Prof. Dr. rer. nat. Hans-Karl Rouette

Encyclopedia of Textile Finishing

Springer

Foreword

The international economy, accompanied by a marked shift in the political landscape in many areas of the world, is currently undergoing profound change. Not only are a great number of industrialised, recently-industrialised and developing countries affected by these developments but also many manufacturing companies and public utilities. Changes are likewise taking place from the sociological standpoint: due to a constantly increasing world population, resources and jobs are becoming scarcer, the threat to the environment is increasing, more and more people are being excluded from active employment and the number of old people is on the rise.

The consequences – especially in the political sphere – are far-reaching. Within the realms of corporate strategy the process of industrial concentration continues; associations and institutions also follow this trend by combining to form more efficient units. The struggle for market shares, skilled labour and young talent, for greater competitiveness and business survival is becoming harder and harder. The textile industry, in particular, is seriously affected by these developments. Despite increasing productivity in certain sectors, factories and jobs are both victims to these events. The market for textiles now demands an ever quicker supply of merchandise and the more development a company pursues, the greater its need for information on research in the industrial field. As a common objective of theory and practice, the translation of scientific knowledge into new products and production techniques is a necessary prerequisite for the promotion of structural change in small textile companies. Various avenues present themselves for an effective transfer of knowledge, e. g.:

- technology centres,
- trade conferences,
- specialised seminars,
- expert consultancy,
- trade exhibitions with accompanying symposia and, of course,
- publications in technical journals and books.

The rapid progress of technology has meant that complete works on the subject of textile finishing, including its peripheral fields, are either no longer available or out of date, and have become less comprehensible due to continual amendments. Communication problems between theorists and practitioners are an additional factor. Process technology, as the link between theory and practice, represents the optimum means for bringing together theoretical knowledge and practical procedure in order that reproducible and profitable products can be manufactured.

Against this background an encyclopedia has been compiled which provides a comprehensive treatment of textile finishing technology and all its peripheral fields. The underlying concept has been to structure the data and consider different user perspectives, since the **Encyclopedia of Textile Finishing** is intended to serve the needs of several user groups. Thus, responsibility for locating desired information should not lie with the reader – rather he/she should be guided by the system itself. An information system of this nature offers the textile finisher a wide range of directly usable information on textile technology which, with regard to the amount of dedicated effort and extent of compilation involved, has simply not been available hitherto. The **Encyclopedia of Textile Finishing** describes common and new terms methodically by means of concise definitions. Keywords of special significance are dealt with in their entirety and treated more extensively in their ecological, process technological and application-oriented contexts, e. g.:

- manufacturing technology,
- products,
- by-product areas,
- energy, mass and information flows,
- human environments,
- complete production lines for textile and clothing manufacture up to waste disposal,
- eco-balances.

The **Encyclopedia of Textile Finishing** thereby serves to describe the wealth of information involved in the dyeing, printing, finishing and coating of textiles such as clothing, home textiles, industrial textiles, medical textiles and geotextiles. At the same time, particular attention has been paid to the environmental problems peculiar to textile finishing. The German laws and regulations mentioned in this work are exemplary for the worldwide environmental protection. Chemical concepts are explained with the aid of formulae. Knowledge of textile chemistry is regarded as fundamental for a clear understanding of textile finishing and, for this reason, knowledge relating to:

- macromolecular chemistry,
- dye chemistry,
- water and tenside chemistry,
- colloid chemistry,
- and physical chemistry

has received prominent coverage.

Polymer physics is responsible for shaping the morphological structure of natural and synthetic fibres, and the properties of the fibres themselves are related to their structure. These interrelationships are important to the textile finisher and have received comprehensive treatment.

The processes of diffusion, adsorption and immobilisation are kinetic aspects of all chemical and coloristic modifications to fibres which only seldom proceed to thermodynamic equilibrium. From such considerations, a modern concept of the processing technology involved in textile finishing results which aims to satisfy the quality standards demanded in the application of fibres. Extensive information on the machinery, equipment and installations used in these applications, with typical modern examples, forms the basis of detailed descriptions. Problems of such vital importance as environmental pollution are treated in encyclopedic scope by the **Encyclopedia of Textile Finishing.**

Since the range of knowledge covered by the encyclopedia extends far beyond the realm of textile finishing per se, and necessarily includes the preceding and succeeding production stages of textile technology, an integral view predominates in many of the definitions. The **Encyclopedia of Textile Finishing** has been so named because comprehensive knowledge from every specialised area having a bearing on textile finishing has been amassed for the benefit of the textile finisher. The **Encyclopedia of Textile Finishing** has its origin in the Department of Textile and Clothing Technology of the University of Applied Science, Fachhochschule Niederrhein where teaching is practised by "specialists in the field". This English version is a translation and update of the German edition published in 1995 by Laumann-Verlag. It is nevertheless not surprising that the **Encyclopedia of Textile Finishing** represents the culmination of seven years painstaking effort and that it draws on numerous outside publications. Because of the great number of publications involved, it has not been possible to quote this borrowed intellectual property which forms such a substantial part of the encyclopedia. Literature references have been dispensed with entirely, for which we kindly request the understanding of the various authors concerned. Their published work is considered to reflect the latest state of knowledge and, in a few cases, has been acknowledged at the end of a keyword with the postscript "according to XY". Manufacturer's and trade names have also been omitted from the text as far as possible. Where, occasionally, it has been necessary to describe individual products (e. g., machines, dyes, etc.), details of the respective manufacturers have been given. Diagrams borrowed from outside publications have likewise been acknowledged according to manufacturer or source.

It is anticipated that the **Encyclopedia of Textile Finishing** will appeal particularly to:

- plant owners, directors, management,
- factory managers, qualified engineers, technologists, practitioners, foremen, environmental officers,
- chemist-colourists, clothing manufacturers, textile designers, fashion designers, quality inspectors, dry-cleaners,
- students, professors, teachers, lecturers, trainees, research workers,
- buyers, sales personnel, wholesalers,
- personnel in various authorities and ministries,
- machine makers, personnel in supply industries catering to the needs of textile manufacture, representatives of the chemical industry,
- organizers of trade fairs, journalists,
- lawyers, judges and experts in the judiciary,
- consumers, who either enjoy close contact with the end-products of textile finishing, ore use them in a variety of ways as technical or medical textiles.

…

To facilitate searching for specific terms and to make cross-references easier to find, an electronic version of the **Encyclopedia of Textile Finishing** is available on a CD-ROM.

Aachen, autumn 2000

Prof. Dr. Hans-Karl Rouette

Instructions for Use

1. Keywords are printed in bold.

2. Keywords are listed in alphabetical order.
   Terms beginning with capital letters are listed before those beginning with small initial letters, e.g.:

   D, symbol for:
   I. → Debye.
   II. → Dielectric constant.
   III. → Diffusion coefficient.
   IV. deuterium.

   d,
   I. unit prefix for: …
   II. abbrev. for: …

   DA, abbrev. for: …

   da, symbol for: …

3. All keywords are written with a capital letter. Exceptions are terms or abbreviations which are always written with a small initial letter, e.g. pH.

4. Cross-references are indicated with an arrow:
   → see
   →: see following terms

   No cross-references are given for keywords which are recognised as generic terms such as dyestuff categories (reactive dyes, acid dyes etc.) or fibres (cotton, wool etc.). Cross-references should serve as a source of secondary information.

5. Textile fibre symbols are not used within the body of the text, as the various co-existing systems contradict one another to a certain extent. The textile fibre symbols are listed as keywords. The current standard DIN 60 001 is taken into consideration (valid as of 1991).

6. All units used in the text are based on those stipulated in the SI system of units. Reference should be made to the entry under → SI system of units for any necessary conversions.

7. The current chemical nomenclature is used for keywords and in the definitions of the terms, e.g. sodium hydrogen carbonate (as opposed to sodium bicarbonate), ethene (as opposed to ethylene).
   The correct chemical terms are used in place of trivial names, e.g. sodium carbonate (not soda).

Abbreviations

abbrev.	abbreviation(s)

A

A, abbrev. for:

I. → Ampere.

II. (Ger.) Arbeitsausschuß (independent working committee within the → DNA = Deutscher Normenausschuß).

III. (Ger.) absetzbare (Schad-)Stoffe im Abwasser → Settlable solid pollutants in waste water.

a, abbrev. for:

I. amplitude.

II. acceleration.

III. → Anionic.

°**a** symbol for American degree of water hardness (→ Water hardness units).

Å symbol for → Ångström.

AA (Ger.) abbrev. for: Arbeitsausschuß (working committee within the standards committees of the → DNA = Deutscher Normenausschuß).

Aachen felting test is used to measure the felting propensity of wool. A ball of loose wool fibres, formed by hand, is introduced into a shaker flask filled with milling liquor. The flask is shaken for a specific period of time to allow the wool fibres to begin felting. On completion of the test, the ball of fibres shrinks in size to a particular radius which corresponds to the felting characteristics of the wool. After drying, this represents a measure of the felting propensity of the fibres tested.

Aachen fine cloth Descriptive term of origin generally applied to high quality cloth and fabrics of pure wool. The worldwide reputation of Aachen quality lies behind these original fabrics, produced in plain weave constructions from fine carded yarns based on very fine merino wools and finished with a fine closely napped surface. Such high quality fabrics were founded, above all, on Aachen's thousand year old tradition as a cloth city. Since the turn of the century, however, Aachen has concentrated less on the production of carded wool fabrics and more on the manufacture of high quality worsted cloths, both piece-dyed and as fine worsted novelties.

AAE abbrev. for: American Association of Engineers; → Technical and professional organizations.

AAQTC (Sp.) abbrev. for: Asociación Argentina de Químicos Textiles y Coloristas, Buenos Aires (Argentine Association of Textile Chemists and Colorists); → Technical and professional organizations.

AAS abbrev. for:

I. → Alkyl aryl sulphonates.

II. → Atomic absorption spectroscopy.

AATCC abbrev. for: American Association of Textile Chemists and Colorists → Technical and professional organizations.

AATCC Fading Unit (AFU) Unit for the evaluation of → Colour fastness to light. 20 AFU corresponds to the amount of light exposure necessary to bring about a just perceptible change of shade in a specified blue standard (AATCC blue scale).

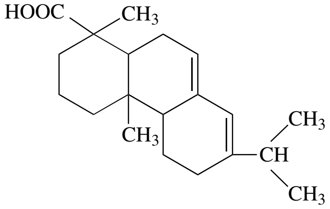
AB → Manila fibre, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

Abaca → Manila fibre.

Abietene Oily resinous hydrocarbon. Formed by the chemical decomposition of → Abietic acid. Contains less than 1% of abietic acid. Used in the manufacture of → Resin sulphonation products.

Abietic acid (abietinic acid, sylvic acid), is the most important of the → Resin acids, and is the main component of → Colophony. It consists of a yellowish mass, melting at 173°C. Insoluble in water, soluble in alcohol and ether. Alkali salts form water-soluble, capillary-active rosin soaps.

Heavy metal salts are insoluble. Uses: in the form of colophony (modifications) with synthetic resins, etc. or rosin soaps, e.g. as the basis for anti-slip/snag and ladderproof finishing agents (→ Resin sulphonation products).



Abietinic acid → Abietic acid.

Abietinols, abietyl alcohol → Resin alcohols.

Abnormal fibre (wool) Originating from sick animals, displays anomalous thickening and necking. → Evenness.

ABNT (Port.) abbrev. for: Associacão Brasileira de Normas Técnicas, Rio de Janeiro (Brazilian Technical Standards Association); → Technical and professional organizations.

Above floor level → Underfloor.

Abrasion ghosting → Ghosting, Ghosting effects.

Abrasion resistance The ability of textile fabric surfaces to withstand abrasive stresses. It is used as a measure of their wear resistance.

In DIN 53 863 the standard requirements for abrasion tests are given:

- Abrasion: the relative movement, combined with friction, between a textile test specimen and an abrading body or abradant.
- Abrading action: test carried out within a prescribed time of abrasion without causing any visible damage to the test specimen.
- Destructive abrasion: test carried out to the point of destruction (i.e. the formation of holes).
- Abrasive wear: change occurring in the surface or structure of a textile test specimen as a result of abrasive action.
- Abrasion loss: weight loss of a textile test specimen as a result of abrasion.

In testing for abrading action the abrasion resistance is evaluated according to the extent of abrasion, changes in material properties (tensile strength, extensibility, etc.) or changes in appearance (formation of pills, surface roughening, exposure of the weave structure, etc.).

In testing for destructive abrasion either the time required, or the number of strokes required for holes to appear in the test specimen are given. For abrasion testing, a number of different (non-standard) methods and test instruments are used which are intended to simulate the various kinds of abrasion stresses encountered in practice. Methods differ in the type of contact between the textile test specimen and the abradant, the type of abradant (textile material, emery paper), the direction of abrasive stress, the tension applied to the test specimen as well as technical parameters of the various test instruments such as the pressure, speed and duration of abrasive action, removal of fibre dust, etc.

ABS, abbrev. for:

I. acrylonitrile-butadiene-styrene copolymer.

II. → Alkyl benzene sulphonates.

Abscissa Horizontal axis of coordinate systems. Vertical axis → Ordinate.

Absolute alcohol, water-free ethanol; → Alcohols.

Absolute humidity → Air humidity.

Absolute system of measure, physical system of measure.

Absolute temperature → Temperature.

Absorbency →: Wettability, Hydrophilic treatments.

Absorbent The capacity of a substrate to take up liquid. In the case of textile fabrics, absorption takes place within the fibre, adsorption or adhesion on the fibre surface, intercapillary absorption between fibres in a yarn structure and absorption between the loops of knitted fabrics. Since, in the case of knitted fabrics, the pore volume (excluding intermolecular pores) occupies at least 70–95% of the entire material and is much greater, expressed in cm^3/m^2, compared with flat fabrics, the absorbable quantity of liquid is high. Absorbency is proportional to the pore volume (→: Moisture behaviour of fibres and yarns; Wetting process). The pretreatment of cotton fabrics is carried out, among other things, to increase the absorbency to such an extent that sufficient liquor is absorbed in continuous dyeing processes even during the shortest possible contact times in the padder.

Absorbent compounds These are substances which swell and are capable of absorbing several times their own weight of liquid, especially water. Starting products are polymers containing OH or NH_3 groups, e.g. cellulose, starch and polyacrylamides which, by suitable modification, are converted into absorbent compounds.Uses: particularly for the hygiene sector. → Superabsorbers.

Absorptiometer An instrument for measuring the absorption of light, based on a similar principle to the → Photometer.

Absorption The ability of one material to take up another. In this way, for example, gases are absorbed by liquids (ammonia, hydrochloric acid), or liquids, gases and radiation by solid materials. Selective absorption is based on different strengths of absorption of monochromatic radiation. In the visible spectrum, this is the reason for colour vision, where a balance is reached between absorption colours and complementary colours. Radiant absorption is that portion of incident light which is not reflected. The radiated body gains energy through absorption, e.g. by conversion into heat. In this way, the radiation absorbed by atoms causes an increase in the kinetic energy. Opposite term → Reflection.

Absorption colour Absorbed spectral colour; → Complementary colour.

Absorption of dye in dyeing Absorption of dye from the liquor during dyeing. Many dyes are very slowly absorbed by the substrate, and treatment must therefore continue for a fairly lengthy time in order to exhaust the dye liquor. For testing the exhaustion capacity of a dye, undyed fabric of the same type is used at the end of the dyeing process for the dye liquor used, in order to test bath exhaustion by subjective assessment of the subsequent absorption by the sample then taken.

Absorption of liquids → Wetting properties, hydrophilic treatment process.

ABTN, abbrev. for: Brazilian Standards Association → Technical and professional organizations.

ABwAG, (Ger.) abbrev. for: → Abwasserabgabengesetz (German Waste Water Disposal Law).

Abwassertechnische Vereinigung (ATV) → Technical and professional organizations.

AC → Acetate fibres, → Standard abbrev. for textile fibres, according to the → EDP Code; DIN standard abbrev.: → CA.

Ac,

I. chemical symbol for the element actinium (89).

II. abbrev. for acetate, acetyl.

III. abbrev. in chemical formulae for → Acyl. For example, as frequently encountered in scientific and patent literature, any monobasic acid (hydrochloric acid, for instance) can be represented in the following form:

$H^+ + Ac^-$

The corresponding salts (sodium chloride) are thus represented as follows:

$Me^+ + Ac^-$ (→ Me = symbol for cation, usually an alkali metal)

From the same standpoint, a cationic compound of a quaternary ammonium base with an acid group (Ac) is represented as follows:

$[R\text{-}NH_3]^+ + Ac^-$.

ACANOR, (Fr.) Association des Cadres de Normalisation d'Enterprise, Paris (Association of Industrial Standardization Offices); → Technical and professional organizations.

Accelerator →: Carriers, vulcanization accelerators.

Accelerotor The Accelerotor is an instrument for making rapid laboratory determinations of the abrasion resistance and wear characteristics (including pilling propensity) of textiles and other flexible materials. The instrument was developed and patented by the → AATCC. The Accelerotor simulates all of the various types of dry, moist, and wet abrasion encountered in normal end use situations. The random motion of an unfettered test specimen employed in the Accelerotor frees it from the limitations of rigidly mounted test specimens. This principle produces samples with a close and completely realistic relationship to end-wear use. The Accelerotor is routinely used for testing woven, nonwoven, knitted, felted pile, tufted and coated fabrics. It is also applicable to combinations of fibres including glass as well as flexible samples of paper, leather, plastic films, etc. Manuf.: Atlas Electric (USA).

Acceptable quality level AQL (acceptable quality level), standard value, under which acceptance sampling specifications are compiled into an acceptance sampling plan. Batches with a fault content equal to or less than AQL are very probably accepted in acceptance sample testing.

Acceptance sampling Used for acceptance testing in the supply of finished products, mainly by taking a random sample and testing its quality (e.g. good/bad characteristics, defect criticality) or measurement testing (e.g. calculating the characteristic rejection rate from mean value and standard deviation).

Acceptance testing → Quality control of finished products. Final inspection.

Acceptor An atom, molecule, or ion that is electron deficient and which can form a coordinate link with an electron donor, e.g. proton acceptors (bases) are substances which take up OH^- ions in aqueous solution. Opposite term → Donor.

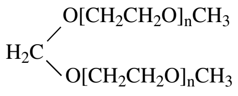
Accomodation Adaptation, e.g. the term, accomodation point, is used in relation to thermoplastic fibres, i.e. → Melting point.

Accumulation, build up, superimposition, e.g. tone shifts in dyed goods resulting from, e.g. improper treatments. The problem is particularly important in the case of domestic detergents containing fluorescent brightening agent additives. After a certain number of washes with such products, an equilibrium establishes itself between the fluorescent brightening agent dissolved out of the textile and that which exhausts on to it again.

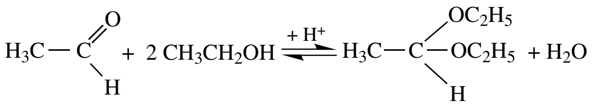
Accumulators → Fabric accumulators which are used as compensating stations in continuous fabric throughput on an extremely wide variety of finishing lines.

ACESA, abbrev. for: Australian Commonwealth Engineering Standards Association → Technical and professional organizations.

Acetal reactants Reactant type crosslinking agents for cellulose which are not subject to chlorine retention.



Acetals Compounds derived from the reaction of an aldehyde or ketone with an alcohol using an acid catalyst, as a result of which water is split off and 2 oxygen atoms are linked to 1 carbon atom, e.g.:

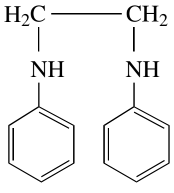


Acetaldehyde *Ethanol*

Constitutionally, acetals are comparable with ethers but possess different properties due to the double C-O-C bond. Acetals are completely stable to alkalies, but on boiling with dilute acids, they split up again into the respective aldehyde and alcohol. Polymer chains with cyclic acetals are present in, e.g. → Polyvinylacetals. The cyclic hemiacetal (a C-O-C bond) of glucose participates decisively in the molecular structure of cellulose.

Acetate cellulose → Cellulose acetate.

Acetate dyeings, colour fastness The colour fastness of disperse dyes to chlorine and gas-fume fading is variable. The latter is improved by gas-fume fading inhibitors which can be applied either during or after dyeing. A product with a very effective inhibiting action is, e.g. N,N'-diphenylethylenediamine. On acetate, cationic dyes have adequate wet fastness properties but poor light fastness.



N,N´-diphenylethylenediamine

Acetate dyeings, identification tests Separation of water-soluble from water-insoluble dyes (see Table 1). Confirmatory test: treat the dyed specimen at room temperature for approx. 15 min in a mixture of alcohol and ethyl acetate (1 :1). After evaporating off the solvent, dissolve the residue in water. Substantive dyes can be distinguished from cationic and acid dyes by carrying out dye staining tests on cotton, wool, etc.

Acetate dyes, identification of dye class The dye classes listed in the table (Table 2) can be identified by applying the test methods given.

test method	disperse dyes	disperse developing dyes	cationic dyes
boiling water test (boil for 5 mins in distilled water)	B: + o W: o	B: o or + o W: o	B: + W: s +
wash test (5 g/l of soap, 5 mins, 80 oC)	B: + + W: st + + +	B: + W: st at the most +	B: + + + W: st + + +
activated charcoal-boiling water test	S: mostly + + +	S: o	S: mostly + + +
benzene test	positive: benzene dyed	negative	positive: aqueous phase dye
paraffin test	negative	slightly positive	negative

Tab. 2

Key to abbrev. given in the table 2:
S = stripped
B = bleeds
W = white acetate sample
W:s = W soiled
W:st = W stained
+++ = very heavily or completely
++ = heavily
+ = lightly
+o = very lightly
o = no change

test method	cationic dyes	disperse dyes	diazotising dyes	naphthols (acetobenzoic dyes)
water test (boil for 5 mins)	slight bleeding, interconnected acetate fibres are slightly soiled	very slight bleeding, acetate white test specimen not stained	only very slight or no bleeding, no white test specimen staining	
wash test (5 g/l of soap, 80° C, treat for 15 mins)	very severe bleeding, interconnected acetate fibres stained	substantial bleeding, white test specimen stained	slight bleeding, white test specimen slightly soiled at the most	dye mostly completely exhausted
Boiling test with water + activated carbon	dye mostly completely exhausted		dye not exhausted	
benzene test	positive	positive	negative	
	(see above for difference)			
paraffin test (?)	negative	negative	slightly positive	very positive.

Tab. 1: Acetate dyestuffs verification.

Acetate fibres belong to the class of man-made cellulosic fibres, sub-group: cellulose ester fibres. Acetate fibres are manufactured by treating cellulose in the form of pure wood pulp or, less frequently, cotton linters, with a mixture of glacial acetic acid and acetic anhydride at low temperature (under cooling) in the presence of an activation catalyst such as sulphuric acid, perchloric acid, zinc chloride or similar salts. The strongly exothermic reaction results in the formation of cellulose triacetate (primary acetate, $C_6H_7O_5$ $(OC–CH_3)$). On the assumption that all 3 OH groups of the glucose units forming the cellulose molecule are acetylated, cellulose acetate contains 44,8% acetyl or 62,5% acetic acid content. For many purposes, the complete acetylation of cellulose is neither necessary nor desired and, during a subsequent stage of hydrolysis, some of the original cellulosic OH groups necessary for solubility are regenerated. This saponification process with dilute sulphuric acid may be terminated at any desired point with sodium acetate. A partial esterification to produce partially-acetylated cellulose is not possible, and a mixture of free and triacetylated cellulose is obtained instead. The cellulose acetate produced in the above manner is described as secondary acetate, and corresponds to the ester group content of “2,5 acetate” (37,5% acetyl or 57% acetic acid content).

Fibre manufacture: the cellulose acetate flake is precipitated in water, washed, purified and dried. In the case of triacetate, it is then dissolved in dichloromethane and, in the case of 2,5 acetate, acetone and alcohol are used. The resultant highly viscous solution is filtered, freed from air, and extruded through spinnerets in the dry spinning process. Filament yarns composed of several filaments (depending on the number of holes in the spinning jets) are produced by this means. In the manufacture of staple fibre, the filaments from numerous spinnerets are combined into tow form, crimped, and cut to the required length. Fibre properties: moisture regain 6–6,5%, water retention 25–28% (lower in comparison to cotton, cupro and viscose), High affinity towards organic solvents (alcohol, acetone, chloroform, glacial acetic acid, ethyl ether, etc.) in which the fibres either dissolve or swell. On the other hand, cellulose acetate, being an ester, is itself a good solvent for numerous organic substances (dyes, etc.); → Acetate/triacetate fibres – solubility in organic solvents. As a result of the properties conferred by acetylation, acetate fibre exhibits a different affinity towards dyes compared to other cellulosic man-made fibres, and is extremely sensitive to alkalies (action of alkalies causes deacetylation or saponification = loss of characteristic properties) and also acids. Melting point 225°C, max. ironing temperature 180°C. Drycleaning is carried out exclusively with tetrachloroethane (perchlorethylene), fluorocarbons or special boiling point spirits.

Acetate fibres, determination of acetic acid content Approx. 2 g of prewashed and dried fibres are weighed and saponified for 48 h in 50 ml 0,9 n alcoholic potassium hydroxide solution at 20°C. After the addition of hydrochloric acid, the fibres are treated for a further 45 min. at 50°C and then titrated with sodium hydroxide solution using phenolphthalein as indicator. A blank control test (blank test on alcoholic potassium hydroxide solution) must also be carried out.

$$Q = \frac{(a - b) \cdot 0{,}06 \cdot 100}{E}$$

Q = acetic acid content in% based on dry material,
a = consumption of potassium hydroxide solution in ml required to bind the acetic acid liberated,
b = consumption of blank test in ml,
E = weight of dried material in g.

Acetate fibres, dyeing of Although acetate is a regenerated cellulosic fibre it bears a greater resemblance to synthetic fibres because of its hydrophobic character, i.e. neither direct nor vat dyes can dye the fibre satisfactorily. For this reason, the following dye classes are used to dye acetate:

1. Cationic dyes: brilliant shades with relatively poor colour fastness are obtainable with selected dyes of this type.
2. Acid dyes: pale to medium depth dyeings are obtained with selected dyes.
3. Disperse dyes: universally applicable.
4. Disperse dyes capable of diazotization and development: applied by special dyeing methods; used for the production of deep shades with high wet fastness properties.
5. Pigment colorants: applied with a pigment binder. Seldom used on acetate and then only for pale (pastel) shades.

Disperse dyes are by far the most important class of dyes for the dyeing of acetate.

Acetate fibres in direct printing Nowadays, woven and knitted acetate fabrics are printed almost exclusively with selected disperse dyes. Liquid dyes are preferred because of the simplified print paste preparation, i.e. without the need to predisperse the dye. Disperse dyes are selected on the basis of shade, light fastness, wet fastness, sublimation fastness and processing fastness. The importance of the individual criteria depends on the type of article and fibre. Typical print paste recipe (1000 g): 1–150 g disperse dye, x g water, 500 g thickener (guar or locust bean derivative 9–12% solution), 0–50 g fixation auxiliary. Urea, thiodiethylene glycol, glycerol esters and glycol derivatives are used in limited quantities as fixation auxiliaries.Whilst these additions assist dye fixation, excessive amounts can cause fibre damage. Very occasionally, cationic dyes are used to achieve particularly brilliant shades. The colour yield is likewise improved by the addition of urea. When printing cationic and disperse dyes alongside each other in the same design, it is helpful to precipitate the cationic dyes in a finely dispersed form by the addition of an anionic auxiliary. Fixation of prints on acetate with disperse and cationic dyes is carried out by steaming the goods in the star or universal loop steamer with saturated steam at 102°C for 20–40 min. Acid and metal-complex dyes are also still used occasionally, in which case dye fixation can be achieved without steaming.

Acetate fibres in discharge printing Dyeings with selected disperse and cationic dyes are used as dischargeable grounds. The best white discharges are obtained with zinc formaldehyde sulphoxylate. For coloured discharges, tin (II) chloride is used as the discharging agent, which permits a wider range of discharge-resistant dyes to be used. Discharge printing methods based on thiourea dioxide have also been employed on acetate.

Acetate fibre solvents Spotting agents which can dissolve or swell acetate fibres include: formic acid, ethyl ether, ethyl acetate, ethylenediamine, acetone, benzaldehyde, chloroform, glacial acetic acid, (acetic ether = ethyl acetate), nitrobenzene, phenol liquid, pyridine, (sulphuric ether = ethyl ether) and tetrachloroethane. Particularly dangerous are warm solvents besides solvent mixtures, e.g. benzene/alcohol and chloroform/trichloroethylene.

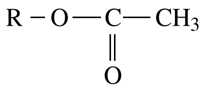
Acetate fibres, test for chemical damage Determination of the → Viscosity index of a very dilute solution of acetate in m-cresol.

Acetate of alumina → Aluminium acetate.

Acetates contain the typical CH_3COO– acetate group.

I. Salts of acetic acid (CH_3COOH) of the type CH_3COONa (sodium acetate). All neutral acetates are water-soluble, basic acetates sparingly soluble. Properties: →: Aluminium, Ammonium, Calcium, Chromium, Iron, Sodium and Tin acetates.

II. Acetic acid esters, e.g. of the cellulose acetate type which have the following configuration:



$$R-O-\underset{\underset{O}{\|}}{C}-CH_3$$

Acetate/triacetate fibres – solubility in organic solvents Differences in solubility can be used for the identification of both these textile fibres. In principle, acetate fibre dissolves in polar solvents such as acetone whereas, by contrast, triacetate fibre, which no longer has any free -OH groups, dissolves very well in certain non-polar solvents such as dichloromethane (see Table).

solvent	acetate	triacetate
formic acid	soluble	soluble
amylacetate	soluble	swells
acetone	soluble	swells/soluble
benzine (doubled)	resistant	resistant
benzine, petroleum ether	resistant	resistant
benzene, toluene, xylene	resistant	resistant
benzyl alcohol	soluble hot	insoluble/agglomerates
chlorinated benzenes	swells	swells
chloroform	swells	swells/soluble

Tab.: Acetate and triacetate solvents.

Acetic acid (glacial acetic acid, ethanoic acid), CH_3COOH. Most important member of the → Fatty acids. MW 60,42. Salts are known as acetates. The water-free acid is a clear, colourless liquid with a pungent odour irritating to the eyes. The 100% acid is known as glacial acetic acid. Acetic acid is miscible in all proportions with water, alcohol, ethers, carbon tetrachloride, chloroform, glycerol and ethereal oils. Synthetic acetiñ`acid is pure. Typical impurities can be: hydrochloric, sulphuric and sulphurous acids as well as catalysts (mercury, manganese, iron). Properties: pure acetic acid is flammable, turns litmus paper red only after moistening; medium strength acids burn the skin; dilution with water causes evolution of heat and diminution in volume; volatile. Uses: dyebath additive (for dyes exhausting under weakly acidic conditions, especially acid and chrome dyes); in printing it has a slower dye-exhausting action than sulphuric acid (reduces lake formation); souring and neutralizing; pH adjustment of water; solvent for cationic dyes; spotting agent (for dyes, as well as resin, oil and blood stains).

Acetic ester → Ethyl acetate.

Acetoacetanilide (acetylacetanilide) → Acetyl compounds.

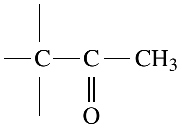
Acetoacetic ester $CH_3CO–CH_2–COO–C_2H_5$; used in the printing of acetate fibres with water-soluble acetate dyes.

Acetone (propanone, dimethyl ketone), CH_3COCH_3, MW 58, density 0,79, b.p. 56°C, flashpoint 17°C. Acetone is a clear, colourless, volatile liquid with a sweetish odour. Hazard: flammable, dangerous fire risk. Properties: neutral reaction; miscible with water, alcohol and ether in any proportions. Uses: spotting agent (for grease, rubber, varnish, oil and pitch stains, etc.); fibre reagent (→ Acetone solubility test); swelling agent in printing, etc.

Acetone solubility test For the identification of acetate and polyvinyl chloride fibres. Acetate is either partially or completely dissolved in acetone. In doubtful cases, add water – a precipitate confirms the presence of acetate. More reliable is the → Glacial acetic acid solubility test. Polyvinyl chloride dissolves slowly in acetone.

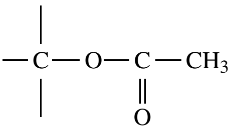
Acetosole → Tetrachloroethane.

Acetyl cellulose An inappropriate term widely encountered in the literature for → Cellulose acetate. A true “acetyl cellulose”, stable to hydrogen and hydroxyl ions, must, as an → Acetyl compound, possess the following molecular grouping:



$$-\overset{|}{\underset{|}{C}}-\underset{\|\atop O}{C}-CH_3$$

This is not the case, however, for actual cellulose acetate which, as an acetate, contains the typical ester group:



$$-\overset{|}{\underset{|}{C}}-O-\underset{\|\atop O}{C}-CH_3$$

As is well-known, this is the reason why cellulose acetate, as a cellulose ester, is very sensitive towards H and OH ions, which makes it necessary to dye the fibre under conditions that are as close to neutral as possible.

Acetylacetone method A test method based on acetylacetone (pentanedione-2,4) for the quantitative colorimetric determination of free formaldehyde on textiles in accordance with Japanese Law 112–1973. It involves aqueous extraction of the test specimen, the addition of acetylacetone reagent solution and colorimetric measurement.

Acetylated cotton Modification of cotton by esterification with glacial acetic acid. The treatment results in chemically modified cotton which is especially characterized by improved resistance against microbial attack, rotting, heat and acids. Depending on the degree of acetylation, partial, high and fully acetylated cottons are obtained. The acetylation takes place mainly in the readily accessible amorphous regions of the fibre. Continuous and discontinuous acetylation processes are subdivided into the following sub-stages: cleaning, activation, acetylation and rinsing.

Acetylation Introduction of the acetyl group, CH_3CO (→ Acyl group) into an organic compound containing either an OH-group or NH-groups. Not to be confused with the introduction of the acetate group, CH_3COO (→ Acetates) since acetylation does not involve esterification. → Acetyl compounds.

Acetyl compounds, are formed by → Acetylation and thus contain the typical acetyl group CH_3CO (→ Acyl group), e.g. acetamide CH_3CONH_2, acetyl chloride CH_3COCl. Other acetyl compounds are e.g. acetoacetic anilides of the type $CH_3COCH_2CO–NHC_6H_5$ which are important in dye chemistry, e.g. as developers and Naphthol AS dyes (Naphthol AS-G = diacetoacetic tolidide). Cellulose acetate, on the other hand, is not an acetyl compound.

Acetylene (ethyne), C_2H_2; colourless and virtually odourless toxic gas, lighter than air, ignites above 335°C, burns with a bright and smoky flame, combined with oxygen it develops temperatures of approx. 3000°C (1 m^3 = 60 060 joules), commercially available in pressure-tight steel bottles (22,5% acetylene and 40% acetone in 25% kieselguhr, to reduce the risk of explosion). Produced by the action of water on calcium carbide. Acetylene is the most important gas in chemical synthesis (dyestuffs, chemical auxiliaries, solvents, etc.)

Acetylene dichloride → Dichloroethylene.

Acetylene diurea, glyoxal diureide. The methylol compound of acetylene diurea is used, among other applications, as a resin finishing agent. → Tetramethylol acetylene diurea.

Acetylene tetrachloride → Tetrachloroethane.

Acetylides → Carbides.

Achema, exhibition of chemical instrumentation within → Dechema.

Achromatic, colourless. A property of optical instruments (mostly compound lenses) to avoid chromatic aberration, i.e. prevention of coloured fringes surrounding the image.

Achromatic colours According to Ostwald the colours “white, grey, black and all those that lie between”. →: Grey series; Pure spectral colour; Chromatic colours.

Achromatic objectives Optical objectives with compound lens systems having the highest degree of correction for chromatic aberration.

Achromatic point (white point) The achromatic point is effective as the colour point of the lighting-dependent physical → Ideal white.

Achromatism → Colour blindness.

Achromatopsia, total → Colour blindness.

Acid ager This type of steamer is used for dye fixation (development) on printed fabrics by acid steam development. →: Flash ageing process; Rapid ager.

Acid amides are organic compounds containing the functional group -NH-CO-. They are formed from → Oxo acids, through substitution of hydroxyl groups

(OH) by monovalent amide groups (NH_2). Oxo acids are of great significance in the manufacture of dyestuffs and textile auxiliaries. Amongst the latter, detergents and wetting agents derived from paraffin hydrocarbons as sulphamides or → Sulphimides are of particular importance. These are formed by the action of ammonia on the sulphochlorides of paraffin hydrocarbons. An example of a polymer acid amide is → Polyamide.

Acid anhydrides, are formed by the removal of water from → Acids, e.g.

$$2\,HOCl \rightleftharpoons Cl_2O + H_2O$$

Some acid anhydrides can form several acids with different numbers of water molecules, e.g. phosphorus pentoxide, P_2O_5

$+ 1\ H_2O \rightarrow (HPO_3)_2$ metaphosphoric acid
$+ 2\ H_2O \rightarrow H_4P_2O_7$ pyrophosphoric acid
$+ 3\ H_2O \rightarrow (H_3PO_4)_2$ orthophosphoric acid

As an example of the tribasic → Phosphoric acids,

- ortho acid is an acid without elimination of H_2O which, in this case, is referred to as phosphoric or orthophosphoric acid H_3PO_4.
- meta acid is formed from one molecule of a tribasic acid with elimination of one molecule of H_2O, in this case metaphosphoric acid HPO_3.
- pyro acid (from Gr. pyro = fire, since heat energy must be supplied) is formed from two molecules of a polybasic acid with the elimination of one molecule of H_2O, in this case pyrophosphoric acid $H_4P_2O_7$.

Substitution of the remaining acidic hydrogens, e.g. by alkali metals, yields the corresponding salts; i.e. orthophosphates, metaphosphates and pyrophosphates.

Acid chlorides are formed from → Oxo acids through the substitution of hydroxyl groups by chlorine. Acidic chlorides of wide importance in the chemical industry are products such as e.g. sulphuryl chloride: sulphuric acid $H_2SO_4 = SO_2(OH)_2 \rightarrow SO_2OHCl$ (chlorosulphonic acid) → SO_2Cl_2 (sulphuryl chloride) etc.

Acid chlorination, colour fastness to → Colour fastness to acid chlorination.

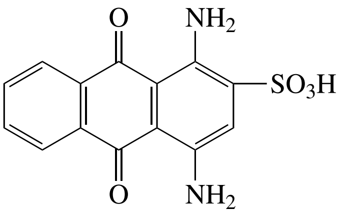
Acid damage to cellulose → Hydrocellulose.

Acid discharges (discharge resists), → Discharges based mainly on citric or tartaric acids or their salts. Used e.g. for mordant and cationic dyes.

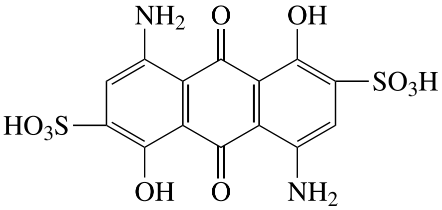
Acid donor A term used in resin finishing for inorganic and organic compounds which break down under certain conditions, mainly at elevated temperatures (e.g. 150°C), liberating acids. They are used as reaction accelerators for the crosslinking of resin finishes. → Resin finishing catalysts.

Acid dyes, are mainly alkali salts of sulphonic and/or carboxylic acids (containing SO_3H, COOH or OH groups):

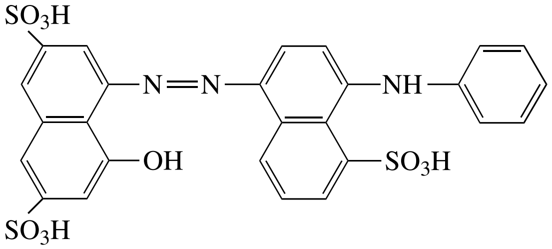
- type monosulphonated dye



- type disulphonated dye



- type trisulphonated dye



Acid dyes have good water solubility and excellent affinity for wool, silk and polyamide fibres. The acid dyes represent an important dye class for these fibres: they are easily dyed, have generally good levelling properties, and produce uniformly exhausted, well penetrated dyeings. Fabric handle and lustre are unaffected. An extensive range of acid dyes is available.

Acid dyes exhaust directly from neutral to strongly acidic dyebaths. Additions of acid accelerate, whilst additions of salt retard the rate of exhaustion (regulator for levelling). When dyeing is correctly carried out, the dyebath exhaustion is generally complete (clear liquor). Attention must be paid to dye selection, e.g. for wool/polyamide blends, monosulphonated acid dyes are the most suitable (higher rate of saturation, deeper dyeings, good parity between both fibres), whilst disulphonated acid dyes exhaust preferentially on to wool depending on the acidity of the dyebath (wool has a higher acid-binding capacity than polyamide). For this reason, combinations of mono and disulphonated acid dyes (with few exceptions) should not be used to produce plain-dyed shades on wool/polyamide blends since the monosulphonated dye will be absorbed preferentially and the disulphonated dye displaced by the polyamide component (blocking effect), thereby increasing exhaustion of the latter on to the wool component.

The examples of di- and trisulphonated acid dye types illustrated by the formulae given at the beginning of this section are representative of polysulphonated acid dyes. In practical applications, no technical distinction is made between di-, tri- or multifunctional dyes. The application of disulphonated acid dyes in wool dyeing can also be extended by the use of trisulphonated dyes according to their affinity. The quantities of auxiliary additions, which may be necessary to prevent tippy dyeings, are frequently different for di- and trifunctional dyes. The dyeing of homogeneously dyeable polyamide materials with polysulphonated acid dyes is not based on considerations of technical application but rather on lower cost. In order to achieve high contrasts in the dyeing of differential-dyeing polyamide, di- and trifunctional acid dyes are recommended, with preference being given to the former type.

Acid dyes are important dyes for natural protein fibres (wool, silk) as well as various synthetic fibres (e.g. polyamide) and even, to some extent, for cellulosic fibres.

I. Wool dyeing in particular (yarn, piece and fully-fashioned articles); e.g. cheaper qualities of carpet yarns; braids; tapes; cheaper menswear and lightweight women's (dress) fabrics; flannel; blankets; furnishing and upholstery fabrics; flags, etc.; plush; felts; knitwear and hat dyeing.

II. Silk dyeing (hanks, piece and fully-fashioned articles); also for weighted silk (exception: black).

III. Fibre blends, e.g. with cellulosics (and fully-fashioned articles). Acid dyes are particularly versatile in these applications:

a) two-bath method for plain-dyed shades (= better handle, avoidance of heat creases), involves pre-dyeing with acid dyes and topping with substantive dyes.
b) single or two-bath methods for two-tone or resist effects with selected dyes.

IV. Acid dyes are used for bright and cheap dyeings on jute; for bright shades etc. on hemp (sisal); coconut fibres and yarn; bast fibre braids (with substantive dyes); raffia bast; fibres (for upholstery purposes, brushes); hog's bristles; horsehair for linings, fillings, brushes, etc.; paper (yarns and fabrics).

The dyeing behaviour of acid dyes on wool can be characterized as follows:

1. Migration: a dye property which is dependent on the rates of desorption, diffusion and sorption.
2. Build-up: a factor which is determined by affinity of the dye for the fibre under specific conditions of pH. Further dye properties of decisive importance in practical application may be derived from the above two factors, e.g. dye combinability and wet fastness.
3. Combinabilty: Good combinability exists when the particular dyes selected exhaust and migrate tone-in-tone. This behaviour is dependent on dye affinity as well as the rates of diffusion/desorption, and can therefore be characterized equally effectively by the much more familiar dyer's terms of migration and build-up.

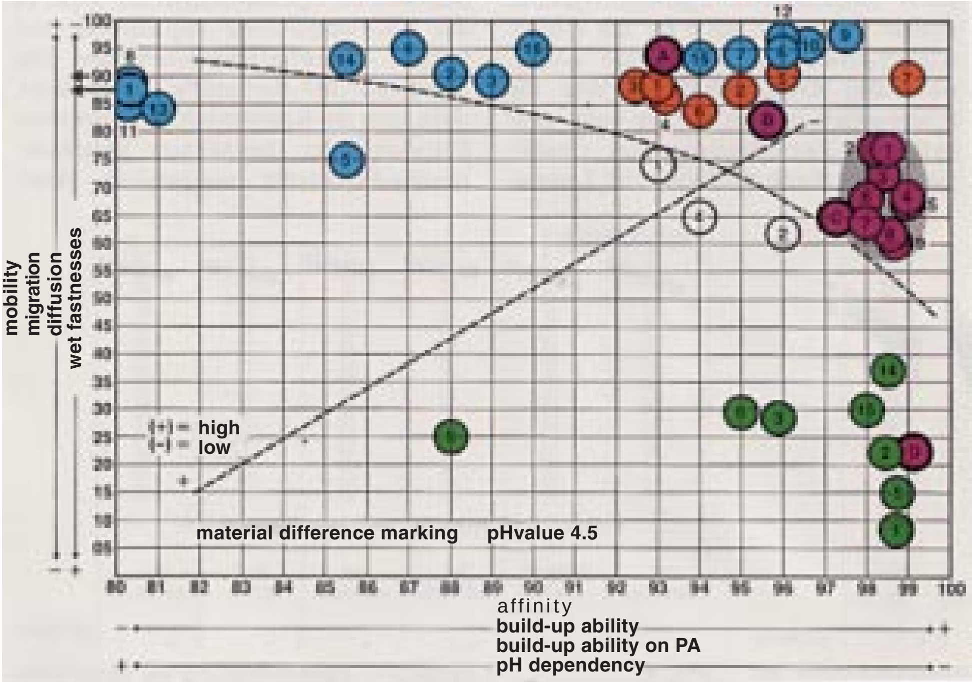


Fig.: Dyeing behaviour of acid dyes on wool. A (blue) = levelling dyes; B (red) = levelling dyes with good perspiration fastness; C (violet) = Sandolan MF dyes (Clariant); D (green) = milling dyes.

4. Wet fastness properties: Since the processes of desorption, diffusion and adsorption are likewise responsible for wet fastness, a close relationship between migration and wet fastness properties has to be assumed. For this reason, therefore, it cannot simply be expected that dyes with high wet fastness will also migrate readily. In order to achieve this objective as closely as possible in practice, special dyeing systems have been developed. If acid dyes are schematically represented on a graph according to their migration/mobility and exhaustion/affinity behaviour then each dye will take up a position on the graph corresponding to its properties (see Fig.). These positions are characterized by the dye chemistry, e.g.:

- degree of sulphonation,
- molar dye strength,
- chemical constitution,
- molecular weight.

As a prerequisite for the reliabilty of this classification, test conditions such as those listed below must be maintained exactly:

- depth of dyeing,
- pH of dye liquor,
- dyeing time and temperature,
- dyeing substrate and its pretreatment.

The Figure illustrates the positions of a series of well-known types of acid dye. Dye mobility (which is expressed as levelling behaviour), is indicated by strength differences between dyed material and adjacent material after a migration test: 100% = complete levelling, 0% = no levelling) and is represented along the vertical axis of the figure. Dyebath exhaustion, under specified conditions, is represented along the horizontal axis (100% = complete bath exhaustion; 80% exhaustion = 20% of the dye used remains in the dyebath). The curved line running from upper left to lower right of the figure separates the monosulphonated from the disulphonated dyes. Those dyes positioned in the upper right-hand sector exhibit high affinity resp. a high exhaustion capacity, good migration properties and good levelling of root/tip differences in wool dyeing. With decreasing affinity and migration capacity (towards lower left), this levelling ability falls off (increased selective exhaustion). In this last sector, special dyeing methods are usually necessary to achieve good equalizing resp. good levelling of root/tip differences, as is the case, e.g. with turquoise dyes of high wet fastness.

Good combinability exists therefore when dyes which are applied in combination exhibit uniform dyeing behaviour irrespective of their application quantities in the recipe, and when they have no influence on each other. Thus the closer dyes are positioned to one another in the schematic diagram, the more ideal, i.e. concentration-independent, their suitability in combination, and the greater is the likelihood that their wet fastness properties will be similar. (Frauenknecht, Hextall and Welham).

Acid dyes in dyeing

I. Wool: Acid dyes exhibit wide differences in affinity for wool fibres. However, a strict subdivision is not possible since fluid transitions exist. The starting pH of the dyebath ranges from pH 1,8–6 depending on the affinity of the dyes used. Initial acidity, however, depends not only on dye affinity characteristics but may also be determined by other factors from time to time. With high acidity, the dyeing process does indeed proceed more quickly since more ammonium cations are present. However, the electrostatic bond of dyes exhausting from strongly acid baths is not particularly stable, i.e. the dye salt may be broken down hydrolytically during the course of dyeing, which means that non-uniform dye uptake is levelled out again through dye migration. For this reason, dyes which exhaust from strongly acid baths are also known as levelling or equalizing acid dyes. Acid dyes which exhaust from weakly acidic baths are less easy to level because of their stronger bonding to the wool fibre, so that greater care is necessary in dyeing. Such dyes are generally known as milling acid dyes. They find application for knitted and warp-knit fabrics in deep shades, swimwear, women's wear, milled fabrics, etc. Acid dyes exhausting under strongly acidic conditions are employed when, in the interests of gentle treatment of the wool fibre, the dyeing process should be as short as possible, and their use appears advisable because of problems with levelling or penetration. They may only be used, however, provided that the wet fastness properties are sufficient to meet the particular end-use requirements. Applications include the dyeing of knitted and warp-knit fabrics in pale to medium shades as well as upholstery fabrics, etc. Their main use is for the dyeing of wool qualities that are prone to felting. They are also important in yarn dyeing, being especially suitable for the dyeing of yarn packages where their use ensures perfectly penetrated dyeings. Sodium sulphate promotes levelling by reducing the effective forces which exist between the wool fibre and the dye anion, thus keeping the dye in solution longer without exhausting on to the fibre.

II. Silk: In general, the same methods can be used for dyeing silk as for wool. Peculiar to silk dyeing, however, is the use of bast soap in the dyebath, which functions as a levelling agent and is beneficial for fibre quality. In many cases, the bast soap is broken by the addition of acids, and dyeing is carried out in a broken bast soap bath, in which the fatty acids separated from the soap are maintained in a finely dispersed state by the sericin. Many acid dyes may also be dyed on silk from a neutral bath containing soap and, possibly, sodium sulphate.

III. Polyamide: Because of their cationic character, polyamide fibres may be dyed with acid dyes, including those which exhaust under strongly acid as well as weakly acid or neutral conditions. It is recommended that dyeing be carried out only in the presence of ammonium acetate, ammonium sulphate or acetic acid. Due to the stable bonding of acid dyes on polyamide, dyeings on this fibre possess wet fastness properties which are to some extent superior to the corresponding dyeings on wool. The light fastness of many acid dyes on polyamide is also good. It is, however, important in the dyeing of polyamide to select only those acid dyes which are particularly suitable for dyeing this fibre having regard to levelling properties, combinability (blocking effect), ability to cover material-inherent streakiness, and achievement of desired fastness properties. (→: Dyeing of polyamide fibres; Acid dyes in printing)

Acid dyes in printing

I. Wool: Printing is mainly carried out on wool which has been given an oxidative pretreatment. The most commonly used thickeners are locust bean and guar derivatives, crystal gum and British gum. As acid components, acetic or formic acids are used (20–30 g/kg) or, less frequently, tartaric, oxalic or glycolic acids. For dark shades and dyes which are sensitive to reduction in the steamer, an addition of sodium chlorate (10–15 g/kg) is often made to the print pastes. Urea, *inter alia*, is used as a dye solvent. For areas of heavy coverage in hand printing, an addition of sodium tungstate is also useful (promotes levelling). Coacervate-forming chemicals also have a favourable effect on levelness. As hygroscopic agent, an addition of glycerol (20–30 g/kg) is used. After printing, the goods are dried (not too intensely) and finally steamed for 40–60 min. at 101–103°C. Good fixation of the prints can only be achieved with saturated and moist steam. After fixation, the goods are well rinsed, lightly soaped if necessary, then hydro-extracted and dried.

II. Silk: The most commonly used thickeners are locust bean and guar derivatives, crystal gum and British gum. In roller printing, gum arabic is still frequently used. Formic acid is mainly employed as an acid component (10–20 g/kg). For dark shades and dyes which are sensitive to reduction in the steamer, an addition of sodium chlorate (10–15 g/kg) is often made to the print pastes. Urea, *inter alia,* and occasionally benzyl alcohol are used as dye solvents. Where levelling problems are encountered, particularly in the printing of large areas in pale to medium shades, it is advantageous to work without formic acid or neutralize the print pastes with ammonia. Alternatively, the formic acid may be substituted by ammonium tartrate 20°Bé (10–40 g/kg). After printing, the dyes are fixed in saturated steam for 30–50 min., rinsed well with a plentiful supply of cold water and, if a scroopy handle is desired, finished (1–2 ml/l acetic acid 80% or formic acid 85%; 5–10 min. cold). To improve wet fastness, 1–2 g/l of a cationic surfactant can be added to the finishing bath or applied from a fresh bath. Finally, the goods are hydro-extracted and dried.

III. Polyamide: As thickeners, preference is given to low-viscosity locust bean or guar derivatives as well as crystal gum. Instead of free acids, additions of acid donors such as ammonium sulphate and ammonium tartrate are employed. Urea, *inter alia,* is used as a dye solvent. In order to prevent frosting effects, 3–5 g/kg of special surfactants can be made to the print pastes. For reasons of improved levelling when printing pale shades, it is recommended to add 5–10 g of a levelling agent to the print pastes. After printing, the dyes are fixed by steaming for 20–30 min. at 0,2 bar, rinsed cold (at pH4 to prevent staining of white grounds), soaped at 50°C, rinsed again cold and, to improve fastness if desired, given an aftertreatment (pH4) with 2 g/l of a cationic surfactant.

IV. Acetate: With selected acid dyes, excellent wet fastness ratings are obtained on acetate which are far superior to those achieved in printing with disperse dyes. Moreover, bleeding and staining in the washing process is largely avoided. As thickeners, locust bean and guar derivatives, as well as crystal gum, possibly in admixture with carboxymethylcellulose, are used. Urea, *inter alia,* is used as a dye solvent. After printing and drying, the dyes are fixed by steaming for 20–30 min. in saturated steam, rinsed well cold and, to achieve optimum wet fastness, soaped at approx. 60°C, rinsed again cold, then dried.

V. Triacetate: Brilliant shades with excellent wet fastness are obtained on triacetate with selected acid and metal-complex dyes. Moreover, bleeding and staining in the washing process is largely avoided. As thickeners, locust bean and guar derivatives, crystal gum, carboxymethylcellulose and starch-ethers are used. Benzoic acid, thiourea and resorcinol are employed as fibre swelling agents. Products such as e.g. benzyl alcohol and ethanol are used as solvents. After printing and drying, the dyes are fixed by steaming for 10–15 min. in saturated steam, rinsed well cold, soaped at 80–90°C to achieve optimum wet fastness, rinsed again cold, then dried.

VI. Viscose: Prints of outstanding brilliance and adequate wet fastness, e.g. as occasionally demanded by the fashion apparel market, are obtained with selected acid and metal-complex dyes on this fibre. Locust bean and guar derivatives, as well as crystal gum are used as thickeners.

After printing and drying, the dyes are fixed by steaming for 20–30 min. in saturated steam, rinsed well cold, then aftertreated with 2 g/l of a cationic surfactant in the final rinse bath for 5–10 min. Finally, the prints are hydro-extracted and dried.

Acid dyes on textiles, identification tests

1. A sample of the dyed material is boiled with 3 ml dilute sodium hydroxide solution in a test tube, cooled, approx. 3 ml ether added, then shaken. The ether is poured off into a second test tube and dilute acetic acid added. If an acid dye is present, the lower layer (dilute acetic acid) must remain uncoloured.

2. Finally, a wash test is carried out: the sample is boiled for exactly 2 min. in 1% ammonia solution. The dye is lightly to heavily stripped. Remove the sample from the liquor. Carry out a dyeing test in the liquor by adding both white wool and white cotton material together with sodium sulphate, then boil for 5–10 min. Heavily stained wool indicates the presence of an acid dye (control reaction: borax beads must remain uncoloured). If the cotton is likewise heavily stained, a direct dye is indicated.

Acid equivalent of protein and polyamide fibres (Acid binding equivalent), (acid saturation value), the binding equivalent of acid dyes per unit of weight of protein fibres (wool, silk) as well as polyamide fibres is normally dependant on the respective numbers of free amine groups in the fibre molecule available to form salts. This number is comparatively low in polyamides where only amino end groups exist, whereas protein fibres have additional amine side groups. Consequently, the acid dye equivalent and, with it, the saturation value for anionic dyes (acid dye type) is significantly lower for polyamide fibres than for protein fibres. This also explains the higher acid dye affinity of Polyamide 6 as opposed to Polyamide 6.6 as well as the general differences in acid equivalents of the various polyamide fibre types. In protein fibres, the acid binding power increases with falling pH (optimum condition between pH 1–2) until between pH 1.3–0.8 a saturation value is reached. Then under pH 0.8, the acid take up climbs quickly again due to the charge on the imino group in the peptide linkage and the acid links thus freed. In Polyamide fibres, the acid binding power increases with reducing pH and reaches saturation at between pH 3.0–2.4. Beneath pH 2.4 there is once again a sharp rise caused by the charged amino groups contributing to the acid binding. At this stage, the acid binding power approaches that of wool.

fibre type	acid gramme equivalent per kg of fibre (millequivalent)	equivalent weight as base
wool	0,8 –1,0	approx. 1 200
silk	0,2 –0,3	approx. 4 000
polyamides	0,04 –0,08	approx. 17 000
polyamide 6	0,06 –0,08	approx. 14 000
polyamide 6.6	0,04 –0,06	approx. 20 000

Tab.: Acid bonding capacity of protein and polyamide fibres.

Acid fading, is caused by the breakdown of dye-fibre bonds under acidic atmospheric conditions, resulting in a deterioration of wet fastness properties. The problem occurs chiefly with reactive dyes. → Gas fume fading.

Acidic boiler feed water is the cause of boiler corrosion and breakdown, risk of explosion, costly repairs, etc.

Acidic chlorination (also known as wool chlorination) Fastness to acid hypochlorite solution: the test sample is soaked in 6ml/l of hydrochloric acid solution (d = 1.16 g/cm^3) at 20°C for 10 min. (liquor ratio 25:1), an equal volume of hypochlorite solution containing 1 g/l active chlorine is added, and the sample is left for another 10 min., rinsed in fresh water and dechlorinated with 3 g/l sodium sulphite (crystals) for 10 min. at 35–40°C, rinsed again in running water and dried at a maximum of 60°C. The assessment is with the grey scale.

Acidic washing prevents bleeding of cheap dyeings produced from dyes having poor wash fastness. The process is used especially for white effects, white discharges, or white goods washed together with dyed materials of poor wet fastness.

Wool, in particular, benefits from the mildest treatment conditions when washing is carried out at its → Isoelectric point of pH 4,9 which corresponds to the minimum solubility of free amino acids. At the isoelectric point, wool exhibits the lowest degree of swelling, the least reactivity and the greatest stability, so that the risk of felting is minimal. In order to improve the fibre's processability, and thereby achieve troublefree spinning, the fibres must be treated at the isoelectric point during raw wool scouring with an antistatic agent in the last rinsing bath. For the best effects, only nonionic surfactants which maintain their washing activity in strongly acidic liquors even at the boil are employed (possibly combined with dyeing at the same time). Corrosion-resistant processing equipment is necessary.

Acidimetry → Titration.

Acidity is a property of acids and acidic salts whereby hydrogen ions are split off in aqueous solution. → Dissociation. Opposite term → Basicity.

Acidity, degree of → Acidity; pH.

Acid metal-complex dyes → Metal-complex dyes.

Acid milling → Milling in liquor acidified with sulphuric, acetic or formic acid plus the addition of acid-stable oils (highly-sulphonated Turkey red oils), either (after a good prescour) for 30–60 min. acid treatment followed by hydroextraction and milling with the residual acid, or (without prescour) as an "acidic soil-milling." In the latter case, the process is only carried out in the presence of suitable fibre lubricants. A final neutralization must be given in all cases (especially with wool materials containing cellulosic fibres). Alternative process: after prescouring, the goods are treated with 100% water and 25–50 g/l alkylnaphthalene sulphonic acid with/without acetic acid. This method is used for milling high quality cloths, sports fabrics, blankets, scarves, etc., since it offers advantages of higher tensile strength, better preservation of the material and more favourable milling time compared to the usual acid and alkaline milling treatments. It is more advantageous to carry out milling in the pH range which extends downwards by 1–2 pH units from the (isoelectric) neutral point of wool of pH 4,9 into the more strongly acidic region, than upwards by 5–6 units into the alkaline region around pH 10, for the following reasons: more gentle fibre treatment, reduction in the milling time by approx. one half, better tensile strength and extensibility values, less risk of bleeding with dyeings of poor fastness, firmer handle etc. The process is also used for technical felts. Corrosion-resistant machines and equipment are, of course, a prerequisite for acid milling.

Acid peroxide bleaching of wool (acidic wool bleach) In contrast to alkaline peroxide bleaching (→ Bleaching of wool), acid peroxide bleaching proceeds in the isoelectric range of wool which, in addition to savings in time, represents a far gentler treatment of the material. The action involves the oxidation of natural fibre impurities (conversion to the colourless form). As stabilizer, water glass, which is commonly used in cotton bleaching, is also suitable for wool although it may also be substituted by sodium pyrophosphate or proprietary stabilizers. The pH is adjusted with ammonia provided silicate is not used. The optimum temperature is 50°C for a treatment time of 3–4 h. Peroxide bleaching is carried out under acidic conditions because of the alkali-sensitivity of wool. Opinions on the results of acid peroxide bleaching in comparison to alkaline bleaching are varied. In the final analysis, however, better and more stable whites, without any appreciable fibre damage, should be achieved by this process.

Acid radical The negatively charged residue of an → Acid minus its electropositively charged hydrogen (H^+) ions, e.g.:

Hydrochloric acid:	HCl	→	$H^+ + Cl^-$
Sulphuric acid:	H_2SO_4	→	$2\,H^+ + SO_4^{2-}$
Acetic acid:	CH_3COOH	→	$H^+ + CH_3COO^-$

Due to their negative charge, acid radicals are always anions and are also present in salts in this form. Thus, e.g. sodium sulphate dissolved in water breaks down (dissociates) again into the basic radical cation and the sulphuric acid radical anion: $Na_2SO_4 \rightarrow 2\,Na^+ + SO_4^{2-}$.

Acid-resistant linings for processing machinery and vessels Materials such as rubber, ceramics, or acid-resistant plastics (including fibreglass) are normally used for this purpose.

Acids, are compounds containing hydrogen which dissociate in water to give positive hydrogen H^+ ions (protons) and function, therefore, as proton donors. The general formula is H_nA where A = acid radical or conjugate base, n = basicity of A. The dissociation of acids (protonic reaction) proceeds thus:

$$H_nA + H_2O \rightleftharpoons n\,H_3O^+ + A^{n-}$$

or shortened

$$H_nA \rightleftharpoons n\,H^+ + A^{n-}$$

Acids have a an acidic reaction ($pH < 7$) and a sharp taste. They turn blue litmus red and cause colour changes with other indicators. Inorganic acids include → Hydrogen halides (e.g. hydrochloric acid HCl) and → Oxo acids (e.g. sulphuric acid H_2SO_4) whilst organic acids include e.g.: dye acids, fatty acids, carboxylic acids, oxy-acids, amino acids, phenols. Strong acids are almost completely dissociated in water (more than 50%) whilst weak acids are only partly dissociated (below 1%). See also → Dissociation, degree of.

Acid salts These are → Salts of polybasic acids (i.e. acids having two or more acidic hydrogens) in which not all the hydrogen atoms have been replaced by positive ions. For example, the dibasic acid carbonic acid (H_2CO_3) forms acid salts (hydrogen carbonates) containing the ion HCO_3^-.

Acids, colour fastness to → Colour fastness to acid spotting.

Acid shock dyeing A process for the continuous dyeing of polyamide wovens and knits with acid and metal-complex dyes. Principle: the dye is applied by padding followed by heat setting on the stenter. Fixation of dye on the fibre is achieved by a shock treatment on the jigger or open-width washing range in a boiling bath containing 3 ml/l formic acid 85%.

Acid soaps These are sulphonated oil products which have not been fully neutralized (→ Sulphonated surfactants) based on castor oil, e.g. monopol soaps (fairly resistant to hard water and acids, with good wetting, levelling and softening properties). Designation for free fatty sulphuric esters or fatty alcohol sulphuric acid esters, sulphonic acids etc. that are present in acid baths and that bind chemically to wool protein and hence effectively protect the fibre. Remain surface active in → Acid washing.

Acid traces, tests for Extract the sample by boiling with distilled water and test the filtrate. Alternatively, moisten the sample with distilled water and place in contact with an appropriate test paper between glass plates. For qualitative determinations, colour changes with indicators such as litmus, potassium iodide-starch solution or paper, Congo red, methyl red or violet are suitable. Quantitative determinations are carried out by titration of the aqueous or alcoholic extracts using phenolphthalein as indicator.

Acid value A measure of the free acid content of natural oils, resins, waxes etc., indicated by the number of mg of pure potassium hydroxide (KOH) required to neutralize 1 g of the substance. In practice, this is carried out by shaking with a few drops of phenolphthalein solution and titrating with standard KOH solution until a pink colour develops. 1 ml of 0,1 n potassium hydroxide solution = 0,00561 g pure KOH. Although fresh fats and oils contain glycerides of fatty acids and very little free acid, the glycerides decompose slowly with time due to hydrolysis through the action of light and air which causes an increase in the acid value. Examples:

1. Widely scattered acid values between 0–50: coconut oil 5–50; olive oil 2–50; castor oil 0,1–15; rapeseed oil 1,4–13,2; sesame oil 0,25–20.
2. High acid values: beeswax 19–21; Japan wax 18–25; palm oil 24–200; wool fat 13–25.
3. Low acid values: peanut oil 1–8 (technical oils up to 40); cottonseed oil 0–2; linseed oil 1–8; palm kernel oil 8,5; beef tallow 2–7 (when old up to 50); sunflower oil 0–1; sperm oil = traces.

ACIMIT, abbrev. for: Associazione Costruttori Italiani di Macchinario per l'Industria Tessile, Milano (Italian Association of Textile Machinery Manufacturers); → Technical and professional organizations.

ACIT, abbrev. for: Association des Chimistes de l'Industrie Textile (French Association of Chemists of the Textile Industry); → Technical and professional organizations.

Acoustic pressure (sound pressure) Symbol: p. It describes the periodic pressure variations which occur in a sound wave and is measured in pascals.

Acraldehyde → Acrolein.

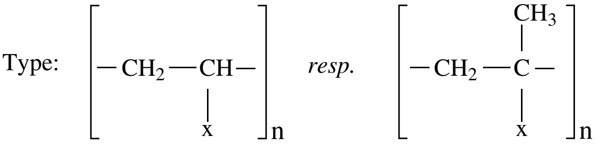
Acramin dyeing process Pigment pad process. Pigment colorants, together with a binder and a catalyst, are fixed on textile fabrics by a heat treatment. Good fastness properties. Suitable for the production of pale to medium shades on cotton and viscose fabrics; pale shades only on blend fabrics. The process may be combined with resin finishing as a single-bath application, or with other finishes and softeners in the pad liquor (Bayer). Other pigment systems are also suitable for application by this process, e.g. Helizarin pigments and binders (BASF); Imperon pigments and binders (Hoechst), etc.

Acrolein (acraldehyde, acrylaldehyde, allyl aldehyde, vinyl aldehyde, propenal), $CH_2{=}CH{-}CHO$, is the simplest unsaturated aldehyde; mobile, colourless, toxic liquid with an intensely pungent disagreeable odour. TLV: 0,1 ppm in air. Acrolein is very reactive. Soluble in organic solvents, e.g. alcohol, ether, etc.

Acrylaldehyde → Acrolein.

Acrylamide group, $-NH{-}CO{-}CH{=}CH_2$ Reactive group, reacts *inter alia* in the presence of alkali with the OH-groups of cellulose ($-NH{-}CO{-}CH_2{-}CH_2{-}O{-}Cell$). Contained in → Methylolacrylamide as an ambivalent crosslink.

Acrylate polymers (acrylic polymers), are polymers and copolymers of → Acrylic acid (→ Polyacrylic acid) and methacrylic acid (polymethacrylic acid).



$$\text{Type: } \left[-CH_2-\underset{\substack{|\\ x}}{CH}-\right]_n \quad \textit{resp.} \quad \left[-CH_2-\overset{\substack{CH_3\\ |}}{\underset{\substack{|\\ x}}{C}}-\right]_n$$

As acids [$x = COO^-H^+$], salts [$x = COO^-Me^+$ (Na^+, NH_4^+, Mg^{2+}, Ca^{2+})], esters [$x = COOCH_3$ (C_2H_5, C_4H_9, etc.)], nitriles [$x = CN$], polyesters [$x = OOC{-}CH_3$].

An extensive group of polymers which also includes methacrylate resins (acrylic glass) and many acrylonitrile copolymers. Produced by polymerization in solution, emulsion, suspension or solid form. Crosslinking occurs on thermosetting (the thermoset products have the properties of duroplasts). As a rule, acrylate polymers are transparent and, depending on the monomer building blocks, degree of polymerization, functional groups, cations, degree of neutralization etc., are capable of yielding products with a wide range of properties between liquid and solid in any desired transitions (water-insoluble – dispersible – water-soluble), hydrophobic, hydrophilic and so on, e.g. for sizing agents, dispersing agents, migration inhibitors, and thickeners for printing and finishing (→ Polyacrylate …).

The structure and properties of synthetic water soluble acrylate polymers are as follows:

a) unidimensional (chain structure):

MW	100 000	readily soluble, easy flowing
MW	1 000 000	somewhat less soluble, ropy
MW	2 000 000	poor solubility, very ropy, slightly thickening

b) two-dimensional (polymers):

Polymers with many branches	readily soluble, easy flowing, slightly thickening

c) three-dimensional (crosslinked polymers):

low crosslinking	good increase in viscosity, fairly poor solubility, tendency towards gel formation
high crosslinking	low solubilty, high swelling, give thixotropic pastes.

Water soluble acrylate polymers mostly contain carboxyl groups [–COOH, –COOMe] in the macromolecule. In aqueous solutions the free acids behave like poly acids and the salts like anionic polyelectrolytes. They consist of thread-like macromolecular structures which are, to a greater or lesser degree, extensively tangled in aqueous solution. The extent of tangling can vary considerably depending on the composition of the aqueous solution (influenced by pH and electrolyte content); this has a great effect on viscosity. This latter property is increased by longer chain length and rising concentration; it is reduced, however, by increase in temperature and water soluble salts. Tangling of the macromolecule, as well as reduction in viscosity, are further determined by the counter ion (cation). In polyacrylate sizes for example, the polymerized acrylic acid is present mostly in the form of sodium or ammonium salts; and in the newer, increasingly important alkaline earth polyacrylates (higher content of alkaline earths causes a greater reduction in viscosity) preferably in the form of calcium or magnesium.

Acrylate sizes and finishes → Polyacrylate sizes.

Acrylic Generic description (U.S. Federal Trade Commission) for a manufactured fibre in which the fibre-forming substance is any long chain synthetic polymer composed of at least 85% by weight of acrylonitrile units → Polyacrylonitrile fibres.

Acrylic acid (acroleic acid, propenoic acid), $CH_2=CH-COOH$. Important, organic, unsaturated carboxylic acid used as a polymerizable starting product for polyacrylic acid derivatives.

Acrylic dyeings, identification of dye class

1. Identification scheme: The dyed or printed fibre material is subjected to a series of different tests with the first five tests being carried out one after the other on the same fibre specimen (6–8 min. boiling in each case, with intermediate rinsing only after the glacial acetic acid test). → Dye class identification tests on the fibre.

2. Staining tests: strip the dye by boiling with glacial acetic acid, concentrate by evaporation, add water, and carry out dyeing tests. Vat dyes remain insoluble (but will dissolve in caustic soda solution + sodium dithionite).

Acrylic dyes Commonly used term in practice for dyes suitable for dyeing polyacrylonitrile fibres. The following dye classes are suitable:

I. Cationic dyes are the most widely used.

II. Disperse dyes are suitable for pale shades only.

III. Acid dyes are suitable only for acid-dyeable fibre types, i.e. the incorporation of special comonomers in the fibre is essential here.

Acrylic fibres Expression for → Polyacrylonitrile fibres with a min. 85 wt% → Acrylonitrile.

Acrylic monomers are used as finishing agents for crosslinking on the fibre.

Acrylic resins, polyacrylate resins (→ Synthetic resins) including the corresponding copolymers.

Acrylonitrile (propenenitrile; vinyl cyanide), $CH_2=CH-CN$. Raw material for the manufacture of → Polyacrylonitrile fibres, derived mainly by the Sohio process from propene, ammonia and oxygen, b.p. 77°C.

ACS, abbrev. for: American Chemical Society.

Acticarbone → Activated carbon as a clarifying agent.

Actinic, chemically active. The term relates to actinic rays and radiation (sunlight, ultraviolet light, etc.) and their effect on substances which undergo chemical change on exposure to such rays. It is the basis of photochemistry (→ Photochemical reactions), e.g. cellulose, certain vat dyes (→ Fibre damage by vat dyes) and printing effects on vat-dyed grounds etc., e.g. with ferric salts (reduction by exposure to a strong arc lamp).

Action plan Strategically developed procedure for the achievement of a specific objective, e.g. the quality assurance of finished fabrics (see Fig.).

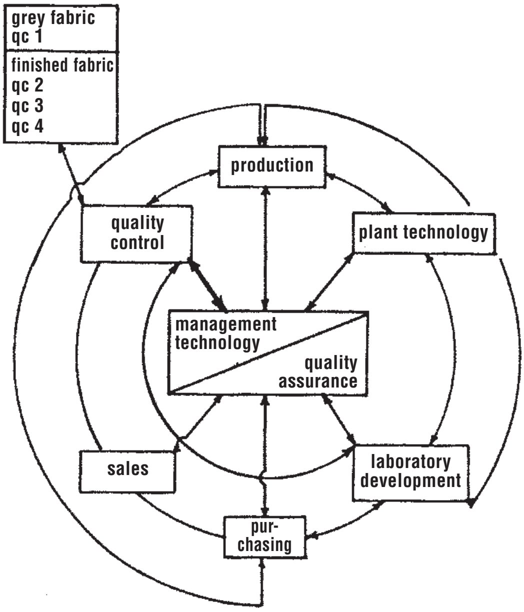


Fig.: Action diagram of quality assurance according to Windel.

Activated carbon (active carbon, decolorizing charcoal) Amorphous form of → Carbon (carbon content above 90%) with a honeycomb-like, porous, internal structure, characterized by high adsorptivity for many gases, vapours and colloidal solids. The carbon is obtained as a residue from the destructive distillation of organic matter (wood, coconut shells, peat, brown or hard coal, oil or gas coke, etc.) in the absence of air. It is "activated" by heating to 800–900°C with steam or carbon dioxide, or by treatment with zinc chloride or acids. This activation removes impurities and results in an open structure containing innumerable ultramicroscopic fine capillaries, pores, fissures and cracks. Disordered and unsaturated carbon atoms which are accessible on the crystal faces represent the focus of attraction for adsorption and are responsible for the active properties. The structure of the carbon particles can be made more or less open depending on the degree of activation thus providing a correspondingly high adsorption energy. Activated carbon is an extremely absorbent medium for gases and solvent vapours which are adsorptively bound almost immediately in the capillaries (the adsorptive capacity can amount to 100% of its own weight). Regeneration is achieved by stripping out in steam.

The properties of the material to be adsorbed are also decisive for the adsorptive capacity of activated carbon. In a homologous series the adsorptive capacity rises with increasing molecular weight until a maximum is reached whereafter it decreases again. Activated carbon has a lower affinity for aliphatic compounds in comparison with aromatics. Hydrophilic substituents such as OH, COOH or SO_3H built into the molecule result in a reduced adsorptive capacity. From this it follows that low molecular weight alcohols and carboxylic acids as well as highly sulphonated aromatics are much less readily adsorbed than aromatic nitro compounds, aromatic amines and phenols. The adsorptive capacity of activated carbon is also influenced by the pH of aqueous phases. Whilst e.g. aniline is better adsorbed from an alkaline medium, phenol may be separated more readily in the acidic range.

For the solution of practical applications where the separation of several substances is frequently required, knowledge relating to the behaviour of individual components is of only limited value since the adsorptive behaviour of mixtures is considerably impaired e.g. by coadsorption with displacement effects, different adsorption kinetics or hydrophilic characteristics. Influences of this kind make the selection of a suitable grade of activated carbon by the evaluation of adsorption isotherms for individual products more difficult, so that reliable operational data is often only obtainable after laborious on-site semi-industrial trials with the actual mixtures involved.

Uses: solvent recycling (drycleaning machines), decolorizing and deodorizing of aqueous liquids, organic solvents, etc. (filters in drycleaning systems), water dechlorination, removal of oil from water, etc.

Activated carbon as filler for coatings Fillers like chalk or carbon are used in coating masses. For this purpose, activated carbon has an especially pronounced fine structure which provides typical consistency in the mixing of the coating paste.

Activated carbon/boiling water test Used for the detection of cationic and disperse dyes on acetate (→ Acetate fibre dyeings, identification tests). The dyeing (or print) is boiled for 20 min. in water with the addition of some activated carbon. Positive test: the dyes are, for the most part, completely stripped and adsorptively bound by the carbon from which they are readily removed by rinsing in hot water containing a little soap.

Activated carbon filter → Sewerage filter.

Activated carbon in dyeing and printing Used as an addition to wash baths when washing off dyeings and prints to prevent staining of grounds by redeposition.

Activated carbon in waste water treatment Both communal and industrial waste waters can contain a variety of different pollutants which may be classified according to their treatment characteristics. Whilst aspects such as density, solubility, sedimentation properties and biodegradability are decisive for the efficacy of individual treatment stages in standard mechanical-biological waste water treatment processes, for activated carbon useage it is the adsorptivity and carrier function for microorganisms that are of primary importance. The most important target groups for adsorptive or adsorptive-biological waste water treatment are organic substances which

- are not biodegradable and can therefore only be removed by adsorption,
- have a toxic action on bacteria and would therefore damage the biological treatment,
- are only slowly biodegradable and, for this reason, must first be bound adsorptively where advantages of accumulation are observed,
- can only be broken down by microorganisms with a low rate of growth for which purpose their immobilization on a carrier material such as activated carbon is necessary.

Depending on which category the pollutants are to be classified under, the activated carbon is used for another function and in a different area of the entire cleaning concept as

- an adsorbent in the mixing process,
- an adsorbent in filtration plants,
- a carrier material in anaerobic bioreactors,
- a carrier material in aerobic bioreactors,
- an adsorbent and carrier material in activated sludge processes.

Activated carbon treatment, chemical → Waste water treatment.

Activated sludge process Micro-organisms, bacteria in particular, can degrade organic materials, using them as nutrients. The simplest equation for aerobic respiration is $\langle CH_2O \rangle + O_2 \rightarrow CO_2 + H_2O$. The dynamics of a simple activated sludge unit can be described mathematically: the yield, y, of the mass of bacteria created (or the concentration of bacteria, B) is related to the decrease in the mass of the substrate, S:

$$\text{Yield } y = \frac{dB}{dS} = \frac{\text{bacteria mass increase}}{\text{substrate mass decrease}}$$

The exponential growth of the bacteria can be expressed by

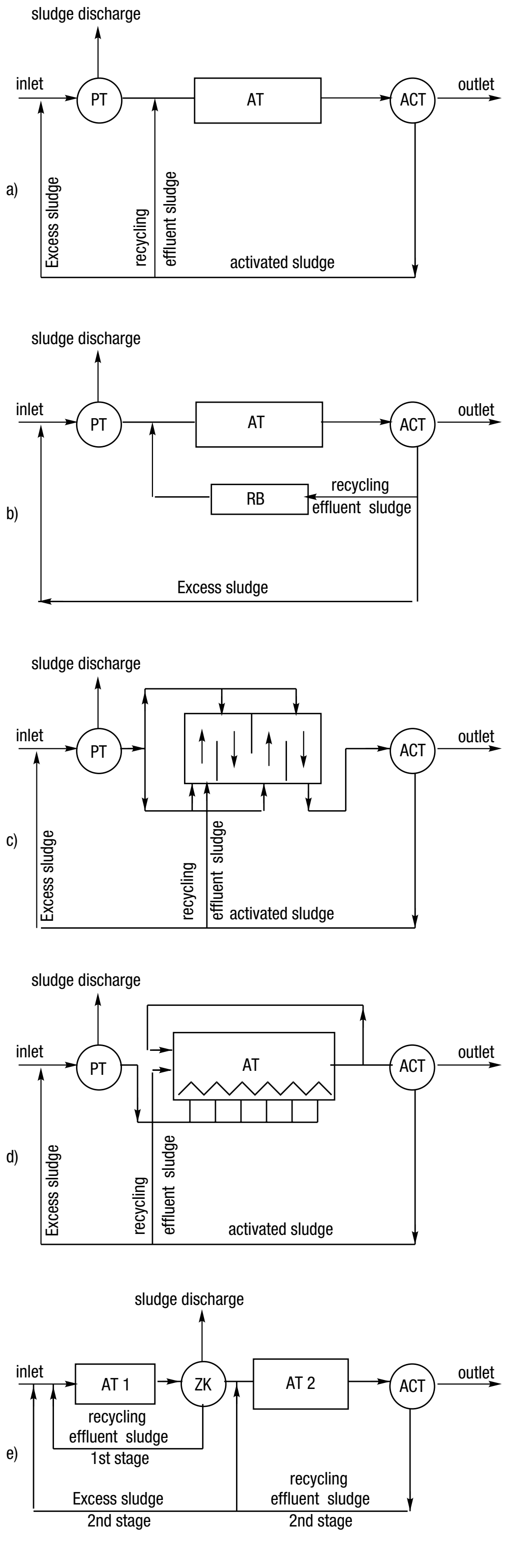

Fig. 1: Development stages of the conventional activation process; PT = pre-clarification tank; AT = activation tank; ACT = after-clarification tank.
a) conventional activation process (with sludge discharge from the pre-clarification vessel); b) activated sludge process with sludge regeneration; c) stepwise addition according to Gould; d) Schmitz-Lenders distributed effluent input; e) two-stage activation process (after Mangold et al.).

$$\frac{dB}{dt} = \mu B \,;\; B = B_0 \cdot e^{\mu t}$$

where μ is the rate of growth and B_0 is the mass bacteria (per unit volume) at time $t = 0$. The rate of growth of the bacterial biomass is determined only by the hydrodynamics of the activated sludge plant.

In an activated effluent treatment plant, activated sludge is used for → Biological waste water treatment. Such plants consist of aeration tanks, after-clarification tanks and aerating equipment (Fig. 1). The activated sludge consists largely of micro-organisms that form flocks and it is mixed with the effluent and dissolved oxygen. The organic content is absorbed by the micro-organisms and a biomass sludge is formed. The biological processes take place on the flocks of sludge. Mangold et al. have outlined the development stages of the conventional activation process:

a) in the original form, the effluent flowed through a pre-clarification tank, was aerated with the activated sludge for 6–10 hours and then separated from the sludge in an after-clarification tank. The sludge was returned to the activation tank. Excess sludge with a water content of 98–99% is known to be difficult to dewater. In the process developed by Imhoff, excess sludge was returned to the pre-clarification tank where its concentration was increased by mixing it with fresh sludge from the crude water to give a water content of about 95%.
b) Shortening the aeration time allows the sludge that has been separated from the aeration tank to be regenerated.
c) Gould introduced stepwise addition to improve the process. The recycling effluent sludge is fed into the aeration tank slowly and in stages at several points until the whole charge has been added.
d) In the Schmitz-Lenders system, the effluent is fed in along the whole length of the tank. In this way the activated sludge is charged evenly.
e) The high-capacity, economical two stage activation process was a further advance.

The Magdeburg P process activated sludge plant is a well-known purification unit (Fig. 2) (contributed by Peschel and Belouschek).

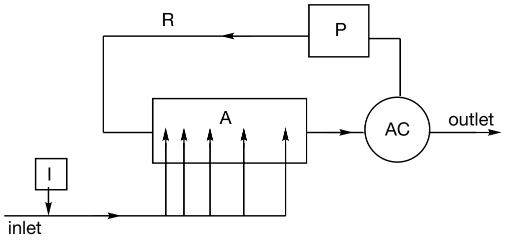

Fig. 2: Diagram of a Magdeburg P activated sludge process. I = input of nutrient salts; A = aeration tank; AC = after-clarification tank; P = recycling pump (after Meinck et al.).

Activation

Activation (Lat.: *activus* = work)

I. In general: put to work.

II. Chemically: the process of treating a substance or a molecule or atom by heat or radiation or the presence of another substance so that the first mentioned substance, atom or molecule will undergo chemical or physical change more rapidly or completely.

Activation energy Generally the heat that is required to make a chemical reaction go. An “energy barrier” has to be overcome before a starting material can be converted into a product. The height of the barrier is directly proportional to the rate of the reaction.

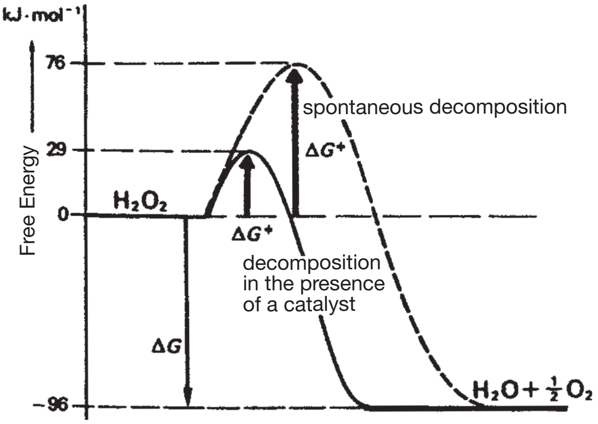

Fig. 1: Activation energy G for spontaneous and catalysed decomposition of hydrogen peroxide.

Apart from water, hydrogen and oxygen can also form hydrogen peroxide (H_2O_2). When this is dry, it is a blue liquid with properties that are very similar to those of water (boiling point 150.2°C, freezing point –0.43°C). The molecule is diamagnetic. In the diagram (Fig. 1), the metastable initial state is separated from the final product (water) by an energy barrier, the “activation energy”. This means that the decomposition of hydrogen peroxide is thermodynamically possible:

$$H_2O_2 \rightarrow H_2O + {}^1/_2\, O_2 ; \quad \Delta G = -96 \text{ kJ/mol}$$

However at room temperature, very few molecules have sufficient energy to reach the free energy of activation (ΔG) of 76 kJ/mol. Decomposition can be accelerated greatly by heating; it can also be accelerated by catalysts (catalytic effect of simple metal ions).

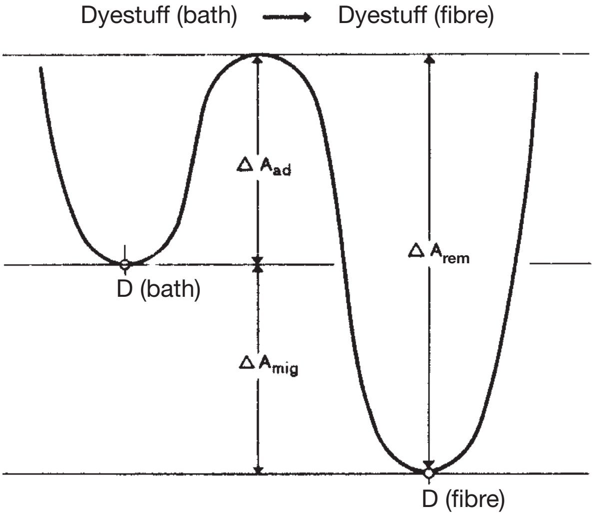

Fig. 2: Diagram of energy relationships in dyeing.
ΔA_{ad} = Activation energy for adsorption of dyestuff;
ΔA_{mig} = Activation energy for migration of the adsorbed dyestuff;
ΔA_{rem} = Activation energy for removal of the adsorbed dyestuff.

As a rough approximation, dyeing can be considered to be a solution process in which the dyestuff is more soluble in the substrate (D_{fibre}) than in the dyebath (D_{bath}). From a kinetic point of view, D_{bath} and D_{fibre} correspond to the initial and final states. As the starting and finishing states of a reaction are always thermodynamically stable, both states lie in an “energy valley”. It can be seen from the shape of the energy curve (Fig. 2) that a direct transition from D_{bath} to D_{fibre} is not possible because the energy barrier has to be overcome. Only dyestuff molecules that have acquired enough energy (ΔA_{ad}) by heating are capable of escaping from the water and dissolving in the substrate. This energy corresponds to the energy of activation well-known in chemical reactions. It is determined from the increase in the rate of a reaction as the temperature is increased; the smaller the temperature increase, the greater the activation energy needed. In dyeing, the ac-

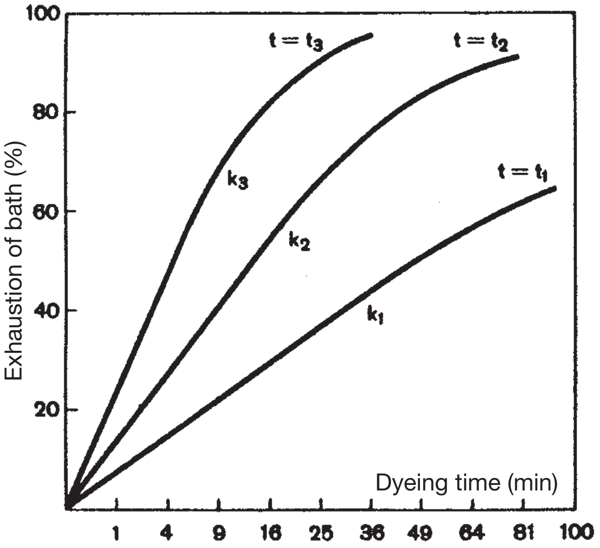

Fig. 3: Dependence of rate of dyeing on temperature.
k = rate coefficient; t = temperature.
$t_1 < t_2 < t_3$ and $k_1 < k_2 < k_3$.

celeration is determined from the quotients of the exhaustion rate coefficients k with increasing temperature T (Fig. 3).

It can also be seen from the energy relationship diagram that the end state D_{fibre} is at a much lower energy level than the initial state D_{bath}. The significance of this is that the dyestuff is much more soluble in the substrate than in the dyebath (the reversal of the dyeing process is greatly hindered because of ΔA_{rem}). The difference in the levels is a measure of the affinity.

Whether the dyeing proceeds quickly or slowly is determined essentially by the activation energy needed to form the activated complex. When the activation energy is high, only few molecules have enough kinetic energy; dyeing proceeds slowly. If ΔA_{ad} is too high no dyeing takes place at all. This is expressed by the Arrhenius equation:

$$k = P \cdot Z \cdot e^{-\Delta A_{ad}/RT}$$

Z = the collision number,
P = the steric factor.

If $\Delta A_{ad} >> RT$, the Boltzmann factor $e^{-\Delta A_{ad}/RT}$ is very small and consequently the rate constant k is also small. A lot of reactions are thermodynamically allowed but proceed very slowly because of the high activation energy and are therefore kinetically inhibited. In principle, the inhibition can be eliminated by increasing the temperature. If T is increased, the negative exponent in the Boltzmann factor becomes smaller, i.e. the rate constant increases (Fig. 4). On the atomic scale, the energy distribution changes with the increase in temperature so that the number of dyestuff molecules with high kinetic energy increases.

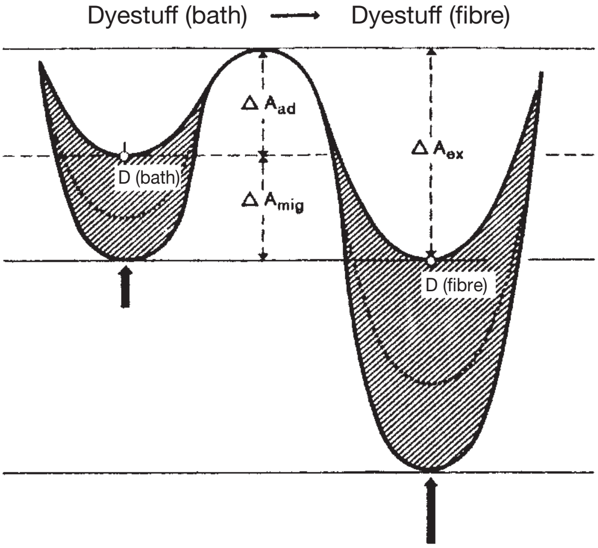

Fig. 4: Energy diagram showing the effect of the dyeing temperature on the rate of dyeing.

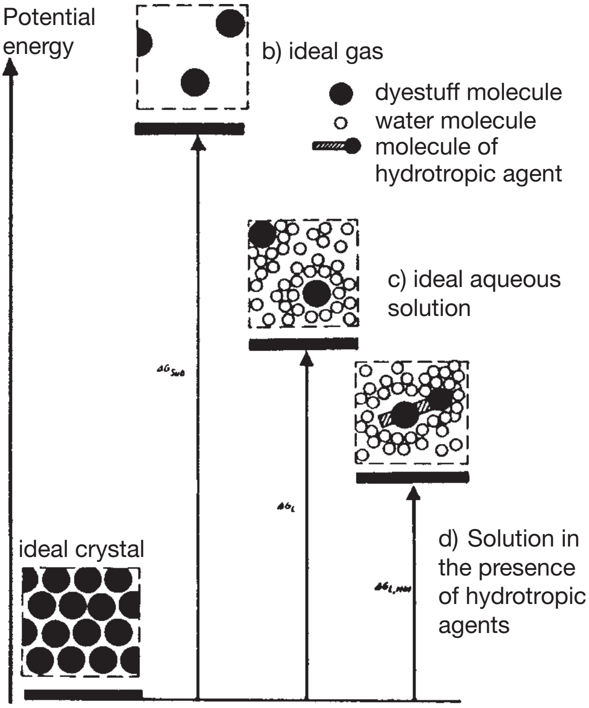

Fig. 5: Energy diagram for disperse dyes in various states.

The activation energy depends essentially on the dyeing mechanism. For disperse dyes in transfer printing, a lot of energy has to be put in to convert the dye molecules from their (assumed) form of ideal crystals into the gas phase (Fig. 5). This is expressed in the fundamental thermodynamic equation:

$$\Delta G = \Delta H - T \cdot \Delta S$$

G = free energy,
H = enthalpy,
S = entropy.

For example, about 120 kJ – calculated from 0°C – (the so-called sublimation enthalpy ΔH_{sub}) is required to vaporize completely 1 mole of crystalline C.I. Disperse Red 73 in a vacuum. This value is obtained from the Clausius-Clapeyron equation and the change in the vapour pressure of the dye with temperature. ΔH_{sub} is a measure of the strength of intermolecular forces in the crystal. At room temperature almost 15% of the lattice forces are accounted for by the heat $T\Delta S_{sub}$ that comes from the surroundings, so that only a free sublimation energy ΔG_{sub} of about 105 kJ/mol is required to destroy the crystal completely.

