaded with an additional weight of 0.6 N which provides a pretensioning force to smoothen out the test specimen. The test specimen then passes via a guide roller between the friction sensor and the metal plate. The actual measurement is carried out on the metal plate. At the other side of the apparatus, the test specimen is firmly clamped to a large diameter metal roller by means of a metal pin housed in a recessed notch. By turning on its own axis, this metal roller causes the test specimen to move forward beneath the friction sensor (Fig. 7).

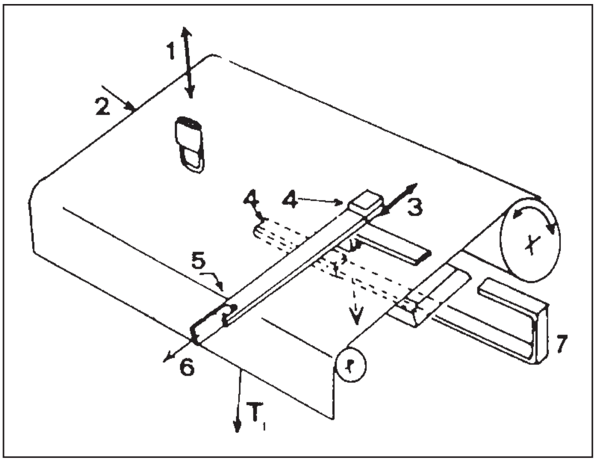

Fig. 7: Principle of the apparatus for determining surface characteristics (friction and profile).
1 = sensor for the measurement of roughness (profile); 2 = fabric test specimen; 3 = sensor for the measurement of friction; 4 = counterweights; 5 = bolt connection; 6 = connection to measuring device for frictional force.

Friction

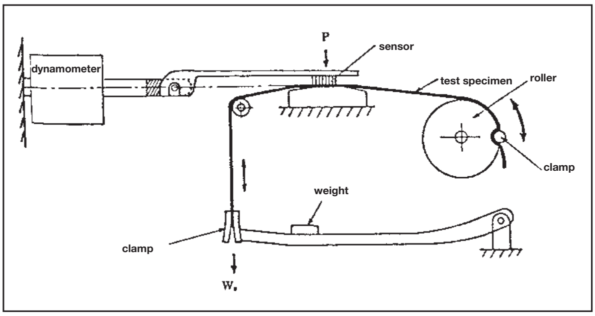

Fig. 8: Functional principle of test apparatus for the measurement of surface characteristics (KES-F-4).

After conditioning the fabric in the standard atmosphere for textile testing, two samples in both the warp/knitted wale and weft/knitted course directions are cut out to the dimensions of 2.5 x 20 cm required for the test specimens. Two measurements are taken on each test specimen; i.e. after the first measurement the test specimen is turned through 180° (the face side remains uppermost). In this way, four measurements are obtained in each of the warp and weft directions. All the data from these measurements is directly displayed with the aid of the in-built computer. It is therefore unnecessary to plot a graph.

The test specimen is laid out, with its threads aligned as parallel to each other as possible, and tensioned at both sides (Fig. 8). The friction sensor is now loaded with the 0.5 N weight, anchored in the measuring cell and the fabric specimen laid out on the test apparatus. The test specimen is transported progressively at a speed of 1 mm/s beneath the friction sensor. The test distance is 2 cm after which the direction of movement is reversed and the test distance is scanned in the opposite direction. The integrated values for the forward and reverse movement are determined directly by the computer and do not need to be recorded during measurement. If a plotter were to be connected to the test apparatus, the recorded curve would appear as shown in Fig. 9.

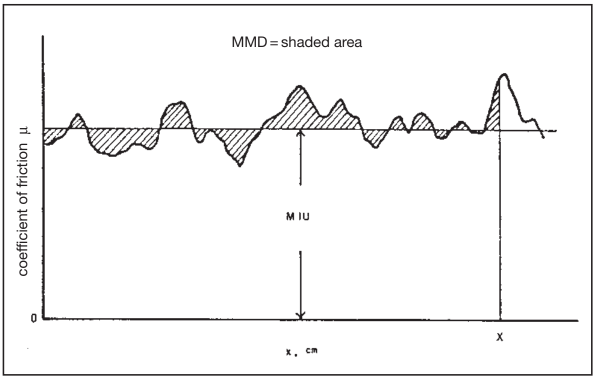

Fig. 9: Friction measurement curve.

Friction is defined as the force of resistance opposing the movement of one surface over another with which it is in contact. It acts parallel to the frictional surface and against its direction of movement. For stick-slip friction, the following formula applies:

$$F_R = \mu \cdot F_N$$

The coefficient of friction μ represents a proportionality factor, i.e. the greater the value of μ the higher the frictional force F_R.

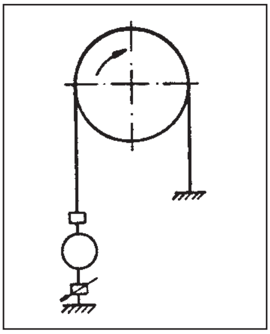

Fig. 10: Sketch of apparatus for determining the coefficient of friction.

The coefficient of friction between fibre and metal cylinder can be established as follows (Fig. 10). The textile fabric is stretched over a roller and subjected to a pretensioning force F_1. As soon as the roller is set in motion by a motor, an increase in force is registered on the measuring meter. The coefficient of friction can be calculated by means of the Eytelwein equation. The mathematical background is as follows:

$$\frac{F_2}{F_1} = e^{\mu \cdot \alpha}$$

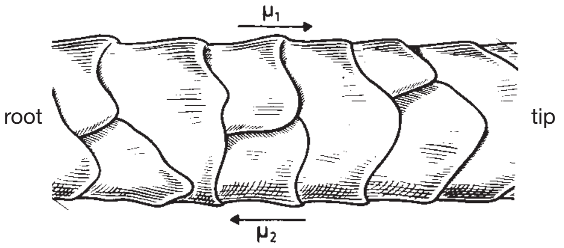
$$\ln \frac{F_2}{F_1} = \mu \cdot \alpha$$

$$\mu = \frac{\ln \frac{F_2}{F_1}}{\alpha}$$

for the angle of wrap α:

$\alpha = 180°$
$\alpha = \pi$

The coefficient of friction is dependent on:
- condition of the roller surface,
- fabric tension,
- speed,
- applied force,
- angle of wrap,
- moisture content.



Capstan method: $P_2/Pi = e^{\mu\Theta}$

directional friction effect (DFE) = $\dfrac{\mu_2 - \mu_1}{\frac{\mu_2 + \mu_1}{2}}$

Fig. 11: Definition of the coefficients of friction on the surface of the wool fibre.

To determine the directional coefficient of friction of wool fibres (Fig. 11), the individual fibres are rubbed over a horn (keratin). The coefficient of friction between a textile fabric and other materials can be determined in a similar way. Since the friction values between a textile fabric and the rubber calender within the fibre material itself are important in the case of shrinking machines, the metal cylinder would have to be substituted by a rubber cylinder in order to obtain coefficients of friction between the fabric and the rubber. Likewise, the metal cylinder would need to be wrapped with textile material in order to determine the fibre/fibre friction values.

cloth moisture (%)	6	6	6	65	65
cloth speed (m/min)	20	20	20	20	20
F_1 (N)	50	100	200	50	100
cloth tension (N/m)	71	142	284	71	142
F_2 (N)	75	140	260	80	133,3
cloth tension (N/m)	106,4	198,6	368,8	113,5	189,1
coefficient of friction μ	0,13	0,11	0,08	0,15	0,09

Tab. 2: Dependence of the coefficients of friction of a cotton fabric on process-specific parameters.

The fibre/fibre coefficient of friction for cotton is μ = 0.22. The friction values presented in Table 2 for a cotton fabric of 105 g/m^2 were determined between the fabric and a Teflon-coated steel cylinder.

These empirically determined results allow the following conclusions to be made:

a) The higher the tensile forces acting on the fabric (with the same moisture content), the lower the coefficient of friction.

b) Low tensile forces on moist fabric cause an increase in the friction values compared to air-dry fabric.

c) With high tensile forces, the moisture content of the textile fabric exercises only a minor influence on the coefficients of friction.

VI. Garment manufacture: in order to prevent loop damage in knitted fabrics during making up it is possible to apply a finish to increase the sliding characteristics of the individual yarns so that the loops can widen during insertion of the sewing needle. In the textile industry, silicone oils in emulsified form are widely used as softeners and sewing thread lubricants. Silicone products have excellent sewability properties. They have an extremely low surface tension with the result that they are able to spread very easily on almost all types of surface.