The molecules that leave the surface of a crystal and pass into a vacuum cannot interact with other molecules to lower their high potential energy. The situation is much more favourable for dissolving a crystal in water. The dispersion forces that act universally (including those between water and dyestuff molecules) have a considerable stabilizing effect on the individual

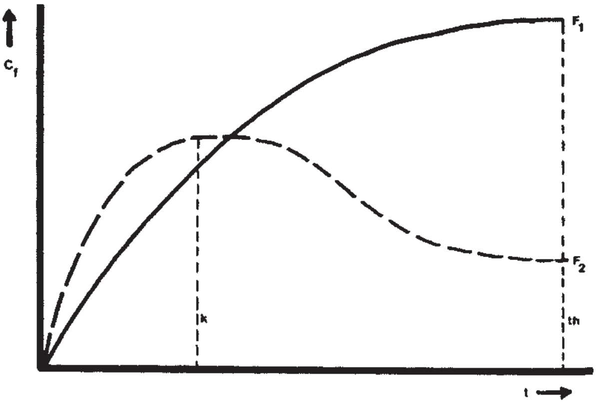

Fig. 6: Source of kinetically or thermodynamically controlled dyeing in competitive adsorption of two dyestuff molecules (1 & 2).
k = kinetically, th = thermodynamically controlled.

molecules that are removed from the crystal lattice. The free energy of solution ΔG_L required to destroy the lattice can be calculated from the molar solubility c_L:

$$\Delta G_L = - R \cdot T \cdot \ln c_L$$

R = gas constant = 8.3 kJ/mol · K

At 22°C pure (unstandardized) C.I. Disperse Red 73 has a molar solubility of $8.6 \cdot 10^{-6}$ mol/l. The free energy of solution ΔG_L at 22°C (= 295 K) is calculated from this to be 28.6 kJ/mol. To dissolve 1 mole of this dyestuff completely in water requires only 27% of the heat needed to vaporize it in a vacuum. This shows very clearly the extent to which the dyeing medium stabilizes the state of monomolecular solution.

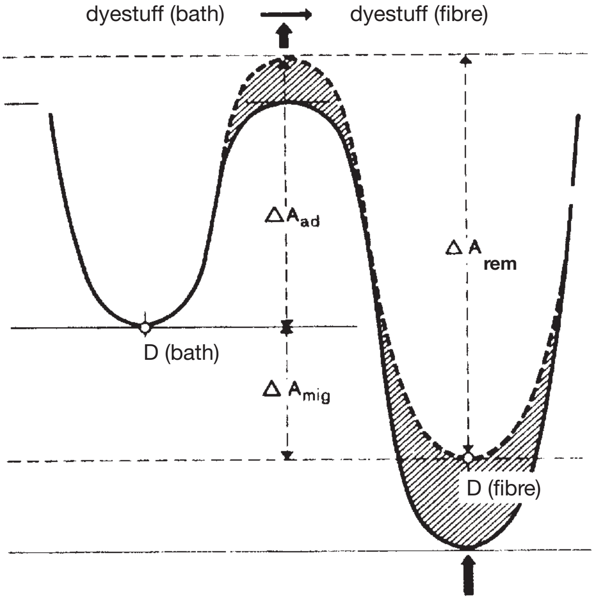

Fig. 7: The effect of higher (arrowed) pH of the dyebath on the activation energy in dyeing wool with acid dyes.

There is a further increase in the strength of interactions between the dissolved dyestuff and its molecular surroundings when hydrotropic compounds are added to the dyebath, and this reduces the potential energy by another "step". Solvent complexes are formed where a dyestuff molecule is held by relatively strong bonds to one or more molecules of the hydrotropic agent. An especially low relative energy level is subsequently reached if the dyestuff can interact with the polyester fibre "solvent" (giving the thermodynamically favoured product). When there is competition between two types of dye molecules for adsorption into a substrate, the dyeing may be controlled kinetically (Fig. 6), with the smaller dyestuff molecules being distributed quickly and more evenly in the fibre at the beginning of dyeing. If dyeing is continued until the dye equilibrium is effectively reached, the larger (slower diffusing) dyestuff molecules with the higher affinity will displace the smaller ones, which may then be partly desorbed.

In dyeing wool, increasing the pH of the dyebath raises the activation energy (Fig. 7).

Active bleach → Available chlorine.

Active chlorine losses, due to the consumption of active chlorine by organic components in soiled goods during a thermochemical disinfection wash. The extent of active chlorine loss is dependent on the nature and quantity of the soil: the active chlorine released by organic chlorine compounds (hypochlorite) is more or less bound (consumed) by the soil, and impairs the efficiency of disinfection. For this reason (according to the regulations of the Federal Board of Health in Germany) disinfection wash processes susceptible to active chlorine losses are not suitable for heavily soiled goods. The alternative, i.e. to overdose with products capable of liberating active chlorine can result in loss of textile strength and the fading of coloured goods (with dyeings having poor chlorine fastness).

Active content A term used to describe the active content of a pure substance or auxiliary which is supplied as a diluted product in water, solvent, etc.

Active earths → Bleaching earths.

Active oxygen is oxygen in the formative state, i.e. at the moment of decomposition (from bleaching agents). Formerly regarded as being responsible for the bleaching resp. decolorizing action in bleaching processes.

Active substances A group of highly active chemical compounds which are essential to life through their control functions in organisms, e.g. →: Ferments, Enzymes and Vitamins.

Active wear A term used to describe → Functional clothing, for active leisure and sports activities, e.g. fashionable jogging coordinates. In contrast to → Casual wear.

Activity sampling Fixed component of work study as a “quick method” of determining work quotas in order to clarify in relatively simple ways the question of multiple machine minding. It enables the actual state of the locational-spatial and organisational data of studied work stations to be represented for time recording, i.e. it offers time content percentages, but no handling times and no mandatory data on causes or causal connections of the cycle types or processes studied. It helps however to isolate causes. The main advantages of this activity analysis are in simple recording processes without time measurement. It cannot however replace time study with timing equipment.

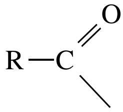
Actual blend ratio (DIN 60 003) In a textile product, the ratio of different fibres determined by analysis.

Actuator → Servo component.

Actuator drive Servomotor and transmission, main component of the actuating unit for producing actuating power for operating the → Actuator, the actuating power being obtained from secondary energy.

Acyclic compounds Compounds containing chains, possibly branched, but without rings. See also → Cyclic compounds.

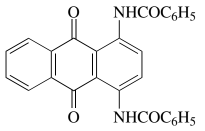
Acyl General name for organic acid groups which are the residues of carboxylic acids after removal of the –OH group:



The names of the individual acyl groups are formed by replacing the *-ic* of the corresponding acid by *-yl*. Examples:

formic acid	H–COOH	formyl
acetic acid	H_3C–COOH	acetyl
propionic acid	H_3C–CH_2–COOH	propionyl

Acylaminoanthraquinones Structurally, these are representative of the simplest vat dyes and give mainly yellow, orange, red or violet shades. Example: Indanthren Red 5GK:



Due to the sensitivity of the acyl group to hydrolysis, these dyes are applied by cold dyeing methods for preference.

Acylation The introduction of an organic or inorganic acid grouping into a molecule during chemical processses. An example of its practical application in textile processing is acylation of the cotton component in polyester/cotton blend fabrics for heat transfer printing. As a result of this modification to the cotton, only a thirtieth of all the cellulosic OH groups are acetylated, which corresponds to an average degree of substitution of 0,12. This is nevertheless sufficient to provide the cotton with an affinity for disperse dyes.

Acylcellulose Acyl substituted cellulose, e.g., cellulose esters → Cellulose derivatives.

Acyl polyglycolethers → Polyglycolethers.

Adamkiewics Reaction

1. Test for protein in starch analysis (1 part conc. Sulphuric acid + 2 parts Acetic acid, warmed = red violet colour).
2. Test for damaged (degraded) wool: sample + Acetic acid (= solution of protein) + conc. Sulphuric acid = violet colour; fluorescent solution.

Adaptation Adjustment of eyes to light levels. With a so called normal sighted eye, one refers to the ability of the eye to adjust to light i.e. the automatic change in sensitivity of the human retina (→ Colour vision) which makes it possible to see well in wide variations in light levels provided that the eye has sufficient time to adapt itself to the light variations (→ Chromatic adaptation).

Adaptive system, also called adaptive digital process control, is a self-regulating or self-adjusting system that is not controlled by a rigid programme but that has a mode of action that adapts to changing conditions by target-oriented responses so that a defined state can be reached or a particular function can be maintained.

ADC, abbrev. for → Analogue to digital converter.

Addition complexes → Complex compounds.

Addition high-wet pick-up In this process the damp cloth (from a preliminary washing stage e.g. for the removal of water-soluble sizing agents) is squeezed out and run through a special high-wet pick-up plant without liquor exchange; this is obtained with extremely low liquor contents and rapid continuous liquor renewal. This means that up to 80% by weight additional liquor is taken up by the interstitial volume of the cloth (e.g. Flexnip by Küsters, Fig. 1).

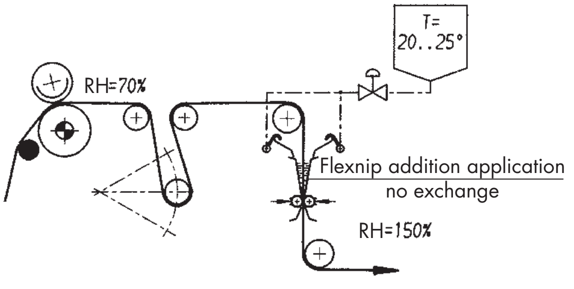


Fig. 1: Addition pick-up in the Flexnip system by Küsters (used in bleaching since approx. 1989; first used for dyeing in 1987).

Addition high-wet pick-up

If the liquor quantity is increased (to 100–150% pick-up) in cotton fabrics during preliminary finishing (desizing, boiling off, peroxide bleaching), the following improvements can be achieved:

1. Lower tendency of the cloth to crease during the steaming pass with tension-free cloth travel, as the greater availability of swelling agent leads to reduced swelling differences and no migration from higher to lower alkali concentrations.
2. More effective alkali activity on the primary wall and seed coat because more alkali is available in longer liquors consumed by neutralisation during boiling off.
3. Less fibre damage, as at sites well wetted-out with liquor there is less possibility of attack by atmospheric oxygen.
4. One-stage bleaching only with peroxide (i.e. without ecologically suspect hypochlorite), as greater amounts of oxidizing agent are available; in addition the optimised boiling off process means the fibre is better prepared for the bleach process (even more efficient if mercerizing is carried out as part of the addition process between boiling off and bleaching).

For the addition process a liquor strengthened at most up to 1.5 times is all that is needed. The liquor addition also means that the requirement for alkali stability of the auxiliary is substantially reduced, thus offering a greater choice of tensides with optimum qualities. The selection of a good stabilizer system makes it possible to supply the ready-for-use alkali/bleach liquor including all components from one formulating tank. The liquor formulation can be carried out manually, or semi- or fully automatically. Differences in concentration on the fabric are eliminated, as no liquor exchange takes place at this point in time. Titration of the alkali/bleach liquor is not necessary. The cloth finally progresses to the catalytic steamer with a total liquor volume of up to 60–70% + 80% = 150%. In the case of the Küsters Contidos System (Fig. 2), for example, the chemicals are continuously supplied to the Flexnip (Fig. 3).

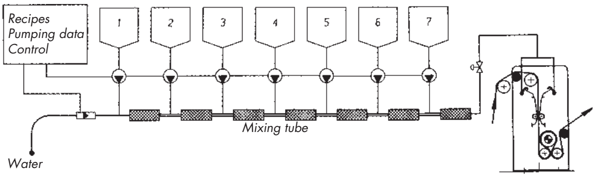

Fig. 2: Computer-controlled continuous chemical metering by the Contidos from Küsters.

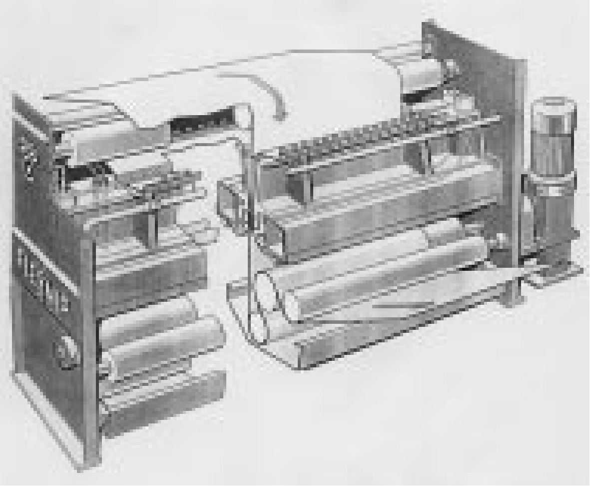

Fig. 3: The Flexnip, introduced in 1987 by Küsters as the first high-wet addition pick-up system.

Since 1991 other machine manufacturers have also offered high-wet pick-up systems:

a) Optimax by Menzel: 2 horizontal squeeze rollers, part of a high-performance squeezing system, express the cloth at high pressure so that it draws in large quantities of liquor due to the sponge effect when "opening up" as it enters the liquor in the trough. The nip of a superposed squeeze unit strips off the excess liquor (Fig. 4).

b) In the Super-Sat 2 by Babcock, several rollers are traversed, so that each time as much liquor as possible from the trough is squeezed through the cloth (Fig. 5).

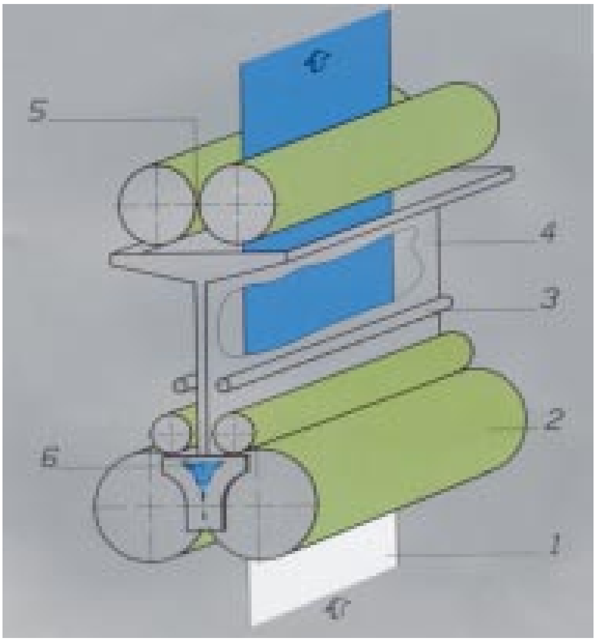

Fig. 4: The Optimax System by Menzel.
1 = cloth path; 2 = high-performance squeeze rollers with Rowatex roller; 3 = liquor feed with level control; 4 = liquor return plates; 5 = application squeeze unit; 6 = liquor trough.

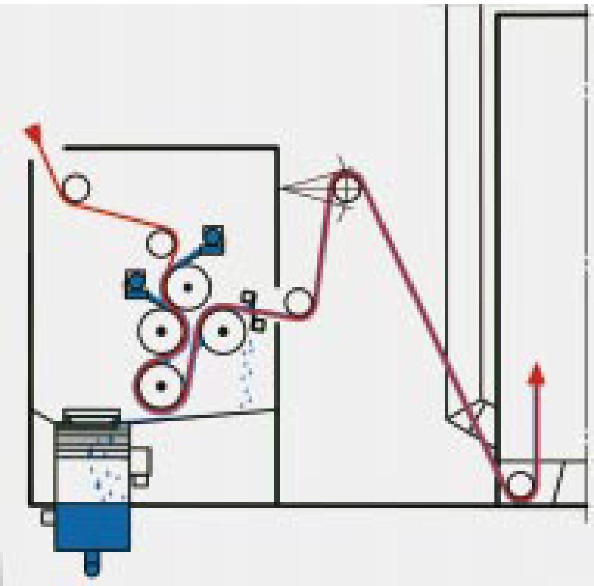

Fig. 5: Super-Sat 2 by Babcock.

c) By the Preyet-technology from Kleinwefers KTM a binary mixing nozzle combines steam and treatment liquor. The cloth runs past a series of jets and is thoroughly saturated with excess liquor. As with all such plant the Preyet-technology also requires an elaborate chemical metering system (Fig. 6).

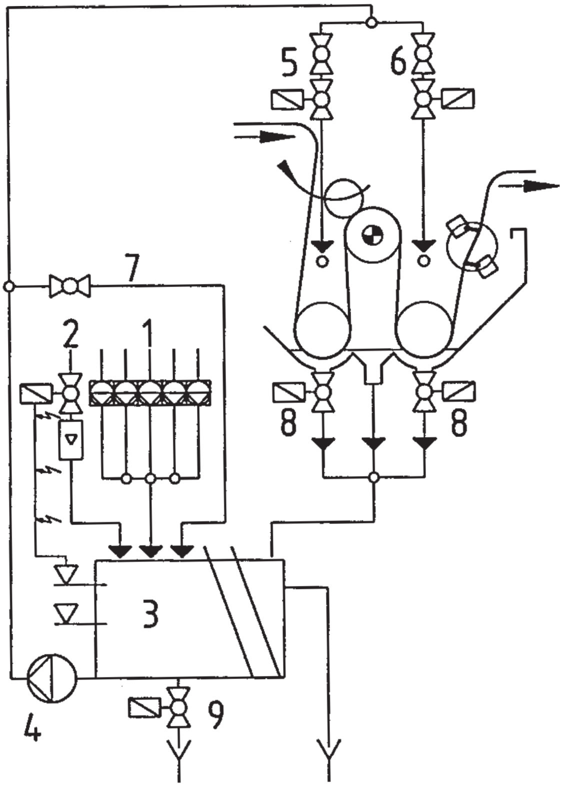

Fig. 7: Goller Dip-Sat System.
1 = dosing pumps; 2 = water feeding via transmitter; 3 = mixing tank; 4 = feeding pump; 5 = front distribution channel; 6 = rear distribution channel; 7 = mixing pipe; 8 = liquid return pipe; 9 = discharge valve.

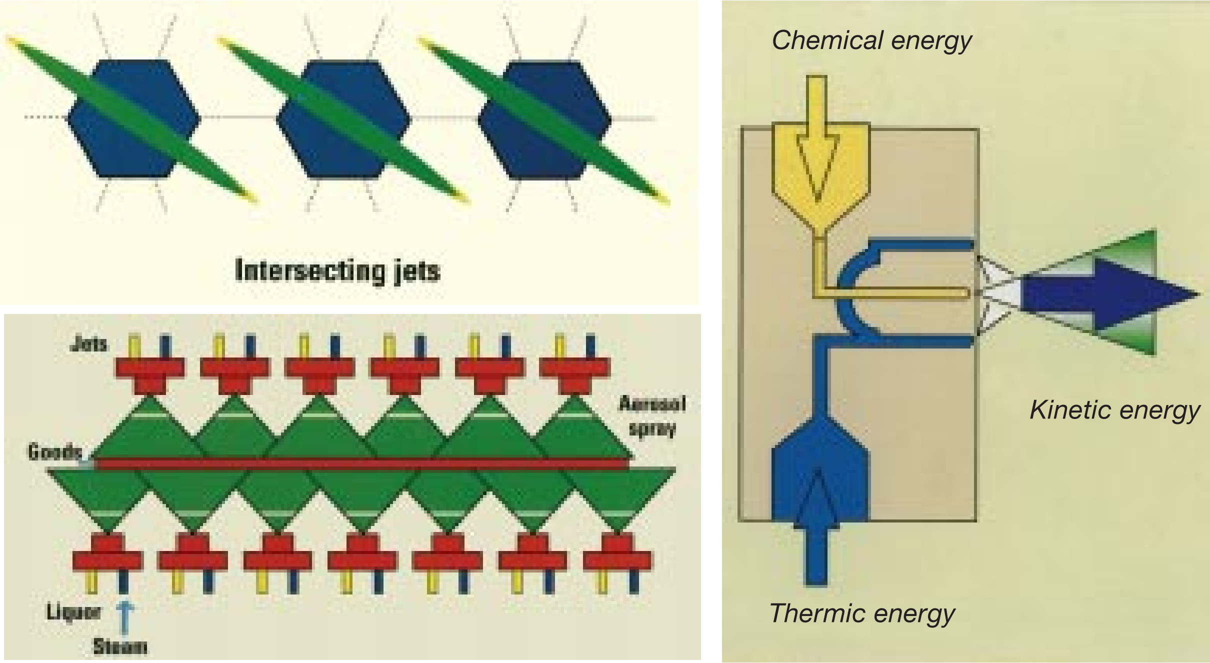

Fig. 6: Preyet-technology from Kleinewefers KTM.

d) The Dip-Sat System by Goller, like the Babcock plant, uses a system of impregnation from a trough (Fig. 7).

e) The Benninger system brings about high-wet pick-up by means of a combination of saturator and booster.

Addition (in dyeing) A term used to describe each corrective addition of dye made during the course of dyeing which is needed to achieve the closest possible colour match to a given colour standard or pattern.

Addition mercerisation The most feasible processing sequence incorporating the mercerising process would be obtained if mercerisation were to be effected between scouring and bleaching, or in subsequent single-stage processes. This gives the advantage of a clean and absorbent fabric, and reduces any lye contamination problems in concentrating lye by evaporation. In the case of cotton products, the most highly pre-quetched fabric possible, with a residual moisture content of 50–70%, is fed into the mercerising machine in order to save energy for an intermediate drying process. In the mercerising section of the line, the fabric is brought into contact as constantly as possible with a mercerising liquor concentration (300 g of NaOH/l or 30°Bé). Many squeeze points on roller mercerising machines, the liquor temperature, any necessary addition of wetting agents, and fabric absorbency, have a decisive effect on the dwell time required for obtaining approximately identical fabric NaOH and surrounding liquor concentrations. Substance interchange and diffusion processes are dependent on concentration gradient and liquor viscosity (and temperature).

Fig. 1 shows the considerable effect temperature has on the viscosity of highly concentrated NaOH in particular. This circumstance and the relationships between the relative swelling of cotton and time illustrated in Fig. 2 are used in applying hot mercerising technology. In this way, adequate cotton swelling for the mercerising process can be achieved after only 20 seconds dwell time.

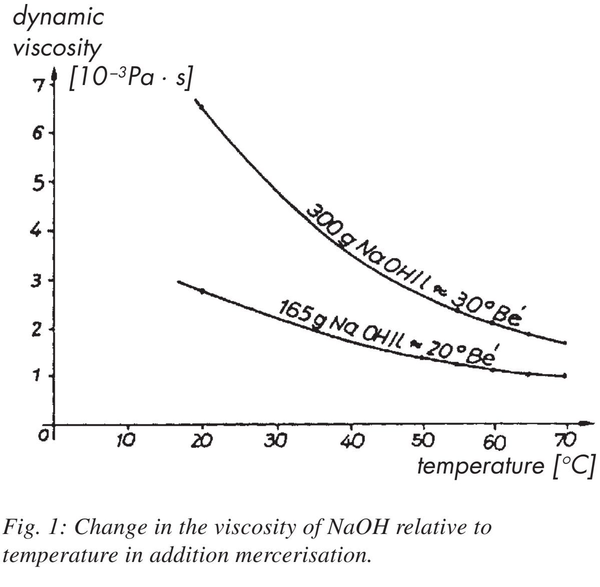

Fig. 1: Change in the viscosity of NaOH relative to temperature in addition mercerisation.

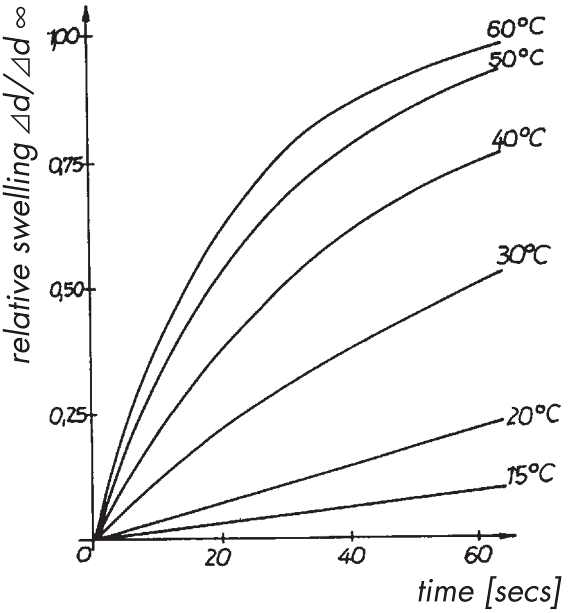

Fig. 2: Relative swelling of cotton (raw, desized) in relation to time (according to Bechter).

Comprehensive trials with various machine variants and relevant evaluation of the particularly interesting textile technical parameters during the mercerising process led to the addition mercerising process (Fig. 3). After a pre-scouring process, carried out with one or more scouring sections depending on the specific conditions, the fabric passes through a high-performance squeezing unit. Relative to the quetch effect, NaOH in the required concentration and quantity is applied uniformly to both sides of the fabric with the Flexnip (Küsters) addition unit already familiar from dyeing and pretreatment equipment, setting up the required mercerising lye concentration in the fabric after a short diffusion passage.

According to the large-scale trials available to date, the high degree of concentration of the added lye has the following main advantages over the processing technology employed up to the present:

1. A high concentration gradient between the water carried along with the fabric after the high performance squeeze unit and the strong lye added in the Flexnip result in significantly accelerated diffusion, the necessary dwell and mercerising times being reduced to about 10 seconds.
2. The entire lye circulation system in the earlier mercerising – now the diffusion – section with lye vats, containers, pumps, spray tubes etc is eliminated. This section can be significantly shortened on account of the short dwell times required.

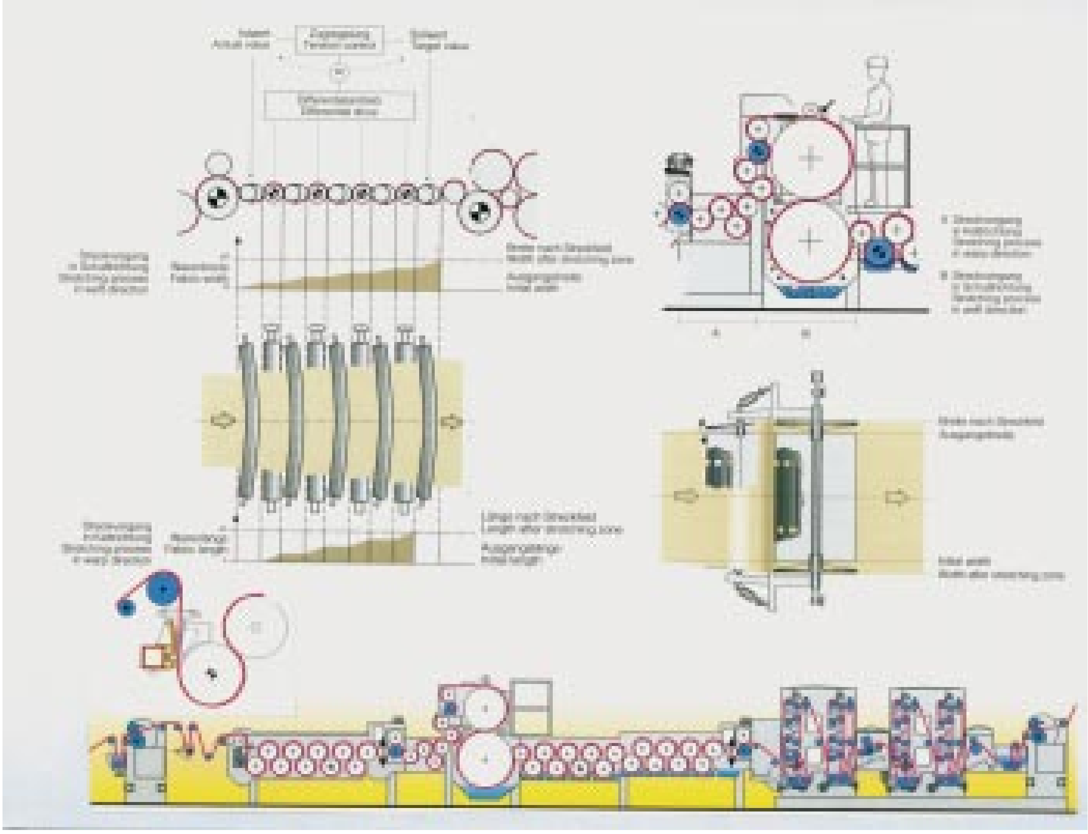

Fig. 3: Küsters addition mercerising line.

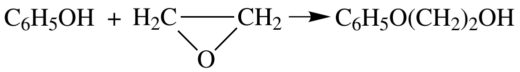
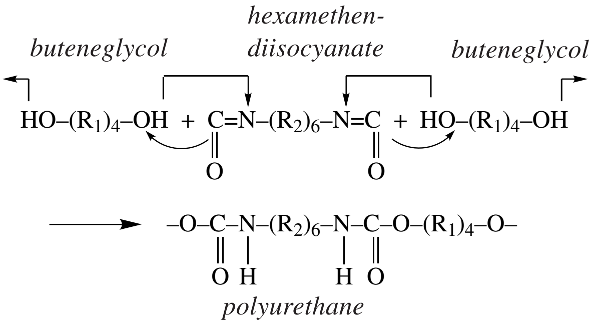
3. The addition of lye in a considerably higher concentration than before gives rise to immediate, practically spontaneous fibre swelling, resulting in the same mercerising effect with up to 25% less caustic soda usage/kg of fabric than with the processing method hitherto employed, resulting in significant savings in water, steam and chemicals, plus a considerable reduction in the ecological problems posed by the mercerising process (according to Greif).

Addition polymerization involves the production of high molecular weight synthetic compounds (→ Addition polymers) in which the participating components are joined together due to transmolecular rearrangements caused by the shifting of hydrogen atoms. Addition polymerization takes place without low molecular weight substances (e.g. water) being split off. Addition polymerization is employed *inter alia* in the manufacture of non-ionic detergents of the type:



$$C_6H_5OH + H_2C\!-\!CH_2\,(O) \rightarrow C_6H_5O(CH_2)_2OH$$

Other well-known examples are →: Polyurethanes, Polyureas. Thus, polyurethane fibres are formed by molecular linkage involving the shifting of hydrogen atoms as shown in the formular:



$$HO{-}(R_1)_4{-}OH + \underset{\displaystyle O}{\overset{}{C}}{=}N{-}(R_2)_6{-}N{=}\underset{\displaystyle O}{C} + HO{-}(R_1)_4{-}OH \longrightarrow {-}O{-}\underset{\displaystyle O}{C}{-}\underset{\displaystyle H}{N}{-}(R_2)_6{-}\underset{\displaystyle H}{N}{-}\underset{\displaystyle O}{C}{-}O{-}(R_1)_4{-}O{-}$$

→ Polymerization reactions for fibre-forming macromolecules.

Addition polymers, are synthetic products obtained by → Addition polymerization. Typical examples are the polyurethanes as a) linear macromolecules and b) crosslinked spherocolloids.

Additions in dyeing, coloristic justification for One of the main tasks of the colourist is to decide whether a dyeing represents a satisfactory colour match to a given standard or pattern or whether a further shading addition must be made to a dyeing as a correction. An absolute colour match between a dyeing and a standard is an exception; as a rule, there is always a slight difference in shade between both samples. In the evaluation of a dyeing, the colourist makes a visual assessment of these unavoidable differences and then makes his decision. It is well-known that the quantitative visual evaluation of colour differences with the human eye is difficult, even for the trained eye of an experienced colourist. Moreover, these limitations of colour matching, and consequently, the quality of evaluation, are not only dependent on subjective factors of the human eye but may also involve psychological considerations. These can include, e.g.: knowledge of the customer's tolerances, knowledge of the technical possibilities of the production process and, all too frequently, the time pressure under which the dyer has to work.

In the figure, the colour matching limit is represented in the form of a vertical line based on the ΔA_T value of 1,9 AN units. It divides the 100% field of significance for dyeings requiring correction in the opinion of the colourist into two frequency fields of different size. The shaded area of the curve to the left of the colour matching limit indicates the frequency of dyeings which were already within the colour matching tolerance limit but were falsely subjected to further corrections by the colourist. The area enclosed by the right hand curve of the colour matching field corresponds to the frequency of dyeings which were judged by the colourist as well as an instrumental colour matching system as unacceptable. As illustrated by the area of both curve fields in the example, 70% of the corrected dyeings already lay within the colour matching limit and therefore did not require any further correction. Only 30% of all the corrections made were really necessary. In this case, therefore, the dyer could have saved 70% of the corrections without any deterioration in the quality of colour matching.

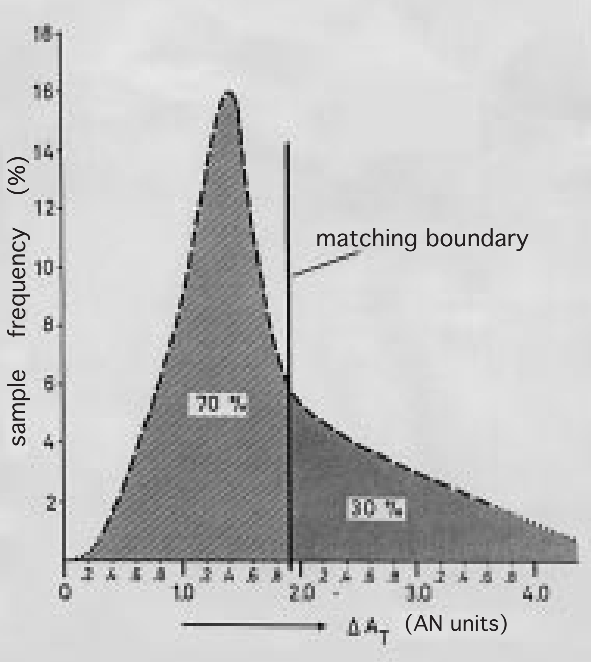


Fig.: Proportions of superfluous and necessary colour corrections, determined by statistical evaluation of the colorimetry data (specific to firm and product) (according to Rieker).

Addition test The quality of a dyeing is determined largely by three factors, i.e. sample conformity, levelness and fastness, dyeing levelness playing a central role. For this reason, the dyer tries to ensure and optimise levelness during processing. To this end, he has available the following instruments:

- the choice of dyestuff in terms of levelling behaviour,
- the concurrent use of suitable levelling agents,
- the choice and optimisation of the dyeing process.

The levelling behaviour of dyestuffs, auxiliary products and processes can be assessed by various means. The most well known is the method of measuring exhaustion and migration curves under defined dyeing conditions described as "classic". The resultant values of this operation (frequently in graph form) form the basis of the relevant dyestuff and auxiliary product manufacturers' documentation. All these test methods have their disadvantages of course. One important disadvantage in the "classic" combination of exhaustion and migration curves is that both aspects, regarded in fact in combination, have to be added to some extent in evaluation; a process which, from experience, gives rise to problems, due to a lack of integration potential. To this is added the fact that determining exhaustion and migration curves is time-consuming, requires a relatively high degree of accuracy, and depends on the substrate. Assessed overall, this "classic" process is therefore too expensive for practical application, too inaccurate in the overall aspect, and, moreover, too unadaptable (operation-specific factors like the nature of the substrate, the packing density of packages, water conditions etc. can be adopted only to a limited extent here).

The "addition test" process is derived from yarn package or beam dyeing, i.e. a dyeing technique which is, on principle, especially problematic in levelling terms (the package acts first of all as a filter, where the individual layers do not come into contact with the liquor simultaneously, but one after the other).

The processing principle is derived from the term "addition test".

Circulation dyeing is effected (on yarn package or beam), the total dye quantity being added only at final temperature (e.g. 98°C in wool or polyester dyeing), as an "addition", as it were, as is usual in shading addition in dyeing. The liquor circulates from inside to outside throughout the test, the dye naturally exhausting itself preferentially on the inner layers of the package; colouration intensity decreases from inside to outside. The degree of distribution depends first of all on the dye exhaustion rate and the retardant action of the levelling agent employed. As the test proceeds (dyeing is effected for 20–30 mins at the final temperature specified for the relevant process), the effect of the migration phase is added, dye distribution being improved in the inside to outside direction. After the specified test duration, a degree of distribution is reached which characterises the levelling behaviour of the dye employed and the dyestuff combination or the levelling agent.

The result comprises both rate of exhaustion and migration, and is, in this sense, to be evaluated as an overall statement of the levelling behaviour of the dye or the dye/auxiliary agent combination. The process is particularly suitable for comparative tests, i.e. evaluating and comparing different dyestuffs, dyestuff combinations and auxiliary agents (according to Bihn).

Additive An additive is generally a substance which, when added to a product, brings about a significant improvement in its desired properties and/or extends the range of properties still further. Additives are now particularly relevant in the case of surfactants and detergents, e.g. as antistatic agents, bactericides, colouring matters, corrosion inhibitors, fluorescent brightening agents, fragrances, etc.

Additive antifelt finishing → Antifelting finish.

Additive colour mixing → Colour mixtures.

Additive finishing Finishing process in which substance is supplied to the textile material (e.g. polymers for felt-free finishing). Conversely: processes in which the textile material loses weight and substance = subtractive finishing (e.g. scouring).

Additive pick-up Impregnation of moist fabric (max. 40–45% water) on a pad mangle with a small trough content. Here, the fabric takes up an additional 30–35% of liquid, there being no interchange between adhering water and impregnating liquid. Conversely: → Interchange impregnation.

Additives in resin finishing have a favourable effect on the technological properties, especially the abrasion resistance and to some extent, also the fabric handle. Dispersions based on polyesters, polyacrylonitrile esters and copolymers are of particular importance here. In the case of fabrics containing cellulosic fibres, finishing is frequently understood to mean resin finishing. The objective of resin finishing with formaldehyde crosslinking agents is to improve the crease resistance and shrinkage behaviour. Undesired side effects of resin finishing are strength losses in the form of tear strength, resistance to further tearing, and abrasion resistance, as well as a distinct firmness of handle. In order to overcome these side effects, softeners of various chemical types are employed, particularly fatty acid/alcohol derivatives, as well as products based on polyethylenes and silicones. They are not used here as processing aids but to improve the serviceability properties of the textile material. They can therefore be described as functional softeners. Technological properties are, to a large extent, important for woven fabrics. On the other hand, sewability is important for knitgoods, i.e. the avoidance of damage to the knitted loops during garment making with industrial high speed sewing machines. Consequently, softeners used to improve sewability in garment making often have the character of process aids.

Adduct (Lat.: *adducere* = to bring to)

I. Addition product, e.g. an ethylene oxide from which substituted polyglycolethers are formed.

II. An unstable compound formed between dyes and levelling agents which, after a long time of dyeing, gradually break down either partially or completely, thereby achieving a slower exhaustion of the dye = improved dye levelling.

Adhered water Water collects at the intersection of the warp and weft and is so tightly bound that it cannot be removed as easily as other surface water. When fabric is passed through a washing range, a layer of adhered water is formed directly on the surface of the fabric (Fig. 1) which forms an obstruction to the diffu-

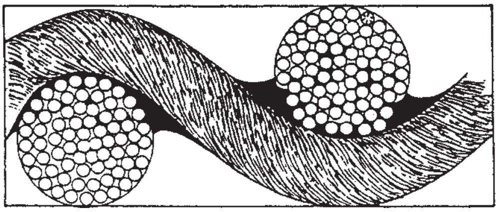

Fig. 1: Adherent water in nips (warp and weft in a woven fabric cross-section).

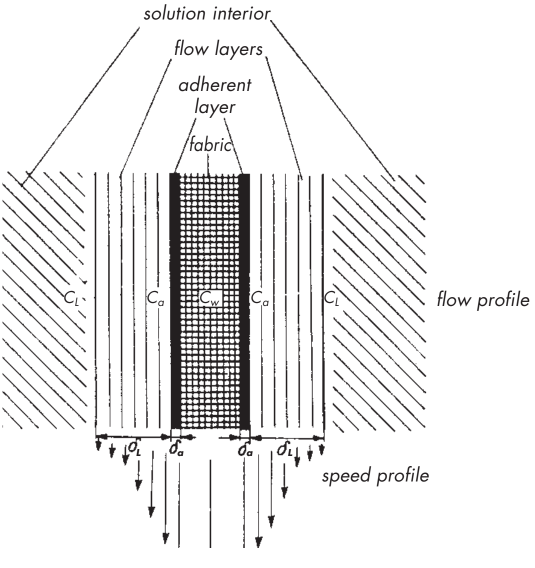

Fig. 2: Schematic diagram of the flow and concentration relationships in an open-width scouring machine.
c_w = chemical concentration on the fabric; d_a = adherent diffusion layer; c_L = chemical concentration in the liquor; d_L = laminar flow layer with concentration c_a at the limit d_a/d_L.

sion of dissolved soil. Only a vigorous flushing will disturb the lamellar film boundaries (Fig. 2).

Adhering water (wetting water, surface water, adhesion water), superficially loosely adhering water, chiefly in yarn and fabric interstices etc. Removal by pre-drying.

Adhesion Adhesion between solid materials arises principally through the following types of interaction: covalent chemical bonding, dispersion forces and polar forces. Covalent bonding is ruled out for most fibre and soil components. Chelate bonds can form only between cellulose and iron (III) compounds. On the other hand dispersion forces act between all fibres and every kind of soil. This is a non-specific type of attraction that results from the movement of electrons in molecules. It is related to the tendency of particular fibres to soiling. Surface roughness affects the attraction by changing the supporting surface and the distances from the fibres. The generic term polar forces covers all interactions caused by permanent dipoles or ions that are adsorbed or formed by dissociation at the surface. The specific adhesion is proportional to the dipole moment of the molecular or ionic groups at the surface. No precise methods for determining this quantity are known. → Soil adhesion; cohesion.

Adhesion energy, free Potential energy, at a steady temperature, released when a free liquid surface is formed from the separation of 2 phases (liquid/solid). To cause an increase in free energy (Adhesion energy expressed in Ergs or Joules).

Adhesion water → Adhered water.

Adhesive-bonded cloqué Two woven fabrics (e.g. wool) are stuck together by applying adhesive and then laminating, one fabric being shrunk and the second remaining untreated. By subsequent crêping in hot water or alkaline crêping baths, the untreated fabric shrinks, producing a crêpe effect. The adhesive is applied in strips or dots. Two-component adhesives are mainly used.

Adhesive bonded knop textiles Fabrics in accordance with DIN 60 000 which are produced by sticking a knop yarn or fibre web on to a textile or plastic substrate.

Adhesive bonded, nonwoven → Nonwovens.

Adhesive-bonded pile coverings In the style of → Adhesive-bonded pile textiles for adhesive-bonded carpeting. The running layer frequently consists of a fibre web. The material is first of all laid by machine in small folds, and then stuck on to a prefabricated woven ground fabric, resulting in a continuous rib structure. When the ribs are shorn, the covering has a typical velours look.

Adhesive-bonded repair Tears, cuts, small holes, worn corners/edges of linen and industrial clothing, for which → Adhesive-bonded textiles are used.

Adhesive-bonded textile Textile fabric for permanent adhesion as a thermal adhesive for adhesive repairs etc. A fabric layer is sintered by the dry or wet process, preferably with powdered thermoplasts by air doctor application, electrostatic sprinkler (→ Powder dot coating) or combined roller/brush units. Subsequently sintered or gelled (mainly in a heating flue with infra-red heaters) on to the textile material under the effect of heat. The sintered fabric layer is applied to the textile material to be glued (partner textile) under the influence of pressure and temperature. Optimum adhesive effects are dependent on sintering quantity, pressing time, pressing temperature and pressure. Automatic setting presses are preferable to irons for producing an adhesive bond. → Adhesive-bonded fabrics.

Adhesive bonding nets Strong polymeric textile fabrics as a net structured adhesive system based on a whole range of polymers. Supplied in roll form. Adhesive processing, e.g. with the aid of an ironing press or, following prior thermal activation with infra-red radiators for example, lamination on to the substrate. Adhesive bonding nets offer various advantages: practically no impairment of the air permeability of the united system, elimination of the danger of bleeding through, no unpleasant fabric stiffening. If necessary, adhesives can be placed in the form of a discrete layer.

Adhesive, contact For the production of self-adhesive floor and wall coverings. Contact adhesives are two-phase systems comprising a polymer phase and an adhesive resin which comes on to the surface under pressure.

Adhesive lamination Laminating process for applying a foamed material film to textile material. Advantages: no loss of thickness as in → Fusion lamination.

Adhesive strike-through This problem occurs in screen printing if excessive quantities of adhesive film are applied to the printing blanket causing it to penetrate through the fabric being printed.

Adipic acid (1,4-butanedicarboxylic acid; hexanedioic acid), $HOOC–(CH_2)_4–COOH$. It is the acid component used in the synthesis of polyamide 6,6 (→ Adipic hexamethylene diamine salts) and also for the manufacture of 1,6-diaminohexane (hexamethylene diamine), alkyd resins, and esters used as plasticizers. Its former derivation by the oxidation of fat (Lat.: *adeps)* was the origin of the name adipic acid. Manufactured e.g., from cyclohexanone.

Adipic acid fibres Polyamide fibres of the polyamide 6,6 type, produced from adipic acid and 1,6-diaminohexane (hexamethylene diamine).

Adipic hexamethylene diamine salts (Polyamide 6.6 salts), Hexamethylene diamine adipate; monomeric exchange product of adipic acid and 1,6-diamino hexane (hexamethylene diamine) which, once purified by crystallisation, forms Polyamide 6.6 by polycondensation.

Adire Name given by the Yoruba tribe in Nigeria to the patterns created by reserve Africa print techniques on cotton using indigo.

“Adire oniko” is a tie-and-die technique (Fig. 1). In “Adire eleso” small plant seeds, fruit capsules, shells or stones are incorporated in the damp cloth as a means for producing circular and star-shaped patterns. The “Adire alabere” technique employs basting and whip stitches to produce reserve patterning. Two superposed fabrics arranged in a particular way are thus basted with offset rows of stitches passing through the two plies of cloth. By means of an additional rolled-in pleat a feather-type design is produced called “Agosofin” by the Yoruba (Fig. 2).

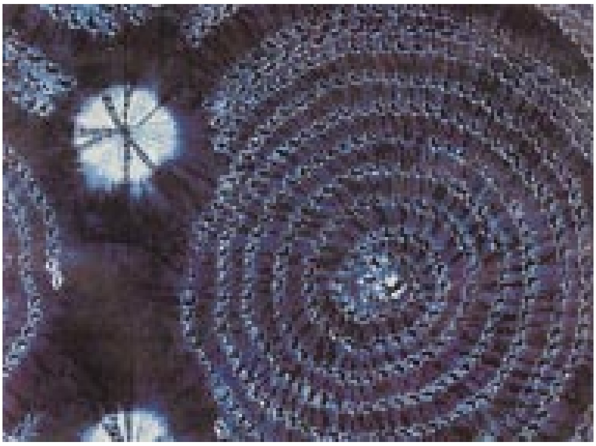

Fig. 1: “Adire oniko”.

One of the most popular traditional designs created with reserve paste is called “Olokun” by the Yoruba. As distinct from the tie-dye and stitched reserve techniques, “adire eleko” is an African variant of the Indonesian batik technique. The reserve agent used is “eko”, a vegetable starch prepared in the form of a paste from rice or cassava root (manioc). The starch is thickly applied to coat one face and no cracks must appear in the paste during drying as these would cause indistinct outlines in subsequent dip-dyeing.

Fig. 2: “Agosofin”.

Adjacent fabric (colour fastness testing) Undyed white fabric composed of one or several types of fibre used in → Colour fastness tests to determine the degree of staining from an accompanying dyed or printed test specimen. Such test fabrics must be completely free of finishes or other impurities. (1) Single fibre adjacent fabrics are standard fabrics of average weight composed of a single fibre type in a plain weave construction. For a particular colour fastness test, one piece made of the same fibre as the test specimen as well as one piece made of a different fibre type (specified) are required. (2) Multifibre adjacent fabric is supplied in strips woven from yarns of 6 different fibre types. Type DW = acetate, bleached cotton, polyamide, polyester, polyacrylonitrile, wool; Type TV = triacetate, bleached cotton, polyamide, polyester, polyacrylonitrile, viscose. Only one multifibre adjacent fabric is required for a particular colour fastness test.

ADR, abbrev. for: American Dyestuff Reporter (An American technical journal published monthly).

Adrianopolis red Identical with → Turkey red. Named after the Turkish city of Adrianopolis (Edirne).

Adsorbate → Adsorption.

Adsorbent → Adsorption.

Adsorbents for clarification purposes →: Bleach earth; Kieselguhr; Active carbon.

Adsorbing substances → Adsorption.

Adsorption (Latin: ad = to + sorbere = to suck in) is taking up, normally of soluble substances (adsorbate) onto the surface of a solid body (adsorbant) (see Table), e.g. dissolved substances onto fibres, moisture onto machine parts, gases onto solid bodies. It is extremely important in almost all dyeing and finishing processes. Adsorption is understood to involve various phenomena including chemical forces and the forces that act between solid/solid and solid/liquid phases where the phases adhere through another substance. The dissolved adsorbant (textile auxiliaries, dyestuffs etc.) or their ions (e.g. the fatty anions of auxiliaries) are forced out of solution by the water molecules onto the interfaces (fibre-water, soil-water) (see Fig.) and tend to diffuse into the surface. The concentrating effect produced at the surface can be 100–1000 times the concentration in the bath. When the dissolved substances are ionic they transfer their electrical charge to the boundary or surface (fibre, soil) (when there is ion exchange = exchange adsorption; when ions of one type accumulate at an interface = polar or hydrolytic adsorption; when the ion types are concentrated in the

adsorbent	form	examples of use
activated charcoal	granulate, powder, ball, fibre (untreated, doped)	exhaust air/exhaust gas decontamination,gas purification, water purification, dye stripping, catalyst or carrier medium
activated coke	granulate	exhaust gas decontamination, special flue gas desulphuration/ denitrification, preliminary filter (exhaust gas/water)
carbon-molecular sieve	granulate	separation of gases and hydrocarbons
scavengers	granulate	water purification, dye stripping, gas purification
silica gel	granulate	drying, catalyst or carrier medium
aluminium oxide	granulate	drying, catalyst or carrier medium, adsorption of polar substances
molecular sieve	granulate, powder	drying, gas separation, exhaust gas decontamination (polar substances)

Tab.: Technical absorbents: products, form, examples of application.

same proportions as they are present in the solution = normal or apolar adsorption). When e.g. soil becomes electrically charged with ions of the same sign, its mobility is increased and the soil particles separate from the surface.

Adsorption carbon → Activated carbon.

Adsorption chromatography → Chromatography.

Adsorption displacing activities For example, polyphosphates have the ability to reverse the adsorption of surface active agents to fibres etc.

Adsorption isotherms From the application point of view (exhaust processes, mechanical application), dyeing processes can essentially be divided into the following groups:

1. Mechanical anchoring of dyestuff on the substrate (pigment dyeing).
2. Sorption processes in which transport (diffusion) phenomena occur first and which are often accompanied by chemical reactions. In each case migration of the dyestuff is followed by its fixation in the substrate; when water-soluble dyes are being used, dyeing is a case of equilibrium distribution of the dyestuff between the liquid phase of the dyebath and the solid phase of the fibre.
3. In dyeing with (sparingly water-soluble) disperse dyes, the particles of the dispersion act as a 3rd phase; dye is transferred from these solid particles into the solid substrate via solution in water.
4. Thermosol dyeing and transfer printing are high temperature processes (180–200°C) in which the disperse dyestuff is transferred by sublimation from

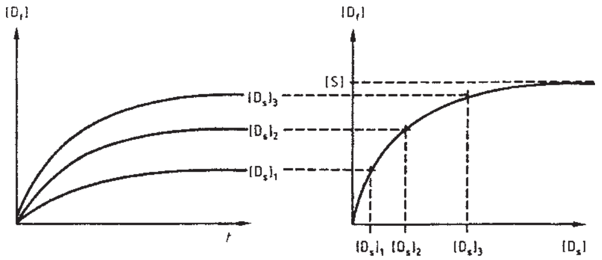

Fig. 1: Kinetics and thermodynamics of a dyeing process (from Zollinger).
D_s = concentration of dyestuff in solution (mmol/l);
D_f = concentration of dyestuff in the fibre (mmol/l);
t = dyeing time (s); S = saturation value.

the solid phase through the gas phase into the polyester substrate.

The distribution of a dyestuff between two phases in sorption dyeing can be described by the kinetic (transport and reaction phenomena) and equilibrium characteristics (thermodynamics of adsorption and desorption in dyeing equilibria) (Fig. 1). The results of static and kinetic dyeing experiments shown as graphs of the dyestuff concentration in the dyebath against the dyestuff concentration in the fibre are called dyeing isotherms. They are obtained from exhaustion curves. → Sorption isotherms

Ionic dyes are taken up according to a Langmuir adsorption isotherm, whereas disperse dyes exhaust by a Nernst (linear) or a Freundlich adsorption isotherm (Figs. 2 and 3).

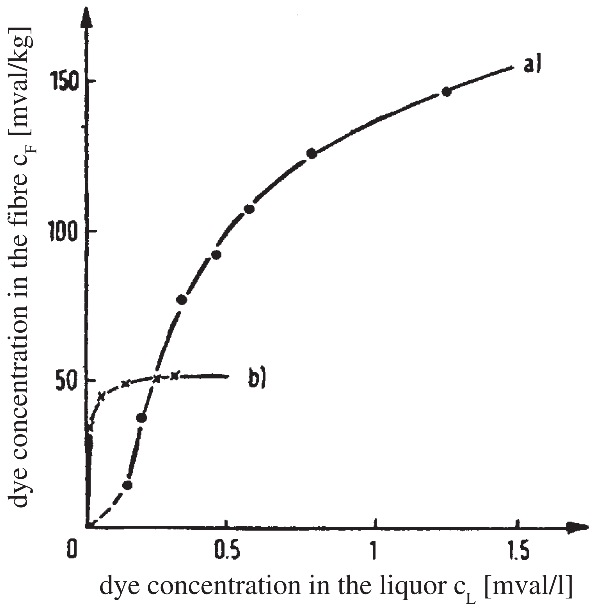

Fig. 2: Uptake of an acid dyestuff (C.I. Acid Blue 25) by a) an Elasthane fibre and b) a nylon-6 fibre (100°C, pH 4.7, 4 h); b) corresponds to the Langmuir and a) to the Freundlich or Nernst isotherm.

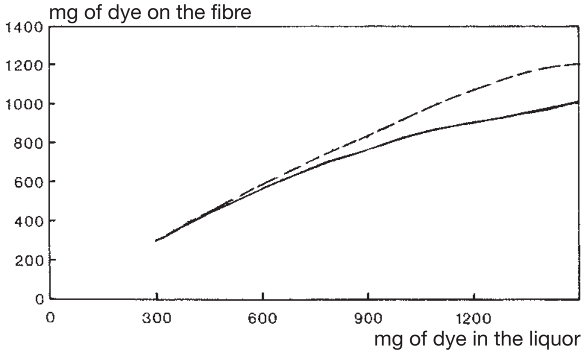

Fig. 3: Adsorption isotherms of cashmere (– –) and cashgora fibres (—) dyed with the same wool dyestuff to compare the dyeability of the two types of fibre.

Adsorption liquid Liquid retained as a deposit of liquid molecules in amorphous areas and on the surface of crystalline areas of fibres. The binding takes place through valency forces provided that the liquid has polar properties.

AECC, (Sp.) abbrev. for: Asociación Española para el Control de la Calidad, Madrid (Spanish Quality Control Association); member of the → EOQC; → Technical and professional organizations.

AEK, abbrev. for “Amerikanische Echtheitskommission”, Fastness Committee of AATCC → Technical organizations.

AEQCT, (Sp.) abbrev. for: Asociación Española de Químicos y Coloristas Textiles (Spanish Association of Textile Chemists and Colourists); → Technical and professional organizations.

Aeré Woollen yarn fabric with a tweed-like character, and a marked crocheted openwork pattern effect.

Aerobic bacteria (Gr. *aer* = air), are microorganisms which thrive especially in the presence of atmospheric oxygen, so-called aerobes. Opposite term → Anaerobic bacteria.

Aerobic degradation Biological degradation or biodegradation occurs as a result of any conversion of dissolved or solid matter into other compounds through the action of organisms. Besides assimilation by photosynthesis in which dissolved substances are taken up by biological systems, the biodegradation of organic compounds by microorganisms such as bacteria and moulds represents the most important process. In this process, organic substrates are oxidized and part of the energy released is used by the microorganisms for reproduction (see Fig.). This type of respiration (also often referred to as mineralization) consumes oxygen or, if this is not available, other oxidizing agents such as nitrates, sulphates or organic compounds that are already partially oxidized.

Aerobic respiration: In this process, organic substances are oxidized and oxygen is reduced. Under ide-

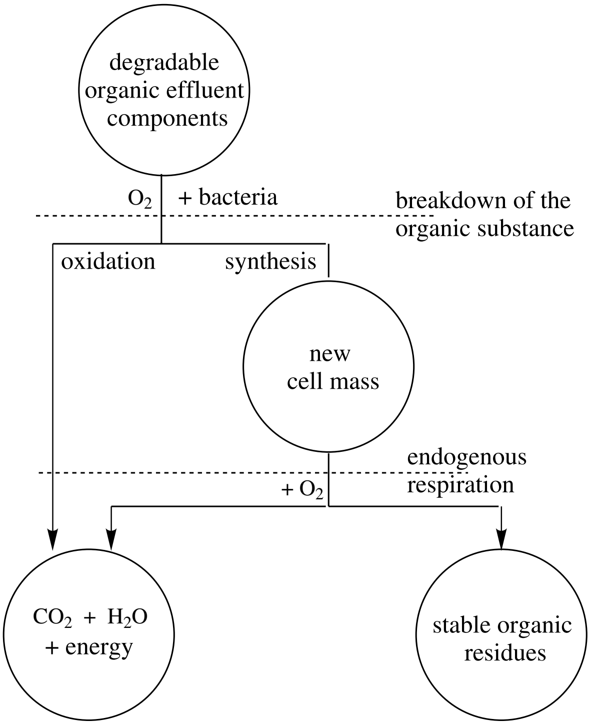

Fig.: Diagram of the aerobic breakdown of the organic effluent components in activated sludge.

al circumstances, this oxidation proceeds to carbon dioxide and water:

$$CH_2O + O_2 \rightarrow CO_2 + H_2O$$

These various stages of reaction have been thoroughly investigated and, together with anaerobic processes, are employed in the biological purification of waste water. By this means, about 50% of the organic substrates are oxidized through the release of energy in aerobic respiration and the remainder is converted into bacterial mass (sewage sludge). In anaerobic methane fermentation, on the other hand, only about 10% of the substrate is converted into bacterial mass (Kummert and Stamm).

Aerobic fermentation During biodegradation of the organic constituents in waste water, an oxidative degradation of substances catalyzed by bacteria takes place. However, new cell mass is built up at the same time since the nutrient supply promotes bacterial growth. This cell mass also breaks down itself by endogenous respiration through oxygen consumption, as a result of which organic residues no longer capable of further degradation are formed. In total, the products of aerobic degradation are CO_2, H_2O, besides energy and waste substances.

Aerodynamic dyeing systems In a rope dyeing machine, a distinction is drawn between the dwell zone (diffusion in the fibre) and the liquor exchange system (reduction of the laminar boundary layer through intensive fibre flushing in order to improve uniform dye absorption on the fibre surface). The liquor to fabric substance interchange is effected in various systems (Fig. 1):

1. Mechanically in the winch with a 20 : 1 liquor ratio.
2. Hydraulically in overflow or jet dyeing machines (depending on the fabric propulsion system principle in the fabric to liquor interchange zone) with a straight (12 : 1 liquor ratio) or circular (10 : 1 to 5 : 1 liquor ratio) fabric store.
3. Aerodynamically: the fabric is propelled by a gas flow; the treatment liquor is injected into the gas flow. Liquor ratio: 4 : 1 to 2 : 1 (Fig. 2).

As the liquor supply is greatly reduced in consequence, the textile fabric liquor charge is reduced, i.e. in the case of fabric movement in a gas flow, the free space between fibres is not completely filled with liquor. Depending on the physical parameters of the gas, as air with a differing water vapour content, a state of equilibrium occurs in which the injected liquor quantity is interchanged with the textile fabric moisture charge. This flows out of the treatment vessel (Fig. 3) back into the injection circuit in the same quantity as the injected liquor. The suction conditions of the injection pump are better than those of a liquor pump, and only a small liquor supply is therefore necessary.

The aerodynamic system developed with the Then Airflow moves and controls the fabric by means of the

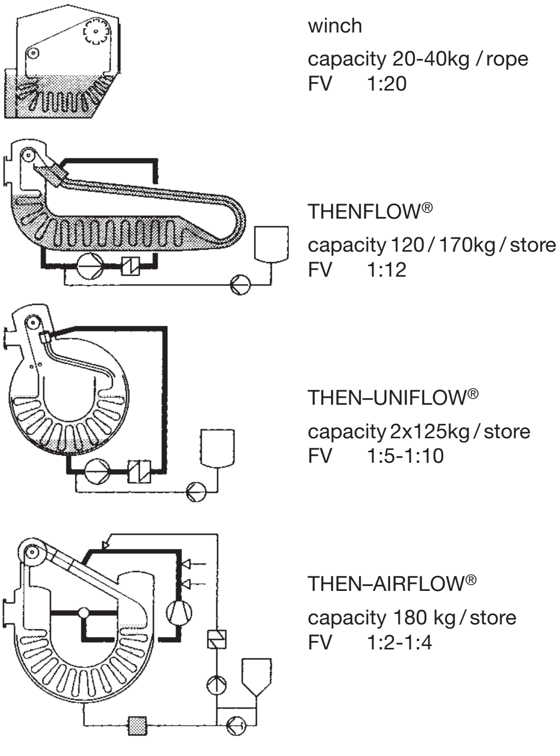

Fig. 1: Then piece dyeing machines in development from the winch to the Airflow aerodynamic dyeing system.

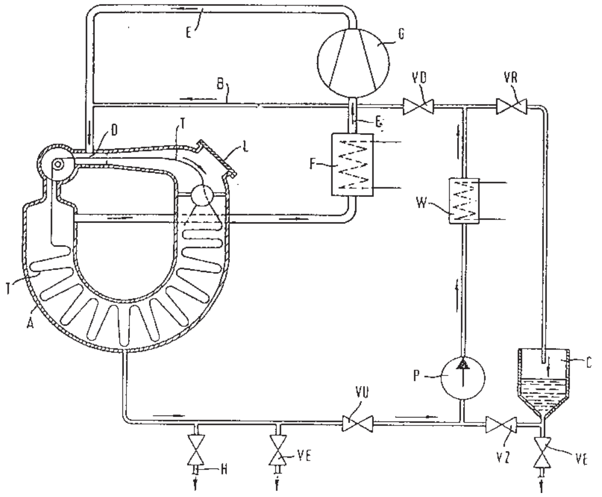

Fig. 2: Diagram of a jet dyeing machine with aerodynamic-fabric drive (Then).
A = dye jet; B = liquor circulation system; C = preparation vessel; D = nozzle section; E = gas circulation; F = air heater; G = fan; H = HT drain; L = sampling window; P = circulation pump; T = textile fabric; VD = throttle valve; VE = emptying valve; VR = return flow valve; VU = circulation valve; W = heat exchanger.

circulating gas. Higher fabric speeds can be used in the gas flow than is possible in a hydraulic system, since the fabric rope is carried neither in the liquor nor with the liquor, and is consequently subject to lower tension during acceleration. There are therefore different prerequisites in bath exhaustion, produced not by the liquor encompassing the textile fabric but from the dye and product preparations distributed through the textile fabric. In this respect, the liquor ratio is largely dependent on textile fabric liquor absorption. In finishing operations, there is a thermodynamic equilibrium, e.g. at the dye fixation temperature, between the distributed dye preparation and the gas flow the gases largely employed being air and water vapour, which are in direct contact with the dye and product preparation distributed over the textile surface and with the liquid phase of the preparation distributed in the gas flow. With a change in temperature and pressure, a coupled heat and substance interchange takes place between these media with the aggregation states of the liquid and gaseous phase.

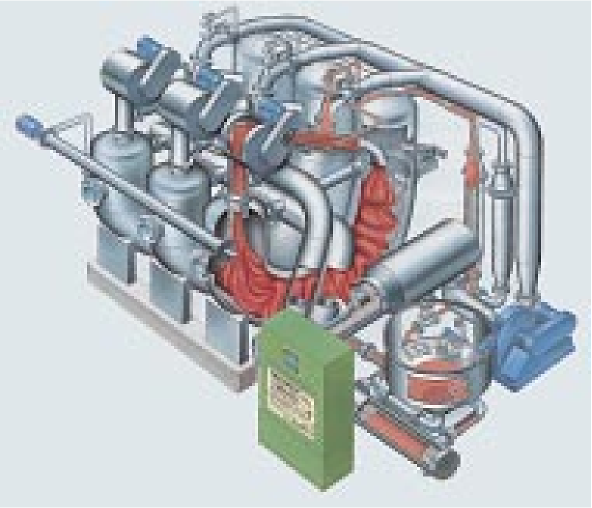

Fig. 3: Then Airflow AF 540.

Atmospheric air is a mixture of air and water vapour, i.e. the available water content is in a gaseous state until the air reaches saturation point. Water vapour is a gaseous water phase, for the formation of which water has to be heated to boiling point, passing into a proportional gaseous state due to further heating. This heat content is described as heat of vaporisation, which is approximately equivalent to five times the heat quantity of water heated to boiling point. The H,s diagram of moist air applies to the constitutional values in the case of treatment processes up to approx. 100°C and with the use of air as the gaseous medium. The heat content of the air is plotted on the ordinate axis in right-angled coordinates. The heat content of the moisture proportion of the air is related to steam with 0°C. The temperature curves (straight lines) rise to the right in the diagram, so that the heat contents of the dry air and of the moisture content can be read off. In addition, curves are drawn in for the saturation state of the air at various total pressures. Since the total pressure in the machine is measured, the moisture or water vapour content of the air in the saturated state can be read off with the temperature. The textile fabric has the property of absorbing moisture from the air. A constant moisture content forms in the textile fabric for a constant air condition.

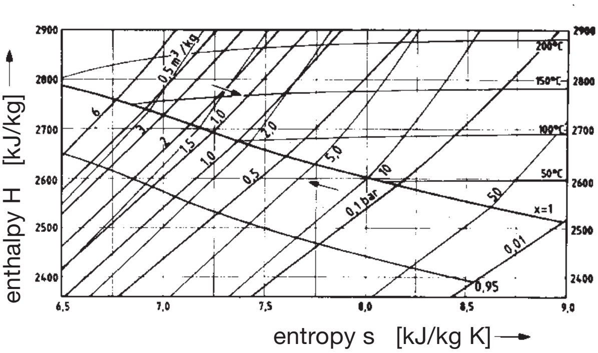

Fig. 4: Mollier H,s diagram for water vapour.
H = enthalpy; s = entropy.

The H,s water vapour diagram (Fig. 4) provides information about the gas condition in the machine for condition changes, e.g. in heating, for the state of equilibrium at fixation temperature, for heat outflow and for the cooling process. Entropy is a variable quantity; its difference is the quantity of heat transferred at a specific temperature. The H,s graph shows the curves for constant pressure, temperature and volume, and with x = 1, the saturation line. Owing to the large textile fabric surface, it is heated rapidly together with the liquor adhering to it. Heating is effected by condensing the water vapour, i.e. the steam transfers the condensation enthalpy to the textile fabric and additionally the heat content of this moisture. The advantage of this system (Fig. 5) lies in the very small temperature differences, since there is thermodynamic equilibrium in almost every stage.

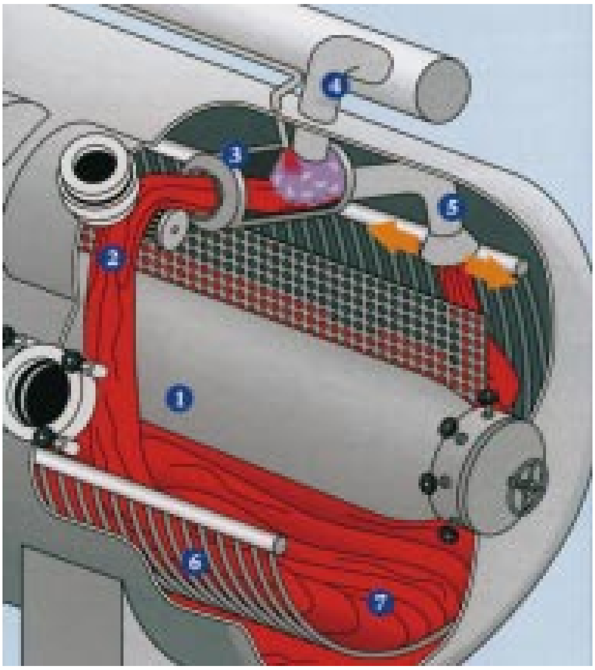

Fig. 5: Advantages of the latest version AFT from Then. 1. Safe fabric transport, optimum displacement and little crease formation are ensured by the aerodynamic drive. 2. By means of the active fabric run control a slip regulation is possible, facilitating the exact monitoring of fabric speed and the best possible fabric handling. 3. The unique rinsing method by spraying fresh water allows short processing times with best rinsing effect. 4. Utmost shade fastness by aerodynamic fabric transport without hydraulic and dye in saturated steam atmosphere. 5. Optimized fabric smooth plaiter ensures an excellent displacement of the fabric. 6. Combined Teflon slide bottom consists of foil and sliding rods for the best, careful treatment of fabric surface and a smooth transport in the storage chamber. 7. By enlarged liquor sump, also in case of difficult dyeing procedures, fabric displacement is always above the dye liquor.

During heat outflow, e.g. from 135°C, a very rapid temperature drop occurs due to steam pressure reduction from 2.13 bar to pressureless operation. The moisture evaporation within the fabric occurring during this process prevents crease marking. Only a few minutes are required for heat outflow, whereas lengthy cooling times are required in the case of jet dyeing machines, as cooling can often be effected only at a rate of 1°C/min.

Aerogel → Gel.

Aerosol (Lat.: *aer* = air, atmosphere; sol = colloidal solution) A dispersion in which finely divided solid or liquid matter is suspended in a gas and the particles are of colloidal dimensions, e.g. smoke or fog. The table shows the number of particles which can be produced from 1 ml of water in the size range from 1–20 µm, together with details of their effective surface area.

particle size in µm	number of particles in billions	surface in cm²
20	0,24	3 140
10	2	6 280
5	15	12 000
2	240	30 000
1	2 000	63 000

Tab.: Aerosol particles in 1 ml of water.

The table clearly shows the enormous increase in surface area compared with the volume of the water particles, and the extreme fineness of the aerosols is inevitably accompanied by rapid vaporization. For this reason, aerosols are the preferred means of air conditioning using jets for atomization (air conditioning plants) or aerosol generators for still greater efficiency.

Aerosol dyeing Principle: dye is applied to a textile material in the form of an → Aerosol composed of air, dye and water vapour.

AFA, Afa, (Ger.) abbrev. for: steuerliche Absetzung für Abnutzung (depreciation/depreciation for wear and tear). → Service life of textile plant and equipment.

AFCT, (Fr.) abbrev. for: Association Française de Contrôle Textile (French Association for Textile Control). Founded by all French manufacturers of cellulosic man-made fibres with the objective of promoting the quality of these materials. → Technical and professional organizations.

Afei French consumer carpet label (Institut National du Tapis) for French and imported goods. Provides information on the name of the manufacturer, the manufacturing process, as well as details concerning backcoating, colour fastness, flammability resistance, flame propagation, sound insulation and a 5 year warranty.

Affinity is a measure of the force which binds e.g. a dye or even a textile auxiliary to a substrate (fibre, etc.). It is generally accepted that, besides dye/fibre interactions in dyeing, interactions between substances present in the dye liquor (dyes, chemicals, water) also take place simultaneously during the dyeing process. For this reason, particular attention is given to the dye/fibre equilibrium state. This equilibri-

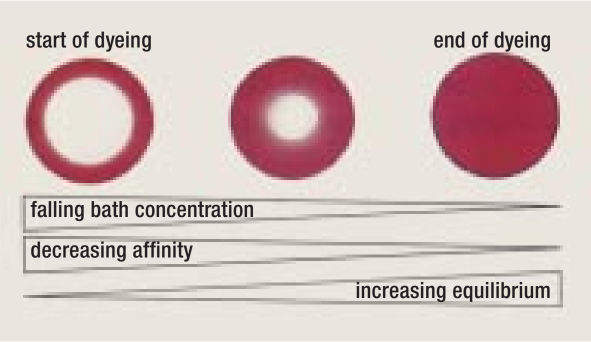

Fig. 1: Dyestuff/fibre equilibrium (thermodynamic affinity).

um can be described physically and chemically by the thermodynamic affinity (Fig.1).

High affinity prevails then, if a max. number of interactions between fibre and dye can be achieved on reaching dyeing equilibrium. For direct dyes on cotton, the planarity of the dye molecule also play a role here, e.g. with regard to the degree of affinity (Fig. 2).

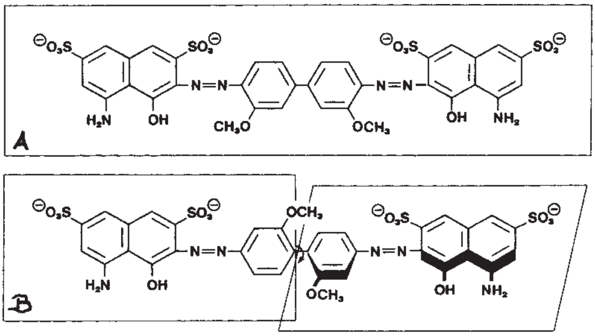

Fig. 2: Importance of the planarity of the dye molecule for affinity for cellulose.
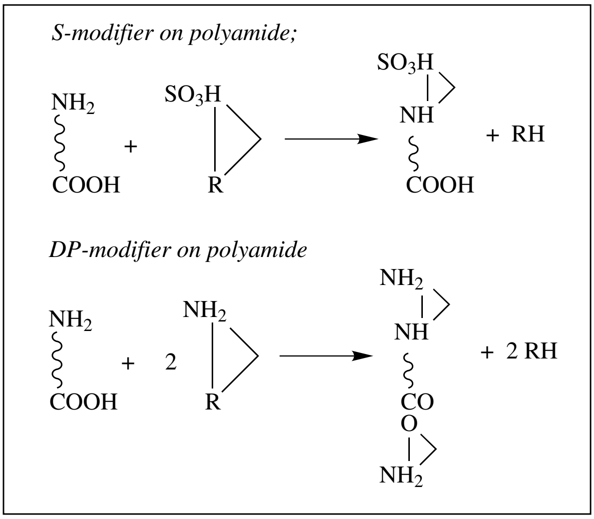
A = high affinity for cellulose (direct dyes);
B = low affinity for cellulose (acid dyes).

Vat dyes (in the vatted form) and direct dyes have affinity for cellulose (cotton or viscose) if their molecules are capable of forming conjugate structures. Delocalizable π-electrons in the conjugated system must polarize the molecule in such a way that the excited phase of the resonance system induced by increased temperature forms a (negatively or positively charged) “charge transfer” complex with the cellulose.(In the case of vat dyes, this corresponds to a quinone-imide structure whereby a proton transfers from the dye to the cyclically-bound acetal-oxygen atom of the cellulose. With direct dyes, a proton from a cellulose OH group can also transfer to a central function of the direct dye which becomes positively charged as a result). Conjugation is therefore a prerequisite for affinity.

Affinity factor Serves to characterise the affinity effect in the pad dyeing process. Also described as x-value: $x = C_f/C_\infty$.

Affinity modification Modification of the dyeing



S-modifier on polyamide;

DP-modifier on polyamide

Fig.: S-modified and DP-modified polyamide fibres.
R = reactive group; |> = undefined bond.

behaviour of (polyamide for example) substrates as against standard dyestuff classes, functional end groups, which are responsible for dye to fibre bonding, being either blocked or multiplies, e.g. shown schematically in the Figure.

Most fibre-reactive affinity modifiers covalently bonded to substrates are produced by the 2-stage application of fast to cross dyeing reserve or mordant effects (shade deepening):

1st stage: treatment of the substrate with affinity modifiers by all possible methods, such as exhaust, printing and spray processes etc. This is followed possibly by intermediate drying and then setting by means of superheated steam, saturated steam or dry heat (storage if necessary).

2nd stage: rinsing (removal of thickener residues and marking colours) and dyeing by the exhaust or continuous process, i.e. subsequent colouration of the treated proportions in competitive reaction with the untreated proportions of the substrate for required differential, reserve and/or two-colour effects.

Affinity modifier Defined chemical group, which, for example in → Acylation or → Affinity modification, is introduced into a fibre molecule, changing the affinity of the fibre for specific dyes, i.e. reducing or increasing.

Afgalaine, afghalaine Soft worsted fabric for ladies’ dress material (similar to → Duvetine), with faint, striped pattern on the back. Originally, the fabrics were produced from Afghan wool (laine = wool). Today, however, the term is no longer a registered name. These days, afghalaine fabrics are mainly produced from single, medium-fine, spun woollen yarns in warp and weft, frequently “1S” and “1Z” twist yarn. Thus, the weave has a somewhat grainy texture with an essentially well-defined finish. Piece-dyed, ladies’ dress materials with soft to full handle in practically all shades, including black for mourning dress, e.g. in pure wool, in blends with max. 50% viscose and also in blends with about 10–15% polyamide.

Afghan carpet Long-pile tied carpet from Afghanistan. Octagonal, clover leaf and camel's foot patterning in bright red, dark blue and ivory colours on a brownish red ground. Goats' hair warp ends, 80 000–150 000 knots/m^2.

AFNOR, (Fr.) abbrev. for: Association Française de Normalisation, Paris (French Standards Association); → Technical and professional organizations.

AFNOR Method → Au portique.

Afric, African Fibre → Crin d'Afrique.

African silk → Anaphe silk.

Africa prints Printing technique on cotton fabrics used mainly in the countries of West and Central Africa (e.g. Congo, Nigeria, Ivory Coast, Senegal, etc.). The prints are characterized by typical naturalistic designs coloured with a few frequently repeated colour combinations. For Africa print styles, fully-penetrated prints are generally demanded. Printing is mostly carried out on naphtholated grounds with diazo fast colour salts in combination with reactive dyes. Indigo, mordant and phthalocyanine dyes are also used. Printing styles: →: Real Wax, Imi Wax, Java Print, Green Ground, Fancy Print (see Fig.)

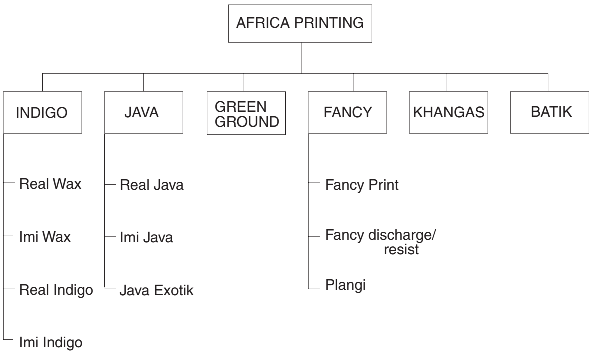


Fig.: Product breakdown in Africa printing.

Textile printing has a long tradition in the countries of West and Central Africa. For several centuries primitive people have added design and colour to textiles. The designs were mainly produced by methods involving the application of resists followed by subsequent dyeing. Original handcraft techniques are still in use today although, as a result of the industrialization of African countries which began in the 1930's, various imitations have since been developed. Despite these changes, the strong traditional attachment in these countries even continues to place extremely high demands on the quality of these technical imitations. Historically, as in Africa, a comparable tradition also developed in Indonesia. The well-known (Java) batik fabrics differ from Africa prints chiefly in design and colour combinations although the technique (processes and dyes used) is nevertheless very similar. → Indigo styles in Africa prints.

After-burn time Time taken between the moment the ignition flame is removed and extinction of the flame on the test specimen. → Burning behaviour of textiles.

Afterchrome dyes Dyes for wool. The chrome dye is applied in a similar manner to an acid dye and then treated in a chrome bath to produce the final shade. Dyeings with good light and wet fastness properties are obtained. → Chrome dyes.

Afterchroming → Chroming of dyes.

Aftercoppering dyes Direct dyes containing mordant-attracting groups in their molecules which are capable of forming stable metal-complexes with metal ions (e.g. o,o'-dioxyazo groups). Aftercoppering dyes are dyed in a similar manner to normal direct dyes then finally aftertreated with metal salts (mainly copper salts) plus an additional cationic treatment if desired.

Dyes possessing a hydroxy group in an ortho position to the azo nitrogen atom are suitable for aftertreatment with copper salts to give dyeings of improved light fastness. The treatment causes a distinct change of shade. Dyes of the benzidine type with two OH groups in the para position to the azo group exhibit improved fastness to light as well as washing after an aftercoppering treatment. Dyes which possess a glycollic acid group –CH–OH–COOH instead of an OH group (some Benzo Fast copper dyes) may also be given an aftercoppering treatment. Benzidine dyes such as e.g. Congo red, have been found to be carcinogenic and are no longer manufactured.

After-coppering of direct dyeings → Copper sulphate aftertreatment.

Aftercoppering test A useful test in doubtful cases to distinguish aftercoppered dyeings from the more usual direct and sulphur dyeings. Test procedure: Place 10 ml hydrogen peroxide 30% in a test tube with 2–3 drops sodium silicate solution. Shake briefly and add 1 ml conc. ammonia. After careful shaking, add the dyed test specimen as soon as the evolution of gas ceases. An effervescent evolution of oxygen occurs in the presence of an aftercoppered dyeing after a few minutes. No other type of aftertreatment gives this reaction.

After-glow Textiles are much more dangerous if they burn without flames, or if they re-ignite, than if they burn with a visible flame. The reason for this is the glow, which occurs after the flame is extinguished. The results depend on fabric weight and after-treatment. If burning with an open flame is controlled by oxidative processes, pyrolysis – polymer destruction in the absence of oxygen, i.e. reductive processes – is the main factor in after-glow.

After-glow time The time during which the test specimen continues to glow after flame extinction.

After-print washing This term is not clear, for

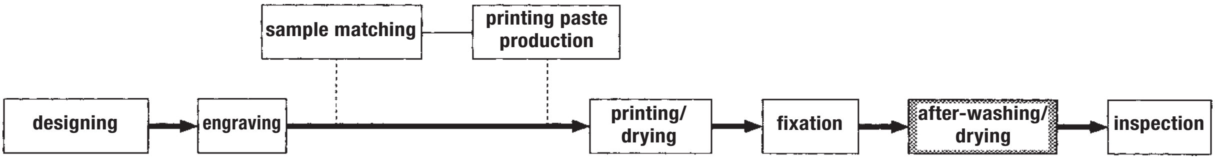

Fig. 1: Textile printing - processing cycle diagram.

after-print washing primarily means “washing off printed fabrics”, which should accordingly be called printed fabric washing. The term after-print washing has of course largely prevailed, although it can also certainly be implemented without printing (e.g. with horizontal or rope scouring machines), i.e. in contrast to spray washing machines operating with low or high pressure jet systems, from which the usual trade term also stems to some extent (e.g. Küsters high pressure jet washing machine).

The washing off process is of quite special importance in the production of high quality printed fabrics e.g. with reactive dyestuffs. Whether the quality requirements imposed as regards colour brilliance, colour fastness, shade consistency, white ground have been met is revealed at the latest by the washing process. The first and most important purpose of after-print washing is to ensure that the required quality in terms of fastness and print appearance is achieved. It happens again and again however that after-print washing must also bear the brunt of ironing out the faults from preceding operations (Fig. 1).

This involves for example

- print fabric pre-treatment,
- printing paste additions,
- printing paste application quantity,
- drying and fixating.

An after-washing process, which is used predominantly for eliminating these faults and irregularities, can scarcely produce optimum results. After-print washing is extremely costly and labour intensive, and is also an operation in which ecological standpoints should be taken into account. A great deal of care must therefore be taken in order to achieve the best possible effect with low water consumption and low effluent contamination.

After-print washing breaks down into four stages:

1. Wetting out: impregnating the print with washing liquor.
2. Swelling: thickener and fibre swelling.
3. Spraying: removing the swollen thickener and associated chemicals.
4. Washing: removing the unfixated dyestuff (fastness wash).

The effect of reaction time, temperature and mechanical action can be seen during the various process stages. Decisive factors are

a) Electrolytes: they increase dyestuff hydrolysate substantivity, for which reason washing in a liquor with as low as possible an electrolyte content should be aimed for.
b) Temperature increase: as the temperature rises, dyestuff hydrolysate decreases, and diffusion from the interior of the fibre consequently increases. Dye disaggregation by way of the highest possible washing temperature is the aim.
c) Sodium alginate: together with calcium ions, this forms a salt which is insoluble in water. The resultant film has a negative effect on washing speed, wet fastness, brilliance, shade and fabric handle. The addition of a sequestering agent is therefore necessary with the use of hard water. Excesses should be avoided on account of electrolyte formation.

After-print washing can be effected with the fabric in open width (Fig. 2), in rope form, or in a combination of rope form and open width (Fig. 3). The 4 stages of the washing process (Fig. 4) are as follows:

Stage 1: attention should be drawn here first of all to a specific peculiarity of the two-stage technique. Whilst, with all single stage fixating processes, the fabric leaves the steamer in a relatively dry state (wet-

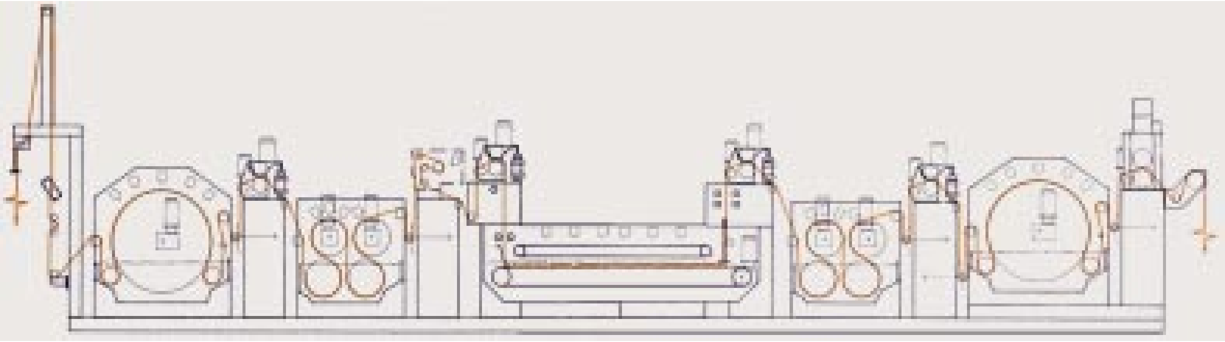

Fig. 2: Arioli open-width after-print washing line.

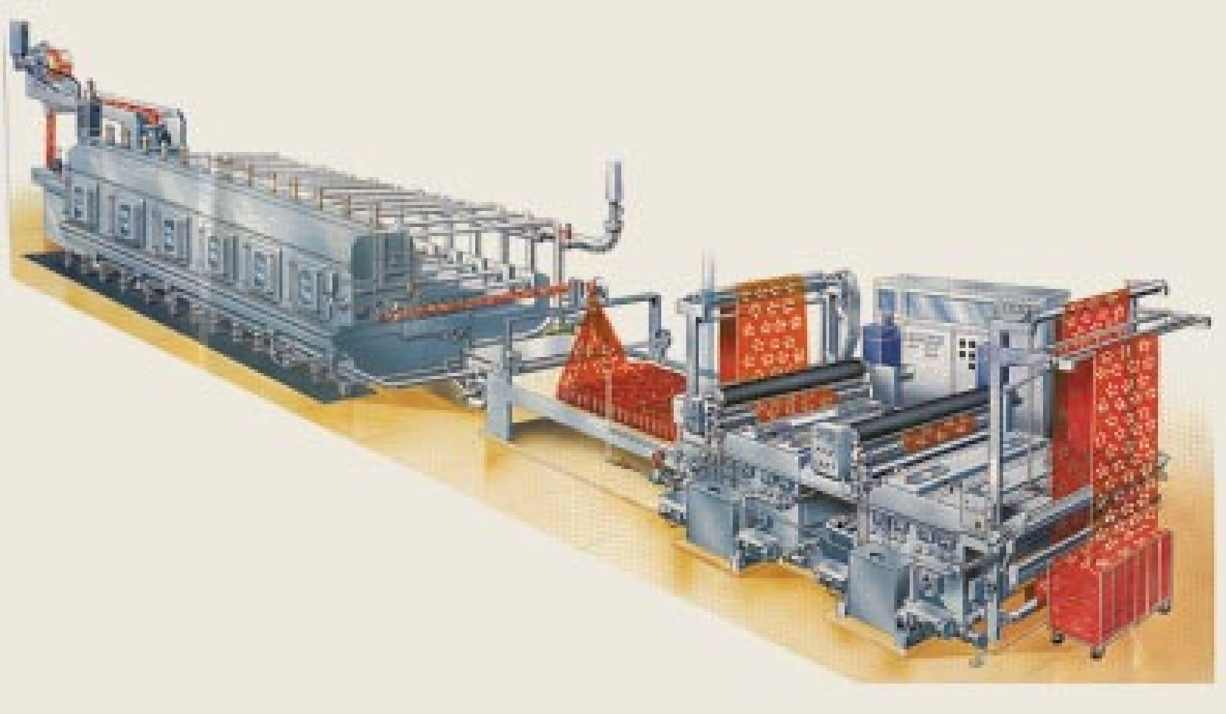

Fig. 3: MCS after-print washing line with open-width section for repelling thickener, and also with a rope washing section for the fastness wash.

ting, swelling and partial thickener film dissolution are time-dependent), the fabric stays damp in the two-stage process. The thickener film and the fibres remain swollen, providing easy access for water. Rapid alkali removal by spraying is therefore first of all important before entry into the liquor baths and a rise in temperature. The operation should be performed with soft water or with the aid of softening agents in order to prevent the formation of calcium alginate, which is difficult to dissolve.

Stage 2: this stage concludes the transfer of the dyestuff hydrolysate still loosely anchored in the fibre structure together with dissolved auxiliary agents. Temperature should be between 40 and 60°C.

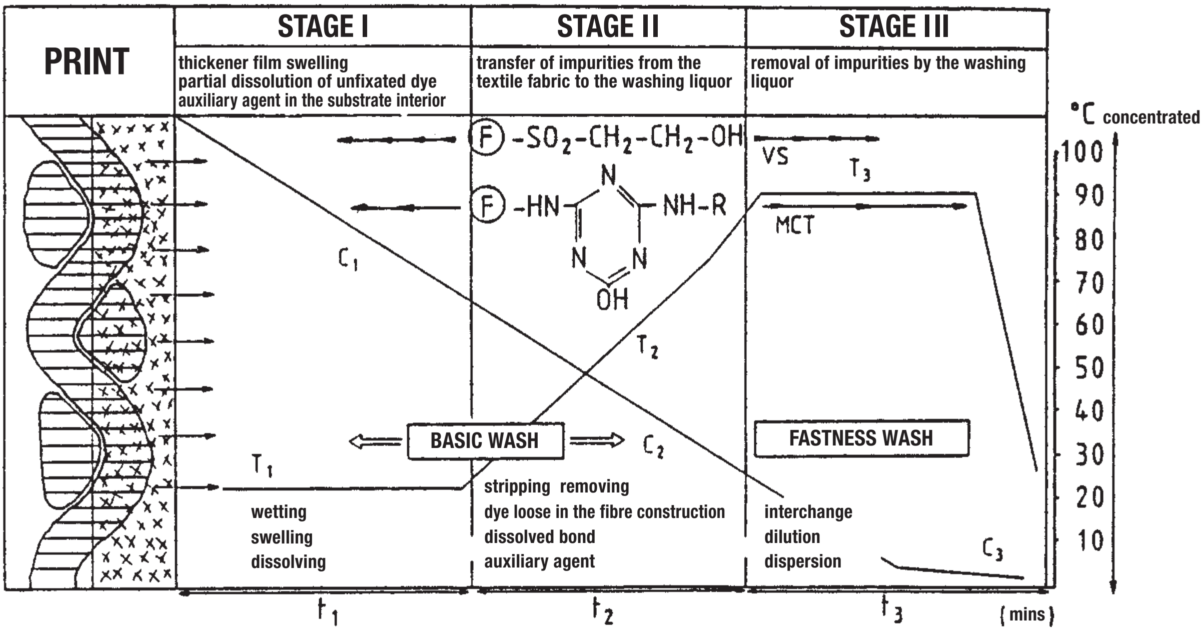

Fig. 4: Reactive print after-treatment (washing process stages) before the final rinse (according to Hoechst).

Stage 3: this stage, also termed fastness washing, requires time and increased temperature, since it largely involves a diffusion process, in which the hydrolysed reactive dye still on and in the fabric can diffuse from the fibre into the baths. As regards the use of a washing agent, no exaggerated expectations should be placed on the effect of a washing agent when washing out water-soluble dyes. It is much more important to ensure that the substantivity of the hydrolysed dyestuff decreases as the temperature rises, while the rate of diffusion increases (Fig. 5), which has a beneficial effect in removing the hydrolysed dye.

Stage 4: rinsing.

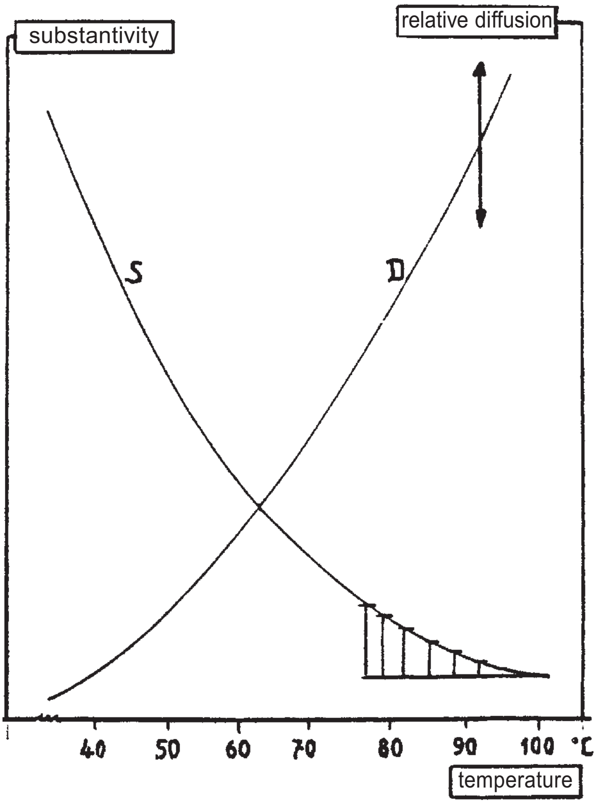

Fig. 5: Effect of diffusion/substantivity relative to temperature (fastness after-wash-reactive printing).

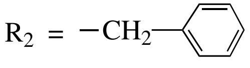
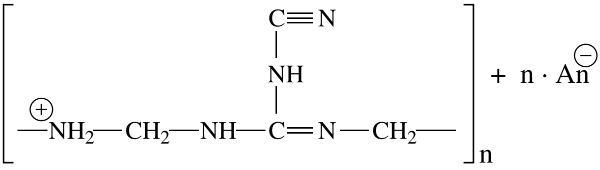
After-treatment of dyeings For improving fastness. Most conventional after-treatment agents are constructed on the basis of formaldehyde condensation products or are polyammonium compounds (Figs. 1 + 2).

It is possible to modify the polyammonium compounds in such a way that a softening effect takes place in addition to the fastness-improving action. Modification is effected by changes in R_1 and R_2. Typical:

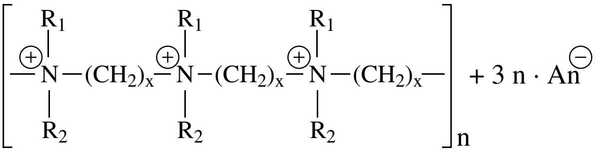
$R_1 = -C_2H_4OH$





$$\left[\overset{\oplus}{-NH_2}-CH_2-NH-\overset{\substack{C\equiv N\\ |\\ NH\\ |}}{C}=N-CH_2-\right]_n + n\cdot An^{\ominus}$$

Fig. 1: Structure in principle of a formaldehyde condensation product.



$$\left[-\overset{\substack{R_1\\ |}}{\underset{\substack{|\\ R_2}}{\overset{\oplus}{N}}}-(CH_2)_x-\overset{\substack{R_1\\ |}}{\underset{\substack{|\\ R_2}}{\overset{\oplus}{N}}}-(CH_2)_x-\overset{\substack{R_1\\ |}}{\underset{\substack{|\\ R_2}}{\overset{\oplus}{N}}}-(CH_2)_x-\right]_n + 3\,n\cdot An^{\ominus}$$

Fig. 2: Structure in principle of a polyammonium compound.