Friction between sewing needles and knitted fabrics can also be reduced with polyethylene dispersions so that the needle can slide past the loops with very little effort. As a result, better sewability is achieved and the risk of loop damage is reduced. To improve sewability therefore, the use of softeners offers significant advantages.

Friction calender In the treatment of cotton fabrics the gloss finish imparted by calender bowls rotating at the same speed only is insufficient to achieve a high surface glaze with a greater closing of the yarns. For this purpose, friction calenders are used in which a highly polished chromium-plated steel bowl travels at a higher circumferential speed than the fabric itself so that the fabric receives a lower or higher degree of glazing depending on the preselected advance speed (friction) of the calender bowl (Fig. 1). An important prerequisite for imparting a closed glaze effect on the fabric surface is an adequate fabric density, i.e. the type of fabric weave. In the case of fine weaves and fabrics composed of thermoplastic fibres, it is possible to close the woven structure by pressure and temperature to such an extent that the high gloss on the surface of the steel bowl is transferred to the surface of the textile

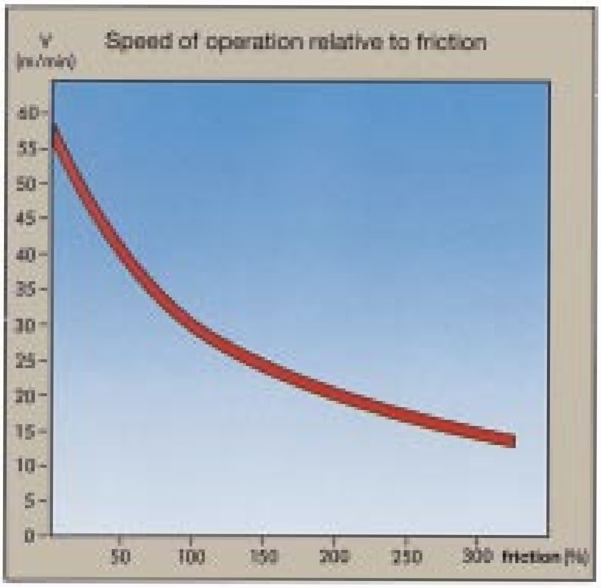


Fig. 1: Speed of operation relative to friction.

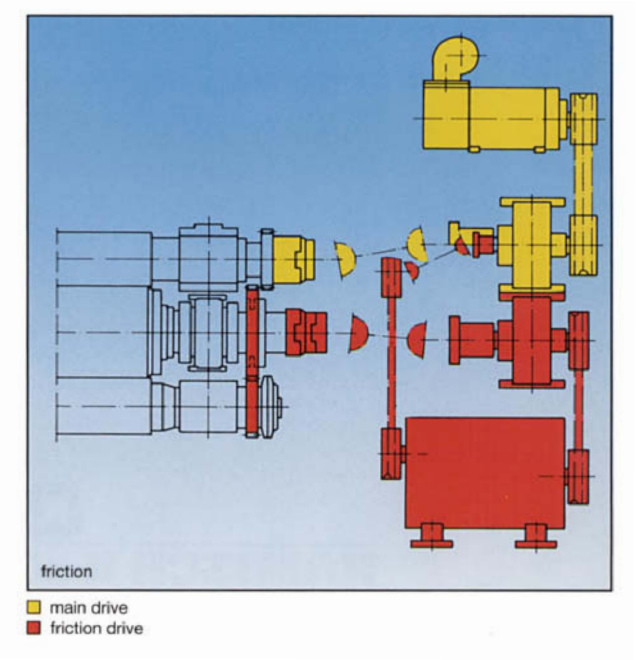

Fig. 2: Ramisch-Kleinewefers friction calender drive.

material with the bowl travelling at the same speed as the fabric (laqué effects). The required gloss can be graded from a mild silk-like lustre to an extremely high glaze.

The friction range is infinitely variable from 0–300%. Pressure is applied hydraulically. The upper steel bowl can be heated by gas, hot oil or electricity, whilst the lower steel bowl which functions as the glazing or support bowl, is mainly heated by steam. A typical arrangement of bowls in a three-bowl friction calender consists of the upper highly polished chromium-plated steel bowl, a highly-elastic cotton or paper bowl, and a lower steel bowl (Fig. 2). The upper steel bowl and the elastic centre bowl are controlled by a variable speed drive in such a way that they can be driven at the same speed or at relatively different speeds.

Friction, coefficient of The coefficient of friction is a measure of the frictional force opposing the movement of one body over another in the area of contact:

$$\mu = \frac{\text{frictional force}}{\text{normal force}}$$

The coefficient of friction is not a fixed parameter since it is dependent on frequently changing boundary conditions such as material pairing, state of the surfaces, frictional load (surface pressure, frictional velocity, temperature of surfaces under friction), type of lubricant and the quantity of lubricant applied. A reduction in the coefficient of friction, as well as a constant coefficient of friction are very important factors in the generally apparent trend towards increased productivity in spinning, throwing, texturing and winding processes, as well as embroidery and warp-knitting, etc. Progress in this development is opposed by highly variable machine productivity and variations in fabric densities which become manifest as transverse and lengthwise streakiness, variable repeats and fabric weight per m^2, as well as variations in the frequency of defects and fabric structure. The dependence of the coefficient of yarn friction (polyester/wool 55/45) on the quantity of lubricant applied is shown in the Figure.

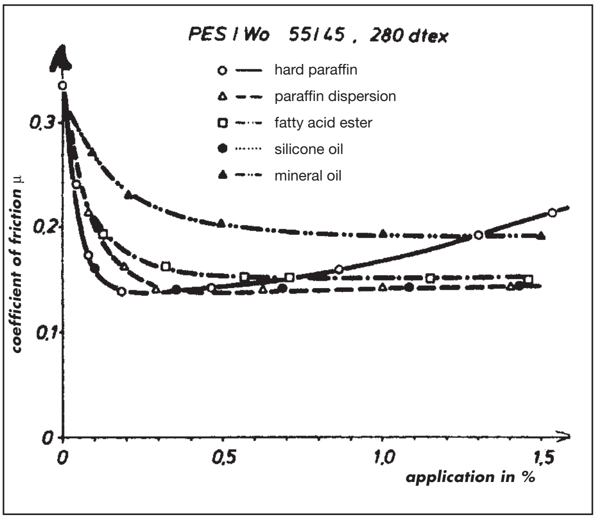

Fig.: Influence of the application of different softeners on the coefficient of friction.

After the application of softener, the mean coefficient of friction is approx. 0.1 µ. Such yarns, especially when they have received a uniform application of lubricant, give problem-free running in subsequent processing. Yarn processors sometimes demand coefficients of friction in the range 0.15–0.18 µ as an “indispensable condition” although it has been established that yarns which have been uniformly softened with paraffin to give a constant coefficient of friction even above 0.2 µ are still capable of further processing without problems. On the other hand, it has been observed that changes in the coefficient of friction exceeding +30%, especially above 0.2 µ, can cause problems on knitting machines such as torn threads, broken loops, dimensional changes and horizontal stripes. → Friction.

Friction marks These defects are formed, e.g. in the dyebath by friction between the surface of a fabric and the walls of the dyeing vessel and/or other hard surfaces. Fabrics of acetate and silk are particularly susceptible to this kind of defect. Appearance of affected areas: darker, matt and roughened surface, fabric surface bulges on one side. Often accompanied by tears and holes. Individual fibres exhibit pressure marks. Some improvement may be possible by rubbing the affected areas with a paraffin-gasoline solution.

Friction testers These instruments are used to check the characteristics of yarn friction (→ Friction, coefficient of). The following types of instrument are available for this purpose:

- simple, non-recording mechanical instruments (e.g. friction balance);
- simple, recording mechanical instruments (e.g. micron meter);
- electronic (computer-controlled) instruments with full data print-out facility for variable measurement conditions.

Complaints have often been made when using these instruments that the measurements obtained can sometimes deviate considerably from one another. The reason for this is due to variations in frictional conditions. If, however, these frictional conditions are brought more into line, then identical measurements will, in fact, be produced.

Friction texturing → Friction texturizing.

Friction texturizing Texturing method in which appropriate overtwist is applied to the running thread using overlapping friction discs (torsion discs, friction discs). The required false twist is achieved by subsequent counter twisting and twist setting. Up to 1960 a rigidly mounted spindle with axial drive was used (friction elements). As entirely uniform, reproducible speeds could not be obtained, spring-mounted magnetic spindles are now used (instead of rigidly mounted friction components).

Friele MacAdam Chickering formulae → Colour difference formulae.

Friezé

I. Handknitting and craft yarns with brushed woolly finish.

II. Soft, thick woollen fabric in plain or twill weave, can also be double cloth with two warp and weft systems, generally with pepper-and-salt effect on face and checked on reverse. Mossy thick hairy nap, either heavily raised on both sides or lightly raised on reverse only. Friezé cloth is simlar to velour but with rougher longer nap. Distinction may be made between randomized nap (with non-directional lay) and brushed nap (with directional lay). Used for ladies winter skirts, jackets and coats.

III. Thick, soft woollen material with raised and laid nap (milled and raised) or may be closely cropped.

Friezing A process used for the production of local patterning on a pile fabric where the pile has usually been formed by raising. The fabric passes between a fixed friezing bed and a moving friezing plate mounted above it which is clothed with sandpaper, plush, cloth or rubber (see Fig.).

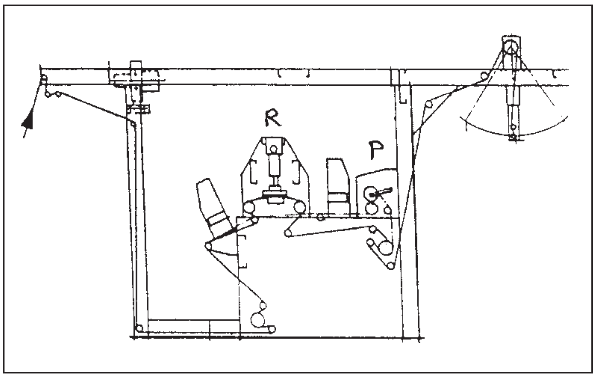

Fig.: Schematic diagram of pile patterning machine with friezing (R) and embossing (P) devices for optional use (Franz Müller).

Depending on the extent to which the friezing plate carries out its short to-and-fro motion, the following effects are achieved: large or small pills or burls (pearl ratiné), fine blocks (Floconné), warpwise stripes (lengthwise or warp ripple), weftwise stripes (transverse or weft ripple), diagonal stripes (diagonal frisé), or even whirl-like effects (plush with whirl effects).

Fringed micelle → Cellulose.

Fringe twisting machines Machines which automatically twist a certain number of warp yarns in woven blankets and plaid travel rugs to form a fringe held in place by the insertion of auxiliary threads until the end of the finishing process (Figs. 1 + 2).

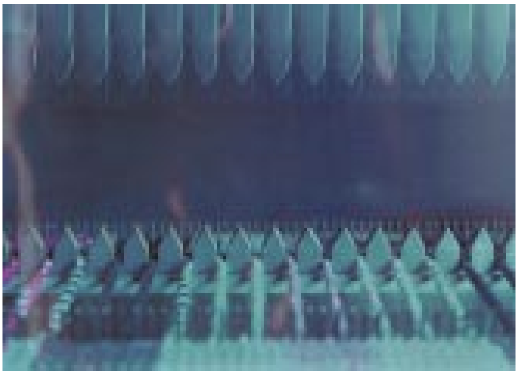

Fig. 1: Fringe twisting machine.

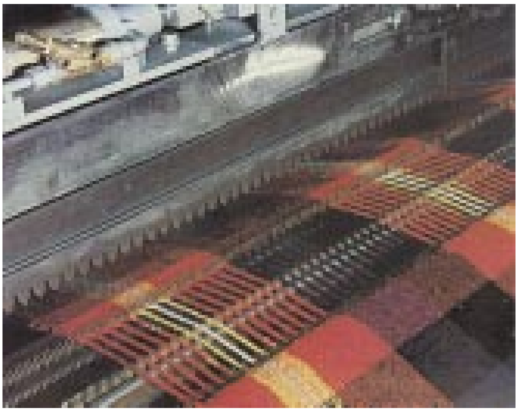

Fig. 2: Lafer fringe twisting unit.

Frisé

I. Originally the finest grade of linen made in Friesland, Holland.

II. A French term meaning "curled".

III. A coarse ratiné fabric made with slub yarns in a plain weave.

IV. A looped pile fabric usually of uncut loops which may be cut at various heights to provide a pattern.

V. A coarse, stout cotton or linen fabric made in a plain weave with a flat, wiry texture and a pronounced rib.

VI. This term is sometimes used for terry or bouclé fabrics.

Frisé carpet A cut pile carpet of twisted yarns in solid colour or produced with vari-coloured yarns. According to DIN 61151, a carpet with alternating closed and cut loops.

Frisons Flock silk (→ Bourette). The first silk waste obtained in the course of cocoon preparation for reeling by agitation in a water bath.

Front fusing A process used in garment making to give garments form stability by bonding with an interlining (with a hot-melt adhesive). Bonding takes place by the action of heat and pressure in heated presses. Problems are encountered with fabrics which have been finished with silicones or fluorocarbon derivatives. Adhesion is improved by double-spot coating. →: Powder bonding; Interlinings.

Front line Upper demarcation line for front of eluent in → Paper chromatography and → Thin-layer chromatography. Parallel distance from start line 15 cm in paper chromatography and 10 cm in thin-layer chromatography.

Front loading washing machine (Front loading washer), cylinder washing machine with a one-piece internal cylinder that is supported at one end and has a loading/unloading opening at the front end, usually with a transparent door made from heat-resistant safety glass. Capacity 8–50 kg of dry material.

Frosted wool process A process for the degreasing and removal of all impurities from raw wool by cooling to –10 to –17°C followed by beating to break off the solidified brittle foreign matter (grease, burrs, sand, etc.). Burrs become so brittle in this treatment that they are easily pulverized by attrition.

Frosting

I. → Sandwich effects in dyeing.

II. Whitish sheen on carpets containing wool and polyamide pile that have been continuously dyed by the pad-steam process. When the padded carpet enters the steamer, condensing steam rinses dye liquor from the tips of the pile, thus giving it a whitish appearance. A remedial measure is to add film and foam-forming agents to the padding liquor. Foam pushes the dye liquor back towards the tips of the pile, thus compensating for the loss of dye.

III. Light patches occurring in viscose crepe in the warp direction consisting of flat, deformed viscose capillaries that are in fact dyed but reflect much more light because of their flat shape. Visible under the microscope as short, thin apparently white capillaries that can be proven to originate from the feedstock and can no longer be rectified. These patches are created during the viscose spinning process and appear to be due to some kind of local stretching.

Frosting in carpet printing (tippiness). Rather than remain uniformly distributed along the individual pile fibres in the printing of carpets, especially those with a high pile) the print paste may flow from the tips of the pile towards the carpet backing before the dye fixation stage. This results in a depletion of dye at the tips of the pile, i.e. frosting.

Froth dyeing A variant of → Foam dyeing. Principle: the process is carried out in an open vat as the dyeing vessel. Foam is produced by the vigorous boiling of a dye liquor containg soap or other high-foaming detergent. The dye liquor occupies approx. 20% of the dye vessel volume, and the material is dyed by suspension in the foam above the dye liquor.

Frotté Name for

I. Yarn: 5–7 fold effect twist yarn in form of knop yarn, loop yarn, in cotton, viscose, wool (woollen spun).

II. Plain-weave fabric with smooth warp and knop yarn weft, irregular, contoured surface; brushed, rough finish. Sold as piece goods or by the metre; also used in outerwear.

Fruit fibres → Hard fibres of the coconut fibre type.

Fruit-ice stains The stains are tacky when fresh and often hard when old. Most have a fairly sharp outline and can be of various colours. Removal: white spirit or trichloroethylene (tetrachloroethane), then ammonia 1–3%. Colour residues are subsequently best removed with alcohol.

Fruit juice stains (from berries). The stains can be of various colours with a sharp outline when fresh or more blurred when old, often only on the surface of the fabric. Removal: a) treat the affected area in a fatty alcohol sulphate solution 3–15 min (warm/hot), if necessary with ammonia or ammonium carbonate 2–5%, soak (with formic acid); b) treat with a fatty alcohol sulphate solution plus 10% formic or citric acid (or sodium bisulphite especially for bilberry stains). Colour residues: treat with sulphurous acid (sodium hypochlorite-oxalic acid, potassium permanganate or hydrogen peroxide).

Fruit wall hairs Vegetable hairs of the inner fruit skins of tropical plants such as the cotton tree (Bombax species). Fruit wall hairs are seed fibres such as those of the kapok tree, etc. (Bombax cotton, Ceiba fibre).

FSDC, abbrev. for: Fellow of the Society of Dyers and Colourists, Bradford, U.K. Professional qualification.

	Wood %	Peat %	Brown coal %	Coal %	Anthracite %

Tab.: Composition of various heating fuels.

FSW (Ger.), abbrev. for: Forschungsstelle Wäscherei (Laundry Research Unit), Hohenstein; → Professional and technical organizations.

FTC,

I. Abbrev. for: Federal Trade Commission. A US government customer protection agency which, amongst other activities, has been responsible for the definitions of most of the internationally valid man-made fibre classifications.