Cationic after-treatment agents can bond with anionic dyestuffs. Bonding can take place in different places. Reactive dyes and direct dyes are bonded on the same principle. A molecule of the cationic after-treatment agent can make a number of different bonds. The easiest bonding to understand is achieved with the anionic dyestuff. The water solubility of the dye is reduced by this bonding. Agglomeration can also take place via any metal contained in the dye. Furthermore, the after-treatment agent can bond not only with the dye but also with the cellulose itself. This is observed when undyed cellulose was treated with a cationic agent; the cellulose takes on a high degree of dye affinity via the mordanting effect.

Printing and dyeing wet fastness improvement is the primary aim in after-treatment. Dye migration, whether it be substantive dye or reactive dye hydrolysate, is prevented. Dyes not after-treated can migrate in the material to be dyed. This process is observed in uneven water extraction or drying, higher temperatures accelerating migration. The migrating dye moves with the escaping water. In package dyeing for example, this phenomenon results in visible outside-to-inside unlevelness. In tricot dyeing, cloudy unlevelness is observed if the moist fabric is allowed to stand for some time. This is caused by migrating dye in places starting to dry, or in places retaining water as the water level falls. Much greater damage occurs due to migration in made-up goods. In a hot, humid medium, e.g. in steaming garment components, edging and spotting may occur. Reactive dyes tend less to this type of phenomenon of course. They are securely bonded to the cellulose, and the chemically fixated dye cannot migrate. Reactive dyeing not only contains fixated dye; dye hydrolysates are also present. These form during dyeing if the reactive dye reacts with the water instead of the hydroxyl group of the cellulose. The fast-soaping process following dyeing should remove these dye hydrolysates from the cellulose. In addition to the dye hydrolysates which remain in the fibre, others can occur through subsequent dye hydrolysis. With dye hydrolysis, the dye fixated on the cellulose is split on account of various conditions. Under certain circumstances, high temperatures, such as occur during drying, for example, split the reactive bond between dye and fibre to some extent. This process is termed thermohydrolysis. Dye/fibre splitting in an acid medium is termed acid hydrolysis. This frequently occurs following softener application, since softeners have to be applied in an acetic acid medium in order to improve exhaustion. Softening is not followed by rinsing; the acid remains in the fabric, and can in time damage dye to fibre bonding to a greater or lesser extent until it is removed by drying. In the same way, acid exhaust gases or hot and humid climatic conditions have an effect during storage. With reactive dyes, after-treatment has frequently won favour due to this phenomenon, reactive dye hydrolysates being bonded to the cellulose via the after-treatment agent (according to Kahle).

AFU → AATCC Fading Unit.

AG, abbrev. for:

I. (Ger.) Aktiengesellschaft (joint stock company, corporation).

II. (Ger.) Arbeitsgemeinschaft (study group, joint venture).

III. → Alginate fibre → Standard abbrev. for textile fibres, according to the → EDP Code; DIN standard abbrev. → ALG.

Ag,

I. → Alfa grass → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988, from 1991 → AL.

II. chemical symbol for → Silver (47).

AgA, (Ger.) abbrev. for: Ausschuß für gefährliche Arbeitsstoffe (Committee for dangerous working materials) of the Federal German Ministry for Work and Social Order. The AgA is responsible, *inter alia,* for establishing technical guide concentrations (TRK values).

Agar agar is extracted from marine algae (China, India) and is a mixture of two polysaccharides, agarose and agaropectin. It swells greatly in water, dissolves in hot water and sets on cooling to a jelly at a concentration as low as 0,5%. Its gel-forming power is 6 times greater than gelatine. Agar agar is extracted from various red and brown algae which grow on the sea bed in warm temperate seas. It is marketed as a dry powder, flakes or strips which may be yellow or bleached (greyish to yellowish-white). It has found application as a textile finishing agent (“natural finish” for cotton = soft voluminous soapy handle without natural firmness; also for wool). Apart from this it is used as a clarifying agent, thickener or gelling agent, and as a biological culture medium.

Agave fibres belonging to the group of → Hard fibres, a sub group of plant fibres. All Agave fibres are recovered from leaves. Through their common origin from leaves, different Agave types (elongated, fleshy spear shaped leaves upto 1.5 m long) from subtropical areas are similar to one another in many respects. Among Agave fibres can be found → Henequen, Pita, Cantala and Sisal fibres.

Ageing The change in the colloidal state over time, normally a change from the labile to the stabile form, where the particles increase in size and the degree of dispersion falls accordingly. Ageing processes are known e.g. in soap solutions, in certain dye baths and finishing baths. Thus, fresh artificial resin solutions give much better crease resistance than those stored for any length of time. Ageing can progress to such an extent that water solubility can be partially or completely lost; an important reason why auxiliary firms only offer limited guarantees on storage life on some artificial resins.

Ageing fastness → Light-induced ageing, resistance to.

Ageing of carpets (artifical) → Carpet ageing.

Ageing of textile materials at room temperature is a slow deterioration or improvement in the mechanical properties of materials, caused by intrinsic instability or by normal atmospheric action.

Some of the causes are crystallization, separation, crosslinking and oxidation. Ageing of materials can be accelerated by heating or by combined heat and oxygen.

I. Air ageing (heat ageing): the textile sample is exposed for a set time in an oven at a temperature of 70°C.

II. Oxygen-pressure ageing: the textile sample is exposed for a set time in a chamber at a pressure of 200 N/cm^2 and a temperature of 70°C.

The ageing time will be chosen according to the purpose of the test. The recommended times are 1, 2, 4, 8, 14 days etc. (DIN 53 896).

Age-related erythropsia A normal phenomenon in persons over approx. 40 years of age who tend to see all shades redder than younger persons. Age-related erythropsia is not to be regarded as a form of → Defective colour vision, although it can lead to problems in colour matching.

Agglomerate (Lat. *agglomerare* = to form into a ball) A combination or → Aggregation of colloidal particles, molecules, ions, dyes, particulate dirt, etc., in the form of clusters of approximately spherical shape.

Agglomeration The tendency to form → Agglomerates, resp. → Associates, e.g. the agglomeration of dye molecules which results in unsatisfactory dye levelling, especially with vat and disperse dyes. The problem is minimized by special dyeing methods or the use of levelling agents.

Aggregate,
I. material state (solid, liquid, gaseous).
II. assemblage of several separate units.
III. → Aggregation.

Aggregate Dyestuff occurs in, amongst other things, flat bed screen printing due to surplus dye paste passing through the screen. The dye paste is not adsorbed by the substrate during the squeegee process, but nevertheless ends up on the printed goods when the screen is lifted and causes dyestuff aggregation there.

Aggregation (Lat. *aggregare* = to attach to), chemical association of dissimilar molecules to form molecular associates, e.g. as occurs typically between dyes and levelling agents which possess dye-affinity.

Aggregation number Number of molecules in an → Aggregate. → Association value.

Aglycone Non sugar component of → Glycoside, mostly containing hydroxy (alcohols/phenols) or containing nitrogen (amines).

AGV, (Ger.) abbrev. for: Arbeitsgemeinschaft der Verbraucherverbände (Study Group of the German Consumers' Association); → Technical and professional organizations.

AI, abbrev. for: → Artificial intelligence.

AIC, abbrev. for: American Institute of Chemists → Technical and professional organizations.

AIChE, abbrev. for: American Institute of Chemical Engineers.

AICQ, (It.) abbrev. for: Associazione Italiana per il Controllo della Qualità, Milano (Italian Society for Quality Control), member of the → EODQ; → Technical and professional organizations.

AICTC, (It.) abbrev. for: Associazione Italiana di Chimica Tessile e Coloristica, Milano (Italian Association of Textile Chemists and Colorists); → Technical and professional organizations.

Aida canvas Coarse yarn, openwork, highly chemically finished woven fabric (cotton, viscose filament), also double weave consisting of 2–3 layers (and often patterned on both sides), in so-called mock leno or shoe canvas weave. Used as ground fabric for embroidery, runners, table cloths etc. A small gap occurs after every 4th longitudinal or transverse end due to counter-construction and relevant denting. The fabric is already considerably strengthened in finishing so that Aida can be more easily embroidered. Natte is the collective term under which the Aida weave is to be found; they reveal the chequered Panama surface all the more clearly.

Aids International, abbrev. for: Association of Interior Decor Specialists. Formed in 1972 out of the NIRC as an international association of "interior cleaning specialists" for home textiles with departments for the cleaning of carpets, fitted carpets, upholstery, drapes and fire damage limitation. Centres: Aids International (USA), Arlington (technical journal "Voice"), and Aids International (Deutschland), Hamburg (technical journal "Stimme"); → Technical and professional organizations.

AIF, (Ger.) abbrev. for: Arbeitsgemeinschaft Industrieller Forschungsvereinigung e.V. (German Study Group of Industrial Research Associations); → Technical and professional organizations.

AIIE, abbrev. for: American Institute of Industrial Engineers → Technical and professional organizations.

AIM, (Ger.) abbrev. for: Arbeits-Ist-Minute bei Zeittesten (work clock minute in time testing).

AIME, abbrev. for: American Institute of Mechanical Engineers → Technical and professional organizations.

AIP, abbrev. for: American Institute of Physics → Technical and professional organizations.

Air → Atmospheric air.

Air as a textile finishing medium Air is used in textile finishing applications as a substitute for water or in combination with water (air/water mixture):

1. Foam application in finishing and carpet backcoating as well as textile printing (e.g. pigment printing in areas of high coverage).
2. In the drying of textiles as a medium for absorbing water vapour and conducting it away from the surface of the textile material.
3. As a means of maintaining textile fabrics in the open state during open-width washing, e.g. Flainox and MAT machines (Fig. 1).

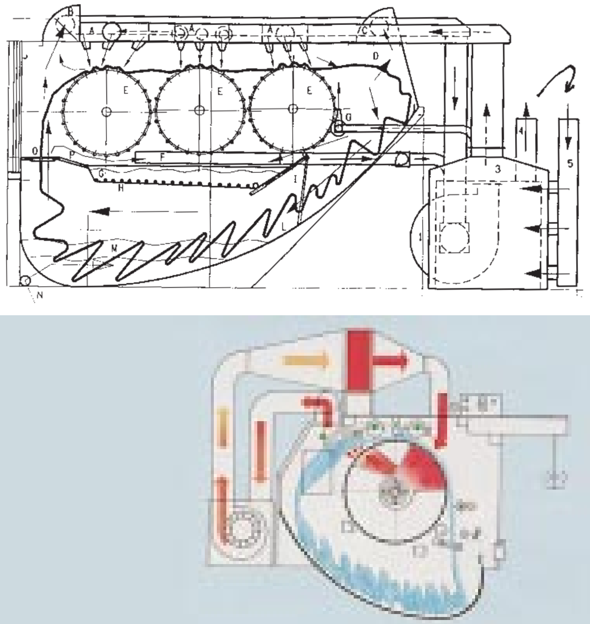


Fig. 1: Open-width scouring machines for woven fabrics width controlled by airflow (Flainox and MAT).

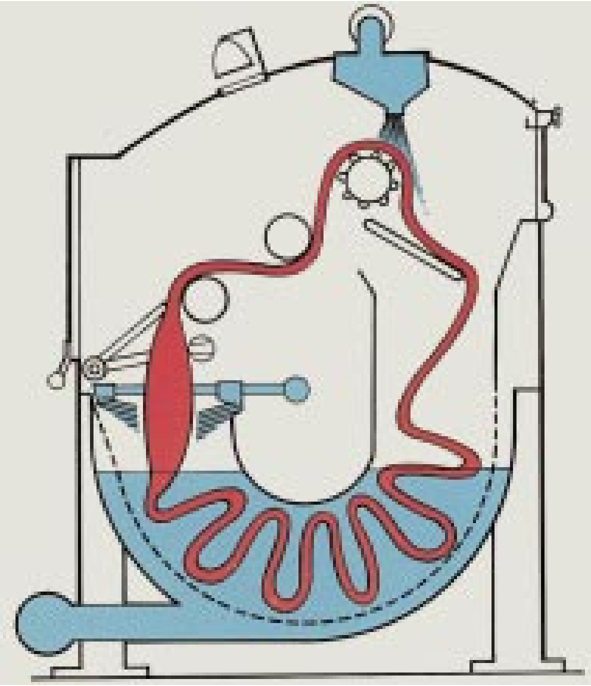

Fig. 2: Béné-Flow with fabric ballooning by air inclusion (similar to Krantz Blow-Dye).

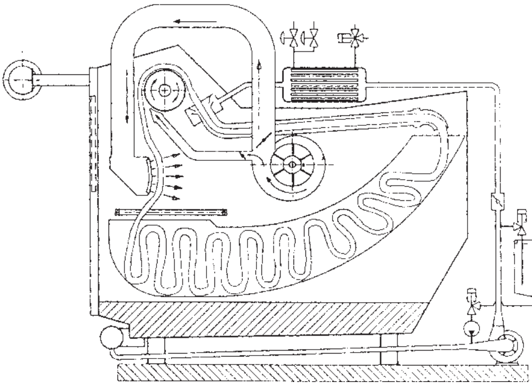

Fig. 3: Blowing unit in the dyeing machine for fabric laying (Flainox).

4. In dyeing to promote the shifting of fabric creases by “ballooning” (Figs. 2 + 3), or as a fabric transport medium in the “Aero-Dye” system (Krantz) (Fig. 4) and the “Airflow” system (Then) as well as the Raco-Yet principle (Ramisch-Kleinewefers) for the production of aerosols besides, e.g. the SuperSoft-Air-Tech process of Longclose (Fig. 5) for the uptake of aerosols containing dyes and levelling agents by the material.

A unique machine for the application of air as a transport medium is the “Airo 1000” machine from Biancalani (Fig. 6). The endless ropes of fabric which have been sewn together are propelled in an upwards direction by (hot or cold) air (up to 1000 m/min.) in 2 diago-

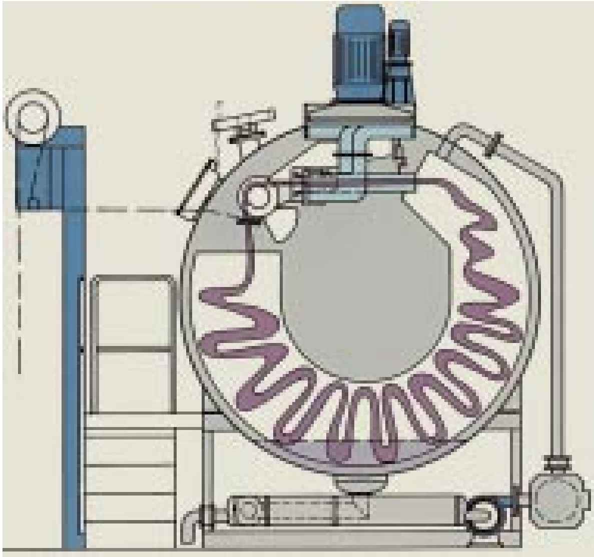

Fig. 4: “Aero-Dye” with fabric transport by air (Krantz).

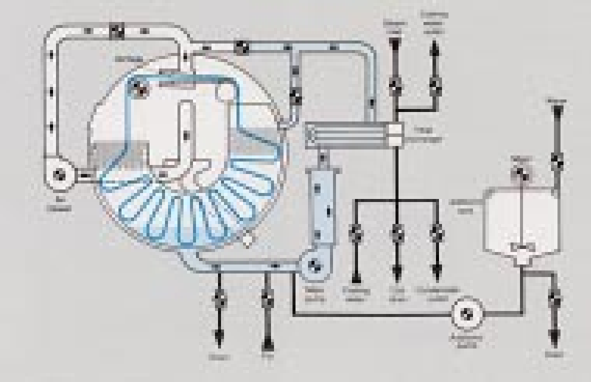

Fig. 5: SuperSoft-Air-Tech with fabric transport by air (Longclose).

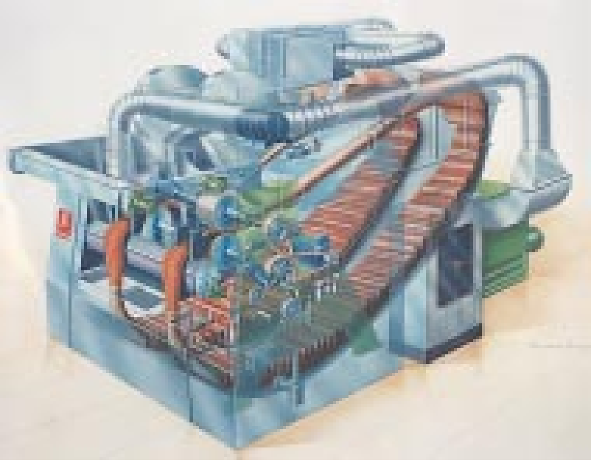

Fig. 6: “Airo 1000” rope treatment machine (Biancalani) with the use of air as a finishing medium.

nally arranged channels. Behind these channels is a baffle plate from which the fabric is again transported via a rope scray into the front section of the machine. The fabric is relaxed by the intensive mechanical action which gives the material a soft handle. The machine may also be used for carrying out chemical treatments such as wool carbonizing or enzyme treatments.

Air-balloon system English term by Calator for air injection for the untwisting and crease-free ballooning of tubular knitted fabrics.

Air blade →: Air knife; Squeegee.

Air blanket in dyeing machines An air pressure blanket created by compressed air and positioned above the dyebath is employed in some yarn and piece dyeing machines to reduce the liquor-to-goods ratio and prevent boiling of the liquor (see Fig.). Pump cavitation is also avoided by this means.

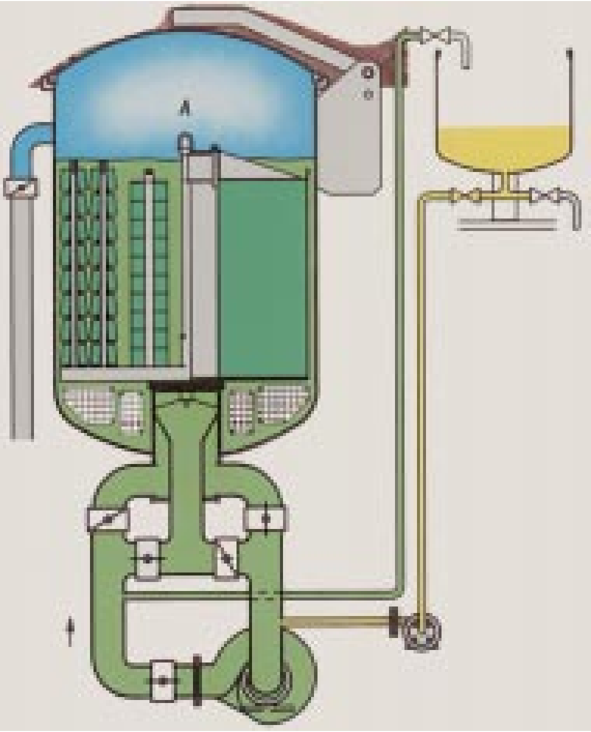

Fig.: Pressure cushion (A) by means of compressed air above the dye liquor in a yarn dyeing machine.

Air bottle A vessel used to determine the → Air content in steamers.

Air bubbling Blowing air into HT beam dyeing machines in order to accelerate the dyeing process (L. Svenson, Kinna/Sweden patent).

Air conditioning,

I. Setting defined temperature and humidity conditions in rooms by means of air conditioning equipment. This is particularly important in the textile sector, as almost all textile raw materials react sensitively to variations in temperature and humidity. The so-called standard climate for laboratory premises has therefore been laid down in DIN 53 802 at 65 ± 2% relative humidity and 20 ± 2°C room temperature.

II. By the air conditioning of textile (fibre) material is meant its adjustment to specific climatic conditions. This takes place by absorption (from a lower to a higher moisture content) or desorption (from a higher to a lower moisture content), the textile moisture content being dependent on which of the two routes is selected (hysteresis). Test specimens for textile testing should basically be brought to the standard condition by absorption.

Air conditioning plants are used to produce desired conditions of air humidity and temperature in closed rooms automatically, e.g. spinning plants, weaving sheds and storage facilities. Air conditioning plants must be equipped with systems for cleaning, warming, cooling, humidifying and possibly dehumidifying the incoming air which comply with VDI ventilation regulations so that any desired climatic conditions can be produced and maintained irrespective of the outside temperature and moisture (see Fig.).

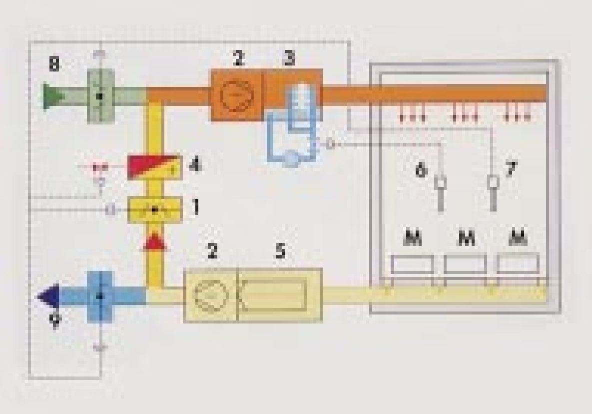

Fig.: Air conditioning plant diagram.
M = textile machine; 1 = control flap; 2 = fan;
3 = air washer; 4 = air heater; 5 = exhaust air filter;
6 = moisture sensor; 7 = temperature sensor; 8 = supply air;
9 = exhaust air.

Air conduction in textile driers The ducting of air flows in drying machines is an important factor in energy consumption. The total air circulation in a drier consists of that portion which, as moist air, is discharged as exhaust air and that portion which is reheated after passing through a heat exchanger (see Fig.). The latter should be as large as possible in the conception of a drying machine.

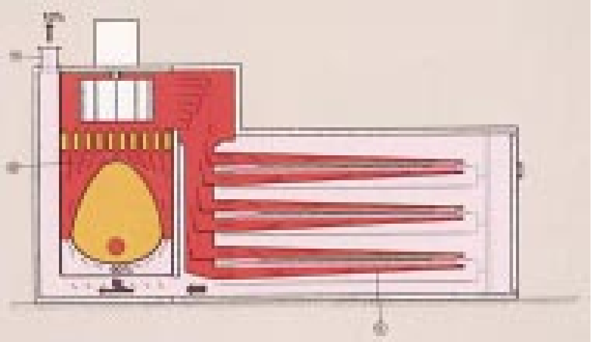

Fig.: Air control in the Monti shrink dryer.
8 = hot airflow on the fabric; 11 = moist, cooled air exhaust (pink); 12 = heat exchanger with freshly heated air (red).

Air content in steamers The generation of air-free steam is of general importance with regard to the production of highly saturated steam, as generally preferred for optimum dye fixation, but which is disrupted by the presence of other gases. It is, however, especially important in the fixation of vat dye prints due to the oxidative effect of atmospheric oxygen. It is for this reason that the determination of air content in a steamer is an important means of preventing inadequate dye fixation. A simple method employs a so-called air bottle (Fig. 1) filled with water and connected to a side opening of the steamer by means of a flexible tube. When the steamer is heated up to operating temperature, water drains off slowly through a tube (7) and forms a slight underpressure in the bottle (6). A portion of the steam atmosphere is drawn into the bottle (6) via the flexible tube connection (3, 4, 5). The water vapour component condenses in the cold water contained in the bottle (6) whilst the air component escapes at point "X" from the tube (5) clearly visible in the form of bubbles and collects in the upper part of the bottle (6).

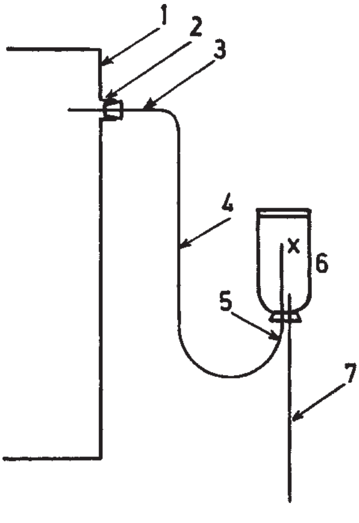

Fig. 1: Qualitative air indication.

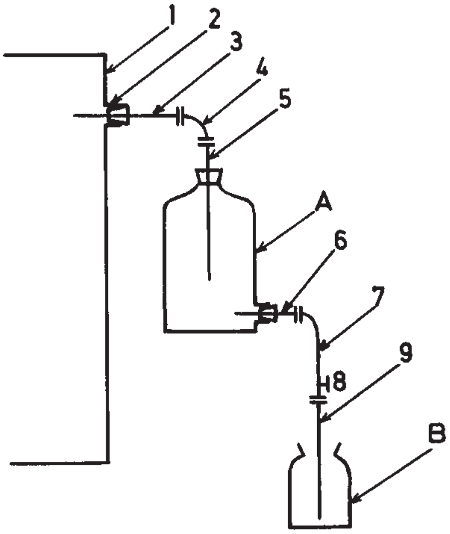

Fig. 2: Quantitative air indication.

The tube (7) is at least 350 mm long and of small diameter so that no air bubbles can flow back through the tube. Quantitative determinations are also possible by this means (Fig. 2).

Air detection → Air content in steamers.

Air dryer → Conveyor drier.

Air drying of textiles is carried out in the open (so-called drying rooms), with the goods suspended by hanging over rods or wooden slats, or on frames. It is the simplest and most gentle method of drying and involves no energy consumption.

Air-entangled yarns A process of Akzo Faser AG may be taken as an example of an environmentally-friendly concept in which draw-winding machines deliver filament yarns without protective twist on cross-wound packages (Fig. 1). The required yarn cohesion is achieved by air-entanglement. This process produces yarn with a high degree of stability due to the

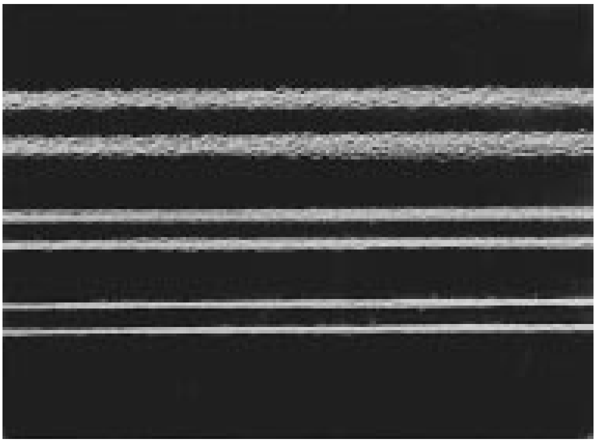

Fig. 1: Textured polyester yarn (76 dtex f 36 mt) not tangled (Akzo).

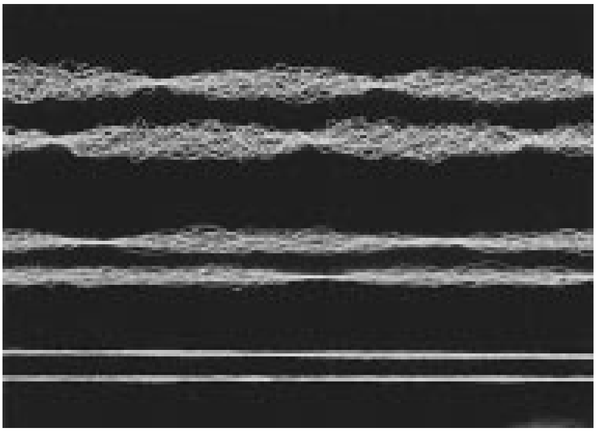

Fig. 2: Textured polyester yarn (76 dtex f 36 mt) tangled (Akzo).

introduction of intermingling points or knots which occur at intervals of 8–10 mm (Fig. 2). Depending on the yarn density in weaving, air-entangled flat yarns as well as textured yarns do not require sizing. The intermingling points should not, of course, remain visible in the final fabric. For this reason, in finishing, where no desizing is necessary, the fabric is heat set (30 s at 190–210°C) so that the fibres shrink and the intermingling points are smoothed out (disentangled). On no account must the intermingling points or knots come undone before finishing especially as a result of the tensile strains to which the yarn is subjected during fabric formation.This method of production, considered through all its production stages, offers clear environmental advantages since fabrics produced with air-entangled yarns require neither sizing nor desizing.

Air filter Generally a component of → Air conditioning plants to facilitate the wet or dry precipitation of airborne impurities (air scrubber).

Airflow Then piece dyeing machine on the → Aerodynamic principle, with 1–6 storage compartments, each of 180 kg nominal capacity, large savings in water and steam consumption, a high degree of reproducibility, no foaming, simple recipe transfer. Then started development of the “Then Airflow” in 1979. This machine is based on the first time use of the principle of propelling the fabric by means of an airstream, to which finely dispersed dyes and auxiliary products are fed via jet systems. This new and now patented development was pushed ahead in conjunction with Hoechst AG; it also precedes the patented process comprising fabric propulsion by means of a vapour flow.

The fabric rests above the liquor level in a store furnished with Teflon bars. It is fed to the air jet via a feed winch, and then distributed in the store with or without a plaiter. Fabric speeds well beyond 600 m/min, with a peak of even 1000 m/min, can be attained, and even in liquor dropping operations the fabric can be kept in motion with no liquor flow. The injection system constantly sucks the liquor from the store, distributing it under controlled temperature on to the fabric through suitable nozzles. Dyes and auxiliary agents, dosed in quantity as required, are also sprayed.

The Airflow-System provides the following advantages:
- shortened dyeing time,
- shorter liquor ratio with consequent water and heat energy savings,
- salt, chemical and auxiliary product savings,
- a bulkier fabric due to the airflow,
- high circulation speed,
- problem-free fabric run.

Typical of the Airflow principle is the simultaneous use of a gas stream with treatment medium injection, and, after contact with the textile fabric, the separate return of the gas flow and part of the treatment bath depending on the quantity injected as the case may be (Fig. 1).

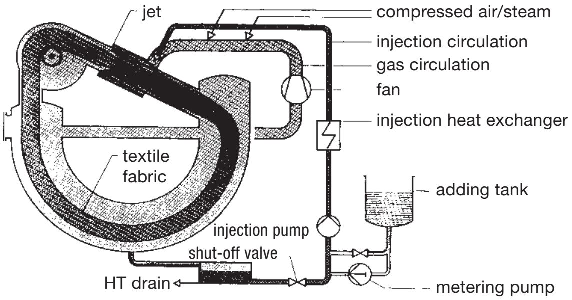

Fig. 1: Then Airflow aerodynamic system connection diagram.

The gas circulation maintains the circulatory fabric motion, the feed action being created by the fan. The gas flow is fed and contact made with the textile fabric in the jet zone, fabric movement being independent of the textile fabric moisture charge. The injection system is connected to the gas circulation. Due to the direct introduction and atomisation of the liquid treatment media in the gas flow, these are distributed in the textile fabric by contact with the gases in the jet zone, i.e. the atomised liquid condenses on the fabric, and is distributed in it. This function breaks down into:
- feeding the treatment bath from the adding tank with closed cut-off unit,
- feeding a treatment medium from the adding tank into the injection circuit via a metering pump,
- the injection circuit with no adding tank connection.

With the 3 basic connections of the injection system to the gas circulation, the main treatment stages of a finishing process can be implemented together with rins-

Air-flow doctor blade system

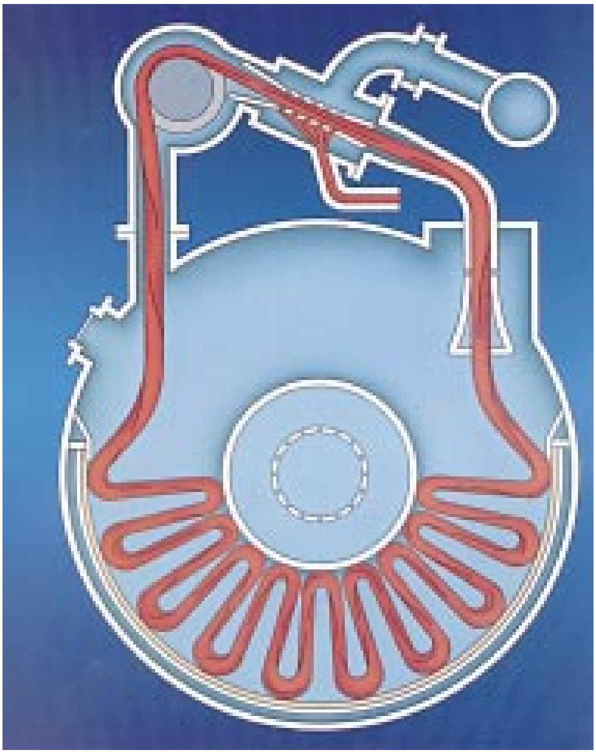

Fig. 2: Then Airflow AFS.

ing processes. The constant loading of the textile fabric in the jet zone is denoted by the density of hatching in Fig. 1. The moisture uptake of the textile fabric is determined by contact and the distribution of a specified treatment bath quantity over the circulating gas flow. The max. liquor uptake of the textile fabric, i.e. the fabric retention capacity, is therefore dependent on the fibre material, the nature of the product – such as yarn, type of construction and density – and the viscosity of the treatment liquor for example. A state of equilibrium of this type occurs in a very short time with the fabric circulating in the treatment vessel with the injection system in operation. The liquor charge due to the injection flow is therefore interchanged with the liquor proportion in the textile fabric, volume interchange being aided by the force effect of the fabric drive in the jet zone. This produces a faster concentration interchange.

Since 1991, Then has built with the Airflow AFS a simplified handling system (Fig. 2) as compared with the AF (Fig. 4) and AFT as the latest version (Fig. 3).

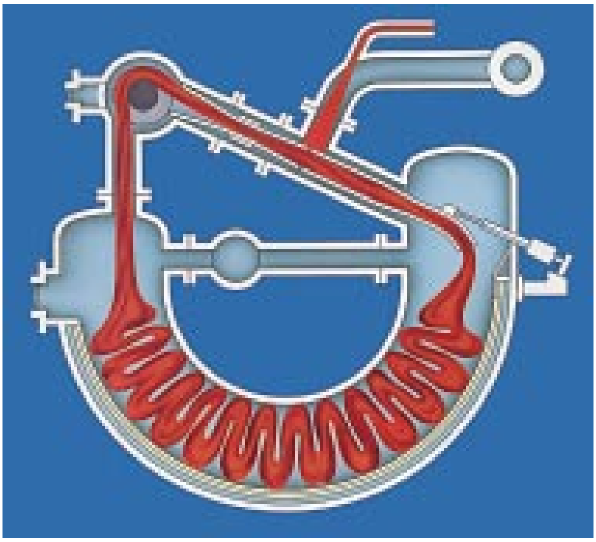

Fig. 4: Then Airflow AF.

Air-flow doctor blade system Steel doctor blade system with a plastic profile making possible precise control of colour paste application and penetration during printing by independent adjustment of doctor blade angle and contact pressure (Fig.).

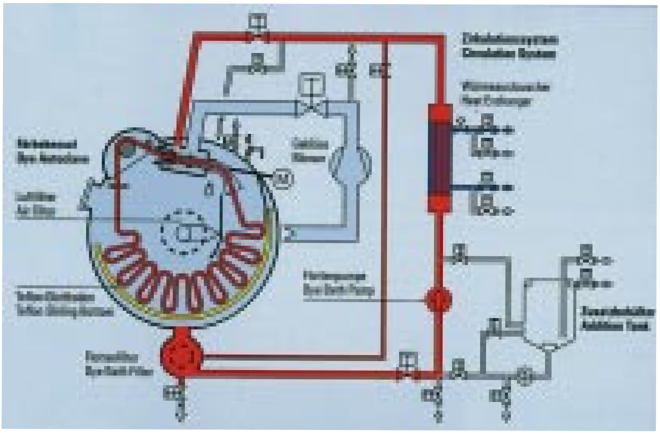

Fig. 3: Then Airflow AFT.

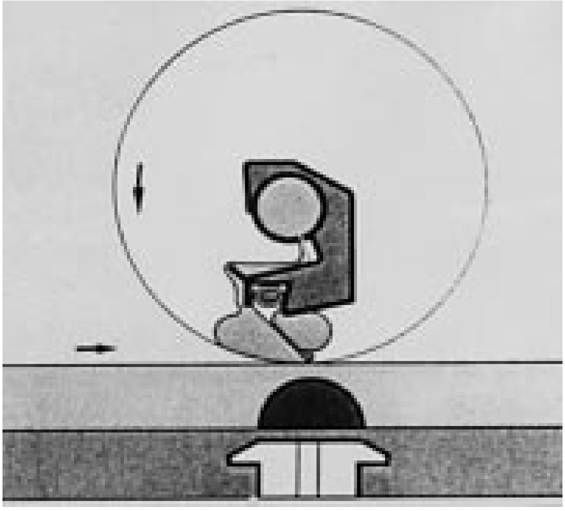

Fig.: Stork Airflow doctor blade.

This results in greater printing precision. The plastic profile ensures uniform printing across the entire fabric width, while computer controlled automatic pre-registration simplifies machine operation. – H. Stork.

Air humidification Achieved by using a water spray or atomizer (→ Air conditioning plants). A centrifugal atomizer installed within an air duct of up to 2 m diameter can, for example, humidify the air passing though it with a very finely dispersed spray of water droplets (see Fig.).

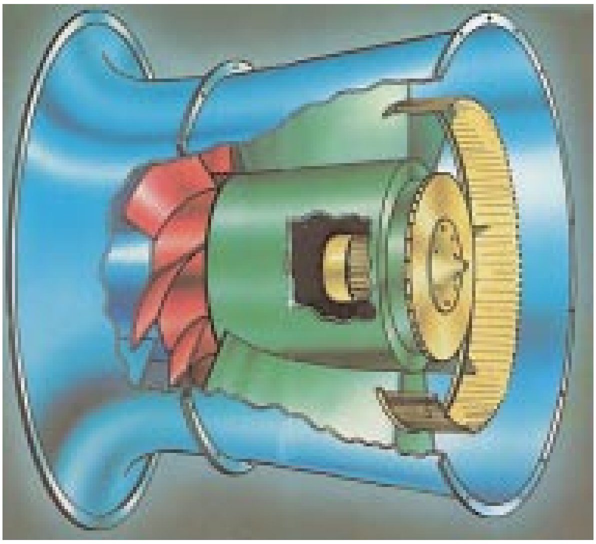

Fig.: Centrifugal atomiser for air humidification (Prött).

Air humidity A distinction is made between:

I. Absolute humidity: i.e. the complete temperature-dependent saturation of air with water with the water content expressed in g/m^3 of air (Table 1).

°C	g/m^3	°C	g/m^3
0	4,85	40	51,12
5	6,80	50	82,98
10	9,41	60	129,81
20	17,32	80	290,80
30	30,39	100	580,00

Tab. 1: Absolute air humidity.

II. Relative humidity: the ratio of the actual vapour pressure of moisture in air to the saturation vapour pressure at ambient temperature. Air saturated with water vapour at a specific temperature is therefore always of 100% relative humidity and corresponds to the values given in Table 1, e.g. as occurs in predominantly foggy weather. In dry weather conditions or in heated rooms, however, this degree of saturation is never reached and such unsaturated air then has a humidity below 100%. If, for example, the relative humidity at 20°C amounts to 60% then this will correspond (see Table 1) to only 10,39 g/m^3 instead of 17,32 g/m^3 (absolute humidity), i.e. a saturation "deficit" of 40% humidity or 17,32 – 10,39 = 6,93 g/m^3 of water. The relative humidity must always be considered in relation to the specific temperature at which it is measured since the same relative humidities correspond to different absolute water content values at different temperatures (Table 2).

% r. H.	20 °C	25 °C	30 °C	40 °C
40	0,007	0,009	0,012	0,020
50	0,009	0,012	0,015	0,025
60	0,010	0,014	0,018	0,031
70	0,012	0,016	0,021	0,036
80	0,014	0,019	0,024	0,041
90	0,016	0,021	0,027	0,046
100	0,017	0,023	0,030	0,051

Tab. 2: Relative air humidity in g/m^3 at different temperatures.

III. Specific humidity: expressed as the water vapour content in g/kg of air.

IV. Normal humidity: in Central Europe this corresponds to the daily mean of approx. 65% relative humidity at mid-year.

V. Standard atmospheric conditions: In DIN 53 802 the standard atmospheric conditions for textile testing are specified as 65 ± 2% relative humidity at a room temperature of 20 ± 2°C.

Air injection dyeing A dyeing procedure employed in beam dyeing machines which involves the injection of fine bubbles of air in order to reach dead zones in the yarn package and disperse the air contained therein.

Air jet spinning was developed by the Japanese firm of Murata. The roving is fed directly to the spinning machine through a drawing frame into the spinning zone in which two air jets are arranged one behind the other (Fig.). In the first jet the yarn is given a false twist effect that is untwisted by the second jet. Hence the conditions are similar to those of an OE spinning process. With this process fine yarns can be spun at high velocity. The yarn is wound directly onto bobbins. In this system pre-spinning as well as subsequent winding operations are eliminated. The yarn produced has better breaking strength than rotor spun yarn (80–90% of ring spun), is more even that ring spun yarn and less hairy, but is somewhat harder in handle. The process is not suitable for all spun fibres as a minimum fibre length is necessary.

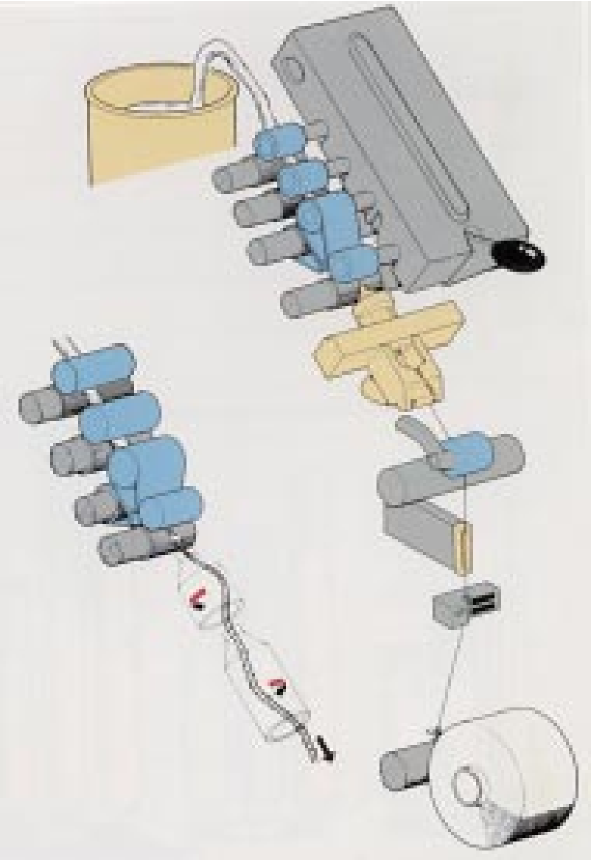

Fig.: Air jet spinning.
Left: arrangement of drawing frame and jets; right: flow of material from roving to the bobbin.

Air-jet texturing → Texturizing.

Air jet weaving machines An intermittently directed stream of compressed air, with or without additional air jets (via relay nozzles), serves as the weft insertion medium by conveying tweft yarn through the shed (see Fig.).

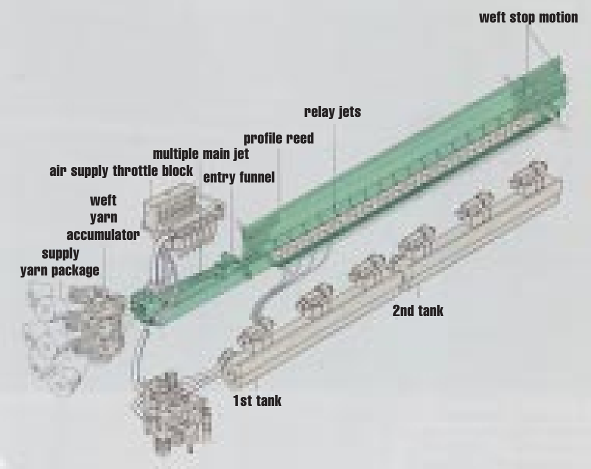

Fig.: 6-colour weft insertion system on the Dornier air jet weaving machine.

Weft yarn reaches the multiple main jet via a self-threading weft accumulator. The main air jet is electronically controlled so as to give maximum energy transmission with minimum air consumption for the correct acceleration of each pick. For optimum economy, the start and end of the air blast is controlled in accordance with the yarn flight time. Yarn quality differences are consequently balanced out during weft insertion. Since air pressure is monitored at the point of compressed air supply, the machine can be automatically stopped if the air pressure falls below an adjustable level. Centering of up to 6 different weft packages is achieved by means of a fixed feed system and a conical comb. Relay jets insert the weft yarn across the entire fabric width. These are electronically controlled and, in conjunction with an integrated database, the reliable and simultaneous weft insertion of different as well as multiple yarns is assured. The compressed air supply to the relay jets is taken from 2 tanks so that different air pressures can be selected for savings in air consumption. Horizontal or vertical tensioning jets for staple and filament yarns guarantee low weft wastage and clean selvedges. The sensitivity of both weft detectors is controlled pick and pick according to the thickness and lightness of the weft yarns. The weft insertion systems, as well as all other functions, are controlled by multiprocessor technology.

Air knife A paste application system used in coating. The blade (see Fig.) applies a coating paste to the free-running fabric web, i.e. without support from underneath (the fabric web is maintained under tension by passing over one roller located in front of, and one roller behind, the knife contact area).

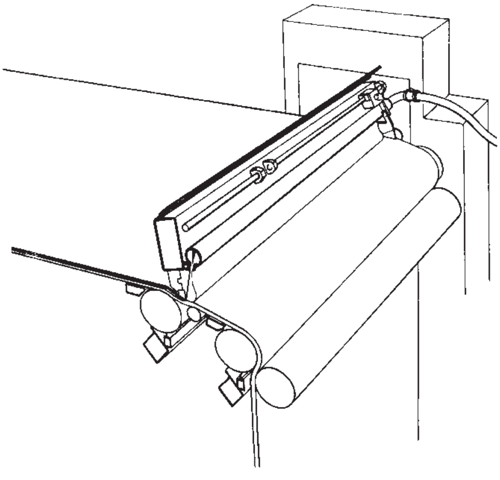

Fig.: Air knife coating technology, suitable for paste application.

Air laces These are etched-out products (burnt-out products) produced without printing. Yarns are embroidered on to a ground fabric which is then burnt out in subsequent after-treatment. Cotton, silk or synthetic fibres for example can be embroidered on to acetate ground fabrics, and the woven acetate fabric then dissolved out with acetone. The process is expensive and intricate, for which reason only simple etched-out products are produced as a rule.

Airo-1000 washing machine A rope washing machine developed by Biancalani in which the rope of fabric is transported by hot air through an upwards directed tube against a baffle plate. Very high circulation speeds are achieved by this means with optimum transport of the fabric rope.

Air pad batch This is a cold pad batch process for dyeing tubular knitgoods of cotton or other cellulosic fibres with reactive dyes. The principle is based on air injection using jets of compressed air → Air balloon system (Air-Tex technology) to prevent fold creases in the tubular fabric. Balloon formation occurs between the pad trough and the padder nip. After squeezing, the padded goods are batched on a roll and allowed to rotate for the required time of dyeing.

Air permeability An important performance requirement for impregnated, coated and metallized water-repellent apparel fabrics. The opposite requirement is placed on e.g. tent, balloon and parachute fabrics. Quantitative relationships exist between air permeability and → Porosity. The same applies between both terms and the skin breathability of a particular apparel fabric. The term “breathable fabrics” is used for, e.g. impregnated rainproof clothing which still possesses a certain permeability to air and water vapour (both directly proportional) even in the wet state, thereby avoiding the retention of heat, moisture and perspiration which promotes a degree of moisture and temperature regulation in the air environment next to the body thus favouring the natural transport of air. A certain relationship also exists, of course, in the case of non-impregnated, but preferably hydrophobic, low or non-swelling textiles composed of synthetic fibres between air permeability and the drying properties. The same applies to textiles with a swelling-resistant finish in the wet state. →: Breathability; Air permeability of textile fabrics; Air permeability tester.

Air permeability of textile fabrics The air permeability of textile fabrics (DIN 53 887) ranges between 1000 and 7000 l/h for wool articles depending on their construction. With increasing yarn fineness (20–100 tex) the air permeability decreases by twisting different numbers of yarns together. The degree of twist (measured by the coefficient of twist α_z = 90–140) has less influence on air permeability than the twist direction of ply yarns: fabrics produced with Z-twist yarns have higher air permeability values than those with S-twist. Yarn density (number of threads per cm of warp resp. weft), i.e. fabric density, likewise has a great influence on the permeability. The air permeability of fabrics increases sharply with the reciprocal of the square of the yarn density (1000–4000 l/h). With the same yarn density, the air permeability for plain weave fabric is relatively low (loomstate: 2500 l/h; finished: 1000 l/h) and higher for twill weave fabric (finished: 2000–3500 l/h). However, the influence of weave type is only slight with similar fabric densities. The air permeability of twill fabrics decreases considerably after finishing (2/2 twill by a half; 1/7 twill from 6000 to 4000 l/h) (Vesper).

Air permeability tester Apparatus for testing the → Air permeability (Schopper or Pohl-Schmidt method) of textile fabrics by suction of air through a restrained textile test specimen.

Evaluation by measurement of the air pressure as indicated by a manometer.

Another instrument is the Shirley Air Permeability Tester which uses a compressed air source and is suitable for carrying out tests in accordance with BS 5636: 1990.

Air pollution, is caused by changes in the natural composition of atmospheric air due, in particular, to the presence of smoke, soot, dust, gases, aerosols, vapours or foul-smelling substances. → Exhaust air problems in textile finishing.

Air pressure (gas pressure) A distinction is made between:

I. low pressure: → Vacuum.

II. standard pressure: 1,0133 bar.

III. overpressure: → Pressure above atmospheric pressure (standard pressure).

Air pumps (compressed air pumps) → Compressors.

Air recirculation in drying machines involves the recirculation of dry air within the drying machine (see Fig.) as a result of which optimum utilization of drying energy is assured. This performance-enhancing

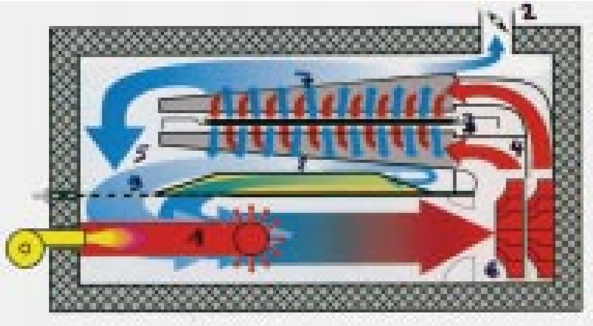

Fig.: Process control in the drying process in a circulating air stenter (Monforts) with twin-air-system.
1 = bare tube heat exchanger air/air; 2 = exhaust stubs with control flaps; 3 = woven fabric selvedge guiding; 4 = circulating air heated by gas burner; 5 = circulating air; 6 = fan; 7 = upper nozzle system; 8 = lower nozzle system; 9 = air filter screens.

and energy-saving process can be applied, quite independently of the ventilating system, to all driers based on the air circulation principle which contain several drying zones with separate heating and control systems. The process offers the maximum advantage when the fresh air is applied by counter-current flow (e.g. in a sieve drum drier). If, on the other hand, the drier is sectioned off into several zones with one exhaust air duct each, the drier must be operated with reduced quantities of exhaust air in the zones where the second drying phase takes place to avoid damaging the textile material (= higher energy losses through exhaust air).

Air retentivity By this term is meant all the forces existing in a garment which participate in retaining the layer of air which is in close contact with the human body even under stormy weather conditions. This layer of air is an outstanding warmth retaining medium. Measurement of air retentivity involves the analysis of a gas (carbon dioxide) in contact with a textile material and its displacement by a an entirely uniform flowing second gas (oxygen or nitrogen). Both the time taken for the first gas to be displaced as well as the amounts of gas displaced at specific time intervals are determined. Packing density and fibre weight must also be taken into consideration.

Air technology Collective term which includes refrigeration, climate, drying, dust removal and associated energy savings.

AIS, (Fr.) abbrev. for:

I. Association Internationale de la Savonnerie (International Association of Detergent Manufacturers).

II. Association Internationale de la Soie (International Silk Association).

AISI, abbrev. for industrial standards of the American Iron and Steel Institute.

AITIT, (Fr.) abbrev. for: Association Internationale de la Teinture et de l'Impression Textiles (European Association of Textile Dyers, Printers and Finishers); → Technical and professional organizations.

À jour fabrics Open-work woven or knitted fabrics produced with fine yarns. The open-work effects (holes) are due to the fabric construction. In woven varieties the ground is of plain weave and the open areas of leno weave construction. Used for dress materials and curtaining.

Ak, → Angora, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988. From 1991 → WA.

Akund (Asclepias fibre, Calotropis floss) A natural cellulosic fibre belonging to the → Vegetable hairs group. Seed hairs of the Asclepias type (Africa, Asia, Central and South America). Similar to the → Kapok fibre, it grows up to 50 mm in length. Akund is yellowish in colour, smooth, silklike, and lustrous but coarser and stiffer than kapok, very lignified, of low extensibility and slightly brittle. Main uses are for stuffing upholstery or braids. Seldom spun or blended. The fibre may be distinguished from cotton by zinc chlor-iodide solution = yellow staining.

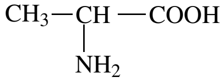
AL,

I. → Alfa grass, → Standard abbrev. for textile fibres according to DIN 60 001 T4/08.91.

II. → Alginate fibre, → Standard abbrev. for textile fibres according to DIN 60 001 until 1988. From 1991 → ALG.

Al, chemical symbol for → Aluminium (13).

Alanine, is an amino acid (monoaminomonocarboxylic acid) present e.g. in wool (4,4%) and silk (24,5%).



$$CH_3-\underset{NH_2}{\underset{|}{CH}}-COOH$$

Alarm and indicating equipment operating on a variety of principles, e.g. bimetal pulse generators or photocells. Used for safety and alarm purposes, triggering a visual display (e.g. red light) or emitting an acoustic warning when optimum operating conditions are exceeded or for automatic fire or intruder protection systems.

Albumen (albumin) Protein from animals (egg, blood, fish and milk albumens) or vegetable sources (soya). Albumens are water soluble, coagulated by heat, and can be salted out from their solutions by ammonium sulphate in the presence of alkali. Their former importance as printing thickeners and fixing agents in textile printing and finishing has greatly declined.

Alcantara Artificial leather consisting of 60% polyester and 40% polyurethane. It is manufactured from extremely fine polyester fibres (0,1 dtex, Ø 4 µm) which are bonded in polystyrene (matrix-fibril fibres), then processed into needle-punched felts and impregnated with polyurethane. Finally the polystyrene matrix is removed with dimethyl formamide so that the fibrils have relative freedom to move in the entire system. Properties: considerably lighter in comparison to natural leather (0,135 g/cm^3), crease-resistant and washable. Uses: clothing sector and the shoe industry.

Alcoholates Derived from → Alcohols in which the H atom of the –OH group is substituted by → Alkali metal. For example from ethanol (ethyl alcohol) C_2H_5-OH comes ethyl alcoholate (Sodium ethoxide) C_2H_5-ONa. Alcoholates react with water (humidity) to form the original alcohol and metal hydroxide, e.g.

$$R\text{-}ONa + H_2O \rightarrow R\text{-}OH + NaOH$$

A well known higher molecular alcoholate is → Soda cellulose. Alcoholates also play a role as alkylating agents in the preparation of acyclic compounds. → Metal alcoholates.

Alcohols (Arab.) contain the OH-group. They are the OH-substituted products of the corresponding hydrocarbons; alcohols may be divided into aliphatic and aromatic according to the type of hydrocarbon → Synthesis alcohols.

I. Aliphatic alcohols: formula C_nH_{2n+1}–OH. By far the largest and most important group of alcohols. They can be classified in various ways:

a) by the saturation of the hydrocarbon:

	Formula	Example	
Saturated alcohols (alkanols)	$C_nH_{(2n+1)}OH$	CH_3OH methyl alc.	$C_{18}H_{37}OH$ stearyl alc.
Unsaturated alcohols (alkenols)	$C_nH_{(2n-1)}OH$	$C_{18}H_{35}OH$ oleyl alc.	

b) by the number of OH-groups (functionality):

	Formula	nomenclature
monofunctional alcohols	$\underset{OH}{CH_3}$ methanol	C1-18 homologous series, see below
difunctional alcohols (diols)	$\underset{OH}{CH_2}–\underset{OH}{CH_2}$ glycol	after glycol (diol), the simplest member of the series
trifunctional alcohols (triols)	$\underset{OH}{CH_2}–\underset{OH}{CH}–\underset{OH}{CH_2}$ Glycerine	after glycerine or triol, the simplest member of the series
4-6 functional alcohols	$\underset{OH}{CH_2}–\underset{OH}{CH}–\underset{OH}{CH}–\underset{OH}{CH}–\underset{OH}{CH}–\underset{OH}{CH_2}$ sorbitol, mannitol	sugar alcohols, because of their relationship to sugars
polyfunctional alcohols	$CH_2–\underset{OH}{CH}–\left[CH_2–\underset{OH}{CH}\right]_x–CH_2$ polyvinyl alcohol	polyalcohols, polyglycols, polyglycerines, etc

c) by the type of end group:

	Formula	Example
primary alcohols	$R\text{-}CH_2OH$	CH_3CH_2OH ethanol
secondary alcohols	$R_{2\text{-}}CHOH$	$(CH_3)_2CHOH$ isopropanol
tertiary alcohols	$R_3\text{-}COH$	$(CH_3)_3COH$ tertiary butanol

The very low alcohols with $C_{1\text{-}3}$ are fluid liquids, $C_{4\text{-}12}$ are oily liquids, but the higher alcohols are solid waxes at normal temperatures and have no smell. The lower and middle alcohols, apart from their use as intermediate products, are important commercial solvents and components of a great many textile auxiliaries of various types, e.g. the saturated, monofunctional homologous series:

CH_3–OH	→	methanol (methyl alcohol)
C_2H_5–OH	→	ethanol (ethyl alcohol)
C_3H_7–OH	→	propanol (propyl alcohol)
C_4H_9–OH	→	butanol (butyl alcohol)
C_5H_{11}–OH	→	pentanol (pentyl alcohol)
C_6H_{13}–OH	→	hexanol (hexyl alcohol) etc.

Higher molecular weight alcohols are very important starting materials for textile auxiliaries, especially the high molecular weight alkyl sulphates (e.g. → Fatty alcohol sulphates), for many detergents, emulsifiers, finishes, hydrophobic agents etc. These alcohols, in the range of about $C_{10\text{-}18}$, are known as fatty alcohols because they are derived from fatty acids or waxy alcohols because they are derived from natural waxes. The most important high molecular weight monofunctional alcohols are e.g.:

a) saturated:

$C_{10}H_{21}$–OH	→	decyl alcohol
$C_{12}H_{25}$–OH	→	lauryl alcohol
$C_{14}H_{29}$–OH	→	myristyl alcohol
$C_{16}H_{33}$–OH	→	cetyl alcohol
C_6H_{13}–OH	→	stearyl alcohol

b) unsaturated:

$C_{18}H_{35}$–OH → oleyl alcohol.

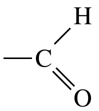
II. Aromatic alcohols: this group includes aromatic and cyclic molecules with OH-groups in side chains. Aromatic ring systems with OH-groups directly attached to the hydrocarbon ring are not considered to be alcohols but are called → Phenols and → Naphthols.

Alcohol tannin Tannin purified in alcohol. → Tannin.

Alcosol → Colloidal solution in alcohol.

Aldehyde green The first green synthetic mordant dye produced from rosaniline and formaldehyde by the manufacturing process of Eugen Lucius (1863).

Aldehydes, (alcohol dehydrogenatus) are obtained by the removal of 2 H atoms from alcohols. They are characterized by the presence of the aldehyde group:



Many aldehydes have a fruity or flowery odour and, for this reason, are used in perfumes and synthetic flavours. Boiling points rise with increasing molecular weight and lie below those of the corresponding alcohols. Lower aldehydes are water soluble, higher aldehydes water insoluble. Aldehydes have a neutral to weakly acidic reaction. They can be readily oxidized to the corresponding organic acids and behave as reducing agents towards Fehling's solution and ammoniacal silver nitrate solution.

Aldehydes, identification test (for formaldehyde) → Schiff's reagent.

Aldehyde-sodium bisulphite Resist agent used for the production of reactive dye resists under reactive dyes on cellulose. The thermally-unstable aldehyde-bisulphite compound releases sodium bisulphite on heating which reacts with the vinyl sulphone groups of the corresponding reactive dyes and thus prevents their reaction with the cellulose OH groups. Formaldehyde and glyoxal are the main aldehydes used.

Aldoses → Sugars.

Alfa grass (esparto grass), belongs to the group of → Hard fibres (natural cellulosic fibres) and is obtained from esparto grass stalks (North Africa, Spain, Sicily) by alkaline boiling and subsequent retting. Hemplike fibre without lustre, stiff, greenish yellow, 10–14 cm in length, 90–500 µm thick, with low tenacity. Uses: jute substitute, cellulose extraction, cheap rope products, mats, nets, hats, bags, etc.

Alfol alcohols and derivatives → Synthesis alcohols from the Ziegler Process, straight chained and even numbered homologous alcohols with chain lengths C_2-C_{22}. Also the alcohol sulphates and ethoxylates. Use: raw materials for detergents and hard surface cleaners including high and low foaming detergents for heavy duty and delicate laundry use.

ALG, → Alginate fibres → Standard abbrev. for textile fibres, according to DIN 60001 T4/08.91.

Algae, stemless unicellular or multicellular water-plants (phytoplankton, seaweed etc.) containing predominantly →: Alginates, Chlorophyll, Starch and sugar. Used as a finishing agent, e.g. →: Agar agar and Carrageen.

Alginate fibres These are cellulose-ester fibres and belong to the group of → Cellulosic man-made fibres. They are manufactured from calcium alginate which has a structure ($C_6H_8O_6$) resembling that of cellulose. Alginic acid is dissolved in sodium carbonate and wet spun into a coagulating bath containing calcium chloride dissolved in hydrochloric acid (wet spinning). Properties: high density (1,78), moisture uptake of 20,5%, soluble at room temperature in weakly alkaline solutions (e.g. soap solution). Applications: pattern effect yarns, support threads, base fabric for burn-out lace articles. Alginate fibres were first manufactured in Japan in 1939 and also in England after the Second World War. They are of no importance today.

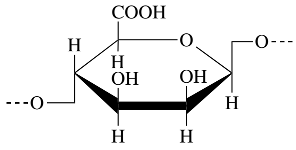
Alginate fibres, identification test The fibre specimen is boiled in a 10% solution of sodium carbonate which dissolves alginate fibres. On acidifying with dil. sulphuric acid, a gelatinous white precipitate is obtained which redissolves in conc. sulphuric acid. An addition of potassium (II) hexacyanoferrate solution produces a brownish black colour with alginate solution.

Alginate film consists of calcium alginate and is manufactured by precipitation from a soluble alkali alginate. Used as a paper substitute in heat transfer printing.

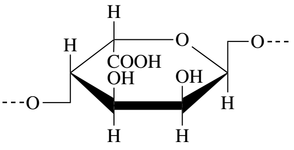
Alginates Salts of → Alginic acid. Sodium, potassium and magnesium alginates are water soluble whilst the calcium and chromium salts are insoluble. Alginates are used in the manufacture of alginate fibres and are employed as thickeners in finishing and sizing as well as textile printing. Derivation: moist or dried seaweed is broken down into coarse pieces and washed. The alginic acid is dissolved in alkali and the hemicelluloses and other insoluble components removed by subsequent flotation and filtration. Alginic acid is precipitated from the filtered solution with acid, filtered off, pulverized with sodium carbonate and dried.

Alginic acid is the main component of algae (→ Alginates) and belongs to the → Pectins. Insoluble in water and soluble in alkalies. Alginic acid is a polyuronic acid with long chain molecules composed of D-mannuronic acid and L-guluronic acid units. These polymer chains have 3 different structures:

a) a homopolymer chain of mannuronic acid,
b) a homopolymer chain of guluronic acid, and
c) a chain molecule containing alternate mannuronic and guluronic acid units:



β-*1,4-D mannuronic acid*



α-*1,4-L guluronic acid*

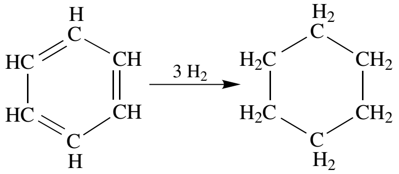
ALGOL English: algorithmic language = problem-oriented programming language.

Algorithm A set of mathematical rules which specify a sequence of actions to be taken to solve a problem. Each rule is precisely and unambiguously defined so that in principle it can be carried out by machine. Frequently based on a sequence of cyclic repeating rules.

Algorithm theory Theory of the definition, preparation, writing, evaluation and use of algorithms. It has its roots in mathematical logic and is the basis for algorithm or programming languages, such as Algol, Fortran, Pascal, Logo, Modula Pearl, PL1 etc.

Alicyclic (cyclo-aliphatic) → Alicyclic hydrocarbons.

Alicyclic hydrocarbons (cyclynes, cycloparaffins, naphthenes) A group of cyclic organic compounds characterized by arrangement of the carbon atoms in closed ring structures sometimes resembling boats, chairs, or even bird cages. These compounds have properties resembling those of aliphatics and should not be confused with aromatic compounds based on the hexagonal benzene ring. Many of their structures are formed from CH_2 groups (e.g. cyclohexanol, tetrahydronaphthalene) and such compounds may be regarded as hydrogen addition products of aromatic hydrocarbons in chemical properties but which are closer to the aliphatic hydrocarbons. Cyclohexane, which is present in some petroleum oils, but may also be produced from benzene by hydration, is the parent substance of this series:



Cyclohexane is, e.g. an important primary raw material (via adipic acid or caprolactam) of polyamide fibres and a range of important solvents which, as hydrated phenols, e.g. cyclohexanol, methylcyclohexanol and hydrated naphthalenes such as tetrahydronaphthalene and decahydronaphthalene, are well-known and are used as components in numerous textile auxiliaries because of their hydrotropic properties. They generally possess remarkable solvent properties for linseed oil sizes, fats, waxes, resins, mineral oils, etc., and, to some extent, for cellulose acetate, rubber and celluloid, etc., as well. The terpene hydrocarbons may also be mentioned under this group.

Aliphatic compounds (acyclic compounds) consist of open, straight or branched carbon chain organic compounds. Originally used to describe the fats (Gr. *aleiphar* = oil) and fatty acids which are typical of this structure. Derived from aliphatic → Hydrocarbons of the methane type CH_4. Typical examples of this group of compounds include, e.g. fats, oils, soaps, sugars, alcohols and fatty acids. See also → Aromatic compounds.

Aliphatic fats High molecular weight aliphatic compounds with a fatty character, e.g. →: Fatty acids; Fats.

Aliquot (Lat. Aliquantum = a small amount), in analytical chemistry, the term used for the analysed fraction of the total sample. From the composition of the aliquot, one can arrive at the composition of the whole analytical sample by simple multiplication.

Alizarin synthesis, first carried out by Graebe/Liebermann together with Caro (BASF) in 1868 and, independently by Riese (Hoechst) in 1869. Preparation: fusion of anthraquinone-2-sulphonic acid with alkali.

Alkali absorption Absorption of alkali hydroxides by fibres (mainly cellulose), sometimes involving reaction with the fibre.

Alkali binding agents (neutralizing agents), are employed in naphthol dyeing for the neutralization and pH adjustment of coupling baths. Typical alkali binding agents are acetic and formic acids; aluminium, zinc and magnesium sulphates; as well as mono and disodium phosphates. Also used for the buffering of coupling baths.

Alkali cellulose ($C_6H_9O_4$–O^-Na^+), primary intermediate product in the conversion of cellulose to viscose by treatment with caustic soda.

Alkali damage Caused by alkali retention on the fabric, e.g. after kier boiling, treatment in boiling water, caustic soda treatment and mercerising or alkaline dyeing processes. Alkali cannot be removed by rinsing alone, and acidification with after-rinsing is therefore advisable. Alkali damage gives rise to darker local shading with almost all dyestuffs. Wool may be dissolved by alkali.

Alkali donors are chemical compounds which release OH^- ions under the influence of heat during dyeing. The alkaline salts of volatile or easily decomposed organic acids are used for this purpose.

Alkalies Aqueous solutions of → Hydroxides and (basic) salts of → Alkali metals and alkaline earth metals, as well as ammonium hydroxide. They are characterized by “alkaline reactions” (→ Bases); e.g. caustic soda liquor, sodium carbonate.

Alkali fastness of dyeings and prints → Colour fastness to spotting: alkali.

Alkali metals Elements in the first main group of the periodic system: lithium, sodium, potassium, rubidium, caesium (cesium) and francium. Alkali metals are silver-white in colour, have low melting points and very low hardness. They possess a single, relatively weakly-bound electron in the outer shell which is a prerequisite for high reactivity. They are powerful reducing agents; their oxides and hydroxides form bases, hence the description caustic alkali. Qualitative identification by colour of the flame (potassium = vivid red-violet, lithium = deep red, sodium = intense yellow). Quantitative determination by spectrometric methods or specific chemical reactions.

Alkalimetry → Titration.

Alkaline discharge-resists Printing process for polyester. The prerequisite is that disperse dyes, which can be saponified by alkali, are used for the ground. Alkaline lyes, alkali carbonates, silicate of soda and alkali dispensers are used as alkalis. Advantages over alkaline discharge-resists containing reducing agents are a wider choice of illumination dyestuffs and their stability in light shades.

Alkaline discharges → Discharge printing using a discharge paste consisting of potassium carbonate (potash) or caustic soda.

Alkaline earth metals Collective term for the metallic elements calcium, strontium, and barium, which are classified under Group IIA of the periodic table. Magnesium is also often included as an alkaline earth metal, whilst the elements beryllium and radium, which are likewise classified under Group IIA, have properties that are closer to aluminium and may be considered as alkaline earths but not as actual alkaline earth metals. They are more stable in dry air than the → Alkali metals, and mostly (in the form of volatile compounds) give characteristic colours in a flame test (barium produces a yellow-green, calcium a reddish yellow, and strontium a red coloured flame). They are all divalent metals and, as cations, form colourless salts with colourless anions. They form hydroxides of a strongly basic character with water. On heating, they form oxides ("alkaline earths") which react alkaline in water. The alkaline earth metals may be distinguished from the alkali metals by their carbonates, phosphates and sulphates which are either insoluble or only sparingly soluble in water. The solubility of alkaline earth metal fluorides, hydroxides and oxalates increases in the order: calcium, barium, strontium, whilst that of the sulphates decreases in the same order.

Alkaline earths → Alkaline earth metals.

Alkaline earth soaps Identical with → Lime and magnesium soaps, which are formed as water-insoluble compounds from alkali soaps and water hardness salts.

Alkaline HT dyeing process for polyester In order to reduce the number of problems with oligomers, polyester lining fabric for example can be dyed at pH 9.5 in accordance with the HMK (Hoechst/Mitsubishi/Kaney) process with selected disperse dyes on a beam dyeing machine (but also suitable for jet and tops dyeing). As many azo dyes have a tendency, depending on pH, temperature and reduction conditions, to deteriorate in boiling, anthraquinone dyes in particular are used as more stable types for this purpose. In a Mitsubishi and Hoechst joint venture, a range of Dianix (anthraquinone) and Samaron (azo) dyes perform for the HMK process.

Alkaline milling → Milling.

Alkaline polysulphides Used for the stabilization of alkaline sulphur liquors in sulphur dyeing against the action of atmospheric oxygen when dyeing in jiggers or winch becks.

Alkaline reaction →: Dissociation; pH.

Alkaline scour combined → Alkaline scouring (alkaline boiling without pressure for the purpose of colour bleaching with Sodium Carbonate, and if necessary pressurising) and Chlorine bleach. A procedure for cotton (flock, thread, crosswound packages, warp beams) and cotton/viscose goods. Disadvantages: poor scale removal (cotton), lack of a hard white effect that does not post yellow. Advantage over → Kier boil-chlorine bleach: lower viscose loss.

Alkali phosphates Salts from → Alkali metals with phosphoric acids. Not to be confused with → Alkyl phosphates.

Alkali polyphosphates Alkali salts of so called polyphosphoric acid (condensed phosphates). As well as their known use in detergents and ion-exchange treatment of water, alkali polyphosphates are used as buffer agents.

Alkali resists → Aniline black and leuco vat esters in resist printing.

Alkali scour-chlorine-peroxide Combination bleach for cotton (flock, thread, crosswound packages, warp beams etc.) and viscose. On cotton, full scale removal occurs. In general, a good spin capability (flock) and a hard white that doesn't yellow results. In the case of → Viscose spun fibre one can count on a lower fibre loss when compared to a → Kier boil-chlorine-peroxide bleach treatment and this is an even more important consideration in comparison to → Kier boil-chlorine bleach.

Alkali scour peroxide bleach Bleach process for cotton and viscose spun fibres, especially for articles which cannot be pressurised. As a prebleach for printed goods etc. Process details → Bleaching of cotton.

Alkali shock process,

I. Scouring: short period process for the open-width scouring of woven cotton and cotton/polyester blend fabrics. Principle: impregnation with caustic soda, wetting agent and complex former followed by steaming and washing.

II. Printing: a two-stage process for reactive dyes, the printing paste containing no alkali, in contrast to the single-stage process. Normally, the fabric is treated with lye and electrolytes in an open-width scouring machine (1–2 boxes) in order to fixate the printed dyestuff. The treatment temperature is dependent on the reactivity of the reactive dyes employed. → Caustic shock process.

III. Alkali shock process (TT): when fixation is achieved by a sudden (shock-like) reaction due to external conditions (concentration, temperature), the pro-

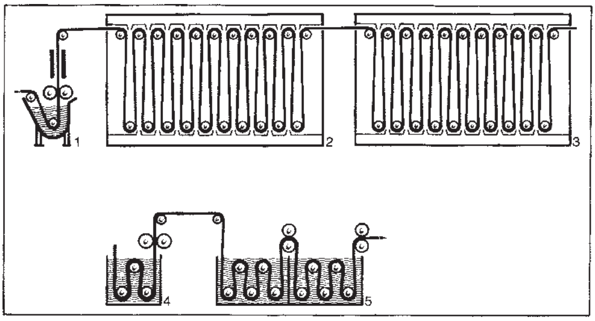


Fig.: Alkali shock process diagram (Bayer).
1 = pad/pre-dry; 2 = dry; 3 = thermosol; 4 = shock bath; 5 = after-treatments.

cedure is called a “shock process”. When, in the continuous dyeing of polyester/cotton fabric, the reactive dye is fixed by a pad mangle passage in concentrated caustic soda (Fig.), this fixation is called alkali shock.

Alkali solubility of wool is dependant on the wool treatment e.g. it can be increased by heat, light exposure, acids, oxidising or reducing agents and reduced by alkali treatment or crosslinking. Therefore alkali solubility can be used as a means of gauging any previous treatment of the wool. Procedure: a) determine the dry weight (m_1 in g); b) a second weighed sample is left 1 h in 0.1 n caustic soda at 65°C, filtered and the dry weight determined (m_2 in g). Calculation formulae (in %:)

for acid-free wool $$A = \frac{m_1 - m_2}{m_1} \cdot 100$$

for wool containing acid $$A_K = (A - S) \cdot \frac{100}{100 - S}$$

S = % dry weight

Alkali stains on textile fabrics Stains caused by alkalies are generally lighter in the centre, becoming gradually deeper towards the edges, then merging with no clear outline into the dyed background. Alkali test: a 10% solution of phenolphthalein produces a red colour which disappears again on acidification (e.g. with a fatty alcohol sulphate solution + 10% acetic, formic or citric acid). Alkaline residues on cellulose, mainly due to caustic soda, give rise to darker areas in subsequent dyeing. However, in the case of aniline black dyeings, such alkaline residues act as resists.

Alkali traces in textiles Detected with the aid of methyl green (0.01 g in 100 ml of distilled water): allow the fabric test specimen to exhaust with distilled water at 100°C, remove it and add 1–2 ml of methyl green solution. Alkali traces in the water cause the methyl green solution to lose colour.

Alkali treatment of polyester Alkaline pre-treatment for polyester. Under controlled conditions (pH, temperature and time), a staged, surface → Weight reduction of polyester fibres, also called “hole corrosion”, takes place (10–20% anticipated weight loss). In this process, the polyester molecules on the surface are hydrolytically split, and partially dissolved, producing a silk-like handle and drape together with reduced lustre and increased dye uptake.

Batch-type, semi-continuous and continuous processes are familiar in polyester alkaline treatment; batch processing on winches and jet and HT beam dyeing machines with 15–30 g/l of caustic soda; semi-continuous by impregnation and dwelling with up to 190 g/l of caustic soda; continuous by impregnation followed by steaming; with diluted NaOH: Apollotex machine; with highly concentrated NaOH: flash ager with downstream open-width scouring machine and Debaca process as a modified pad-steam process (Figs. 1 + 2). Reaction times of 120 secs. are possible for continuous processing when operating with superheated steam (Fig. 3).

Fig. 1: Surface of a polyester fibre after 22% degradation (alkali treatment) in the pad-steam process (125 g/l of NaOH); 165°C superheated steam).

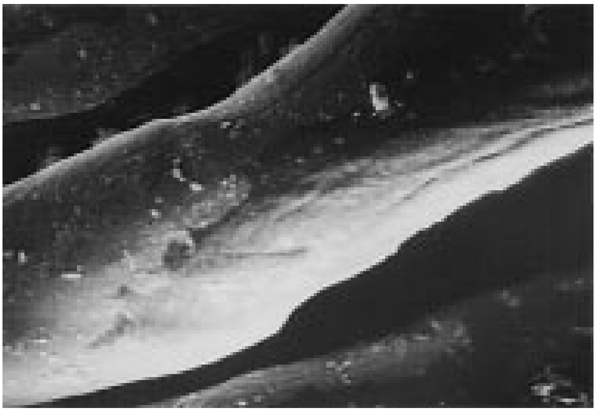

Fig. 2: Surface of a polyester fibre after 17% degradation (alkali treatment) in the application process (125 g/l of NaOH; 165°C hot air).

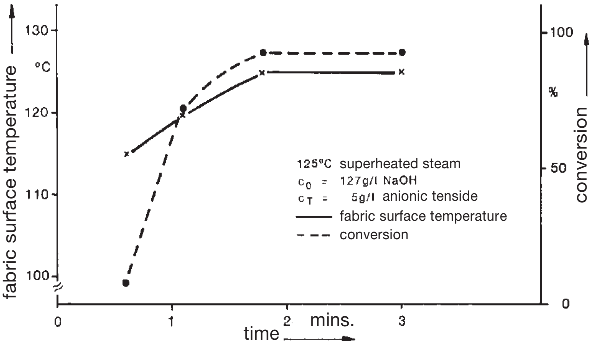

Fig. 3: Fabric surface temperature and polyester conversion relative to time.

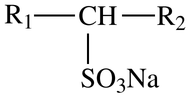
The following framework conditions must be met in order to obtain the required finishing result with the pad-steam or pad-dry process:

1. Liquor application must be uniform and reproducible. The same requirements as for continuous dyeing processes must therefore be placed on the application unit. Liquor uptake must be set as low as possible in order to keep the water charge in the textile fabric to be evaporated in the dryer as small as possible.
2. An anionic, alkali-stable wetting agent should be employed for wetting the textile fabric with the caustic soda and for adequate penetration into the yarn interstices. The tenside concentration in the padding liquor should be set relatively high, taking account of the best possible dissemination of the liquid film on the fibre surface, tenside concentrations of 3–4 g/l in the padding liquor having been found adequate. The quantity of tenside remaining on the fabric additionally facilitates washing out of the decomposition products.
3. Next to the initial charging of the textile fabric with caustic soda, the drying cycle in the machine represents the decisive criterion for the conversion achieved. Due to the fact that extremely different products, in terms of weave and the degree of weight reduction required, are alkali treated in practice, only general recommendations can be given here. Since little conversion is achieved in the first drying section, passage through it should be as fast as possible. Uniform temperature and moisture distribution must be guaranteed in the machine in order to prevent migration. The second drying section is decisive to the reaction, reaction times of approx. 10 secs only being necessary in this phase. In any case, the fabric must leave the dryer or steamer in the dry state in order to obtain optimum and reproducible conversion.

Alkaloids are base-like nitrogen-containing narcotics and poisons derived from the plant and animal kingdoms (quinine, morphine, strychnine, etc.)

Alkanes Saturated acyclic (aliphatic) → Hydrocarbons. The generic formula reads as C_nH_{2n+2}, where n = number of C atoms. Homologues in this series end in “ane” e.g. Methane.

Alkane sulphonates (Paraffin sulphonates, PS), Formula



$$R_1{-}\underset{\displaystyle SO_3Na}{\underset{|}{CH}}{-}R_2$$

Detergent raw materials from petrochemical origins. Starting products are unbranched paraffin cuts (certain fractions from mineral oil distillation) which are free from olefins and aromatic compounds. Further processing through chlorosulphonation or sulphoxidation and saponification (caustic soda) leads to alkane sulphonates. The surface active properties of paraffin monosulphonates are essentially dependant on the paraffin chain length and the position of the sulphonate group on the paraffin chain. So for example, with hexadecane sulphonate, the hexadecan-8-sulphonate has the best wetting power and the -2-sulphonate has the worst. On the other hand, the detergency is reduced by the movement of the sulphonate group towards the centre of the chain (“effective chain length”), which also agrees with research into other anionic detergents. In relation to → Alkylbenzene sulphonates (ABS), alkane sulphonates have better solubility, similar hard water tolerance and are especially suitable for use in liquid detergents and cleaning products. The biodegradability is good, slightly higher even than ABS. Alkane sulphonates have only limited suitability in powdered products due to their tendency to high hygroscopicity. Just as with the ABS, the foaming properties of alkane sulphonates are adjustable.

Alkanols Saturated acyclic (aliphatic) → Alcohols.

Alkanon Special silicate as a filter aid for chlorohydrocarbon processing and stabilisation: used for pH optimisation. Used acidic tetrachloroethylene baths are re-adjusted to the alkali range 7.4 – 7.8. Procedure (in addition to the use of Kieselguhr filter aid): reduce the Kieselguhr by 15–20% v/v and replace the balance by Alkanon. This allows longer running of dry-cleaning plants and gives an improvement in the product odour.

Alkenes Unsaturated acyclic (aliphatic) → Hydrocarbons with one or more double bonds. With I double bond, the formula reads C_nH_{2n} with n = number of C atoms. Homologues in this series end in “ene”. So a product derived from ethane = ethene. → Olefins.

Alkene sulphonates → Olefin sulphonates.

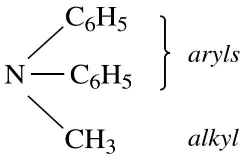
Alkenols, alkynols Unsaturated, acyclic (aliphatic) alcohols → Hydrocarbons.

Alkoxyalkylcarbamate → Dimethylol mono carbamate (DMC).

Alkyd resins represent an extensive group of synthetic resins formed by the condensation of polyhydric alcohols with aliphatic acids. The → Phthalate resins (glyptals), which are produced from glycerol and phthalic acid, also belong to this class. Typical applications of alkyd resins are: baking enamels, finishes, impregnations, coatings, print pastes, thickeners, etc. Further valuable products are the so-called modified alkyd resins (“oil-alkyds”), the principle of which is based on the fact that the OH groups of polyhydric alcohols (e.g. glycerol) are partially substituted by groups from monobasic resin or fatty acids. Such polycondensed alkyd resins are not only of interest in the varnish and paint sector, but also find use in sizing, crease-resist finishes, finishing and coating compounds, matt prints (in pigmented form) and washfast prints with coloured pigments, etc.

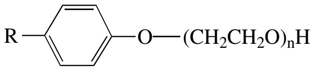
Alkylamines → Amines with substituted alkenes. The lower alkylamines are represented by, e.g. the methylamines: monomethylamine CH_3NH_2, dimethylamine $(CH_3)_2NH$ and trimethylamine $(CH_3)_3N$. Higher alkylamines correspond e.g. to the $R–CH_2–NH_2$ type.

Alkyl aryl compounds Substitution products which contain → Alkyl groups e.g. methyldiphenylamine:



Not to be confused with → Aralkyls which contain e.g. a benzyl group $–CH_2-C_6H_5$.

Alkyl aryl polyglycol ethers Originating from the ethoxylation of alkyl aryls. Alkyl aryl polyglycol ethers are frequently used in general detergent and cleaning products.

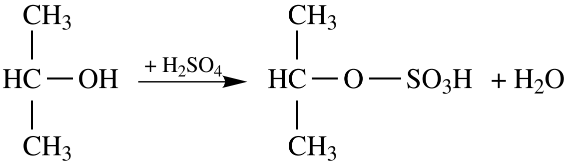


They are non-ionic and possess excellent detergency and emulsifying properties.

Alkyl aryl sulphonates (AAS), a term for aralkyl sulphonates. They are surface active substances with 1 or 2 aromatic rings which contain one or more alkyl chains and a sulpho group. Alkyl aryl sulphonates are classified into lower molecular weights (wetting agent types) and higher molecular weight (detergent types). The general rule is the more branched the chain, the better the wetting power and the better the detergency, the higher the molecular weight of the alkyl chain.

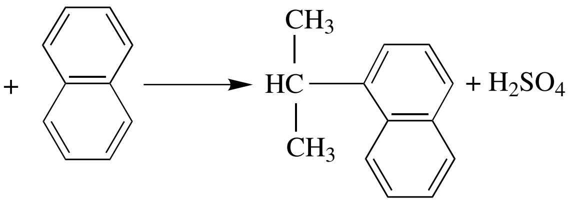
Alkylation involves the introduction of alkyl groups into organic compounds by substitution or addition. It is generally carried out by incorporating a succession of interlocking individual reactions into a single process:

1st. phase: esterification

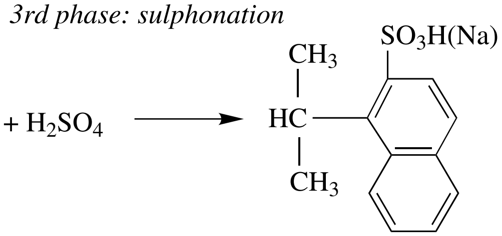


$$\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{HC}}}-\mathrm{OH} \xrightarrow{+\mathrm{H_2SO_4}} \underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{HC}}}-\mathrm{O}-\mathrm{SO_3H} + \mathrm{H_2O}$$

2nd phase: alkylation



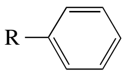
3rd phase: sulphonation



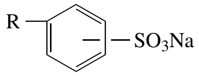
A wide range of application and utility properties for dyestuffs and textile auxiliaries can be achieved through alkylation, as well as the production of sizing and finishing agents, thickeners and man-made fibres from cellulose (alkyloses). An important factor in determining the utility properties is the → Alkylation, degree of.

Alkylation, degree of Descriptive term for the quantitative proportion of alkylated groups in a molecule. The respective degree of alkylation plays an important role, especially e.g. in so-called substituted celluloses with regard to their solubility and serviceability properties. Both these properties are influenced by the degree of alkylation so that it is possible to manufacture finishing agents, sizing agents and printing thickeners with the desired solubility properties, i.e. solubility in water, alkali or organic solvents; e.g. (cellulose derivatives): a) alkali-soluble = low degree of alkylation (compounds with low alkyl content); b) water-soluble = medium degree of alkylation; c) soluble in organic solvents = high degree of alkylation.

Alkyl benzenes Generic description for aromatic hydrocarbons in which the benzene ring is substituted with an alkyl chain. Because of the required biodegradability, straight chain alkyl benzenes have taken on a greater significance. The straight chain alkanes (n-alkanes) with C_{11-16} are based on mineral oil or α-olefins derived from the cracking of paraffins, polymerisation of ethene (Ziegler process), or chlorinated dehydration (Hüls).



Alkylbenzene sulphonates (ABS) Starting products are → Alkyl benzenes, which are then sulphonated. Alkylbenzene sulphonates, in the form of their sodium salts, are used in heavy-duty detergents and mild washing agents, generally in combination with other surfactants. They are also used as auxiliaries in the textile and paper industries. With alkyl chains of 8–15 C atoms they have good detergency and emulsifying properties, are high foaming and possess good stability to hard water. The potassium and triethanolamine salts of alkylbenzene sulphonates are employed in liquid washing agents and detergents because of their better solubility. Alkylbenzene sulphonates with alkyl chains with approx. 20 C atoms and above are soluble in hydrocarbons and organic solvents. Their share of the anionic surfactant market amounts to approx. 70%.



Alkylenes →: Alkenes, olefins.

Alkyl ether sulphates, are produced from alkyl sulphates by the inserion of an intermediate link consisting of one or several glycol ether groups linked to one chain between the hydrophobic alkyl chain and the hydrophilic sulphate group:

$C_nH_{2n+1}\ OSO_3Na$	alkyl sulphate
$C_nH_{2n+1}\ (OCH_2CH_2)_mOSO_3Na$	alkyl ether sulphate

Insertion of the glycol ether group brings about an extension of the hydrophobic chain.

Alkyl ether sulpho acids → Fatty sulpho acid esters.

Alkyl naphthalene sulphonates They are mainly based on short branched alkyl chains and lead to excellent (cold) wetting, dispersing and emulsifying agents, mostly with very good hard water and acid stability. They act especially as special wetting agents as well as dye penetration agents, levelling agents etc.

Alkyl naphthol polyglycol ethers → Polyglycol ethers.

Alkylphenol polyethylene oxide compounds (alkyl phenols) → Polyglycol ethers.

Alkyl phosphates In a similar manner to inorganic compounds → Alkali phosphates, organic compounds can also be made as esters of phosphoric acids in which one or more acid H atoms are replaced by → Alkyds (e.g. fatty acids, fatty alcohols). Most of the higher molecular organic phosphates originate in this way with many properties similar to soap, e.g. good dirt suspension and improved material handle.

Alkyl polyglycolether → Polyglycol ether.

Alkyls A term for saturated alkyl chains of general formula C_nH_{2n+1}; one obtains them if one removes an H atom from an alkane molecule. They are denoted by the ending "yl" e.g.

Methane	CH_4	→	Methyl	CH_3
Ethane	C_2H_6	→	Ethyl	C_2H_5
Propane	C_3H_8	→	Propyl	C_3H_7
Butane	C_4H_{10}	→	Butyl	C_4H_9
Pentane	C_5H_{12}	→	Pentyl	C_5H_{11}
Hexane	C_6H_{14}	→	Hexyl	C_6H_{13}

Alkyls can be bound to any of the following atoms: Carbon, Oxygen, Nitrogen, Sulphur, Silicon and various metal atoms.

Alkyl sulphates are important raw materials for detergents and textile auxiliaries. They have the general formula $RO\text{-}SO_3H(Na)$ and are fatty esters of sulphuric acid, better known as → Fatty alcohol sulphates.

Alkyl sulphides → Mercaptans.

Alkyl sulphonates Formula: $C_nH_{2n+1}SO_3Me$. Used in spin finishes.

Alkynes (Acetylene), unsaturated acyclic (aliphatic) → Hydrocarbons with one or more triple bonds. In the same molecule, a double bond may also be present. Only single bonds are available next to a triple bond so the general formula for a compound with 1 triple bond reads C_nH_{2n-2} where n = the number of C atoms. Homologues in this series end in "yne" from which follows that the derivative of ethane is ethyne.

Allergens are substances which give rise to allergic reactions in living organisms.

Allergy Abnormal hypersensitivity of the human body to foreign materials (allergens) in susceptible individuals. The development of an allergy is due to an inappropriate reaction of antigen-antibody responses (which form an important part of the body's normal immune defence system) to substances in the environment. Practically all substances outside the human body (haptens, e.g. even bacterial metabolites) can react with the serum albumin to form antigens. In simple terms, the immune system "learns" how to produce so-called specific antibodies on contact with antigens. On renewed contact with these same antigens, a reaction occurs in the organism releasing antibodies which then react with the corresponding antigens and, at the same time, further immune defence mechanisms are activated such as, e.g. the distribution of cell hormones. When an over-reaction occurs, as is the case with an allergy, inflammations and/or other health damaging manifestations are triggered.

For the purposes of industrial hygiene it is important that sensitization, i.e. provocation of the organism towards a state of over-reaction readiness, is avoided by ensuring that exposure is never so great that the immune system becomes overloaded. The following relationship thus applies:

Risk of sensitization = exposure x antigen.

Unfortunately, the equation is no longer valid once sensitization has occurred. Since an over-reaction is comparable to a chain reaction, even the smallest amount of a sensitizing substance is often sufficient to trigger an allergic reaction. Under such circumstances, the risk of allergic reaction can only be eliminated by the complete avoidance of any exposure whatsoever. The prerequisites for an allergic reaction are hereditary predisposition and contact with certain (sensitizing) substances. In view of the fact that more and more people have become susceptible to allergic reactions, it would appear to be a disease of civilization; the condition being properly described as medical atopy. A typical atopic subject will have parents who suffer from hay fever, asthma or other allergies, and who have passed on the genetic predisposition for over-reaction to natural substances such as plant pollens, animal hairs, etc. The specific sensitivity to skin allergens (→ Skin diseases) may also be explained on this basis. Atopic subjects should be particularly meticulous in the choice and care of their clothing.

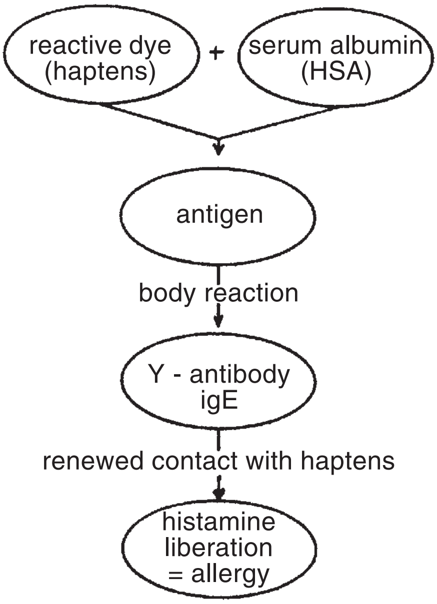


Fig. 1: Occurrence of allergies due to reactive dyestuffs as haptens.

The course of the reaction represented in Fig.1 can be postulated as follows: the reactive dye (hapten) reacts with human serum albumin (HSA) by forming a dye-HSA conjugate which functions as an antigen. As a response to this antigen, the body forms Y-shaped antibodies (immunoglobulin E, IgE) which take root on the surface of mast cells in the nasal mucous membranes. The mast cells release highly active substances such as, e.g. histamine, on renewed contact with the reactive dye and the condition becomes manifest as allergic rhinitis (which also includes allergic bronchial asthma).

The various factors responsible for the extent of antigen-antibody production, the initiation and intensity of sensitization, as well as the severity of the symptoms, are still not fully understood. It may well be that, e.g. physical properties such as the water-solubility of the reactive dye, steric factors (molecular forms of antigens and antibodies) and the degree of exposure have a role to play here. Determination of the cutaneous resorption rate of a substance is often of particular importance in this regard, i.e. determination of the quantity of a substance which can penetrate the skin barrier and thence become systemically distributed and active. In the interests of reducing or even eliminating the need for animal tests, whilst still maintaining the necessary safeguards to ensure freedom from health risks, the following possibilities exist:

1. Where a substance is not cutaneously resorbed, the test for subchronic toxicity may be waived in certain circumstances.
2. Where the cutaneous resorption rate of a substance is known. In this case, and under certain circumstances, a subcutaneous toxicity test may be carried out with only one dose.
3. Where the "no observed effect level" of a substance is known from a subcutaneous toxicity test, the determination of cutaneous resorption can be waived if this value is greater than the maximum quantity of substance which, having regard to the safety factor, can penetrate the skin according to pure calculation.

As far as textile finishing plants are concerned, the following precautions should be taken: a) careful handling of dyes and auxiliary chemicals, b) avoidance of any skin contact as far as possible, c) no inhalation of product dusts or vapours, d) the use of automated, dust-free product dispensing, weighing, and dosing systems, as well as e) the optimization of commercial forms of product (e.g. non-dusting brands).