II. Abbrev. for: Fastness Tests Commission.

FTCC, abbrev. for: Fastness Test Coordinating Commission, the British Fastness Tests Commission; → Professional and technical organizations.

FTI, abbrev. for: Fellow of the Textile Institute, Manchester, U.K. Professional qualification.

Fuchsin B. A cationic dye used *inter alia* as a special indicator for anionic substances: aqueous Fuchsin solution + anionic solution = colour change from red to cornflower blue.

Fuchsin dyes Rosaniline, cationic red, violet and bordeaux dyes. These dyes are chemically very sensitive: reaction with acids = yellow (brown), reaction with alkalis = brown precipitate, reaction with oxidizing agents (chloride of lime) and reducing agents (sodium bisulphite) = decolorization. They are still used in the Far East as cationic red dyes for dyeing textiles and leather. Also used as a colour reagent in the laboratory for aldehydes (→ Schiff's reagent).

Fuel composition Varies according to the intensity of carbonization and the age of the fuels (Tab.).

Fuel gas →: Natural gas; Liquefied gas.

Fuel oil Liquid fuel, mainly from mineral oil processing. The subject of standards in Germany in accordance with DIN 51 603. Types of fuel oil: production and use almost exclusively restricted to EL fuel oil (extra light) which is mainly used for space heating and is also used for heating processes in commerce and industry, and S fuel oil (heavy), which is the preferred fuel for most industrial heating processes (Tab. 1). L fuel oil (light) and M fuel oil (medium heavy) are exclusively products of tar oil processing and only play a quantitatively minor role (less than 1% in the Federal Republic of Germany).

Full bath treatment A dyeing process carried out at a long liquor ratio by → Exhaust dyeing, in contrast to the → Foulard therm process.

Full cover print A printed design which covers the entire surface of a textile fabric.

		Fuel oil EL		Fuel oil S

*Tab. 1: Fuel oil parameters. (*Some fuel oil S with lower sulphur content (max. 1%) available).*

Full depth shade in printing The maximum depth of shade which can be achieved with a normally engraved screen or printing roller.

Fuller's earth Impure clay (refined and pulverized) with a greyish-green to yellowish-brown colour and a greasy feel, often of variable composition (e.g. 11–18% aluminium oxide, 44–42% silica, 5–4% lime, 2% magnesia, 10–6% iron oxide, 5% sodium carbonate, 3% water).

Quality test: stir the sample with water and allow to swell and crumble into a paste-like mass. On standing, a powdery precipitate should be gradually formed (without sandy, granular or dirt impurites). Uses: after-washing and milling of woollen materials which have been washed in soap (especially for fine cloths, white and semi-coloured flannel, woollen blankets, etc.).

Fulling stock Mechanism in open-width milling machines in which woollen fabric is compressed in a stuffer box using a hinged top board.

Full penetration dyeing The full penetration dyeing of fibres or textile materials occurs when a completely uniform distribution and penetration of the fibre occurs, i.e. when the interior of individual fibres is fully penetrated (not ring-dyed) and when the closely packed fibre material in slivers are completely dyed. Full penetration in dyeing is a function of the dye exhaustion rate, the control of which determines the degree of dye penetration.

Fully automatic In the context of textile wet processing, a fully automatic process is understood to involve the automatic operation of all machine processing stages (including the metering of additives) according to a program with preselected parameters. → Automation.

Fully fashioned A term used for knitgoods produced on a flat-knitting machine that have been shaped by adding or reducing stitches. The material has ribbed edges (not cut) as it leaves the knitting machine. Fully fashioned flat-knitted materials are referred to as true to shape articles. Fully fashioned knitgoods are used e.g. for socks, stockings, tights, underwear, outerwear, pullovers, etc. Fully fashioned fabrics are the opposite of → Cut fabric.

Fully fashioned dyeing → Garment dyeing.

Fully-washable textiles Finished textiles which can be washed in a washing machine without excessive shrinkage, creasing or other significant deterioration in quality. The term is particularly applicable to blend fabrics of polyester/cotton or polyester/acrylic (→ Machine-washable wool; Easy-care finishes).

Fumaric acid Exists in the cis form. Used especially in synthetic resins. Fumaric acid polyester is used as a plastic.

Functional clothing Clothing that is designed to be light, comfortable, pleasant to wear and easy-care; e.g. → Active wear; Sportswear.

The human body tends to sweat heavily during any strenuous activity, particularly when taking part in many forms of sport. The evaporating perspiration cools the skin and the body, which feels extremely pleasant because of the occurrence of the chill limiting temperature on the skin. Clothing that is in contact with the skin absorbs moisture and releases it to the outside air. If the moisture absorption is greater than the evaporation rate, the textile material stays wet on the skin and usually causes an unpleasant sensation. For example, the way in which functional knitwear functions is to wick perspiration away from the body as quickly as possible, whereby the textile surface that is in contact with the body may not remain wet. This is caused by the structure of the material. Fabrics are mainly double-faced knits, the inner surface of which comprises hydrophobic synthetic fibres and the outer surface of which comprises absorbent cotton or modal fibres. Most fine fibril synthetic fibres (polypropylene, polyester, polyamide) quickly transport moisture to the absorbent outer layer via the capillary spaces, without absorbing moisture.

An important prerequisite for a clothing system to function correctly can be described as follows: the comfort of textiles worn next to the skin is determined by two things: thermophysiological and skin sensation properties. Wearer comfort associated with skin sensation is considered to be the way that materials feel to the touch, i.e. pleasant sensations such as softness and suppleness, but also unpleasant sensations such as scratchiness, sticking to sweaty skin etc. The thermophysiological wearer comfort of textiles is determined by the heat and moisture transmission processes within and through the layers of textiles. The two transmission processes serve to provide a balance between the temperature of the body and its environment. The textile layers next to the skin have to provide good sweat evaporation to the surface of the skin. However, in many practical cases the evaporative heat flow in the clothing is inadequate, because the body produces superfluous amounts of perspiration that cannot evaporate on the surface of the skin and remain there in the form of liquid perspiration. These quantities of perspiration have a thermoregulatory effect on the one hand and produce an unpleasant skin sensation on the other. Textiles worn next to the skin therefore have to remove these excessive perspiration components as rapidly as possible.

The climate of the skin involves two factors: the microclimate (→ Clothing physiology): during strenuous activity the skin must be capable of releasing water vapour from its pores to the outside air without hindrance, which is only possible if there is a partial pressure differential of vapour pressure between the skin and the air in the environment. It should therefore be attempted to make the air next to the skin as dry as possible. In the reverse case, in cold weather conditions there should also be dry air next to the skin i.e. within the textile surface structure, in order to provide the necessary heat retention, the insulation characteristics. The clothing therefore becomes part of the person's energy balance, with its moisture penetration resistance and thermal insulation, expressed as the moisture transmission index i_m. Both values can be measured on the Hohenstein thermal regulation model/system (heated sintered metal plate that emits steam and therefore simulates the human skin), or “Charlie”, a life-sized metal mannikin that moves, sweats and is fitted with a range of measuring probes, and can also be used to measure the wearer comfort of textiles.

Functional group control (Automatic function group system), control using the principle of program control, whereby the technological process is split into self-contained function groups.

Functional groups Typical groups of atoms responsible for the characteristic reactions of entire classes of chemical compounds, e.g. functional hydroxyl groups (OH) are characteristic of alcohols, carboxyl groups (COOH) are characteristic of organic acids, amino groups (NH_2) are characteristic of amines, etc. Compounds are described as mono, bi, tri or polyfunctional depending on the number of such functional groups present in the molecule.

Fungi as textile parasites → Moulds; Microbial damage to textiles.

Fungicidal finishes These finishes are applied especially to textiles which frequently come into contact with the ground, soil, wind and weather, such as tenting, truck tarpaulins, fire hoses, etc. Suitable preservatives for such articles include, in particular, organic acid salts of zinc, copper, and mercury, phenols, chlorophenols, anilides of aromatic acids, sodium salts of chlorocresols, chloroxylenols, tri and pentachlorophenols, copper salts of cellulose glycollic acid, as well as quaternary ammonium bases, etc. Free aromatic compounds of the above type generally have a stronger fungicidal action than their salts, but are more susceptible to volatilization and are more easily removed by wet treatments. For this reason, it is preferable to precipitate the heavy metal salts of these fungicides on the surface of or within the fabric. From an American survey, the parameters used to evaluate the suitability of a fungicide for textile use are stability, efficacy, toxicity, odour and effect on colour. Stability is required against heat, UV radiation, weathering and oxidizing substances; only a few chemical compounds have all these properties. A fungicide should remain unchanged during the entire working life of the fabric as well as during prolonged storage. Effective fungicidal action must already be achieved with relatively small doses of the fungicide.

Fungicide (Lat.: *fungus* = mushroom, fungus). A substance or product capable of killing or destroying fungi.

Fungistat A substance or product that inhibits the growth of fungi.

Fungistatic finishing Prevents the growth of fungus on textiles; the same products as those recommended for → Antimicrobial finishes are usually used.

Funnel test A test method for the evaluation of water-repellent finishes on textiles (not as severe as the → Permeability bag test or the water pressure test, but of advantage for lightweight fabrics since less distortion and extension of the test specimen is involved). Procedure: a test specimen measuring 30 x 30 cm is folded into a filter form and placed in a glass funnel supported on a stand (width at top approx. 15 cm, angle of 60°), then filled with 500 ml water. The water-repellency is evaluated by the time taken for the first penetration of water to occur (1 h or 1 day) and also, if necessary, by measuring the quantity of water collected in a measuring cylinder placed beneath the funnel.

Furan (furfuran) →: Furfural; Furfuryl alcohol.

Furan polymers → Furfuryl alcohol.

Fur bleaching → Bleaching of animal fibres, carried out on a previously prepared skin which must not have been subjected to chrome tannage.

Fur dressing → Fur finishing.

Fur dyes Metallizable types. These dyes are applied on the same principle as metallizable wool dyes and produce fast dyeings on fur skins by brushing or dipping. The classical dyeing technique is based mainly on the application of aromatic amine bases at a temperature of 30°C from which dyes are synthesized on the fur hairs by oxidation (probably by a process analogous to → Aniline black) and fixed with the aid of metal mordants. Appropriate azo dyes capable of exhausting on to mordants are also used in fur dyeing. Similar dyes can also be dyed to some extent by oxidation. However, these dyes exhaust more rapidly with improved levelling and better fastness to storage and light when applied on fur skins which have been pre-mordanted with a metal salt. The metal-complex dye lake thus formed exhibits a considerably increased colour intensity and covering power the properties of which are greatly dependent on the respective type of mordant employed. In Europe, fur dyeing can only be carried out nowadays with non-toxic and non-carcinogenic dyes.

Fur finishing The finishing of fur materials covers all the processes and technical operations which affect the original character of the fur. These changes are mainly concerned with the fur's natural colouring.

The dressing of fur materials includes all the operations carried out with the objective of exploiting the characteristics of the fur in clothing applications to the widest possible extent. A properly dressed fur should not be susceptible to putrefaction and should be largely insensitive to the effects of water. The skin should be of low mass and exhibit a high degree of softness, flexibility and durability; the hairs of the fur must be clean and firmly rooted in the skin and should not be susceptible to any changes which could impair the results of further finishing or the serviceability of the fur. Specific finishing effects are already achieved during the dressing treatment. The entire dressing process must be optimally adapted to possible further finishing involving dyeing or other operations as well as subsequent use of the fur as far as fitness for purpose and fashion requirements are concerned.

During the course of dressing, the fur is subjected to a variety of treatments which have a physico-chemical or mechanical effect on the skin and thereby bring about the required changes in its properties. Both types of treatment are applied one after the other in the overall dressing process but the sequence differs from one type of fur to another as well as from source to another.

In the initial stages of fur dressing, the fur is reconverted by the softening process into the fully hydrated (water-saturated) state, as it existed on the live animal and, during subsequent digestion of the skin, the skin protein material, i.e. the collagen, is broken down. Any non-leather-forming tacky impurities are removed. The loosened state of the skin is then fixed with tanning agents or other substances which create a similar effect (pseudo-tanning) whereby the skin is converted into a non-putrefiable water-resistant leather or, at least, a non-putrefiable leather-like form. Furs with soiled hairs are cleaned by a washing treatment which is usually given after the softening process. Softening, washing, skin digestion and tanning resp. pseudo-tanning, involve physico-chemical processing of the fur material and are mainly carried out in the bath in aqueous media on a large number of fur pieces in a single batch.

Mechanical treatments are interposed as required before, after or in-between other processes. The objective of these treatments is to remove redundant parts of the fur material such as heads, paws, etc., as well as skin resp. leather substances which are not absolutely necessary for the strength of the leather and the secure anchoring of hairs and which would otherwise increase the fur's mass unnecessarily. Moreover, the more or less firm adhesion of leather fibres which occurs during drying of the fur material is eliminated, prevented or reduced by the mechanical treatment. If necessary, the hair coat is likewise loosened and shortened. The mechanical treatments are carried out manually or by machine either individually or in batches. The flexible and soft character of the fur leather is further increased by fat-liquoring. The hair and leather are cleaned by a treatment with abrasive and absorbent materials in the clarifying process. A treatment in organic solvents is given to achieve a light leather through the removal of excess fats as well as a further cleaning of the hair coat.

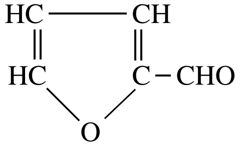
Bleaching (a process which is usually coupled with dyeing in practice) is a treatment to change the natural shade of the fur. Chemical reactions between the fur and the chemical substances used play the key role in this process. Because of the naturally variable appearance of fur materials, an absolute levelling out of the shade is not possible when a large number of fur pieces are treated as a single batch.

Depending on the animal's age, sex and nutrition as well as the origin of the live animal to some extent, furs react very differently to each other and this is further influenced by all the physico-chemical processes involved in the course of finishing. An additional problem here is the fact that not only do the woolly and long coarse hairs behave differently in dyeing, but a range of different types of fur over the entire surface of the fur material (e.g. the back of foxes, belly parts, etc.) react differently in terms of dye uptake and therefore in the uniformity of shade obtained.

As far as creation of the shade is concerned, imitations of genuine wild furs were originally produced on cheap commodity materials. Nowadays, the line between the terms fur dyeing (which was formerly understood to mean a uniform dyeing, e.g. black) and fur finishing has become blurred since, besides the production of imitations, the production of standard fashion shades on all types of furs by all processors of hides and furs is now of equal importance.

In addition, the hair length of the fur, the original composition of the hair coat, or the form of the individual hairs, are changed by the mechanical operations applied in fur finishing. Only in the rarest cases are these operations unconnected with changes in the dyeing properties of the hair coat. Shearing can not only result in the achievement of a uniform hair length, but certain effects such as furrows or patterns can also be produced in the fur. The ratio of woolly hairs to long coarse hairs is changed by depilation or plucking whereby the long coarse hairs are removed from the fur mechanically. The production of rumbled nutria should be mentioned as an example of a very labour intensive process (removal of the dense long coarse hairs already begins in the dressing stage). Processes which influence the shape of the individual hairs themselves are of relatively recent introduction. On the one hand, this involves stretching out the woolly hairs which are crimped or curly on the live animal and the production of crimp in naturally straight hairs on the other, e.g. to achieve Persian curls or South American markings.

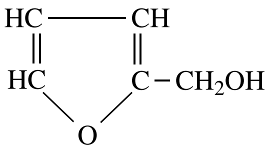
Furfural, Lat.: *furfur* = bran (furfuraldehyde, 2-furaldehyde, bran oil).



A readily accessible starting product for furan derivatives. In the USA it is manufactured on an industrial scale from cereal wastes (oat hulls, rice hulls, corn cobs, etc.). Used as an intermediate product in the fabrication of polyamide 6.6; as a solvent for decolorizing natural rosin for varnishes; for the production of phenoplast resins in place of formaldehyde, etc. Hydrogenation results in the formation of tetrahydrofurfuryl alcohol.

Furfuran → Furan.

Furfuryl alcohol, $C_5H_6O_2$, density 1,13, b.p. 170–171°C, a derivative of furfuran. A colourless to yellowish liquid with a characteristic odour. Soluble in water, alcohol, ketones, etc.



Solvent for nitrocellulose, certain dyes, synthetic resins, etc. Manufactured on an industrial scale in the USA for solvents, wetting agents, synthetic resin components, etc. It forms furan polymers, e.g. in aqueous solution with phosphoric acid (as catalyst). The low-viscosity furan polymers are soluble in alcohol, whilst high-viscosity types, on the other hand, are soluble in acetone, ethyl acetate, aromatic and chlorinated hydrocarbons. Also used for high quality cold-curing sealants, cements and plastics (transparent, elastic) which are also used as components of other synthetic resins, e.g. for improving the alkali stability and adhesive properties of phenoplasts.

Furnisher roller (colour furnisher roller). Used in roller printing to supply the engraved printing roller with print paste from the colour box in which it rotates. Both brush furnisher rollers and smooth rubber-coated rollers are used. → Brush furnisher roller.