Textile dyes known to be potential allergens include, e.g.:

- Anthraquinone dyes such as Disperse Red 11, 15 and Disperse Blue 1, 3, 7, 26, 35;
- Azo dyes such as Disperse Red 1, 17 and Disperse Blue 102, 124, as well as Disperse Orange 1, 3, 76;
- Nitro dyes such as Disperse Yellow 1, 9;
- Methine dyes such as Disperse Yellow 39, 49;
- Quinoline dyes such as Disperse Yellow 54, 64;
- Triphenylmethane dyes such as Acid Violet 17;
- Others, such as, e.g. chromates.

In this connection, two examples of practical relevance may be given here:

1. A range of textile dyes based on p-amino-azobenzene structures exists which, after extraction from dyed materials, e.g. through the action of perspiration alone, or after their transformation into p-phenylene diamine (derivatives) are able to function as haptens and can induce sensitization or trigger an allergic reaction (Fig. 2). In this case, the stability (wet fastness) of the dyeing is particularly important.

Next Page

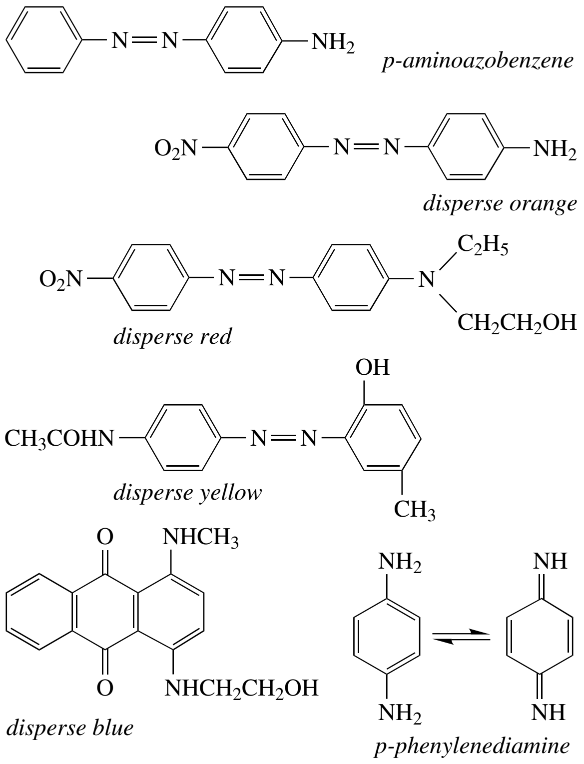

Fig. 2: p-aminoazobenzene dyestuff derivative which can function as haptens in the metabolism.

2. Formaldehyde is a toxicologically-relevant substance, especially as an allergen. From the results of toxicological tests, however, a distinct carcinogenic potential does not appear to have been clearly established in the case of formaldehyde. On the other hand, the potential allergenic activity of formaldehyde is indisputable, and for which a minimum concentration is necessary both to induce as well as to trigger an allergenic reaction. From the results of dermato-toxicological tests on cosmetic products, it is known that even those subjects allergic to formaldehyde only react to concentrations above 0,05% as a rule, provided the skin of the affected subject is not exceptionally easy to penetrate, e.g. as a result of abrasions (Lüpke, Moll, Rosenthal, Anliker and Steinle).

Allgaeu carpet (ribbon carpet, patchwork carpet), hand-made smooth carpet in a strong cotton yarn warp with a ribbon-like weft (fancy weft carpet) in strips of woven and knitted fabric remnants, stockings, selvege trimmings etc.

All-in method,

I. Dyeing: method for dyeing reactive dyes with dye/s, alkali and all the required auxiliaries from a single bath; e.g. as used for dyeing cotton fabrics with reactive dyes in a modern jet dyeing machine (Bayer method); see Fig.

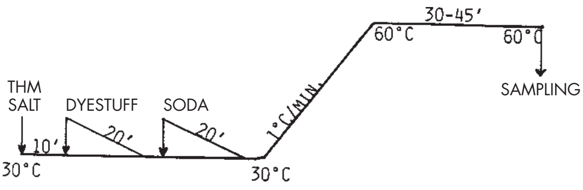

Fig.: Bayer all-in process for dyeing cotton with reactive dyes on jet dyeing machines.

II. Printing: A process in which the print paste contains, besides the dye/s, all the chemicals necessary for fixation, in contrast to the →: Two-phase printing process, Wet fixation process.

Allotrope (Gr.) One of several possible forms or modifications of a substance, e.g. the element carbon exists as soot, coal, graphite and diamond. Viscose fibres, as regenerated cellulose, represent an allotropic form of native cellulose.

All-over screens, flat or rotary printing screens which allow total flow of print paste across the entire squeegee width = 100% coverage.

Allowance In accordance with REFA, all irregularly occurring times in fabric processing, as (supplementary to → Basic time) those times which cannot properly be logged in every timing process or time calculation. Allowance is objectively and personally determined (independently of operation).

Alloys Solid or liquid mixtures of two or more metals, or of one or more metals with certain nonmetallic elements, as in carbon steels. Alloys are partly physical mixtures and partly chemical combinations. The physico-chemical properties of alloys are usually considerably different from their individual components (particularly with regard to melting point, strength, extensibility, hardness, processability, technical applications, and resistance to chemical corrosion).

All-skin fibres This means modified viscose fibres of the so-called Supercord and Superfest-S type, the cross-section of which no longer consists, as with normal viscose fibres, of core and skin, but exclusively of a highly oriented skin substance as a carrier of special quality features such as increased tear strength and higher wet modulus. According to electron microscope examination, HWM fibres reveal, apart from an also microscopically detectable skin zone, few small hollow spaces, whilst the polynosic fibre on the other hand has larger hollow spaces in the fibre interior (→ Modal fibres).

All-weather articles In order to qualify for the Indanthren quality label, such articles must be dyed with vat dyes. Certain types of apparel, bathing suits, knitgoods and, to some extent, home textiles composed of cellulosic fibres belong in this category.

Allwörden's reaction → Elasticum reaction.

Allyl aldehyde → Acrolein.

Previous Page

Aloes fibre → Mauritius hemp.

Alpaca The alpaca is a close relative of the llama and is similar to the guanaco. It lives exclusively in Peru, Bolivia, Chile and the higher levels of the Andes. Its fleece belongs among the finer animal hair qualities. Shearing takes place every 2 years and, because of the prevailing raw climate, the alpacas are not shorn to the skin. The fleece is soft, lustrous and slightly curly.

Alpaca wool does not have a uniform colour; the colours extend from black, dark brown, chestnut, through to biscuit, camel, beige, etc., and from dark grey to silver grey. Up to 22 different shades are obtained by hand sorting. Alpaca is used, *inter alia,* for dress fabrics as well as jacket materials, e.g. with a warp of twisted cotton and a weft composed of alpaca or other llama-type fibre. Fabrics are mostly produced in plain or twill weave with a napless finish. Used for dresses, women's coats and lightweight summer jackets. → Animal fibres.

Alpha-naphthol (α-naphthol, 1-naphthol, 1-hydroxynaphthalene), see example under → Cyclic hydrocarbons.

Alpha rays → Radioactive emission.

Alum → Aluminium potassium sulphate.

Alumina → Aluminium oxide.

Alumina gel, $Al_4(SO_4)(OH)_{10} \cdot 2H_2O$. A strongly alkaline → Aluminium sulphate which is insoluble in water but soluble in acids. It is used to prepare aluminium mordants for dyeing and printing.

Aluminium, (aluminum**,** Al, atomic weight 26,98), is a silver-white highly-lustrous soft metal which is very ductile and extensible, capable of being rolled out into very thin foil (sheet aluminium). It has very good electrical conductivity (62% of the conductivity of copper). Aluminium is soluble in hydrochloric and sulphuric acids and forms aluminates (so-called acidic aluminium salts of the AlO_2Na type) on reaction with alkaline liquors which is accompanied by the evolution of hydrogen. When these are mixed with other metallic oxides, aluminium oxide Al_2O_3 and the corresponding metal are formed, often with explosive evolution of heat. Alloys with other metals generally give increased strength although corrosion-resistance is reduced, e.g. duralumin with 0,5% magnesium, 4,5% copper and 9,7% manganese. Aluminium is also used for aluminium bronze colours in textile printing.

Aluminium acetate (aluminium ethanoate, acetate of alumina, red liquor), $Al(CH_3COO)_3$, MW 204,19. Available as a relatively strongly acidic solution (approx. 8–10%) which should be sulphuric acid free, or as a white powder of high purity. Gives approx. 15% aluminium oxide on the fibre. Over time (and particularly on heating), the basic salt $Al(CH_3COO)_2OH$ separates out.

Aluminium acetate can also be made on a do-it-yourself basis from e.g. aluminium sulphate, acetic acid and calcium carbonate, or from the basic acetate on addition of sodium carbonate. Used for water-repellent finishing: e.g., treatment with 2–6°Bé (1,013–1,042 g/ml) aluminium acetate alone at 20–40°C for 1–2 h, followed by drying at 60–65°C, or in combination with paraffin wax and similar products. Aluminium acetate is also employed as a mordant in dyeing and printing.

Aluminium alcoholates are colourless liquid or solid compounds in the pure state, formed from metallic aluminium, aluminium amalgam and alcohols, which are then cleaned by filtration or vacuum distillation. Aluminium alcoholates are decomposed by water into their corresponding alcohols and aluminium hydrate. For this reason, they find application, when dissolved in organic solvents, as water-repellents, especially for the dry impregnation of cotton goods (e.g. poplin outerwear).

Aluminium ammonium sulphate (Ammonium alum), $NH_4Al(SO_4)_2 \cdot 12H_2O$, mol.wt. 453.54, colourless crystals, soluble in cold or extremely soluble in hot water. Uses: analogous to and replacement for potassium aluminium sulphate (alum).

Aluminium bronze powders for printing → Metal powders in textile printing.

Aluminium chlorate, $Al(ClO_3)_3$, MW 218. White crystalline deliquescent solid. Commercially available solutions have a variable aluminium chlorate content. Uses: substitute for sodium chlorate in discharges; oxidizing agent for aniline black; printing with vat leuco ester dyes; oxygen carrier (e.g. in aniline black dyeing).

Aluminium chloride, $AlCl_3$, MW 133,6. Available as colourless or (with traces of iron chloride) yellowish crystals, soluble in water and many organic solvents, or as a strongly acidic solution of 30°Bé (1,261 g/ml) (31–32% $AlCl_3$ as "chloraluminium"). Used for carbonizing dyed wool materials, especially reclaimed wool (gentle treatment) and, less frequently, as a mordant or in the production of burn-out prints on velvets.

Aluminium formate (formate of aluminium), $Al(HCOO)_3$, MW 162. Available mostly in solutions of 10°Bé (1,074 g/l). Can be prepared on a do-it-yourself basis as follows: 70 g aluminium hydroxide 100% is dissolved in 600 ml water and 150 ml formic acid 85%; this solution contains approx. 200 g/l of aluminium formate. Uses: water-repellent finishes, aftertreatment of dyeings, alizarin printing (does not attack the fibre; no lake formation during steaming under pressure).

Aluminium hydroxide (alumina trihydrate, hydrated alumina), $Al(OH)_3$, MW 78. White crystalline powder, balls, granules or in paste form (alternatively, it can be produced by hot precipitation from aluminium sulphate solution with ammonia, followed by thorough washing).

Used for the production of dye mordants and colour lakes.

Aluminium in dyeings, identification tests

1. Ash the dyed or printed specimen. Colour of ash = pure white (alizarin dyeing resp. aluminium mordant, wash test).
2. Transfer the ash to filter paper and make into a roll. Moisten well with dil. nitric acid and carefully pass the roll several times through a small flame (until the surface has dried); then place a few drops of dil. cobalt nitrate solution on the filter paper and heat until red hot in the flame: distinctive blue ash.
3. Place a little of the ashed specimen on to a molten bead of sodium or potassium carbonate fused on to a platinum wire, then refuse the bead for approx. 5 min. Dissolve the bead in dilute acetic acid and add a few drops of morin solution (1 pinch of morin in 50 ml ethanol).
   Greenish fluorescence which is very clearly visible if the solution is first heated slightly, cooled again with water, and held against a dark background. Daylight essential! The presence of iron or copper interferes with the test and, for this reason, these metals should be precipitated out with sodium hydroxide solution beforehand.

Aluminium oxide (alumina), Al_2O_3, exists in at least 5 known varieties. It forms an extremely thin corrosion-protective layer on aluminium surfaces exposed to air. Also obtained as an intermediate product in the extraction of aluminium. → Corundum.

Aluminium potassium sulphate (alum, potash alum), $Al_2(SO_4)_3 \cdot K_2SO_4 \cdot 24H_2O$. MW 949, density 1,94. Colourless crystals or white crystalline powder. Water soluble. The solution is weakly acidic and the free sulphuric acid content is mainly slight. Uses: aftertreatment of developed dyeings; mordant for alizarin dyes (dyeing and printing); weighting of silk; auxiliary mordant for resorcin dyes; neutralization of alkali blue (wool); water-repellent finishes; flame-retardant finishes; tanning (white) of rabbit pelts (alum tannage).

Aluminium silicates Collective term for compounds with varying proportions of Al_2O_3 and SiO_2 which occur in nature as andalusite, cyanite etc., or as components of other minerals (→: Kaolin, Bentonite, Fuller's earth, China clay).

Aluminium sulphate (sulphate of alumina), $Al_2(SO_4)_3 \cdot 18H_2O$, MW 666, density 1,62. White mass, broken pieces, grains or crystals with 15,33% Al_2O_3. Soluble in cold or hot water; the solution has a strongly acidic reaction and attacks metals such as iron, lead, copper and zinc. For use an alizarin mordant, the iron content must not exceed max. 0,001%. Uses: substitute for aluminium potassium sulphate (alum) (cheaper, more readily soluble, more effective); for water-repellent finishes (aluminium triformate is more effective for this purpose); dye mordant (iron-free); weighting of textiles; addition to print pastes (risk of metal corrosion); water purification; production of burn-out styles on velvets.

Aluminium thiocyanate (aluminium sulphocyanide), $Al(CNS)_3$, MW 402. Uses: as a mordant for printing alizarin pink on cotton, wool and silk (does not attack doctor blades, protects against the action of iron, no damage to the fibre on steaming) where the presence of iron is indicated by a red colour; also used for resists under aniline black.

Aluminium triformate, $Al(HCOO)_3 \cdot 3H_2O$. White crystalline chemically-pure aluminium formate (approx. 23% Al_2O_3 and 63% HCOOH). The aluminium content is 5 times higher than that of typical commercial grades of aluminium formate. Good solubility in hot water, slightly soluble in cold water. Stable to boiling without separation, resistant to hard water. Dissolve at 80–100°C and boil with direct steam. Uses: instead of liquid alumina products for water-repellent finishes (1–6°Bé = 1,006–1,042 g/ml); aftertreatment of dyeings; alizarin printing (no damage to the fibre on steaming); and for increasing the colour fastness of dyeings to water. Quantities: approx. 1/5 that of 13°Bé alumina solutions (1,098 g/ml) or 1/6 that of the 10°Bé solution (1,006 g/ml).

Aluminosilicates → Zeolite; Sodium aluminium silicate.

Am, chemical symbol for Americium (95).

Ambergris → Spermaceti.

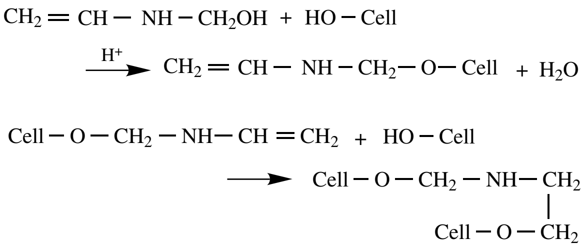
Ambient air Because of the hygroscopicity of textile fibres, the ambient air inside textile plants is of great importance for the entire processing operation. → Conditioning; air humidity.

Ambiente printing process, registered printing process of the Ambiente company, Helsinki, for the local coloration of open-width woven or knitted fabrics with thickened dye solutions in the nip of a two-bowl padder. A wide range of different lively variations in colour and design are obtained with stripes of variable widths and directions including circular, speckled and cloudlike motifs. Additional design variations are possible by employing different print paste viscosities. Both the face and back sides of the fabric have the same depth of colour, and each production batch represents a unique colour way since reproducibility of the prints is only possible to a certain extent from the basic design. In principle, wovens and knits of all kinds of fibres can be coloured by the Ambiente printing process. Print pastes are prepared according to customary recipes and their viscosity is adjusted as necessary to suit changes in conditions. Fixation and afterwashing are carried out under the same conditions as conventional textile prints.

Ambiphilic (Lat.: *ambo* = both, and Gr.: *phil* = loving). Ambiphilic substances have double solubility, i.e. in oil (→ Lipophilic) as well as in water (→ Hydrophilic). The term relates to the ambiphilic molecular structure of e.g. emulsifiers.

Ambivalent Term used in resin finishing to describe crosslinking agents with two different types of group capable of reacting with cellulose. → Ambivalent crosslinking.

Ambivalent crosslinking The crosslinking of cellulose with resin finishing agents containing different types of reactive groups. The term is mainly used to describe the two-stage resin finishing process based on methylolacrylamide as crosslinker (stage I: dry crosslinking; stage II: wet crosslinking):



$$CH_2{=}CH{-}NH{-}CH_2OH + HO{-}Cell \xrightarrow{H^+} CH_2{=}CH{-}NH{-}CH_2{-}O{-}Cell + H_2O$$

$$Cell{-}O{-}CH_2{-}NH{-}CH{=}CH_2 + HO{-}Cell \longrightarrow \begin{array}{l} Cell{-}O{-}CH_2{-}NH{-}CH_2 \\ \qquad\qquad\qquad\quad | \\ \qquad\qquad Cell{-}O{-}CH_2 \end{array}$$

AM cotton → Aminoethylated cotton. The introduction of amino groups confers an affinity for acid dyes.

Ames test A simple *in vitro* bacterial mutagenicity test devised by the American biochemist Bruce Ames for the relatively rapid screening of substances to detect those which are mutagenic (mutation-causing) and therefore potentially carcinogenic (cancer-producing). In the Ames test, mutant (His –) strains of the bacteria *Salmonella typhimurium,* lacking the ability to synthesize an essential nutrient, the amino acid → Histidine, and which can only grow in media where histidine is provided, are used. → Mutagenic agents which cause changes in their genetic material may induce reversion to the normal (His +) condition and thus facilitate growth in a histidine-deficient medium whereupon the change can be readily detected. Spontaneous reversion mutations occur but the extent of this is low and can be determined in experimental controls.

Some substances are not intrinsically mutagenic or carcinogenic but only become so when modified by metabolic processes. This may be simulated in the Ames test by adding mammalian liver homogenate (rat, S-9) to the preparation. Further refinements of the test include the use of bacterial strains in which the ability to repair the genetic material (DNA) is impaired, thereby increasing the probability that mutation will occur, and also by using strains with cell-wall defects which allow easier penetration by large molecules. Strains of histidine-deficient *Salmonella typhimurium* have been selected in which the actual genetic structural fault is known and thus the mode of action of the mutagen can be determined.

Amidases These are → Enzymes, belonging to the hydrolase group which can bring about the hydrolytic cleavage of C–N bonds. They include e.g. ureases (urea-splitting); arginases (which split the amino acid arginine into urea and ornithine and are also used for the analytical determination of arginine); and asparaginase (which splits asparagin into aspartic acid and ammonia).

Amide oils, identical with fatty acid amides; → Fatty acid condensation products.

Amide resins → Synthetic resins of the type which includes urea resins, melamine resins and dicyanodiamide resins.

Amides Organic compounds derived from ammonia by substitution of one or more of its hydrogen atoms by organic acid groups. Example: NH_3 → Oxamide $(CONH_2)_2$ → Urea $CO(NH_2)_2$.

Amido group $-CONH_2$ group, e.g. in formamide, urea and acetamide. In the past the → Amino group was often described as an amido group.

Amine odour on finished textiles See → Fish odour on finished textiles.

Amine oxides Amine oxides which are suitable as detergents originate from the condensation of a fatty alcohol with dimethylamine and subsequent oxidation. Their solubility is due to the hydrophilic amine oxide group. At higher temperatures, amine oxides decompose. They act as weak oxidising agents and possess good wetting and emulsification properties.

Amines Organic compounds derived from ammonia NH_3, by replacement of one or more of its hydrogen atoms by → Alkyl, or → Aryl groups, e.g. primary amines ($R{-}NH_2$): methylamine CH_3NH_2 and aniline $C_6H_5NH_2$; secondary amines (R2–NH): dimethylamine $(CH_3)_2NH$; tertiary amines ($R_3{-}N$): trimethylamine $(CH_3)_3N$. → Polyamines.

Amino acids (Amino carboxylic acids), $R{-}NH_2{-}COOH$, building blocks for → Proteins. Comprising of a carboxylic group (–COOH), an amino group ($-NH_2$) and a, mostly very complicated, chain (e.g. fatty acid chain) which can be aliphatic or aromatic. As a result of the simultaneous presence of amino and carboxylic groups, amino acids react as both acids and bases i.e. they are amphoteric and form Zwitterions with two opposite electrical charges which neutralise each other within the molecule (Isoelectric point). Through the joining of several amino acids, proteinaceous molecules are formed (see Table) (Peptide, Di-, Tri- and Polypeptide). Amino acids also arise from the decomposition of protein molecules. Test with Ninhydrin. In the composition of wool and silk, the knowledge of amino acid types with reactive or unreactive side groups is important. So one distinguishes:

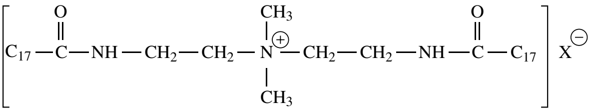
	Wool keratin	Silk fibroin	Groundnut protein	Paracasein	Gelatine
Alanine	4,40	24,50	4,1	1,5	8,7
Arginine	10,40	1,05	13,5	2,5	8,2
Asparagine	7,27	2,00	5,2	6,7	3,4
Cysteine	0,50	–	–	–	–
Cystine	12,20	–	1,5	0,2	–
Glutamic acid	15,27	2,03	16,7	15,5	5,8
Glycocoll	6,50	42,30	4,1	1,9	25,5
Histidine	0,70	0,47	1,9	5,9	0,9
Lanthionine	0,50	–	–	–	–
Leucine (isomers)	11,30	0,80	8,0	9,3	7,1
Lycine	3,30	0,44	5,0	1,5	5,9
Methionine	0,71	2,59	0,7	3,5	1,0
Oxyglutamic acid	–	–	–	3,8	–
Phenylalanine	3,75	1,50	2,6	3,2	1,4
Proline	6,75	1,50	5,3	10,5	19,4
Serine	9,41	16,24	5,2	0,5	0,4
Threonine	6,76	1,50	2,6	4,5	–
Tryptophane	0,70	1,00	0,7	0,7	–
Tyrosine	5,80	10,60	5,7	4,5	–
Valine	4,72	3,20	4,8	7,2	–

Tab.: Aminoacid composition of the most important proteins.

1. Amino acids with aliphatic side groups: Alanine, Glycine, Leucine, (Isoleucine), Valine (also Sarcosine and Betaine).
2. Cyclic amino acids: Phenylalanine, Proline, Tryptophan.
3. Amino acids with –OH groups: Serine, Threonine, Tyrosine.
4. Basic amino acids ("Hexon bases", diamino carboxylic acids): Arganine, Histidine, Lysine.
5. Amino acids with acid (carboxylic) groups: Asparagine, Glutamic acid.
6. Sulphur containing amino acids: Cysteine, Cystine, Methionine.

[3.-6. with reactive groups].

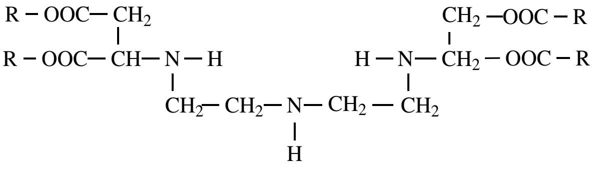
Aminoamides Are of increasing interest as cationic active finishing products e.g. dimethyl difatty acid ammonium salts as softeners:



$$\left[C_{17}-\overset{\overset{O}{\|}}{C}-NH-CH_2-CH_2-\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{N^{\oplus}}}-CH_2-CH_2-NH-\overset{\overset{O}{\|}}{C}-C_{17}\right]X^{\ominus}$$

Aminocaproic lactam → Caprolactam.

Amino carboxylic acid ester (ACAE),



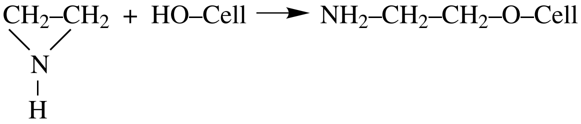
R = cetyl, stearyl and oleyl residues

They have cationic characteristics in the weakly acid pH range and after being taken up by the fibres, regain the properties and advantages of a non-ionic structure. As a rinse finish on cellulosics, the softening effect improves with falling pH and increasing concentration of active substance. Good results are achievable with 4g/kg material at pH 6. Amino carboxylic acid esters are especially effective as softeners on wool and synthetic fibres.

Aminocarboxylic acids → Amino acids.

Amino end-groups, so-called terminal → Amino groups (NH_3) which occur in the molecules of keratin (wool), fibroin (silk) and also polyamide fibres, with the difference that polyamide fibres only contain amino end-groups, i.e. no additional → Amino extra-groups, as is the case with wool and silk. For this reason, the acid equivalent and maximum dye-acid absorption of polyamide fibres is considerably lower: polyamide = 0,004–0,008 g/100 g; silk = 0,023 g/100 g and wool = 0,085 g/100 g.

Aminoethylated cotton is produced by the alkylation of cotton cellulose with aminoethylated compounds in acidic medium e.g. 2-aminoethylsulphuric acid in sodium hydroxide:



Aminoethylated cotton possesses increased swelling capacity, increased reactivity, somewhat lower strength, and increased elongation properties. It is dyeable with acid dyes and its wrinkle properties are scarcely influenced.

Amino extra-groups, originate from the diaminocarboxylic acids present as side-groups in the keratin and fibroin molecule, mainly from arginine, histidine and lysine. In addition to the → Amino end-groups, the number of amino extra-groups determines the fundamental behaviour of wool and silk towards acids, i.e. by reacting as bases. Since wool contains considerably more amino extra-groups than silk, it possesses an accordingly higher acid equivalent (0,085 : 0,023 g/100 g) and consequently a correspondingly higher dye-acid binding capacity. Polyamide, on the other hand, possesses no amino extra-groups.

Amino group $-NH_2$, is a monovalent radical that can occur in vastly different organic compounds which are then described as → Amine or amide. The amino group (as well as its derivatives) is classified as an auxochrome e.g. in cationic and diazo dyes. NH_2-compounds with carboxylic groups (–COOH) are known as → Amino acids (proteins).

Aminoplasts → Self-crosslinking resins. Application, *inter alia*, as resin finishing agents. Collective term still used very occasionally for urea-formaldehyde and melamine-formaldehyde compounds.

Aminopolycarboxylic acids A group of important organic complexing agents which are of particular value in water softening applications and which also find use in complexometry. Ethylenediaminetetraacetic acid (→ EDTA) and → Nitrilotriacetic acid (NTA), as well as their sodium salts are particularly important examples. The most notable property of these compounds is their ability to form very stable water-soluble complexes with metal ions in aqueous solution. The stability of these complexes is, however, influenced by external factors. Thus an increase in the stability of EDTA trisodium salts is achieved by raising the pH and raising the temperature. In the case of the EDTA tetrasodium salts (weak compounds) on the other hand, electrolyte additions, increasing valency of electrolyte anions and increasing temperatures reduce the stability. EDTA also functions as a stabilizer in peroxide bleaching.

Aminotrimethylcarboxylic acid, identical with → Nitrilotriacetic acid (NTA).

Ammonia → Ammonium hydroxide; the gas NH_3 dissolved in water.

Ammonia aftertreatment of reactive dyeings A mild (ammoniacal) aftersoaping treatment generally given to reactive dyeings on wool for the purpose of removing unbound dye and thus improving the colour fastness.

Ammoniacal silver nitrate solution, 100 ml of 0,1 n silver nitrate solution is dissolved in 15 ml ammonia and 40 ml of 38°Bé sodium hydroxide solution. Used for the detection of oxycellulose and hydrocellulose: Place the test specimen for a few minutes in the above solution heated to 80°C, then finally rinse off with dil. ammonia. Damaged cellulose exhibits a yellow to yellowish brown colour.

Ammonia cure process Ammonia condensation process. Application technology for certain flame-retardant finishes which crosslink with ammonia (mainly during a separate processing stage, often by gas treatment), e.g. Proban, Pyroset process, THPOH–NH_3 finishes.

Ammonia finishing → Liquid ammonia process.

Ammonia liquor → Ammonium hydroxide.

Ammonia process → Liquid ammonia process.

Ammonia soaps → Soaps. Used as lubricants for cotton or wool (with oleic acid and neutral fat = wool spinning oil) which can be readily washed out. Soaps for sensitive materials, finish additives, etc.

Ammonia test (for dyeings)

I. Specifically for the identification of wool/cotton unions resp. the differentiation of direct and acid dyes. Strip the dye/s from the test specimen by boiling several times with conc. ammonia. Combine the stained liquors and reduce the whole to 1–2 ml by evaporation. Dilute with 4–5 ml dist. water and take 2 ml of the resultant liquor in each case for the following dyeing tests: a) acidify with conc. formic acid, add one sample of wool and one of cotton, heat to the boil for 5–10 min. then rinse thoroughly with cold water; b): add 0,5 ml of 10% sodium sulphate solution and dye one sample each of wool and cotton for 5–10 min. at the boil, then rinse thoroughly in cold water; c): as for b) but with the addition of a little sodium carbonate solution followed likewise by dyeing of wool and cotton.

Evaluation: 1. Only the wool is stained in a) + b) and a) is more heavily stained than b) whilst in c) the wool is either unstained or only lightly stained = definitely acid dye. 2. Cotton is heavily stained in b) and possibly in c) as well = substantive dye. 3. Wool and cotton are more or less equally stained in a) + b) = wool/cotton union dye or a mixture of acid and direct dyes.

II. For the identification of fast dyes on synthetic fibres by separation (→ Dye class identification).

Ammonium (NH_4), monovalent radical of so-called ammonium compounds (type: ammonium hydroxide NH_4OH) which, in terms of structure and behaviour, possess many similarities to potassium and sodium compounds: e.g. especially their easy solubility and dissociation in solution into positively charged $[NH_4]^+$ cations and negatively charged acid anions.

Ammonium acetate (acetate of ammonia), CH_3COONH_4, MW 77, density 1,171. White, deliquescent solid, readily soluble in water and ethanol giving neutral solutions. Can be easily prepared on a do-it-yourself basis by mixing acetic acid and ammonia (720 ml acetic acid 30% + 280 ml ammonia liquor 25%; slight excess of ammonia is recommended, neither red nor blue litmus paper should change colour to any significant extent). On heating ammonium acetate liquors, acetic acid is slowly split off. This property is made use of in dyeing for the acidification and exhaustion of difficult levelling and too rapidly exhausting acid, developing and mordant dyes. Other uses, e.g. in wool dyeing, include the elimination of undesired shine in worn garments (brushing with ammonium acetate dissolved in ethanol).

Ammonium acetate bridges, salt bridges in wool keratin.

Ammonium alum → Aluminium ammonium sulphate.

Ammonium carbonate (crystal ammonia, ammonium sesquicarbonate, hartshorn), $(NH_4)_2CO_3$, MW 96. Hard white solid or fine powder (ammonium bicarbonate) with a strong smell of ammonia, slowly turns into a yellowish solid. Contains approx. 31% ammonia, and releases ammonia into the air (store dry in well-closed containers in a dark place). Slowly dissolves in 15 times its own weight of water. Decomposes with the formation of ammonia at 58°C. Uses: as the mildest alkali (wool scouring); neutralizing agent; spotting agent (for berry and red wine stains) etc.

Ammonium chloride (sal ammoniac), NH_4Cl, MW 53, density 1,52. White crystalline solid with a bitter salty taste, stable in air, soluble in cold water 1:3, in hot water 1:1,5, in alcohol 1:50 or in glycerol 1:8. Solutions are neutral but become weakly acidic on prolonged boiling (hydrolysis). Uses: various applications, especially in printing (aqueous solutions decompose into ammonia and hydrochloric acid).

Ammonium chromate $(NH_4)_2CrO_4$, MW 152. Lemon yellow crystalline needles or powder, readily soluble in water (approx. 40% solution at 30°C); decomposes readily on heating. Use: as a mordant for chrome dyes in printing (well-proven in printing alongside vat dyes).

Ammonium compounds, quaternary → Quaternary ammonium compounds.

Ammonium hydroxide (ammonia solution, ammonia liquor), NH_4OH. Colourless liquid: (volatile ammonia content) slippery, burns the skin, usually with 20–25% ammonia content (density 0,91, the density rises with falling concentration). Impurities: carbonate, tarry substances, alcohol, acetone; less frequently: sulphate, sulphide, chloride, copper. Properties: volatile (storage containers must be kept well-closed) and mild alkali; cellulosic and protein fibres are virtually unaffected; saponifying action on fats; attacks copper vessels (= blue stains); binds heat on evaporation. Uses: as a mild alkali in the scouring of wool, silk, etc.; degreasing agent (forms ammonia soaps which are easily rinsed out) and removal of soaps; for final neutralization in textile wet treatments; as a spotting agent (dissolves stains from metallic oxides, indelible markers, grass, etc.); volatile alkali, etc.

Ammonium linoleate Used as an emulsifier for fats, oils, waxes and solvents. Also used in the manufacture of spinning oils, washing agents, milling agents, etc.

Ammonium persulphate (ammonium peroxodisulphate), $(NH_4)_2S_2O_8$, MW 228,2. White crystals, soluble up to 559 g/l in water at 20°C, 98–99% purity, contains 6,8% active oxygen, good shelf-life in the dry state, decomposes under damp storage conditions, heating of aqueous solutions is accompanied by the evolution of oxygen. Uses: desizing; soap bleaching, oxidizing agent in dyeing and printing.

Ammonium phosphates,

I. Primary or monoammonium phosphate (ammonium phosphate, monobasic; ammonium diphosphate; ammonium dihydrogen phosphate), $NH_4H_2PO_4$, density 1,803. Colourless salt, readily soluble in water (368 g/l at 20°C), acid reaction. Uses: treatment of boiler feed water, specifically for sensitive high-pressure boilers as a corrective treatment (alkaline boiler steam); impregnation of candle wicks (prevention of afterglow and drops).

II. Secondary ammonium phosphate (ammonium phosphate, dibasic; diammonium hydrogen phosphate; diammonium phosphate (DAP); common ammonium phosphate), $(NH_4)_2HPO_4$, MW 132,07, density 1,619. Contains 53,75% P_2O_5 and 25,8% NH_3. Colourless, very soluble salt, 686 g/l at 20°C and 976 g/l at 60°C in water. Weakly alkaline reaction, 1% solution pH 7,62. On heating (fire) ammonia is split off and a phosphate melt is formed (flame-retardant). Uses: boiler feed water treatment, acid catalyst in pigment printing, flame retardant finishes.

Ammonium polyacrylate → Polyacrylate sizes.

Ammonium stearate, $C_{17}H_{35}COONH_4$, MW 301,50. Wax-like solid, soluble in alcohols. Use: foam generation in coating applications.

Ammonium sulphoricinoleate Yellow liquid, soluble in alcohol. → Turkey red oils.

Ammonium thiocyanate (ammonium sulphocyanide), NH_4CNS, MW 76, density 1,3. Colourless crystals, hygroscopic (deliquescent), readily soluble in water (up to 1620 g/l at 20°C), also soluble in alcohol. In aqueous (acidic) solution it forms the insoluble copper thiocyanate with copper salts, and the deep red iron (III) thiocyanate with trivalent iron salts. Uses: silk dyeing with vat leuco ester dyes; dyebath additive in copper vessels (as protection for copper-sensitive dyes); analytical detection of trivalent iron.

Ammonium thioglycolate, ammonium salt of → Thioglycolic acid.

Amorphous (Gr.: *amorphos* = shapeless), without structure or ordered arrangement. Noncrystalline in contrast to crystalline (→ Crystallite) as a highly ordered structure (see Fig.).

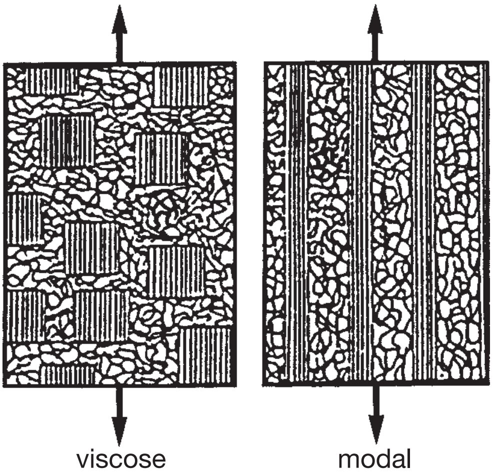


Fig.: Difference in submicroscopic structure of crystalline and amorphous areas in vicose and modal fibres.

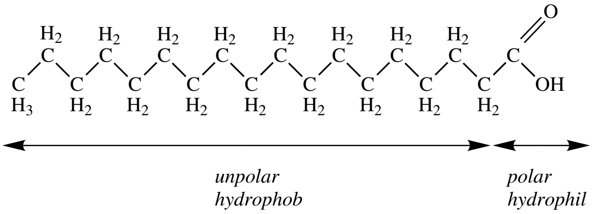
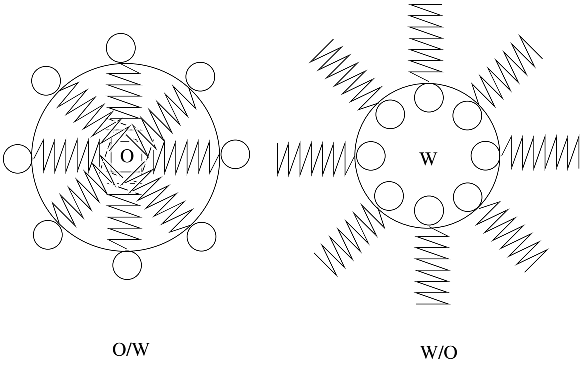
Amortisation Depreciation of value of buildings and fittings of all kinds. Amortisation rates set by taxation authorities are subject to varation → Service life of textile plant.

Amortisation of utility →: Amortisation, Service life of textile plant.

Amphiphilic Contains → Hydrophilic, (polar) and → Hydrophobic, (non-polar) molecular groups and therefore encompasses all → Surface active compounds.



In order to be able to achieve a large and stable surface of the inner phase of an oil/water emulsion system, surface active agents, so called emulsifiers, must be added. Such substances have an amphiphilic molecular construction and adsorb onto the oil/water interface. As a result, a water or oil stable emulsion film arises, which stops the droplets coalescing. It has been determined that effective emulsifiers have a small molecular volume. However the surface tension alone is not of decisive significance for the stability of the emulsion. The adsorption and orientation of emulsifiers in the oil/water interface depends on the solubility of the emulsifier in one of the two phases. In general, the emulsifier is more soluble in one phase than the other. With increasing solubility of the emulsifier, the interaction of the molecules of both phases with the emulsifier increases and there is a tendency for the two phases to separate. A surface film formed through the adsorption of the emulsifier is deformed in the direction of the phase with the higher surface tension. Therefore, the mechanical dispersion of two immiscible phases (water and oil) results in the phase with the higher surface tension being dispersed in the other phase in the form of droplets. According to Bancroft's Rule, the liquid in which the emulsifier is more soluble forms the outer phase. This means that a water soluble emulsifier is more likely to form O/W emulsions and an oil soluble emulsifier is more likely to form W/O emulsions. The adsorbed emulsifier molecule is so orientated at the interface that its hydrophobic (lipophilic) part dips into the oil and its hydrophilic (lyophilic) part dips into the water. This process can be seen in the diagram for W/O and O/W emulsions.



O/W W/O

Fig.: Orientation of the emulsifying agent molecule adsorbed at the water/oil emulsion.

Ampholyte Amphoteric electrolyte, a substance which can behave both as an acid and a base, i.e. it can donate as well as accept protons. → Zwitterions.

Ampholyte ion → Zwitterion.

Ampholytic surface-active compounds → Surface active compounds possessing two or more functional groups capable of ionization in aqueous solution which as a consequence, depending on the conditions of the medium, confer anionic or cationic properties on the product. In the broadest sense, this ionic behaviour is analogous to that of the → Amphoteric compounds.

Amphoteric The capacity to behave either as an acid or a base. A property typical of proteins and protein fibres which, due to the simultaneous presence of active amino groups ($–NH_2$) and carboxyl groups, possess the capacity to chemically bind acids and alkalies (by conversion to salts). → Ampholyte.

Amphoteric surfactants, ampholytic surfactants with several functional groups which become ionized in aqueous solution thereby giving the products an anionic or cationic character depending on the state of the medium. → Amphoteric.

AMSR Term for a solution of sodium methyl siliconate containing aluminium ions. Used for water repellent impregnation.

AMW, abbrev. for: → Average molecular weight.

Amyl alcohol (fusel oil, pentanol), $C_5H_{11}OH$, MW 88, density 0,82, boiling point 129–131°C, Fl.p. approx. 44°C. Mixture of two isomeric amyl alcohols. Oily liquid with highly flammable properties. Evaporation number 72. Uses: additive to process liquors of all kinds as a defoamer; spotting agent (for varnish, oil and tar stains, etc.); solvent for cationic dyes.

Amylases, (Gr.: *amylum* = starch) → Enzymes of the polyase family from plants, animals and bacteria (malt, pancreatic and bacterial diastases) which break down starch via dextrine into soluble maltose (starch degradation). Mixtures with lipases and proteases are also used in starch desizing agents. All amylases are only effective in the presence of monovalent anions

basis	optimum pH	optimum temperature
bacterial amylase	6,8	75 ˚C
pancreatic amylase	6,8	55 ˚C
malt amylase	4,5–5,5	60 ˚C

Tab.: Optimum effects of various amylases.

(e.g. chlorine ions). Not to be confused with → Amylose. Amylases achieve their optimum efficiency, like all enzymes, under specific conditions of temperature and pH (see Table).

Amylolytic Property of starch-decomposing → Enzymes

Amylopectin Constituent of the cell substance of starch grains (→ Starch).

Amylose The internal constituent of starch grains (→ Starch).

Anaerobic bacteria are bacteria which can live in the absence of oxygen (so-called anaerobes) such as typical saprogens which can also damage textiles. Sewage sludge can be reduced to hydrocarbons (especially methane, CH_4) in digestion towers with anaerobic bacteria under the exclusion of oxygen. Opposite term → Aerobic bacteria.

Anaerobic biodegradation Biological decomposition in the absence of oxygen. The question of the degree of biodegradation of a surface active agent in the environment points to the fact that a significant proportion of surfactants found in waste water is already eliminated by adsorption in the mechanical cleaning stage with so called "primary sludge". The slurry (primary and overflow sludge from the biodegradation stage) usually ends up in the settling tanks, where it is treated anaerobically and finally deposited, incinerated or used as a fertiliser. In many of the areas of the environment affected by surface active agents e.g. (sewage plant) settling plants, septic tanks for domestic sewage, soil and sometimes river sediments, anaerobic degradation plays an important role in the whereabouts of these substances in the environment. Doubtless, from an ecological standpoint, there exists the additional safeguard if surfactants are degraded not only aerobically but also anaerobically; thus it is assured that decomposition into natural end products can occur under all microbiological conditions.

Anaerobic respiration: organic substances are oxidised to form carbon dioxide, carbon dioxide is reduced to methane (methane fermentation):

$$CH_2O + {}^1/_2\,CO_2 \rightarrow CO_2 + {}^1/_2\,CH_4$$

or

$$CH_2O \rightarrow {}^1/_2\,CO_2 + {}^1/_2\,CH_4$$

With nitrate or sulphate:

$$2\,CH_2O + NO_3^- + 2\,H^+ \rightarrow 2\,CO_2 + NH_4^+ + H_2O$$

$$2\,CH_2O + SO_4^{2-} + 2\,H^+ \rightarrow 2\,CO_2 + H_2S + 2\,H_2O$$

Decomposition is also a multi-stage process in the anaerobic milieu in which many groups of bacteria partake consecutively. In particular in the settling towers, carbon dioxide and methane, along with a relatively small amount of biomass, form the main end products of anaerobic decomposition. The final decomposition of test substances can be followed from the generation of these gases. Admittedly, there exists at the present time no generally used standard test methodology, nevertheless the measurements for a series of surfactants are available on the basis of published test methods. Whilst the available simulation test, valid only for ^{14}C labelled compounds, represents a simple model of the sewage decomposition stage, the "ECOTOC-Screening

Tab.: Anaerobic decomposition behaviour of some surfactants under screening or simulation conditions.

Test on Anaerobic Degradability" allows for the testing of a wide range of substances. Just as with aerobic screening tests, a positive decomposition result can definitely be carried over into practice on account of the stringent requirements of this test (Table).

For a long time, the advantages (Biogas production, no energy consuming aeration and a small slurry yield) were unconvincing in comparison with the disadvantages (a supposedly small substrate spectrum, little slurry activity, an unstable process and small reactor capacity). The main drawback lies in the long generation times of anaerobic micro-organisms in comparison with aerobic bacteria. Through the fixation of the anaerobic biomass e.g. on sand, plastic beads or highly porous glass, it has become possible to uncouple the time spent in the decomposition reactor by the biomass from that spent by the substrate. Thus, high space/time yields are also achieved during anaerobic decomposition. Owing to the different optimum pH values of the micro-organisms involved in anaerobic decomposition, further optimisation was achieved by the use of 2 stage plants.

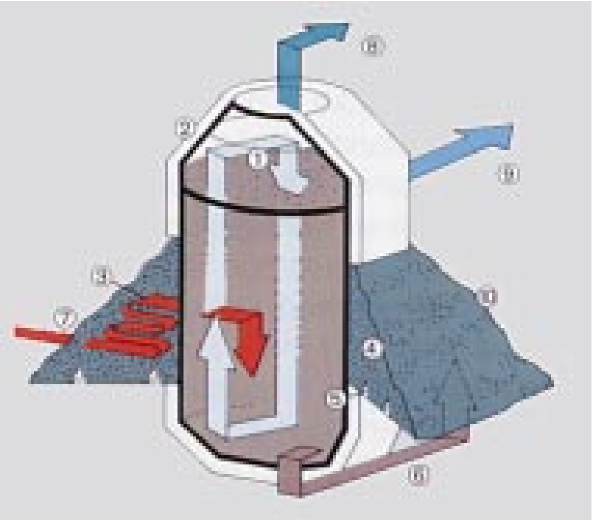

Fig.: Fermenter for anaerobic effluent purification (Hoechst).
1 = movement by pulsating circulation; 2 = insulation against hear radication; 3 = heat exchanger; 4 = heat supply by heat transfer from compost source; 5 = stack effect aeration; 6 = sludge discharge; 7 = effluent (liquid phase); 8 = biogas; 9 = purified effluent; 10 = compost.

Thus, today the anaerobic purification of industrial effluent is proving to be of interest. The fermenter, represented in the diagram, is particularly suitable for effluent which contains predominantly acetic and formic acids. The apparatus has a purification capacity of 16.4 tonne CSB/day (Chemical acid requirement/day) and produces up to 11000 Nm^3 Biogas with a methane content of 53%.

Various micro-organisms are involved in the anaerobic decomposition of organic substances. The first step in decomposition, which is mostly managed by fakultativen anaerobes, leads to the formation of fatty acids (Acidogenesis). With further decomposition acetic acid appears (Acetogenesis) along with carbon dioxide and hydrogen. The micro-organisms involved up to this stage of decomposition favour a slightly acidic environment. In the third stage of decomposition, Methanogenesis, acetic acid is broken down into methane and carbon dioxide on the one hand and on the other hand a portion of the carbon dioxide is reduced to methane by the hydrogen that has been formed. The methane forming bacteria function best in a neutral environment. Anaerobic decomposition is purposely carried out at 35°C and without light. →: Aerobic degradation; Methanation in the biogas process.

Anaerobic fermentation Anaerobic bacteria can reduce sewage sludge to hydrocarbons, particularly methane (CH_4), under exclusion of oxygen in digestion towers.

Analog digital control Hybrid control, or analog to digital control, is referred to when a → Digital controller operates as a master controller on an underlying analog cycle sequence. The dynamic behaviour is determined by an analog control circuit, to which a digital correction value is connected in order to achieve a high degree of long-term constancy.

Analogue computer A computer that performs computations (e.g. summation, multiplication and integration) by manipulating continuously varying physical quantities, commonly voltage and time. The variables are analogues of the quantities involved in the computation. Used in the design of computer models for dynamic systems.

Analogue displays Electrical equipment (direct reading instruments) which function according to the analogue principle. Physical systems are thus analagous to each other if they can be described by the same mathematical relationship.

Analogue output Functional part of the input and output system of a process control computer. Used to transmit signals to an output. The signals may be further modified by analogue processes and are suitable for use in set value transmitters, analogue recorders, regulating units etc.

Analogue to digital converter (ADC). Encoder, functional unit for the conversion of analogue signals into digital signals.

Analysis The breaking down of chemical compounds resp. the identification of individual components, either according to their type = qualitative (e.g. from hydrochloric acid HCl into hydrogen and chlorine) or their amount = quantitative (e.g. from 36,50 g HCl into 1,01 g H + 35,5 g Cl). Analysis involves the application of chemical procedures, frequently in the presence of an indicator (→ Titration) in which precipitates and colour reactions are obtained that are characteristic for each element. The various analytical procedures can be subdivided into e.g. →: Gravimetric analysis, Colorimetry, Complexometry, Volumetric analysis, etc.

Anaphe silk (African silk), → Wild silk, produced by a silkworm of the Anaphe family (Africa) which feeds on fig leaves. Groups of these caterpillars build large nests inside which they make their individual cocoons. The nests and cocoons are made entirely from silk. Anaphe silk is very fine and is processed into bourrette and schappe silk.

Anatase One of the three naturally occurring forms of → Titanium dioxide. Used as a white pigment in textile printing.

Anatolian carpets (Turk.: *Ana-doli* = eastern country). Oriental carpets originating from the interior of Asia Minor. They are mostly based on large geometric designs with highly stylized plant motifs in vivid, fresh colours. Figural motifs are absent. The principal regional varieties are: Bergama, Brussa, Dermirschi, Ghiordes, Hereke, Kayseri, Konya, Kula, Ladik, Mekri, Milas, Mudjur, Nigde, Panderma and Yuruk carpets.

Anchor-coating Used with woven cord fabrics for anchoring the pile on the underside in order to prevent the yarn loops from being pulled out when cut open, by means of stiffening agents which are applied on the back by brush.

Andanthron → Anthrone.

Anellation (Lat.: *anellus* = small ring). The term is used e.g. in dye chemistry, to describe anellated carbonyl compounds and anellated ring systems (synonym for condensed ring systems), when 2 carbon atoms lying next to each other together form part of 2 neighbouring rings, e.g. as in → Naphthalene and anthracene.

Anemometer (Gr. *anemos* = wind). Measuring instrument for air velocity, air quantity and gas flow.

Angle blade Used for applying the lacquer layer in → Screen production.

Angora Woven or knitted fabrics produced from angora wool. Fabrics composed solely of blends containing these animal hairs are also often falsely described as angora. Used for high quality outerwear, knitwear and hand-knitted articles.

Angora goat hair → Mohair.

Angora rabbit hair Hair of the angora rabbit, cultivated in Europe and East Asia, can be counted amongst the finest of the → Animal hairs. The annual yield amounts to 250 g of hair per rabbit from 3 to 4 shearings. The hair is mostly pure white, lustrous and silk-like (specific gravity 1,1–1,2). The coarse hair content, which is responsible for the fluff, amounts to approx. 2,2%. Hair thickness approx. 12,7 µm, tensile strength approx. 20 cN/tex., elongation at break approx. 38%, thermal retentivity approx. 50–70%. The fibres are obtained by shearing or combing. Angora hair has a high thermal retentivity due to the internal air-containing medulla (Fig.1) and is also very soft, light and free of pigment.

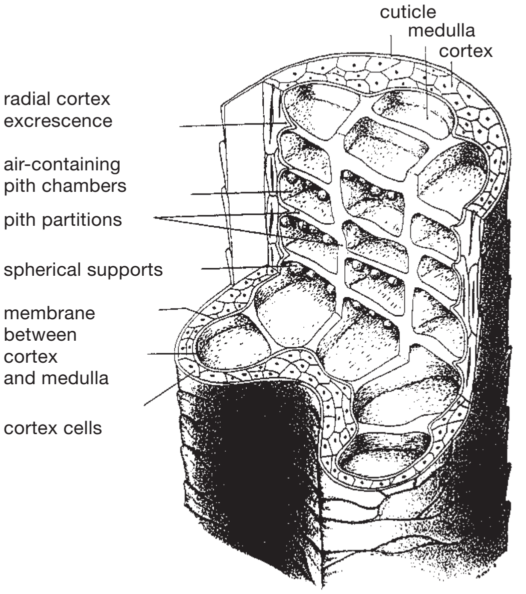

Fig. 1: Angora fibre morphology.

For technological reasons, these fibres are frequently spun with wool, a proportion of synthetic fibre or with cotton. Chemically, angora is a keratin fibre. The polypeptide chains of angora keratin are composed of approx. 20 different amino acids (see Table).

general formula of aminoacid	$HOO\text{–}\underset{NH_2}{CH}\text{–}R$	formula of the residue R	angora aminoacid content [%]
cystine	$-CH_2-S-S-CH_2-CH(NH_2)-COOH$		14,96
glutamic acid	$-CH_2-CH_2-COOH$		13,56
arginine	$-CH_2-CH_2-CH_2-NH-\underset{\overset{\|}{NH}}{C}-NH_2$		10,33

tyrosine	$-CH_2-C_6H_4-OH$		3,78
valine	$-CH-(CH_3)_2$		3,50
phenylalanine	$-CH_2-C_6H_5$		3,08
alanine	$-CH_3$		3,01
isoleucine	$-CH(CH_3)-CH_2-CH_3$		2,71
histidine			2,65
citrulline	$-CH_2-CH_2-CH_2-NHCONH_{2-}$		0,27
methionine	$-CH_2-CH_2-S-CH_3$		0,00

Tab.: Aminoacid composition of angora hairs.

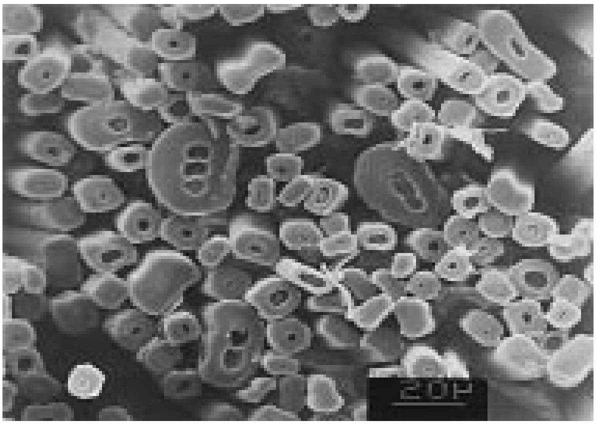

Fig. 2: Angora fibres in cross-section (magnified approx. 500 times).

Angora fibres consist of 3 main components (Fig. 1):

1. Cuticle: 0,3–0,4 μm thick, makes up 10% of the fibre weight. The typical arrangement of scales on the fibre surface can be described as chevron-structured (Fig. 3); they have a protective function, i.e. to prevent the penetration of foreign matter into the fibre interior.
2. Cortex: composed of microfibrils and matrix.
3. Medulla: depending on fibre type, the medulla is represented more or less frequently. It can be continuous or discontinuous and occurs only in fibres with a $\varnothing > 10\ \mu$m. In correlation with the diameter, the medullation increases in form so that the fibre can be marked with one or several rows.

In cross-section the fibres do not have a round, but an H, V or Y shape (Fig. 2). The longitudinal section (Fig. 3) reveals the scale structure of the angora hair.

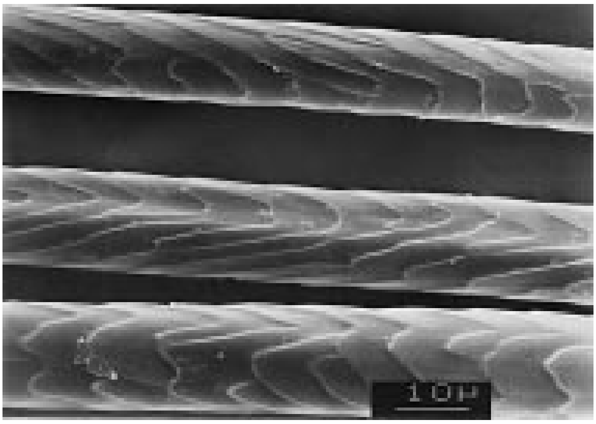

Fig. 3: Longitudinal view of angora fibres (magnified approx. 1000 times).

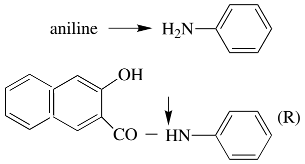
Ångström (Å), Ångström unit; 1 Å = 10^{-10} m. Named after the Swedish physicist A. J. Ångström (1814–1874). A unit formerly in common usage within the range from 1 Å to approx. 1000 Å principally for the measurement of molecular and fine internal fibre structures. Nowadays replaced in the metric system by the nm = 10^{-9} m, or the μm = 10^{-6} m.

Anhydride, water-free compound, e.g. from methanol CH_3OH = methyl ether $(CH_3)_2O$. The term is mainly used today for → acid anhydrides.

Anhydrous phosphates Identical with → Phosphate, condensed.

Anilides are derived from → Aniline, in which one hydrogen atom of the amide group is replaced by an organic acid group, e.g.:



(naphthol AS base type).

Aniline (aniline oil, phenylamine, aminobenzene), $C_6H_5NH_2$, MW 93, density 1,0265, b.p. 182°C. A constituent of coal-tar. In the pure state, a colourless, oily, highly hygroscopic liquid with a sweetish odour which turns brown on exposure to air. Hazardous blood and nerve poison which can be absorbed through the skin and via the lungs (MAK value = 8 mg/m^3, which corresponds to the odour threshold). Aniline is a weak base and forms salts with strong acids, readily soluble in aqueous solutions and miscible in all proportions with alcohol, ether and benzene. Aniline is the parent substance of the first synthetic dye (1856).

Aniline black (single-bath black, oxidation black, steam black, hanging black, Prud'homme black, prussiate black, Koechlin's black, diphenyl black). Insoluble oxidation dye from → Aniline, produced on the fibre (mostly cotton, less frequently wool/cotton unions) from individual soluble components. Chlorates and chromates are used as oxidizing agents and ferrocyanides, ammonium vanadate and copper salts as oxygen carriers. During development of the black, acid is liberated which, under inappropriate processing conditions, can cause damage to the fibre. Aniline black is one of the most beautiful blacks and is unsurpassed in depth and bloom. Shifts in tone towards green can occur on storage. Process variants:

I. Single-bath application (single-bath black) of a mixture of dissolved aniline salt, mineral acid and a chromium salt. Aniline black is gradually built-up on the fibre during the course of dyeing.

II. By subsequent oxidation (oxidation black, hanging black) of goods, impregnated with aniline salt, oxidizing agent, hygroscopic agent and oxygen carrier using dichromate/sulphuric acid.

III. By subsequent steam development (steam black) of goods, padded with aniline salt, yellow prussiate of soda and sodium chlorate. Only used for textile printing (in resist printing).

IV. Diphenyl black, produced by padding the black base followed by oxidation with sodium chlorate/oxygen carrier. Diphenyl black is free of the disadvantages associated with methods I–III above, namely, fibre damage and "greening" on storage of dyed goods.

With the exception of variant III, the other methods are no longer of any practical significance. A full handle accompanied by an increase in weight of up to approx. 10% is typical for goods dyed with aniline black. It is mainly used as the cheapest black with the highest fastness on cotton, dyed in hank form or in the piece. Its importance has now declined, however, in favour of sulphur black. Other applications on hank yarns, piece goods and knitgoods for stockings, linings and umbrella fabrics. Direct or sulphur dyeings are frequently overdyed with aniline black to achieve higher rub fastness.

Aniline black fastness properties Aniline black has excellent all-round fastness properties (including colour fastness to light, air, weathering, washing and alkaline perspiration). It is however sensitive to chlorine, which causes the shade to turn brownish. Aniline black produces blacks of the highest fastness on cotton. Single-bath black: has lower fastness properties, especially the colour fastness to rubbing and "greening" during wear (exception: diphenyl black).

Aniline black on the fibre, tests for →: Paraffin test for dyeings on cellulosic and protein fibres; Chlorine test for dyeings on cellulosic fibres; Chrome test for dyeings.

Aniline dyes Any of a large class of synthetic dyes made from intermediates based on or made from aniline. The term is still in use for individual brands.

Aniline salt (aniline hydrochloride), $C_6H_5NH_2$–HCl, MW 129,5. Colourless, large crystalline plates or lumps which turn dark green on prolonged storage, m.p. 192°C, readily soluble in water and alcohol. Often contains free hydrochloric acid. May be identified by the production of a green colour with methyl violet test paper.

Aniline sulphate test, for the identification of hemp resp. jute fibres: Place the fibres in a 1:20 solution of aniline sulphate (on a boiling water bath) for 20 min., rinse and dry. The fibres are stained a) pale yellow = hemp, or b) intense golden yellow = jute. Pure cellulosic fibres (including linen) remain unstained.

Animal colloids Stiffening agents such as →: Glue, Gelatine, Casein, used for sizes and finishes. → Colloids.

Animal fibres → Natural protein fibres.

Animal glue → Glue.

Animal hair fibres Angora, cashmere, mohair and other fine animal hair fibres (→ Natural protein fibres) occupy a significant place among textile fibres and play a considerable role in the fashion sector (Fig. 1).

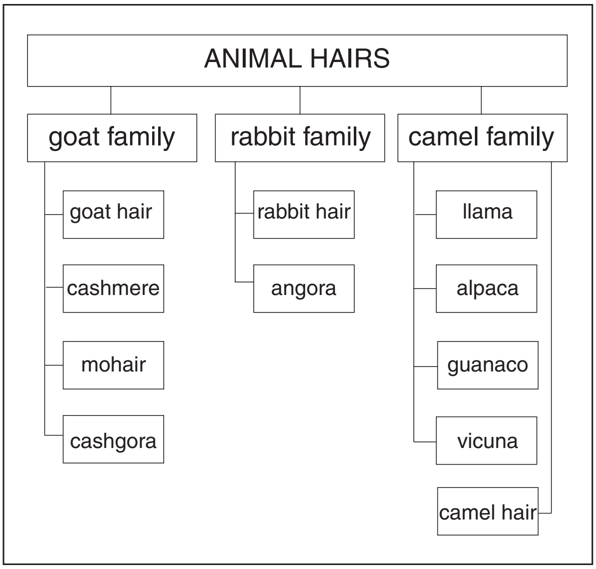


Fig. 1: Survey of the best known animal hairs which play a role in the textile sector.

In relation to world textile fibre production, however, the proportion of rarer animal hair fibres (excluding wool and silk) is very small (Table 1). The incentive to use these "luxury fibres" (rarer textile fibres) is due, on the one hand, to the commercial advantages of these materials such as, e.g. extreme softness, fineness and consequent low weight, as well as their rarity value and relative freedom from competition since fine animal hair fibres are of limited availability and they are able to justify a high price because of the general difficulties involved in their production. Moreover, a continuous trend towards the use of natural fibres in the apparel and home textiles sectors has been apparent for some years now. World production of the rarer animal hair fibres, as well as some specific data on these fibres, is given in Table 2.

	production x 1000 tonnes	percentage [%]
cotton	18 122	49,55
synthetic fibres	13 758	37,62
regenerated cellulose fibres	2 833	7,75
wool	1 753	4,79
silk	63	0,17
rare animal hairs	42	0,12
total	36 571	100

Tab. 1: World production of textile fibres (1987).

Tab. 2: World production of high-grade animal hairs (1987).
** varies with the situation on the international currency market.*

I. Rabbit hairs: → Angora rabbit hair is mainly used for high quality outerwear, knitwear, and hand-knitted articles. In the Federal German Republic the fibres are obtained by shearing and in France by plucking; the fibres are pigment-free, fine and supple, light and lofty. Because of their high warmth retention they may be beneficial to persons suffering from rheumatism.

II. Goat hairs: cashmere (cashmere goat) is used for scarves, blankets and fine outerwear fabrics. Depending on the provenance, a distinction is made between natural white, grey-beige, and brown cashmere, of which natural white cashmere is the rarest and most expensive quality. After combing, sorting, blending and washing, the long coarse hairs are separated from the fine downy hairs by means of a laborious depilatory procedure and the latter are further processed. The depilation of cashmere is based on a modified carding and combing process which often reduces the weight of the fibre by more than half. → Mohair (angora goat), which is obtained by shearing, is used in high quality wovens and knits and, in the form of worsted materials, for travel rugs, ladies' outerwear, and hand-knitting yarns in blends with wool. Mohair is a cool fibre which is comfortable in wear, crease-resistant, and possesses a silk-like lustre. Kid mohair, which is the fine wool of the young angora goat, is highly favoured in lightweight tropical clothing. → Cashgora is hair from the downy undercoat of the cashgora goat which was originally produced by crossbreeding female cashmere and male angora goats in New Zealand.

III. Llama-type fibres: →: Alpaca and llama are likewise obtained by shearing and are mainly used in their natural colours of white, cream, beige-brown and grey-black, for the production of cloths, apparel fabrics, high quality lightweight blankets and knitgoods. Vicuna and guanaco are the rarest animal hair fibres of this group and are supremely fine and soft. They are used on a limited scale in the production of high quality textiles.

IV. → Camel hair: the camel has an outer coat of dark, coarse hairs that may reach 30 cm or more in length, which are difficult to spin.These fibres are used in felts and blankets. Beneath the outer coat is a downy undercoat of fine soft hair 2.5–15 cm long. This camel hair undercoat is the really valuable part of the fleece and is as soft and fine as merino wool. These fibres are used for blankets, ladies' outerwear, loden and coat fabrics either alone or in blends with wool.

Fine animal hair fibres are frequently used in blends with wool, silk, and/or synthetic fibres to achieve particular effects with regard to shade, softness, lustre and handle, as well as improved technological properties and strength.

The growing interest of the consumer in high quality textiles produced from fine animal hair fibres and their blends, as well as the desire for labelling such

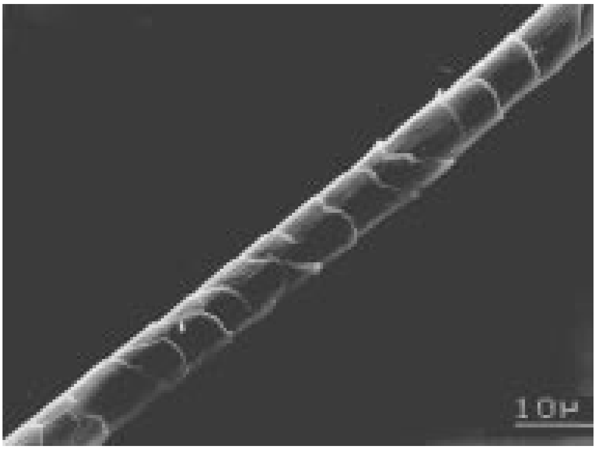

Fig. 2: REM photograph of a vicuna hair.

textiles to distinguish between wool and the higher quality animal hair fibres, was decisive in encouraging research aimed at the development of unambiguous analytical methods capable of characterizing these fibres. Fabrics containing blends of fine animal hair fibres are associated with higher quality textiles by the consumer. Blending of pure virgin wool with up to 20% of fine animal hair fibres is permitted by the International Wool Secretariate for the purposes of the Woolmark having regard to country-specific circumstances.

The application of electron microscopy (Figs. 2–4), chemical protein methods, as well as DNA analysis have provided the means for reliable identification of rare fibres as well their finishing treatments, and made the precise characterization of such textiles possible. Increasing efforts to breed finer and finer lambswool and merino qualities could pose a competitive threat to highly expensive, fine animal hair fibre varieties in future.

Animal hair fibres are mainly composed of keratin, a mixture of closely related structurally-bound proteins with a high cystine content. The keratins are localized in the exocuticle and macrofibrils of the cortex. From its morphological structure, the merino wool fibre is representative of a typically fine wool quality; it has a thin cuticle, contains the cortex as its main component, and the fibres are not medullated. By contrast, the fine animal hair fibres have a different morphology; they are often highly medullated to a greater or lesser degree, and the cuticle can consist of several layers.

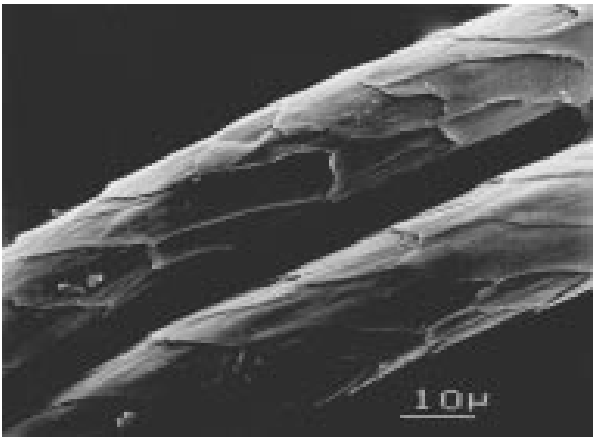

Fig. 3: REM photograph of camel hairs.

The proportion of medullae influences the cortex structure and, as a consequence, also the hair properties. Medullated hairs are stiffer than unmedullated ones, and exhibit variable dyeing behaviour. The fibre diameter, shape of cross-section, surface structure (scale structure) and the dyeing behaviour of animal hair fibres have an influence on the shade obtained in dyeing.

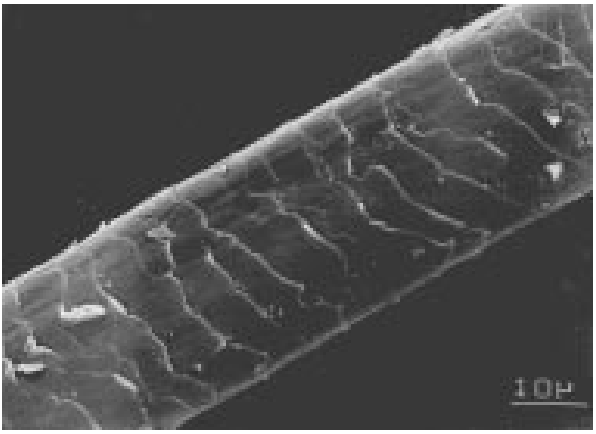

Fig. 4: REM photograph of an alpaca hair.

Photomicrographs of fine animal hair fibres clearly reveal the different fibre structures which must be responsible for their variable behaviour in finishing processes. Thus cashmere has a similar structure to wool. Mohair is partly medullated and oval to round in cross-section. The fibre has a lustrous surface and appears deeper in shade than wool after dyeing due to its surface reflection. The air-filled medullations in angora produce a different light refraction than wool (optical phenomenon) as a result of which light is reflected from the air enclosed in the medullated regions. As a result, the fibres appear much paler after dyeing in comparison to those without medullae. Fibres of this type, which have very marked medullae, contain insufficient cortex to take up adequate amounts of dye. The more or less large proportion of coarse and short bristly hairs, which are difficult to process and dye, and which, as a rule, remain paler in shade after dyeing, must also be taken into consideration. On the other hand, however, even the short bristly hairs (e.g. mohair or reindeer hair) are also used to advantage in blends for the production of special effects (Flensberg and Hammers).

Animalization Treatment to confer wool-like properties on regenerated cellulosic fibres with the aim of developing an affinity for wool dyes. Achieved by making suitable additions to the spinning solution (e.g. proteins, glue, casein, gelatine) or, alternatively, through the addition of, or an aftertreatment with, ethyleneimine and finally carbon disulphide (CS_2). Another technique involves a causticizing treatment with a 25% caustic soda solution containing an addition of β-aminoethylsulphuric acid.

Anionic Salts dissociate in water to give a positively charged hydrated cation and a negatively charged hydrated anion so that such solutions are electrically conductive. If, in the presence of an anode or cathode (direct current) the anions and cations migrate, they are active, i.e. they have an affinity for each of the opposite poles: anions migrate to the positively charged pole and are therefore anion-active (anionic). Opposite term → Cationic.

Anionic-cationic compounds → Electrically neutral compounds.

Anionic dyes → Dye ions.

Anionic exchanger → Ion exchanger.

Anionic retarders are retarding agents with dye affinity and are used in the dyeing of polyacrylonitrile fibres with cationic dyes. → Retarders.

Anionics contraction for anionic active → Surfactants (Anionic surface active agents).

Anionic surface-active compounds → Surface-active compounds, having one or several functional groups which ionize in aqueous solution to form negatively charged organic ions that are responsible for surface-activity.

Anionic surfactants Surfactants that are anion-active → Surfactants.

Anions → Ions.

Anisomorphic (Greek: an = not, isos = equal, morphe = shape/form), non-uniformly configured, in contrast to → Isomorphic.

Anisotropic (Gr.: *an* = not, *isos* = equal, *tropos* = direction), having different properties in different directions, e.g. the capacity of a dye in solution to dye only the fibre surface or only certain internal regions of the fibre due to various reasons (fibre structure, fibre damage, dye characteristics, etc.). See also → Isotropic.

Annealing Common term for the effect of moist heat on wool fabric. After-stretching of synthetic fibres and monofils mainly at high temperature (different depending on fibre type, use etc., dry, in steam, hot water etc.), aimed at improving orientation, as is particularly important for tyre cord ply yarns, e.g. by increased tear strength (in the case of polyamide filaments from about 44 to 70–80 cN/tex) and reduced elongation at break (from about 22 to 12%).

Anode →: Electrode; Electrolysis.

Anodic oxidation A problem encountered e.g. in yarn package dyeing machines. Metal dye tubes or package spindles become oxidized through the anodic action of two different metals used in the dyeing machine construction, thus causing a higher consumption of reducing agent in vat dyeing or premature oxidation of vat dyes. Rarely occurs nowadays due to the fact that dyeing machines are, without exception, constructed from stainless steel.

Anomaloscope An optical instrument for the testing and classification of anomalous and defective colour vision. It consists, in principle, of a direct-vision spectroscope. The examination involves the mixing of two spectral colours on an illuminated matt surface and matching the result with a third; i.e. the standard anomaloscope presents two halves of a circular field in contact. The lower half of the field consists of relatively pure yellow light connected to a dial which varies *brightness* only. The upper half of the field is filled with a mixture of two lights, red and green, the ratio of which can be varied by a second dial all the way from pure red to pure green. The testee is asked to obtain a perfect match between the two halves. The respective deviation in the amount of yellow used to obtain a match indicates the degree of anomalous colour vision. The anomaloscope provides reliable information on colour discrimination ability and suitability for colour matching in dyeing, etc. (screening test for new entrants to the colour using industries, career advice, etc.).

Anomalous colour vision (colour anomaly), congenital → Defective colour vision, which manifests itself as deviant → Colour vision. Two main types of anomalous colour vision can be distinguished: Individuals with a weakened sensitivity to mid-band wavelengths (green) are described as deuteranomalous trichromats and those with a weakened sensitivity to long wavelengths (red) are described as protanomalous trichromats. In colour matching work, the former type require more green to produce a colour match with yellow than individuals with normal vision whilst the latter type require more red.

Anormal fibre (wool) Originating from sick animals, displays anomalous thickening and necking.

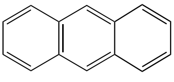
ANSI, abbrev. for: American National Standards Institute, New York → Technical and professional organizations.

ANS unit A colour difference unit in the → Colour difference formula of Adams, Nickerson and Stultz.

Antagonism A term used in environmental protection to describe the total effect of two harmful pollutants which is less than the sum of the individual pollutants. → Antagonistic.

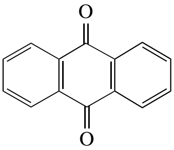
Antagonistic (Gr.), contrary, the combined effect of mutually opposed influences. Antagonistic effects are encountered in textile finishing when, e.g. water-repellent finishes are applied to textiles that are not free of wetting agents.

Anthracene is a linear condensed homocyclic hydrocarbon. It forms colourless plate-like crystals which sublime readily and have a blue-violet fluorescence. Used in the manufacture of → Anthraquinone, the parent substance of many synthetic dyestuffs.



Anthranol → Over-reduction.

Anthraquinone, $C_{14}H_8O_2$, MW 208. Oxidation product of → Anthracene. Outstanding reduction catalyst which increases the activity of reduction products (sulphoxylates). Used in the discharge printing of cationic dyes, naphthols, mordant dyes and bromoindigo.

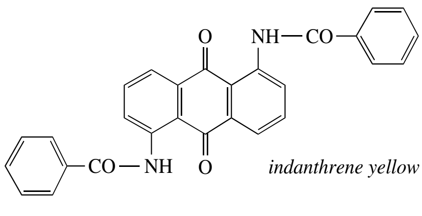


Anthraquinone dyes are derived from the parent compound → Anthraquinone, and belong to the quinonoid class of dyes. Simple anthraquinone derivatives are coloured when at least two further donor substituents (–OH, –NH_2) are present in addition to the basic anthraquinone structure. The more donor substituents that are available, the greater the adsorption of light in the long wave region of the spectrum. Quinone dyes based on the parent anthraquinone structure include disperse and mordant dyes, water-soluble quinone dyes, quinonoid vat dyes (Indanthren), acid, direct and reactive dyes.

The following systematic classification of some historically important anthraquinone dyes also includes details concerning their derivation:

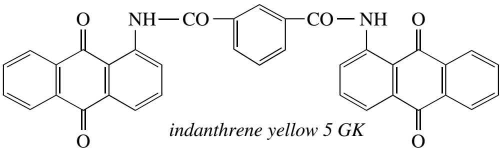
I. Chain-substituted and chain-linked anthraquinone derivatives:

a) Acylaminoanthraquinones:
- C.I. 61725 (F. Nölting, W. Wortmann, 1906; J. Deinet, 1909); Bayer; from the condensation of 1,5-diaminoanthraquinone with benzoyl chloride.



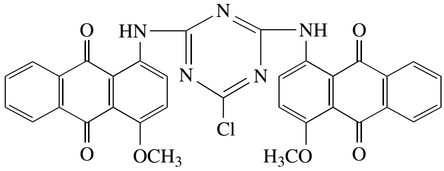
indanthrene yellow GK

- C.I. 65 410 (K.-H. Mayer, H. Hopff, A. Krause, 1925); BASF; from the acylation of 1-amino-anthraquinone with isophthaloyl chloride in dichlorobenzene at 145°C.



indanthrene yellow 5 GK

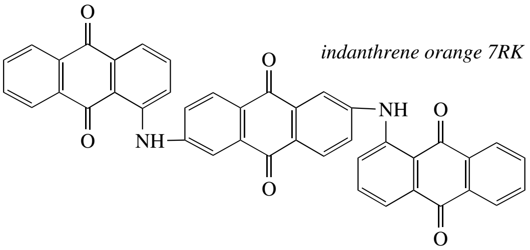
b) Anthraquinonylaminotriazine:
- C.I. 65 705 (1921); Ciba; from the condensation of cyanuric chloride with 2 mol. 1-amino-4-methoxy-anthraquinone.



cibanon orange 6R

- C.I. 65 710. Cibanon Red G. Chemical structure as for C.I. 65705 above but with an NH_2 group attached to the cyanuric ring in place of chlorine.

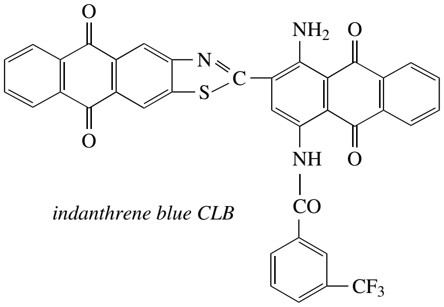
c) Anthraquinonylamine or anthrimide:
- C.I. 65 205 (M.-H. Isler, F. Kacer, 1907); BASF; condensation of 2,6-dichloroanthraquinone with 2 mol. 1-aminoanthraquinone in the presence of cuprous chloride and sodium acetate in nitrobenzene solution.



indanthrene orange 7RK

II. Derivatives of anthraquinone with a fused ring structure:

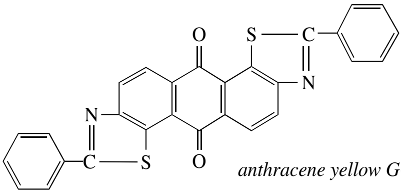
a) Anthraquinone-thiazole:
- C.I. 67 110 (H. Schlichenmaier, L. Berlin, E. Berthold, 1938); condensation of 1-amino-4-nitro-2-anthraquinonecarboxylic acid with 2-amino-3-chloroanthraquinone. From the mercaptan, cyclize, reduce and acylate with m-trifluoromethylbenzoyl fluoride.



indanthrene blue CLB

- C.I. 67 300 (M.-H. Isler and F. Kacer, 1912); BASF,

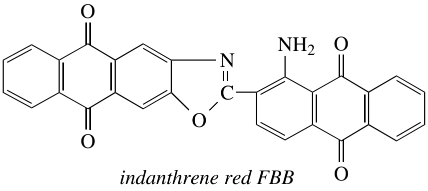
1. Reflux 2,6-diaminoanthraquinone, benzotrichloride and sulphur in naphthalene.
2. Condense 2,6-diamino-1,5-dimercaptoanthraquinone with benzaldehyde in sulphuric acid.
3. Condense 2,6-diamino-1,5-dichloroanthraquinone with benzaldehyde and sulphur.
4. Convert 2,6-dibenzamidoanthraquinone to the iminochloride (2,6-bis (α-chlorobenzylideneamino) anthraquinone), then sulphurize with sulphur and naphthalene or with aqueous sodium sulphhydrate and close the thiazole ring with chlorosulphonic acid.



anthracene yellow GC

(b) Anthraquinone-oxazole:

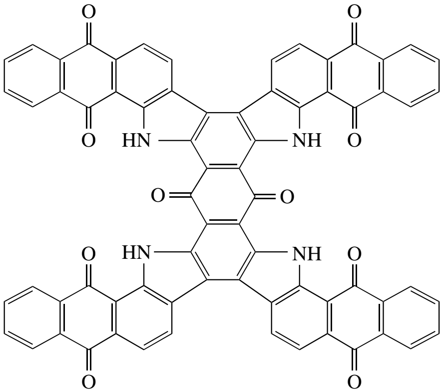
- C.I. 67 000 (M.-A. Kunz, G. von Rosenberg, E. Goffarjé, 1926); condensation of 1-nitro-2-anthraquinonecarbonylchloride with 2-amino-3-hydroxyanthraquinone in o-dichlorobenzene (pyridine, 140°C, 5 h) to the carbonamide; oxazole ring closure in 90% sulphuric acid, 90–105°C, 2 h. Substitution of the nitro group in 15% ammonia at 125°C, 12 h.



indanthrene red FBB

c) Anthraquinone-carbazole:

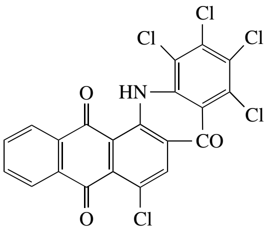
- C.I. 71 050 (E. Hepp, Frobenius, 1911); condensation of 4 mol. 1-aminoanthraquinone with 1,4,5,8-tetrachloroanthraquinone in the presence of copper and sodium carbonate in nitrobenzene at 205°C, 36 h. Cyclization of the pentanthrimide so formed with aluminium chloride and sodium chloride at 160°C, 2–3 h.



indanthrene khaki GG

d) Anthraquinone-acridone:

- C.I. 67 900 (I.G. 1931); conversion of 2-methyl-1-nitroanthraquinone to 1-amino-2-anthraquinonecarboxylic acid, condensation with aniline, cyclization and chlorination.

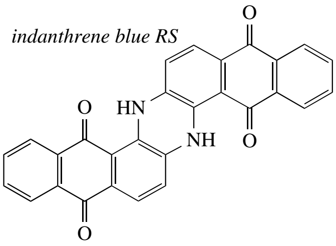


indanthrene brilliant pink BBL

e) Anthraquinone-N-hydroazine or indanthrone:

- C.I. 69 800 (R. Bohn, 1901); BASF.

1. 2-aminoanthraquinone is treated with potassium hydroxide in the presence of KNO_3, $KClO_3$, glucose or a salt of an organic acid such as potassium formate or acetate or a mixture of the two.
2. 2-aminoanthraquinone is treated with potassium hydroxide in the presence of ethanol and the mixture exposed to air.
3. Condensation of 1-amino-2-bromoanthraquinone in the presence of $CuCl_2$.
4. Reduction of 8-nitro-1-anthraquinonesulphonic acid to 8-hydroxylamino-1-anthraquinonesulphonic acid. Conversion to indanthrone disulphonic acid followed by desulphonation.

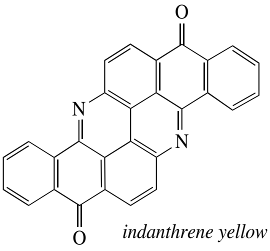


indanthrene blue RS

f) Flavanthrone:

– C.I. 70 600 (R. Bohn, 1901); BASF.

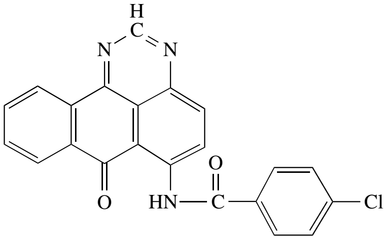
1. Treatment of 2-aminoanthraquinone in nitrobenzene with titanium tetrachloride or antimony pentachloride at 100–175°C.
2. Treatment of 2-aminoanthraquinone with potassium hydroxide in the presence of an oxidizing agent.
3. Conversion of 2,2´-biphenyldiamine into the diphthalimido derivative. Heat with aluminium chloride and cyclize with sulphuric acid.



indanthrene yellow G

g) Anthrapyrimidine:

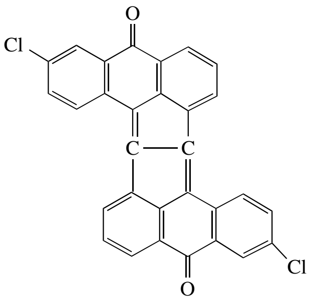
– C.I. 68 400 (M. Kunz, K. Köberle, 1931); I.G. Ludwigshafen; acylation of 4-amino-1,9-anthrapyrimidine with p-chlorobenzoyl chloride in the presence of pyridine.



indanthrene yellow 7 GK

h) Acedianthrone:

– C.I. 59 500 (I.G., 1930); treatment of 2-chloroanthrone with glyoxal sulphate, fusion with alcoholic potassium hydroxide and treatment with sulphuric acid.



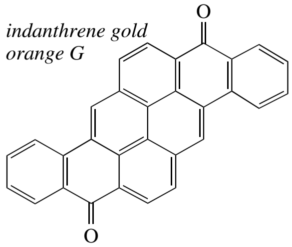
indanthrene red brown RR

III. Anthraquinonoid dyes with a pyrene structure:

a) Pyranthrone:

– C.I. 59 700 (R.-H. Scholl, 1905).

1. Elimination of 2 mol. water from 2,2´-dimethyl-1,1´-bianthraquinone by heating alone at 350–380°C or with dehydrating agents at lower temperatures.
2. Heat an aqueous paste of 2,2´-dimethyl-1,1´-bianthraquinone with or without the addition of ammonia or salts at 230–250°C under pressure for 10–12 h.
3. Heat 2,2´-dimethyl-1,1´-bianthraquinone with alcoholic potassium hydroxide.
4. Fuse 1,6-dibenzoylpyrene with aluminium chloride and sodium chloride and pass in oxygen.

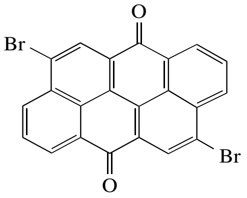


indanthrene gold orange G

b) Anthanthrone:

– C.I. 59 300 (L. Kalb, 1913).

1. Bromination of anthanthrone.
2. Ring closure of 1,1´-binaphthalene-8,8´-dicarboxylic acid in sulphuric acid and bromination.
3. Bromination may precede ring closure in (2) above.

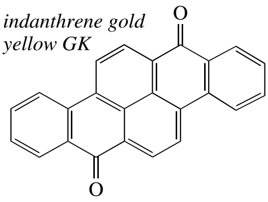


indanthrene brilliant orange RK

c) Dibenzpyrenequinone:

– C.I. 59 100 (G. Kränzlein, M. Corell, R. Sedlmayer, 1922)

1. Ring closure of 3-benzoylbenzanthrone with aluminium chloride and an oxidizing agent.
2. Ring closure of 1,5-dibenzoylnaphthalene in the presence of sodium and aluminium chlorides.



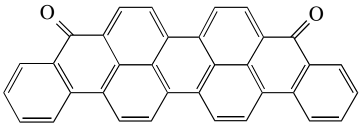
indanthrene gold yellow GK

IV. Anthraquinonoid dyes with a perylene structure:

a) Dibenzanthrone or violanthrone:

– C.I. 59 800 (O. Bally, M.-H. Isler, 1904)

1. Condensation of 9-anthrol with glycerol in the presence of sulphuric acid and fusion of the so formed benzanthrone with potassium hydroxide.
2. Heat 4,4´-dibenzoyl-1,1´-binaphthyl with aluminium chloride.
3. Fusion of benzanthrone with potassium hydroxide in the presence of glucose and an inert high boiling solvent.

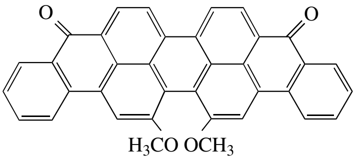


indanthrene dark blue BO

– C.I. 59 825 (A.-H. Davies, R.-F. Thomson, J. Thomas, 1920).

1. Methylation of the oxidation product of violanthrone in nitrobenzene.
2. Fusion of 2-methoxybenzanthrone with potassium hydroxide.
3. Oxidation of benzanthrone with manganese dioxide in sulphuric acid; condensation with alcoholic potassium hydroxide and alkylation.
4. Methylation of 16,17-dihydroxyviolanthrone.

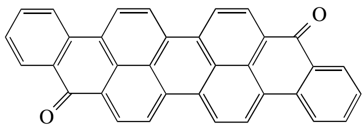
indanthrene brilliant green FFB



b) Isodibenzanthrone or isoviolanthrone:

– C.I. 60 000 (O. Bally, H. Wolff, 1906); BASF.

1. Chlorination of benzanthrone and treatment with alcoholic potassium hydroxide.
2. Heat benzanthrone with alcoholic potassium hydroxide in xylene, chlorobenzene or kerosine.
3. Conversion of 3-chlorobenzanthrone into the corresponding sulphide or selenide and reaction with alkali.

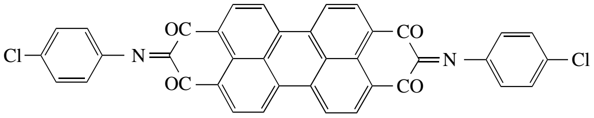


isoviolet anthrone

c) Perylene tetracarboxylic acids:

– C.I. 71 140 (P. Friedländer, 1919); condensation of 3,4,9,10-perylene tetracarboxylic acid with p-chloroaniline.

indanthrene scarlet R

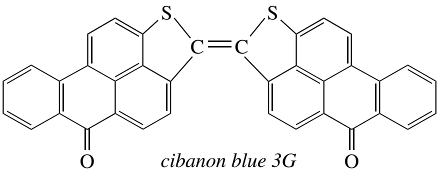


V. Benzanthronoid vat dyes:

a) Thiobenzanthrone:

– C.I. 70 305 (B. Mayer, A. Pfannenstiehl, 1908).

1. Condensation of 3-mercaptobenzanthrone with chloroacetic acid, fusion with potassium hydroxide and oxidation.
2. Technical production: heat 4-methylbenzanthrone with sulphur alone or preferably in the presence of a diluent.

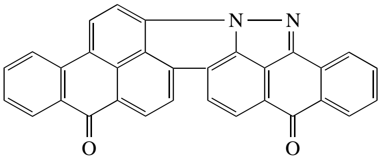


cibanon blue 3G

b) Benzanthronylpyrazole-anthrone:

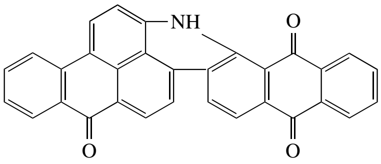
– C.I. 70 500 (K. Wilke, 1925); condensation of 3-bromobenzanthrone with anthrapyrazole and melting the product with alcoholic potassium hydroxide.

indanthrene navy blue R



c) Benzanthronylaminoanthraquinone:

– C.I. 69 500 (H. Wolff, 1908); condensation of 3-bromobenzanthrone with 1-aminoanthraquinone in boiling naphthalene in the presence of sodium carbonate and copper oxide. Cyclization with potassium hydroxide in isobutanol.



indanthrene olive green

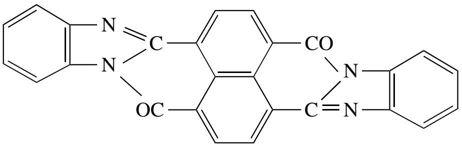
VI. Naphthalene derivatives:

a) Naphthoylene-benziminazole:

– C.I. 71 105 (W. Eckert, H. Greune, 1924)

1. Heat a mixture of o-phenylenediamine and 1,4,5,8-naphthalene tetracarboxylic acid in glacial acetic acid or pyridine solution.
2. Heat 1,4,5,8-naphthalene tetracarboxylic acid with o-nitroaniline. Reduce the nitro groups and cyclize.
3. Treatment of N,N´-diaryl-1,4,5,8-naphthalene tetracarboxylic acid diimide with 2 mol. o-phenylenediamine.

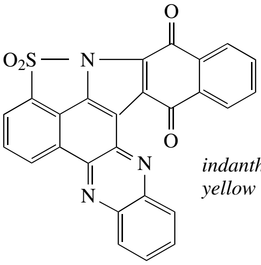
A mixture is formed consisting of 40–45% of the *cis* and 60–65% of the *trans* form. The mixture is heated with ethanol and potassium hydroxide and the so formed addition product is filtered and hydrolyzed with water.



indanthrene brilliant orange GR

b) Naphthoquinone:

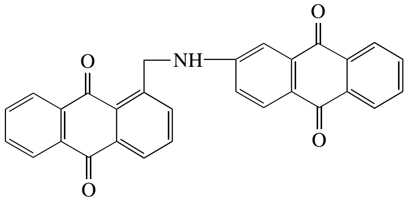
– C.I. 56 080, BASF; condensation of 5-aminobenzo-α-phenazine-4-sulphonic acid with 2,3-dichloro-1,4-naphthoquinone.



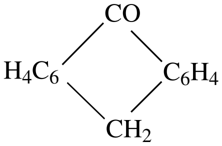
indanthrene yellow 6 GD

Anthrenus beetle protection → Moth- and beetle-proofing finishes.

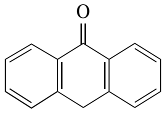
Anthrimides Anthraquinone imines produced from at least 2 → Anthraquinone groups linked by an → Imido group. Anthrimide structures are present e.g. in various Indanthren and Algol dyes, e.g. Indanthren Orange 6 RTK:



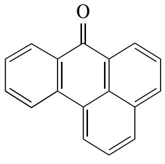
Anthrone Parent substance of a range of valuable anthraquinonoid vat resp. Indanthren dyes which are characterized by their high affinity for cellulose and, for this reason, are dyed without salt by the IN method.