Furnishing fabrics Collective term for printed, plain-dyed or jacquard-woven textile fabrics for room decoration purposes, e.g. upholstery fabrics, curtains, drapes, etc. Dyes with very high colour fastness to light are required for these applications.

Fused bonded nonwoven → Bonded fabrics which have been bonded, e.g. through the loops of the warp threads with a thermoplastic compound.

Fusel oil → Amyl alcohol.

Fusible fibres These are used in the form of fibres, threads and monofilaments to achieve adhesive-free consolidation/permanent bonding of textile fabrics. After thermal fusion with the aid of an ironing press, hot air, etc., the cohesive strength is intense and permanent. Fusible fibres are of particular interest for nonwovens, textile floorcoverings and in the making-up of garments. (→ Binder fibres).

Fusible interlinings → Interlinings produced with a fusible adhesive coating by the powder-dot process.

Fusible seaming A textile bonding technique in which fabrics are joined by fusion of thermoplastic fibres in the fabric or a thermoplastic resin that has been applied to the fabric. The latter requires special nozzle applicators. From experience with knitted and woven fabrics, felts and nonwovens, seam strengths corresponding to those of conventional seams are obtained. In addition to the high shear strength of welded seams, savings in time are also achieved; moreover, the mechanical piercing of fabric with sewing needles is dispensed with. The speed of operation is determined solely by the rate of feed of the material being seam welded.

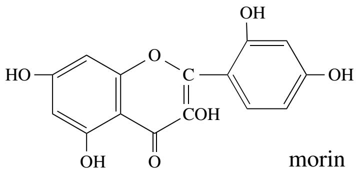
Fusion lamination A special process in which the surface of a foam sheeting is liquefied under the controlled influence of heat and bonded in this state to the material being coated. The liquid foam hardens on cooling to form a firm bond between the foam sheeting and the textile material. Advantages: good drape characteristics and extensibility, perfect air permeability, the bonding is resistant to washing and drycleaning, and the process is suitable for knitgoods. The loss in thickness of the foam is approx. $^1/_{32}$.

Fustian A general term used to describe a group of cotton fabrics, usually heavily wefted, raised on one or both sides, and produced in various weaves, e.g. twill fustian, satin fustian, corduroy fustian. The description also refers to the end-use, e.g. bed-fustian, lining fustian, dress fustian.

Fustic (yellow wood)

I. Brazilwood, Cuba wood, fustic wood: tropical dyewoods; hard, solid, light yellow or pale lemon yellow, turning darker with age. Available commercially in block form, raspings and powder.

II. Yellow dyes of the flavone type. Fustic consists mainly of morin or morin acid ($C_{15}H_{10}O_7$) and maclurin or morintannic acid ($C_{13}H_{10}O_6$).



morin

Fustic is completely soluble in a 50% water/alcohol mixture. Fustic extracts are highly viscous or solid (yellowish-brown/olive) waxlike lustrous lumps with a conchoidal fracture. Fustic gives coloured precipitates with metal salts: alumina, tin and chrome mordants = yellow; lead acetate = orange; copper sulphate like antimony potassium tartrate oxide = brownish-yellow; iron salts = olive green. Fustic is still used from time to time in silk dyeing, often combined with weighting. → Logwood.

Fuzz A term analogous to → Lint, used mainly to describe small hairs, fibres, etc. projecting from, or lying on, the surface of a textile fabric.

FWA, abbrev. for → Fluorescent whitening agent (→ Fluorescent brightening agents).

G

G, symbol for giga, i.e. 10^9. A prefix used in the metric system to denote one thousand million times, e.g. 10^9 joules = 1 gigajoule (GJ).

g, symbol for gram, a metric unit of mass equal to one thousandth of a kilogram. 1 g = the weight of 1 cm^3 of water at +4°C. 1 cm^3 = 1 g = 1000 mg. 1000 cm^3 = 1 l = 1 kg (of water). 1000 l = 1 m^3 = 1000 kg = 1 t.

Ga, chemical symbol for gallium (31).

Gabardine The word gabardine (alternative spelling in U.K. = gaberdine) is a collective term for certain woven fabrics and also describes a type of woven pattern. Gabardine is generally a fine, tightly woven warp-faced fabric. The warp density is generally considerably greater than the weft density and the diagonal cord or rib (steep twill line) is distinct, closely set, and raised. Gabardine is produced from carded or combed, single or ply yarns of wool, cotton and viscose. In one type of gabardine, the rib effect is produced with a secondary twill or a multi-shaft satin weave but most gabardines are usually woven in 2/1 and 2/2 twills where the higher the warp density the steeper the twill line. Without exception, coat fabrics (e.g. for trench coats) are woven in 4-shaft reversible twill or 2/1 or 3/1 warp twill. Some gabardines are produced with changeant or shot effects but, as a rule, this type of fabric has not attracted much interest for fashion goods or fashion styling. Good quality gabardine coat fabrics are woven from folded yarns in the warp, or even in both weft and warp. Because of the fine, uniform appearance of wool gabardine fabrics, they are produced almost exclusively with combed yarns in medium-fine to fine yarn counts from pure wool as well as wool blends based on all the usual blend ratios. Even blends with up to approx. 20% max. of polyamide fibres are possible (for alpine and ski gabardines). In practice, carded yarns have only found application as weft material and some fabrics of this type also have a viscose warp. Gabardines are closely cropped to emphasize the weave structure. Commercially, wool gabardine is vigoureux printed, yarn and piece-dyed, with the latter being the most important. Gabardines are usually produced in weights between 240–400 g/running metre and even up to 600 g/running metre in exceptional cases.

Galactomannan (mannogalactan). The main chemical component of e.g. → Carob (locust bean gum) and guar which is built up from the two simple sugars ($C_6H_{12}O_6$) → Mannose (which forms the main long straight chain of the basic skeleton) and galactose (as side chain linkages).

Galacturonic acid The fundamental building block of → Pectins; similar to → Glucose in starch and cellulose.

Galalith → Casein plastics.

Galanga gum A medium quality grade of → Senegal gum.

Gall extract Produced from the gallbladders of mammals, e.g. ox gallbladders, as a brownish-green mass giving a clear solution in water. Cattle gallbladders contain 6–8% dry substance consisting chiefly of so-called bile acids. Cholic acid, $C_{23}H_{36}(OH)_3–COOH$ is the main constituent linked to glycocoll in an amide-like form as glycocholic acid $C_{23}H_{36}$ (OH)3–CO–NH–CH_2–COOH or to → Taurine as taurocholic acid $C_{23}H_{36}(OH)_3–CO–NH–C_2H_4SO_3H$, the alkali salts of which possess soap-like properties. The gall soaps, which contain approx. 8% gall extract and above, are characterized by a high emulsifying capacity and outstanding surface activity. Despite the useful properties of pure and concentrated gall extract preparations as good scouring soaps their importance has declined since the development of synthetic wash-active detergents.

Gall nuts Plant growths containing tannins which in Europe are mainly spherical and in Japan of irregular shape. The former are formed by the sting of the gall wasp on oak leaves and the latter by aphids. European gall nuts contain 7–28% of readily water-soluble tannins (→ Tannic acid) whilst the Japanese variety contain 58–75%.

Gallon,

I. British or imperial gallon. Non-metric unit of capacity equivalent to 4.543 l or 1.20 U.S. gallons.

II. U.S. gallon. Non-metric unit of capacity equivalent to 3.785 l.

Galloon A narrow band of cord, embroidery, braid, etc., used as a decorative trimming. → Braid.

Gall-Riedel formula → Depth of shade of dyeings and prints.

Gall soaps → Gall extract.

Galvano screen → Rotary screens for screen printing.

Gambier A Chinese textile speciality consisting of deep black clothing suitable for everyday use made from non-degummed, heavily-weighted butterfly silk (lightweight base fabric, plain weave) glaze-calendered on one or both sides (with polished stone rollers). Highly resistant to wear (washable, suitable for dry cleaning). The deep black is produced by piece dyeing with a reaction product from a gambier-like tanning substance (juice of the so-called kaki fruit) and a river sludge containing iron.

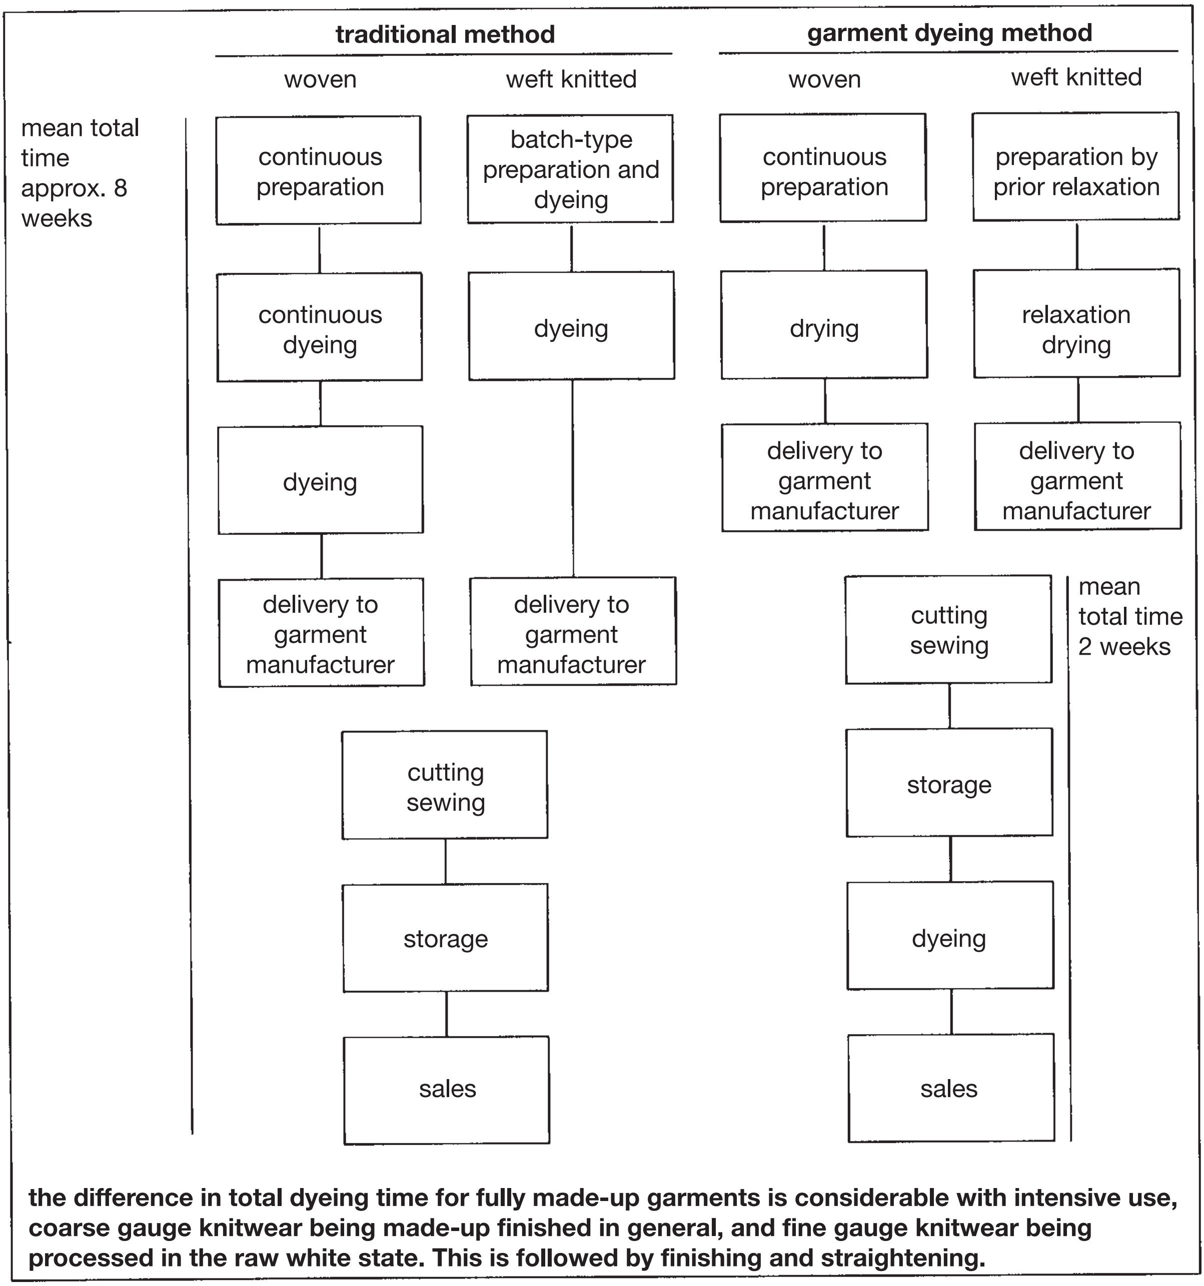
Gambo hemp (gombo hemp) → Kenaf.

Gamma rays → Radioactive emission.

Gamut A term used in the dyeing and finishing industry for colour scale or palette (e.g. dye ranges illustrated in pattern cards).

Garden carpets Oriental carpets with designs representing gardens, e.g. the garden carpet of Chosroes, a Persian carpet of the Sassanid dynasty (AD 224–641) in which the whole design depicts a garden in springtime.

Garment brushing in dry cleaning pretreatment A treatment given to garments before



the difference in total dyeing time for fully made-up garments is considerable with intensive use, coarse gauge knitwear being made-up finished in general, and fine gauge knitwear being processed in the raw white state. This is followed by finishing and straightening.

Fig. 1: Garment cutting and sewing, up to dyeing.

basic dry cleaning. Purpose: the brushing treatment reduces the time taken to dry clean garments which have been particularly heavily soiled and improves both the cleaning effect and the stain removal with little or no necessity for further aftertreatment.

Garment dyeing (fully fashioned dyeing). For garment dyeing, textile material passes through all stages of manufacturing (with the exception of dyeing) up to the completed garment stage in order that garments can be stored and dyed in appropriate shades on demand. The dyeing of completed garments in the greige state has become increasingly important in recent years especially in the leisurewear and sportswear sectors. There can be no doubt that this form of dyeing represents a particularly economic alternative to conventional dyeing methods (Fig. 1). The significant growth in the demand for garment dyeing has, however, accelerated since the early 1980's due to the greater dependence of retailers on quick colour changes to meet their need for rapid fashion response (just-in-time concept) e.g. the dyeing of fashionable denim garments and T- shirts. Because of the reduction in lead times between garment dyeing and traditional dyeing methods (e.g. 4/5 days compared to 2/3 weeks), the dyeing of ready-made garments has proved so successful that the market place now has a tremendous demand for leisurewear and casualwear garments produced by the garment dyeing route, and these types of garments are very much colour and fashion orientated .

In 1989 the proportion of textiles dyed in garment form in the Federal Republic of Germany amounted to just 6%. It is obvious that, in Germany, only a limited opportunity has been seen to dye greige garments from the warehouse at short notice in the rotary dyeing machine even in the case of single-colour items. On the other hand, the potential advantages of this technology have been recognized in Italy and the U.K. for a long time both on the side of the manufacturer as well as that of the retailer. Benetton (Italy) and Marks and Spencer (U.K.) have both successfully embraced garment dyeing technology. Moreover, rapid developments in this field have also been observed in other countries, e.g. the USA and Japan. The reason for the cautious response of many companies to this technology is, to some extent, based on the fact that garments dyed in rotary dyeing machines have not always met required quality standards in the past. Insufficinet knowledge regarding the preparation requirements for garments to be dyed in rotary machines was one of the reasons for this market hesitancy. Another important reason, however, was the design of the rotary dyeing machine itself. These machines work on the principle of "movement of textile material and a stationary liquor". In order to achieve faultless dyeing, especially as regards seam penetration and levelness, the rotational speed of the dyeing drum must be relatively high in order to ensure intensive liquor exchange. This movement subjects the garments to a considerable amount of mechanical stress causing the garments to have a "used" appearance after dyeing which is not always desirable. One possible solution for a more gentle treatment of the garments involves dye liquor circulation by means of a pump. With this system liquor is pumped from the lower part of the machine through a by-pass circuit and then sprayed into the inner drum (Figs. 2 and 3).

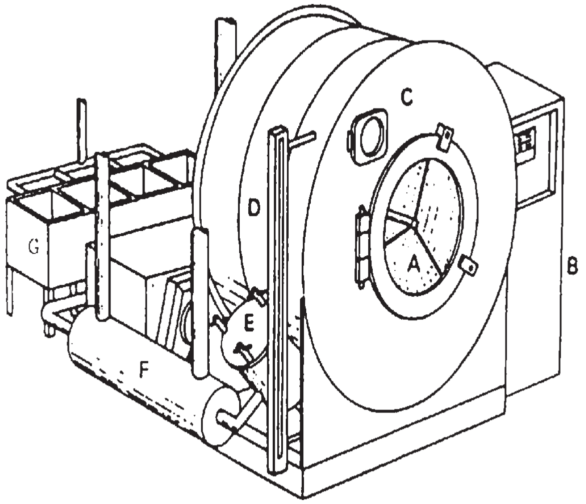


Fig. 2: Sketch of a drum dyeing machine for garment dyeing. A = perforated drum (with or without different subdivisions); B = machine control; C = sampling unit; D = liquor level indicator; E = fluff filter; F = heat exchanger; G = chemicals and liquor tanks.