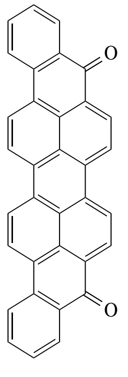
As illustrated by the above formula anthrone, unlike → Anthraquinone, possesses an anthracene molecule with only one keto group (CO). The important dye, dibenzanthrone, is derived from anthrone, e.g. via benzanthrone, i.e. the excellent violet-blue dye Indanthren Dark Blue BO and as iso-dibenzanthrone, the dye Indanthren Violet R extra, with its outstanding fastness properties (both are perylene derivatives):



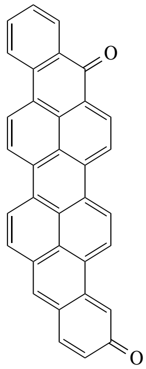
anthrone



benzanthrone

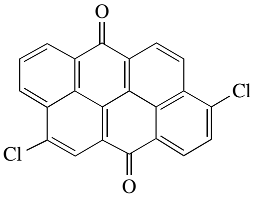


dibenzanthrone
(indanthrene dark blue BO)

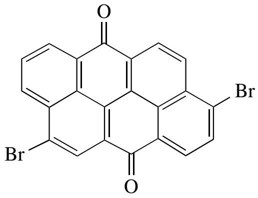


isobenzanthrone
(indanthrene violet R extra)

Instead of illustrating many other examples of this type, it will suffice to mention andanthrone here, a pyrene derivative which, in its chlorine and bromine-substituted forms, yields vat dyes with vivid shades and high light fastness:



indanthrene brilliant orange GK



indanthrene brilliant orange RK

Anthropometry (Gr.: *anthropos* = human, *metron* = measure), the comparative study of sizes and proportions of the human body which are of importance, e.g. in → Method study.

Antiadhesives Special textile auxiliaries which are used to prevent the adhesion of hosiery on metal formers during the postboarding process (→ Boarding). Also facilitates the rapid removal of hosiery from formers. Typical commercial antiadhesives increase the hosiery elasticity and also function as softeners.

Antibacterial → Bacteriostatic.

Antibacterial finishes (→ Antimicrobial finishes). The application of products to textile fabrics capable of preventing the growth of various microorganisms and which, therefore, also contribute to deodorizing. Such products are subdivided into → Bactericides (destruction of bacteria) and bacteriostats (inhibition of bacterial growth). In the literature there is often no distinction made between these terms. Bactericidal finishes are hardly ever used for apparel since the necessary auxiliaries are not compatible to the skin. These finishes are of relatively minor importance for carpets. Antibacterial finishes are effective not only against bacteria but also against → Mycotoxins.

Antibacterial textiles The Institut Textile de France in Ecully Cedex developed what are termed “biotextiles”. In these textiles (Fig.) grafted with antiseptic substances, the molecular chains with antiseptic agents are grafted onto the parent polymers of the raw material. The parent polymers are activated by electron discharge. In the process they open up at certain sites. The graft priming monomers are deposited at these sites. The polymer chains propagated laterally impart the bactericidal properties to the textile. The textiles provide very quick-response bactericidal protection in direct contact and this property is fully retained after laundering. Applications for biotextiles include medical and surgical textiles plus interior furnishings for the contract, hotel and office sector as well as in workwear for the pharmaceutical and foodstuff industries and in speciality fields such as air filtration.

Antibiotics Biosynthetic or chemically-manufactured substances which are capable of inhibiting or destroying vegetable or animal microorganisms (penicillin type). In the textile sector, “antibiotic auxiliaries” are used especially for →: Bactericidal finishes, Fungicidal finishes, etc.

Antichlor Any product which serves to decompose residual chlorine on textile materials following → Chlorine bleaching processes, as a result of which oxidative damage to cellulose is avoided. A distinction is made between antichlor agents used to eliminate residual available chlorine in the form of a) hypochlorous acid and b) protein compounds (→ Chloramines). During the course of a kier boil-chlorine bleach process no significant amounts of a) are formed so that, in this case, post-souring [$NaOCl + 2\ HCl \rightarrow NaCl + Cl_2 + H_2O$] followed by rinsing is sufficient. In cold bleaching without an alkaline prescour, however, residual chlorine of type b) is formed. There are consequently different antichlor agents for a) [= post-souring, hydrogen peroxide], for b) [= sodium or potassium hydroxide, sodium carbonate] and for a) and b) [= ammonia, sodium bisulphite, sodium hydrosulphite, sodium pyrosulphite, sodium sulphite, sodium thiosulphate and sulphurous acid]. Antichlor treatment after a) + b) = cold rinse after chlorine treatment, followed by treatment in 1–2 g/l cold bisulphite for 15–30 min. then post-souring in the same bath with 2 ml/l hydrochloric acid. The 1st phase of the much more commonly used thiosulphate method results in the formation of: sodium sulphate, hydrochloric acid and sulphur [$Na_2S_2O_3 + Cl_2 + H_2O \rightarrow Na_2SO_4 + 2HCl + S$] whilst in the 2nd phase: sulphuric and hydrochloric acid [$S + 3Cl_2 + 4H_2O \rightarrow H_2SO_4 + 6HCl$] are formed; this being the origin of the obligatory final, thorough rinsing treatment to remove residual acid. Neutralization (as above) with hydrogen peroxide and soap under hot conditions (= whites stable to storage).

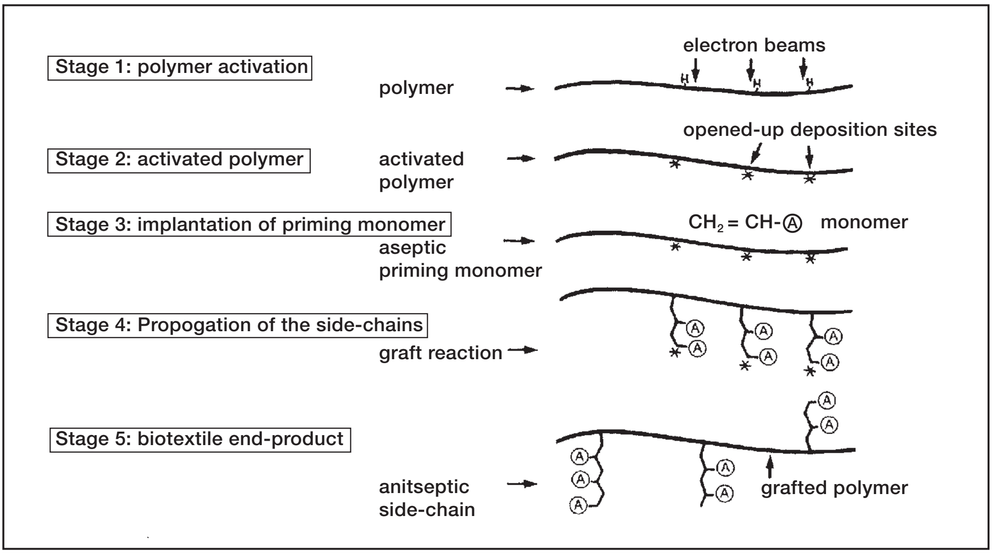


Fig.: The chemical grafting technique of antibacterial finishing.

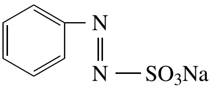
Anti-cling finishes are applied to fabrics made from synthetic fibres in order to prevent garments from clinging to the body. Identical with → Antistatic finishes.

Anti-cockling treatment Elimination of possible loop distortion in garment pieces made from combed wool yarns during subsequent wet processing (→ Chlorine/Hercosett process) by treatment in boiling sulphite or bisulphite solutions.

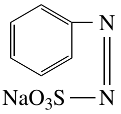
Anti-corrosive → Corrosion inhibitors.

Anti-crease finish → Resin finishing of cellulose for reducing creasing tendency to the lowest possible dimension.

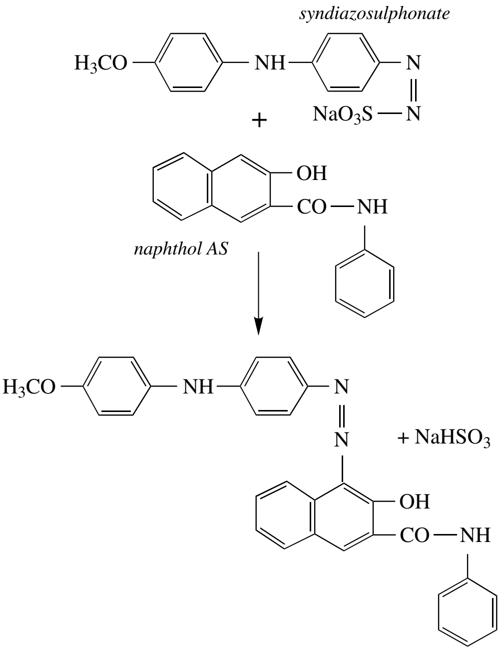
Antidiazosulphonates play a role e.g. in combinations with naphthols. In this case, they act as components which are not capable of coupling of the type:



After printing, this structure undergoes rearrangement due to the action of steam or light energy into the syn-diazosulphonate which, from now on, is capable of coupling with naphthols:



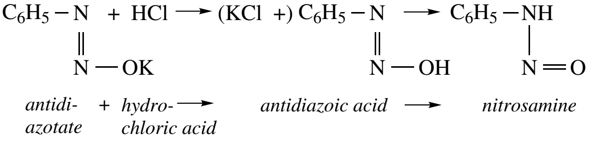
such as takes place, e.g. in the formation of an insoluble azo dye from the coupling of Rapidazol Blue IB with Naphthol AS:



A remarkable property of compounds of this type is that the all-important rearrangement reaction is also initiated by the action of light. In this process, oxygen carried along with the fabric can be activated by powerful light energy, especially with the addition of sensitizers, which then results in a photochemical rearrangement and coupling. This type of reaction forms the basis of photographic printing.

Antidiazotates (isodiazotates). These products were originally described as → Nitrosamines. They are representative of fairly stable naphthol diazonium salts (no longer capable of coupling) in solid form and are derived from → Amines with very weak basic properties. As reaction products of alkalies (NaOH) on diazonium salts they offer the advantage that the nitrosamine necessary for coupling is only formed after an acid treatment (→ Naphthols in printing).

Principle:



$$\underset{\text{N}-\text{OK}}{\underset{\|}{\text{C}_6\text{H}_5-\text{N}}} + \text{HCl} \longrightarrow (\text{KCl} +)\ \underset{\text{N}-\text{OH}}{\underset{\|}{\text{C}_6\text{H}_5-\text{N}}} \longrightarrow \underset{\text{N}=\text{O}}{\underset{|}{\text{C}_6\text{H}_5-\text{NH}}}$$

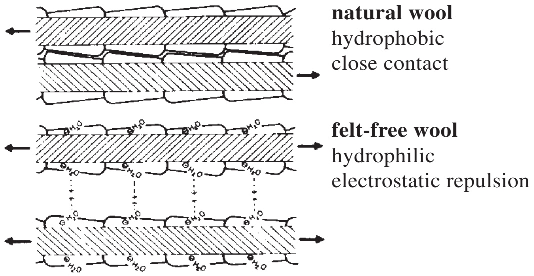
Antifelting finish The typical scale structure of the wool fibre can be affected by means of different processes so that it is no longer detrimental in terms of felting. A distinction is drawn between various processes:

I. Subtractive process: in the exocuticle A, wool scales are hydrophobic, whilst the endocuticle is hydrophilic. Hydrophilisation of the exocuticle A by oxidation of the 35% cystine there with hypochlorite results in the oxidised outer fibre areas containing cysteic acid being covered by a film of water when they are washed. This water film results in neutralising the ratchet effect (as the innermost parameter of the felting process).

II. Additive process: masking the scales with polymers (forming a film-like cover). The additive process enables woven or warp knitted fabrics to be finished from an aqueous or organic medium. Synthetic resins are applied to the fibre by padding (or sometimes also by the exhaustion process). Their action is mainly based on the so-called "spot weld effect", i.e. the polymers, in condensing, glue the individual fibres together at their contact points (unsuitable for tops), providing good shrink-proof effects at low cost.

III. Combined process, like the → Hercosett process for example.

The action of chemical antifelt finishing is therefore no longer explained merely by the morphological degradation of the wool scales (→ Wool felt), but also by the introduction of ionised groups. The surface of natural wool contains only a very few ionised groups, and is hydrophobic, which produces very close fibre contact in the aqueous felting medium. The formation of ionised and hydrated groups in antifelt finishing makes the fibre surface hydrophilic; at the same time, an electric double layer is produced. Both factors together reduce fibre contact in the aqueous medium, and prevent the longitudinal anisotrophy of the frictional characteristics responsible for felting from being effective on wool fibres (Fig. 1).



[← → favoured direction of movement under the effect of mechanical energy]

Fig. 1: Electrostatic relationships with natural and antifelting finished wool in water.

Subtractive antifelting finish: mainly represents oxidative antifelting finish. The oxidative decomposition reaction on main chains, cystine bridges and some other side chain remnants must be regarded in terms of the different chemical composition of the morphological components. Whilst the peptide group concentration in all components is of about the same dimension, the cystine content of the exocuticle is approx. 20%; in contrast, the orthocortex contains only about 8%. The Allwörden reaction demonstrates the favoured reaction of the chlorine with the scale cells. Chlorine penetrates the intact epicuticle, and attacks the underlying layers. Osmotic swelling results in the formation of external blisters and scales. This explains the special position of chlorine in antifelt finishing with its specific action on the peptides in the exocuticle, which is expressed in selective splitting of the peptide bonds near the tyrosine remnants. The fragments are still high-molecular of course, but water-soluble. Since they cannot pass the epicuticle, they induce osmotic swelling of the scale cells as soon as the fibre is immersed in water. Consequently, chlorinated fibres have higher coefficients of friction both in the tip and root directions, and reveal a less pronounced differential friction effect (DFE) than natural fibres. In practice however, this results not only in plasticisation but also decomposition. In chlorination, the sulphur-rich cuticle proteins, which provide soluble products, are preferably decomposed. The amino acid compositions of proteins in chlorinating liquors and exocuticle are coincident, but there is a whole series of other hypotheses on the action mechanism of oxidative antifelting finishes: the original hydrophobic fibre surface becomes hydrophilic due to the introduction of ionic groups. At the same time, an electric double layer is formed. This reduces fibre contact, increasing the DFE. According to Speakman, the antifelting effect of chlorine among other chemicals is explained by the oxidative splitting of cystine bridges, and the consequent reduction in wool fibre elasticity.

Additive antifelting finish: these processes operate with polymers or prepolymerisates which cross-link under specific conditions after being applied. Additive antifelt finishing is effected therefore in two stages:

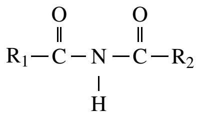
a) Polymer application (exhaustion or application process);
b) Cross-linking reaction.

The polymers employed must therefore be soluble or dispersible in their original form. The formation of three-dimensional networks is supposedly of advantage in obtaining effects fast to washing and dry-cleaning. Most effective antifelt finishing agents therefore contain either a prepolymer or a cross-linking component with a functionality of at least 3. Additionally, the polymer must have a low brittle temperature in order not to impair handle. Satisfactory tear strength plus elasticity and the ability to swell must guarantee the resistance of the polymer film to mechanical action. It has been unequivocally established that cross-linked polymers can provide acceptable antifelting effects only through covalent bonds. For this reason, suitable polymers contain reactive groups.

The most important additive antifelting finishes are produced with the aid of a polyurethane polymer. This finishing agent consists of a concentrated solution of a polyether/polyurethane mixture with an isocyanate content of approx. 4 weight percent in organic solvent. The sensitivity to hydrolysis of the isocyanate group necessitates application from an organic solvent. Finishing can be carried out both continuously and in batch form. Cross-linking is effected by the action of moisture or by steaming.

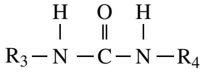
$$R\text{–}NCO + H_2O \rightarrow R\text{–}NH_2 + CO_2\uparrow$$

The formation of biuret and urea groups etc. can be assumed.



$$R_1-\overset{\overset{\displaystyle O}{\|}}{C}-\underset{\underset{\displaystyle H}{|}}{N}-\overset{\overset{\displaystyle O}{\|}}{C}-R_2$$

Biuret group



$$R_3-\overset{\overset{\displaystyle H}{|}}{N}-\overset{\overset{\displaystyle O}{\|}}{C}-\overset{\overset{\displaystyle H}{|}}{N}-R_4$$

Urea group

One water-soluble polyurethane for antifelt finishing is the 50% aqueous solution of a prepolymeric aliphatic polyurethane which contains a number of carbamyl sulphonate groups. This product is produced by the accumulation of sodium hydrogen sulphite on the polyurethane isocyanate groups:

$$R{-}NCO + NaHSO_3 \rightarrow R{-}NHCOSO_3^-Na^+$$

Use from aqueous solution is possible with this modification; cross-linking takes place in the alkaline medium:

$$R{-}NHCOSO_3^- + OH^- \rightarrow R{-}NHCOOH + SO_3^{2-}$$

$$R{-}NHCOOH \rightarrow R{-}NH_2 + CO_2$$

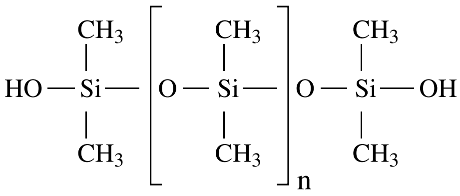
$$R_1{-}NH_2 + R_2{-}NHCOSO_3^- \rightarrow R_1{-}NHCONH{-}R_2 + HSO_3^-$$

The prepolymers are bonded to each other via the urea groups. The water-soluble polyurethane is used together with an acrylate or polyurethane dispersion, since this combination has a synergistic effect. The product is particularly suitable for the additive antifelt finishing of fabrics and made-up products, adequate felting resistance being achieved without prechlorinating.

Two exhaustion processes have been developed in addition to the application process. With both processes, it is possible to cross-link the polymer as early as in the finishing bath. This is necessary in finishing knitted fabric, which is dried under gentle conditions in a tumbler after a wet process, and then steamed for just a brief period. The rate of exhaustion is controlled by the temperature in the drip feed process, and, in the isothermal method, via the salt concentration. Another product is based on a 50% water-soluble polyurethane prepolymer with carbamyl sulphonate groups, which cross-links in the alkaline medium. In the interest of greater production reliability and short processing times, the following padding variants are recommended for piecegoods:

a) Condensation process: padding (80% liquor uptake), drying (100°C), condensing (5 mins at 140°C), decatizing.
b) Wet cross-linking process: padding, rotational dwelling (16 hours at 25 ± 3°C), rinsing/washing, drying.
c) Moist cross-linking process: padding, drying to 30–40% residual moisture content, rotational dwelling (shorter than b), rinsing/washing, drying.

In the condensation process, the liquor contains cross-linking agent, sodium hydrogen carbonate, the water-soluble polyurethane, a polyurethane emulsion and a silicone-based soft handle agent.



$$HO-\underset{CH_3}{\overset{CH_3}{\underset{|}{\overset{|}{Si}}}}-\left[O-\underset{CH_3}{\overset{CH_3}{\underset{|}{\overset{|}{Si}}}}-\right]_n O-\underset{CH_3}{\overset{CH_3}{\underset{|}{\overset{|}{Si}}}}-OH$$

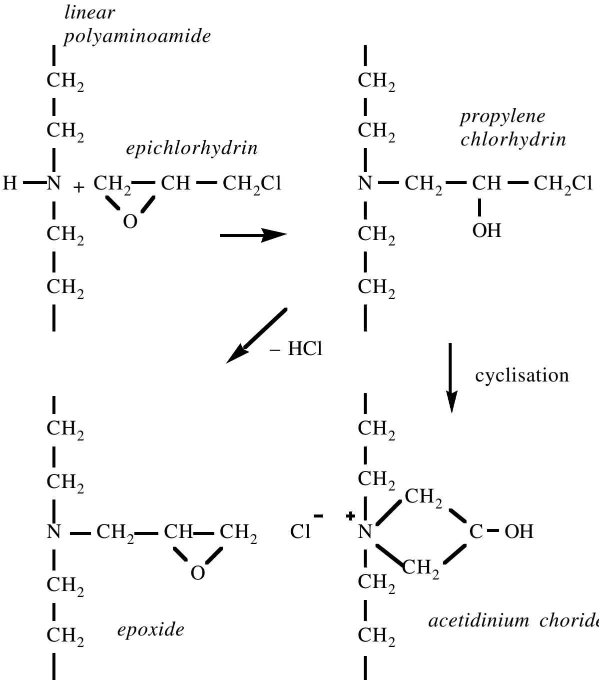
Silicone elastomer

With identical polymer concentration however, the handle turns out softer in the exhaustion process, a fact which is attributable to migration during padded fabric drying. Intensive rewashing and treatment with a softening agent should provide a remedy in this respect. In the wet and moist cross-linking process, a starch and cellulose-based thickening agent is added to the liquor, a factor which should improve the cross-linking effect, levelness, running characteristics and liquor uptake. This thickening agent displays a certain extender action, whereby the quantity of antifelting polymer can be reduced. It evidently makes the handle harsher in cross-linking with the polymer, but this can be compensated by wet-on-wet finishing with silicone elastomer I. The dwell time can be substantially shortened by adding magnesium chloride. In comparison with the condensation process, both the wet and the moist cross-linking processes engender better antifelting behaviour.

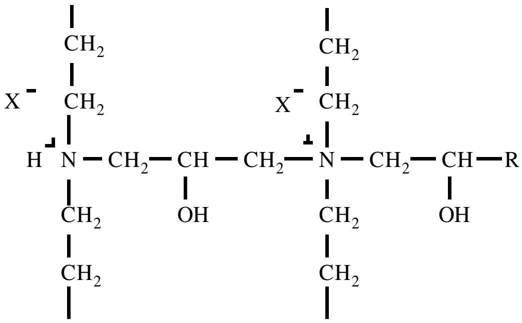
Electron microcope photographs reveal adhesion points between the wool fibres. A fibre immobilised in this way can no longer move, and consequently no felting can take place. The reduced DFE plays merely a subordinate role. The mechanical characteristics of the polymer, its tear strength and also adhesion to the fibre surface are of particular importance. The adhesion between polymer and fibre is occasioned by van der Waal forces, electrostatic interaction and possibly by the penetration of polymer segments into the scale cells. The subject of covalent bonds between resin and wool is controversial. It has however been shown that these are not essential for a good antifelting effect.

Combined antifelting finish: this process consists of a combination of additive and subtractive methods. The most important combined process is doubtless the Hercosett process, consisting of chlorination and additive resin application. Tops are mainly antifelt finished by this process. The Hercosett polymer is obtained from adipic acid and diethylene triamine with the addition of epichlorhydrin.

$$n\,[HOOC{-}(CH_2)_4{-}COOH + H_2N{-}(CH_2)_2{-}NH{-}(CH_2)_2{-}NH_2] \rightarrow -[CO{-}(CH_2)_4{-}CONH{-}(CH_2)_2{-}NH{-}(CH_2)_2{-}NH]_n$$



The epoxide groups and acetidinium cations already react during synthesis with the secondary and tertiary amino groups, producing cross-links between the polymer chains:



In order to prevent uncontrolled additional cross-linking, the reaction mixture is acidified, hydrolysing the free epoxide groups. The product is a partially cross-linked, but still water-soluble polymer which contains acetidinium cations as reactive groups. The operational sequence is as follows:

- acid prechlorination (NaOCl or Cl_2),
- neutralisation and antichlorine treatment (Na_2CO_3 and $NaHSO_3$),
- rinsing,
- resin application (polyamide-epichlorhydrin resin),
- softener application.

In top finishing, it is most particularly important that the fibres are completely covered by a polymer film. Uniform dissemination of the cationic polymer is made possible by oxidative pretreatment, by which the critical surface tension of the wool fibre is increased, and anionic groups are formed. Polyamide-epichlorhydrin resin applied to the untreated wool has no effect on felting tendency, because it is aggregated. The action is explained as follows: the resin swells substantially in water, and reduces the DFE, which is insignificantly changed by the weak chlorination. Another theory is that a water film on the swollen polymers reduces the frictional differences in consequence of a lubricating effect. The best results are obtained with combined antifelting finishes; the washing test results on purely additive antifelting finishes are worse (Fig. 2).

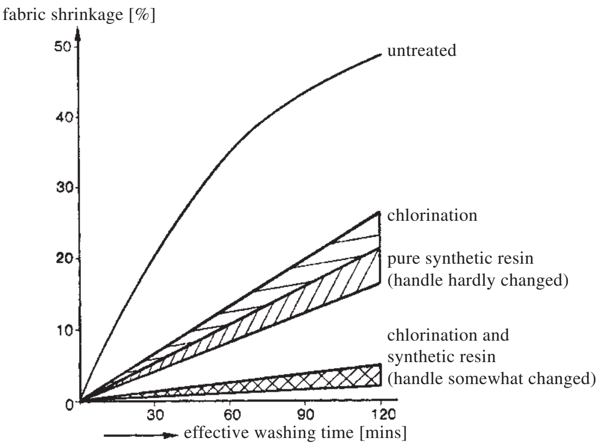


Fig. 2: Fabric shrinkage over time of knitted test specimen pieces in felt testing in accordance with DIN 54 321.

Antifoamers → Antifoams.

Antifoams In package dyeing as well as in sizing, finishing and, above all, printing, problems can arise due to the foaming of liquors or print pastes. Universally applicable antifoams as well as antifoams for specific applications are available based on a wide variety of chemical types. Tributyl phosphate (TBP) in particular, is an excellent antifoam agent. In exceptionally problematic situations, well-proven combination products are recommended, particularly in the case of print pastes, where further valuable properties can be incorporated, e.g. to improve flow properties, prevent doctor streaks and provide a simultaneous lubricating and protective action on printing rollers and doctor blades in roller printing. → Defoamers.

Antifoams in drycleaning are used in the form of e.g. organic halogen compounds to overcome distillation problems due to foaming which can be caused by e.g. dissolved silicones from drycleaned articles.

Antifrosting agents Textile auxiliaries based on alkylaryl polyglycol ethers for the prevention of → Frosting.

Antifungal, generic term for → Fungicidal and fungistatic finishes.

Anti-greying agents → Antifrosting agents.

Antimetabolic substances block the formation of products important for the life of cell structures, e.g. even the structure of bacteria cells (e.g. in → Bacteriostatic finishes).

Antimicrobial A term used to describe the action of growth inhibition, or the destruction of, → Microorganisms, e.g. as a property of man-made fibres which have been spun with antimicrobial compounds (→ Antimicrobial fibres) or as in → Antimicrobial finishes.

Antimicrobial agents, bacteriostatic, bactericidal, fungistatic, fungicidal textile protective agents especially for rot-proofing applications. Phenolic compounds, quaternary ammonium salts and organometallic compounds (Hg) are among the most important antimicrobial agents.

→ Antimicrobial finishes are of particular importance in the household sector, e.g. for those types of article that are seldom or never washed or drycleaned, such as fitted carpets, upholstery fabrics and mattress ducks. In addition to their action in preventing the transmission of pathogenic microorganisms, antimicrobial finishes should also be capable of counteracting the development of odour from the bacterial decomposition of perspiration in clothing (linings, socks, etc.). For such applications, as well as for household textiles, the descriptions: deodorized and → Sanitized finishes are also used.

Antimicrobial fibres (medical fibres), are man-made fibres with antimicrobial properties which include: inhibition of microbial growth, prevention of pus formation, acceleration of wound healing and reconvalescence. Used in the production of bandages, medical gauze, cotton wool and tampons.

Antimicrobial finishes, are effectively produced on textiles by e.g.:

1. Addition of microbicidal substances to the spinning solution in fibre manufacture.
2. Modifications involving grafting or other chemical reactions.
3. The finishing of textiles with suitable active substances. Such substances are fixed on textile materials after a thermal treatment (drying, curing) by incorporation into polymers and resin finishing agents.

Antimicrobial effects, resistant to washing resp. drycleaning, are obtained e.g. by the incorporation of microbicides into spinning solutions as well as by chemical modification of the fibre itself. As a result, the textile material is protected from microbial attack and can no longer serve as a culture medium. It is, however, also necessary for the active constituent to be carried to the microorganism cells being targeted, either by water, e.g. after hydrolytic breakdown, or by leeching out of the textile material. This is an important prerequisite for an effective antimicrobial effect.

Many active substances suffer reduced effectiveness or even inactivation as a result of chemical reaction with e.g. the fibre. For this reason, finishing processes, which apply substances that can be incorporated into textile auxiliaries, and which do not crosslink with, but rather exhaust on to the fibre from where they are slowly released during use, have gained increasing importance. In this case, of course, resistance to washing and drycleaning is limited. This limited resistance is actually desirable in terms of effective germ-resistance. Probably the oldest substances with an antimicrobial action are the salts of mercury (mercuric chloride) and silver (silver nitrate). The introduction of antiseptic wound disinfection and the disinfection of bandaging with phenol can also be regarded as early efforts in the campaign to eliminate the germ-carrying potential of cellulosic textiles through the addition of active substances. The wide application of chlorinated phenols, pentachlorophenol and 2,4,6-trichlorophenol for rot-resistant finishes on tarpaulins and tent fabrics was a later development, although these are now no longer used because of their toxicity.

No sooner had measures for hygiene and disinfection become firmly established, than the original rot-resistant finishes for heavy fabrics composed of cellulosic fibres was further developed in the application of antimicrobial resp. sanitized finishes to apparel and household textiles. As the most important active agents, quaternary ammonium compounds, as well as products based on phenylmercuric acetate, hexachlorophene and salicylanilide, have found wide application in such finishes. Finishing treatments with these products are less effective in affording protection to textile materials against decomposition (rotting) under unfavourable conditions at high temperatures and high air humidity. They are, rather, of much greater value in preventing the transmission of pathogenic organisms and, through inhibition of microbial growth, in counteracting the decomposition of skin fats and perspiration, without actually interfering with their natural formation, thereby checking the development of undesirable odours.

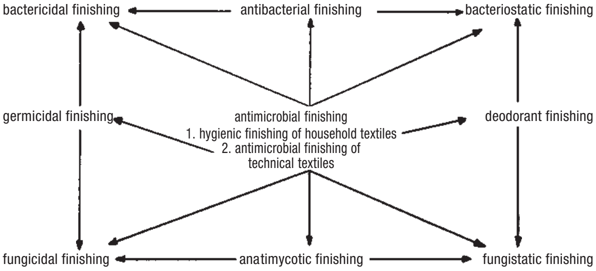

Fig.: Breakdown of antimicrobial finishing.

Antimicrobial finishes may be subdivided into the following types (see diagram):

- Germicidal finishes: germ-destroying finishes. The term is mainly used in connection with rot-resistant finishes.

- Hygienic finishes (hygiene = the science concerned with the maintenance of health): sanitized finishes. Elimination of pathogenic microorganisms by the application of appropriate finishes.
- Antibacterial finishes: include both bactericidal and bacteriostatic finishes.
- Bactericidal finishes: have the effect of causing the destruction of all bacteria.
- Bacteriostatic finishes: have the effect of inhibiting the growth of bacteria already present without causing their destruction.
- Antimycotic finishes: finishes designed to kill moulds or prevent their growth.
- Fungicidal finishes: the use of active substances capable of killing moulds already present.
- Fungistatic finishes: the use of compounds which have the effect of inhibiting mould development only, i.e. the moulds or their spores are not killed.
- Algicidal finishes: the growth of algae on textiles can be prevented by the application of suitable active substances.
- Deodorizing finishes: finishes designed to prevent the development of unpleasant odours.
- Rot-preventive finishes: finishes designed to protect textiles against the action of bacteria and moulds under unfavourable storage conditions, i.e. at high humidities and temperatures.

The purpose of an antimicrobial finish is therefore:

a) to prevent the transmission and spreading of pathogenic (disease-causing) microbes (hygiene sector);
b) to inhibit odour development resulting from microbial degradation (deodorizing);
c) to avoid loss of textile serviceability resulting from fibre decomposition due to microbial attack.

A distinction is made between hygienic finishes on apparel and household textiles and antimicrobial finishes for technical textiles. The requirements given under a) and b) are crucially important for hygienic finishes, whilst c) is particularly relevant in the technical textiles sector.

“Sanitizers” are products capable of limiting microbial attack to a certain extent only.

Applications of such products to textiles are described as → Sanitized finishes. The use of formerly well-known products is no longer permitted due to the introduction of statutory regulations. Suitable non-toxic products, resistant to washing and drycleaning, are difficult to find. Attempts have therefore been made to attach suitable products to the fibre through covalent linkages: e.g. by employing reaction products of cyanuric chloride and halogen derivatives for cellulosic fibres; or the attachment of nitrofurylacrolein and p-nitro-chlorocinnamic aldehyde to wool; and various derivatives for polyamide and polyvinyl alcohol fibres.

Antimicrobial finishing of carpets Application of compounds capable either of destroying or inhibiting the growth of moulds and bacteria to textile floorcoverings by padding on one side or spraying. They consist mainly of products based on phenol derivatives, heavy metal salts, formaldehyde-releasing agents and quaternary ammonium compounds.

Antimicrobic → Antimicrobial.

Antimigration, opposite of → Migration. Measures taken to influence, inhibit or prevent the undesired migration of dye by physical, e.g. drying, or chemical means by the addition of suitable products. → Migration inhibitors.

Antimigration agent, textile auxiliary designed for → Antimigration. e.g. as in pigment-pad and continuous dyeing processes. → Migration inhibitors.

Antimony (Sb), atomic weight 120, mp 630°C, density 6,7. White or bluish white crystalline metalloid, lustrous, brittle and stable in air. Not attacked by hydrochloric acid and soluble in sulphuric acid. Used in alloys as a hardening component (hard lead, tin-antimony). It forms antimonic compounds in its + 5 oxidation state and antimonous compounds in its + 3 oxidation state, most of which are colourless, exceptions are yellowish orange. Sb(III) compounds: the oxyhydrate (also known as antimonous acid, $Sb_2O_3 \cdot H_2O$) forms salts with strong acids and alkalies. The cold-water soluble trifluoride SbF_3 and its double salts are also of importance, as well as antimony oxalate. Sb(V) compounds: the dark red double sulphide ($Na_3SbS_4 \cdot 9\ H_2O$) is particularly important as an accelerator in the vulcanization of rubber.

Antimony potassium oxalate → Potassium antimonyl oxalate.

Antimycotic finishing subdivided into → Fungicidal and fungistatic finishes. For clothing material, fungicidal finishes are hardly ever considered because the skin cannot tolerate the required finishes. → Antimicrobial finishes.

Anti-odour finishes Textile finishing for inhibiting the smell of oils and greases etc in textiles by substances applied during production, or for producing special fragrances (lilac, lavender etc). A deodorant effect during wear is not of course associated with this finish. The technique of micro-encapsulation for anti-odour garment finishing is meant in this connection. (→ Sanitized finishing).

Antioxidants (oxidation inhibitors). These compounds inhibit, or even prevent, oxidation processes (→ Inhibitors). Antioxidants are of practical importance, e.g. in the form of a small additions to drying oils used in oil sizing to prevent the evolution of heat and attack on the fibre due to an excessively rapid self-oxidation or autoxidation. For this purpose, certain substances with OH and NH_2 groups capable of being oxidized such as e.g. phenols, amines, aldehydes, ketones, benzyl alcohol, diphenylamine, hydroxydiphenylamine, hydroquinone, etc. are used. Antioxidants perform the same function with textile lubricants, subject to spontaneous combustion, which have poor → Mackey test values.

Antiperspirants (deodorants). These products mainly contain mildly astringent and acidic salts, e.g. aluminium chloride (15–30% solution). The effect is based on the observation that these compounds prevent the decomposition of perspiration in the alkaline range. Antiperspirants also contain antiseptics (e.g. formaldehyde). Antiperspirants based on aluminium chloride, in particular, represent a potential source of damage to textiles (30% solution = pH 1; acid content by titration calculated as hydrochloric acid = approx. 13%, which corresponds to a degree of acidity equivalent to a 1:2 dilution of conc. hydrochloric acid).

Antipilling Processes intended to minimise or prevent → Pilling (pill formation), mainly applicable to fabrics produced from high-tenacity, man-made fibres and their blends. The pilling propensity can be detected by means of an abrasion test. Pilling may be prevented by initial heat-setting, total shrinking and singeing, besides impregnation in finishing with film-forming products capable of inhibiting fibre migration. Such products are generally based on acrylates or polyurethanes. The films formed with these products must be as resistant to abrasion as possible in order to be effective. Another antipilling possibility is fibre modification.

Antipodal pair → Optical activity.

Antiredeposition agent Additional component of a → Washing agent for increasing the → Soil suspending property; also called "builders".

Antirheumatic A term generally applied to textile fibres which are effective against rheumatism, e.g. pain relief achieved from the use of polyvinyl chloride fibres in underwear and quilt fillings. Wool also possesses antirheumatic properties.

Antirotting preservatives Used in textiles exposed to moisture to protect against rotting by microorganisms. They are similar products to → Preservatives.

Antiseptics are agents with a powerful antiseptic action. They find general application for the protection of all materials where the growth and further development of bacteria must be arrested or inhibited (→ Preservatives).

Antishrink setting → Heat setting.

Anti-slip and anti-snagging agents These serve to reduce the slippage of open set woven fabrics, to prevent the formation of ladders in warp knitted fabrics and the so-called → Snags in stockings and finished fabrics of fine synthetic yarns. The effect is based on the production of a thin, rough, adherent film on the fibre surface of the treated fabrics. Preparations of plastics (e.g. polyvinyls, polyacrylates, polymethacrylates and polystyrene) and natural resins or silicic acid.

Antislip finishes These finishes are used to avoid the shifting of crossing warp and weft threads in fabrics containing a low number of yarns or woven in open constructions to prevent the formation of holes, splitting of seams, etc. (→ Slip resistance). Antislip finishes involve the application of antislip finishing agents by wet processing.

Fabrics for technical applications (e.g. geotextiles, glass-fibre wallpaper) are often woven with such thin constructions that there is a great risk of yarn slippage as they are delivered from the weaving machine. In order to overcome this problem, a finish applicator device, consisting of an applicator, hot air and drum drier and rising roll batcher, is installed directly at the weaving machine. Suitable antislip finishes include film-forming polymer dispersions or silicic acid hydrosols. Additional auxiliaries, such as antistatics etc., may also be applied at the same time.

Antisnag finish for velvets A finish applied to velvet or plush fabrics in order to prevent the pile becoming detached from the warp. The effect is similar to that of an antislip finish and involves impregnating the back side of the fabric with starch products, cellulose derivatives or various synthetic resins.

Antisoiling finish, are finishes designed to achieve active → Stain blocking. The term is also used to describe various technical measures applied in finishing to keep soil away from textiles. Soiling propensity is dependent on the fibre material, the technological structure of the yarn and fabric as well as the finish. Crease-resist finishes and water-repellent treatments increase soiling propensity. The man-made fibre producer's solution to the problem is to create a "clean fibre", e.g. by the incorporation of additives into the spinning solution.

Anti-soiling finishes A distinction is drawn between:

I. Dirt repellent finish for preventing wet soiling, based particularly on → Water repellent finishing and, if necessary, a swelling-resistant finish.

II. Dirt repellent finish against dry soiling, based on principle on the fact that fibre surface unevenness due to specific soiling, mainly inorganic metal oxides, Al_2O_3, SiO_2 or so-called white pigments, is evened out, producing a specific rebound effect as a barrier against dirt.

III. Dirt repellent finish against oil soiling: → Soil release finish.

Antisoiling finishes on carpets Finishes applied to textile floorcoverings by dipping, slop padding or spraying with substances capable of reducing the soiling propensity of carpet materials (→ Stain blocking). There is also a close relationship with → Antistatic finishes. Fibre origin, cross-section, delustring and carpet construction have no significant influence on the degree of soiling. Coloration, however, has a considerable influence on soiling. In finishing, the application of fluorocarbon-based products by spraying is the most widely used method up to now. In the case of wool carpets, the pretreatment has been found to influence soiling propensity. Antisoiling finishes are of particular importance for carpets in rooms with underfloor heating (dryness). In addition to the application of antisoil finishes, the use of special pile material is also necessary.

Anti-soil redeposition Prevention of redeposition on textile materials of already dissolved or dispersed soils in wash baths → Soil release finishes.

Antistatic agents Textile auxiliaries (anionic, cationic or non-ionic) used to prevent the development of electrostatic charges during the processing and use of synthetic fibres and yarns (which also includes some natural fibres such as e.g. wool). In the case of anionic and cationic antistatic agents, the antistatic effect becomes greater with increased chain length of the fatty acid residue. Presumably this is because a marked molecular adsorption, perpendicular to the fibre surface, becomes possible with longer chains. Antistatic action is essentially due to the combined effects of increased ionic conductivity, increased water absorbing capacity and, possibly, a fibre lubricating effect as well. Antistatic agents have only a very limited effect on soil-repellency. Wash-resistant antistatic agents are based on the principle of applying to the fibre, e.g. polymer compounds whose water solubility is due to the presence of hydrophilic side-groups, after which the water-solubilizing groups are blocked by salt formation or esterification.

Antistatic fibres To eliminate the build-up of electrostatic charges on textiles (especially textile floorcoverings), permanently antistatic polyamide or metallic fibres are used. By using antistatic polyamide fibres, the electrostatic charge is reduced to a level below the sensation limit (2000 V) even at a relative air humidity of only 20–30%. The man-made fibre industry has introduced numerous antistatic polyamide fibres to the market (Fig. 1) based on different principles, e.g. embedded carbon particles, metallized fibres, copper sulphide deposition on the fibre surface besides the incorporation of antistatic agents into the spinning solution, etc. Antistatic polyamide fibres with a graphite core (Fig. 2) are already used to a considerable extent in women's clothing, including nightwear, as well as technical textiles (e.g. for the EDP sector).

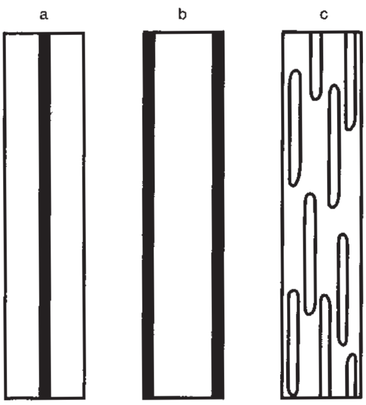

Fig. 1: Antistatic fibres: a) conductive core, b) conductive mantle, c) fibrillar distribution of the antistatic product.

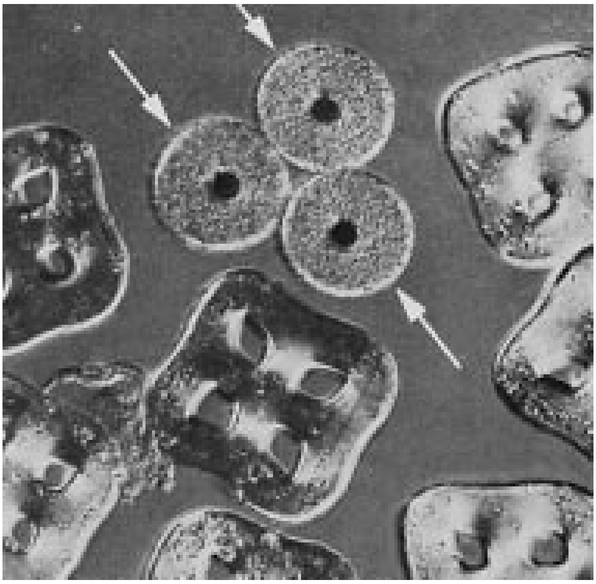

Fig. 2: Antistatic fibres with a conductive core (IFK 500 : 1): Dupont Antron-III-HF-hollow fibre with which graphite fibres with a polyamide mantle are mixed.

Antistatic finishes on carpets The application of electrostatic finishes to textile floorcoverings by:

I. Slop-padding or spray application of antistatic agents.

II. Incorporation of steel fibres into the carpet construction.

III. Addition of electrically-conductive products to the carpet backcoating.

IV. Use of antistatic pile fibres in the form of synthetic fibres with hollow spaces and electrically-conductive additives.

V. Use of electrically-conductive adhesives to facilitate the discharge of static electricity.

Antistatic agents are effective on practically all types of fibre, especially polyamide, polypropylene, polyethylene and polyacrylonitrile. Application quantities are dependent on the carpet structure, in which intermediate layers of metallic fibres or powders as well as carbon black may assist the discharge of electrostatic charges but cannot entirely substitute the use of electrostatic agents. Antistatic finishes for floorcoverings in rooms with underfloor heating demand special consideration. In this case, the pile fibres must also possess antistatic properties. At present, there is still no ISO walk test for testing such carpets. Investigations have revealed that a specific base material behaves differently with different carpets; even the test person alone has an influence on the test. Poor reproducibility of test results is therefore unavoidable. Considered as a whole, the antistatic finishing of carpets is still problematic, which is why there is great interest in intrinsically antistatic man-made fibres.

Antistatic finishing The treatment of textiles with special chemicals to increase surface conductivity in order to prevent the build-up of electrostatic charges (especially at relative air humidity levels below 30%) during spinning, combing, sizing, weaving, knitting and also for finished goods. These finishes cause a reduction in friction associated with increased softness and smoothness. The antistatic finishing of clothing materials for persons working in situations involving the risk of explosion is an area of increasing importance. The prescribed maximum concentration for each product must on no account be exceeded in any process application (problem of adhesion to machine parts). A permanent antistatic finish for polyamide still awaits development, and the main effort is concentrated on the production of intrinsically → Antistatic fibres.

Antistatics in drycleaning for prevention of spontaneous ignition of spirit in drycleaning, increase its conductivity and prevent fires and explosions (resulting from frictionally generated electricity or electrostatic charging). Antistatics used include anhydrous magnesium oleate products, (magnesia soap), drycleaning soap and drycleaning detergents.

Anti-swelling agent Finishing product for → Swelling-resistant finish, Resin finishing agent.

AOX A term for adsorbable organic halogen compounds. Most natural fibres can be treated with hypochlorite solutions (for bleaching cotton and treating wool either for print preparation or fluff removal), so inherent impurities in cotton and substances from skin and cellular cement in wool are halogenised and carried away in the waste water. When cotton is bleached with sodium hypochlorite, compounds are formed which, in accordance with DIN 38 409 H 14, can be shown to exist as AOX in the bleach bath. The AOX content demonstrates a significant dependence on the initial condition of the cotton used. The more goods that are in the bath and the dirtier the goods, the higher the AOX content after the bleaching process. The highest AOX concentrations are measured when untreated goods are placed directly into the hypochlorite bleach. The period of AOX formation is coupled directly to the success of the bleaching process. It is certainly interesting to note that an alkali boil before bleaching reduces the AOX content to a fraction of that from untreated goods.

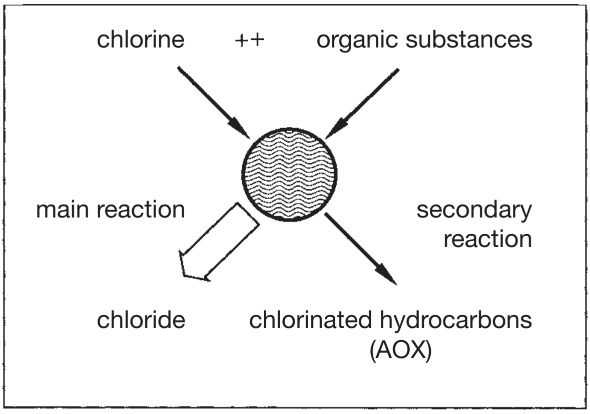

Fig: Possible reactions of active chlorine with organic substances.

Active chlorine, for example, can, in certain cases, lead to the formation of AOX in a side reaction with organic compounds. For this reason, the indirect discharge rules state that a license is required for waste water that contains more than 0.2 mg/l and 4 g/h of active chlorine (this level is similar to that of drinking water). Although there is a correlation between active chlorine and AOX, the acceptable level for active chlorine is independent of the acceptable level for AOX because the latter can originate from multiple sources, e.g. from

- Dirt from washing, e.g. waste oil (petrol stations), or disinfectants
- Washing powders and liquids
- The side reactions of active chlorine already mentioned
- The fresh water used.

The chlorine donor dichloro-isocyanuric acid, although it is itself a chlorine containing organic compound, does not react as an AOX since the chlorine is only loosely bound; that is to say, it can be compared to inorganic hypochlorite in this respect.

The AOX content of waste water is one of the fundamental criteria for judging the quality of industrial waste water. This is even more important since legal regulations such as the "Order for Licensing Requirements for the Release of Substances into Waterways, their Regulation (German abbrev. VGS)" of 27.9.1985 set very low acceptable levels and increased pollution taxes. The release of organic halogen compounds into the water is undesirable because of their immense potential for endangering the drinking water supply. Therefore, as a precaution, the legislators have set very low limits for the emission of organic chlorine compounds into the water. Given the multitude of possible compounds, regulations concerning single substances have little meaning so adsorbable organic halogen compounds (AOX) are measured as a single group. The measuring procedure is carried out during the cleaning process which is used to remove the halogenated hydrocarbons in the preparation of drinking water. Pollutants are extracted from the water by adsorption onto active carbon for analysis. The adsorbed organic halogenated compounds are burned (in a stream of oxygen) along with the active carbon and the resulting hydrochloric acid is titrated microcoulometrically.

1. Adsorption onto active carbon:

$$CH_3\text{–}CH_2\text{–}Cl + C_n \rightarrow [C_n \cdot CH_3CH_2Cl]$$

2. Washing out of chloride.
3. Incineration:

$$[C_n \cdot CH_3CH_2Cl] + (n+3)O_2 \rightarrow$$
$$2\,H_2O + (n+2)\,CO_2 + HCl$$

The AOX determination is in accordance with DIN 38 409 H 14 e.g. using the column technique with a TOX-analyser. The analysis is performed by taking an aliquot of the bleach bath, diluting 1:100, reducing excessive active chlorine with sodium sulphite and acidifying with nitric acid. Until the completion of the AOX determination, the samples are stored at 4°C in the dark in closed glass containers in accordance with the DIN regulations.

AOX value of waste water The AOX value describes analytically a definite quality of the effluent; it is a → Total parameter, i.e. it does not cover a single chemical, but a group of substances contained in the effluent. A range of substances is covered which differ widely in their ecological and toxicological properties: volatile chlorohydrocarbons (e.g. Dichloromethane, Tetrachloroethene) along with Polyvinylchloride, Green pigments and Chlorophenols, reactive dyes with Chlortriazine rings and Chlorine in the chromophore.

The procedure for analysis includes:

a) Adsorption onto activated carbon,
b) Washing out the chloride,
c) Incineration and measuring the HX (X = Halogen).

All of the organic substances present in the effluent are adsorbed onto activated carbon. The carbon is washed with a dil. Sodium Nitrate solution to fully remove any chloride ions. During the incineration, Hydrogen Halide is formed from the adsorbed organic halogenic compounds which is measured separately.

The parameter AOX occurs in the effluent tax law as well as in the regulations of the various German states; it is thus of equal importance for direct and indirect discharges. It is also certain that future effluent control provisions under the amended § 7a of the water purity law will include the parameter AOX among the "Dangerous Substances" (i.e. remove to the limits of available technology).

The AOX value of effluent from textile processing results from:

1. Auxiliaries with organically bound halogens; these are seldom used nowadays (e.g. Polyester dyeing carriers on the basis of chlorobenzene).
2. The use of Chlorine or Chlorine precursors which can lead to an AOX content in the effluent through reaction with other substances present in the water. Chloroform is often formed during this process.
3. Preservatives on the basis of Chlorophenol or other aromatic chloro compounds are for example present in several natural thickeners.
4. Dyestuffs frequently contain organic halogens so that if any dyestuffs get into the effluent, they can contribute to the AOX content. Such dyes are
   - some vat dyes
   - some disperse dyes
   - reactive dyes
   - a few pigments
   - occasional anionic dyes
   - cationic dyes

Water insoluble dyes are of particular interest here. On account of their low solubility, these dyes have limited toxicity but due to the AOX parameter, some of them could be rated as "Dangerous Substances" with respect to the disposal of effluent. In practice, water insoluble dyes can be easily eliminated by conventional methods of purification (precipitation/flocculation or adsorption onto activated sludge) and after suitable effluent treatment (e.g. in a municipal sewage plant which works in accordance with generally recognised processing rules), they therefore cause no AOX contamination to the outfall.

Still unclear is the contribution of reactive dyes to AOX. On the one hand, most reactive dyes contain an organic bound halogen in the reactive moiety: on the other hand it is expected that the reactive halogen splits off under dyeing conditions to become halide. In the chromophore of reactive dyes, organic bound halogen will occur with the same frequency as in anionic or cationic dyes. The problem of the elimination of reactive dyes has nevertheless not been satisfactorily solved.

The application of German state regulations which set a threshold concentration of 0.2 mg/l for AOX causes problems in some cases: In order to ensure the necessary total adsorption of all organic matter onto the active carbon, the sample under test must contain a max. of 10 mg/l → DOC; the detection limit for AOX is then 0.01 mg/l. In the textile industry, but also in other branches of the economy (e.g. the food industry), effluent can contain a DOC of 1000 mg/l (or higher). A water sample with a DOC of 1000 mg/l would have to be diluted by a factor of 100 for AOX determination; the detection limit for AOX thus becomes 100 times higher at 1g/l. In such a test it cannot be analytically proven whether the threshold limit of 0.2 mg/l AOX (for a release of effluent without further approval from the local water authorities) has been adhered to or exceeded.

Ap, → Alpaca, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988. From 1991 → WP.

APCA, abbrev. for: Air Pollution Control Association (USA).

APEO Alkyl phenol ethoxylates were, for a long time, recognised as having good biodegradability. The biodegradation essentially stopped at the level of the alkyl phenol or double ethoxylated alkyl phenol. In toxicological tests, however, these metabolites were shown to be fish toxic. In further studies it was also shown that the degree of degradation is significantly decreased at lower temperatures for higher levels of ethoxylation e.g. in winter. Once this ecological failure of APEO became known, the producers and users of these products in Germany subjected themselves to a voluntary self-regulation. The Association of Tegawa (Registered Association of Textile Auxiliaries, Leather Auxiliaries, Tanning and Surfactant Raw Materials Industries) has, since the end of 1988, willingly abandoned the use of APEO in the wetting and washing agents used in the textile industry.

As an alternative, the fatty alcohol ethoxylates were developed. In contrast to the alkane sulphonates, all nonionic surfactants based on ethoxylation are not composed of a single substance but are a mixture of molecules with different numbers of ethylene oxide blocks which in turn can occur in different distribution patterns. During the chemical reaction of the base alkyl phenol or fatty alcohol with ethylene oxide, there are large differences in the reactivity of the components (Fig. 1).

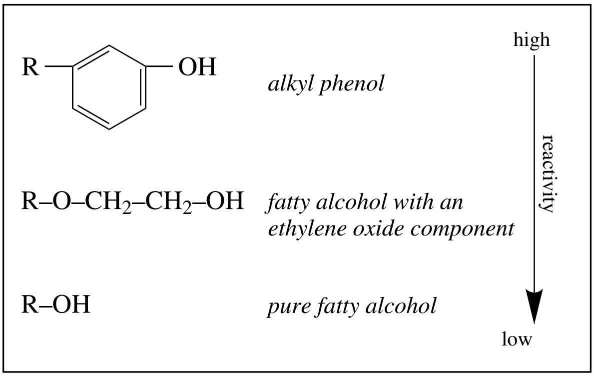

Fig. 1: Reactivity of basic materials for surfactant production.

Alkyl phenols possess the highest reactivity (Fig. 2) and thus it is possible to synthesise an end product which contains a high percentage of the desired substance, whether or not a high or low degree of ethoxylation is sought. Since fatty alcohols are the reactants with the lowest reactivity, all fatty alcohol ethoxylates always contain a considerable proportion of unreacted fatty alcohol. Fatty alcohols are not water soluble and reduce the alkali stability of the final products.

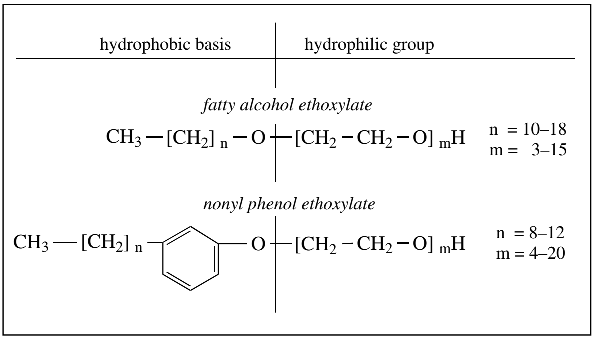

Fig. 2: Nonionogenic surfactants, chemical structure.

Aperture (Latin: opening) In optics, aperture is the moderating part of lens systems. For the finest details, the brightness and definition of the microscope objective increases with increasing aperture. In micro-examination with immersion fluids, the numerical aperture increases, e.g. with the use of monobromonaphthaline, to 1.6 (air = 1). The total usable enlargement, which determines the value of the microscope, should, according to the Abbe rule of thumb, lie somewhere between 500 and 1000 times the numerical aperture of the objective lens at maximum objective power.

Ape skin (velveteen) Raised, closely shorn or sanded cotton sateen or twill with short, close velvety pile (imitation velvet). →: Duvetine; Apricot skin).

Apochromatic objectives Microscope objective lenses with maximum resolution and consequently outstanding image quality.

Apollotex Electron Reactor Pad-roll system especially designed for heterogeneous alkaline hydrolitic surface saponification of polyester fibres to produce a handle similar to that of natural silk, alkaline treatment and weight-reduction. The process is based on the fact that the chemical structure of polyester fibres allows hydrolytic degradation in the presence of acids or alkalis. The nature and severity of this treatment produces different degrees of modification in the structural make-up of the fibre, with effects on the utilitarian properties especially the otherwise high mechanical strength. On the other hand, alkaline hydrolysis of polyester fibres in textile finishing is used specifically to modify certain properties. The best known and most widely used in terms of product volume is the alkaline treatment of polyester with caustic soda solution, in which a fine denier fibre is obtained by hydrolysis taking place on the fibre surface. This method is based on early patents by ICI and Dupont. It is also a known fact that cationic surface-active agents accelerate degradation, i.e. in the presence of these auxiliaries the same weight reduction is obtained in appreciably shorter dwell times and/or at low NaOH concentrations. At the same time the fibre surface is "roughened" in such a way that pigment binder adhesion is superior to that in untreated fibre. The procedure sequence is alkali impregnation (10–30% NaOH), liquor pick-up 75%, heat-zone dwell (100°C, 10 min) incorporating saturated steam and microwave heating (300 MHz). Weight reduction as high as 50% can be achieved with the Apollotex Electron Reactor. Maker: Ichikin.

Application methods When textile finishing products (dyestuffs, auxiliary products, chemicals) are employed on textile fabrics on the basis of capillary suction forces, these finishing substances have to be brought into contact with the textile fabric in dissolved, solid or paste form (this does not include application from the gas phase).When the products have been applied in a suitable form they are fixated.

Application processes:

I. Dwell process: principle: minimum application with a moving fabric (with an aqueous liquor), stationary development. Woven or warp knitted fabric impregnated on a padder (padding) and batched in open width, i.e. crease-free; with beginning and end.

After this pre-treatment:

a) Cold dwell process: dwell (lengthy dwell time) for developing the dye by rotating the cloth beam under atmospheric conditions.
b) Hot dwell process: dwell (short dwell time) by rotating the cloth beam in a steamer.

II. Continuous process: principle: minimum application, development and after-treatment in one operation with running fabric. Woven or warp knitted fabric, fed in open width and spread; infinite length. Treated on: continuous dyeing machine in accordance with:

a) Pad-steam process: padding on pad mangle (from an aqueous dye liquor), fixation in steamer. Washing unit.
b) Thermosol process: (for woven polyester/cotton fabric); padding on padder, infra-red pre-drying, finish-drying, fixation.

III. Printing:

a) Screen printing: fabric moves intermittently: two-dimensional pattern stencils are applied and doctored.
b) Roller printing: fabric constantly moving; engraved and doctored rollers apply the colour.
c) Transfer printing: fabric constantly in motion; dye compounded with simultaneously moving paper. Print transferred by temperature action.
d) Rotary screen printing: fabric in constant motion; rollers perforated in accordance with the pattern apply the colour, the dye being doctored inside the rollers. → Padding process.

Applicator Device for applying dye, fixation, treatment or coating liquors.

Applicator roller (metering roller, slop padding roller, tip roller), in the case of a twin-roller padder, the bottom padding roller with controllable liquid immersion depth; embossed or dot engraved (thousand point roller). Used for finely dosed, singlesided liquor application to piece goods in the squeeze nip. In coating by the reverse roll process (Fig.), the roller running in the application direction, from which excess of molten polymer is doctored at each revolution, is described as the applicatior roller (in contrast to the metering roller, which runs at a different speed against the paste application direction).

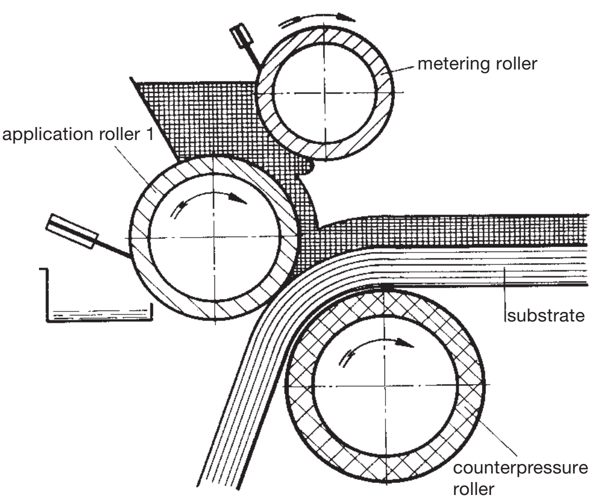

Fig.: Metering and application principle of the reverse roll process, with which highly viscous, thixotropic media are largely processed.

Appliqué Decorative materials, e.g. piping, pearl cotton yarn, cord sewn onto textile fabrics with special patterned effect.

Appliqué carpets Hand-made non-pile carpet comprising a base fabric to which are stitched are affixed by adhesive pieces of fabric and/or yarn. Used for floorcovering and wallcovering.

Apposition dyeing or deposition dyeing, in which only the periphery of the fibre cross-section and not the inner core of the fibre is dyed. In printing this may be called → Surface print, and the opposite in which only the inner core of the fibre is dyed is → Intussusception dyeing.

Apricot skin (peach skin) similar to → Ape skin. Usually cotton warp and Schappe silk or woollen yarn weft.

Aprotic solvents inert neutral → Solvents (with low dielectric constant) containing no ionisable proton in the molecule e.g. benzene, chlorobenzene and chloro hydrocarbons.

AP, USP, abbrev. for: American patent (United States patent).

AQL, abbrev. for: → Acceptable Quality Level.

Aqua fortis (Lat.: literally: strong water). An obsolete name for conc. → Nitric acid which dissolves all metals with the exception of gold.

Aquagraphics A development on a 600 years old Turkish dyeing technique called Ebru. A multi-coloured design is produced using a fluid medium thickened with a synthetic auxiliary in which a prepared dye with fastness to light and washing is incorporated at number of sites. These are then intermingled by stirring, in accordance with the pattern determined by the designer, and by this means a non-repeatable design can be created. The design is applied by introducing the textile to the mobile mass and removing it, with subsequent fixation by techniques specific to natural or synthetic fibres. Transfer printing is also possible using this technique. Maker: Lamlee Studio, New York.

Aqua regia (Lat.: literally: royal water). A yellow, fuming, corrosive mixture of 1 volume conc. nitric acid and 3 volumes conc. hydrochloric acid. Dissolves all metals including gold.

Aquatic (Lat.: *aqua* = water), growing, living or found in water, e.g. aquatic ecosystems, aquatic organisms (e.g. fish), aquatic toxicity (e.g. fish toxicity).

Aquatic fungi (phycomicetes) → Moulds.

Aqueous emulsion An → Emulsion of the oil in water (O/W) type.

AR → Aramid fibre → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

Ar,

I. chemical symbol for argon (18).

II. abbrev. in chemical formulae for → Aryl, e.g. benzene sulphonic acid: $C_6H_5–SO_3H = Ar–SO_3H$; alkylaryl sulphonates: type $R–Ar–SO_3H$.

Arabic gum → Gum arabic.

Arabinic acid Main component of Gum Arabics, belonging to the → Polysaccharides. Also occurs to a greater or lesser extent in the form of Calcium, Magnesium or Potassium salts in most other plant rubbers. Amorphous substance, colourless, transparent, shiny, brittle, odourless and tasteless. Easily soluble in water to a glutinous consistency, insoluble in alcohol, ether, fats and etheric oils. Aqueous solutions are optically polarised to a sinistra rotation, and are thickened by Sodium Tetraborate. Decomposition by Nitric acid leads to Oxalic acid, and by warming with dil. Sulphuric acid leads to Dextrin and Glucose.

Identifying reactions:

1. Aqueous solutions are precipitated by alcohol.
2. With Caustic Potash and a few drops of Copper Sulphate solution, a blue precipitate appears (Arabin and Copper Oxide) which does not turn red-brown on heating.

Arachidic acid (eicosanoic acid), $C_{19}H_{39}COOH$. A widely distributed but minor component of the fats of peanut and rapeseed oils.

Arachin fibre A fibre belonging to the group of → Man-made protein fibres, derived from the vegetable protein arachin which is present in peanuts. Produced by the wet spinning process (coagulation bath: sulphuric acid, sodium sulphate) to give a wool-like fibre with a tenacity of 6–8 cN/tex and 40–60% elongation. Now very seldom used in mixtures with wool or cellulosic fibres, e.g. in the making of hair felts.

Aralkyl A term used to describe compounds containing both → Aryl and → Alkyl structures, e.g. of the toluene type (methylbenzene) $C_6H_5CH_3$. Not to be confused with → Alkyl aryl compounds.

Aralkyl sulphonates → Alkylaryl sulphonates.

Aramide (fibres) The word Aramide comes from “aromatic polyamide” (Polyaramide) and means that it has to do with polyamides that contain aromatic six carbon rings in the polymer chain (Fig. 1).These make polyamides, which would otherwise soften and burn at 260°C max., into unmelting and temperature stable compounds of a slightly yellowish colour. They can be converted into textile fibres by a special spinning process and thus form the basis of asbestos substitutes in many application areas. They are of high strength because the crystalline content is high due to the intensive interaction between the highly structured polymer molecules. The chemical properties are similar to those of Polyamide 6.6.

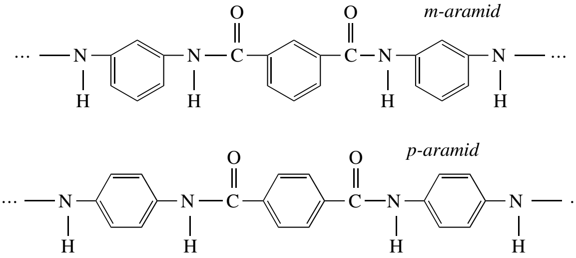

Fig. 1: Aramid fibre structure.

Dupont has developed and marketed two families of fibre products on an aramide basis under the names of “Kevlar” and “Nomex”. Both are extraordinarily resistant to heat, stable at elevated temperatures and posses a high electrical resistance. Their structures and additional properties are however very different.

Nomex was the first aramide fibre, commercialised by Dupont in the mid 60’s. It is a meta orientated aramide, based on poly-m-phenylene-isophthalamide. The meta orientation of the carbon-aramide bonds gives a relatively supple molecule which gives textile properties to the fibre. The areas of use therefore include protective clothing, filter cloths for hot gases, papers for electrical insulation and honeycombs for composite components for aircraft and rockets. Kevlar: the para orientation of the benzene ring and the symmetrical arrangement of the amide bridges in the resultant molecule leads to a linear polymer chain of high rigidity which is directly responsible for the great stability of this product. Kevlar is, chemically, a poly-p-phenylene-terephthalamide and is produced by the condensation of terephthaloyl chloride with p-phenylenediamine. It exhibits the same excellent thermal and electrical properties as the m-aramide, but in addition offers high resistance to tearing and cutting and a high modulus of elasticity. It is therefore used for cut-resistant substances, for ballistic materials, as a replacement for asbestos in brake and clutch linings and to reinforce rubber products and laminates.

The theoretical knowledge that para orientated fully aromatic polymer systems, particularly polyamides, must lead to fibres of high linear strength and modulus of elasticity, due to their rigid molecular structure, can be wholly confirmed by the development and industrial production of Kevlar. It may however be mentioned that, because of the insolubility of poly-p-phenylene-terephthalate in conventional organic solvents, the production and spinning of the polymer into fibres are extraordinarily difficult and took many years of development.

The polycondensation is carried out with p-phenylenediamine and terephthaloyl chloride, by reacting both monomers in a solvent e.g. methyl pyrrolidone in the presence of a relatively high amount of $CaCl_2$ (Fig. 2). The polycondensate is freed from the solvent, dried and dissolved in conc. sulphuric acid at about 80°C for spinning. Prerequisites for good fibre properties are the concentration of the polymer in the sulphuric acid and the temperature of the spinning solution so that the polymer solution exhibits a liquid crystal structure. Spinning is done by the usual wet spin process. The use of an air break between the spin jets and the spin bath can be advantageous. Direct spinning methods are impractical. After drying, the thread filaments are stretched at a ratio of 1:1.001–1.021 in a secondary process at 250–550°C in a Nitrogen atmosphere and under a tension of 4–6 cN/dtex. The filaments then possess a higher modulus of elasticity than the spun wares and with the same strength and stretchability and can be used in the production, particularly, of high performance composites.

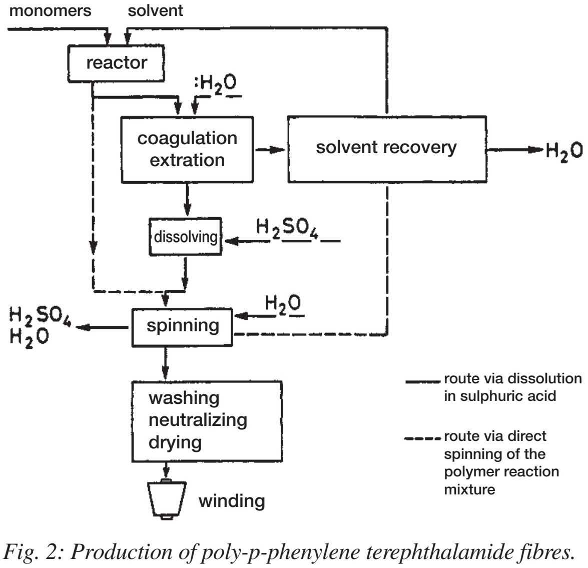

Fig. 2: Production of poly-p-phenylene terephthalamide fibres.

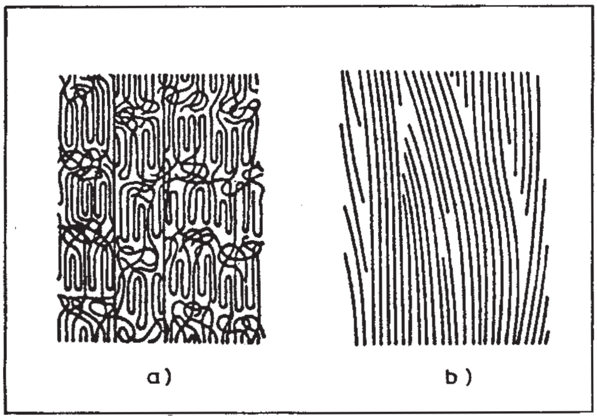

Fig. 3: Microstructure of a) polyester and b) aramid fibres.

The structure of the poly-p-phenylenediamine fibres shows some characteristics differing from those of other synthetic fibres. The distribution of orientation of the polymer chains is very narrow on account of the wet spin process; this leads to a high initial modulus of elasticity of 70 Gpa which can be raised to 140 Gpa by the aforementioned stretching. The high linear strength is caused by the extreme elongation of the very long polymer chains and the rigid rod shaped form of the monomer units which can crystallise in spite of the rigidity because hydrogen bonding and the planar phenyl and amide groups make possible a high degree of structure. The size of the crystallite varies between 20 and 100 nm in the direction of the fibre axis and between 4 and 10 nm radially. The quality of the crystallite is far better than can be inferred from the lattice deformation parameter. The relevant values vary between 1% for thermofixed and 3% for untreated fibres. Since no X-ray diffraction is observed in poly-p-phenylenediamine fibres, they do not possess the usual 2 phase structure; they are paracrystalline and monoaxial (Fig. 3).

Aramide laminates are superior to steel and aluminium, particularly in respect of strength and modulus of elasticity. However in mechanical bending, their properties under pressure play a large role in most constructive uses. Thus, in all situations where the material is flexed, compression is also present. By experimental determination, the compression strength of aramides is only 20% of their tensile strength and this low value represents a significant limitation to their use in structural components. This can be remedied by the use of a hybrid composition (carbon fibre in the compression zone and aramide in the tensile zone). With respect to malleability, aramides are significantly superior to carbon fibres. The poly-p-phenylene-terephthalate fibres possess good resistance to heat and oxidation which allows them to withstand relatively high temperatures for a reasonably long time, and still suffer only insignificant losses to their properties (Glass transition temperature approx. 300°C, Heat shrinkage at 160°C approx. 2%) (contributed by von Falkay).

Aramidimide, in analogy with Aramide and, a contraction for fibres from polyaryl amidimides. Typical members are e.g. organic → High temperature fibres.

Aramina fibre → Urena fibres.

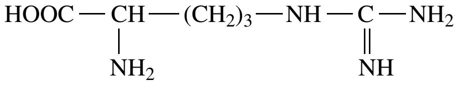
ARBE, (Ger.) abbrev. for: Arbeitsgemeinschaft Bekleidungsindustrie e.V. (German Clothing Industry Study Group); → Technical and professional organizations.

Archil → Natural dyes.

Arch steamer → Continuous steamer as a mainly floor-mounted, vertical, semi-circular type machine, through which the fabric to be steamed is passed over side rollers; particularly for two-stage printing processes.

Area bonding Descriptive term for the production of nonwovens where adhesion takes place over the entire surface. See also → Point bonding.

Arginine (guanidine aminovaleric acid; amino-4-guanidovaleric acid). A basic → Amino acid present in wool (10,4%) and silk (1,05%).



$$\mathrm{HOOC-\underset{\displaystyle NH_2}{\underset{|}{CH}}-(CH_2)_3-NH-\underset{\displaystyle NH}{\underset{\|}{C}}-NH_2}$$

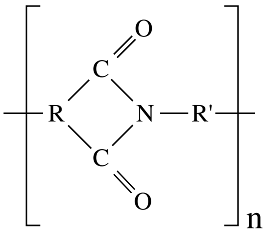
Armoured woven fine cloth Metal woven filter fabric with the finest orifices (max. 17 µm). This fabric is therefore employed in areas where it appears to be suitable for fine filtration without auxiliary filtering agents.

Aromatic compounds (aromatics, alicyclic or cyclic compounds). In the widest sense they are derivatives of benzene *inter alia* → Hydrocarbons. Also includes the → Cyclic hydrocarbons and their derivatives (cyclohexene type), heterocyclic compounds (pyridine type), as well as their derivatives. The name "aromatic" is due to the strong and not unpleasant odour characteristic of most substances of this nature derived originally from natural sources (balsams, resins, etc.). See also → Aliphatic compounds.

Aromatic nuclei → Cyclic hydrocarbons (benzene type).

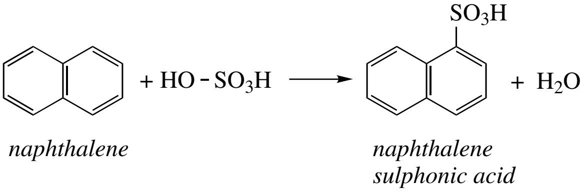
Aromatic polyamide fibres → Aramide fibres.

Aromatic polyimide fibres in analogy with → Aramide fibres, this is the commonly accepted term for fibres based on aromatic polyimides: → High temperature fibres, whose chemical base module is characterised by aromatic rings connected by imide bonds.



Through their properties and areas of use, they are classified with the Aramides (e.g. Nomex), the Aramidimides (e.g. Kermel) and the polybenzimidazole fibres (PBI-fibres). Use area: equipment for aircraft, space craft and rescue craft, upholstery material, hot gas filters, electrical insulation, life jackets and the like.

Aromatic sulphonic acids and sulphonates are produced from aromatic hydrocarbons by sulphonation resp. the introduction of sulpho or sulphuric acid groups. Example:



The soap-like properties as well as their foaming, wetting, dispersing, emulsifying and softening characteristics increase with increasing size of the molecule. Aromatic sulphonic acid products have good stability to water hardness salts and acids and may be used in alkaline as well as neutral liquors. Uses: versatile wetting agents for desizing and dyeing, also for pasting and dissolving dyes in vat dyeing (also naphthols). Further uses in carbonizing, milling, oiling auxiliaries, finishing, sizing, etc.

Arrhenius equation Describes the temperature dependency of the speed constant k. The following formula applies:

$$k = A \cdot e^{-\frac{E_A}{RT}}$$

R is the gas constant, E_A is described as the activating energy of the reaction. From experience, it is almost independent of temperature over a wide temperature range. The pre-exponential factor A can be regarded as the limit value of the reaction speed constants for T → ∞. It is also called frequency factor or impact factor. For many reactions, the Arrhenius equation represents, with a good degree of approximation, the dependency of reaction speed on temperature. For determining activation energy and frequency factor, it is used mainly in the form

$$\ln k/k^+ = \frac{-E_A}{RT} + \ln A/A^+$$

k^+ and A^+ have the numerical value 1 and the dimension of k. If ln k/k^+ is plotted against l/T on a graph, the activation energy E_A can be determined from the gradient m of the straight line curves, and the frequency factor A from the axis intercept.

Arrowroot (curcuma starch), West Indies (W) so-called arrowroot flour; East Indies (O): Bombay or Malabar arrowroot (cheapest); Brazilian (B); also cassava starch, small translucent lumps (tapioca/sago). Outward appearance: A + O = matt, white; B = matt, greyish white. Feel: A = highly scroopy; O = less. Arrowroot very often appears adulterated. Water content is approx. 15–20%. It swells up at approx. 50°C, while it sticks together around 70°C. Paste: A = clear bluish, mucilagenous; O = pure white; B = like potato starch. Finish handle: differs greatly, but like potato and wheat starch. Use like starch.

Arsenic (As), atomic weight 75. Arsenic is a typical transitional element which exhibits metallic and non-metallic characteristics. Silver-grey, yellowish, brownish or black powder with a metallic lustre. Arsenic is very poisonous and starts to burn when heated in air (garlic odour).

Compounds: with hydrogen = arsenic hydride (arsine) AsH_3 (extremely poisonous) which is made use of in the analytical detection of very small traces of arsenic (→ Arsenic traces, test for); with sulphur = sulphides, halogenides, etc. Uses: arsenic salts are used in the preparation of hides and skins; as a colour pigment (copper acetoarsenite, Schweinfurt green, Paris green – toxic); as a depilatory in tanning, etc.

Arsenic film consists of a brownish-black coating of metallic arsenic which is deposited on the surface of glass test apparatus e.g. by heating arsenic hydride, or arsenic and carbon. → Arsenic traces, test for.

Arsenic sulphides → Orpiment.

Arsenic traces, test for Marsh's test for arsenic. Hydrogen gas is produced in a gas generator vessel by the action of sulphuric acid on zinc and the solution to be tested is poured in. If arsenic is present, arsenic hydride AsH_3 is formed which, after drying, is passed through a hot zone where the AsH_3 decomposes with the preciptation of arsenic as a dark lustrous film and hydrogen is burnt off. In contrast to antimony film which can also be formed in a similar manner, the arsenic film is soluble in sodium hypochlorite solution.

Arsenometry Titration method for detecting pure hypochlorite chlorine (active chlorometry).

arté Term for insect fretted silk.

Artefact (Lat.: *ars* = skill; *facere* = to make), e.g. microscopical structure not present in an original substance but which is formed after a preparation treatment (comminution, solution, swelling, electron-beam action).

Article When, for example, the textile pattern designer of a woven or knitted fabric manufacturer is assigned to create the season's new range, each type of fabric is given a designation in the form of a number, often with an additional fantasy name. Each new fabric quality thus produced is referred to as an article, this being subdivided into designs in the case of patterned fabrics and into colours with plain fabrics. Where printed fabrics are concerned, a design is also produced in different colourways (colourations).

Not only clothing fabrics are referred to as articles; in other areas too, like garment manufacture, specific materials (dyed, printed, coated and/or finished) that belong to the finished article are purchased from the fabric manufacturers. Hence, the textile finisher plans the disposition of his product range according to the article directory pertaining to the next step in the production chain, i.e. garment manufacture, wholesale and retail. The catalogue of requirements stems from the article directory and is what the process technology for textile finishing is based on. The finisher must, however, take into account the fibre type in the article directory to suit the respective field of application.

Article specific designs Fabrics produced for a specific end-use and incorporating a design of dimensions appropriate to the item being woven (as opposed to designs continuing through the piece for goods sold by the metre or by the piece) in the form of a centre piece, corner design or border, as for example in blankets, towels, headscarves, handkerchiefs, tablecloths, serviettes and carpets.

Artificial flower finish Stiff finish predominantly on woven viscose fabrics for producing artificial flowers. The finish may not impair dip dyeing.

Artificial fur Woven → Imitation furs from woven pile fabrics (e.g. astrakhan, karakul, sealskin), high-pile → Plush (previously of mohair or wool), mainly from synthetic fibres.

Artificial intelligence covers the science of endowing machines with intelligence similar to human intelligence. Naturally a system, a science or a machine cannot be intelligent, but they can be made to use similar deductive processes to those of human beings, even if only to a very limited extent. This means that a computer should be able to understand the state of the system from one or several sources of information, and on the basis of the relationships known to it, to decide what is the best action to take. The intelligence of a computer is therefore directly proportional to the knowledge and relationships that have been entered into it. This is nothing other than knowledge of the functional dependence of a target value on a set of individual parameters together with all the interactions associated with them. The practical application of artificial intelligence is in → Expert systems; these should mimic skilled personnel. The design and construction of an expert system is called knowledge engineering. Knowledge engineers ask experts for specialist knowledge of their trade and formulate the knowledge so that it can be structured and arranged in knowledge diagrams. The knowledge gleaned in this way from the specialists is stored in knowledge databanks where it can be accessed quickly.

Artificial leather → Coated textiles in accordance with DIN 60 000 having leather-like characteristics and/or a leather-like surface structure, e.g. embossing. Main types: fibre, woven fabric, film, nonwoven fabric and warp knitted fabric artificial leather. Artificial leather is mainly produced from polyvinyl chloride and polyurethane, less often from polyacrylates and polyamides. Relevant important details: paste production, filling material, viscosity control, stabilizers, dyestuffs and pigments, adhesive agents etc. Machine park comprises: a) paste producing machines, b) coating equipment, c) printing and lacquering or spraying equipment, d) embossing calender, e) raising machine, f) tumbler or creasing machine, g) re-rolling, inspection and cutting machine. Despite great efforts, no one has succeeded in producing a substitute equal in quality to natural leather. The problems of moisture absorption and air permeability have not yet been satisfactorily solved.

The largest proportion of artificial leather produced goes into the automobile and leather goods industries and also into the production of awnings, tarpaulins and roller blinds. Only some 10% is taken by fashion sectors like clothing and shoes. Compared with natural leather, artificial leathers have the same appearance, but are to some extent independent products with specific advantages like low weight and easy care. → Imitation suede.

Artificial silk Obsolete term for regenerated cellulose filaments.

Artificial soil (3 component combination) → Soiling test.

Aryl (Ar), aromatic → Alkyl: monovalent aromatic hydrocarbon radicals, e.g. from benzene C_6H_6: → Phenyl C_6H_5; from naphthalene $C_{10}H_8$: → Naphthyl $C_{10}H_7$.

AS,

I. → Asbestos fibre, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

II. abbrev. for: Australian Standard.

III. (Ger.) abbrev. for: Auslegeschrift (patent specification). In addition to important bibliographical data in a patent application, it also contains the description, patent claims, and design. Available for reference purposes in Patent Offices.

As,

I. chemical symbol for → Arsenic (33).

II. → Asbestos fibre, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988, from 1991 → AS.

Asbestos (Gr. *asbestos* = inextinguishable). A fibrous variety of magnesium silicate. Its particular value is due to a combination of 3 properties: i.e. the material is stable to temperatures up to 1000°C and above, it is resistant to acids and also forms fibrous crystals with good tensile strength. Asbestos occurs in nature in the form of fibre bundles. The fibres are strong and flexible so that spinning into yarn is possible with the longer fibres. It has a long history of use as a raw material for fireproof clothing, heat insulating jackets, heat shields and heat insulation boards in the space, aeronautical and building industries. It has also found wide application in brake linings. Since 1. 1. 1987, however, the use of asbestos in new automobile brake linings is no longer permitted. The inhalation of fine asbestos fibres can, over the long term, cause cancer in humans. It is for this reason that research has been directed towards finding less hazardous substances with asbestos-like properties. In this regard, certain textile fibres have been developed possessing similar properties to asbestos but without the health risks since they have been manufactured in such a way that, unlike asbestos, no lung-threatening fibres are formed from the outset. Depending on the field of application, the natural raw material asbestos can be substituted by glass and ceramic fibres, aramid and carbon fibres.

Properties: Asbestos is, in fact, incombustible. Depending on the variety, however, asbestos fuses at high temperatures, i.e it becomes hard and brittle depending on how much chemically-bound water is removed. The chrysotile variety gives up water slowly at 315°C but at 650°C it becomes water-free, friable, and loses strength. Even when heated frequently at high temperatures, white asbestos (Canadian) exhibits only a slight loss in strength but a considerable loss in extensibility. The strength of blue asbestos (East African) falls on first heating by approx. 12% and again on subsequent heating by the same amount. Chemical properties: only the brown and blue African asbestos varieties are stable to acids, all other varieties have limited stability. Dilute mineral acids have a more intensive action here than the conc. acids. Asbestos is attacked only slightly by alkalies and oxidizing substances at normal temperatures.

Asbestos fibre, further developments Asbestos fibre dust has proved to be dangerous to health (highly toxic by inhalation of dust particles – a carcinogen). The American company Raybestos/Manhattan has developed an automatic process for the manufacture of asbestos yarns which even meets the stringent OSHA Regulations. Similar further developments from Eternit AG with Hoechst and Kuraray Synthetic Fibers as substitutes for asbestos are Kolanit 10 (Hoechst) and Kuralon (Kuraray) as well as modified polyacrylonitrile and aramid fibres.

Asbestos fibres Naturally occurring → Mineral fibres (Europe, Russia, Africa, America, Canada) as hydrated silicate of magnesium $Mg_6Si_4O_{10}(OH)_8$ in fibrous varieties of *Serpentine* resp. *Chrysotile,* which were of chief importance for textile purposes, or as the weathered products of hornblende (complex silicates of calcium, iron and magnesium). The fibres consist of long, fine, soft crystalline needles in a chain silicate structure. X-ray investigations carried out as long ago as 1930/32 already revealed the fine structure of these fibres (see Fig.). The basic building block of asbestos minerals is, as for all silicates, the SiO_4 tetrahedron. The oxygen possesses the characteristic property of being able to belong to two different tetrahedrons at the same time. The various arrangements and linking of SiO_4 tetrahedrons in combination with different metal atoms is a characteristic feature of the fundamentally variable structure of asbestos minerals (*Serpentine* and *Amphibole* asbestos). The density varies according to origin, e.g. *Chrysotile* 2,2–2,8 and blue South African asbestos 3,2–3,6. Depending on mineral impurities, the colour varies from white to grey, green and brown. Fibre length in the raw mineral is 15–25 cm (the most valuable are the very long curled Bostonite and Canadian asbestos fibre varieties). Fibres of 2–5 cm are used in spinnable form. There is virtually no limit to the fineness of asbestos fibres; the crystals may be subdivided until they are so fine that they cannot be seen through an optical microscope. Fibre lustre is extremely variable depending on origin. Amianthus is silky with a mother of pearl-like translucent appearance; Chrysotile has a metallic shot-like waxy or matt lustre. The fibres have a more or less waxy smooth handle. Good quality asbestos fibres should be soft and flexible. Uses: Nowadays the use of asbestos has been largely forbidden because of its carcinogenic properties. Formerly, asbestos rovings were spun on conventional spinning frames (ring or flier) frequently mixed with other fibres before spinning, e.g. often with 2–10% cotton. Its main applications were those in which its resistance to heat and burning were all-important, such as fireproof fabrics (furnishing fabrics, theatre curtains and scenery, fireproof clothing), heat insulation, seals and packings (flanges, manhole gaskets, glands, etc.).

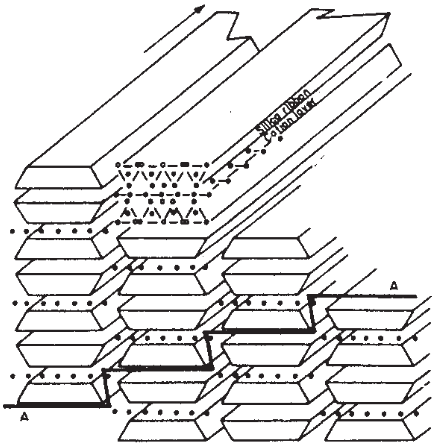


Fig.: Schematic diagram of the structure of an asbestos fibre (arrow = fibre axis direction).

Asbestos substitutes These include fibres that are suitable for use as substitutes for asbestos. For most fields of application, asbestos can only be substituted by fibrous materials. Packings and gaskets are an exception, however, since flexible graphite films are used for these applications. In order to qualify as possible substitutes, synthetically produced fibres must:

- be able to satisfy physico-technical requirements,
- be available in sufficient quantities at an acceptable cost,
- have either a low biological effect or none at all.

An overview of possible fibre substitutes is given in the Fig. Each specific property of asbestos can be covered by a different fibre material. Evaluation from the technical and economic points of view indicates that all inorganic amorphous fibres are suitable, e.g. textile and non-textile glass fibres. Substitution by crystalline

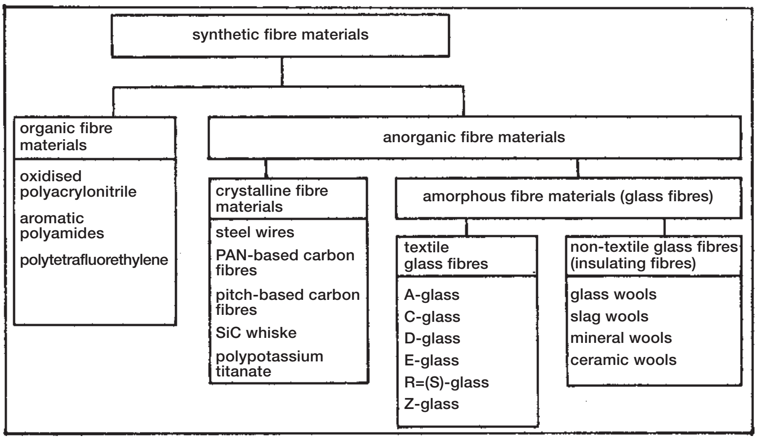

Fig.: Survey of types of synthetic fibres suitable as asbestos substitutes.

inorganic as well as organic fibres is likewise an acceptable alternative, although comparatively higher costs must be reckoned with in this case. From the technical and medical standpoints, oxidized polyacrylonitrile and carbon fibre products can be used in all fields of asbestos substitution.

ASBL, (Fr.) abbrev. for: Annales Scientifiques Textiles Belges (Belgian Scientific Textile Records), Belgian textile research centre. → Technical and professional organizations.

Ascending design Pictorial carpet motifs which are mainly discernible only when seen from one viewing direction.

Asche test For the verification of electrostatics eliminated in synthetic fibres by soft rinsing agents.

Asclepias fibre → Akund.

ASD, (Fr.) abbrev. for: Association Suisse de Documentation (Swiss Association for Documentation), identical with → SVD.

ASDC, abbrev. for: Associate of the Society of Dyers and Colourists; professional qualification of the → SDC, Bradford, U.K.

ASENET, (Fr.) abbrev. for: Association Suisse des Entreprises de Nettoyage à sec et d'Entretien des Textiles (Swiss Association of Drycleaning and Fabric Care Enterprises), (analogous to the VSCTU); → Technical and professional organizations.

Aseptic, germ-free condition, → Sterile. Opposite of septic.

Ash non-volatile mineral residue in powder form produced when matter is burnt.

Ash content Ash residue remaining after the complete combustion of a specific material. The ash content of wood pulp is 0,2–0,3% and of viscose approx. 0,1%.

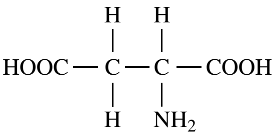
Ash tests, specifically for the detection of metals in dyeings; →: Aluminium, Chromium, Iron and Copper in dyeings, detection of.

Asiatic gums → Vegetable gums, with a greater or lesser content of arabin and bassorin. They are generally only swollen in hot water, but are dissolved by pressure boiling to give thick, viscous liquids with excellent flow characteristics. Asiatic gums include Ghatto, Karaya and Shiraz gums which are used as industrial gums for textile printing thickeners (alkali-sensitive).

Karaya gum, which mostly contains over 50% bassorin, is similar to Bassora gum and Tragacanth, somewhat more readily soluble than the latter it is often used for the adulteration of these gums.

Asociación Espanola de Quimicos y Coloristas Textiles (AEQCT) Spanish Association of Textile Chemists and Colourists. → Technical and professional organizations.

Aspartic acid A naturally occurring → Amino acid (asparaginic acid, asparagic acid, aminosuccinic acid, monoamino dicarboxylic acid) which is present in wool (up to 7,27%) and silk (up to 2%).



$$\mathrm{HOOC-\underset{H}{\overset{H}{C}}-\underset{NH_2}{\overset{H}{C}}-COOH}$$

Asphalt A dark brown to black cementitious material, solid or semi-solid in consistency, in which the predominating constituents are bitumens which occur in nature as such or are obtained as residues in petroleum refining. Melting range 70–150°C. Asphalt is soluble in benzene, chloroform, carbon disulphide and turpentine. Uses: special paints, adhesive in electrical laminates, insulation primers and leather lacquers.

Aspirated psychrometer → Psychrometer.

ASQ, (Ger.) abbrev. for: Arbeitsgemeinschaft für statistische Qualitätskontrolle (German Study Group for statistical quality control). Since the end of 1972 → DGQ.

Assimilated carbon In biological clarification systems for waste water an assimilation, which is independent of light, takes place with some strains of bacteria through chemosynthesis.

The required energy is obtained through the oxidation of ammonia, nitrite, iron oxide, hydrogen sulphide, etc. The assimilates (products of assimilation) are further broken down to some extent by mineralization (at first with an increasing and later a decreasing number of bacteria), see Fig.

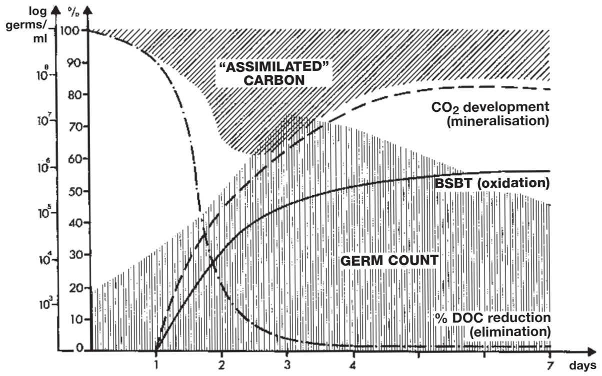


Fig.: Elimination, oxidation and mineralisation of citric acid in the GF test.
Assimilated carbon = 100% – (% DOC + % CO_2).

Associate The result of → Association. An associated compound.

Association (Lat.: *associare* = to ally with). Chemically: combination of molecules of the same type to form molecular associates such as e.g. micellar colloids. The stability of such associates varies greatly:

decomposition takes place sooner or later on heating into the individual molecules. In the case of dyes, association allows a concentration of dye to form in close proximity to the fibre, e.g. an important factor for dye exhaustion on cellulose (therefore a high tendency to form associates = good → Substantivity). Dyes which form weak associates or none at all are e.g. → Acid dyes.

Association colloids (micellar colloids) → Colloids.