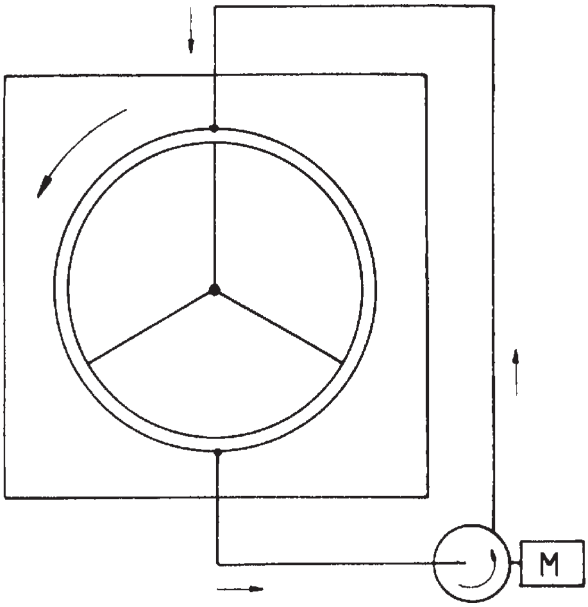

Fig. 3: Garment dyeing with liquor circulation (Proll & Lohmann) – old system-

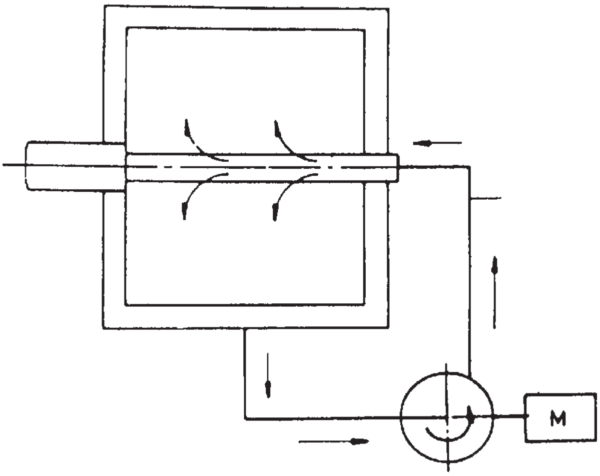

Fig. 4: Colour combi system, introducing the circulated liquor through the drum axle resulting in better dyeing liquor exchange.

This design was not, however, successful in providing the desired results since dye liquor was deflected by the revolving drum on entry. As a consequence, a ring of liquid was formed between the outer and inner drums which was unable to penetrate the perforations of the inner drum and could not therefore reach the textile garments. This shortcoming has since been eliminated with the development of the Colorcombi dyeing system of Proll & Lohmann, Hagen. This system is based on the principle of “movement of textile material and movement of liquor”. With this system, dye liquor is pumped from the lower part of the machine and returned to the dyeing drum via its central axle (Fig. 4).

In principle, all completed textile garments suitable for dyeing by the exhaust process can be dyed by the garment dyeing route. All the chemical and technological considerations involved in the dye/fibre interactions in conventional dyeing are equally applicable to garment dyeing, i.e. all the various dye classes used in exhaust dyeing are, in principle, also suitable for application in garment dyeing. As far as the textile composition of garments for dyeing is concerned, most of the experience gained up to now relates mainly to cotton garments. However, wool, polyamide, acrylic and, to a lesser extent, polyester garments, may also be dyed successfully by this process. Since mixtures of textile materials are always involved in garment pieces (in the simplest case, the garment fabric itself and the sewing thread), account must be taken of the dyeing and chemico-technological properties of the various textile components present. In this regard, particular attention must be paid to the selection of component materials having similar shrinkage properties if problems of puckering, crimping, garment distortion and sewing thread breakages, etc., are to be avoided. Garments produced from several components (e.g. different outer materials, linings, interlinings, elastic waist bands) are particularly likely to give rise to problems of this kind; such cases demand considerable technical know-how, not only to ensure minimum possible damage to the respective materials during dyeing as well as their optimum pretreatment, but also to achieve the same hue and depth of shade on all the garment components. The various accessories attached to garments such as studs, buckles and zip fasteners can also represent a frequent source of problems in garment dyeing. These components must be constructed of non-ferrous metal alloys or break-proof plastic materials. In practice, however, it has been found that these requirements have, in many cases, not been observed. The consequences are rust stains, catalytic damage in bleaching with consequent fibre damage, and dye stains. It also has to be borne in mind that the surface effects given to the undyed, pretreated, fabrics before making-up (e.g. embossed and chintz effects, calender glazes) may be either partially or totally lost after treatment under dyeing conditions. On the other hand, unwanted changes in the surface appearance of sensitive articles such as surface roughening or felting, and irreversible creasing can result from the relatively high mechanical stresses to which the garments are subjected in the dyeing machine, during hydro-extraction, e.g. in the centrifuge, or in tumbler drying.

It is not only for economic reasons that dyeing processes where the maximum temperature of dyeing is as low as possible should be selected, without having to make concessions to full penetration of the textile material. A few machines capable of garment dyeing under high temperature conditions (140°C) are, in fact, available, e.g. as required for the dyeing of polyester. However, for the most efficient dyeing of garments, the use of polyester sewing thread in the making up of garments should be avoided in all cases. It is for these reasons that only specially selected articles are suitable for garment dyeing. Thus, leisurewear, sportswear, and jogging suits made from cotton, or cotton blends with polyamide, acrylic or modal fibres are particularly predestined for the garment dyeing route. For such articles, preference is given to woven or knitted fabrics which, in addition to having a low propensity to creasing or shrinking, also possess good dimensional stability to tensile stresses (Krämer and Hilden).

Garment leather Leather manufactured from skins and hides subjected to various tanning and dressing treatments suitable for the production of leather garments of all kinds. Both garment → Leather itself and the garments produced from it, whether in part or entirely, must always be labelled with the name of the animal from which it has been produced (e.g. leather, calfskin, goatskin, sheepskin, lambskin, deerskin, buckskin, etc.). Garment leather should only be labelled as “washable” if it has sufficient resistance to washing; likewise "drycleanable" garment leathers should only be labelled as such providing no significant changes in dimensions, handle and shade occur after a proper drycleaning treatment and appropriate testing.

Garment-making accessories These include all the various items necessary to produce a completed garment, e.g. underarm pads, interlinings, linings, belts, buttons, sewing thread, zip fasteners (zip fastener tapes), buckles, shoulder pads, edgings, stiffeners, waddings, etc. To be correct, consideration should also be given to garment accessories in the respective care labels since otherwise, e.g. unwanted staining or discoloration of the garment can occur due to differences in colour fastness of the various components.

Garment manufacturing A term for the standard production of garments, garment pieces and various items of clothing.

Garment manufacturing technology If the process of garment manufacturing is divided into its basic elements, then in almost every clothing type the following sequence can be observed: cutting, arranging, pre-fabrication, intermediate ironing, assembling, final ironing, press finishing. This process-related sequence is not suitable for discerning technological trends in manufacturing technology. Depending on the actual garment, the scale of process etc., this sequence can change completely. It is therefore expedient to systematically subdivide the manufacturing processes. Accordingly, one divides into original forming, re-shaping, separating, joining and finishing, and it appears expedient to sub-divide the terms once more.

1. Original forming: injection moulding, e.g. buttons, creation of endless threads (polymer shape forming).
2. Re-shaping: ironing, styling, shape fixing, hot forming, knitting to shape etc.
3. Separating: cutting, stamping, pinking, weld-stamping.
4. Joining: sewing, fixing, gluing, welding, riveting, tacking, clipping.
5. Changing the material characteristics: heating, steaming, drying, cooling.
6. Coating: printing, applying adhesive.

A precise study of this system shows that a manufacturing process changes the work piece in order to achieve a certain state and a certain appearance. As a rule, tools and machines are necessary for this. Through mechanisation, automation and control, the individual elements are linked together, in conjunction with planning and organisation, to form garment technology.

Garment prebrushing in drycleaning → Garment brushing in dry cleaning pretreatment.

Garment steamer A steaming unit for garments; → Steaming dummies.

Gas → Natural gas; Thermal value of fuels.

Gas bubble The hollow space in a → Foam which is filled with gas (air) and surrounded by a thin envelope of liquid.

Gas bubble method A procedure for determining the maturity of cotton (→ Cotton maturity index). It is based on the permeability of the fibre wall to nitrogen; the thin walls of immature fibres have higher permeability.