Association, degree of Amount of → Association, which increases as the electrolyte content (salt addition) rises and falls with temperature for direct dyes. For dissolved cationic and acid dyes, the Degree of Association (according to Roth) is about 1.1–2.6, for substantive Benzopurpurine 4B (dependant on concentration and salt content) 6–800, and for Chicago Blue 6B between 3 and 37. → Aggregation, degree of.

Association des Chimistes de l'Industrie Textile (ACIT). French Association of Chemists of the Textile Industry. → Technical and professional organizations.

Association Internationale de la Soie (AIS). Worldwide organization for the entire field of silk cultivation (silk trade, finishing, garment making) with headquarters in Lyon. Founded in 1947. → Technical and professional organizations.

Association Internationale de Savonnerie et de la Détergence (AIS). International Association of Washing Agent and Detergent Manufacturers in the European Community. → Technical and professional organizations.

Association of surfactants The physico-chemical principles underlying the rheological properties of surfactants in aqueous solutions have been thoroughly investigated. As illustrated schematically in Fig. 1, surfactants form micelles in aqueous solutions which exist in different geometrical forms and which can aggregate to form mesophases resp. liquid-crystalline phases depending on the concentration, the presence of electrolytes and the addition of co-surfactants.

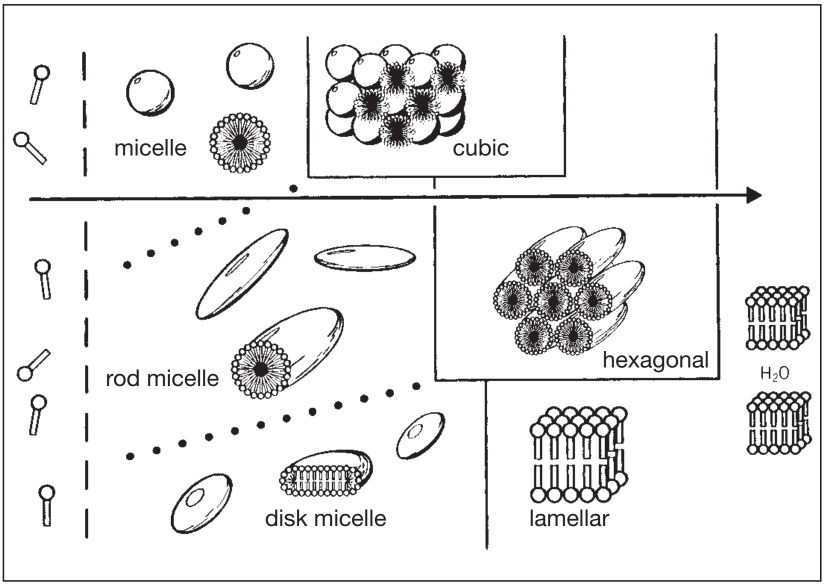

Fig. 1: Phase diagram of surfactant association in aqueous solution (Henkel).

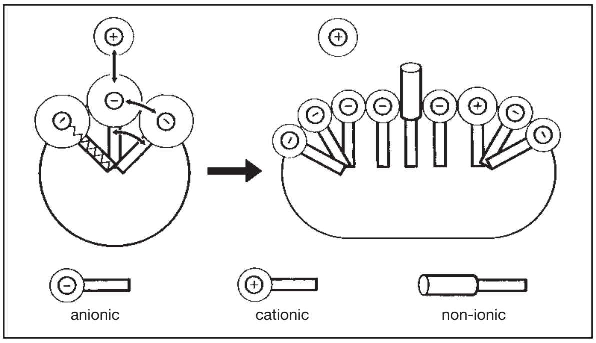

Fig. 2: Diagrammatic view of the transition from spherical to rod micelle (Henkel).

The viscosity and rheological behaviour of such a system depends on which way has been taken in changing the parameters represented in the phase diagram. In dilute anionic surfactant solutions a transition from isometric spherical micelles to anisometric rod or wafer micelles takes place (Fig. 2) on the addition of co-surfactants (fatty acid alkanolamides, amphoterics, fatty alcohol ethoxylates *inter alia*, additives of low molecular weight). As a result, a state is reached in which the anisometric surfactant micelles constantly collide with each other due to thermal mobility thereby preventing their free rotation. A dynamic network is formed which manifests itself macroscopically as an increased viscosity of the surfactant solution.

The parameters influencing the transition from a spherical micelle to a rod micelle are quite diverse. In the main, however, they may be attributed in a graphic model to the geometrical properties of the surfactant, i.e. their molecular structure and the spatial relationship of the hydrophilic head groups to the hydrophobic carbon chain, and by electrostatic effects such as the screening of mutually repellent charges and hydrate clouds of neighbouring head groups of ionic surfactants. For a given chemical structure, the probability that anisometric micelles will be formed is increased by any measure which results in a reduction in the distance between neighbouring ionic head groups (Behler, Hensen, Raths, Tesmann).

Associazione Italiana di Chimica Tessile e Coloristica (AICTC). Italian Association of Textile Chemists and Colourists. → Technical and professional organizations.

ASTI, (Ger.) abbrev. for: Arbeitgeberverband der Schweizerischen Textilveredlungsindustrie, Zürich (Employers' Association of the Swiss Textile Finishing Industry). → Technical and professional organizations.

ASTM, abbrev. for: American Society for Testing and Materials. Industrial standards organization. → Technical and professional organizations.

Astrakhan

I. The skin of still-born or very young lambs (originally from Astrakhan in Russia), the fine grey or black curly hair of which resembles fur.

II. Real astrakhan is a curly lamb's fleece (Persian). Substitutes are lambskin imitations like woven plush fabric (frieze velvet) with an uncut (mohair) pile warp; also produced in jute and acetate filament yarn. Loop height is determined by round wire inlay. A distinction is drawn between production methods, a) woven astrakhan (plush), fulled astrakhan and tricot astrakhan (warp knitted fabric). There are also the so-called adhesive-bonded polyamide astrakhans. Used for ladies' overcoats, caps and fur trimmings.

Astrakhan yarn Wool crimp yarn. Forced crimping can be fixated by cross-linking so as to be washfast.

Astrakin Compound woven and warp knitted fabric; base fabric of raw crêpe georgette with a different top fabric glued on. Crêping produces a → Cloqué-like surface.

Astro-dyed Licensed process for dyeing non-repeating effects (→ Space dyeing) on yarns by injection of dye liquor into the inner layers of wound packages up to a maximum of 5 colours with special dyeing equipment (used for carpets and upholstery fabrics). Production rate = 50–60 kg/h. Manufactured by Astro Dyeworks, USA.

Asymmetry Lack of uniformity, i.e. non-uniformity, e.g. the asymmetrical distribution of certain groups or forces (hydrophilic, hydrophobic) in the molecule of a textile auxiliary.

Asymptotic (Gr. *asumptotos* = not falling together) approaching infinity, e.g. the curve of a graph.

At, chemical symbol for astatine (85).

at Technical atmosphere, replaced in the → SI system by Pa (Pascal). 1 at = 0,981 · 10^5 Pa = 0,981 bar.

ATA,

I. abbrev. for: anthranilamide.

II. abbrev. for: aminotrimethylcarboxylic acid resp. → Nitrilotriacetic acid.

III. (Fr.) abbrev. for: aminotriacétique acide.

ATE process (anthrasol-thermosol development process), dry development process for leuco vat ester dyestuffs with the use of an activator and a levelling agent for woven cellulose and cellulose/polyester blend fabrics.

ATF, (Ger.) abbrev. for: Arbeitsgemeinschaft textiler Fachvereinigungen (Working Group of German Textile Organizations). → Technical and professional organizations.

ATI, abbrev. for Associate of the Textile Institute. Professional qualification of the Textile Institute, Manchester, U.K.

atm abbrev. for standard atmosphere, a former practical unit of pressure now replaced in the → SI system by Pa (Pascal). 1 atm = 1,0133 · 10^5 Pa = 1,0133 bar.

ATMA, abbrev. for: American Textile Machinery Association. → Technical and professional organizations.

ATME, abbrev. for: American Textile Machinery Exhibition (held in Greenville, SC, USA).

Atmospheric air is composed of 78,06 vol.% nitrogen, 21 vol.% oxygen, approx. 0,03 vol.% carbon dioxide, variable amounts of water vapour, traces of volatile organic and inorganic substances, dust etc., as well as 0,94 vol.% rare gases.

Atom (Gr. *atomos* = that cannot be divided) the smallest particle of an → Element (chemically incapable of being further split up) which can combine with similar or different atoms to form → Molecules and chemical compounds.

Atomic absorption spectroscopy (AAS). An analytical technique similar to flame emission spectroscopy (FES) for the detection of trace metals in different matrices. The technique is suitable for the qualitative and quantitative determination of metallic elements but does not extend to their stages of oxidation or the structure of their molecular environment. Both methods are preferred for the micro and trace analysis of solid, liquid and gaseous samples.

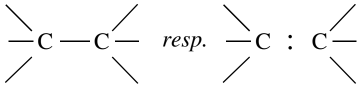
The light beam of a lamp which emits the atomic spectrum of the element being determined, is conducted through a flame or graphite tube in which the metal being analyzed is converted into its ground state atoms by thermal dissociation. As a result, a part of the radiated light is absorbed. The quantity of absorbed light is proportional to the metal concentration. The detection limit of the graphite tube method is lower than the flame technique by a factor of 10-100, and the volume used for analysis is many times smaller than the pore volume for the flame technique. A lengthy calibration with elemental standards at different concentrations is necessary for both analytical methods.

Atomic bond (electron pair bond, homopolar bond, covalent bond, co-ordinate bond, nonpolar bond). Virtually all compounds (with the exception of salts) not containing ions, i.e. nonelectrolytes, consist of molecules built up from atoms held together by very strong bonds. Such bonds are referred to as → chemical bonds *per se*, e.g.:

a) monovalent = single bond, e.g. ≡CH–C≡
b) bivalent = double bond, e.g. =C=C=
c) trivalent = triple bond, e.g. –C≡C–

The atoms are bound to each other by a shared pair of electrons (electron pair bond) which belong to both atoms at the same time. In more precise terms, one positively charged atomic nuclei provides one negative bonding electron so that two together can form an electron pair: H + H → H : H. From this it follows that

– a single bond consists of one shared electron pair:

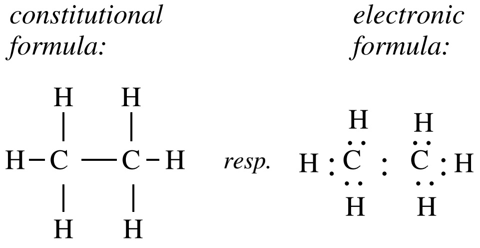


– a double bond contains 2 electron pairs:

– a triple bond contains 3 electron pairs:

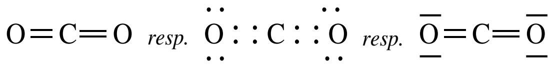
$—C\equiv C—$ *resp.* $—C\ :::\ C—$

If all the shared valence electrons of both atoms are included, then each atom will always have 8 electrons (octet theory of electron shell structure for elements like noble gases with the exception of hydrogen which has 2 electrons = doublet):



$H-C\equiv C-H$ *resp.* $H:C:::C:H$

Free electron pairs (i.e. not shared) can be indicated by a horizontal line thus:



$O=C=O$ *resp.* $\ddot{\underset{..}{O}}::C::\ddot{\underset{..}{O}}$ *resp.* $\overline{O}=C=\underline{O}$

From these formulae it follows that an atomic bond is built up by attraction forces acting through shared electron pairs which are relatively localized in the region of the two nuclei. Bonding forces of this kind are normally very strong, such as e.g. the C–C chains in organic chemistry and, in the widest sense, all primary valency chains.

Atomic mass Relative atomic mass of an isotope resp. nuclide. Defined relative to ^{12}C as exactly 12,0000 (reference basis). The atomic mass rounded off as a whole number is referred to as the mass or nucleon number and indicates the sum of nucleons (neutrons and protons). Since the atomic mass of a proton (1,007276) and that of a neutron (1,008665) are approximately equal, the following relationship is valid; atomic mass ≈ mass (nucleon) number.

Atomic number (proton number), symbol Z. The number of protons (positively charged mass units) in the nucleus of an atom or the number of electrons revolving around the nucleus. The atomic number determines the chemical properties of an element and the element's location in the → Periodic system (atomic theory). It is always the same as the number of negatively charged electrons in the shells. The order of atomic numbers begins with the lightest element, hydrogen with 1. The number of protons and electrons also increases with the atomic number from element to element by 1 each time. All the isotopes of an element have the same atomic number although different isotopes have different mass numbers.

Atomic theory As far back as the history of science permits the basic structure of matter has been a constantly recurring theme as has the search for the most fundamental particles on which matter is based. The Greek philosopher Empedocles postulated the four elements (earth, air, fire and water) as integral and immutable. Aristotle, on the other hand, regarded them as transformable one with the other. Leucippus and Democritus originated the theory that matter is made up of indivisible, infinitely small atoms ("atomos"). It was only in the 19th century that this concept was scientifically substantiated when it was recognized that, to each of the 92 (chemical) elements known at that time, an "atom" had to be allocated; a concept which is still valid even today. Compounds of several atoms form molecules from which substances are built up.

In 1911 the English physicist Lord Ernest Rutherford demonstrated that the atom is similar to a planetary system with the atom nucleus as the sun and electrons as the planets. An entirely new universe had been discovered – a universe of unimaginably small dimensions. Even up to about 40 years ago the world appeared to be relatively simple. The physicists traced back 92 atomic species back to protons and neutrons, which were recognized to be the building blocks of atomic nuclei, and electrons which orbitted the nuclei in shells. However, a series of particles (approx. 300) were next discovered, first in cosmic rays and later in accelerators, which did not fit in the scheme as then understood. Strange names were found for these particles: mensors, hyperons, etc. Attempts to classify them have occupied the most capable theoreticians of the world for 2 decades. It soon became clear that the many particles described as “elementary” up to then, even including the proton and neutron, must in reality be composed of other yet more elementary building blocks. Since 1974 experimental results from particle accelerator laboratories have come thick and fast. These, together with the theoretical knowledge already available, have given an entirely new picture of the fundamental building blocks of matter as well as the forces acting between them. The greater part of today’s main interest in this subject did not exist at all in 1974.

There are currently 2 important questions here: a) whether the variety of matter can be traced back to a few fundamental building blocks and b) what forces act between these fundamental building blocks and are therefore responsible for their stability or reaction.

In the course of time, attempts have also been made to break matter down into smaller and smaller particles (see Fig.). The researcher has progressed through molecules, atoms, atomic nuclei and, finally, protons and neutrons to smaller and smaller units. In order to do this it appears that the smaller the unit the more force is required to break down these particles. To split them further it is necessary to bombard them with energy-rich particles produced in larger and larger particle accelerators. The advance into the microcosmos has proceeded largely parallel with the development of more and more powerful particle accelerators. These are, so to speak, similar to the microscope with which it is possible to penetrate deeper and deeper into the structure of matter. Through bombardment with high energy particles it has been proved that smaller “bodies” are contained in the proton, of which there are 3. Originally they were called “partons” and now “quark” particles. Today, these truly strange elementary particles are the focus of the particle physicist’s attention. Virtually all of the many “elementary” particles have now emerged as double or triple compounds of these elementary bodies. Particularly interesting is the fact that up to today there are no indications of structures even smaller than quarks. They behave as dot-like “sources” of their energy fields. Apart from quarks, only one other type of indivisible particles is known at present: the leptones of which the main representative is the electron. These particles also have no internal structure and, to a certain degree, represent a parallel family to the quarks. They lack only the characteristic nuclear forces of quarks.

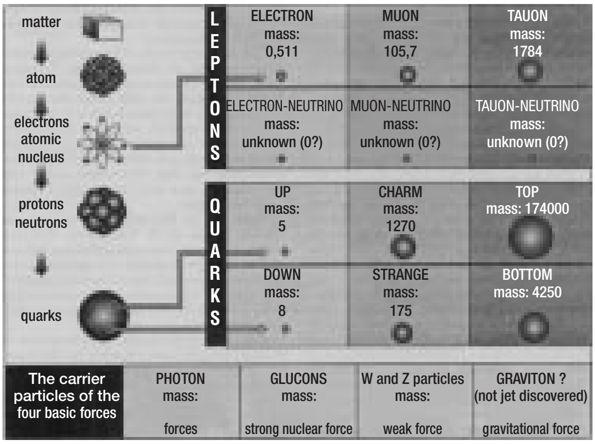


Fig.: Like the chemical period system of the elements, the standard model of physics arranges the elementary particles in groups with identical characteristics. The masses (as far as is known) are indicated in million electron-volt units (eV) (according to CERN). (1 eV is equivalent to the energy which an electron contains after passing through a voltage of 1 volt).

At present 4 different types of interactions between the particles are known. They differ principally in their strength, i.e. the “nuclear interactions” which only arise in connection with quark particles; the “electromagnetic” interactions which are associated with electrical charges; “weak” interactions which occur in radioactive decay and, finally, the “gravitational” interactions which occur with particles (and bodies) having mass. One of the greatest successes of physics in the 19th century was the recognition of electrical forces and magnetic forces as 2 forms of a unitary force, i.e. electromagnetic interactions. This theory formulated by James Maxwell represents the basis on which today’s electronics, radio and television technology has been built.

To the same end, Werner Heisenberg attempted to combine the 4 known interactions into one elementary force in his “world formula” during the 1950s. Today, it is realized that this attempt was made before its time. It is necessary to be content on reaching this objective step by step. With the discovery of the J/psi particle in November 1974, a period full of unimaginable new discoveries and successes opened up both for experimentalists at the DESY particle accelerator as well as quark theoreticians. Since it proved impossible, despite all efforts, to fit the J/psi particle into the accepted 3-quark model of the time, it was finally concluded that a 4th quark must exist differing from the 3 known ones by a new charge with the name “charm”. It is postulated that the J/psi particle consists of one charmed quark and its antiquark. If this assumption is correct combinations of charmed quarks with the well-known quarks must exist, namely the combinations cu, cd and cs. These combinations have been named D°, D+ and F+.

It has now been recognized that it is possible to represent the electromagnetic and the weak interactions as different forms of a general interaction. More and more experimental results have confirmed this theory or, to be more precise, no experiment has disproved it up to now. Interesting experiments on this theory have been carried out in storage rings. Only as a result of the extremely high energies achieved by this means are combined "weak-electromagnetic" interactions to be expected. The same high energies have opened up interesting test fields for details of the quark theory. Successful experiments in storage rings have demonstrated this repeatedly over the past few years. Since November 1974 the so-called J/psi "quark-antiquark" combination has been investigated.

Atomic weight Mass constant of the → Elements. Former name for relative atomic mass. Originally based on naturally occurring oxygen, the atomic weight of which = 16.

Atomizer High performance system using → Jets. A mist of water droplets is formed with an atomizer which, due to the large surface area of the water curtain, is suitable e.g. for the sorption of gases.

In the stenter exhaust air system shown in the Fig., exhaust air is led through a duct containing a water atomizer. This produces large quantities of water droplets and the exhaust air is conducted through the water curtain in a counter-current direction. Due to the resultant cooling to approx. 50°C, the pollutant vapours condense. The pollutants as well as (to some extent) undesirable odours, are consequently adsorbed and the soluble pollutants are partially dissolved in the water droplets. The pollutant-laden air is then passed through a mist collector in which the water droplets, condensation products and pollutants are separated out. In a water container fitted with a filter the non-soluble pollutants are finally separated off and must, if necessary, be disposed of as special waste. The cleaned water is then recirculated back to the atomizer. It is also possible to supply the atomizer with water from wet processing machines where it may be used for exhaust air scrubbing. → High pressure atomizer.

Atomizer nozzles Multi-component nozzles in which a mixture of air and a liquid is formed.

ATPUL, (Fr.) abbrev. for: l'Association Technique pour la Production et l'Utilisation du Lin et autres Fibres Libériennes (French textile research organization for linen and other bast fibres). → Technical and professional organizations.

Attagenus beetles, protection against → Mothproofing.

Attapulgite A hydrated aluminium-magnesium silicate mineral from Attapulgus (Georgia/USA), the chief ingredient of fuller's earth. It is related to meerschaum and has highly adsorbent properties. Used, *inter alia,* as bleaching earth.

Attraction forces Water molecules have a strong attraction for one another. For a molecule on the surface, however, attraction forces only act from the sides and underneath as there is no attraction between molecules of air and those of water. As a result, a force which is directed from the surface to the interior is active, i.e. surface tension. Although the forces acting between the water molecules (hydrogen bonds) are relatively strong, the surface tension of water is particularly high (see Fig.).

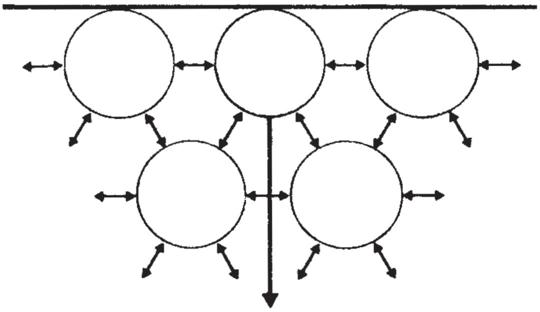

Fig.: Nuclear attraction of water molecules.

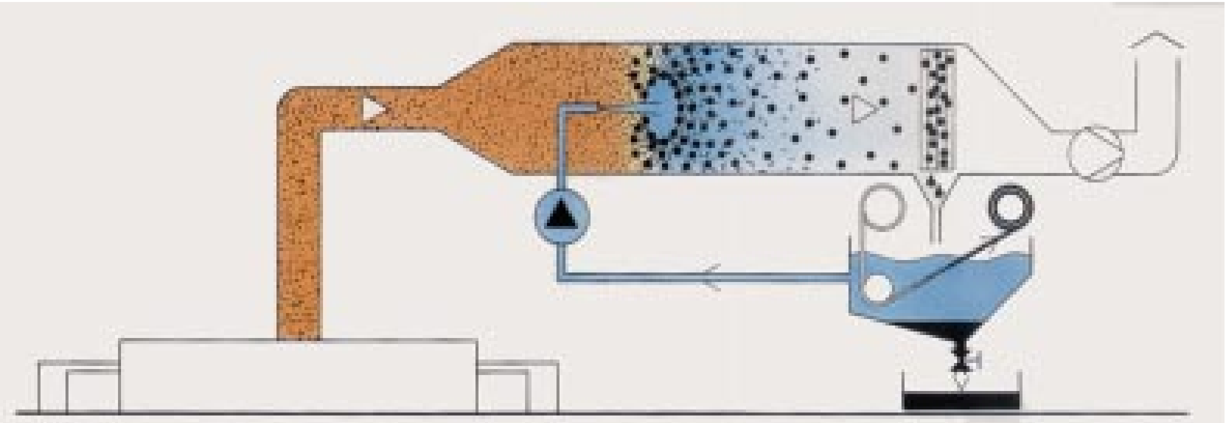

Fig.: Atomizer for stenter exhaust air cleaning (Prött).

ATV, (Ger.) abbrev. for: Abwassertechnische Vereinigung (German technical association for waste water). → Technical and professional organizations.

Au, chemical symbol for → Gold (79).

Au portique (= AFNOR method). French flammability standard which takes the form of a vertical test for upholstery and furnishing fabrics. Visual assessment: burning behaviour and smoke development. Measurements: time of burning after extinguishing the alcohol flame, and length of charred zone.

Autoclaves Pressure vessels constructed of thick-walled steel (usually alloy steel or frequently nickel alloys) of welded, drawn, forged or composite construction, generally in the form of circular kiers. They are always provided with a pressure gauge, thermometer and safety valve for control purposes. Maximum operating pressures are specified for all autoclaves which, if exceeded, can result in explosion. Uses: pressure scouring, high temperature dyeing.

Autoconer Automatic cross-winding machine for rewinding yarn from spinning cops on to cross-wound packages (Fig. 1). Electronic yarn clearers as well as automatic splicing of yarn breaks are state-of-the-art features. Both the spinning machine and the Autoconer can be equipped with automated transport systems (Fig. 2). Manuf.: Schlafhorst.

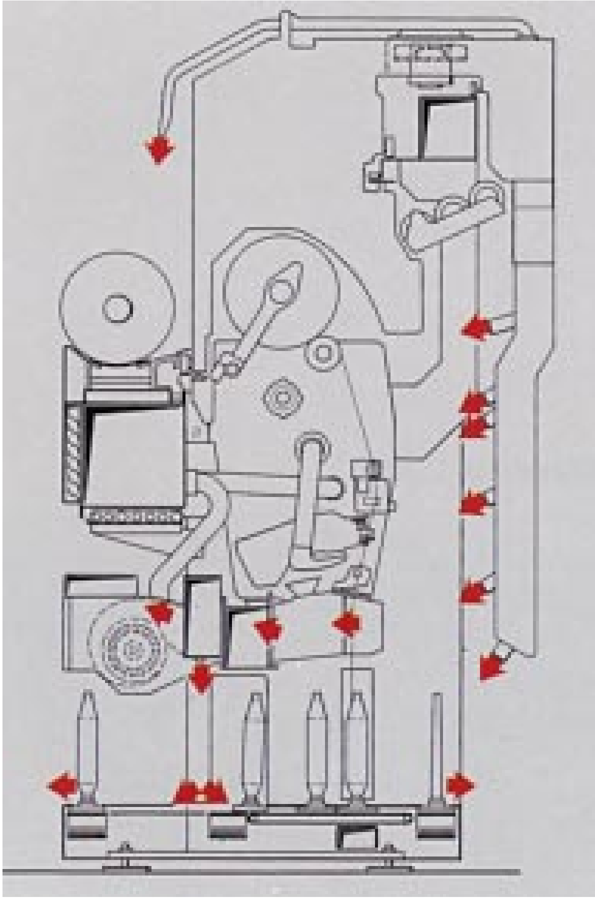

Fig. 1: Autoconer principle sketch.

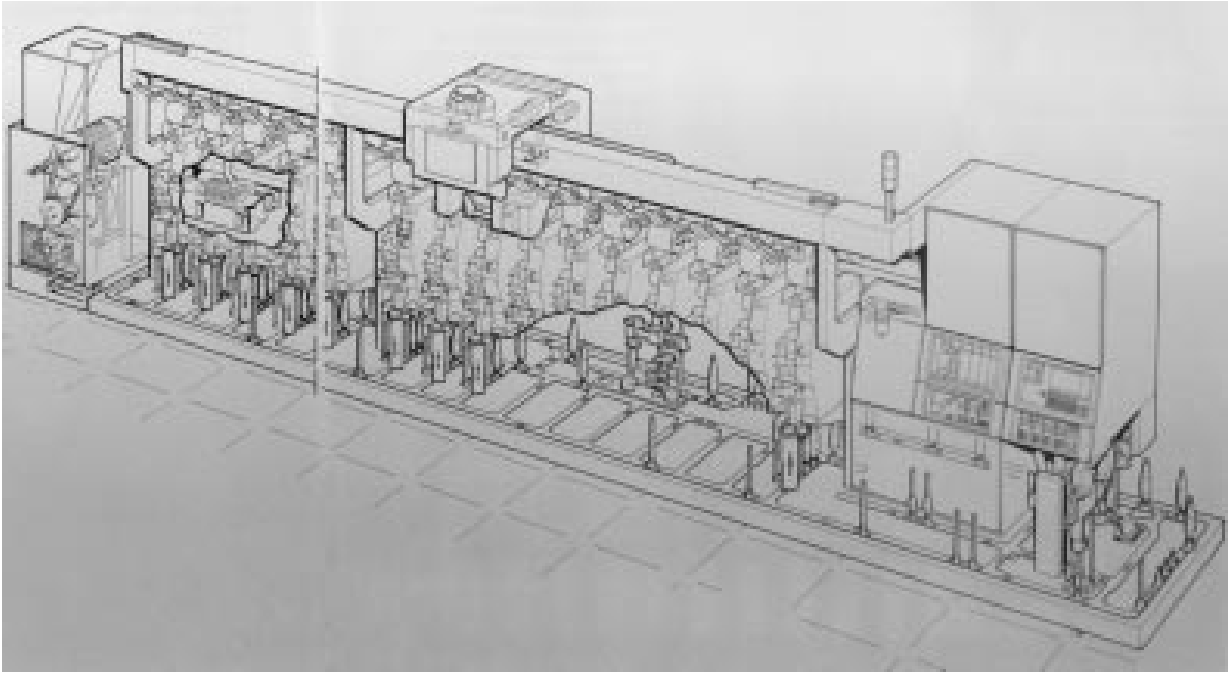

Fig. 2: Schlafhorst Autoconer System 238 with integrated Caddy transport system.

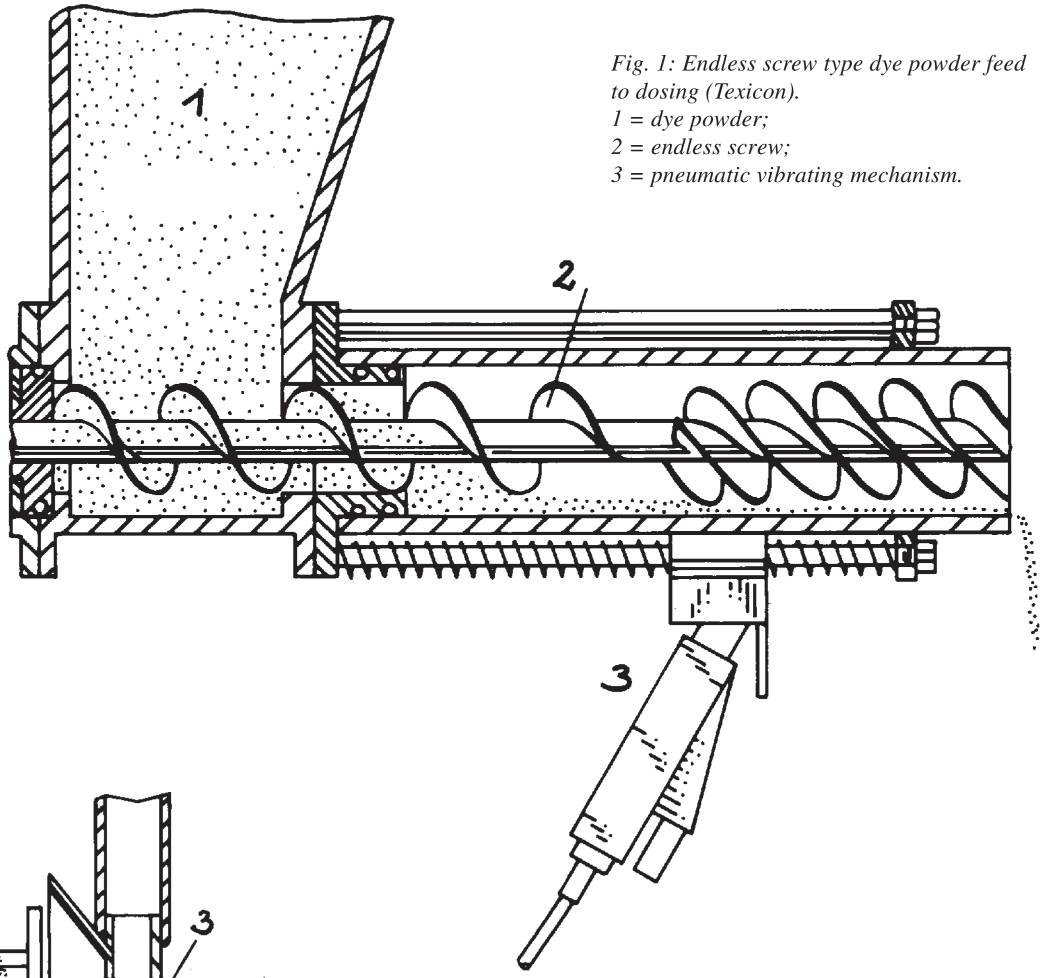

Fig. 1: Endless screw type dye powder feed to dosing (Texicon).
1 = dye powder;
2 = endless screw;
3 = pneumatic vibrating mechanism.

Automated dye weighing and dispensing systems An example of such a system (Figs. 1–3) involves the use of coded plastic cards on the dye powder containers and an integrated recipe print-out facility. Such systems are designed to eliminate weighing errors.

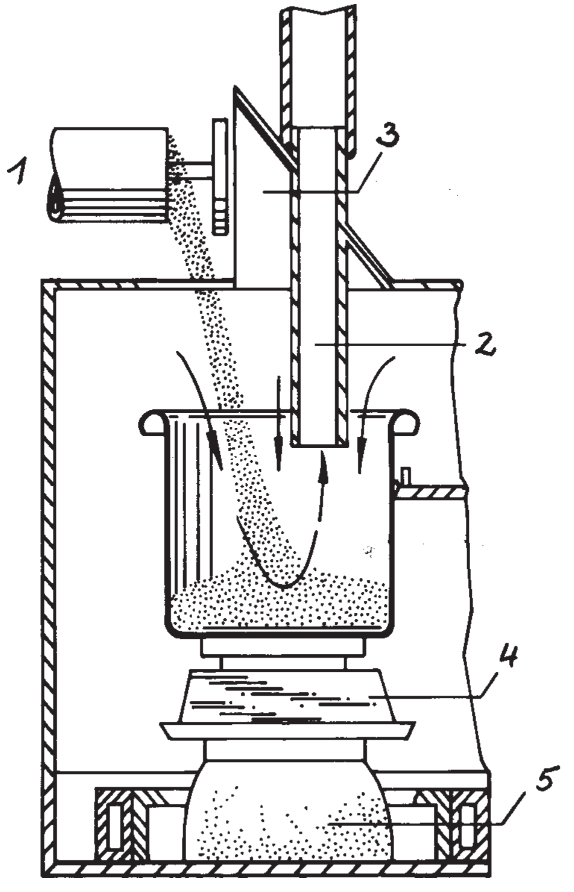

Fig. 2: Dye powder dosing and weighing station (Texicon). 1 = metering valve; 2 = dust extraction; 3 = dust extraction hood; 4 = scales; 5 = pneumatic springing.

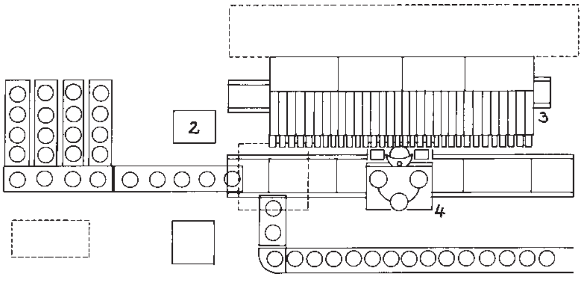

Fig. 3: Typical automatic dye dosing station. 1 = conveyor system; 2 = control panel; 3 = 32 storage containers; 4 = turnable.

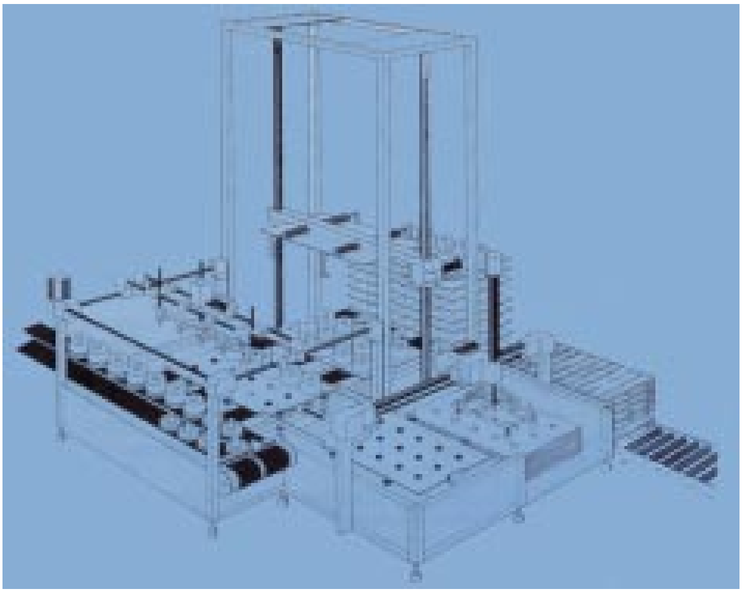

Fig. 1: Automatic palletizing machine for packing cross-wound bobbins (San Grato).

Automated packaging lines Typical examples in textile finishing include: the palletizing of yarn packages (Fig. 1) or rolls of fabric (Fig. 2) and the immediate packaging of fabric rolls in heat sealed polyethylene film (Fig. 3).

Automatic batcher, connected to a stenter; batch changes can be made without stopping the stenter. The goods are cut automatically and cardboard tubes are inserted without batch centres.

Automatic continuous laundering Term for a system comprising → Continuous washing plant, mechanical water extracting unit and an opening/drying unit, fully automatically controlled and technologically interlinked for non-operator assembly line laundering operations, from loading the line through to distribution and transport to the finished area.

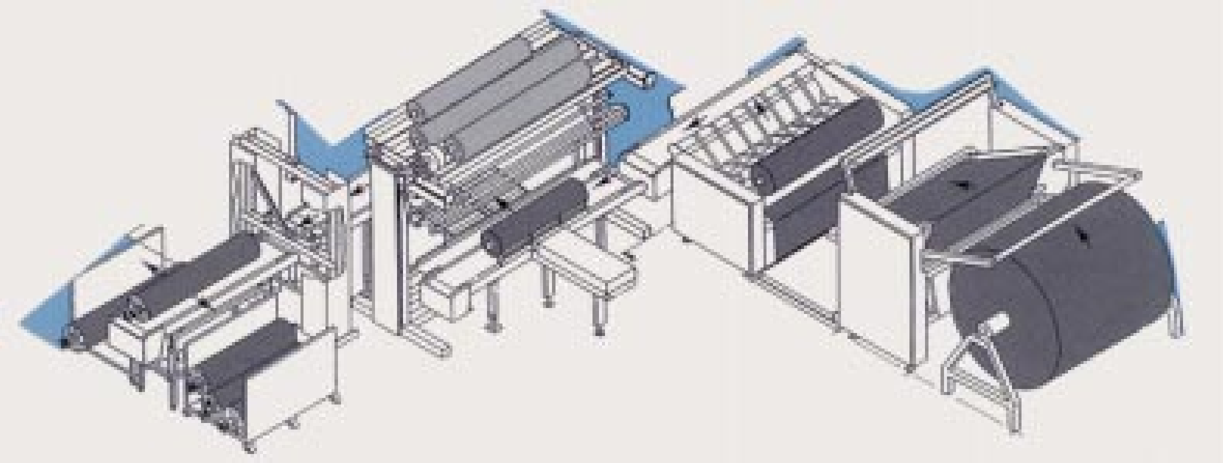

Fig. 2: Campen carpet roll packing.

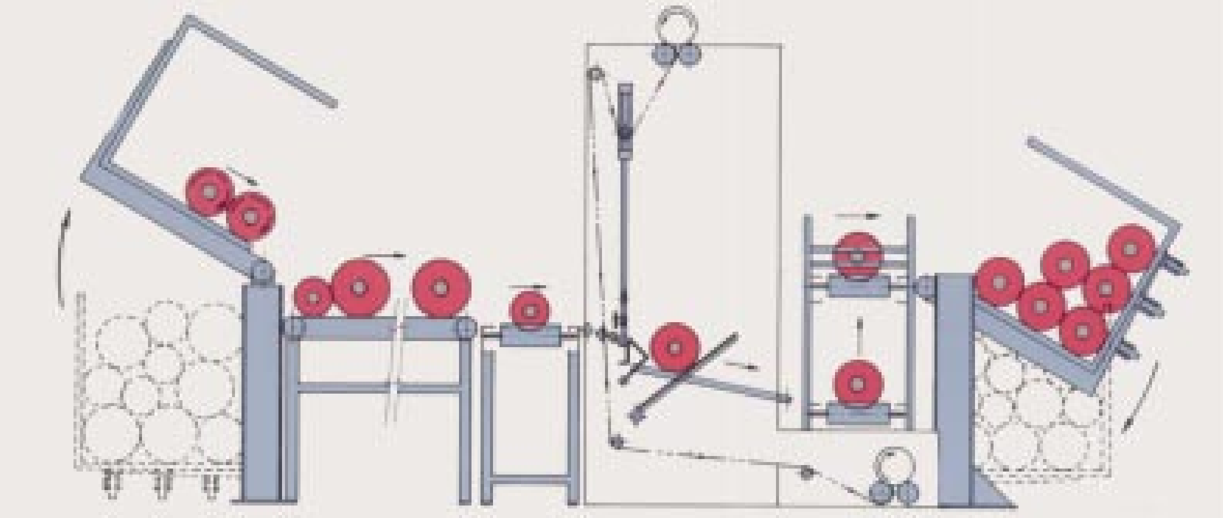

Fig. 3: Welding rolls of woven fabric in film (Krantz).

Automatic control systems processes in a system where one or more parameters (control parameters) are continuously measured by a sensor and the measured value is compared with a preset value, so that the actual value can be adjusted to the set value. A control process works in a circle, a so-called control loop. Fig. 1 shows a simple control loop.

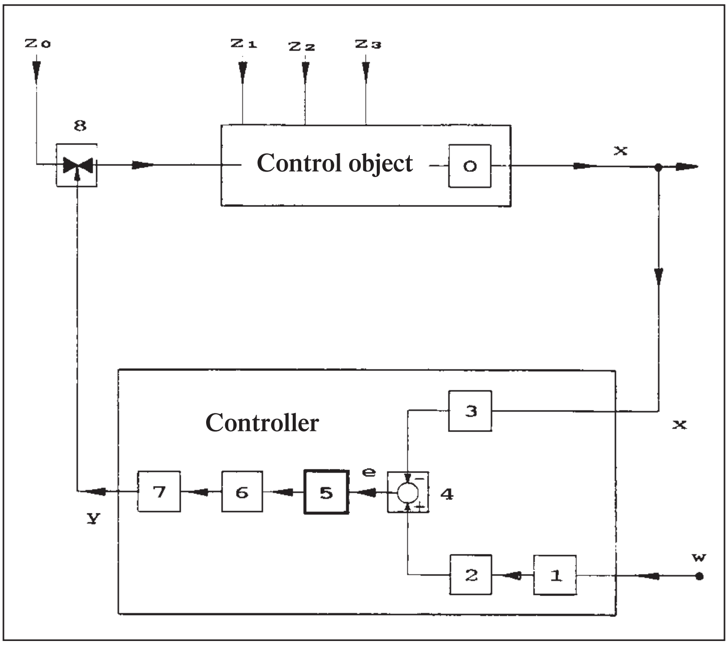

Fig. 1: Control loop. 0: current value detector (x); 1: set value adjuster (w); 2, 3: measured value converter; 4: comparator; 5: controller y = y(e); 6: output amplifier; 7: adjusting drive motor; 8: adjusting unit; Z: disturbance effects.

The principle of a control loop system that has been extensively automated is to eliminate fluctuations as quickly as possible and to bring the „disturbed“ system back to its original stable state. However, while control and adjustment are effected completely automatically and usually quickly in technical or biological control loops, this is not normally possible with industrial management control loops. In general it takes time to recognise a deviation, to decide what measures should be taken and then to put the measures into effect. This reaction time is the main obstacle to flexibility. To increase the flexibility, ways of shortening the reaction time have to be found for all the stages from recognising the deviation through the decision process to making the required corrections. It is appropriate to describe the three main functions of a control loop and to show (Table) how these three functions can be used to increase flexibility.

1. Sensor function: this function is associated with determining the actual or current value of the control parameter. In management economy encoded or operational data take the place of the probes. They serve a two fold purpose, namely finding
   - the current situation, the actual position, e.g. state of orders, stock situation, availability, bottlenecks and so on;

Term	Definition	Heating	Economy
Control loop	Closed feedback system that remains relatively stable to interior and exterior disturbances		
Control object	The object that is to controlled within a system	Room	Production operations
Sensor	Device for measuring the control variable	Thermostat	Operational data and codes
Controller	Controlling equipment	Regulating device	Process control system
Controller variable x	Variable that is to be controlled in the control object	Effective room temperature	Production programme
Guide value w	Set value	Set temperature	State of orders
Adjustable variable y	Values transmitted to the control object by the operation of the controller	Power to valves	Trigger value
Adjusting device	Mechanism for controlling the adjustable variable	Valve	Production systems/purchase
Disturbance variable z	Variables that act from outside the control line	Outside temperature	Customer orders

Tab.: Definitions in management loops (examples: comparison of technical and economic processes).

- an early warning system to detect both interior and exterior changes, such as, e.g. automatic notification of a delay in supply, an increase in the absence rate, material difficulties, changes in customer's orders etc.

In all these cases it is important that this information is sent quickly to the control manager either as encoded or operational data etc. This is carried out in part by operational data collecting equipment and systems. There will be administrative difficulties if the problem involves something which has consequences for material or timing that result in an alteration to a specification or a change in the volume of a customer's order. Above all, valuable time is often lost when changes have to be clarified manually. In these cases well-designed electronic data processing support in the dialogue is invaluable. A prerequisite is of course that the necessary databanks with direct access are available.

2. Control functions: there are three control functions, namely:
   - comparison of the control and set values to detect a deviation;
   - assessment of the deviation and then deciding whether it is large enough to set procedures in motion or if it is so small that nothing needs to be done;
   - deciding what measures should be taken to eliminate the deviation.
3. Regulating function: at this point the measures decided upon are put into effect. These include all activities directed towards eliminating the deviation, e.g. sending a purchase order, repairing a defective machine, arranging overtime, cancelling payment instructions, alteration of works instructions etc.

The control loop of a dyeing system can be represented e.g. as a block diagram (Fig. 2). The object of control is the dyebath. The rate of exhaustion $\dot{c} = dc/dt$ is controlled by the temperature T. There are two control loops, one inside the other, with the inner one (for the temperature) being controlled by the outer (for the rate of exhaustion). In the outer control loop, the rate of exhaustion $\dot{c}$ of the individual dyestuffs in the bath is compared with the current set value, where the set value comes from the critical dyeing rate. The controller for the rate of exhaustion ($\dot{c}$-controller) continuously calculates the set value for the temperature from the difference $\Delta\dot{c}$ between the actual and set values of $\dot{c}$ and from experimental data for both the temperature T_E and the rate of exhaustion $\dot{c}_E$. This set value is compared with the current value of the temperature by the temperature controller (T-controller), and the heating of the dyebath is switched on or off as appropriate. The PD (proportional difference) type T-

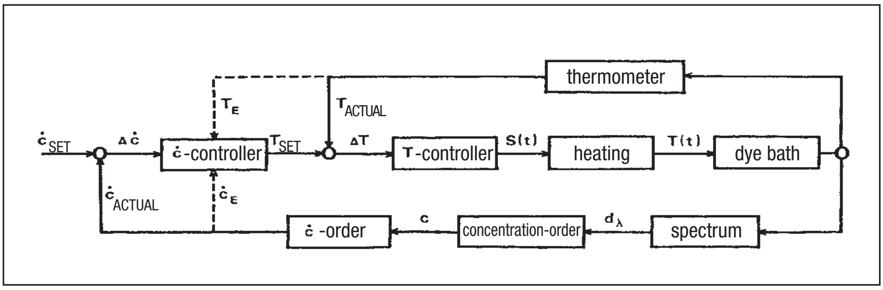

Fig. 2: Block diagram of a control loop.
d_l = optical density as a function of the wavelength, l; S(t) = Set value function for the heating.

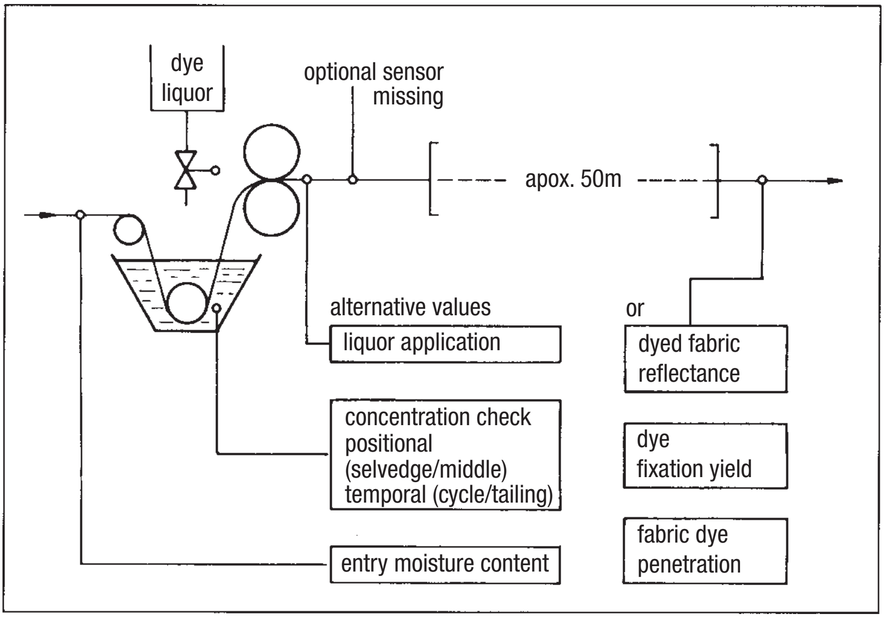

Fig. 3: Optional sensors for the uptake of the dyebath in continuous dyeing (after Rüttiger), uptake in g of dyebath per kg of textile material.

controller works by the normal principles of control engineering.

A management system is distinct from a control system. A management system is a process in a "closed" system in which the target value of a parameter (control parameter) is continuously established from actions based on measurements of this parameter and is kept at its optimum level. Control on the other hand is a process in a "limited" system in which one or several input variables affect other parameters (output variables) according to definite rules. Management is an extension of a control system.

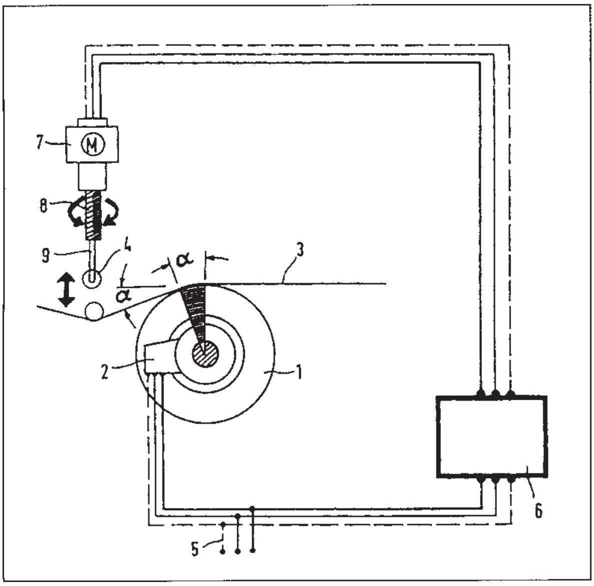

Fig. 4: Control loop for the automatic adjustment of the angle of approach of the textile material to an sueding roller (Menschner).
1 = emery roller; 2 = measurement of friction; 3 = goods; 4 = sensor; 5 + 6 = comparison of set/current values; 7 = controlling motor for adjustable roller; 8 + 9: adjustable roller.

Availability of microprocessors or control units is less critical for the operation of control loops than the existence of suitable sensors, but there is a lack of suitable sensors in textile processing (Fig. 3). However, there are important control loops that involve fabrics. For example, the friction between a fabric being abraded and emery paper on a cylinder can be kept constant in a continuous abrasion process (Fig. 4).

Equipment for this process is fitted with a device for managing the individual abrading surfaces by automatically altering the angle, α, of approach of the fabric to the roller. The required friction at the particular cylinder for the optimum abrasion effect is determined by reference to the current set value. Depending on this value, a motor is operated to readjust the angle of incidence of the fabric, α, until the current being taken by the motor of the particular emery cylinder corresponds to the reference set value. Hence wear of the emery is taken into account. A larger rubbing surface will be required to produce the same degree of abrasion when the emery coating is worn than when it is new. An acoustic or optical alarm can be triggered when the maximum allowed angle of incidence is exceeded, to indicate the degree of wear and the need to change the emery covering.

In a dyestuff uptake measuring system for a pad with adjustable rollers, to keep the control loop from becoming too large (e.g. by measuring the colour of the dried material), the uptake is measured in the middle and at the edges of the fabric directly after the squeeze roller, using wet colour measurement or absorption of microwaves by moisture, and can be adjusted by altering the nip pressure (Fig. 5).

Automatic jigger, → Jigger with control functions which automatically change the direction of running and regulate fabric tension.

Automatic pattern repeat system for screen printing Designed to provide a greater degree of re-

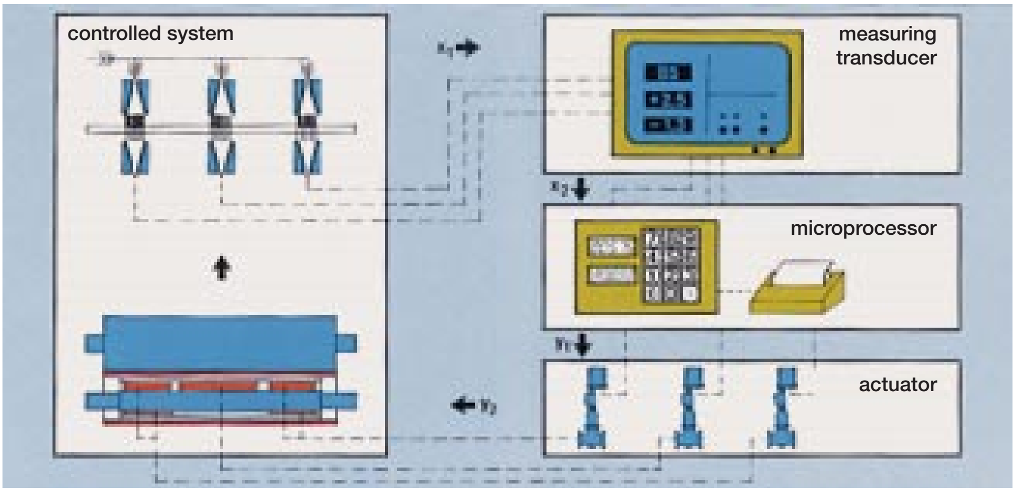

Fig. 5: Control loop for automatic product processing.

peat accuracy as well as time savings in comparison to manual repeat adjustment. In order to set the desired repeat length a movable limit stop is positioned against a graduated scale and fixed. Fixing or releasing of the limit stops is carried out automatically by means of a pneumatic wrench the pressure of which, as well as the advance speed of the screen printing machine, is steplessly adjustable. The automatic repeat system slides along the same guide rails.

Automatic preselector For automatic process control by an industrial computer, which has been simplified for the user by means of manual control panels. The automatic preselector assumes full process control through relevant controllers.

Automatic titration Automatic titration systems are important for routine production control in the continuous pretreatment of cotton and also in continuous dyeing with vat dyes. Development began in the middle 1970's and led to the first automatic titration of small samples. Further developments have resulted in the automatic feeding of concentrates to bleaching baths in which the addition of bleaching agent is controlled via an automatic titrator which operates a control valve by means of a PI controller, whilst the automatic addition of caustic liquor is controlled by electrical conductivity of the bath.

Automation The aim is to control and regulate equipment and processing, e.g. flow of goods, preparation of baths, dosing, temperature and treatment times, by automatic programming. Automation and control can be used in dyeing and printing e.g. in the following processes:

- temperature-time programmes,
- running partial or fully automatic bleaching and dyeing processes, including dye kitchens,
- pH,
- flow pressure/differential pressure,
- dosing of liquid chemicals.

Automation of regulation and control processes in production equipment requires a programme that allows analogue and digital techniques to be mixed on the screen without any problems, the microprocessors that are introduced to be designed so that they can be integrated easily into the bus system, and everything to be managed so flexibly on a PC screen that the user can process and pass on all the information coming over the bus within the framework of the standard programme. In recent years the whole industry has been moving towards more flexible production processes. Newly commissioned plant is equipped with SPC (→ Stored program control) and often also with DDC (direct digital control), so that the computer can make quick change overs in production possible by simple changes to the programme or to a parameter, either on the screen or through a bus system. This equipment provides a smooth, time-oriented flow of information, integrated with quality and monitoring of production costs, as to a large extent the available DDC and SPC controls can be used for the necessary measurement of values, status and flow of material.

In general, automation is the transfer of human activities into the "hands" of machines, equipment, switches or computers, which completely replace the human being, at least temporarily, in a treatment step or sequence of steps. Temporarily here means that substitution of the human being is possible in principle, so long as the automation equipment works perfectly. Complete take over from the human implies that no human intervention is required during the course of production in the tasks or processes for which the automation equipment is being used. Automation in dyeing and printing includes all those measures in which automatic devices replace human mechanical and sometimes thought processes, and in particular those activities that are used to keep given processing and final parameters steady at given values, or to adjust them according to definite programmes. In this sense, automation of dyeing and finishing can be classified as follows:

- regulation and control,
- continuous and batch processes,
- partially automated and computer automated control systems,
- direct and indirect process control.

The following problem areas in dyeing and finishing are probably the most important for introducing automation:

1. Batchwise processing: automatic control of batch processes; control systems in dyeing equipment including monitoring exhaust processes. Process-specific feed-back to the automatic unit to ensure reproducibility, particularly when there are variations in the material. Automatic sampling, calculation of post-additions and switching in shading programmes.
2. Continuous processing: Construction of control loops in continuous stages; regulation and control of connections between continuous stages; automatic input of set values into the control loop; automation of batch changes and intermediate cleaning between small runs to improve flexibility.
3. Bath preparation and transport: automatic bath preparation in finishing- and dye kitchens. Automatic transfer of baths from the make up unit directly to the point of use or into storage vessels in the area where they are to be used.
4. Flow of textile goods: automatic transport of goods between the individual treatment stages of the dyeing and printing operation. Automatic order processes linked to receipt of orders and delivery deadlines. Automated storage (receipt of goods, registration, call off and despatch).

5. Production monitoring: automated determination of process costs. Automatic control of goods (receipt, intermediate steps, despatch). Automated process data acquisition for possible fault tracing and as the basis for development work.

The introduction of → Expert systems as the process control technology (e.g. for stenters or continuous open width washing ranges) has been especially relevant to automation in textile dyeing and finishing. Converting a plant to automatic operation aims to model mathematically the specific knowledge and the actions that experienced operators carry out as a result of it, and to use a computer as an expert system to perform the actions.

In a washing range the following processes can be run automatically (Figs. 1–10: from Brügman):

- control of squeeze rollers,
- pH control,
- dosing of chemicals,
- control of water supply,
- temperature control,

Fig. 1: Squeeze roller pressure control.

Fig. 2: pH control.

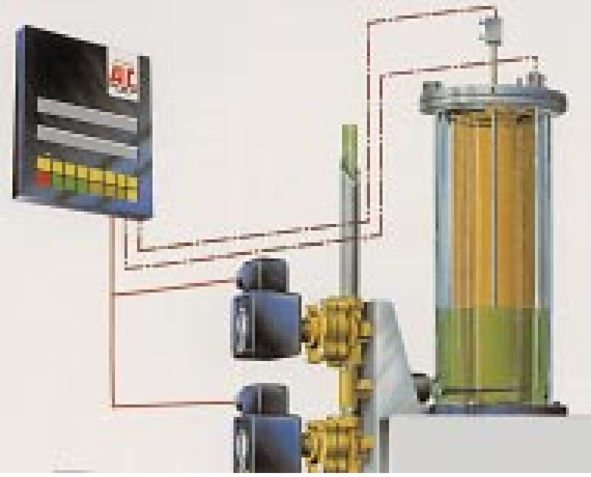

Fig. 3: Dosing chemicals.

Fig. 4: Control of addition of water with a flow meter.

Fig. 5: Temperature control.

- viscosity control,
- control of liquid levels,
- conductivity measurement,
- moisture content measurement.

Fig. 6: Viscosity control.

Fig. 7: Control of liquid level.

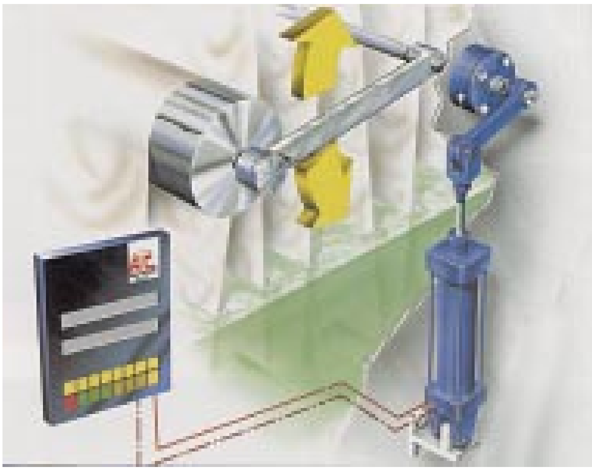

Fig. 8: Control of compensating roller setting.

Fig. 9: Conductivity measurement of padded goods used to control dosing to the pad bath.

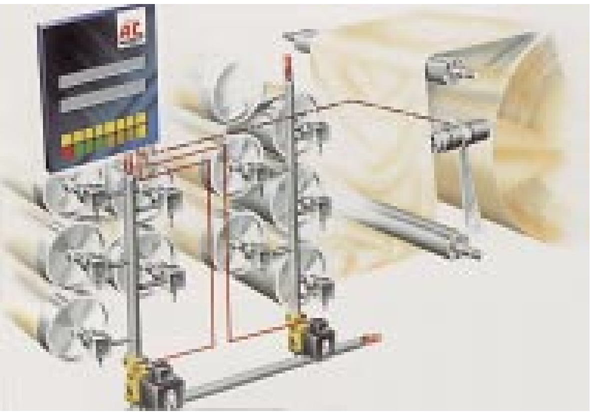

Fig. 10: Measurement of water content of goods used to control steam supply to drying cylinders.

Direct measurements on the goods are not often integrated into automatic systems because of the lack of suitable sensors.

From the economic point of view automation should only be considered by the performance-cost ratio for the user, so the question has to be asked, what is the optimum way of introducing automation to the operation with regard to the use of a specific unit in a plant, i.e. how long it will take for an investment to be repaid? The decision will be made with the individual automation philosophy and taking the unit's importance into account. All the operational, logistical and technical control data from the plant's central computer can only be evaluated as an entity, preferably with the firm's own electronic data processing equipment. The best solution may be to enter and output data individually or in combination using appropriate equipment. If the decision is made in favour of comprehensive automation equipment that can communicate, such an installation can only conceivably be set up with the co-operation of the computer supplier, plant supplier and user. Only in exceptional cases will complete detailed knowledge by one partner about the field of one or even both other partners be required. Working out a programme requires a clear definition of all the necessary parameters, regulations and sequence of events. This means that at least the plant supplier and the user must pool their collected “know-how” on a particular subject.

The chosen computer system must be capable of dialogue in all areas. This includes fitting appropriate interfaces to non-compatible parts of the system. In addition immediate service must be guaranteed in case of faults. For the plant itself, not only must parameters such as provision of steam, water, compressed air and so on be made clear, but also the number of chemicals and the amounts that are used per unit time, as it clearly makes sense to incorporate mixing and storage vessels for chemicals into the automation system. Setting up an appropriate software programme for controlling the plant also fits in here. Arrangements about pipework must be made clear too, as the instrumentation for an automatic plant is much more extensive than for a conventional one. Accessibility for maintenance and inspection should not be ignored.

Loading and unloading, transport and storage can be supervised through a management control system; the manipulation itself is usually manual however. Automatic transport and storage systems (Figs. 11 and 12) are known. Loading and unloading equipment for bobbins and packages and semi-automatic equipment for jets is also available, so that complete automation of the flow of goods is often possible. However, apart from the high price, a big disadvantage so far is the limitation of this system to only a few types of moving goods and operations. Because of this lack of flexibility of the robots, it is to be expected that material in the dyehouse will continue to be moved manually to a large extent. The rate of circulation of the goods and/or pumping capacity can also be adjusted to the requirements of a particular step in the dyeing process: faster circulation in the stage that is critical for levelness, slower in the dwelling and diffusion stages. In this way, the stress on the goods is minimised (Thies Synchron Dyeing System, SDS). Using robots to carry out the processing steps (e.g. in printing) must also be considered during automation.

The automation equipment (microprocessors) is often controlled from a central computer. Because of the lack of suitable sensors, easily measured values, such as temperature, fabric speed, pressure difference and density are used as measuring parameters instead of the actual target values. On-line pH measurement unfortunately still has problems and for a long time has been used only in carpet winch dyeing. On-line control of the rate of dyeing by continuous extinction measurements of the dyebath is available however, but is limited to cases where the extinction actually measures the concentration of active dyestuff in the bath, e.g. in dyeing polyacrylonitrile with cationic dyes. Care must be taken when this principle is used as the rate of dyeing is not always directly related to the levelness: an exhaustion curve that is linear with time is not always the optimum. Equipment of this type is better suited to finding the optimum processing conditions than for automatically guaranteeing each individual dyeing.

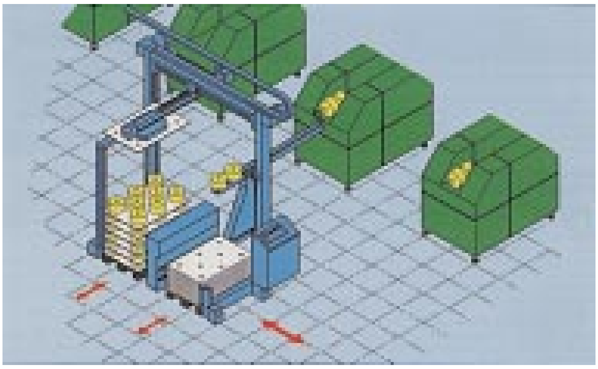

Fig. 11: Automation of transport of goods by putting bobbins on pallets.

Fig. 12: The Jasper automatic system for preparation of bobbins in a yarn dyehouse.

Automation, degree of A measure of the proportion of automatic operations in a particular process related to the total number of operations involved in that process:

Automation, selection of tasks for Selection formulae to help in introducing an automation system. They include regulation and control functions, in particular. The selection of tasks for automation is included in problem solving. There are many reasons for increased automation in production and administration. The most important are increasing productivity or reducing production costs and improving flexibility. Higher quality requirements and moves towards better working conditions are also important.

The rapidly increasing performance of microcomputers and memory banks means that it is now possible to automate complex processes to an extent that was unimaginable only a few yeas ago. However a point has been reached where it has to be asked whether it is sensible to carry out all the automation that is technically feasible. A greater degree of automation in a process does not necessarily lead to higher productivity when parameters such as flexibility, appreciation of the situation, maintenance and the reliability of the overall human being-machine interaction are included. Before starting any automation programme, a list of what is to be automated should be drawn up. The subsequent events are then:

1. Change over from relays in switch-boxes to stored program control (SPC). Enter the set values into the SPC.
2. Identify the interfaces.
3. Choose suitable measuring devices (sensors, units to measure current values), particularly for measurements on the goods.
4. If necessary, change from mechanical or pneumatic to electronic operating devices (transducers).
5. The whole set of measured values should be tested with suitable software. The software should be run by the people who will operate it. The aim is to use the screen to monitor the process.
6. It makes good sense to connect peripheral areas, especially the colour kitchen. Reliable equipment for measuring the flow of material is indispensable.
7. All the effort leads to a process that ensures reproducibility.

Automation technology General term for the processes, equipment and auxiliaries used in → Automation. It is divided into:

- measuring technology,
- regulating technology,
- control technology,
- computer technology.

Automation using these technologies can be split into 3 areas of dyeing and printing:

1. Production control with expert systems,
2. Part automation with closed control loops,
3. Complete automation of transport operations.

The control system carries out the steps “measure – compare – adjust” continuously until a situation is reached where the control quantity x is close to the required set value, $x_i = x_s$, and then it is kept there in spite of changes in other parameters z (z_1, z_2, z_3 in a block diagram) which may affect the process. For a typical textile dyeing or printing process, the set values, disturbance parameters and target values are important. In contrast to this process management in which the actual and set values are compared and fed into an automatic unit for an intelligent intervention in the process to be made, with process control any intelligent behaviour is pre-planned (programmed); the automation carries out the programme in a pre-planned sequence, without regard for anything else that may be happening in the process. The difference is illustrated by 2 examples:

a) A dyeing processes is controlled by a very polished “dyeing management” system, but which does not monitor the whole system. If (in an extreme case) someone forgot to load the dyeing machine with material, this serious mistake would not be noticed by the dyeing machine control, as this control system does not specifically involve the goods in a closed loop control system and the dyeing process is carried out without any measurement of colour changes (transmission of the bath or reflectance of the goods).

b) In textile processing, a real closed control loop must involve the goods and data from measurements on the goods (with suitable sensors) for deciding the operation of the control devices. The dyeing process is controlled meaningfully when the exhaustion of the bath is measured directly by colourimetry, and used to control the shape of the heating curve, which may be specific for each individual dyeing process. In this example however the goods are only involved indirectly (through the exhaustion of the bath).

When the moisture content of the goods coming from a stenter is measured directly, the running speed can be controlled according to the dryness if a set value for the optimum moisture content of the goods has been fed into the controller (by hand or through a microprocessor).

The Triatex “Mafoko” minimum application equipment uses an effective closed control loop; the goods are tested before and after padding for density and water content by radioactivity measurements. The speed is increased or reduced to control the uptake. Control of the temperature of the goods is essential in modern drying technology (by heat balance measurements in convective drying). However measurements of the high water contents at entry are also becoming significant in drying in large scale processes.

Great advances have been made in automating printing processes. Zimmer's Chromojet system represents an extraordinary development. In contrast to the Millitron process in which a stream of dye solution flows continuously but is periodically deflected away from the pile of the fabric by computer controlled air jets, the dye solution is delivered from the jets onto the goods (e.g. carpeting) only when a computer sends a signal. A big advance in screen making has been realized through linkage with computer supported printing systems. Here the submitted pattern is scanned electronically, e.g. with a scanner, subsequently digitized in a computer and transmitted to a screen (where alterations can be made to the pattern) and sent directly from there to laser engraving. In this connection, the Eikonix (USA) company has introduced an interesting computer supported colour design system with its "Design-Master 9000". In the new engraving process, the layer of lacquer is vaporised directly onto a perforated printing screen by a laser beam 0.12–0.30 mm wide. The printing screen is prepared without having to make a photographic film so that the engraving time is reduced considerably. The screen engraving time depends on the width or narrowness of the beam and takes at most 30 minutes for a 160cm screen (Stork).

With such colouristic systems based on electronic data processing, it is important that the respective systems are compatible when the design studios of textile dyeing and printing companies work together with customers' or consulting designers' design studios. The example of the Eikonix colour textile design systems shows how strongly interlinked the coloration processes are. In the future, automation will move towards a fully interlinked system with central guidance, which will also include a fully automated transport system. One pre-condition for the development of such a fully automated transport arrangement is the preparation of a system for controlling handling. In all the euphoria however, it should be noted that there is still no piece identification system that permits automatic location of a particular piece through all its operations and with labelling that can stand up to all the chemical processing.

Automobile safety belts 16 types have been approved to a European standard for use under European conditions. Polyester is the main fibre, although polyamide is also used occasionally. Commercially, both mass-coloured fibres and piece-dyed webbings are used for these applications. Polyester webbings may be dyed with disperse dyes by the thermosol process → Automobile safety belts (polyester), dyeing of. Polyamide webbings are dyed with 1:2 metal-complex dyes by the pad-steam process.

Automobile safety belts (polyester), dyeing of Continuous dyeing by the → Thermosol dyeing process (→ Dyeing of polyester) with appropriate machine combinations, e.g.: entry feed system, padder, IR-predrier, hot flue (for thermosol fixation), cooling zone, continuous washing range (at least 6 compartments if possible), drying unit (generally a cylinder drier) and a batching frame. Requirements include excellent light fastness, very good fastness to rubbing and good fastness to perspiration. A simple afterwash is sufficient for pale shades whilst an alkaline reduction clear aftertreatment is necessary for medium to dark shades. As a padding auxiliary, the addition of a synthetic thickener to the pad liquor is beneficial. Thermosol conditions of 30–90 s at 200–220°C are normally employed for dye fixation.

Automobile textile furnishings, recycling of For the future recycling of automotive textiles it is essential that they are first sorted into products of similar type. Compact system automotive carpeting consists of three layers:

- decorative textile layer (carpet),
- an acoustically effective resilient layer which is supported on
- a soft foam/nonwoven layer.

The composition of this compact system involves a wide variety of polymer types.

In contrast to uniform polyurethane foam, the acoustic layer of the carpet construction consists of several different thermoplastic polymers as shown in the Fig. These differ greatly from one another in structure and, as a consequence, also in their melting points. In order to achieve effective recycling, therefore, a plea must be made for these composites to be made from materials which are as uniform as possible in future.

As a basis for groups of materials of similar type, polyester and polypropylene are appropriate products. Polyurethane remains as the foam material which is separated by a film.

Various recycling procedures are used for textile materials of similar type. For example, after separating the polyurethane foam from the carpet upper layer, it is treated as follows: The foam padding is compacted. After mixing with a resin binder, the particles are either used to produce foam underlays which give improved soundproofing when placed under carpeting or pressed into composites which are used as a substitute for new polyurethane foam by incorporation into new compact system automobile carpets. The thermoplastic upper structure of the carpeting is first shredded then granulated in a further process. Up to now, three valuable applications have been examined for this granulated product:

- It may be incorporated into the recipe of a new batch of low expansion foam for compact carpets in amounts up to 15–25% or

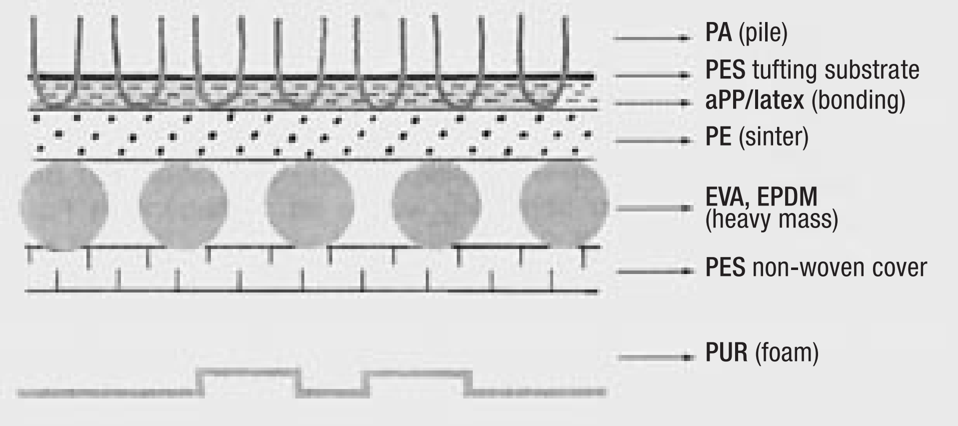

Fig.: Material construction of a carpet compact system.

- It may be added in the same proportion to the coating of carpet tiles.
- Trials made to add this granulated product to asphalt for road building as a bitumen extender have also given good results.

Even components having complex integrated structures (e.g. compact system carpets) can be recycled up to 100% by appropriate pre-sorting of compatible materials resp. the adoption of simple separation procedures for incompatible material composites. Manufacturing costs can be reduced through the use of recycled products in the production of new components. Having regard to the urgent need for recycling, the advantages of floorcoverings made from compatibly integrated materials should not be ignored in future (Laser).

Automotive textiles (car textiles) Since the early days of motor vehicle development producers of textiles and makers of cars have worked together. Over the years there has been continuous progression keeping pace with the changing specialist needs of the car industry in upholstery and trim materials. Since the 1980s there has been a sharp rise in the demand for textiles as a consequence of the greater need for comfort in the private car. Significant new developments such as those in the composites sector or in technical textiles have only been made possible through this spirit of cooperation. A vehicle in the medium quality range is fitted with an average of 10 m^2 of upholstery fabric, in addition there are 8.5 m^2 for floorcoverings and other trim items. This clearly illustrates the status of the car industry as a trading partner for the textile industry along with its suppliers of ancillaries and textile machine makers.

In the automotive industry the constant trend is towards higher quality. This is especially evident in the textiles used in cars. General requirements include:

- use of fibres of similar generic type,
- high lightfastness,
- fully compatible shades and colour uniformity in all consignments,
- optimum design with ideal surface properties for upholstery materials.

Safety and comfort have become important constructional attributes in the car. This is why in recent years there has been a significant rise in textile fabrics used in the interior trim of vehicles, generally at the expense of simulated leather and plastics facing materials. This fashion towards higher quality, luxury trim is continuing. Suitability for purpose and length of useful life are the main critical factors. But also in the technical sector of vehicle parts there is growing use of textiles or fibre products because of their specific benefits for certain applications. One example of extended use is the introduction of the passenger airbag as an additional safety feature. The following list summarises the variety of end-uses and preferred forms of presentation:

1. Seat upholstery fabrics: non-pile fabrics, woven, warp-knit and raschel velours, circular and flat knits, microfibre nonwovens; with or without polyurethane foam backing and secondary backing (generally lightweight polyamide knit), sandwich-laminate, primarily in ployester/wool, polyester, acrylic, polyamide/polyurethane.
2. Upholstery wadding: lightly needled fibrous webs in different fibre compositions including wool, cotton/viscose and synthetic fibres, sometimes with interlay or substrate in polyurethane foam.
3. Upholstery calico: cotton, cotton/viscose or cotton/polyester calico of varying construction.
4. Rubberised hair matting: coarse nonwoven in coconut fibre and hogshair bonded with a synthetic/natural latex mix; layered construction, varying density.
5. Seat trim (sides and back): warpknit and woven velours, raschel plush, knits in polyester and acrylic, generally sandwich-laminated to polyurethane foam.
6. Door and side trim: often the same as the seat upholstery or seat trim, sometimes combined with carpeting and/or plastics foil.
7. Headliner: generally on pre-assembled unit (closed preformed plastics-based unit) in warpknit velours,

non-raised knit, knit laminated to polyurethane foam substrate; in polyester/polyamide (two-tone effect), polyester.

8. A, B and C columns, sun visors: generally in material and colour to match headliner.
9. Carpets: tufted velours, tufted loop-pile, needlefelt almost always moulded and sometimes directly foam-backed (to compensate floor unevenness); various back-coatings, e.g. with solid backing for noise insulation; in polyamide and polypropylene.
10. Parcel shelves: non-pile and loop-pile needlefelts, warpknit velours, woven velours in polyester and polypropylene.
11. Trunk liners: needlefelts, tufted velours, tufted loop-pile often back-coated or impregnated or backed and moulded; in polypropylene, polyamide or polyester.
12. Restraint systems: polyester safety belts, airbags for airbag unit in coated woven polyamide and aramid fabric.
13. Technical nonwovens: Melded nonwovens generally in synthetic fibres, impregnated with the plastics emulsions necessary for the melding function and/or sometimes produced with fusible fibres. Noise insulation, anti-vibration and motion-damping nonwovens, antistatic pads and felts in wool and synthetic fibres with and without polyurethane foam backing,
14. Tarpaulins and covers: tarpaulins in polyester/acrylic outer fabric laminated to cotton fabric sandwiching a dense intermediate layer of chloroprene rubber; coated and impregnated tarpaulins in polyester and polyester/cotton.
15. Tapes, nets, twines: woven tapes, e.g. for edging purposes; in knitted fabric, e.g. for door-edge draughtproofing (in combination with steel inserts and rubber); in felts, e.g. for draughtproofing; securing or separating nets in polyester; sewing twines in polyester, polyester/cotton, polyester.
16. Substrates for simulated leather: knitted and woven fabrics, nonwovens, spunbondeds; in polyester/cotton, polyester, cotton, polypropylene.
17. Tyres, V-belts, hoses, ropes: tyrecord in polyamide and polyester; V-belt liners and hose liners; tow ropes etc.
18. Textile loose covers for seating: knits in polyester.

Car manufacturers have drawn up basic technical specifications which include definitions of the following:

- the scope (with technical demarcation in terms of products and/or techniques);
- the responsibilities of customer and contractor relating to controls on incoming deliveries, in manufacture and on end-product, plus agreement on inspection visits;
- progression of joint developments extending from drafts, pre-production samples and passing samples through to full production , paying particular attention to environmental conservation and industrial safety requirements;
- the technical and testing procedures to be followed for consignments, for example batch sizes, test certificates, labelling/identification, defect description and marking (including indemnity), make-up, packaging and delivery conditions;
- miscellaneous technical requirements, for instance tolerable variability (e.g. of a property affecting making-up due to variations in machinery between two different suppliers making the same product), shelf-life, tolerances and procedure for settling complaints;
- testing procedures which differ the standard methods (DIN, ISO, ASTM, SNV, BS etc.).

Technical specifications include definitions of:

- constructional features (composite items);
- properties affecting making-up: a) elongation, drape, moulding characteristics; b) sewability, adhesion, fusability, bonding potential, vulcanising (curing) characteristics; c) seam strength, needle and stitch tear strength, fraying; d) tear strength;
- end-use characteristics: a) breaking strength, breaking extension, bursting strength; b) abrasion resistance, wear test, simulated service test; d) pilling propensity; e) air permeability, water vapour permeability; f) resistance to compression, recovery from indentation; g) residual and elastic extension, bagging fatigue; h) lightfastness on exposure to high black-panel temperature; i) colour fastness (fastness to rubbing, perspiration, water spotting, water immersion, solvents); k) streakiness, handle, friction index; l) stain resistance, drycleanability; m) delamination resistance; n) dimensional stability; o) flame resistance; p) fogging and odour; r) miscellaneous (residual fatty matter content, extractable matter, electrostatic propensity, pile withdrawal force; s) resistance to weathering and ageing; resistance to environmental influences.

Automotive textiles specifications Textiles are used very extensively in cars, examples of their applications including tyres, hoses, tapes, nets, twines, ropes, V-belts, noise insulation etc. and extending to upholstery materials and carpeting. Textile interior trim in cars is not confined to needled floorcoverings and pile nonwoven covers which are chemically bonded. Laminated woven and knitted fabrics are used as seat upholstery and in side cladding. Flocking also plays a major role in car headliner products.

Five percent of the total annual consumption of textiles comprises use in the car sector. Car comfort has become an important design feature. There is a continuing trend towards luxury textile interior trim of high textile quality. Designers compete to attract the buyer with their ideas. One of the tasks of of the finisher is to convert these ideas into reality whilst taking account of the required end-use efficiency of the textiles concerned. Quality specifications of car manufacturers indicate that the most important colour-related fastness requirements for the end-product in interior trim are associated with lighfastness, the metamerism of dyed shades and fogging. The fact is that the specifications and test procedures called for by car manufacturers vary according to the different substrates and woven or knitted constructions employed. The sometimes extreme demands called for in textiles (ten-year guarantee) are understandable if the stresses involved are considered; for instance, not only light, but also temperatures in excess of 100°C to which the fabric is exposed.

When it comes to scrapping, car textiles are classed as light industrial refuse along with glass, rubber and plastics. Because of the diverse nature of the synthetic materials contained (approx. two dozen types) there is general cause for concern. It is quite possible that toxic fumes will be emitted during incineration. To enable these materials to be recycled they need to be sorted. Under the conditions of current scrapping practices this is not possible. One feasible solution would therefore be to break down the scrapped car into its component parts in the reverse of the production process. To permit recycling of the materials obtained in this way the textile finisher (e.g. producing bonded nonwovens for use as floorcovering) needs to be aware that only thermoplastics can be recycled satisfactorily.

The safety belt is an important feature in the car. Requirements for this are specified in EC Guidelines. Minimum values are prescribed for width and breaking strength. Specifications also cover minimum breaking strength following abrasion and resistance to light exposure, cold, heat and moisture. One important test is a dynamic test simulating an accident which uses a dummy on a sledge, which at a speed of 50 km/h is decelerated over a braking distance of 40 cm. The belt must remain intact. At the end of the test the frontward displacement of the dummy is ascertained. The requirements in this dynamic test do in fact result in increased static strength in safety belts accompanied by reduced belt extensibility. Because of the legal requirements, some car companies have prescribed higher specifications, and some call for additional tests.

Colour fastness to crocking (rubbing) and light in piece-dyed (superficially dyed) belts is governed solely by the dyeing characteristics of the warp yarns used, the quality of the dyes used and the knowhow and dyeing machinery of the dyehouse. As these are inadequate in many cases, car manufacturers in Europe are tending more and more to specify belts made in spun-dyed yarns (Fig.). By this means unforeseeable risks may be avoided because even with good piece dyeing shade variations from batch to batch are inevitable.

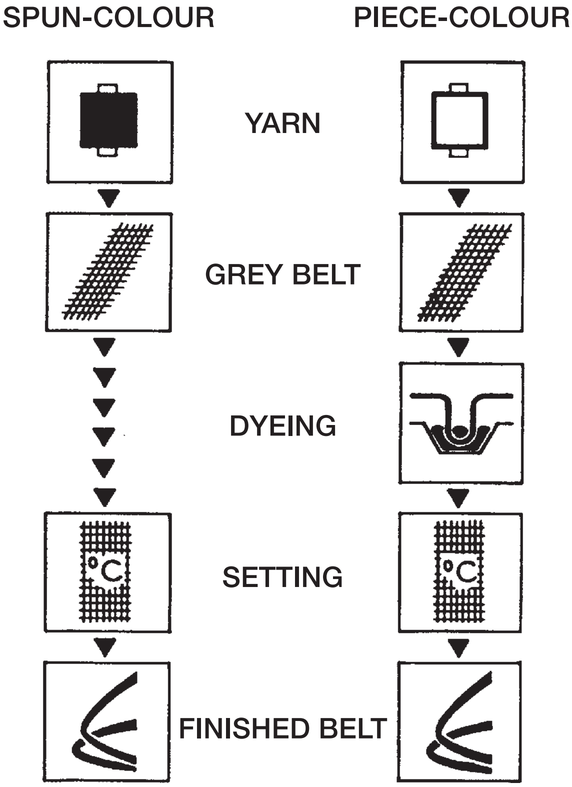

Fig.: Technology of safety belt manufacture.

Crocking and perspiration fastness of spun-dyed products may be regarded as optimum since the dye is fixed on the polymer chemically and physically during fibre production and therefore cannot be rubbed off. In spun-dyed fibre the dye is present not merely on the surface but penetrating its capillaries. The lightfastness of spun-dyed materials is also excellent. Even after 2000 hours exposure, exposed areas of a belt are the same shade as unexposed areas. With piece-dyed belts a distinct shade change is recorded after as little as 200 hours.

Apart from the usual requirements (surface evenness, shade conformity, crocking fastness, comfort) the requirements for lightfastness in exposure to high black-panel temperature are extremely high for car interior trim. These requirements can vary considerably depending on where the material is to be used in the car interior. It is quite possible for different car manufacturers to test using the same test procedure but demand different fastness grades. This means that the test procedures need to be kept strictly separate from what is required in the results. Generally speaking there is distinct trend towards still stricter specifications, though using the same test procedures but over a longer testing time. Another point to be considered is that textile trim materials must be odourless and not be subject to “fogging”. Special additives therefore need to be employed which do not give rise to fogging.

Automotive textiles, light fastness testing Automobile manufacturers have produced their own technical standards which differ from the usual industrial standards and even differ greatly in some respects between manufacturers. This creates problems for producers of → Automotive textiles as well as for the dye manufacturers in recommending a selection of dyes suitable for use in combinations with guaranteed high light fastness properties, since individual dyes can react very differently to external factors (temperature and moisture). As a consequence, the reproducibility and comparability of light fastness ratings in different locations cannot be fully guaranteed. There is thus an urgent need for a cooperative agreement between automobile manufacturers and international fastness testing committees to establish a unique, reliable and highly reproducible test method for automotive textiles. → High temperature light fastness tests.

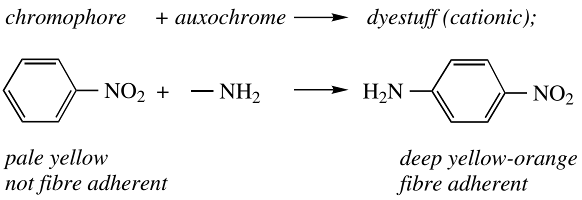
Automotive textiles, recycling of A motor vehicle contains a large number of different materials. Although the proportion of textiles is less than 10%, it is still necessary to use environmentally acceptable and recyclable fibres, to limit the number of different types, and to move away from composite materials with different components. Textile materials should always be viewed in the context of the whole structure and constructions that can be easily dismantled are essential for a successful recycling chain.

Example: Cushioning materials and lining fabrics are frequently combined with polyurethane foams. This combination cannot be used satisfactorily at present. Chemical recycling (alcoholysis, hydrolysis) is possible but expensive and there is no demand for processing foam combined with flock. One solution is to substitute fibrous materials (non-woven fabrics) for the foam, which also allows the flame laminating process with its high emissions to be replaced by adhesive laminating processes. It is also necessary to examine the individual components alone as well as as a part of the whole construction.

Autoradiography is used for the local detection of radioactive substances by means of photographic plates. If, for example, a substance which has been labelled with a radioactive indicator is brought into close contact with a film emulsion, the location of the radioactively labelled areas will be indicated precisely after a suitable exposure time by the black points produced in the film layer caused by the available radiation sources (alpha or beta rays). The method offers the possibility to detect the spacial distribution and location of substances. The photographic plates are interspersed and ionized by radioactive particles over an appropriately wide range. Autoradiography is far superior to methods of detection based on pure chemistry.

Autoxidation The self-catalyzed oxidation of e.g. sulphur dyeings or, to be more precise, the sulphur contained in the dye molecule both on and within the dyed fibre as a result of which free sulphuric acid is liberated causing hydrolysis and destruction of cellulosic fibres through the formation of (hydrocellulose). Autoxidation is promoted e.g. by storage of dyed goods under warm humid conditions. In this case, the valency of the sulphur (at the polysulphide bridges) is chemically changed through oxidation, so that divalent sulphur becomes tetravalent from this point on. → Antioxidants.

Auxochrome A substituent group in a dye molecule having a basic or weakly acidic character which acts as a "colour intensifier" and also confers affinity for textile fibres. The best examples are the groups –COOH, SO_3H, –OH, and NH_2. Only when an auxochrome (electron donor) and a → Chromophore (electron acceptor) are both present is a dye obtained which has affinity for the fibre:



Available chlorine is the chlorine which is active for bleaching (disinfectant-active) and present in chlorine products. In chloride of lime (bleaching powder), for example, it is the quantity of chlorine released by the action of hydrochloric acid: $CaOCl_2 + 2HCl \rightarrow CaCl_2 + H_2O + Cl_2$. Chloride of lime has an active chlorine content of 35–40%; sodium hypochlorite bleach liquor 145–150 g/l and bleaching baths 3–8 g/l. Used, e.g., in → Disinfection washing of textile.

Available chlorine in bleaching baths, determination of 10 ml of the bleach liquor to be tested (diluted to approx. 50 ml with water) is titrated with 0,1n arsenic acid solution until a drop of the liquid no longer turns potassium iodide paper blue. 1 ml of 0,1 narsenic acid is equivalent to 0,003546 g of available chlorine.

Available oxygen content of peroxide bleach liquors Volumetric determination by titration with standard potassium permanganate solution until the end point is reached (faint pink colour).

Average degree of polymerization indicates the average number of monomers contained in a polymer. The mole mass of the polymer is obtained from the product of the average degree of polymerization and the mole mass of the monomer ($M_{Monomer}$). The average degree of polymerization is determined by osmotic methods or viscosimetry. It provides information on polymer hydrolytic breakdown (damage). The specific viscosity ($\eta_{spec.}$) of the solution of a polymer, the average degree of polymerization of which is to be determined, depends on the concentration, chain length (average degree polymerization) and temperature of the polymer (η = polymer solution viscosity) and the solvent (η_0 = solvent viscosity).

$$\eta_{spec.} = \frac{\eta - \eta_0}{\eta_0} = \frac{t - t_0}{t_0}$$

Viscosity is measured in a capillary viscometer (Ostwald, Ubbelode) via the passage time t of suitable solutions. The specific viscosity obtained in this way is connected with the average degree of polymerization as follows:

$$\eta_{red} = \frac{\eta_{spec.}}{c} = K_m \cdot DP$$ (Staudinger equation)

$$DP = \frac{\eta_{spec.}}{c \cdot K_m}$$

c = polymer concentration in g/l,
K_m = constant, depending on polymer structure and solvent,
η_{red} = limit viscosity.

The limit viscosity η_{red} is obtained from the $\eta_{spec.}$ curve against c for c = 0. The average degree of polymerization can be obtained more accurately via the equation of Schulz and Blaschke:

$$DP = \frac{\eta_{spec.}}{K_m \cdot c} \cdot \frac{1}{1 + K_\eta \cdot \eta_{spec.}}$$

K_m = constant for polymer effect,
K_η = constant for solvent effect.

Some values for the average degree of polymerization of fibres:

cotton	3000 – 5000
other natural cellulosic fibres	2000 – 3000
wool	100
silk	1300
viscose	500 – 700
acetate	200 – 300
polyester	12 000 – 20 000
polyamide	100 – 200
polyacrylonitrile	500 – 1500

Average molecular weight (AMW) A term used in polymer chemistry for the mean value of the entire molecular weight range. It affords useful information on the structure of macro- molecules, e.g. oligomers dissolved out of synthetic fibres during specific finishing processes (effect of carriers).

Average value $(\bar{x})$ Statistical parameter in quality control, as the arithmetic mean of an average of random samples from the sum/number of individual values. As an acceptable assessed value, has the practical merit of smallest variance. → Statistical analysis.

AWA, (Ger.) abbrev. for: Arbeitsgemeinschaft Wasser (German Study Group on Water).

Awning cloth or tarpaulin Heavy → Sailcloth; also coated.

Axial drive batcher → Batching drives.

Axial dyeing process Package dyeing in dyeing machines with axial liquor flow.

Axial fans Electric fans used in ducts for the ventilation and extraction of exhaust vapours and steam from inside buildings and industrial plants. They are constructed in such a way that the shaft of the fan is centrally positioned within the duct (see Fig.). The use of glass-reinforced plastics (GRP) ensures excellent resistance to chemicals and can be used at temperatures up to 120°C. The three-phase motor is located externally.

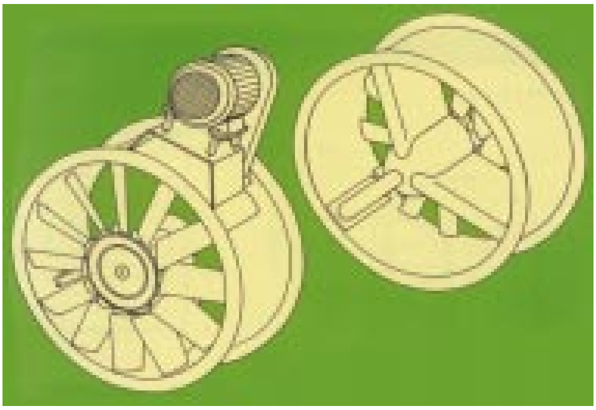


Fig.: Windel plastic axial fan.

Axial-flow pumps With the introduction of high density textile packages, e.g. yarn packages in dyeing machines with press-packed columns through which the dye liquor has to flow (400–500 l/kg) axial-flow pumps are of particular interest. Liquor flow through the pump inlet and outlet sides is axial. In contrast to centrifugal pumps, the load on the motor increases with increasing resistance of the textile material. In the axial-flow pump a rotor is provided for each stator. Multistage axial-flow pumps have several rotor/stator pairs in series. The pump response curve can be changed by regulating the speed of the drive motor.

Axioflexible cylindrical dye tubes In order to produce cylindrical yarn packages suitable for press-

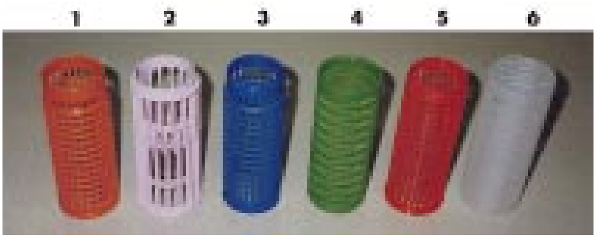

Fig.: Axial-flexible cores from different manufacturers. 1 = Karo core: disposable pressure dyeing core; diam. 54/60 mm. 170 mm (Karo Kunststoffwerke); 2 = Combi-Flex: ribbed core; diam. 54/60 mm, 170 mm (J. Zimmermann-Eisbär Nadelfabrik); 3 = Becker core: disposable pressure dyeing core; diam. 54/60 mm, 170 mm (Karo Kunststoffwerke); 4 = Zet-Flex core: coarse screen core; diam. 54/59 mm, 170 mm (H. N. Zapf KG); 5 = AC dyeing core: coarse screen core; 54/59 mm, 170 mm (J. Zimmermann-Eisbär Nadelfabrik); 6 = "Engel" dyeing core: diam. 58 mm, 170 mm (Engel Multiflex System GmbH).

packed package dyeing machines, plastic → Dye tubes are needed which are capable of compression in the lengthwise direction, either reversibly or irreversibly, without undergoing any significant change in diameter during the press-packing operation. Moreover, the pore volume of the perforations must not be too small so that adequate liquor flow through the yarn package is maintained. From the extensive range of axioflexible cylindrical → Disposable dye tubes and → Reusable dye tubes available in the market a few examples may be seen in the Fig.

Axminster carpets Machine woven carpets, with cut pile, in which successive weftwise rows of pile are inserted during weaving in a prearranged colour sequence. This type of carpet was originally produced in the English town of Axminster. The methods of manufacture enable virtually any type of coloured design to be reproduced, a flexibility which has been particularly exploited in the imitation of oriental carpets. There are four main types of Axminster weave: spool Axminster, gripper Axminster, spool-gripper (gripper-spool) Axminster, and chenille Axminster.

Aza compounds The prefix "aza" is used to denote the presence of nitrogen in an organic heterocyclic ring structure, i.e. when one or more –CH groups are substituted with nitrogen.

Thus pyridine (C_6H_5N) is also azabenzene. Aza compounds are free of sulphonic acid groups and soluble in acids. They are used as (special) coupling components on naphtholated grounds e.g. on wool and silk.

Azeotrope (azeotropic mixture; constant boiling mixture) A mixture of two liquids (or solvents) that boils at constant composition at a specific temperature, i.e. the composition of the vapour is the same as that of the liquid. Azeotropes occur because of deviations in Raoult's law leading to a maximum or minimum in the boiling point composition diagram. When the mixture is boiled, the vapour initially has a higher proportion of one component than is present in the liquid, so that the proportion of this in the liquid falls with time. Eventually, the maximum and minimum point is reached, at which the two liquids distil together without change in their composition. For this reason, separation by simple distillation is not possible. The composition of an azeotrope depends on the pressure. In the case of solvents, the presence of water results in a steady-state temperature which is significantly lower than the boiling point of the solvent.

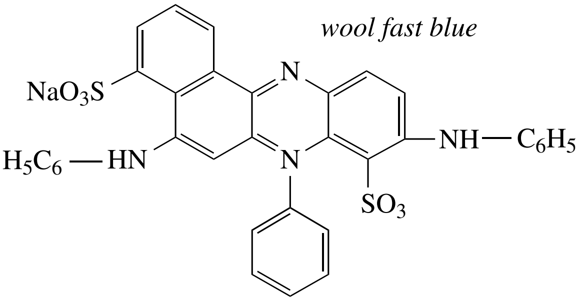
Tetrachloroethylene forms e.g. azeotropes with many solvents:

Azeotropic boiling point in °C (at 1 bar) with:

Water (100,0°C)	87,10	84,0 wt.%
Methanol (64,7°C)	63,75	36,5 wt.%
Ethanol (78,3°C)	76,75	37,0 wt.%
Isopropanol (82,4°C)	81,70	30,0 wt.%
Formic acid (100,7°C)	88,15	50,0 wt.%
Glacial acetic acid (197,5°C)	119,10	94,0 wt.%

Azides Salts of hydrazoic acid, HN_3. The alkali and alkaline earth azides are quite stable compounds whilst heavy metal azides, on the other hand, are sensitive to impact and extremely explosive (detonate violently). The azide group is a good complexing agent. The azide ion is linear. In general, covalent azides are relatively stable.

Azine dyes The first synthetic dye mauveine belongs to this group. Few dyes of this type remain of industrial significance, an exception being safranine (C.I. Basic Red 2). The azine dyes also include acid dyes such as azocarmine and Wool Fast Blue (see Fig.) besides aniline black and a few colour bases (induline, nigrosine) which are oil and fat-soluble.→: Oxazine dyes; Thiazine dyes.

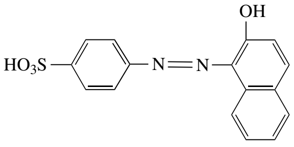


Azo, (French: *azote* = nitrogen) containing the azo group –N=N– which is a useful chromophore in dye chemistry.

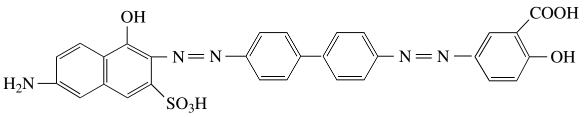
Azo dye coupling The combination of a coupling component with a diazo compound through an azo linkage.

Azo dyes contain the characteristic azo group –N=N– which is present to a greater or lesser degree in nearly all classes of dyes. Over half of all commercial dyestuffs belong in this general category. By varying the chemical composition it is possible to produce acid, basic, direct, reactive, disperse and mordant dyes containing the azo chromophore. This general group of dyes is subdivided into monoazo, disazo and polyazo dyes depending on the number of azo groups in the dye molecule thus:

I. Monoazo dyes with one azo group, e.g. the acid dye, Orange II:

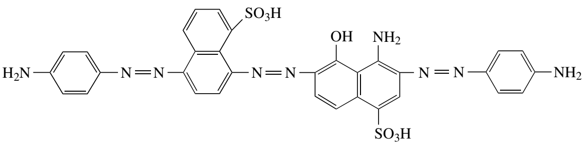


II. Disazo dyes with 2 azo groups must not be confused with → Diazotizable direct dyes. Most of the substantive dyes belong to this class, e.g. Diamine Brown M:



These disazo dyes also contain an amino group (–NH_2) which can be further diazotized so that, exceptionally, a diazo dye is involved here. Furthermore, the carboxyl (–COOH) and hydroxyl group (–OH) can be complexed with metals in this case.

III. Polyazo dyes contain 3 (trisazo), 4 (tetrazo) or more azo groups, e.g. as in the well-known substantive dye Zambezi Black V which contains 3 azo groups:



This dye is also capable of further diazotization (–NH_2) and then becomes a tetrazo dye with 4 azo groups. It can likewise be complexed with metals at the –OH group.

As a rule, azo dyes will not withstand a reductive treatment (see Fig.) and for this reason they cannot be used as vat or sulphur dyes but are particularly suitable for dischargeable grounds in discharge printing.

Direct dyes, in particular, frequently have azo dye structures which are ideally suited for the formation of coplanar configuations with aggregate-promoting properties. Azo dyes are strongly represented in the acid dye class but find only limited application as disperse dyes because of the requirement for low molecular weight. Azo dyes are particularly suitable for the formation of complexes with metal atoms.

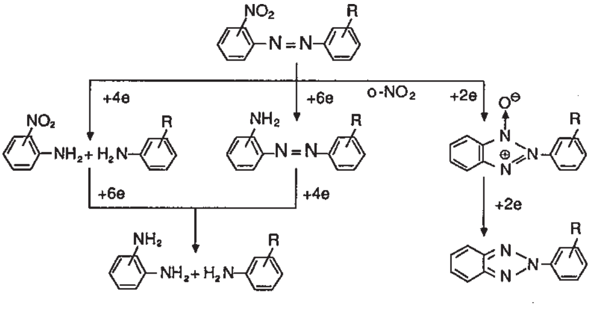


Fig.: Contention reactions for azo splitting.

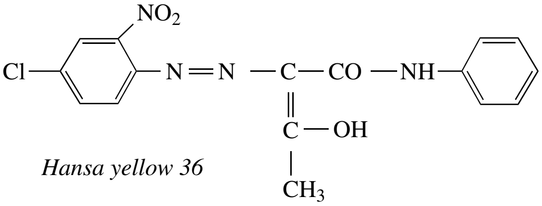
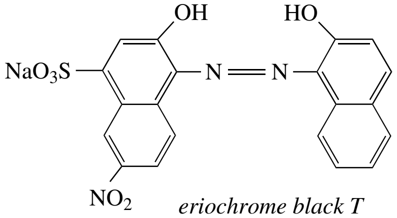
The following historically important azo dyes (with details of their derivation) are intended to illustrate the diversity of this class of colorants:

– C.I. 11670 (H. Wagner, 1909); 4-chloro-2-nitroaniline and acetoacetanilide.



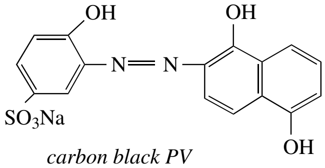
Hansa yellow 36

– C.I. 15710 (I. Hagenbach, 1904); 1-amino-6-nitro-2-naphthol-4-sulphonic acid and 2-naphthol.



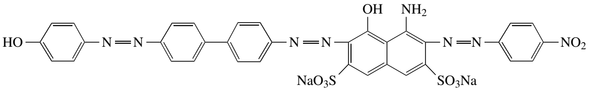
eriochrome black T

– C.I. 16500 (M. Kahn, 1902); 2-amino-1-phenol-4-sulphonic acid and 1,5-naphthalenediol.



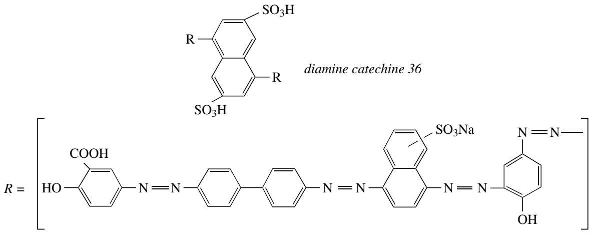
carbon black PV

– C.I. 30295 (M. Hoffmann, C. Daimler, 1891); p-nitroaniline with H-acid, benzidine and phenol.



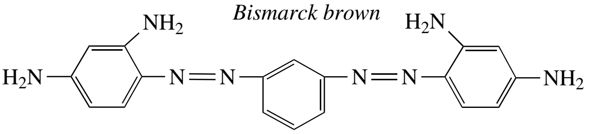
diamine green B

- C.I. 36 300 (1982); benzidine with salicylic acid and 1,6-(and 1,7-) Cleve's acid as well as phenol and 4,8-diamino-2,6-naphthalenedisulphonic acid.



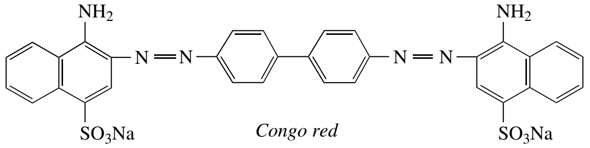
diamine catechine 36

- C.I. 21 000 (C. Martins, 1863); from 3 mol. m-phenylenediamine hydrochloride and 2 mol. nitrous acid.



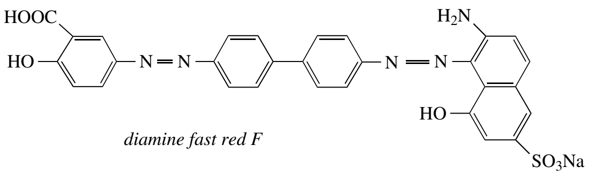
Bismarck brown

- C.I. 22 120 (P. Böttiger, 1884); benzidine with 2 mol. naphthionic acid.



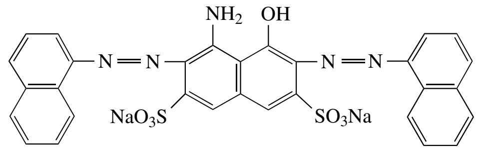
Congo red

- C.I. 22 310 (L. Gans, 1889); salicylic acid with benzidine and gamma acid.



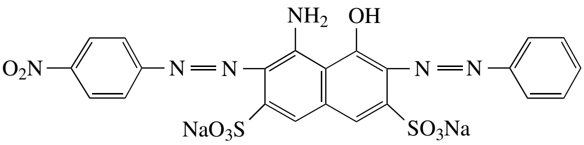
diamine fast red F

- C.I. 20 510; 2 mol. 1-naphthylamine with H-acid. Also contains K-acid as a coupling component.



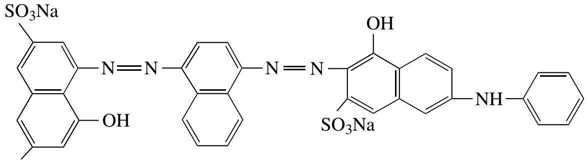
wool black GM

- C.I. 20 470 (M. Hoffmann, 1891); p-nitroaniline, H-acid, aniline.



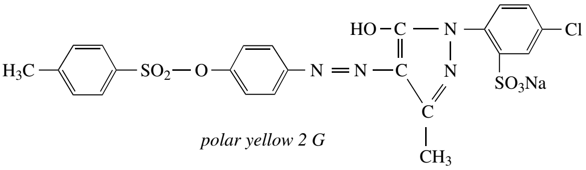
naphthol blue black B

- C.I. 27 950 (O. Günther, L. Hesse, 1906); H-acid, 1-naphthylamine, N-phenyl J acid.



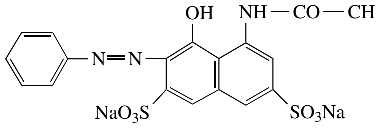
brilliant fast blue GG

- C.I. 18 950 (B. Richard, 1912); p-aminophenol, 1-(4-chloro-2-sulphophenyl)-3-methyl-5-pyrazolone, then treat with p-toluenesulphonyl chloride to esterify the phenolic hydroxy group.



polar yellow 2 G

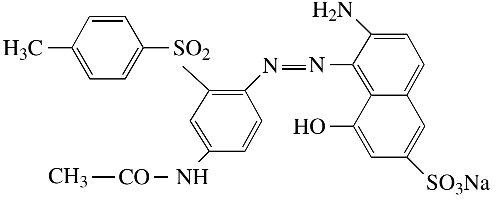
- C.I. 18 050 (1902); aniline, N-acetyl H-acid.



amidonaphthol red G

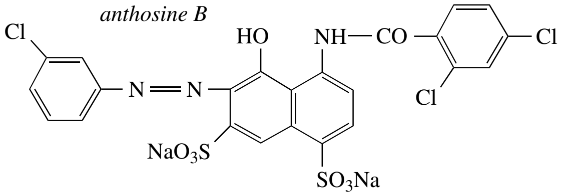
- C.I. 17 080; 4-amino-3-(p-tolylsulphonyl) acetanilide, gamma acid.

Kiton light red 4 BLN



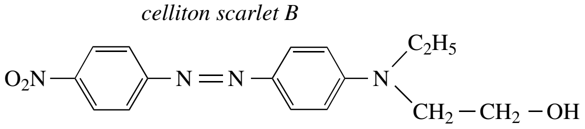
Azo dyes

- C.I. 18 020 (L. Blangey, C. Immerheiser, 1912); m-chloroaniline, N-2,4-dichlorobenzyl K-acid.



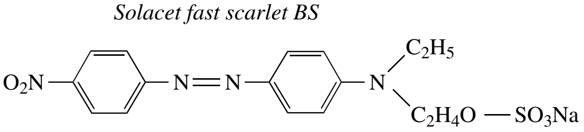
anthosine B

- C.I. 11 110; p-nitroaniline, 2-(N-ethylanilino) ethanol.



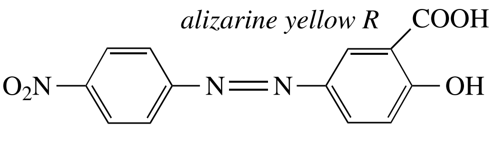
celliton scarlet B

- C.I. 13 055 (A. G. Green, K. H. Saunders, W. G. Perkin, S. C. Bate); p-nitroaniline, 2-(N-ethyl-anilino) ethanol sulphuric ester.



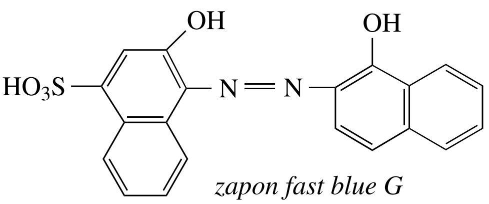
Solacet fast scarlet BS

- C.I. 14 030 (R. Meldola, 1885; R. Nietzki, 1887; Walter 1888); p-nitroaniline, salicylic acid.



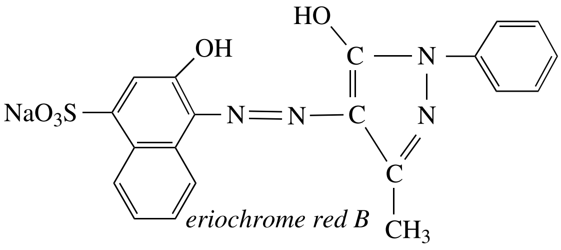
alizarine yellow R

- C.I. 14641.



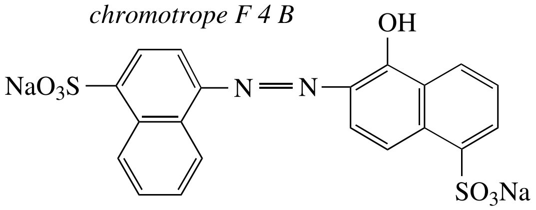
zapon fast blue G

- C.I. 18 760 (H. Hagenback, 1904); 1-amino-2-naphthol-4-sulphonic acid, 3-methyl-1-phenyl-5-pyrazolone.



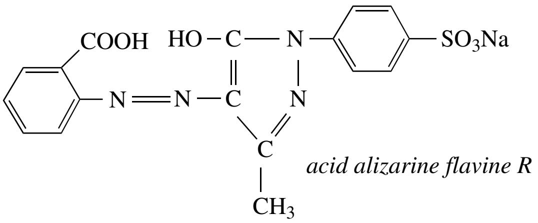
eriochrome red B

- C.I. 14 835; naphthionic acid, 1-naphthol-5-sulphonic acid.



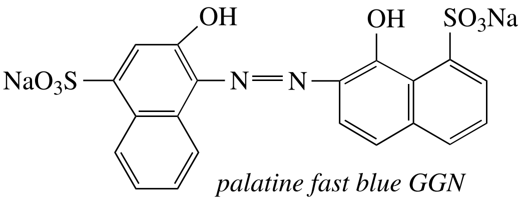
chromotrope F 4 B

- C.I. 18 821; anthranilic acid, 3-methyl-1-(p-sulphophenyl)-5-pyrazolone.



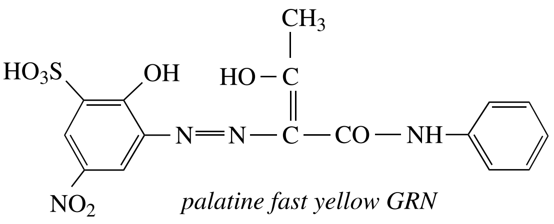
acid alizarine flavine R

- C.I. 14 880 (H. Kämmerer, 1926); 1:1 chromium complex of 6-amino-4-nitro-1-phenol-2-sulphonic acid and 1-naphthol-8-sulphonic acid.



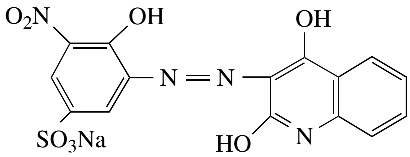
palatine fast blue GGN

- C.I. 13 900 (F. Straub, G. Montmollin, I. Spider, C. v. Planta, 1924); 1:1 chromium complex of 6-amino-4-nitro-1-phenol-2-sulphonic acid and acetoacetanilide.



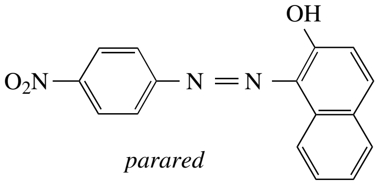
palatine fast yellow GRN

- C.I. 19 355 (H. Kämmerer, K. Holzach, 1927); 1:1 chromium complex of 2-amino-6-nitro-1-phenol-4-sulphonic acid and 2,4-quinolinediol.



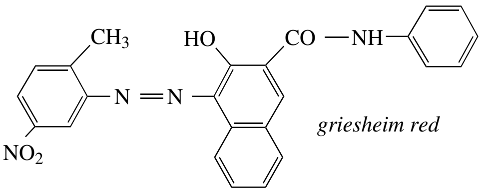
palatine fast red BEN

- C.I. 12 070 (R. Meldola, 1885); p-nitroaniline, 2-naphthol.



parared

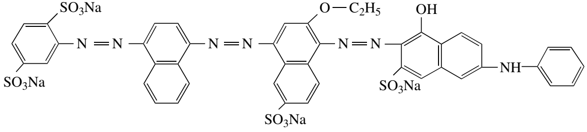
- C.I. 12 315 (A. Winther, A. Laska, A. Zitscher, 1911); 5-nitro-o-toluidine, 3-hydroxy-2-naphthanilide.



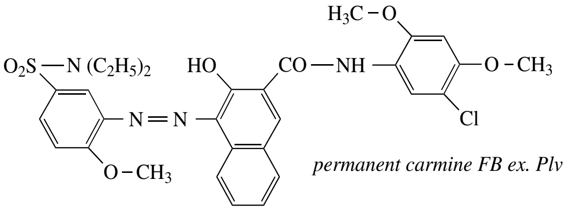
griesheim red

- C.I. 34 230 (H. Schweitzer, 1925); 2-amino-p-benzenedisulphonic acid, 1-naphthylamine, 5-amino-6-ethoxyl-2-naphthalenesulphonic acid, N-phenyl J acid.

sirius blue 6G



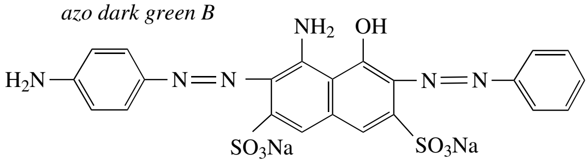
- C.I. 12 490 (W. Neelmeier, W. Lamberg, 1931), N^1-diethyl-4-methoxymetanilamide, 5´-chloro-3-hydroxy-2´,4´-dimethoxy-2-naphthanilide.



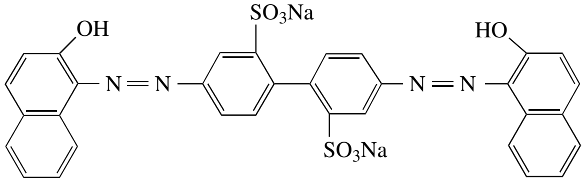
permanent carmine FB ex. Plv

- C.I. 20 495 (1909); by reduction of the nitro group in C.I. 20 470 with sodium sulphide.

azo dark green B



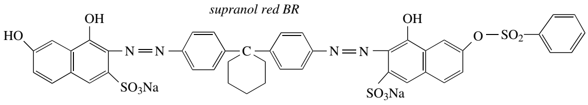
- C.I. 22 890 (1886); 2,2´-disulphobenzidine with 2 mol. of 2-naphthol.



acid anthracene red G

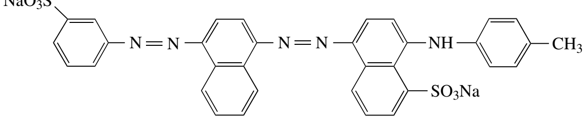
- C.I. 24 790 (R. Schüle, E. Korten, 1928); 4,4´-cyclohexylidenedianiline with 2 mol. 4,6-dihydroxy-2-naphthalenedisulphonic acid then esterify with 1 mol. benzenesulphonyl chloride.

supranol red BR

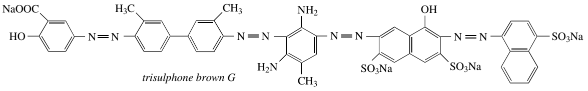


- C.I. 26 400 (P. Ott, 1892); metanilic acid, 1-naphthylamine, N-p-tolyl peri acid.

sulphocyanine GR ex.

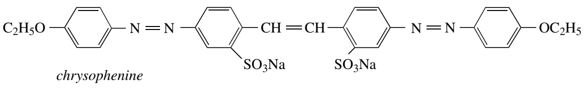


- C.I. 35 670 (M. Böniger, 1897); naphthionic acid with toluene-2,4-diamine and 2R acid, o-tolidene and salicylic acid.



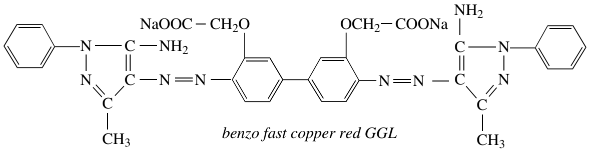
trisulphone brown G

- C.I. 24 895 (F. Bender, 1886); 4,4´-diamino-2,2´-stilbenedisulphonic acid with 2 mol. phenol, then ethylate the phenolic hydroxy groups.



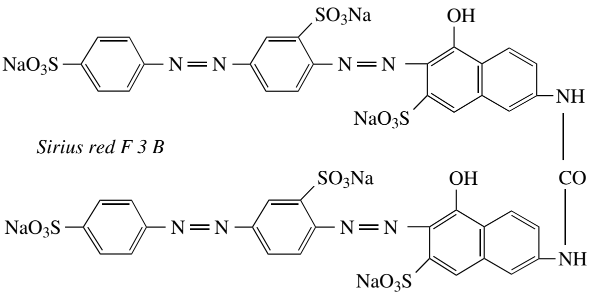
chrysophenine

- C.I. 24 565 (C. Taube, H. Rinke, E. Fischer, 1938); (4,4´-diamino-3,3´-biphenylenedioxy) di-acetic acid with 2 mol. 5-imino-3-methyl-1-phenyl-2-pyrazoline; aftertreated with copper sulphate.



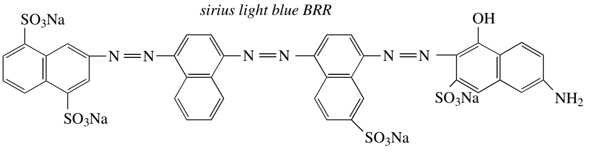
benzo fast copper red GGL

- C.I. 35 780 (J.P. Penny, 1922); a) 4-amino-3,4´-azodibenzenesulphonic acid and N-acetyl J acid then hydrolyze the acetamido group and phosgenate or b) 2 mol. 4-amino-3,4´-azodibenzenesulphonic acid with 6,6´-ureylenebis-1-naphthol-3-sulphonic acid.



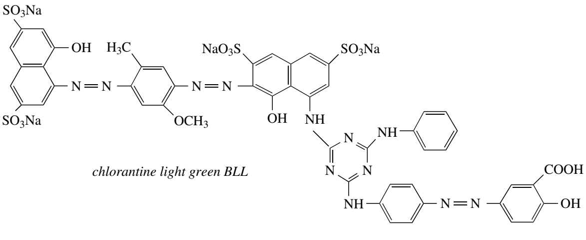
Sirius red F 3 B

- C.I. 34 140 (W. A. Israel, R. Kothe, 1900; H. Jordan, 1913); 3-amino-1,5-naphthalene-disulphonic acid, 1-naphthylamine, 1,7-Cleve’s acid and J-acid.



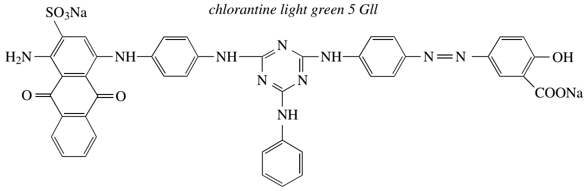
sirius light blue BRR

- C.I. 34 045 (H. Fritzsche, E. Krummenacher, H. Gubler, O. Kaiser, 1923); successive condensation of cyanuric chloride with a) H-acid, b) the azo dye obtained from reduced p-nitroaniline and salicylic acid, c) aniline. The product is then used as a coupling component in H-acid and cresidine.



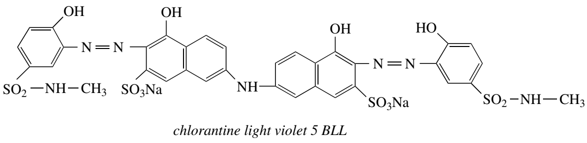
chlorantine light green BLL

- C.I. 14 155 (H. Gubler, E. Bernasconi, 1934); successive condensation of cyanuric chloride with 1 mol. each of 2-amino-5-(4-amino-3-sulpho-1-anthraquinonylamino) benzenesulphonic acid, the monoazo dye 5-(p-aminophenylazo) salicylic acid (C.I. 14 045), and aniline.



chlorantine light green 5 Gll

- C.I. 29 125 (H. Krzikalla, 1926; W. Hentrich, M. Hartmann, J. Hilger, 1926); 2 mol. of 2-amino-N-methyl-1-phenol-4-sulphonamide with 6,6´-iminobis-1-naphthol-3-sulphonic acid and convert to the bis copper complex by treatment with ammoniacal copper sulphate.



chlorantine light violet 5 BLL

Azoic bases Coupling products for development into naphthol dyes. Azoic bases are not dyes themselves but soluble intermediate products with a basic character due to the presence of amino groups (NH_2) which are diazotized before use when they become capable of coupling in a similar manner to → Azoic salts with a naphthol component to form insoluble azo dyes.

Azoic salts These are already diazotized water-soluble coupling components (so-called stabilized diazo compounds) of the corresponding → Azoic bases, used for development into naphthol dyes.

B

B, chemical symbol for boron (5).

Ba, chemical symbol for → Barium (56).

Bacilli, rod-shaped sub-group of bacteria which form → Spores. The terms bacilli and bacteria are often mistakenly confused.

Backbeating An operation which involves beating or vibrating the back side of piece-dyed carpets as they leave a drying machine. Backbeating improves the appearance of acrylic pile carpets, in particular.

Backcoating of carpets (carpet backcoating). In the case of tufted carpets, backcoating is an essential element of their construction. As a result of this process the tufted pile is firmly bonded to the base fabric on the one hand, whilst noise reduction and thermal insulation properties are achieved on the other. The durability of carpets in use is likewise influenced to a significant degree by the type and quality of the backcoating applied. In the classification of carpets, e.g. ability to withstand the effects of castor chairs, the chalking of a pre-coat can cause changes in the appearance of the carpet design itself. If the pile is not anchored satisfactorily, pile shedding and tuft fuzzing occur due to loose threads being pulled out and torn. Fine gauges, fine yarn counts and smooth yarns require just as much attention in the application of a pre-coat as coarse gauges with coarse yarns. In both cases, penetration of the yarn and secure anchoring of the fibres (filaments) is of decisive importance.

In the case of aqueous latices (SBR products) the backcoating is composed either of a pre-coat and foam backing, or a pre-coat and laminated secondary backing. Secondary backings appear to have gained importance because of the ease of laying and carpets with secondary backings offer advantages in many cases with regard to the increased use of underfloor heating.

1. Hot melts: these can be compared with heavy coatings. They consist of thermoplastic compounds with a high filler content which can be applied at high speeds and require no pre-coat since bonding of the pile is outstanding in the thermoplastic state.

a) Ethylene vinyl acetate (EVA): These compounds can be loaded with large amounts of inorganic fillers and therefore fulfil the requirements for backcoatings with good sound insulating properties. A variation of this type of coating is the combination of EVA with polyethylene.

b) Atactic polypropylene (APP): In use since the 1960's principally for the coating of carpet tiles with the object of achieving "self-laying" properties.

c) Polyethylene (PE): These compounds must be regarded as a specialized further development of "hot melts" since (like polyvinyl chloride) high temperatures must not be used in their application. Polyethylene in the crosslinked form can be foamed which, with foam weights of 800 g/m^2 combines, light weight, elasticity and sound absorption.

2. Polyurethane (PUR): These coatings are formed directly on the carpet back from polyhydric alcohols and isocyanates. Typical of all these systems is the low weight per square metre, good flexing resistance of the resultant foam, good edge adhesion and ease of re-use after re-laying.Three systems are offered from different suppliers with the collaboration of certain machine makers.

a) Transfer process: With this oldest technique the polyurethane foam is produced on an intermediate carrier from which it is transferred to the carpet back.

b) Spray coating: This technique uses two traversing nozzles without a knife. Following application, the carpet passes through an infrared zone into a conventional hot air oven.

c) Knife coating: This process can be carried out on conventional plants since the reaction mixture of polyhydric alcohol and isocyanate is foamed mechanically and application is carried out by the usual knife coating process. Fillers can only be applied by this technique and are mixed with the polyhydricalcohols before reaction.

3. Aqueous polymer dispersions: The oldest and by far the most widespread process involves the application of latices, i.e. aqueous dispersions of rubber or synthetic polymers. Natural latices are no longer of much practical significance. Among the synthetic products, SBR latices are used almost exclusively. Cold latices are polymerized at approx. 5°C whilst the carboxylated hot latices are polymerized at approx. 50°C.

Back finishing

a) Pre-coat: With all SBR latices a pre-coat (Fig.) is necessary to lock the tufts into position.The pre-coat is generally applied by means of a kiss-roll and doctor blade; drying is mainly carried out in an infrared zone.

b) Foam coat: The actual foam coat is applied from a trough in which it subjects the foam to a traversing vibration. The latex compound is foamed in a latex mixer, i.e. latex and air are mixed and subjected to a mechanical shear action under pressure. The desired stiffness, flexibility and handle are achieved by mixing a soft and a hard base latex together. The characteristics of the base latice are adjusted by means of the styrene content.

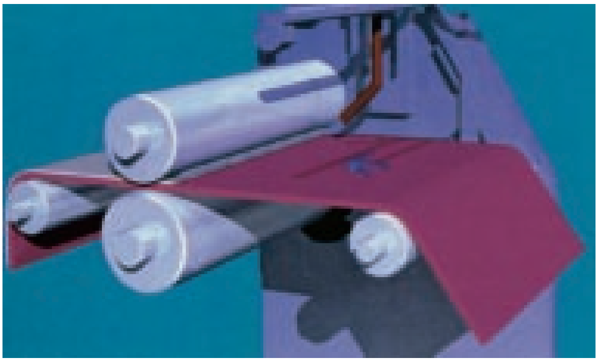


Fig.: Precoat Applicator "Press-Nip" (Küsters) for tufted carpet back coating with foam.

The mixer unit, consisting of a stator-rotor system, produces foam by mixing the latex with a fine and uniformly distributed quantity of air. In order to maintain this structure until it is transformed into the solid state, however, the cell walls of the foam must be stabilized. For gel foams two systems are in use: a heat-sensitive gelation process with a zinc oxide/ammonium salt (ammonium chloride and ammonium acetate) combination as well as a chemically-sensitive gelation process using compounds of fluorine with silicon, tin or titanium. The most well-known are sodium silicofluoride foams. No-gel foams already contain the soaps which are necessary for stabilization during drying from the polymerization stage. Crosslinking occurs either with reactant resins or vulcanizing agents. No-gel foams permit the incorporation of higher quantities of fillers than gel foams. The presence of excess soap represents a risk factor insofar as it can migrate out of the foam on subsequent wetting of the carpet underside.

Foams containing flame-retardants may be produced by the incorporation of halogen compounds or, more simply, by substituting part of the filler content with aluminium hydroxide.

Latex is even applied to woven carpets to provide secure anchoring of the pile. To achieve a firm handle, mixtures with a higher styrene content are used which contain reduced amounts of filler or none at all in order to ensure non-slip properties.

Back finishing The application of finishes to the back side of textiles for material-specific reasons, e.g. preferentially applied to poor quality ribbons and tapes. Also given to velveteen cord and plush fabrics as a so-called tailoring finish (to improve cutting) and in the coating of textiles as back finishes for pile fabrics and carpets.

Back grey This term covers a variety of special cloths used in textile finishing operations as leader cloths, end cloths, back greys and intermediate greys to facilitate the processing of fabrics in jig-dyeing machines, steamers, decatizing machines, roller printing machines, and in screen printing for combining with fabrics (temporary lamination) which would otherwise be difficult to print satisfactorily.

I. Back grey for flat/rotary screen printing machine dryers: woven polyester lattice fabric with good air permeability and therefore rapid printed fabric drying, with practical socket locks for ease of installation/ changing.

1. Model PE 1000 HD: data: woven polyester lattice fabric, mesh 1.0 mm. Wire gauge number 0.5 mm, open area 45%. Heat resistant 160–180°C. Tried and tested standard model for all types of woven fabric, and also for fairly inefficient dryers.
2. Model PE Mono-Multi: data: woven polyester lattice fabric. Wire gauge numbers: warp 0.5 mm, weft special yarn, open area approx. 30%. Heat resistant as in 1. Recommended for lightweight, thin and heavily printed fabrics, especially for synthetics.

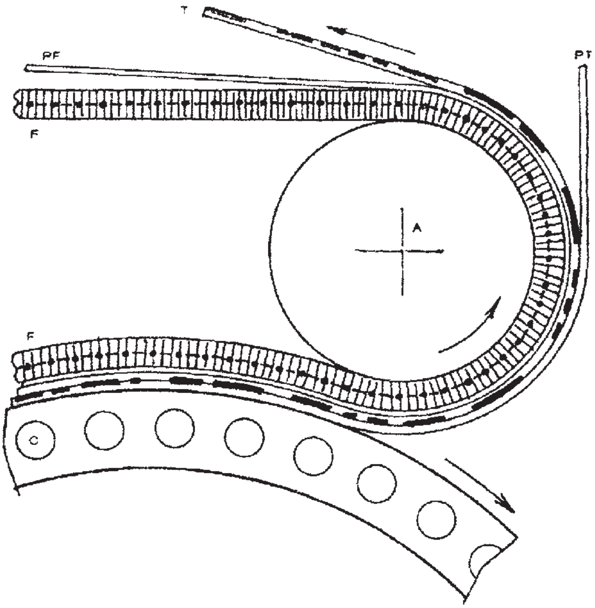

Fig.: Back cloth in a calender.
T = textile fabric; PF = transfer paper; C = heated cylinder; A = roller; PT = protective paper; F = back grey.

3. Model PE Soft: data: woven polyester monofil lattice fabric. Wire gauge numbers as in 2, open area approx. 20%. Specially recommended for lightweight, thin and heavily printed fabrics, particularly for hydrophobic synthetics e.g. discharge prints.

II. Back grey felt in transfer calenders (see Fig.). Functions:

a) Pressing textile fabric (T) and transfer paper (PF) together against the heated cylinder (C) to provide good heat transfer and dye transfer.
b) Conveying textile fabric, transfer and protective paper. Ensuring control in the longitudinal and transverse directions. Keeping flat.
c) Thermal insulation of textile fabric and transfer paper for uniform distribution of heat supply on to the fabric.
d) Roller drive.

Back grey accumulator A system developed for large quantities of back greys in roller printing. Mainly constructed in the form of a channel accumulator on the J-box principle with capacities of 800–5000 m.

Back grey printing In roller printing, a gummed woven fabric which runs constantly tensioned over the printing blanket and lapping covered drum, and is used to support the printing blanket and the fabric to be printed. For gumming piecegoods on screen printing machines.

Back grey washer A unit for the continuous washing of back greys normally located behind or beneath a roller printing machine. An essential prerequisite is the use of back greys composed of fibres that absorb hardly any capillary water and are easily cleaned and (most important) quickly dried; synthetic fibres in blends with cotton are chiefly used for this purpose. The washer is equipped with squeeze rolls and spray nozzles to ensure an intensive washing of the back grey. Drying is carried out either in special compartments or in the print drier itself. A typical unit of this type is the Küsters system. After the printing process, the back grey, which is composed of polyamide/cotton 50:50 (as an intimate blend produced in spinning), first passes through a prewetting zone and subsequently through a “Vibrotex” unit where it is led over a perforated vibrating cylinder and thoroughly washed. The backgrey then passes immediately to a squeezer unit with swimming rollers where it is hydroextracted as it cannot be returned to the printing machine in the wet state.

Back grey washing Depending on the number of passages, coverage of print design and thickness of the textile fabric being printed, used back greys contain greater or lesser amounts of print paste residues containing thickeners, dyes and chemicals. The purpose of back grey washing, therefore, is to remove these print paste residues and make the material soft, absorbent and fit for reuse again.

Back grey washing machines As a rule, winches and heavy-duty rope washing machines are used for washing used back greys. Open-width washing machines are less suitable because of their less intensive mechanical washing action.

Backing → Carpet backcoating.

Back-pressure steam turbine The “classic” method of power-heat coupling, which was also used in many textile mills in the past, illustrates the use of back-pressure steam turbines (see Fig.): a high pressure steam boiler produces superheated steam at 60 bar and, for example, a temperature of 480°C. This steam drives a steam turbine, the exhaust steam connecting stub of which is connected to the plant steam line. In contrast to the → Gas turbine, with which a power parameter of approx. 0.35–0.40 (kWh of power/kg of steam) is produced, a steam turbine process is able to produce a power parameter of only approx. 0.15–0.20. This is one of the reasons for the decline of industrial steam turbine operated, combined heating and power stations which has been observed over the past 20 years.

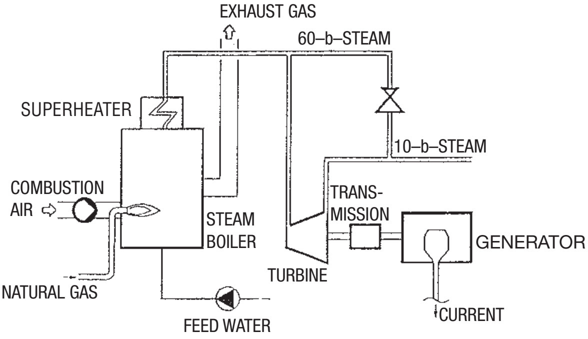

Fig.: Heat-power coupling by means of a back-pressure steam turbine.

Back side (of fabric), i.e. the reverse side of textile fabrics which can also be used as the wearing side.

Back to back Finishing operation for the surface treatment of textile fabrics on a → Table raising/polishing/shearing machine in which both sides of a fabric may be processed in a single passage without a turning arrangement.

Backwash (fleece wash). Commercial term for wool washed on the backs of living sheep with cold water. The treatment is technically worthwhile as the wool stays white longer on storage and its colour is attractive to cloth producers and worsted spinners. The backwash removes the coarsest dirt and impurities thus reducing freight costs. In all cases, however, a subsequent mill wash is necessary to remove wool grease, suint, etc. → Raw wool scouring.

BA cotton Flame-retardant cotton produced by fibre modification with → BAP (American process).

BACPO, abbrev. for: → bis-aziridinyl-chlormethyl-phosphineoxide.

Bacteria, are the smallest unicellular → Microorganisms, and are only visible under the microscope with powerful magnification. They multiply rapidly by simple fission (at an average rate of one division per hour, 16 million bacteria can develop from one bacterium in a day). Types of bacteria include:

I. Spherical bacteria or coccus. These are spherical to oval in shape and 1–2 µm in size.

II. Rodlike bacteria, including spore-forming → Bacilli, with a size of 0,5–2,5 : 1,5–15 µm.

III. Helical bacteria: a) vibrios, curved types. Size 0,3–0,5 : 2–4 µm; b) spiral, with corkscrew-like coils. Size 1–3 : 5–30 µm.

Even these tiny living organisms have their own metabolism. They secrete enzymes with the specific action of breaking down suitable insoluble matter into nutrients (→: Microbial damage to textiles; Microbiological degradation) as in the case of e.g. proteins with the aid of proteases. The products of bacterial metabolism can destroy textiles and, as a source of infection, are extremely toxic as soon as they enters the body's bloodstream. Infections are caused in this way (diseases gain access to the affected body through → Pathogenic bacteria). Certain bacteria can survive adverse conditions by forming highly-resistant spores. Bacteria may be detected microscopically under high magnification of, e.g. x250 up to x600. Their detection is also made easier by special stains.

Bacteria destruction →: Antibacterial finishes; Antimicrobial finishes.

Bacterial damage to textiles → Microbial damage to textiles.

Bacterial desizing agents → Bacterial diastases.

Bacterial diastases The effective → Enzyme (amylases and polyases) is obtained by cultivation of subtilis and mesentericus types (→ Diastases). Bacterial diastases break starches down into glucose with the assistance of sodium chloride as an activator. Compared to → Pancreas diastases the much lower temperature sensitivity of bacterial diastases enables desizing to be carried out at temperatures close to the boil. → Desizing agents.

Bacterial growth inhibition →: Bactericidal finishes; Phenol coefficient.

Bacterial inhibition → Bacteriostatic action.

Bacteria staining → Gram's stain.

Bactericidal finishes, provide textiles with active protection by the destruction of bacteria and → Mycotoxins (→ Antimicrobial finishes). This can be achieved either by the application of copper naphthenate, copper-8-quinolinolate, chlorinated phenols, trialkyl tin derivatives, *inter alia* (→ Fungicidal finishing), or by passive protection, i.e. by preventing the textile material from functioning as a culture medium for microorganisms, which is mainly achieved by the application of aminoplasts (resin finishes). Flame-retardant finishes based on phosphorus compounds also increase rot resistance. The possibilities for applying such finishes to apparel fabrics are extremely limited.

Bactericide A product capable of destroying bacteria, e.g. disinfectants or preservatives.

Bacteriostat A product with bacteriostatic properties.

Bacteriostatic Adjective used to describe products or properties which prevent or inhibit the growth of → Bacteria, e.g. through the use of → Preservatives, etc.

Bacteriostatic finishes (→ Antimicrobial finishes) inhibit the growth of bacteria as well as → Mycotoxins on textiles (→ Fungicidal finishing).

Bagginess A fabric defect especially in viscose and wool fabrics caused by excessive tension in winding, distorted weft threads, etc. which gives rise to tight threads in the weft direction and waviness in the fabric. The effect is further intensified by the influence of moisture.

Bagging,

I. A fabric woven in cylindrical or tubular form on an ordinary cam loom and used for grain bags, etc.

II. A term used to describe the undesirable bulging of fabric caused by extension at the elbows, knees, etc., of a garment lacking dimensional stability.

Bakelite → Phenolic plastics.

Bakelite thickener → Thickeners.

Bakhtiari carpets Strong rustic knotted carpets from the Chahar Mahal region to the south of Isfahan. Bakhtiari carpets are easily identifiable because of their special designs. The field on the carpet is almost always divided into squares or diamonds made to stand out by a plain outline. These geometric figures are decorated either with animal or plant motifs, particularly cypresses and flowering shrubs. Each carpet may contain more than ten different designs. All Bakhtiari carpets are in dark colours, deep red, yellow ochre, bottle green, dark brown and bright blue, with red or natural white grounds. 50 000–200 000 Turkish knots per m^2. The finest qualities of Bakhtiari carpets are also known as → Bibibaff.

Baku carpets Caucasian short-pile, thin, hand-knotted carpets from the region around Baku. They have a marked geometric decoration. Generally the field decoration is of three or four motifs in the shape of diamonds or rectangles and diamonds one above the other which alternate with hooked Greek-key motifs filled in light red or ochre yellow on a light blue ground. The unusually pale colours are characteristic of Caucasian carpets. Also used as prayer mats. Baku carpets contain approx. 100 000 Turkish knots per m^2.

Balanced cloth A term used to describe a woven fabric with yarns of the same linear density and the same number of threads per cm in both the warp and weft.

Bale dyeing This involves taking the fibre in the form of the original bale from the supplier of raw wool, cotton or fibre manufacturer in the case of synthetic fibres. These bales are placed directly in a specially constructed cage designed to hold up to 4 bales (see Fig.). The cage is placed into a conventional dye kier (either vertical or horizontal) and dyeing carried out as usual. After dyeing, the bales are either hydro-extracted or vacuum-extracted to remove excess moisture before drying. The system is ideal for a new installation which processes a limited product range from a minimum of suppliers. The advantages are almost all economic since the stages of bale opening, dye kier loading, and final packing are eliminated, with obvious cost savings.

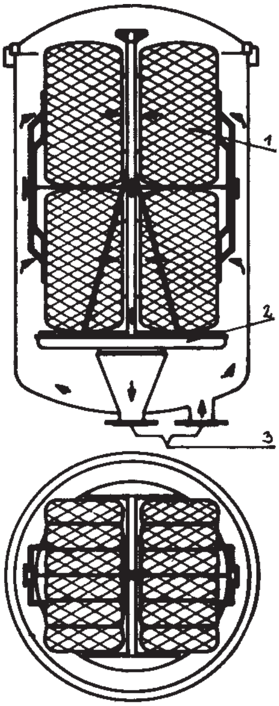

Fig.: Obermaier bale dyeing autoclave (4-bale carrier design).
1 = fibre bale; 2 = special carrier; 3 = circulation pump.

Bale weights → Fabric weight.

Ballard skin Thin layer of electroplated copper on a steel roller for rotogravure printing.

Ball mill A standard method of reducing water-insoluble substances such as pigments or dyestuffs to a fine state of division. It consists of a cylinder, rotating on an axis, partly filled with steel balls, porcelain balls, or common pebbles. The controlling factors are size of balls, relative volumes occupied by balls and substance being milled, type and quality of substance, and rate and time of rotation.

Ball reflectometer (Ulbricht's ball) An accessory unit used in rigid assembly with a photometer, the important component of which is a ball with a matt white inner surface which guarantees all-round, uniform and shade-free light on the test specimen to be examined.

Ball valves The ball valve is a quarter turn valve suitable for gas, compressed air, liquid and slurry service and provides complete sealing in both directions. The use of soft-seat materials such as nylon, delrin, synthetic rubbers, and fluorinated polymers imparts excellent sealing ability. With fluorinated polymer seats, ball valves can be used for service temperatures ranging from –268 to +260°C; with graphite seats, service temperatures as high as 540°C are possible. Also, with metal-backing seats, the valves can be used in fire-safe services. Ball valves are similar to plug valves in operation. They are nonbinding and provide leak-tight closure. The valves exhibit negligible resistance to flow because of their smooth body and port. Major components of the ball valve are the body, spherical plug, and seats. Ball valves are made in three general patterns: venturi port, full port, and reduced port. The full port valve has an inside diameter equal to the inside diameter of the pipe. In the venturi and reduced port variants, the port is generally one pipe smaller than the line size. Stem sealing is accomplished by bolted packing glands and O-ring seals. Valves are also available with a lubricant-seal system which is similar to that available for plug valves.

Ball (yarn) → Yarn package.

BAM (Ger.), abbrev. for: Bundesanstalt für Materialprüfung (German Federal Institute for Materials Testing).

Banana fibre → Manila fibre.

Bandhana (Hindhi: *bandh* = tying). A form of tied batik analogous to the Malaysian → Plangi and the Japanese → Shibori.

Band recorder (strip chart). A recording instrument which produces a graph in strip form.

Band spectrum → Emission.

Bányai system A carpet machine-knotting technique from Hungary.

BAP, American abbrev. for: bromoform allylphosphate (→ BA cotton). The BAP method involves application of an aqueous emulsion of a polymer produced from tribromomethane $CHBr_3$ and triallyl phosphate $(CH_2{=}CH{-}CH_2O)_3PO_4$, which forms crosslinked polymers on cotton with a flame-retardant action.

bar A CGS unit of pressure equal to 10^5 pascal (Pa). It may be used with → SI units, and SI prefixes may be attached to it. Since it describes decimal multiples of the pascal it is convenient in practical use. The millibar (symbol: mbar or mb) is a commonly used unit of pressure in meteorology.

Bare elastane Elastane yarn in the so-called bare state, in contrast to the wrapped form → Core spun yarns.

Barium (Ba), atomic weight 137,4. Silver-white lustrous soft metal. Barium compounds (many of which are very poisonous) are similar to those of calcium. Properties: → Alkaline earth metal. Uses of barium salts: weighting finishes, components in white discharge print pastes (barium sulphate), delustring (barium chloride), analytical reagents, etc.

Barium chloride, $BaCl_2 \cdot 2H_2O$, MW 244,34. Colourless crystals with a bitter salty revolting taste, stable to air, water-soluble (446 g/l at 20°C; 769 g/l at 100°C). With sulphuric acid it gives → Barium sulphate. Uses: as a delustring agent for viscose (two-bath method); weighting and filling agent in finishing (seldom used); reagent for the detection of sulphuric acid and sulphates (= white insoluble precipitate); softening of boiler feed water (calcium sulphate hardness).

Barium in dyeings, tests for Ash the textile specimen and moisten with conc. hydrochloric acid.

I. Green coloration in a flame indicates the presence of barium. Barium sulphate must be reduced to the sulphide in a small flame before moistening with hydrochloric acid.

II. Precipitation as sulphate. Mix the hydrochloric acid moistened ash with dil. sulphuric acid or sodium sulphate = white precipitate in the presence of barium. If insoluble barium sulphate is present in the hydrochloric acid, it must first be decomposed by fusing with 5 times its weight of sodium carbonate and potassium carbonate, followed by washing and dissolving in acetic or hydrochloric acid.

Barium sulphate (barytes, blanc fixe, heavy spar), $BaSO_4$, MW 233,46, density 4,5.

Bark crêpe (tree bark crêpe). Mostly atlas construction clothing crêpe with a woven matt face in a bark-like pattern (produced by embossed printing or construction) made of viscose, acetate, cotton etc.

Bark tannage → Tanning.

Bar marking in screen printing (screen fall-on effect) A problem encountered in printing on flat-bed screen printing machines, whereby the sides of the screen frames at right angles to the direction of printing exert pressure on the preceding print thereby crushing or soiling the printed colours. The problem can be minimised by using screen frames with a triangular profile (i.e. to reduce the area of contact with the printed fabric) and/or by covering the undersides of the screen frames with coarse grains (e.g. wood chippings of approx. 1 mm size) to break up and minimise contact with the fabric during printing.

Barometer (barograph). An instrument for measuring atmospheric pressure, usually in the region of 101 330 Pa (1,0133 bar = normal atmospheric pressure).

I. Mercury barometer: consists of a curved U-shaped tube with a long and a short leg (→ Manometer). The shorter leg of the tube is closed and the lower open end is immersed in a reservoir of mercury. The tube contains no air and the space above the mercury column is known as a *Torricellian vacuum*. The mercury level in the tube indicates the actual barometric pressure in mm. A finely graduated scale also permits readings to 0,1 mm and estimated readings to the nearest 0,01 mm are possible.

II. Aneroid barometer: a device for measuring atmospheric pressure without the use of liquids. It consists of a partially evacuated metal chamber, the thin corrugated lid of which is displaced by variations in the external air pressure. This displacement is magnified by levers and made to operate a pointer against a calibrated scale from 790–670 mm. It is the most common form of barometer. The barograph, a self-recording instrument with a pen which traces a line on a clockwork-driven revolving drum (1, 7, 14, 28 days), works on the same principle.

For more precise barometric measurements the temperature must also be taken into account. Since all chemical constants relating to boiling point, solubility, etc. are always based on a normal pressure of 760 mm, the actual barometric pressure prevailing at the time such laboratory determinations are carried out can have a significant effect on the results.

Barr Textile diffusion resistance to water vapour relative to atmospheric air (1 cm thick calm air layer at 20°C = 1.00 barr). Examples:

air (atm.: 0°C)	1.05
air (atm.: 20°C)	1.00
air (atm.: 40°C)	0.95
nonwoven fabric (20 g/m^2)	2.20
nonwoven fabric (40 g/m^2)	4.20
lightweight suiting fabric	8.50
standard suiting fabric	16.40
sweaters	20.50
blanket material	22.50
overcoat material	40.00
windcheaters	approx. 100.00

The barr value is expressed here in multiples of the barrier capacity of a 1 cm thick layer of calm air.

Barré A term used for

I. Widthwise stripes in textile fabrics, produced by weaving, effect yarns or colours.

II. Irregular stripe defects (so-called bars) in the woven or dyed appearance of fabrics.

Barré effects often occur in warp-knit fabrics produced from textured polyester filament yarns dyed with disperse dyes. This phenomenon is attributed to structural differences in the polyester filaments as a result of texturing.

Barrel pumps → Drum pumps.

Barrel-shaped yarn package A precision wound barrel-shaped package for short lengths of yarn.

Barrier effect of wool fibre epicuticle Prevention of dye from penetrating the fibre interior from a dye liquor at room temperature due to the → Epicuticle layer. Dye can only penetrate through the epicuticle from a heated dye liquor. Chlorination treatment removes the epicuticle which is why deeper dyeings are obtained on chlorinated wool.

Barriness (barry dyeing), longitudinally or transversely striped dyeing of woven or knitted polyamide, polyester and viscose fabrics. Causes:

I. Processing faults such as mixed up yarn and tension and density differences in weaving or warp and weft knitting.

II. Yarn faults: differences in count, yarn twist, lustre and deformational differences.

III. Differences in drawing, crystalline structure and orientation due to varying inner fibre fine structure during production. In texturing and setting: effect of temperature (in the case of polyamide and polyester), moisture (polyamide) on the inner fine structure (microporosity, inner surface).

IV. Chemical differences with polyamide and viscose.

V. Fibre change due to the action of light and chemicals.

Remedy in dyeing: in the case of III and IV only (differences in affinity) possible by means of targeted dye selection, special dyeing auxiliary products (e.g. carriers), dyeing process, intensive relaxation, possibly pre-set at higher temperature.

The phenomenon of "barriness" can be looked at from two basically different directions:

1. Barriness which is attributable to conformational and physical defects.
2. Barriness which is caused by differences in the behaviour of the dyes in their interaction with the active groups in the fibres.

The barriness which is attributable to configurational and physical defects occurs as the result of differences in fibre fineness, lustre, cross-section, thick places in fibre production and also depending on the nature of fabric crossing and other mechanical effects in mechanical processing (spinning, knitting and weaving) and finishing (pretreatment and dyeing). The interaction between the different characteristics which cause barriness is difficult to analyse, since the specific effects of the individual fibre properties of the yarn are difficult to isolate. Each change in the conditions of the production process can cause a simultaneous change in some characteristics; a change in the molecular mass of the polymer, for example, usually produces a change in dyeing power, shrinking power and other physical and mechanical parameters. In addition, there is a level at which barriness is not yet quite clearly pronounced, which makes difficult the possibility of linking the intensity of barriness with the fibre properties.

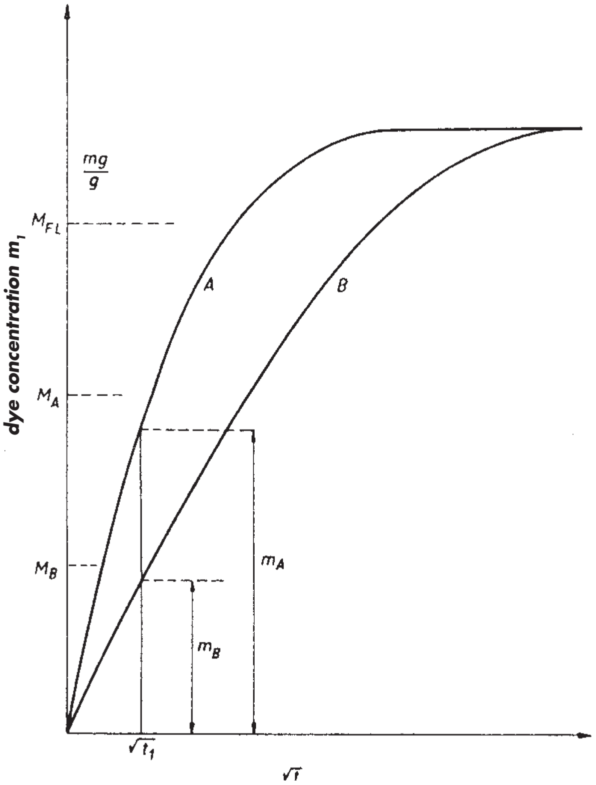

Fig.: Principle of the "single-point measurement" of colour exhaustion rate: dye concentration m_t of the fibre against $\sqrt{t}$ (t = dyeing time). The exhaustion curves of fibres A and B differ in rate of exhaustion, but reach the same saturation value. The measurement values m_A and m_B are approximately proportional to the rates of exhaustion, so that here $m_A > m_B$. M_A and M_B = dye quantities which are taken from fibres A and B in joint dyeing in one dyebath of the total dye quantity M_{Fl} ($M_A + M_B = M_{Fl}$).

Many theoretical studies have been devoted to the problem of barriness which relate mainly to the barriness which is caused by differences in the behaviour of dyestuffs in their interaction with the active groups in the fibre materials. Important in this connection are:

– end-group content,
– degree of order or crystallinity,
– degree of orientation.

With polyamide fibres, the content of end-aminogroups for example is an important parameter, on which the dyeing rate with anionic dyes depends. This parameter is stringently controlled by fibre producers. For determining the end-aminogroup content, there are methods which are suitable for routine laboratory checks, by means of which the aminogroup content is determined. The second parameter, degree of order or crystallinity, embraces the structure and morphology of the fibres which was created in their previous production history, and exerts the one basic effect on barriness and general levelness in dyeing. The effect of the degree of orientation is measured by birefringence (Δn). Each variation in degree of orientation leads to differences in the speed of the dyeing process during its time cycle. The cause of the occurrence of barriness is best represented by the graph: in dyeing two polyamide fibre materials of different structures, the quantity of dye fixated on both substrates prior to reaching the condition of equilibrium is different. When these kinds of fibre material are in one batch, this is characterised by markedly pronounced barriness. The surface layer has a direct relationship with barriness, since it is markedly sensitive to all energetic and thermal effects on the fibre which have been exerted during their previous production and processing history. The surface layer of the fibres plays the role of a surface barrier for the dyestuffs.

Barytes → Barium sulphate.

Basal layer In fibre structure the basal layer is a well ordered active cell layer zone, e.g. in → Wool structure it is the intermediate membrane which acts as the basal layer of the internal scale cell layer. The epidermis in wool fibre structure is formed by the constant growing and dividing of a very active layer of cells called the "basal layer". There is continuous wear on the outermost layer of the epidermis and this is replaced by cells derived from the basal layer. The basal layer is also important bacause it plays a large part in the formation of the wool follicle. At certain positions in the skin the basal layer thickens and begins to grow down into the dermis to form a sort of plug of cell tissue. This plug will ultimately form the wool follicle with its accessory structures.

Basalt fibre A mineral fibre produced from molten basalt at approx. 1100–1400°C. Cheap, very fine, highly ductile, long fibres which are thermostable up to 1100°C. Uses: insulating material against heat, cold and sound; spun and woven for fire-resistant clothing.

Base exchanger → Ion exchanger.

Base material (carpet) → Carpet primary backing.

Base metals In the electrochemical displacement series (→ Standard electrode potential) metals which are higher in the series than hydrogen and metals with negative prefixes.

Base printing → Naphthols in direct printing.

Bases Chemical compounds which dissociate in aqueous solution into negatively-charged hydroxyl ions and positively-charged weak acid or metal anions. They form salts with acids = neutralization. Bases have an alkaline reaction (pH > 7) and turn red litmus paper blue. They have a mainly bitter taste. The number of ionizable OH groups determines whether a base is mono, di or polyvalent etc. Inorganic bases are OH compounds of metals (e.g. sodium hydroxide solution $NaOH = Na^+ + OH^-$, strong base over 50% dissociated; ammonium hydroxide NH_4OH, weak base) which, on losing water, change into the corresponding oxides. Organic bases include e.g. amines (aniline $C_6H_5NH_2$), dye bases and numerous other water-soluble nitrogen (e.g. pyridine C_5H_5N), phosphonium and sulphonium bases. See also → Acids.

Base units The 7 base units as defined in the → SI system (i.e. metre, kilogram, second, ampere, kelvin, mole and candela) for the basic measures (length, mass, time, electric current, thermodynamic temperature, amount of substance and luminous intensity) including their abbrev. forms (m, kg, s, A, K, mol and cd).

BASF, (Ger.), abbrev. for: Badische Anilin und Sodafabrik.

BASF Combi Test Standard method for determining the diffusion properties (diffusion number) of → Disperse dyes under practice-relevant conditions.

Basic alum → Aluminium potassium sulphate.

Basic dyeable polyamide → Differential-dyeing polyamide fibres.

Basic dyes → Cationic dyes.

Basic iron sulphate → Iron (III) sulphate.

Basicity A property of → Bases and basic salts whereby hydroxyl ions of a basic character are formed by dissociation in aqueous solution. See also → Acidity. → Dissociation.

Basicity value The basicity value plays an important role in the weighting of silk, e.g. with basic iron (III) sulphate. The basicity value is obtained by dividing the sulphuric acid content (calculated as H_2SO_4) by the iron content (calculated as metallic iron) = (H_2SO_4 : Fe).

Basics A term used to describe classic jeans fabrics as well as standard jeans qualities which appear regularly each season, in contrast to newly developed styles ("designer jeans"). They include e.g. flats, chambray, blue denim, canvas, toile, cord velvet, scrubbed denim, brushed denim, suedette, duvetine.

Basic salts → Salts.

Basic time According to REFA, all times for fabric processing which occur regularly or frequently, and are determinable in each case by timing or calculation. Subdivided into productive time/non-productive time, processing time/interval, activity time/attendance time.

Basify To adjust the pH of a liquor on the alkaline side, e.g. in naphthol dyeing with fast colour bases or salts to facilitate coupling.

Basinés (basin waste). Silk waste consisting of → Cocoons which have only been partially reeled off due to frequent breaks in the thread.

Basin test Modified → Permeability bag test in which a fabric test specimen is formed into a suitably supported bag and filled with water.

Basolan DC process Wool chlorination under mildly acidic conditions with the sodium salt of dichloroisocyanuric acid, Basolan DC (BASF)) at pH4.

Basolan SW process Superwash finish for wool with the prepolymer Basolan SW (BASF). Crosslinks on drying to form a soft film on the fibre. Application by padding or exhaust methods.

The IWS Superwash Standard was first achieved without any prechlorination, such a treatment is necessary, however, by the exhaust process, e.g. by using a chloroisocyanurate such as → Basolan DC. The Basolan SW process may also be applied to advantage after dyeing. → Anti-felting finishes.

Bassine (Borassus piassava) → Palm fibre.

Bassora gum A tropical → Vegetable gum with a high content of → Bassorin, which has often been used for the adulteration of gum arabic and gum tragacanth. Bassora gum generally occurs in the form of transparent, light amber to brownish-red irregularly-shaped lumps and is only sparingly soluble in water (with a large excess of water it forms a filterable cloudy solution) but swells readily to a thick gelatinous slime.

Bassorin The main → Polysaccharide $(C_{11}H_{20}O_{10})_n$ component of → Bassora gum from which it gets its name. It is also present *inter alia* in gum tragacanth in proportions of up to 60–70%. Bassorin is a tasteless, odourless, yellowish-white, amorphous, brittle, and translucent solid. It is only sparingly soluble in water but swells to a translucent gelatinous paste which dissolves on prolonged boiling.

Bast,

I. Another name for → Phloem.

II. Fibrous material obtained from the phloem of jute, hemp, flax, lime, etc. → Raffia bast.

Bastard vat Combination of the →: Woad vat and sodium carbonate (the first as vat preparation and the second for continuation of the dyeing process). Formerly used for the dyeing of wool with indigo.

Bastella A cellophane product into which narrow cotton threads have been incorporated thereby producing a reed-like appearance. Uses: hat trimmings (braiding) etc.

Bast fibre bundless → Flax stem structure.

Bast fibre cells →: Flax long fibre structure; Flax cell structure.

Bast fibres A sub-group of → Natural cellulosic fibres that form bundles or strands which act as hawsers in the fibrous layer lying beneath the bark of numerous dicotyledenous plants. Principle of construction → Flax stem structure. The strands of bast fibres are normally released from the cellular and woody tissue of the stem either mechanically (green bast fibres) or biologically by a process of natural decomposition called retting (controlled rotting), or by chemical means (→ Cottonizing). The strands are often used commercially without separating the individual fibres one from another.

On a tonnage basis → Jute is the most important of all bast fibres: It is produced in quantities greater than that of all other bast fibres combined. The production of → Flax is roughly one seventh that of jute, but flax is the fibre from which → Linen is made. It is on this basis that flax is considered to be the most important of the bast textile fibres. Bast fibres include →: Flax (linen), Hemp, Jute, Sunn, Kenaf, Urena, Rosella and Ramie.

Bast fibres, differentiation tests,

I. Phloroglucinol/hydrochloric acid reaction: a staining test based on the principle that the higher the degree of lignification, the higher the lignin content, and the deeper the stain: flax and ramie = no staining, hemp gives an irregular pink stain, and jute gives a deep red-violet stain.

II. Aniline sulphate: the fibres are immersed in a 1% solution of aniline sulphate. Depending on degree of lignification, the fibres are stained yellow to yellowish-brown, i.e. no staining with flax and ramie, hemp gives an irregular pale yellow stain and jute gives a deep yellow-brown colour.

III. Cuprammonium hydroxide solution: observation of swelling under the microscope. Flax swells rapidly revealing a fine wavy internal protoplasm thread. Hemp swells rapidly without internal protoplasm thread, often with an accordion pleated cell wall. Ramie has very long individual fibres (60–260 mm).

Bast fibre tow. Flax and hemp waste, etc. Short fibres which arise in the → Hackling process.

Bast layer →: Flax stem structure; Flax long fibre structure.

Bast soap (degumming soap) A term used for the soap used in the → Degumming of natural silk which contains variable proportions of silk gum (sericin) removed from the silk fibres and which is a useful protein material. Bast soap is widely used for dyeing natural silk in “broken bast soap baths”. Bast soap is “broken” by the addition of acid thereby greatly reducing foam formation. Used as a dyeing auxiliary with levelling properties. Even at boiling temperatures, the presence of acids does not cause the complete decomposition of bast soap.

Bast soap substitutes Various products and mixtures, e.g. synthetic →: Fatty alcohol condensation products; Fatty acid condensation products.

Bast tape Tape product consisting of warp ends stuck together, i.e. with no weft ends, e.g. produced from glazed yarn or artificial horsehair.

Batch A group or set of usually similar materials (e.g. fibre, yarn, fabric) for processing at one time as a collective unit.

Batch card (processing card) A progress card used to accompany a batch of material through the entire process of finishing, dyeing, printing coating, etc. It contains all the information necessary for processing the material such as, e.g. the processing sequence, material parameters, processing operations, test requirements, etc. with spaces in which dates can be entered against each stage of processing.

Batch centres In yarn → Packages these are the tubes on which yarn is wound. In the case of piece goods, they are the metal or wooden rollers on which fabric is wound.

Batching device → Roll batcher.

Batching device for screen printing

Batching device for screen printing Removal of the printed fabric from the table is mechanised by means of a "detaching and batching unit", the fabric being batched in spiral form; rods are placed between the individual layers so that the still wet print cannot spot off. The batching unit is run together with the fabric into drying sections provided specially for that purpose.

Batching drives (→ Roll batchers). For various problem solutions there are different versions which differ from one another in certain criteria. As such, the following must be taken into account in the overall range: machine speed setting range, batch diameter range, fabric tension, fabric nature in dimensional terms, fabric type and residual moisture content, plus design data in the form of compensating roller stroke, moment of inertia, friction losses, run-up time and braking time. Peripheral and axial (heavyweight) batcher drive concepts differ for batchers and let-off units. In each case, a compensating roller serves as measuring sensor and regulator (affects the regulating transformer for supplying current to the batcher motor). Various possibilities of tension-free fabric batching and let-off by hydraulic drive.

Batching machine Used for batching piece goods for treatment on perforated beams in (HT) piece beam dyeing autoclaves, jiggers or as large batches for dyeing, printing or finishing; also on cardboard tubes for finished fabrics (Fig. 1).

The following stages are covered in Fig. 2: a) The wind-on head drops over the batching rollers with the cardboard core positioned ready in the loader. The switch is on pile-outside batching. b) The cardboard core is laid in, and the wind-on head is in the operating position. The fabric is fed in, and winding begins. c) The batching process proceeds, and the wind-on head is raised. d) The batching process is finished. The fabric roll ejector starts operation. At the same time, the wind-on head is raised further so that the cardboard core loader can be furnished with a new core for the next batching process.

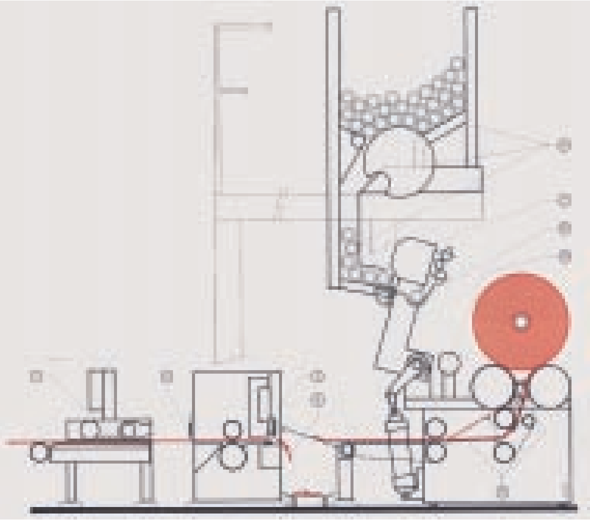

Fig. 1: Finished fabric batcher components.
1 = length measuring unit; 2 = cutting position detection; 3 = motor-operated cross-cutter; 4 = fault point ejection; 5 = pile-outside/pile-inside switch; 6 = cardboard tube magazine and feed; 7 = wind-on head; 8 = cardboard tube loader; 9 = roll ejector.

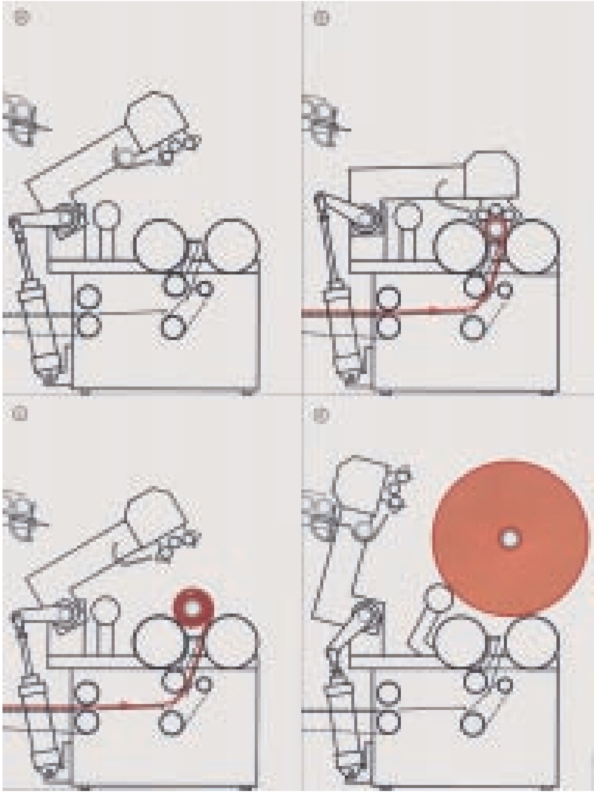

Fig. 2: Finished fabric batching operation cycle.

Batching-off unit A device for debatching textile fabrics from dye beams or giant batch rolls.

Batching roller (batch bearer, batching roll). Cylindrical support (with square inserts) for open-width piece fabric batching.

Batching tension control On a large batch, woven fabrics have to be batched under constant tension. The compensator roller determines the batching tension, and, via a microprocessor (Fig.), regulates the batching speed. In the event of excessive coupling housing temperature, a temperature sensor bridges the batch connection with the housing. In this way, the cut-off signal is fed to the unit without an additional slip ring.

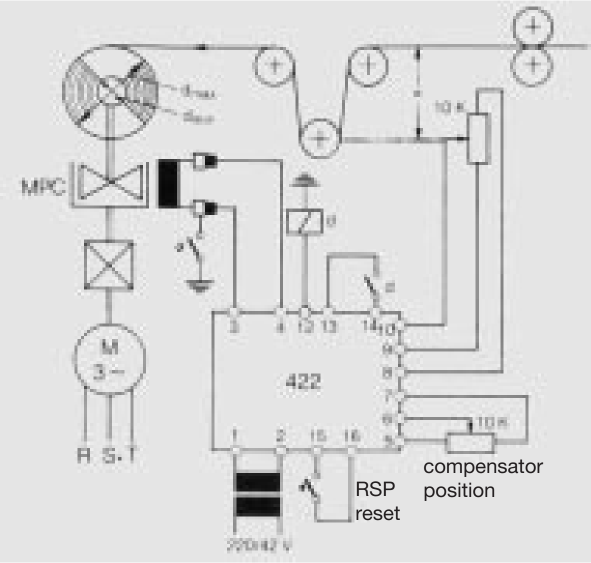

Fig.: Lenze Batcher tension control (x is kept constant). MPC = magnetic clutch; M = electric motor; 422 = microprocessor.

Batch process A batch dwell process, e.g. cold pad batch, etc.

Batch roll (fabric) → Batching roller.

Batch roll system (fabric processing). Offers several advantages compared to single roll processing:

1. Improvement in finishing quality: The beginning and end of each individual piece represents a potential risk for fabric defects. Each time a machine stop occurs the finishing result changes and the effect is impaired, e.g. heat setting.
2. Labour saving: In processing giant batch rolls the number of internal transport operations is reduced to a fraction of the number previously needed so that labour requirements are reduced.
   The same situation applies to batch changes at the machine since, in the case of giant batch rolls, the intervals between batch changes are of the order of one to several hours.
3. Higher throughput of finishing machines: Due to the reduction in machine set-up times and the number of batch changes, the productive output of finishing machines is considerably increased. Examples: a) When giant batch rolls with e.g. 1800 m fabric content are sent for final inspection and separation into merchandisable lengths on inspection machines, batch changes are only necessary every 1,5 h. As a result, the output of inspection machines can be increased by up to 20% due to the reduction in machine stoppages which were formerly necessary for small rolls. b) In the case of sublistatic transfer printing machines the productive output is increased by approx. 10% with giant batch rolls and savings in transfer paper are realized since the formerly numerous piece ends are considerably reduced on giant batch rolls.
4. Extended machine life due to less wear and tear: As experience has shown, finishing machines are subject to wear and tear especially as a result of frequent stopping and starting operations. In continuous non-stop operation over a period of hours, however, both the wear and tear and machine susceptibility to breakdowns are considerably reduced and service life is increased.

In comparison to plaited goods the giant batch roll system (Fig. 1) offers the following advantages:

1. Improved fabric quality: There is always the risk of crease formation with plaited goods which can seriously impair the quality of sensitive fabrics. With giant batch rolls, on the other hand, the fabric is always crease-free. Moreover, the risks of soiling and damage in transport are also less.

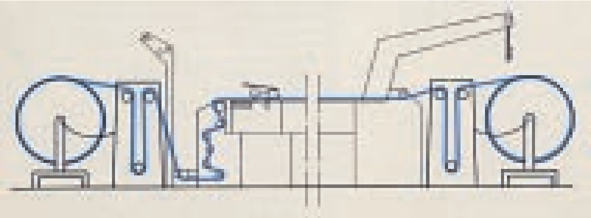

Fig. 1: Typical batch let-off and take-up layout on a continuous finishing machine.

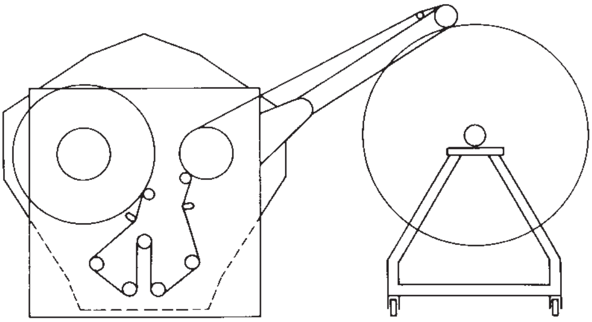

Fig. 2: Batch-type jigger dyeing batch roll system.

2. Reduced floor space requirements: It can be assumed that a giant batch roll with a diameter of approx. 1,6 m depending on type of fabric, contains 3–4 times as much fabric as a typical transport wagon of fabric in plaited form. Moreover, the floor space requirements for a giant batch roll are only marginally greater than those of a single transport wagon (Fig. 2).
3. Tension-free processing (Fig. 3).

Batch roll system for woven fabrics

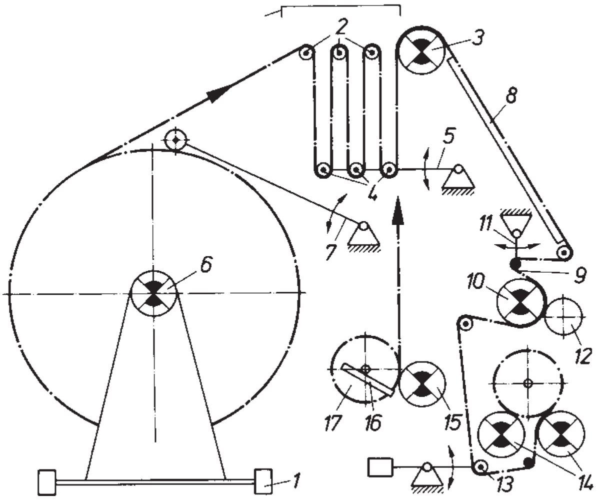

Fig. 3: Large batch roll let-off diagram.

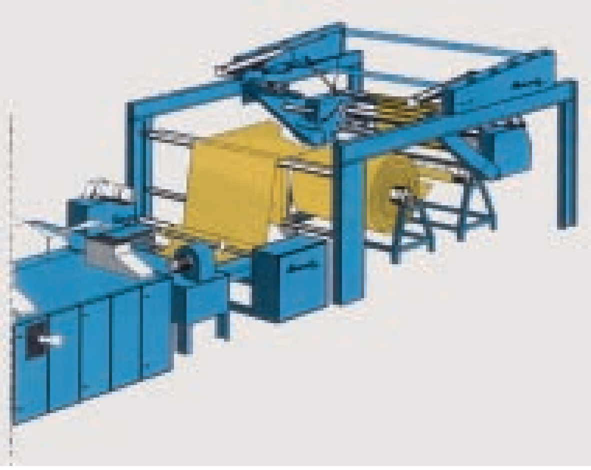

Fig. 1: Quick batch change unit at the exit of a Krantz stenter.

Batch roll system for woven fabrics Batch operation offers advantages over plaiter operation:

- space-saving storage of fabric in circulation,
- protection against soiling and transport damage (especially on plaiting interruptions; with plaiter operation, there is a danger of mechanical damage and soiling in pallet transport),
- no interruption of fabric run due to electrostatic charging of the fabric (which results in plaiting lay creasing in wet processing),
- higher running speeds,
- longer machine running times because of fewer batch changes.

Batch system problems are as follows:

- necessary fabric tension during batching,
- re-batching is necessary in the case of raised products,
- the total quantity of fabric in circulation has to be systematically dealt with; piece identification systems are of great use to this end,
- bulky fabric suffers in batching (raised velvet); necessary under certain circumstances therefore, particularly in decatising, are aluminium trestle-type plaiter trucks, which plait down especially long festoons via stop plaiters, thus preventing pressure creasing,
- high investment cost as regards batches and batching stations on every machine.

Plaiting units are problematic at stenter exits (Fig. 1) precisely because of the high production speeds involved, for which reason special units are also offered.

The basic equipment for installing batch operation in dry and wet finishing consists of so-called batching trestles. A batching trestle has a fixed construction batching roller with parking brake and coupling sleeves for centre drive. For wet fabric, the batching roller can be furnished with a PVC shrink tube. These batching trestles are designed as standard for batch diameters up to 1800 mm, but they have also been built for signifi-

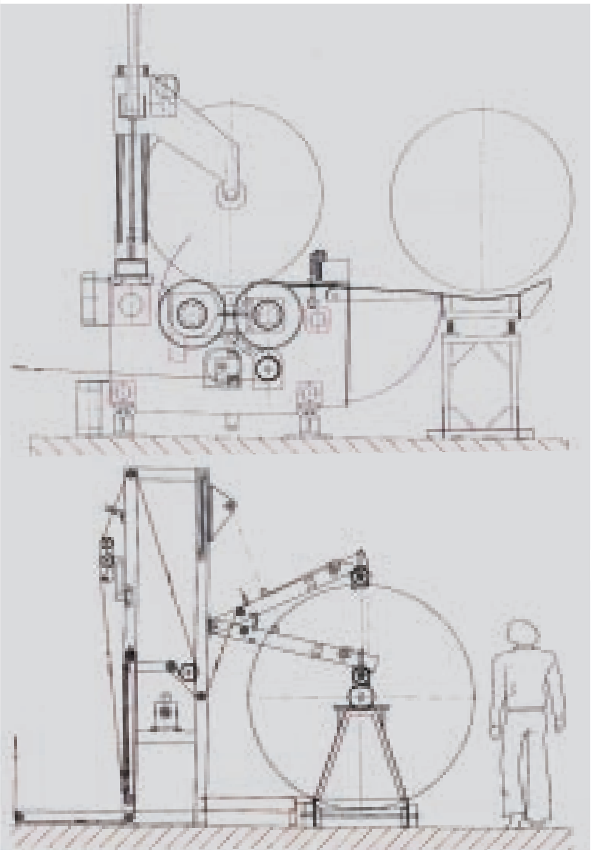

Fig. 2: Surface (peripheral) batcher (above) and hydraulic centre batcher (from Holthausen).

cantly greater batch diameters (up to 3 tonnes load). A batching trestle is transported by means of a crank roller or a standard tractor vehicle. If a batching station is employed, batching must be traversed in order to prevent selvedge build-up. Also to be taken into account is the fact that the tension on the fabric being batched increases as the batch thickness increases. The extent to which this type of tension is problematic for tension-sensitive fabrics must be regulated from case to case. Large batches are normally produced with the aid of hydraulic centre or surface (peripheral) batchers (Fig. 2).

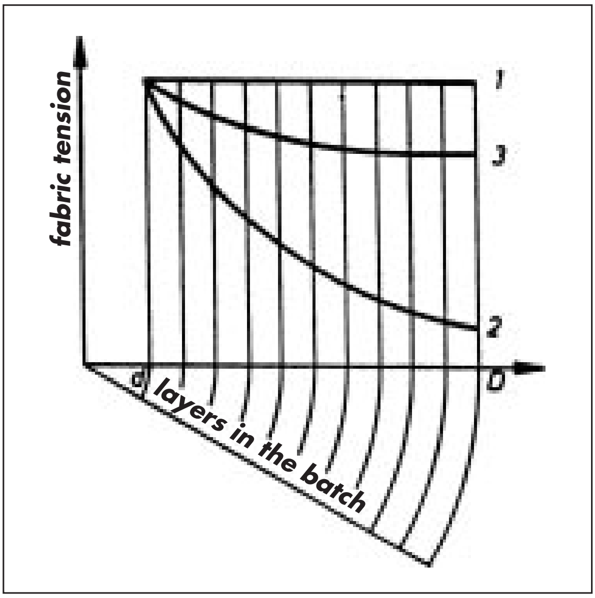

Fig. 3: Characteristic batching curve according to Menzel.

With the surface batcher, the batching process is effected by a driven batching roller which is in contact with the batch; in the case of the centre batcher, a batching motor drives the batch from the core. Constant fabric tension, equivalent to curve 1 in Fig. 3, is produced automatically with the surface batcher, as the batching roller batches with constant torque, which is of course adjustable as necessary. This batching force acts virtually upon the batch periphery only, and therefore has no negative effect on batch quality. With the centre batcher, constantly increasing torque must be applied in order to obtain constant tension. As this increasing moment has to be transmitted outwards via the inner layers in the batch, it is not always advisable to maintain constant tension, since the inner layers are pressed together and squeezed by the unpreventably high tension acting at the greatest batch radius. An ideal fabric tension run will, depending on product and requirement, lie between limits 1 (constant fabric tension) and 2 (constant moment, as with friction drives for example), and follow approximately curve 3, which has largely constant tension at the start of the batch, and a specific tension drop at the end of batching.

A comparison of woven and knitted fabric can be of help in estimating the effect of tension. The large batchers usual for woven fabric are unsuitable for the demands of knitted fabric finishing. Most knitted fabric qualities are sensitive to lengthwise tension. Excessive batching tension results in lengthwise creasing; due to the low degree of fabric stability, the fabric is distorted in the length, and becomes narrower. As a rule therefore, it has to be run under much lower batching tension than is employed with woven fabrics. It is clear therefore that simple centre batchers with constant drive pumps and no output regulation, as are employed in large numbers in the woven fabric industry, are unsuitable for knitted fabric. It can be seen from Fig. 4 that, with such batchers, fabric tension decreases as the batch diameter increases if not manually controlled. Manually controlled tension can be seen from the second characteristic curve of the graph. Apart from the fact that frequent manual regulation cannot be considered on economic grounds, tension varies too much from the ideal line here.

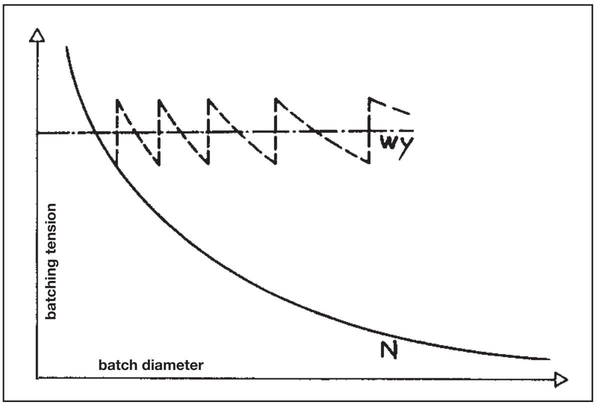

Fig. 4: Diagram with the batching characteristics of a simple hydraulic batcher with (– –) and without manual (N) control; the ideal line drawn in is equivalent to the batching characteristics of the Maier WY batcher.

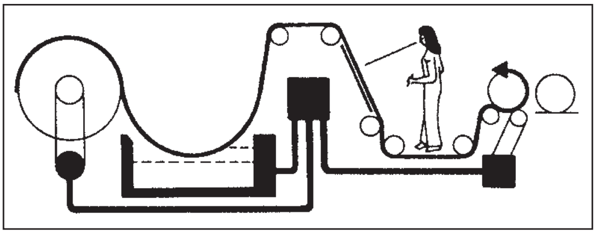

Fig. 5: Use of large batches in fabric let-off and in the microprocessor control of tension-free feed to fabric inspection via selenium cell control.

For operation with tension-sensitive products, batchers can be equipped with a photoelectric control unit (Fig. 5). The fabric is fed in a loop before the actual batching side. The size of the loop is sensed by a photoelectric sensor. Batching speed is then automatically synchronously controlled to the speed of the upstream and downstream equipment via a special electronic-hydraulic control unit. Tension-sensitive fabric can also be controlled during batching by compensating rollers which regulate the power requirement of the subsequent batcher. The batcher is a surface batcher, i.e. the drive roller, fitted to a swivel arm, drives the batch tangentially. In contrast to that are centre batchers, which are generally hydraulically driven. The key plan in Fig. 6 demonstrates oil circulation and shows the motor control unit. The oil drawn out of the supply tank is compressed by the pump (P), and fed to the system. Pressure is adjusted by the pressure reducing valve (A), and can be read off the manometer (M).

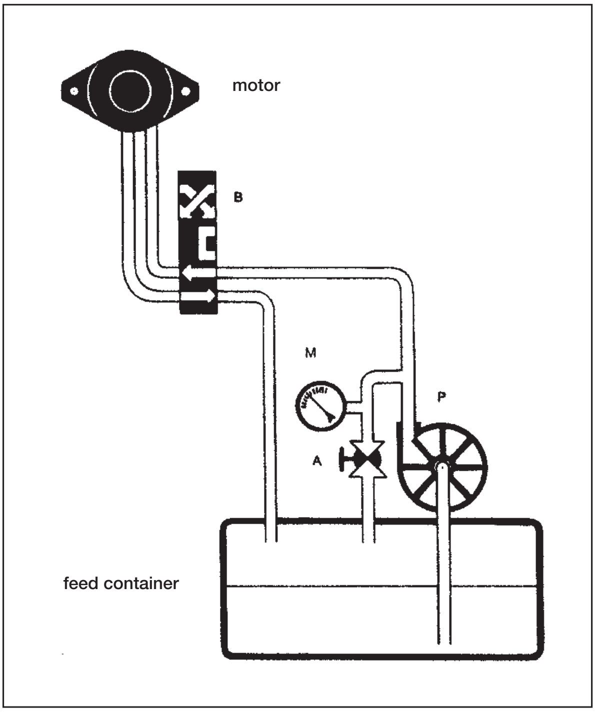

Fig. 6: Hydraulic drive motor (Menzel).

In the position illustrated, the route to the oil motor is opened by the control valve (B), blocked in the middle position, and opened for reverse rotation in the top position. Various variations have proved themselves in operation for centre batching trestle drives. First of all with trestles, direct coupling can be effected by means of through-going hydraulic motor spigots, but with the retrofitting of existing trestles without spigots, a V-belt drive is often fitted because only one hole is then necessary in each trestle for conversion purposes.

The ascending batcher is built in such a way that the full weight of the batch rests on two driven rollers. Also offered for batching and letting-off, however, is a type of ascending batcher where the beam rests on a central axis in swivel arms, while the beam runs against laterally tangential drive rollers (Fig. 2). Batch rotating units are fitted for the rotary dwelling of wet fabric on large batches (in order to prevent water bags during lengthy standing periods).

At the stenter exit, woven fabrics are either batched on large batches or on cardboard tubes for individual piece batching. In both cases, non-stop batchers with a fabric cutting unit are necessary.

Batch rotation Batching piecegoods onto the roller out of the treatment liquor.

Batch steamers Cylindrical steamers in various constructions used for discontinuous steaming processes, especially for printed fabrics, e.g.:

I. Horizontal steamers: front loading with a transportable frame. Textile material in the form of yarn hanks or fabric in book form is suspended on sticks, rollers or square-section rods which rotate during steaming. This type of steamer is generally used for rel. long steaming times of 1–2 hours, also under pressure. Such steamers are also known as cottage steamers.

II. Vertical steamers: various types, e.g. a) universal, Indanthren rapid, or Van-der-Wehl steamers: lid closure at the top. Fabric to be steamed is sandwiched between a back-grey and wound on to a perforated metal cylinder which is loaded into the steam chamber. Direction of steam flow is from outside-to-inside or vice versa, suitable for short runs of fabric, e.g. for small screen printing and hand printing operations; or b) star steamers: in which the fabric to be steamed is pinned to a star frame together with a back-grey on one or both sides. The steam chamber takes the form of a cylindrical pressure vessel, arranged vertically and closed at the top with a door that can be swung into position at its base. The loaded star frame is either raised into the steam or the steaming chamber lowered on to the star frame. Star steamers are preferred by screen printers and for sensitive fabrics, wool printing, etc.

Batch system (charged system). A term used to describe a now obsolete drycleaning process in which predetermined quantities (depending on the type of material) of drycleaning detergent and water were added to each batch processed.

Batch type scouring machine Cycle type/continuous scouring machine for batch scouring. Double drum construction built with five chambers or more (each of 40 kg capacity). Performance range relative to chambers and cycle times and also passage time 200–1600 kg/h. A loading belt divided into sections conveys the individual fabric batches in the set cycle through the adjustable working zones (prescouring, clear scouring, rinsing and starching). Scouring is effected in separate batches, the inner drums moving independently of each other in one direction of rotation. Bridging plates form the passage between the chambers, serving at the same time as large carrier ribs. At the end of the cycle time, the batches are rotated through 360°, transported by bridging plates.

Batch wagon Mobile frame for → Batch loading and internal transport (DIN/ISO 5248).

Bates process A process for the scouring and bleaching of cotton in which fabric impregnated with bleaching chemicals is placed between electrodes and heated to the boil.

Bath The liquid-filled treatment zone in dyeing, washing, finishing, and drycleaning machines. A distinction is made between a standing bath and a circulating bath. In the latter case, liquid is circulated through the textile material by means of a pump and recirculated via a filter. The liquid medium itself is referred to as a → Liquor.

Bath exhaustion A term used for the exhaustion of dye at equilibrium, generally expressed as that percentage of dye originally applied which has been removed from the bath by adsorption on to a textile substrate due to the forces of affinity.

Bathochromic group Colour-intensifying group in a → Dye structure. The presence of a bathochromic group in a dye molecule causes a shift in the absorbed wavelengths from violet towards green (complementary colour) and the colour of the dye in the direction green-yellow–redviolet, i.e. an increase in the wavelength and a reduction in the oscillation frequency. See also → Hypsochromic group.

Bath polarization A method of preventing corrosion in bleaching equipment. Principle: an electric potential is applied to the bleach liquor and the bleaching machine. The bleaching machine is connected to the negative pole of a direct current supply and a positive pole is formed by a carbon electrode in the bleach liquor.

Batik Javanese handcraft technique for the production of characteristic designs and fabrics. It involves the application of molten wax to the fabric by → *Tjanting* (pipe), *tjap* (stamp) or brush as a resist, followed by dyeing, removal of the wax, re-application of wax in the desired areas, followed by a second dyeing and so on. Fine cracks are formed in the wax resists as a result of mechanical action which do not resist subsequent dyeing completely. The typical veining of batik designs is created in this way.

The term batik is derived from a combination of the words “*banyak*” and “*titik*”, which means “many points”. Different types of batik include: mosaic batik, water-colour or sketched batik, ornamental batik and lace batik. The various techniques of batik production are subdivided into:

- the creasing and folding technique,
- the tying and tie-up technique,
- the knotting technique,
- wax batik,
- Shibori alternatives.

Batik pipe → Tjanting.

Batik printing (Real Wax print). Involves the mechanization of traditional batik techniques by retaining the wax resist (→ Wax resists). Principle: fabric is printed with a wax resist, then cooled down quickly in cold water or subjected to a mechanical breaking action in order to achieve the typical crackle effects (fine veining). This is followed by dyeing with indigo (dipping vat), removal of the wax resist by washing or soaping, drying, completion of the remaining colours by screen or hand block printing with the usual dye classes and finally drying and finishing. The production of this style of printing is extremely laborious and expensive. For this reason, a cheaper imitation has been developed under the name of → Imi-Wax, which has now found wide acceptance. → Indigo styles in Africa prints.

Batiste Three types: (1) Cotton or polyester/cotton soft, fine to very fine, tightly woven fabric of the lawn family in plain-weave construction. Produced in various grades from coarse to very fine. Generally woven of fine combed yarns but occasionally of carded cotton. Maco-batiste is a batiste fabric woven from Egyptian maco-cotton. Often highly mercerized, bleached, dyed or printed. Sometimes embroidered. (Coloured-woven batiste is not called batiste but macozefir). (2) Sheer fabric of man-made fibre with dobby woven stripes, jacquard patterns. (3) A light-weight wool fabric in plain-weave similar to plain cambric. It should be of all wool construction unless otherwise described.

Batt-on-base woven felts → Nonwoven materials which are defined in DIN 61 205 as textile fabrics composed of ground fabric/s and one or several fibrous webs which are consolidated and bonded with the ground fabric/s.

BAT value Biological tolerance of workplace toxins, maximum admissible concentration of a workplace toxin or its conversion products (metabolites) in the body (absorbed by the blood or urine through inhalation, swallowing or by skin resorption) which do not generally impair the health of the worker in terms of current scientific knowledge when they are regularly produced by the effect of the work station. In addition to monitoring ambient air in accordance with → TLV values, BAT values serve, within the framework of specific medical check-ups, to protect the health of workers at the work station.

Baumé, degrees (°Bé) A frequently used but unscientific scale for measuring the relative density of liquids by hydrometry (Baumé hydrometer). Hydrometers with direct scale divisions in relative density for liquids are, of course, readily available. Nevertheless, hydrometers with scale divisions in °Bé are still frequently used in practice. The basis of the scale division is as follows: density of distilled water at 4°C = 0°Bé and the density of a 10% sodium chloride solution = 10°Bé; this separation is divided into 10 subdivisions and the scale is continued. Conversion formulae for converting °Bé into specific gravity (ρ):

a) For liquids more dense than water:

$$\rho = \frac{144{,}38}{144{,}38 - {}^\circ\text{Bé}}$$

b) For liquids less dense than water:

$$\rho = \frac{144{,}38}{144{,}38 + {}^\circ\text{Bé}}$$

The formulae are only valid for measurements at 15°C.

Bayer biological tower plant A plant designed for the biological degradation of organic substances in waste water by treatment with bacteria and air in closed towers of up to 30 m height.

Bayonet spiral A term used to describe the upper shearing cylinder blade profile in shearing and cropping machines.

Bazaar dyeing A unique ancient dyeing process still in use today with simple home-produced equipment and almost the full range of synthetic dyestuffs and printing pastes. Mostly as commission dyeing for small weaving mills, 45% of industrial cotton textile products being produced by small plant and outwork production.

BB, abbrev. for: batt on base (nonwovens technology).

BB felt cloths Meaning → Batt-on-base woven felts.

BBP → Butyl benzyl phthalate.

BC Code designation for → Boron (nitride) fibres in accordance with air travel standards.

BCE, abbrev. for: Bachelor of Chemical Engineering; academic degree in the USA and UK.

BCF yarns (bulked continuous filament). Textured continuous filament yarns used for pile yarns in carpets or upholstery fabrics.

BCSIR, abbrev. for: Bangladesh Council of Scientific and Industrial Research (Dhanmondi, Dacca). → Technical and professional organizations.

BDE (Betriebsdatenerfassung) German code designation for "operating datalogging". Electronic data processing: process data, produced by hand, is read into document readers, keyboards and terminals or automatically via sensors.

BE,

I. abbrev. for: Bachelor of Engineering. British professional qualification for graduates of engineering colleges or polytechnics.

II. abbrev. for: Belgian patent.

Be, chemical symbol for beryllium (4).

°Bé → Baumé, degrees.

BEA, abbrev. for: British Engineers Association.

Beam dyeing machines HT autoclaves for piece goods or atmospheric machines for the dyeing of warp beams. Piece dyeing machines are available with internal diameters of 1000, 1200, and 1500 mm and working widths up to 4000 mm. Max. operating pressure 5 bar. Max. dyeing temperature = approx. 135°C. Various dye beam diameters are available depending on weight of fabric batch, e.g. 500, 600, 700 and 800 mm. Blanking collars (to blank off excess perforations in the dye beam) are used to permit the dyeing of narrow fabric widths. Piece dyeing machines are used for dyeing woven and warp-knitted fabrics in open-width. Advantages include freedom from running creases, felting, or fibre loss with surface-sensitive fabrics. In particular, mechanical damage to warp-knits (e.g. stitch deformation, snagging) is avoided. Beam dyed fabrics generally have a firm handle. Short liquor ratios of 10:1 to 12:1 are usual in beam dyeing.

In addition to their use in dyeing, beam dyeing machines can also be used for the hydrosetting and wet decatizing of wool fabrics. Beam dyeing machines are mainly supplied with an external centrifugal pump (and heat exchanger). Alternative models are also available with in-built axial pump and heat exchanger. Batch changes are effected by removing the beam of fabric from the horizontal dyeing vessel on rails and on to a waiting trolley (Figs. 1 and 2).

A reduction in liquor ratio can be achieved by positioning displacement elements in the fabric beam (Fig. 3).

Fig. 1: Running out the dyed fabric beam on a beam dyeing machine (Durand).

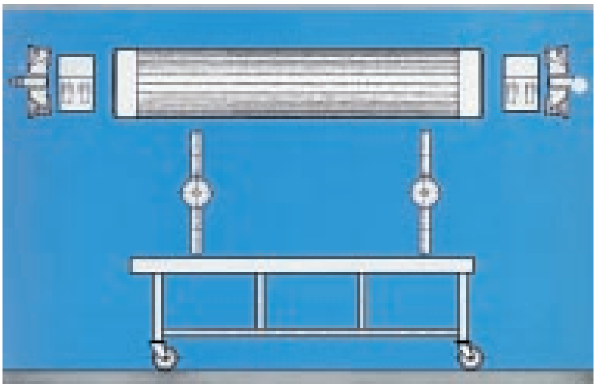

Fig. 2: Dye beam with castors on both cover plates which can run on rails in the dyeing machine and on the transport trolley (Krantz).

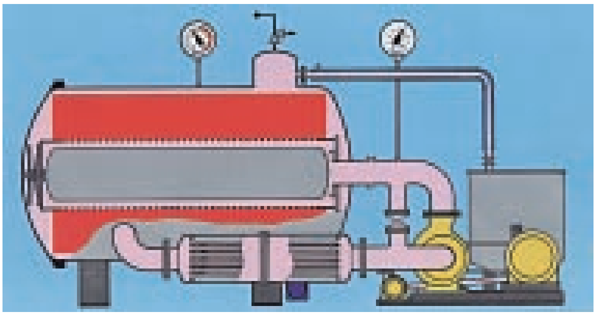

Fig. 3: Beam dyeing machine (Durand) with displacer in the dye beam for shortening the liquor ratio.

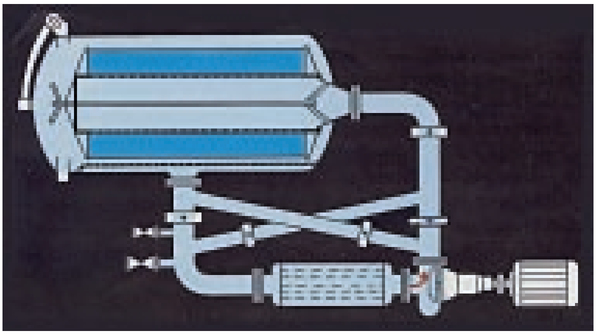

Fig. 4: Lavish piping system with relevant valve controls for changing liquor direction in the centrifugal pump beam dyeing machine.

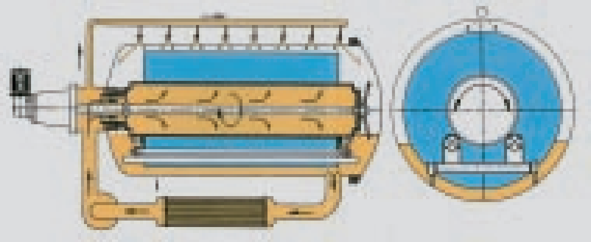

Fig. 5: Alliance-Rotora beam dyeing machine with rotating beamed fabric to reduce the liquor ratio.

With appropriate equipment, liquor flow reversal is also possible which enables the centrifugal pump to run constantly in one direction (Fig. 4). The direction of liquor flow in beam dyeing is normally from inside-to-outside of the beam only. In the case of machines fitted with axial pumps, however, the liquor flow can be easily reversed by changing the direction of rotation (Fig. 5).

Since, in beam dyeing, the textile material is at rest and liquor is circulated through it by means of a pump, the question arises as to whether it is better for the liquor circulation to flow from inside-to-outside or from outside-to-inside of the batch. Liquor circulation from outside-to-inside offers advantages of better uniformity of dye (and chemicals) transport to the fibre surface throughout the diameter of the batch and the virtual elimination of fabric deformation during the dyeing operation (Fig. 6).

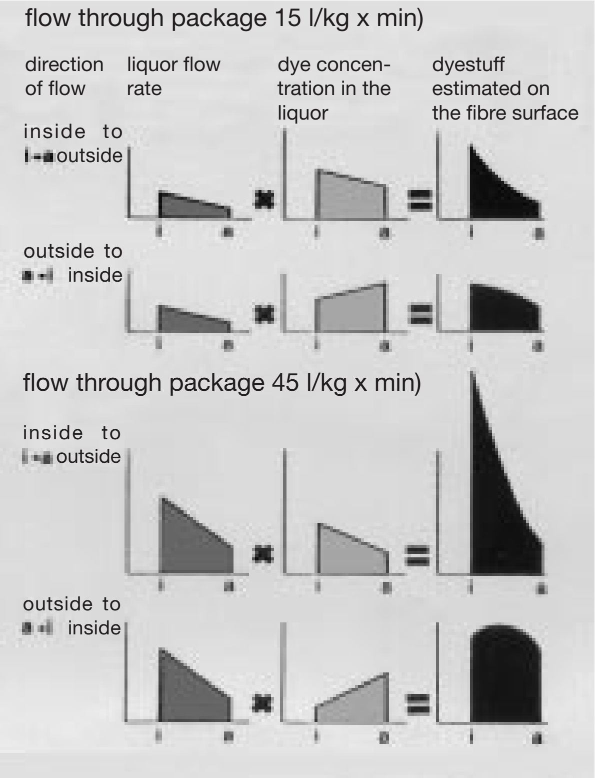

Fig. 6: Dyestuff estimated on the fibre surface in beam dyeing; depending on liquor flow direction (Kretschmer).

This procedure can make a significant contribution to the use of increased batch sizes, even for critical fabric qualities, without sacrificing production reliability. When liquor is circulated from inside-to-outside of the dye beam a pressure loss Δp occurs due to the conversion of mechanical flow energy into friction with the fibres in the interstitial spaces of the material. A distinction is drawn between this differential pressure (or dynamic pressure) and the absolute static pressure within the textile batch which, if excessively high, can cause the fabric to lift off the beam (Fig. 7). It is important to ensure an optimum flow through the textile material in order to save water during the rinsing stages and, to this end, overflow rinsing is carried out in most cases. This is achieved by supplying fresh water from the pressure side of the running circulation pump and allowing the rinse water to flow away via the overflow after passing through the beam so that the dyeing vessel always remains full of rinsing water.

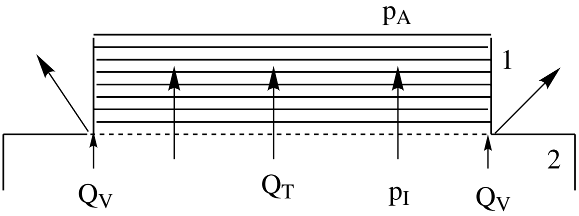

Fig. 7: Differential pressure $\Delta p = p_I - p_A$ in the batch roll in beam dyeing, which can result in liquor losses 2 Q_V by lifting the batch under excessive static pressure p.
Q_T = quantity of liquor in the batch; 1 = batch; 2 = dye beam.

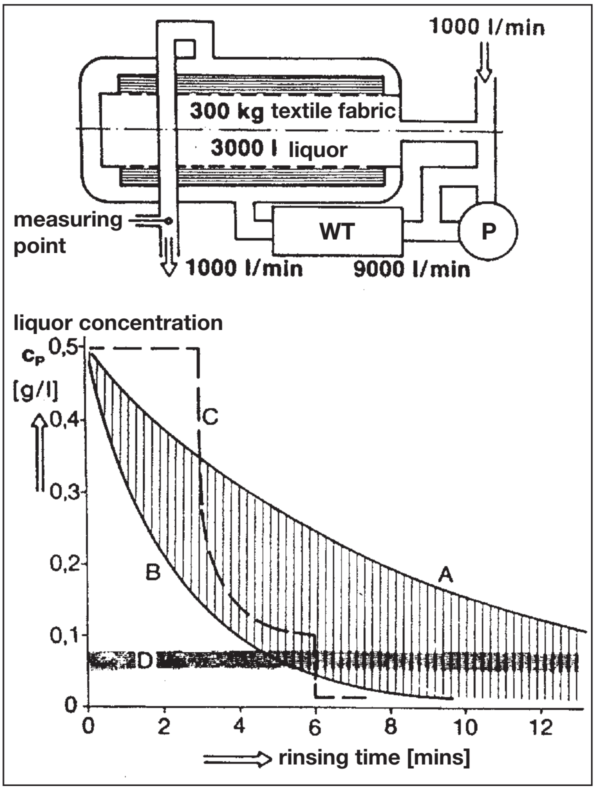

Fig. 8: Liqour dilution and dye concentration reduction relative to rinsing time and rinsing liquor flow in beam dyeing (Kretschmer).
A = intense liquor circulation; B = modest (by-pass) liquor circulation; C = liquor emptying by means of compressed air and fresh liquor filling; D = permissible residual concentration.

In Fig. 8 the reduction in liquor concentration during the rinsing time corresponds approx. to curve A with a closed by-pass, and to curve B with an open by-pass. If the bath has been dropped at the start of the rinsing operation, the proportion of residual liquor remaining in the batch (amounting to approx. 200% by weight) must be diluted with fresh rinsing water. With a closed by-pass, the liquor circulation contributes effectively to a decrease in concentration at the fibre surface and a more uniform dilution of the liquor. The proportion of residual liquor retained in the batch of textile material is reduced to approx. 100% by expulsion with compressed air, especially when liquor flow is from outside-to-inside. On subsequent refilling with rinsing water and circulation, the proportion of residual liquor is then further diluted (curve C, Fig. 8).

Beam dyeing of piece goods Batchwise dyeing of textile fabrics wound in the open-width state on to a perforated beam through which liquor is circulated. Taking a fabric batch as an example, a comparison of the manometer reading with the calculated differential pressure value enables one to recognise immediately whether the batch of fabric has lifted off the dye beam, or whether a secondary flow at the edges of the batch exists which can result in uneven dyeing.

The thickness of the boundary layer decreases with increasing flow rate. A higher liquor throughput can, however, only be used to advantage if the direction of liquor flow is changed so that it flows from outside-to-inside of the batch.

Beater opener Device for opening out fabrics in rope form. The most important component is the rapidly rotating → Beater roller with beater blades.

Beater rollers (vibrator rollers) Employed in open-width washing machines to provide increased mechanical action on the running fabric thereby intensifying liquor movement.

Beating machines (beaters) Two types are in use:

I. Beating machines for the finishing of pile fabrics (velvet, plush, etc.) in which the back side of the fabric

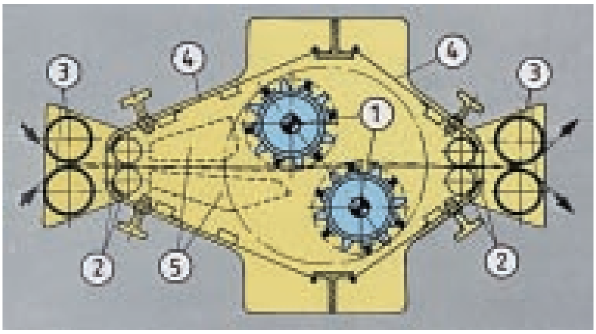

Fig.: Beating and brushing machine (Kleinewefers-Jaeggli).
1 = individually driven brushing and beating rollers;
2 = fabric guiding; 3 = deflector; 4 = housing cover;
5 = extraction ducts.

is subjected to a beating action which results in better alignment of the pile on the face side.

II. Beating machines for the cleaning of carpets and other textiles which cannot be subjected to washing treatments. Dirt is removed by an intensive beating and brushing action (see Fig.).

Beaver cloth A heavy, firm-textured fabric, made from woollen yarns. The lustrous nap of short fibres is produced by milling the cloth and raising the fibres, which are cut level and laid smoothly in one direction. It is intended to have the appearance of natural beaver skin. Soft handle with a longer nap than that of wool broadcloth. Used for overcoating.

Beck → Dyeing vat (a term frequently used in the USA for an open winch dyeing machine).

Bedford cord A woven cord fabric. Plain-weave is usually used on the face of the cords, but other weaves may also be used. → Cord.

Beeswax, raw: yellow-red-brown (African and American beeswax is almost brown), pleasant odour, brittle when cold (accepts chalk marks but not after addition of tallow). It produces a granular fracture. On warming in the hand it becomes plastic. Does not adhere to the teeth on chewing. When bleached it is very brittle and has a rancid odour. Tropical beeswax contains high additions of tallow (permissible amount 3–5%). Beeswax has a melting range of 61,5–68°C (69°C with tallow addition, a higher m.p. is not permissible). Adulteration is mainly carried out with the addition of tallow, Japan wax, stearine, resin, paraffin wax, ceresin, minerals (ochre, heavy spar), pea meal. Beeswax is soluble in turpentine, chloroform, white spirit and hot fats. Very difficult to saponify. Uses: textile sizing and finishing, water-repellent finishes, etc.

Beetling calender A heavy calender usually with 6 bowls, the lower and uppermost of which consist of heated steel rolls whilst elastic cotton bowls are used in the intermediate positions. The fabric passes through all the nips from the lower to the uppermost bowl where it is rolled on to the upper cotton bowl thus producing the → Beetling effect as a result of the pressure exerted by the top steel bowl.

Beetling effect A unique type of lustre finish imparted to cotton or linen fabrics by a calendering treatment on the → Beetling calender or chasing calender.

Behenic acid (docosanoic acid), $CH_3(CH_2)_{20}COOH$, of MW 340,57. Colourless crystalline needles. Sparingly soluble in water but soluble in alcohol. A saturated fatty acid which is a minor component of, *inter alia*, peanut and rapeseed oils. Hydrogenation product of unsaturated C_{22} fatty acids derived from rapeseed oil as well as oils from marine mammals. Uses: the sodium salt (behenate) is used as a foam regulator (its efficiency is dependent on the presence of alkylbenzene sulphonate and pentasodium triphosphate as well as water hardness) and as a foam suppressant especially in washing agents.

Beilstein test Used for the detection of substances containing chlorine or other halogens, e.g. synthetic fibres (such as polyvinyl chloride or vinyl chloride copolymer fibres).

Procedure: A piece of copper wire (or gauze) is heated in an oxidizing flame until the flame is no longer tinged green (= yellow flame); a little of the fibre sample is placed on the copper wire and burnt in a non-luminous gas flame. A green-coloured flame is a positive test for the presence of halogen and is due to the formation of volatile copper chloride through combination of copper with chlorine in the sample. It should also be noted, however, that a positive reaction in this test can also result even in the absence of halogens and in the presence of e.g. volatile copper compounds with oxides of carbon as well as organic compounds containing both sulphur and nitrogen.

Bekleidungsindustrie e.V., Bundesverband → Technical and professional organizations.

Bekleidungsphysiologisches Institut Hohenstein e.V. A textile and clothing research organization in Germany; → Technical and professional organizations.

Bell steamer → Batch steamers.

Belt accumulator → Narrow fabric accumulator.

Belt brushing machines Finishing machines for corduroy fabrics. → Corduroy and velvet finishing.

Belt drives → Motive power engineering by means of transmission belts. The theoretical underlying principle for the calculation of belt drives is the Eytelwein equation:

$$F_1 \leq F_2 \cdot e^{\mu\beta}$$

F_1 = force on taut side of belt
F_2 = force on slack side of belt
e = base of natural logarithms
m = coefficient of friction between belt and pulley
b = arc of belt contact (on the smaller pulley) circular measure by radians

Eytelwein's equation gives the maximum proportion of change in the two belt forces F_1 and F_2 during power transmission, before pulley slippage occurs (the more power transmission, the greater F_1 will be and the smaller F_2 will be) (Fig. 1).

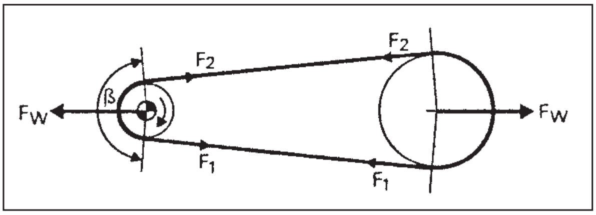

Fig. 1: Forces on belt drive during power transmission F_1 *= force on taut side of belt,* F_2 *= force on slack side of belt,* F_w *= strain on shaft driving small pulley.*

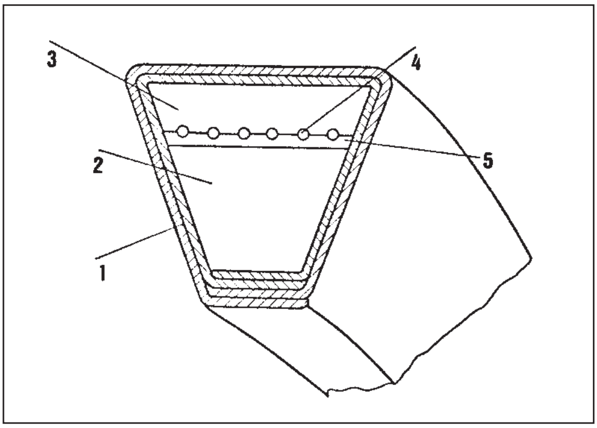

Fig. 2: Narrow V-belt with a cable cord core
1 = encasing fabric, 2 = rubber core, 3 = top layer, 4 = cord, 5 = cushioning rubber

To achieve maximum frictional force, profiled V-belts are used (Fig. 2).

Bending elasticity (crease resistance) Partly elastic, partly permanent shape change of yarns and woven fabrics in the bending test as a criterion of → Creasing (tendency, sensitivity), the so-called angle of recovery (module of elasticity), which occurs after folding or bending under load (effect duration) and subsequent relief, and is at best 180°, playing an important role. → Tensile elasticity.

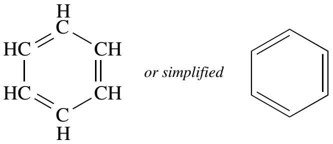
Benedict-Denis reagent (according to Krais-Markert-Viertel) Solution of 25 g of copper nitrate, 25 g of sodium chloride and 10 g of sodium nitrate in 100 ml of water. Used for quantitative sulphur determination in wool.

Bentones Organic derivatives of montmorillonite. Used in printing preparations as a thickener for pigment suspensions etc.

Bentonite Colloidal → Silicic acid (clay, aluminium silicate) composed chiefly of montmorillonite. Very fine white powder which absorbs up to approx. 5–6 times its weight of water by swelling into a gelatinous mass with strongly thixotropic properties. Uses: Thickener for textile printing, also used in the paper, soap and pharmaceutical industries.

Benzanthrone → Anthrone.

Benzene, C_6H_6, MW 78,06, density at 15°C = 0,885, b.p. 80,15°C, f.p. 5,5°C. As a homogeneous chemical compound benzene is not to be confused with → Benzine (special boiling point spirits). Colourless to light-yellow, mobile, non-polar, highly refractive liquid with a characteristic aromatic odour. Forms narcotic vapours which are toxic when inhaled for long periods. Highly flammable, burns with a smoky yellow flame. It forms explosive mixtures with air which sink to the ground. Properties: only very slightly soluble in water (0,82 ml/l) although 2,11 ml water are soluble in 1 litre benzene. Readily miscible with alcohol, ether, acetone, carbon tetrachloride, carbon disulphide and glacial acetic acid. Uses: solvent, spotting agent. → Carcinogens.



Benzene derivatives → Aromatic compounds.

Benzene sulphonates See → Alkylbenzene sulphonates.

Benzene test (for dyeings), specifically for cationic and disperse dyes in → Dye class identification.

Benzidine (4,4´-diaminodiphenyl), $H_2N–C_6H_4–C_6H_4–NH_2$. Aromatic amine, MW 184,2. Properties: greyish-yellow, white, or reddish-grey crystalline powder; m.p. 127°C; b.p. 400°C; soluble in hot water, alcohol, ether; slightly soluble in cold water. Combustible. Readily diazotizes at both amino groups. Uses: parent compound of numerous (direct) dyes as well as diazo compounds for the preparation of mainly brown insoluble azo dyes on the fibre. These dyes are no longer permitted in Europe because of their carcinogenic character. →: Blood, detection of; Carcinogens.

Benzidine test → Blood, detection of.

Benzine Mixture of → Hydrocarbons i.e. not an homogenous chemical compound like → Benzene. Easily mobile, water-white, singular smelling liquid which evaporates relatively quickly at any temperature: petroleum benzine completely below 100°C, leaving behind no odour. Together with air, forms a highly explosive mixture, the explosion limits lying between 1.8 and 8.5 vol.% benzine vapour content. Benzine vapours always sink to the ground, and fans should therefore be installed at floor level. In contrast to benzene, benzine burns without a smoky flame, and also does not dissolve asphalt. The flash point lies between 25 and 55°C; danger class IIIa. Median constants for calculation:

density at 15°C:	0.65–0.79
freezing point:	30–50°C

Various types of benzine differ according to the different fractions (Table). Specific benzine fractions are increasingly used as substitutes for tetrachlorethylene in dry-cleaning machines specifically designed to that end (hydrocarbon systems).

It should be expressly pointed out that the designation of benzine fractions is to some extent differently implemented. Evaporation figures vary between approx. 3–20 times the evaporation time of ether. Properties: insoluble in water, miscible with alcohol, ether, chloroform and other organic solvents. Reduction in spontaneous ignition by benzine soaps and dry-clean-

type	density (15 ° C)	boiling point (° C)
petroleum ether	0,665–0,670	c. 40–70
petroleum benzine light petrol	0,680–0,720	c. 70–90
ligroine white spirit	0,730–0,780	c. 100–135
naphtha	0,735 (12° C)	c. 100–140
heavy petrol	c. 0,770–0,790	c. 140–200
heaviest petrol	0,790 (12 ° C)	c. 180–210

Tab.: Benzine density and boiling ranges.

ing detergents. Application: textile degreasing, dry-cleaning, stain-removing agents for light grease and fresh oil stains, resin spots, dust and light soiling, particularly in conjunction with dry-cleaning detergents; addition to easily foaming printing colours.

Benzine hydrocarbons These mean → Benzines used in dry-cleaning.

Benzine soaps Fat-solvent soaps of various compositions (often highly ethanol-containing) and consistencies (liquid, semi-solid, solid). By reducing the spontaneous combustion of → Benzine (benzol), they facilitate dry-cleaning in organic volatile solvents, and, in benzine cleaning, mostly act simultaneously as an anti-electricum: by increasing electrical conductivity, the electrostatic charge in solvents is reduced in mechanical processing (friction metal/liquid, textiles/metal, textiles/liquid), and consequently effectively opposes discharge with sparking.

Benzothiazolone hydrazone method Spectrocolorimetric method for the quantitative determination of formaldehyde on textiles. 3-methyl-2-benzothiazolone hydrazone reacts with formaldehyde to an azine. The surplus of the benzothiazolone hydrazone method is oxidised by iron(III) chloride to a reactive cation which produces a cationic blue dye with the azine compound.

Benzoylation Introduction of the → Benzoyl group of an aromatic acid residue into a molecule. → Acylation.

Benzoyl group → Acyl (residue) = C_6H_5CO, of benzoic acid. → Benzoylation.

Benzoyl peroxide, $C_6H_5CO–O–O–COC_6H_5$; white crystalline powder with a very faint odour, slightly soluble in water and alcohol, soluble in ether, benzene and chloroform. Produced from benzoyl chloride and sodium peroxide. Highly toxic via inhalation. TLV: 5 mg/m^3 of air. Active oxygen content of 6,3%. Its low moisture content (< 5%) poses a fire risk and for this reason it should be stored under cool conditions and sudden heating or warming with organic substances must be avoided. May explode spontaneously when dry (< 1% water). Never mix unless at least 33% water is present. In burn-out printing, the best effects are obtained in the presence of approx. 5% moisture. Benzoyl peroxide can cause discoloration of dyed and printed textiles. Uses: For the destruction of acetate fibres in mixed fabrics by burn-out printing; burn-out styles; bleaching of cellulosic fibres containing chlorophyll (pandanus straw, etc. for hat braiding) dissolved in gasoline or e.g. alcohol; bleaching materials that are difficult to bleach (hair, feathers, furs, etc.).

Benzyl alcohol, $C_6H_5CH_2OH$; density 1,045, boiling point 205–209°C, flash point 96°C. Colourless liquid with a faintly aromatic odour, sparingly soluble in water but readily soluble in alcohol and ether. Oxidizes slowly in air to form benzaldehyde (odour of bitter almonds). Uses: as a swelling agent and solvent (when heated) for acetate (pigment and metal powder printing); as a solvent for cationic dyes; as a component in fat-solubilizing soaps, etc. because of its good hydrotropic properties.

Benzylating agents Used as printing auxiliaries in discharge printing with vat dyes to form water-soluble benzylated products and leuco compounds which can be easily washed out.

BEP → Break even point.

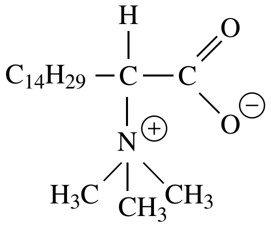
Berber carpets Rustic knotted carpets in natural colour, hand-woven by North African tribes from wool yarn spun by hand from local sheep. They contain a proportion of naturally pigmented wool and may bear simple tribal motifs. The term has also been used in recent years to describe manufactured carpets made from natural coloured wools, or dyed fibre, with a homespun appearance.

Berberine (barberry) → Natural dyes.

Berlin blue (Prussian blue, Paris blue, Turnbull's blue). Hexacyanoferrates (II) and (III). A dark blue solid which is soluble in oxalic acid. Yields a vivid blue which has been used for the blueing of bleached goods. Resistant to light and acids but very sensitive to alkalies.

BESA, abbrev. for: British Engineering Standards Association. → Technical and professional organizations.

Betaine (trimethylglycine). An intramolecular ammonium salt (amphoteric) as a trimethyl derivative of → Glycine. White crystals with a neutral reaction, readily soluble in water, are stable to the action of acids even at high temperatures. Uses: pasting auxiliary either as an addition to the dye itself or to the prepared print paste mixed with glycerol. Substitution of one of the neighbouring hydrogen atoms to the carboxylate group with a long aliphatic chain yields interesting capillary-active textile auxiliaries, e.g.:



Sulphobetaines are formed by substitution of the COO^- group in betaine by the SO_3^- group. The higher molecular weight products are interesting wetting and washing agents whilst the lower molecular weight types are also useful hydrotropic solvents for vat dyes and dispersing agents in dyeing and printing (accelerated fixation, reduced steaming times).

Beta-naphthol (2-naphthol, 2-hydroxynaphthalene, red developer), $C_{10}H_7OH$, MW 144, density 1,21. White lustrous, bulky leaflets or white powder (turns brown on exposure to air) with a phenolic odour. Almost insoluble in water (approx. 1:1000 in cold water; approx. 1:75 in hot water), dissolves readily with its own weight of 33% caustic soda liquor in hot water. Readily soluble in alcohol, ether, chloroform, glycerol, benzene, etc. Concentrated solutions cause skin irritations and inflammation. Uses: developer for navy blue, red, brown, blue and black diazo dyes on cellulosic fibres.

Beta rays → Radioactive emission.

Betriebswirtschaftsstelle Wäscherei-Chemischreinigung (BWC) Industrial laundry and drycleaning management bureau in Germany. → Technical and professional organizations.

BF, official French abbrev. for: “Brevet Française” (French patent).

BFTC,

I. British Fastness of Textiles Committee

II. Belgian Fastness of Textiles Committee.

BHES Abbrev. for → Bis (β-hydroxyethyl) sulphone.

Bi, chemical symbol for bismuth (83).

bi- (or di-). Prefix (Lat.: *bis* = twice or two) used in words such as bicomponent fibres, bifilar, bichromate, etc.

BiAS, abbrev. for → Bismuth active substance.

Biaxial fabric Conventional fabric construction consisting of 1 warp thread system and 1 weft thread system.

Bibibaff The finest quality of → Bakhtiari carpets, with a single weft thread construction.

Bichromate → Potassium dichromate.

Bichromate aftertreatment Treatment to improve the wet fastness properties of selected direct dyes.

Bichromate/copper sulphate aftertreatment Treatment given to selected direct dyeings in order to improve the wet fastness and light fastness properties.

Bichromate of potash → Potassium dichromate.

Bicoflex balanced pressure rolls Flexible elastic padder rolls. The pressure applied in padders with normal rigid rolls is, of course, greater at the edges than in the centre since bowing occurs through lever action due to the application of pressure at the two ends only. This causes edge-to-centre shade variations in continuous dyeing. The Bicoflex roll, (Figs. 1 + 2), on the other hand, consists of a fixed load bearing axle with bearings at each end. Pressure pads are mounted across the full width of the load bearing axle and around its circumference. Each pressure pad is connected to a compressed air supply to provide individual pressure control against the articulated sleeve. Supported on rollers on top of the air-cushioned rubber pads is the flexible outer sleeve which carries the removable shrunk-fit rubber working sleeve. Bicoflex rolls can also be retrofitted into existing padders. Manuf.: Ramisch-Kleinewefers.

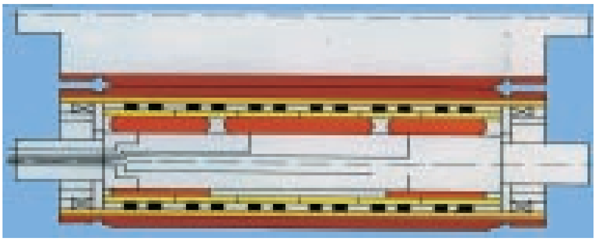


Fig. 1: Bioflex-System (Kleinewefers KTM).

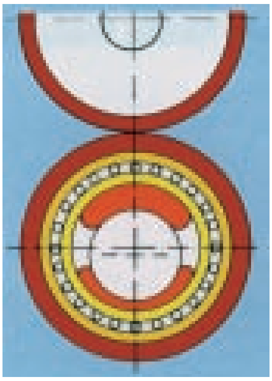

Fig. 2: Inside of a Bioflex-cylinder (Kleinewefers KTM).

Bicomponent fabric crimping → crimping methods.

Bicomponent fibres (bilateral fibres, composite fibres). Man-made fibre combinations composed of 2 distinct and insepararable polymer components having different chemical or physical structures joined together as single fibres either in layers side-by-side or in mixtures with a homogeneous distribution (matrix-fibril types). Bicomponent fibres are products of spin-texturing from the bifilar spinning of heterogeneous spinning solutions (2 different polymers having different shrinkage properties or different solution concentrations of the same polymer), e.g. 2 different acrylic polymers or combinations (acetate/polyacrylonitrile; polyamide 6/polypropylene; polyamide 6,6/polyester, etc.). The various types of bicomponent fibre are classified as follows (see Fig.):

- S/S (side-by-side) having a “bilateral structure” as in wool.
- C/C (centric cover/core) or core-sheath types.
- M/F (matrix-fibril) or fibril/matrix bicomponent fibres, sometimes referred to as biconstituent fibres.

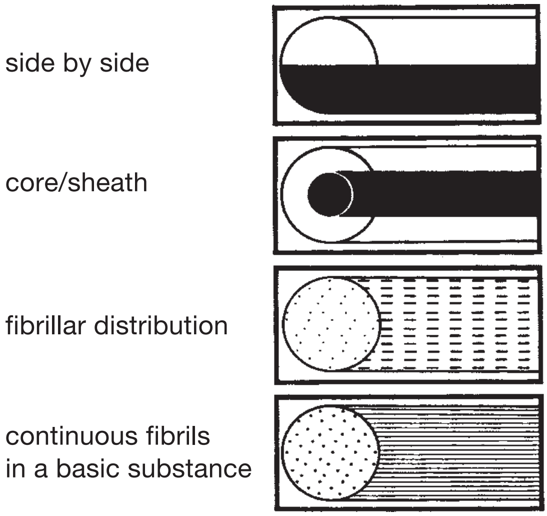

Fig.: Biocomponents fibre structures and cross-sectional forms of synthetic fibres.

According to American convention, only types S/S and C/C qualify for description as bicomponent fibres. Bicomponent fibres having a very wool-like character with a permanent spiral crimp and further combinations of properties are formed after e.g. a simple thermal aftertreatment. Fibres produced e.g. by the combined polymerization (multi or copolymerization) of two monomers, as well as → Heteroyarns are not considered to be bicomponent fibres. The M/F types are, in the widest sense, also bicomponent fibres and consist of very fine fibrils (either continuous or distributed as short fibrils) embedded in a matrix structure. They are also described as biconstituent fibres and are of increasing importance. Up to the present time, however, the S/S types, in which both components are joined excentrically and continue along the entire fibre, are of the greatest importance economically. For this purpose, the components are carefully selected to react in different ways to the effects of heat and moisture or to a combination of both. As early as 1953, such bicomponent-like fibres were already described by Horio and Kondo from the detection of paracortex and orthocortex layers in dyeings of wool fibres. In bicomponent fibres a crimp, which may be reversible or irreversible, is formed by the different reactions of both fibre components to heat and/or moisture. A reversible crimp is lost on washing and regenerated again on subsequent drying. In the case of irreversible crimp, a spiral crimp is developed which becomes permanently set through relaxation of the differential shrinkage potential of both components during the first treatment at high temperature in a dry or moist state. A crimp developed in this way remains largely constant during subsequent dry and wet treatments unless the temperature limit used for the original development of crimp is significantly exceeded.

A reversible crimp, on the other hand, which is lost during wet treatment and can be restored again on subsequent drying, is produced by a different mechanism. The difference in shrinkage results from a reversed swelling of both components; e.g. wool and ionically-modified polyacrylonitrile fibres are typical reversible bicomponent crimp fibres. The latter contain different concentrations of hydrophilic groups in both components. These can cause significant drawing forces to be released at high temperatures in the wet extended state without their final crimp potential being impaired. In this case, the crimp returns on drying which is why decrimping is controlled solely by free movement or tensile forces during the drying process. This is of great practical importance since reversible crimp bicomponent fibres are processed, e.g. under high tension conditions as in package dyeing, and yet their full crimp potential can still be developed during a subsequent tension-free drying operation.

The purpose of all bicomponent crimping is to develop bulk, crease recovery properties and elasticity in yarns and fabrics besides conferring numerous handle variations on textile fabrics.

Bicomponent yarn Spun or filament yarn of two generic fibres or two variants of the same generic fibre. → Textured yarns.

Biconical package A conical yarn package in which the traverse length is progressively reduced to produce tapered or rounded ends; such packages are also described as tapered or → Pineapple cones.

Biconstituent fibres → Bicomponent fibres of the matrix-fibril (M/F) type.

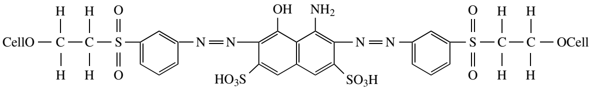
Bielastic, 2-dimensional → Elasticity in knitted textile fabrics.

Bifilar (bi = two; fil = fibre, filament, yarn). A term used for:

I. → Bicomponent fibres/filaments manufactured by bifilar spinning, e.g. the production of polyamide/polyester simultaneously, side-by-side without blending from the same spinneret hole, accompanied by final adhesion to produce a double filament. This is an example of real spin-texturing.

II. In the sense of two thin threads (instead of one thicker one), e.g. as used in knitting/warp-knitting for the production of dimensionally stable, long-lasting men’s underwear (double-thread circular knits).

Bifunctional A term used to describe certain kinds of reactive dyes, i.e. with two reactive groups in the dye molecule. The reactive groups may be identical or possess different reactive properties. Such dyes are also described as → Double anchor types.



C.I. 20 505 reactive black 5 bonded to cellulose

Crosslinking agents containing fibre reactive groups (reactant finishes) are at least bifunctional as well.

Bijar carpets Very densely knotted boardlike stiff carpets from the Persian town of the same name. Naturalistic designs with floral motifs often in a formal interpretation. The ground shades are dark: dark blue, cherry red, bottle green but sometimes camelhair colour, while the colours used for the designs are very vivid. The close-cut pile (10–12 mm high) is of high quality lustrous wool. Approx. 180 000 Turkish knots per m^2.

Bilateral (Lat.), having or involving two sides.

Bilateral fibres → Bicomponent fibres.

Bilateral structure of fibres, relates to the cortical layer present in the structure of wool consisting of the para and orthocortex, as well as the different polymer structure in the cross-section of cotton fibres. Silk which has not been degummed also reveals a bilateral structure.

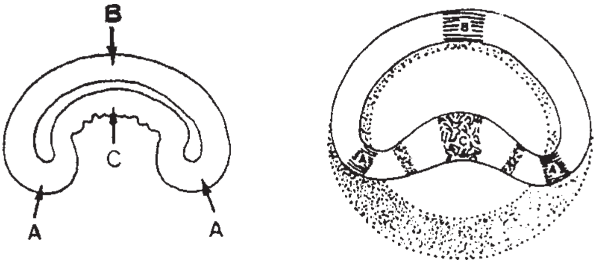


Fig. 1: Bilateral structure of cotton (Kassenbeck).
A = most highly ordered; B = densely packed; C = disordered.

I. Bilateral structure of cotton (Fig. 1): After completion of biosynthesis, cotton is present in the fruit capsule as a cylindrical fibre. The capsule breaks open and the young fibres undergo a drying process. Kassenbeck was able to show that the fibre collapses characteristically depending on its origin (maturity, provenance, fineness), to form the well-known kidney-shaped cross-section. (Another assumption is that the collapsed fibre actually grows in that state). During this collapse (original drying) asymmetrical mechanical tensions are built up that are responsible for zones having different densities. Radial strains acting through compressive forces result in an increased packing density of the fibrils and a parallel alignment of fibril layers in the convex area of the collapsed fibre. The concave internal fibre wall suffers a reduced degree of order due to the compressive forces which act tangentially. From a macroscopic viewpoint, this bilateral structure of the fibre is responsible for the different accessibility of the various fibre regions. This is the reason why e.g. during enzymatic hydrolysis of the fibre (a process, like all finishing treatments, which is associated with a swelling of the fibre wall) the disordered concave region is broken down preferentially; the remaining convex region is only dissolved at a very advanced stage of the hydrolysis. Kassenbeck also showed that this concept also has consequences for fibre crosslinking with formaldehyde. After crosslinking, it was indeed found that far more linkages had been formed in the concave region of the fibre due to its greater accessibility; due to the high degree of swelling during crosslinking, however, the linkages formed were mainly interfibrillar. In contrast, the degree of swelling and accessibility in the convex region of the fibre was so slight that only few (interfibrillar) linkages were formed. These were nevertheless very effective in relation to the desired mechanical stabilization of the fibre. A disadvantage of this aspect of the crosslinking process is the reduction in strength of the already strong convex region of the fibre due to its high degree of orientation. Since the strength of the disordered concave regions is not changed by crosslinking, i.e. undergoes no improvement, the total strength of the fibre decreases.

Kassenbeck has demonstrated that, from a macroscopic viewpoint, swelling of the fibre is dependent on the swelling agent used. Thus, e.g. it was established that, in contrast to sodium hydroxide solution or morpholine, caesium hydroxide has a specific swelling action on the concave regions of the fibre.

II. Bilateral structure of viscose fibres: The usual staple fibre types based on regenerated cellulose fibres in a not very stable crimped form have been known for a long time. In recent years, however, new technologies have been developed, based on special coagulation, regeneration and drawing conditions, which have led to the production of viscose fibres with a "living" reversible crimp. This special spinning technology has the effect of causing the primary external mantle of the newly-spun fibres, formed in the spinning bath during the fibre forming and drawing stages, to tear in small places so that the still plastic fibre core can spread many times along the fibre capillaries to the fibre surface. As a result, a kind of bicomponent structure is formed (→ Bicomponent fibres) in which the elongation and swelling properties induced by the variable fine struc-

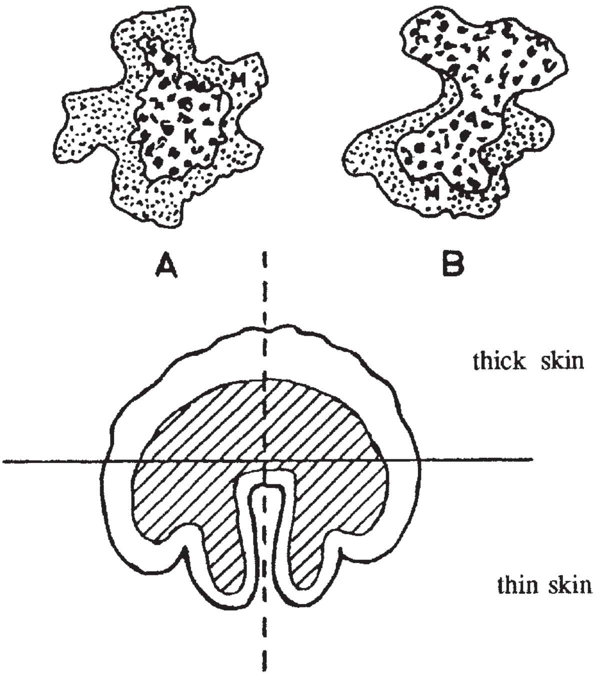

Fig. 2: Bilateral structure of viscose fibres.
Cross sectional structures of normal viscose fibres (A = cord/ sheath; B = highly crimped biocomponent fibre) as developed in accordance with the original Horio and Kondo concept (below) (thick skin = undyeable; thin skin = dyeable).

ture of the core/mantle regions give rise to a latent crimp capacity and crimp recovery properties. The crimp formed in this way is distinguished by the simultaneous presence of overlapping macro and microcrimp characteristics which give these fibres their specific properties. Bicomponent viscose crimp fibres (Fig. 2) were first produced by Horio and Kondo as soon as they had applied the bilateral concept of wool fibres and proved that the existence of the orthocortex and paracortex in wool was responsible for its crimp characteristics.

III. Bilateral structure of wool: In 1953 the Japanese researchers Horio and Kondo found that the cortex of wool fibres does not have a uniform structure but consists of two chemically somewhat different halves, namely the orthocortex and the paracortex. The two portions can be made visible by differences in swelling under the polarizing microscope or by differences in staining. The orthocortex has a higher affinity for cationic dyes, e.g. Janus green or methylene blue. Staining with Rhodamine B is also suitable. The distribution of these cell types within the cortex is variable and extends from a bilateral axial asymmetry to a radial symmetry. The extreme is found in fine, highly crimped merino wool where a characteristic subdivision of the cortex into approx. equal corkscrew-like ortho- and paracortex components lying side by side and intertwined with each other can be observed. The other extreme is encountered in coarse wool sorts, e.g. Buenos Aires wool and Lincoln wool, which are not so highly crimped and in which a core of orthocortex is surrounded in a tube and sheath configuration by the paracortex. Human hair, on the other hand, consists almost entirely of paracortex and the slightly wavy kid mohair almost entirely of orthocortex (Fig. 3). From the finer more highly crimped to the coarser slightly crimped fibres, distribution of the ortho and paracortex changes correspondingly from the merino type with a bilateral asymmetrical structure to the coarse wool type with a centrally arranged orthocortex. In general, therefore, a low

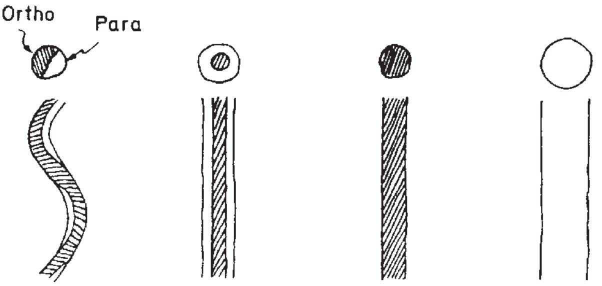

Fig. 3: Cortex forms in keratin fibres with and without bilateral structure.
from left to right: merino wool, Buenos Aires wool, kid mohair, human hair.

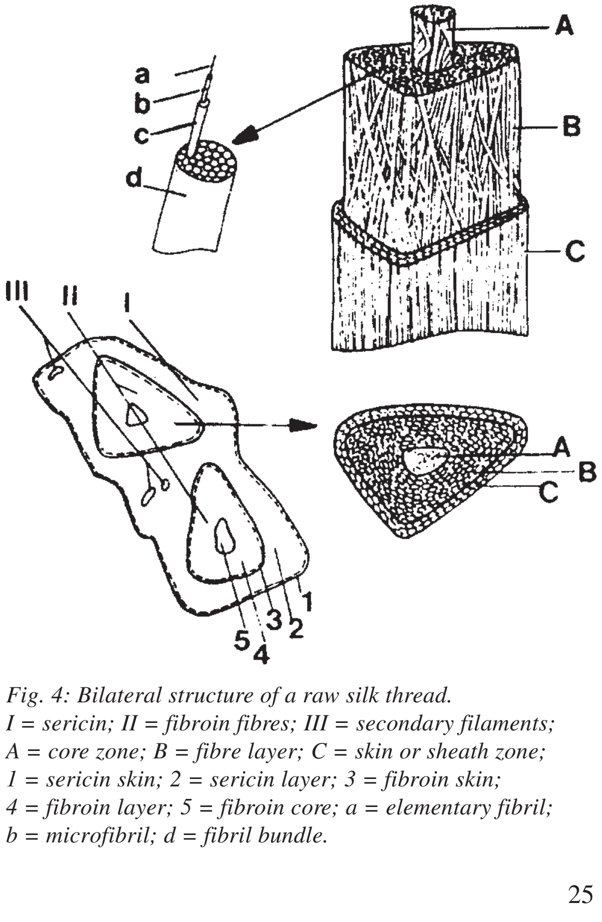

Fig. 4: Bilateral structure of a raw silk thread.
I = sericin; II = fibroin fibres; III = secondary filaments; A = core zone; B = fibre layer; C = skin or sheath zone; 1 = sericin skin; 2 = sericin layer; 3 = fibroin skin; 4 = fibroin layer; 5 = fibroin core; a = elementary fibril; b = microfibril; d = fibril bundle.

degree of crimp corresponds to a more symmetrical arrangement of both components. The orthocortex cells exhibit a distinct subdivision in macrofibrils whilst the macrofibrils in the paracortex appear to have indistinct limits. It has been found that the content of the amino acid cystine is greater in paracortex cells and therefore the paracortex is chemically more stable due to the higher degree of crosslinking.

The high crimp of the merino fibre is consequently due to its peculiar bilateral structure in which one half of the cortex is always found on the inside of the crimp curvature and the other on the outside. The crease recovery of wool fabrics in a moist environment can also be attributed *inter alia* to this phenomenon. Since one half of the cortex swells more than the other because of its somewhat different chemical structure, and to the extent that changes in moisture induce fibre movement and permit recovery of deformations during wear, such changes cause one half to increase in volume more than the other, thereby displacing the other firmly attached half from its position.

IV. Bilateral structure of silk (Fig. 4): Silk also exhibits a bilateral structure before degumming. The two filaments of fibroin are spun together within the sericin so that the fibre cross-section exhibits a distinct double core-mantle structure.

BIL crease-resist process (built-in lubrication). Crosslinking process to preserve the natural mechanical properties of cotton by incorporating stearyl derivatives of 1,3-dichloropropanol-2.

Billinghame's test A test for distinguishing between abaca and sisal. The test, devised by Swett, for the differentiation of abaca (manila) from other fibres used in rope manufacture has certain disadvantages. These are the uneven staining effect, the difficulty in distinguishing at a glance between the colours produced, and the tendency of the colours to fade. The method of applying Billinghame's test is as follows.

1. Wash the sample with methylene chloride to remove oil, and allow to dry.
2. Boil the sample in 5% nitric acid for 5–10 min.
3. Wash out the excess acid with water and immerse the sample in cold 0,25n sodium hypochlorite solution for 10 min.
4. Remove the sample and dry it.

Abaca assumes an orange colour, whereas sisal and other leaf fibres are stained a pale yellow colour.

Bimetallic strip Two metals having different coefficients of expansion riveted, brazed or welded together in the form of strip or wire: an increase in temperature of the strip causes it to bend, the metal having the greater coefficient of expansion being on the outside of the curve. One end is rigidly fixed and movement of the other end can serve to open or close the electric circuit of a temperature control device, or to move the pointer of a pointer-type thermometer.

Bimli jute → Kenaf.

BIN Belgian standards association. → Technical and professional organizations.

Binary Consisting of two components, e.g. of 2 fibres (cellulose/polyester); of 2 solvents (water/alcohol); or chemical molecules composed of 2 elements (CH_4, H_2O, NaCl).

Binary decision A decision between 2 known states, e.g. the two possibilities "yes" or "no", or in telegraphy "character" and "pause" or "current" and "no current" etc. The term → Bit, is derived from "binary digit" (binary code).

Binder and crosslinker combinations for pigment printing In the pigment printing process, pigments are fixed on a textile material with the aid of binders. For this purpose, redispersible condensation binders are employed to produce pigment prints with satisfactory colour fastness for normal usage.These binders are high molecular weight products, i.e. long-chain organic compounds. The softness of the binder film is directly related to the respective glass transition temperature (T_G) or second order transition temperature. This temperature characterizes the transition from a glassy solid to a plastic material. A soft film at room temperature therefore has a low glass transition temperature (see Table).

	film characteristics			
		swells in		glass temperature
monomer		H_2O	LM	T_G ° C
styrene	hard	no	yes	+ 100
acrylate				
(methyl residue)	hard	no	somewhat	+ 5
(butyl residue)	soft	no	yes	– 54
acrylonitrile	hard	no	no	+ 97
vinyl acetate	hard	scarcely	somewhat	+ 32
butadiene	very soft + elastic	no	yes	cis - 102 trans. - 58
methacrylic acid	hard	yes	no	+ 106
acrylamide	hard	somewhat	no	+ 165
ethylene	soft	no	yes	- 125
propene	soft	no	yes	- 8 b. - 13
(di-)chlorethylene	hard	no	yes	+ 81

Tab.: Properties of homopolymers as binder and cross-linker combinations for pigments prints.

Copolymers are produced from these monomers which represent the best possible compromise with regard to their properties since these, in turn, determine the properties required of the actual binder films (linking together of materials by adhesion) and cohesion (the internal molecular cohesion of a substance), softness and elasticity, resistance to hydrolysis, thermoplasticity, ease of fixation, resistance to solvents, stability to light and resistance to ageing. During polymerization, the monomer units are added together to form solid materials which, after completion of polmerization, are present in the aqueous phase (at concentrations of approx. 40–50%) in a finely dispersed state (particle size approx. 100–400 nm). The majority of such binders are acrylate and butadiene binders. The first group have the highest stability to light. Butadiene binders, on the other hand, whilst producing binder films of excellent softness, do not have satisfactory light resistance owing to the action of light and/or heat on the double bonds still present in the polymer which leads to embrittlement and discoloration (browning) of the binder film.

An important requirement for textile printing binders is the balance between ashesion and cohesion. The adhesion of binder film/substrate should be as high as possible with good binder cohesion at the same time. If adhesion is too weak, unacceptable marking of the prints occurs on rubbing. If cohesion is too weak, the pigment particles are detached from the binder film relatively easily on rubbing.

Binders for textile pigment printing contain self-crosslinking free methylol groups which are protected against premature crosslinking by esterification. During drying, film formation of the binder occurs in 2 stages. In the first stage, water and emulsifier are removed from the binder resp. the pigment print by evaporation and capillary action of the fibre whereby the dispersed materials (binder, pigment) coagulate to form an unstable gel layer. In the second stage, the gel layer merges to form a film which, from this point on, bonds (even though loosely) with the textile material. Only after subsequent crosslinking (fixation) does the binder film develop its full adhesion to the substrate and its elastic extensibility. The crosslinking reaction proceeds under acidic conditions (pH < 4) by elimination of water and alcohol to form a 3-dimensional structure. The best fixation medium is hot air treatment at e.g. 150°C for 5 min. (or at 175°C for 45–60 s). Wet steam is not suitable as a fixation medium. Fixation in superheated steam (HT steam) is also less suitable than hot air since only a 60–80% fixation yield is achieved in this case due to partial hydrolysis (HT steam consists exclusively of water vapour).

An additional crosslinking of the binder film is achieved with the aid of so-called external crosslinkers of the esterified melamine type in accordance with the same (condensation) principle (see Fig.). Wet fastness properties, especially on synthetic fibres and their blends with cellulosic fibres, are improved by this further crosslinking although it is accompanied by an increased stiffening of the prints. Due to this undesirable effect on handle, the quantity of crosslinker applied should be limited only to that amount which is absolutely necessary. The binder film, in which the pigment particles are embedded, has a layer thickness of only 8–10 µm, a dimension which is not visible to the human eye. Adsorptive bonding forces are responsible for adhesion between the binder film and the fibre (Wigger).

Binder fibres, are used for the manufacture of composite textiles resp. nonwovens. Synthetic fibres with thermoplastic properties (preferred temperature range 160–190°C) or which are soluble or capable of swelling in specific solvents are used for this purpose. They may be subdivided into the following categories:

1. Soluble binder fibres such as polyvinyl alcohol and alginate fibres.
2. Meltable binder fibres such as copolyamide, bicomponent, copolymer thermoplastic fibres with low melting points. These can function as an adhesive in a web because their softening point is relatively low compared to that of the other fibres in the material.
3. Adhesive binder fibres such as cellulosic fibres (capable of swelling in alkaline solutions) and undrawn polyester fibres which already become tacky at 80°C, shrink markedly and develop their bonding effect under the action of heat and/or moisture in thermo-bonding plants or a hot calendering treatment, etc.

Binder film A film of → Synthetic resin resp. polymers formed around the individual fibres of a textile fabric in pigment printing, and in which the coloured pigment is embedded.

Binder prints on polyester (pigment print) Normally reveal lower rubbing fastness as compared with cotton, since here the binder is surface-abraded, and

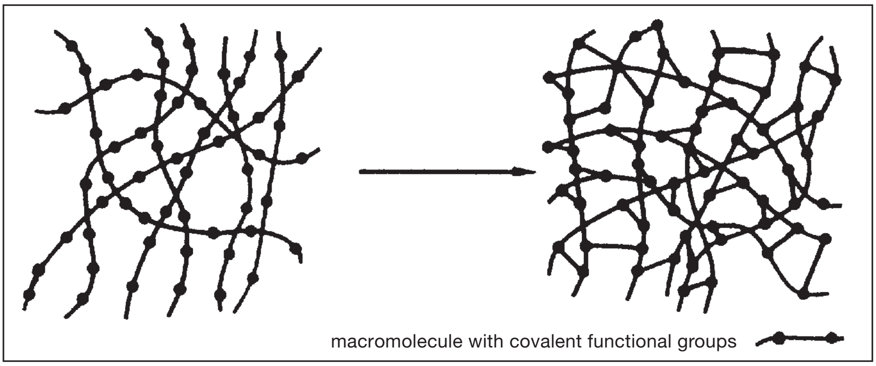

Fig.: Binder film cross-linking in pigment printing.

drawn out from the fibre interior (polyester binder dyeing appears surface blank abraded), while, with cotton, adequate residual binder quantities remain in the fibre cavities (cotton binder dyeing with preserved impression). Fig. 1 shows schematically the distribution and stripping of binder prints on polyester and cotton.

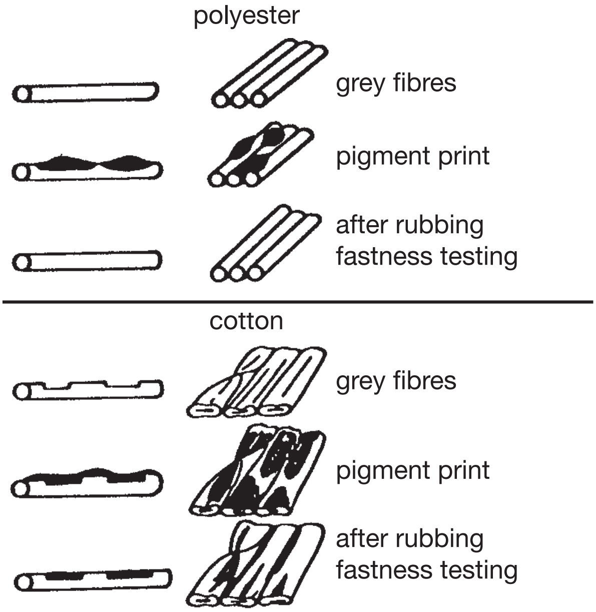

Fig. 1: Deposition of binder in pigment printing on polyester and cotton (Herrlinger).

Mechanical anchorage of the binder film (Fig. 2) can be brought about by the surface modification of chemically raised polyester fibres, by means of which binder print fastnesses identical with those of cotton can be produced.

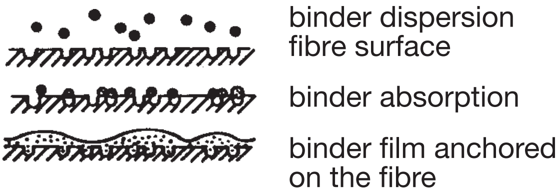

Fig. 2: Embedding of binder and pigment in the pigment printing of alkalised polyester fibres (Herrlinger).

Binders Organic polymer products used for the fixation of pigment prints/dyeings and as adhesive bonding agents for web consolidation in the manufacture of stable composites and nonwovens. They are mainly solid plastic products (e.g. thermoplast powders), plastic solutions and dispersions (also including reactive types, e.g. acrylic ester copolymers). Binder additives based on N-methylol compounds, fatty acid derivatives and polyethers, etc. have binder regulating and/or modifying functions, e.g. for the achievement of elastic resilience, flexibility, absorbency, drycleaning fastness, etc.

Binders for nonwovens Besides thermoplastic materials which, either as fibres or granules (powder bonding) contained in the batt, function as adhesives when the batt is hot calendered, aqueous polymer dispersions are mainly used for the bonding of nonwovens. Actual solutions of binders in water or organic solvents are very seldom used.The main types of polymers, in the form of aqueous dispersions, for these applications are:

- acrylic ester copolymers and homopolymers,
- butadiene-acrylonitrile copolymers,
- styrene-butadiene copolymers,
- chloroprene polymers,
- vinyl chloride polymers,
- vinyl acetate polymers,
- vinylidene chloride polymers,
- natural latex.

The overall properties profile of nonwovens manufactured with the aid of the above-mentioned polymers is influenced to a considerable extent by the type of binder used. Thus, for example, the thermo-bonding of nonwovens based on cellulosic fibres may be carried out if an extremely thermoplastic polymer such as, e.g. polyvinyl chloride or polyvinyl acetate is used.

The choice of binder is dependent on the end-use of the nonwoven material. A wide range of nonwovens is produced by adhesively bonding the individual fibres in the batt with the aid of polymers. In approx. two thirds of all adhesively bonded nonwovens, the actual bonding of fibres in the contact areas is achieved with binders applied in the form of aqueous dispersions. In the remaining cases, the bonding polymers are applied in fibre (→ Binder fibres) or powder form. For the application of polymers dispersions in the bonding of nonwovens, the primary concern is the influence of the respective binder type or dispersion composition on the character of the bonded nonwoven.

This important relationship between dispersion or binder composition and the character of the nonwoven can only be clearly established when the physical and chemical criteria of polymerization on the one hand, and those of the dispersed polymer on the other, are defined. Three temperature ranges are important for thermoplastic polymers:

1. The transition or softening temperature, also known as the first order transition temperature or glass transition temperature: at this point the plastic material is transformed from the solid to the thermoelastic state. This temperature range can be lowered by, e.g. internal softening (copolymerization) or external softening (plasticizer addition).
2. The flow or melting temperature range: at this point

the plastic material is transformed from the thermoelastic to the thermoplastic state.

3. The decomposition temperature: at this point irreversible decomposition of the thermoplast takes place due to thermal decomposition (carbonization).

The glass transition temperature (T_G) provides a great deal of information on the use of thermoplasts as binders for nonwovens. In the first place, it indicates the relative hardness or softness of the polymer. Thus, a high T_G signifies a harder, a lower T_G (–20°C) signifies a softer, and an even lower T_G (–30°C) signifies an adhesive binder film. The T_g is measured by differential thermal analysis. A high T_G also signifies a minimum film-forming temperature. The T_G influences the properties of the bonded nonwoven in various ways. For example, inferences can be drawn from it with regard to the handle of the nonwoven although, in this connection, other factors such as, e.g. the chemical composition of the binder and its additives have a decisive influence here. A relationship between T_g and the dry tensile strength of the nonwoven can also be seen.The T_G can be changed by copolymerization or external plasticizing (e.g. with dibutyl phthalate). Conversely, binders with the same T_G can be obtained from different copolymer compositions (see Table).

binder monomer	T_G (°C)	polymer film character	application method	use
methyl methacrylate	+107	brittle ↑		
acrylonitrile	+105			e.g. nonwoven wadding, filter wadding, needle felt ↓
styrene	+100		↑	
vinyl chloride	+ 83	↓		↑

Tab.: Dependency of T_G and its deducible properties on binder monomer type.

From the number of individual components in the recipe, the preparation of vulcanizable latex mixtures appears to be very complicated. On the other hand, a self-crosslinking polymer dispersion is much simpler to prepare since, as a rule, it only has to be diluted with water. Nevertheless, vulcanizable systems have a range of advantages which self-crosslinking systems are unable to offer. One of the most important advantages has to be the possibility of separating the drying and crosslinking stages from each other. This property makes it possible to manufacture both very thick materials by pressing before vulcanization under pressure as well as specially shaped products by permanent moulding during vulcanization. Technical nonwovens, in particular, are manufactured with vulcanizable latex mixtures. Interesting properties are also achieved with vulcanizable binder mixtures. Such mass-produced articles as disposables or hygiene products are not a field for vulcanizable latex mixtures. Specialized fields such as, e.g. the filtration sector, however, offer a wide range of applications especially when additional requirements for environmental protection are taken into account, e.g. where chemicals, dusts, oils and fats, in particular, must be separated from industrial exhaust air and waste water by filtration methods (partly contributed by Loy).

Binding (edging). Usually a broad tape used as a → Trimming, e.g. as a decorative border for underwear, aprons, national costumes, etc.

Bioactive Term used to describe the function of biologically active substances, e.g. → Biodegradation of surfactants and → Biofouling. → Enzymes are also bioactive.

Biocatalysts → Enzymes.

Biocatalytic exhaust air cleaning in known washing processes for reducing contamination from exhaust air are either → Activated sludge processes used or biological lawns on packing material built. Both processes show in practice for the industrial user significant deficiencies. In particular sludge formation clogging danger and the behaviour/quality/retention of failing nutrition offer in times of plant standstill are some of the unfavourable aspects. By combination of physical absorbers (arranged filling material packets in counter current principle) with a biological carrier recycling water purification plant (Fig.) these disadvantages are avoided and in addition the supervision expenses are limited only to the mechanical part of the system. The contamination in the exhaust air is washed

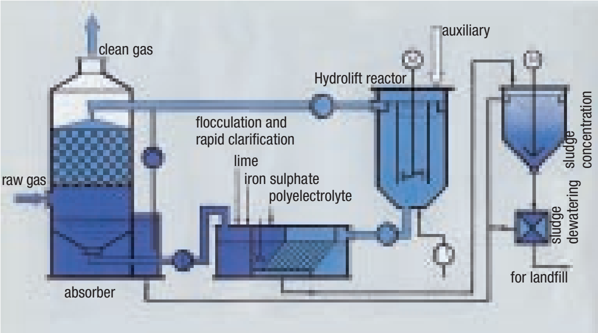

Fig. 1: Biocatalytic exhaust air treatment plant (from Arasin GmbH).

out in the counter current of water. The amount of liquid is adjusted according to the solubility of the contaminants as well as by the partial pressure of the substance in the gas phase and the partial pressure of the substance in the liquid. A part flow of the recycling water is removed continuously. Sand and solid particles are separated in a inclined clarifier; then follows the carrier biological oxidation in a hydrolift reactor. The water treated in this way is led directly back into the washer and recharged with contaminant.

The carrier biology of the activated charcoal offers even more advantages over fixation of bacteria in a reactor. To the possibility of accumulating, large amounts of oxygen contaminants are absorbed temporarily from the wash water. Activated oxygen and contaminants are then available to directly to the microorganisms fixed on the activated charcoal. Likewise exoenzymes are adsorbed on the carrier medium which are necessary for certain degradation reactions. By the immobilisation “bacterial specialists”, which otherwise have a slow rate of growth, also remain enriched, and so are available for substances that are difficult to degrade. The carrier material always remains in the reactor and is practically not used up at all. The reaction event is not determined by the adsorption capacity of the activated charcoal, but by the constant regenerating self oxygen active surfaces of the activated charcoal and the biomass fixed there. The complete, complex degradation process in the fluid bed can be simply summarised by the following reaction equation.

$$C_AH_BO_C + x\ O_2 \rightarrow y\ CO_2 + z\ H_2O$$

Biochemical oxygen demand (BOD) A standardized means of estimating the degree of pollution of water, especially that which receives contamination from sewage and industrial wastes. It is expressed as the quantity of oxygen (in mg) required during the oxidation of decomposable organic matter by aerobic biochemical action in 1 l of waste water. In practice the test is carried out over a period of 5 days at 20°C to give the so-called BOD_5 value which is used as a measure of organic pollution in waste water. A low BOD indicates low pollution whilst a high BOD indicates increased activity of heterotrophic microorganisms and thus heavy pollution. In an optimally functioning biological waste water treatment plant the BOD_5 value of waste water is reduced by 80–95%.

The BOD_5 value is determined in accordance with DIN 38 409 T51/05.87. In this test a series of waste water samples taken from, e.g. the main outfall of a waste water treatment plant, at different dilutions, is injected with oxygen-saturated water containing microorganisms. Optimum physiological conditions, as well as the supply of mineral nutrients, are prerequisites for a correct determination. A so-called nitrification inhibitor is added to the water in order to stop the biochemical oxidation of ammonium nitrogen, since otherwise the results obtained have poor reproducibility and may present problems in interpretation. Measurements of the oxygen concentrations are based on the cathodic reduction of dissolved oxygen on a metal surface in the limiting overload range at constant voltage (amperometric determination). → Chemical oxygen demand.

Biocoenosis A great number of animal and plant species live in a particular → Biotope; they form a living association. Thus, a biocoenosis is the population system of a particular biotope which, due to biological interdependence represents an associated structure (biocoenotic connection). This qualitative and quantitative structure is not only a collection of organisms *per se*, but the basic form of a diverse (heterotypical) collection of organisms that has adapted to a particular biotope. The terms biotope and biocoenosis are as closely related in → Ecology as a lock and key.

Biodegradable textiles Textiles are biodegraded as the final biological treatment in a chain of natural fibre polymer chemical processes (from the raw product via textile fabric production to finishing), when enzymatic breakdown processes of a complex type take place on the fibre polymers. Biological breakdown or biodegradation means the conversion of dissolved or solid substances by organisms into other compounds. Next to assimilation by means of photosynthesis, where dissolved substances are absorbed by the biota, the biological breakdown of organic compounds by micro-organisms like bacteria and fungi is the most important process. In this process, the organic substrates are oxidised, the micro-organisms using part of the released energy for reproduction. This type of respiration (frequently called mineralisation too) consumes oxygen, or, if that is not present, other oxidising agents like nitrates, sulphates or already partially oxidised organic compounds in the sequence reproduced in the illustration.

When a system containing little oxygen is charged with organic components (L) from domestic waste, the following reactions take place:

- oxygen exhaustion; as soon as all the oxygen has been consumed, anaerobic breakdown reactions occur in the subsequent sequence (decrease in free enthalpy):
- nitrate reduction (denitrification)
- reduction of manganese oxide
- reduction of iron hydroxides
- fermentation (e.g. alcohol fermentation)
- methane fermentation.

Other redox reactions are nitrogen fixation and nitrification. Most reactions are catalysed by micro-organisms (bacteria, fungi). The latter are present every-

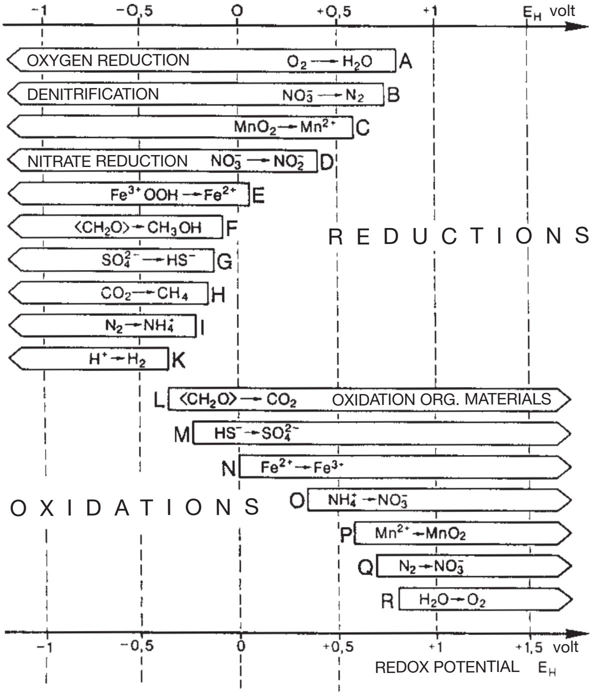

Fig.: Microbial redox process sequences, e.g. in the biodegradation of biologically degradable textiles (according to Kümmert and Stümm).

where, and multiply as soon as suitable reaction conditions are present.

Aerobic respiration: organic substances are oxidised, and oxygen is reduced. In the ideal case, oxidation results in carbon dioxide and water:

$$(CH_2O) + O_2 \rightarrow CO_2 + H_2O$$

Anaerobic respiration: organic substances are oxidised to carbon dioxide, and carbon dioxide is reduced to methane (methane fermentation):

$$(CH_2O) + {}^1/_2\, CO_2 \rightarrow CO_2 + {}^1/_2\, CH_4$$

or

$$(CH_2O) \rightarrow {}^1/_2\, CO_2 + {}^1/_2\, CH_4$$

with nitrate or sulphate:

$$4\,(CH_2O) + NO_3^{\ominus} + 2\,H^{\oplus} \longrightarrow 4\,CO_2 + NH_4^{\oplus} + 3\,H_2O$$

$$2\,(CH_2O) + SO_4^{\ominus\ominus} + 2\,H^{\oplus} \longrightarrow 2\,CO_2 + H_2S + 2\,H_2O$$

The active bacteria here produce enzymes, which, as biological catalysts, make possible (accelerate) the decomposition process. Of the large number of conditions which can interfere with the process of degradation, one can distinguish between two types of finishing chemicals:

1. Anti-catalysts in the form of adherent chemicals.
2. Chemical modifiers of the fibre materials themselves.

In the past, the textile industry has aimed to make finishing as fast as possible, i.e. to bond chemicals and dyes as fast as possible to the fibre, or produce effects against external influences (light, washing water, bacteria, air) by the most permanent finishing possible. Indicated by way of example is antimicrobial finishing, which is used to provide an anti-rot finish for natural fibre textiles. It is necessary to note in this connection that the targeted disposal of textiles by biodegradation, i.e. by biological breakdown, is conceivable only for natural fibres (wool, silk, cotton, linen [flax], and viscose as a semi-synthetic fibre). Synthetic fibres have to be disposed of in other ways; recycling (e.g. by remelting) appears appropriate for these polymers. If we want to pursue the goal of a biodegradable natural fibre collection over the long term, one has to have prior knowledge of textile logistics. The ways in which textile waste is ultimately disposed of have to be clarified. The importance of biodegradation, i.e. ultimate waste textile disposal in refuse by anaerobic (and to some extent aerobic) fermentation (destruction by micro-organisms, i.e. enzymatic hydrolysis as the main process) has to be established in this way.

a) Anti-catalysts or breakdown inhibitors: diverse finishing products, particularly metal-containing dyes, can be anti-catalysts for enzymatic breakdown which is inhibited in the case of textiles dyed or printed with such dyestuffs. If such substances are left out of account, there is a distinction between the biodegradability of these fibre-attendant substances by enzymes with a rough subdivision of the dyestuffs into azo and anthraquinone dyes. Azo dyes can be split by reducing-action enzyme systems, a fact which does not readily apply to anthraquinone dyestuffs. It is not enough just to break textiles down macroscopically, i.e. so that no fibre residues are to be seen; there may be low molecular substances (metabolites) from the textile material to be found in the ground water of the waste disposal site, which may be problematic in this form.

b) Chemical fibre modification: when natural fibres have been compelled to branch at points along the polymer molecules by reactive dyes or cross-linking agents (resin finishing for a low-crease finish) in a polymer-like way, biodegradation can be impeded at those points.

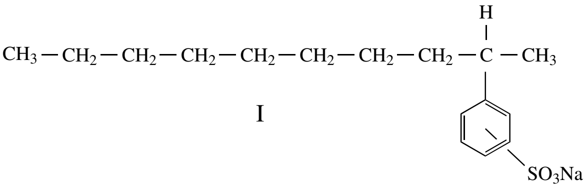
Before non-comprehensive studies on the biodegradation of current finishing products by micro-organisms are carried out, the goal of a biodegradable collection must be pushed a great deal further back. As the first step towards a production line with textiles which are the right target for feasible disposal, one should first of all fall back on such natural fibre products as have been carefully ecologically finished to the state of the art (i.e. with the minimum possible effluent and exhaust air pollution) and also with no significant residues on the fibre material. The equivalent dyestuffs should be as metal-free as possible, and dyeing should abandon brilliance and extreme fastness in order to avoid reactive dyes.

Biodegradation (→: Aerobic degradation; Anaerobic biodegradation). Biodegradation is generally understood to be the sum of all processes which reduce the load or concentration of polluting substances in water courses. As soon as biodegradable pollutants enter a water course the respiration rate increases through the reproduction of microorganisms which are universally available thereby reducing the load or concentration of pollutants. A succession of organisms is therefore built up. This heterotrophic activity is termed saprogenic (intensified decomposition of organic matter).

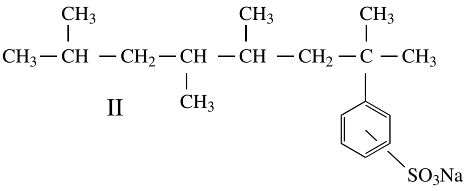
Organic carbon compounds may be broken down by aerobic biodegradation. Carbohydrates, proteins and fats biodegrade relatively quickly in waste water. Provided oxygen is available in sufficient quantity these substances are broken down into CO_2, H_2O and cell material. Nitrogen originally present in an organically-bound form is encountered as NH_4^+. A good assessment of the possibility for biological purification of a particular waste water can be made if details relating to the degradability of the respective pollutants are known. The following list of substance groupings with their biodegradability behaviour has been taken from Meinck et al:

- Saturated hydrocarbons: virtually non-biodegradable, some are toxic;
- Olefins with 5–7 C atoms: difficult to attack biologically;
- 1-chlorosubstituted hydrocarbons: non-biodegradable;
- Alcohols: readily biodegradable; exceptions are: tertiary butanol, amyl alcohol, pentaerythritol;
- Phenols: in general, readily biodegradable; chlorophenols are, however, less accessible, especially 2,4,5-trichlorophenol;
- Aldehydes: readily biodegradable after adaptation of the microorganisms; exception: benzaldehyde in higher concentrations;
- Organic acids, their salts and esters: readily biodegradable; exception: thio acids;
- Ethers: usually exhibit poor biodegradability or degradable only after adaptation of the microorganisms; exception: methylal (dimethoxymethane);
- Ketones: in terms of biodegradability these fall between organic acids, alcohols and aldehydes on the one hand, and ethers on the other;
- Amino acids: biodegradable almost without exception; exceptions: cystine and tyrosine;
- Amines, amides: readily biodegradable are: monoethanolamine, ethylene diamine, acrylamide, di- and triethanolamine, pyridine, picoline, acetanilide; difficult to biodegrade are: thioacetamide, morpholine, acetyl morpholine;
- Cyano compounds: in concentrations up to 50 mg CN/l biodegradability is usually good after adaptation of the microorganisms;
- Unsaturated compounds: readily biodegradable: allyl alcohol, acrylamide, crotonaldehyde, butadiene, styrene, cinnamic aldehyde;
- Synthetic detergents, alkylaryl sulphonates: with straight side chains in concentrations up to 150 mg/l these still exhibit good biodegradability after adaptation of the microorganisms;
- Alkyl sulphates: easily biodegraded;
- Fatty acid alcohols: easily biodegraded;
- Carbohydrates: simple as well as high molecular weight carbohydrates such as, e.g. dextrin and starch are easily biodegraded.

Biodegradation of surfactants, by means of bacterial oxidation involving the action of aerobic and anaerobic bacteria. Soaps, fatty alcohol sulphonates, alkylbenzene sulphonates with unbranched carbon chains, alkyl poly (oxyethylene) sulphates, fatty acid condensation products and saccharose fatty acid esters are readily biodegradable. In general, surfactants with straight C- chains (= “soft”, formula I) are biodegradable whilst surfactants with branched C-chains (= “hard”, formula II) have very poor biodegradability such as, e.g. alkylarylsulphonates of the tetrameric propylenebenzene sulphonate type:



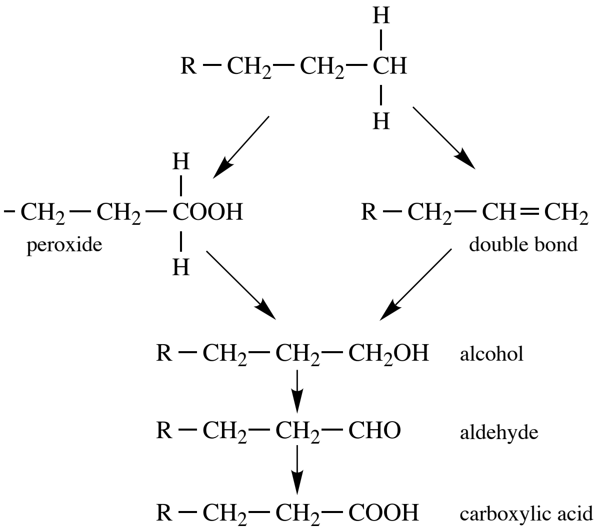
I



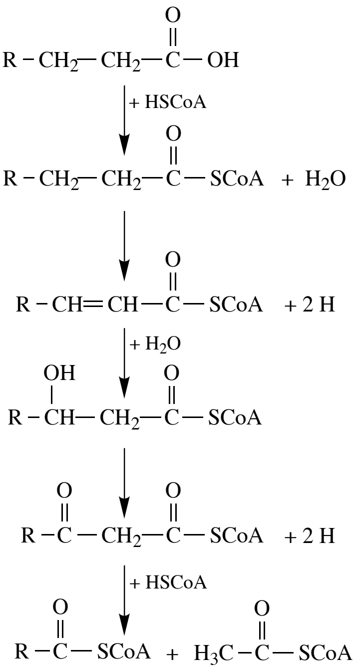
II

Of decisive importance for the degradability of surfactants are their hydrophobes. On the other hand, the hydrophilic groups of surfactants (hydrophiles) have less influence on degradability, although they are important for water solubility (as a water transport medium for bacteria cells). In general, the process starts out from an attachment of hydrophilic parts of the surfactant molecule to the enzyme and oxidation begins at the ends of the chains. There are two possibilities for the biochemical oxidation of chain molecules: ω-oxidation and β-oxidation. The ω-oxidation begins at the hydrophobes (greater than C_6), and β-oxidation at the carboxyl group in the presence of coenzyme A. Expressed with the aid of chemical formulae the reactions proceed as follows:

ω-oxidation:



β-oxidation:



No biodegradability problems exist in the case of anionic surfactants. Alkylbenzene sulphonates as well as alkane sulphonates and α-olefin sulphonates are biodegradable up to 90% and more. The question of metabolites arising from these products and the associated problem of remineralization have also been adequately answered. The same applies to the group of fatty alcohol sulphates, fatty ether sulphates and the alkyl phosphates. Even in the case of nonionic surfactants, straight-chain and partially branched-chain alcohol ethoxylates meet the requirements of the German Detergents and Cleaning Agents Law; i.e. they are more than 80% biodegradable. → Surfactant biodegradability tests.

Biodegradation of textile chemicals The long-term biodegradability of textile chemicals is a subject of great concern to the textile industry and the determination of their biodegradability is therefore very important. The biodegradability of a few chemicals, dyes and plastics in common usage by the industry has been determined over a 30-day period (BOD_{30}) in accordance with the method described below. A solution containing 150 mg/l each of glucose and glutamic acid was used as a comparison in accordance with US standard procedure. The results have shown that various chemicals investigated in this way have poor biodegradability, e.g. resin finishing chemicals based on urea-formaldehyde, melamine and glyoxal resins besides a non-ionic polyethylene emulsion and polyvinyl alcohol. The latter product can, however, be biodegraded up to 60% after 30 days under certain conditions, e.g. depending on concentration and the commercial grade. Over the same time period BOD_{30}:COD values of 92% for acidic potassium phthalate and 73% for butyl benzoate were achieved. The dyes tested also revealed very low degradation with only an insignificant reduction in colour. Pigments and inert substances can be removed by adsorption in a waste water treatment plant with a high sludge content (5800 mg/l) provided a sufficiently long reaction time is given. Measurement principle: since the five-day → Biochemical oxygen demand test (BOD_5) is insufficient for chemicals with low biodegradability the test must be carried out over a longer time period. The → Chemical oxygen demand test should also be used for the determination of degradability. On taking the duration of the test period into consideration, the quotient of both determinations, BOD/COD, gives an indication of biodegradability in most cases.

Bioelimination According to the German Federal Law on Epidemics, the Drinking Water Regulations and DIN 2000, drinking water must be free of substances harmful to human health.

With the refinement of analytical techniques it has been found that pollutants cannot, as a rule, be totally avoided (production of drinking water from riverine sources). Most of these pollutants may be detected in trace quantitites in large volumes of water. Surfactants which are used on such a large scale in domestic, commercial and industrial applications for washing, rinsing, wetting and emulsifying are also of interest here. The commercial production of washing agents and detergents for general use is only permitted if the raw materials and finished products fully satisfy all the statutory requirements relating to toxicological and ecological risks (German Washing Agents and Detergents Law, Hazardous Substances Regulations and the voluntary agreement between manufacturers to cease production of alkylphenol ethoxylates).

Surfactants introduced into waste water treatment plants in waste waters should be eliminated by adsorption or biological oxidation with the aid of bacteria and their enzymatic systems (e.g. the *pseudomonas* family). It is only due to the diverse metabolism of microorganisms that even toxic aromatic compounds (benzene, phenol) can be removed from waste waters. Primary degradation of surfactants is said to occur when it leads to the complete breakdown of biodegradable surfactants into CO_2, H_2O, inorganic salts and “normal” metabolites following bacterial metabolitic processes.

A prerequisite for the classification of a surfactant in terms of its bioelimination is a suitable test method which a) can predict possible consequences to the environment after introduction of the surfactant and b) provides an insight into the biochemical stages of bacterial metabolism (possible formation of toxic metabolites) after introduction of the surfactant (OECD screening test resp. confirmatory test, methylene blue test, bismuth test, BOD, CO_2 formation, reduction in DOC). In addition to soap, linear alkylbenzene sulphate (LAS) is the most important surfactant used in washing agents in the Federal Republic of Germany since ca. 1964 (85 000 t/year).

It is now assumed that, as primary degradation, ω-oxidation followed by subsequent β-oxidation and ring scission rapidly brings about the loss of surface-active properties. However, complete → Biodegradation to CO_2 and H_2O (secondary degradation) proceeds more slowly.

Biofinishing The treatment of cotton fabrics with cellulases (enzymes) which, accompanied by mechanical action, brings about the removal of projecting surface fibres. The treatment results in a softer handle and different fabric appearance, including stone-wash effects (e.g. applied to denim articles).

Biofouling Occurs in industrial pipework and pumps through bacterial adhesion due to contact between an aqueous medium and a solid surface. A boundary layer fauna is formed first of all by the slimy secretions from microorganisms in the boundary layer region. The influencing factors are surface roughness, surface energy, unfavourable flow behaviour, hydrophobicity, pH, oxygen concentration and viscosity.

The growth of adhering microorganisms and embedding of new bacteria is based on chemical bonding through hydrogen bonds. This adhesion is assisted by polysaccharides, proteins and lipids from the cell walls. The affected surface then reaches a state of high colonization through the development of microbial activity. The bacteria in this biofilm have a higher degree of protection against biocides than when present in a suspension. Microbial corrosion is due to the products of bacterial metabolism, organic and inorganic acids, secreted by the microorganisms which, as a rule, depend on the availability of free oxygen as an oxidizing agent (oxidative metabolism). As far as corrosion is concerned, those microorganisms which are capable of producing sulphates resp. sulphuric acid are important, e.g. through the oxidation of SO_2 and elemental sulphur by the genus *thiobacillus* to sulphates resp. sulphuric acid which will corrode virtually all metallic materials. In this regard, it is the sulphate-reducing bacteria which are of greatest importance since they are responsible for pitting corrosion, e.g. in fuel tanks where sulphates and organic compounds have been introduced by water and the bacterial formation of sulphide takes place. Microorganisms with a similar high risk of corrosion are the iron bacteria which, in the presence of chlorides, will even attack high alloy steels. Bacteria of the *pseudomonades* genus break proteins down into mercaptans, other types release acetic acid, butyric acid and ammonia. Even plastics are subject to quite dramatic corrosion damage due to the action of microorganisms. 250 types of microorganisms are known which are capable of attacking plastic materials, although some plastics, e.g., polypropylene and polystyrene, have high resistance to microbial degradation. As a rule, it is the C- or N-sources of the plastic which serve as nutrients for the particular microorganisms; the plastic is damaged and discoloured by the products of microbial metabolism.

Biofouling and the biochemical processes which take place in the boundary layer fauna are highly dependent on the surface topography (and its cleanability). On rough pore-rich surfaces colonization occurs earlier and the films still adhere longer after cleaning treatments. The greater the roughness of a material surface, the greater the boundary layer habitat for microorganisms.

Peptide residues as well as the life-sustaining oxygen of vital importance to the microorganisms are stored by these films. After the fats, particles and colloidal films have become anchored mechanically, and slimes of microorganism metabolism products and proteins have begun to accumulate, the size of these germs is a function of the surface roughness, where sizes of 0,1 μm (bacteria) to 5 μm (yeasts) are relevant.

BIOI method A variant of the → LOI test for testing the flammability of textiles.

Biological filter media In → Biological waste water treatment processing technology with biological filter media, the biomass is immobilised by being anchored on the widest variety of filter media. Slag, lava tuff, activated charcoal, coco slag, plastics and the like come into consideration for filter media. After a running period of some weeks, a biocoenosis is formed on these filter media when charged with effluent. All biological filter media have the following advantages more or less in common:

- relatively low floor space requirements and shorter reaction times due to higher biomass concentrations;
- volume reduction or elimination of the final sedimentation tank due to the favourable sludge index (Mohlmann index: the volume in cm^3, which 1 g of activated sludge dry substance takes in after half an hour's precipitation);
- a lengthy sludge period is possible (beneficial for slowly multiplying bacteria and for specialists);
- no bulking sludge or scum formation;
- due to suitable synergistically acting filter media, like activated charcoal for example, increased process stability and breakdown activity as compared with refractory effluent content substances which are biologically difficult to break down.

Translated into processing technology, these types of biological filter media are used in percolating filters (Fig.), immersion filters and suspension reactors. In the percolating filter process, the effluent is sprayed through stationary or moving nozzles over the large-pore filler with sessile biocoenosis. The water percolates slowly down through the fragmentary material (which may be stratified up to 20 m high), while air is constantly passed through the cavities, supplying the micro-organisms with adequate quantities of oxygen.

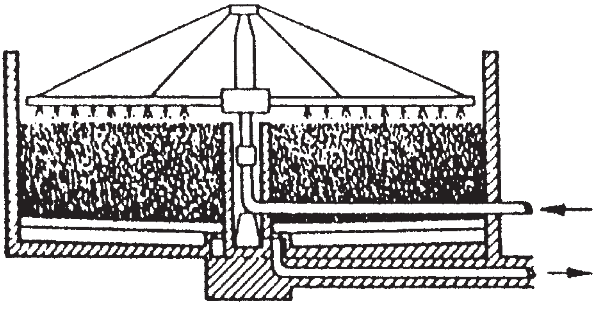


Fig.: Percolating filter.

In addition to favourable growth conditions for micro-organisms, the cleaning power of this type of immobilised reactor is dependent on the availability of geometric surface, on which the biological sward can form. Among other things therefore, performance increases are to be achieved by increasing the specific surface in the reactor. Increased performance in the practical sense however also means process stability, which, in the case of percolating reactors, suffers from the latent danger of choking, particularly with dense, large surface fillers. The following considerations arise when comparing the percolating filter technique with the activated sludge technique:

- With activated sludge plants, performance is identical with that of the percolating filter with more than double the volume charge, a fact which can be explained by the shorter contact time in the percolating filter.
- With the percolating filter process, breakdown performance falls off to a much greater extent as the volume charge is increased than with the activated sludge process, and the percolating filter consequently reacts sensitively to shock loading.
- Maintenance costs are higher with activated sludge plants than with percolating filters.
- In percolating filters, the effluent quantity is moved rather than the air or the biologically active mass.
- Approx. 30–60 Wh of power per m^3 of effluent are required with the percolating filter process, while, with the activated sludge process, the requirement is 150–350 Wh for oxygen supply and thorough mixing, plus some additional Wh for the return sludge.

By immersion filters we mean fixed bed reactors, in which fillers or baffles alternately dip into the effluent and rise into the air. The most well-known representative is the biological disk filter. In the biological section, this consists of plastic disks mounted on a shaft with a biomass clinging to both sides of the disks. These disks dip up to half their length into trough-like vessels (adapted to take the disks) and are traversed by the effluent. By means of a continuous rotary motion, the disks are first of all exposed to the effluent, being impregnated by it; they are then lifted into the air, where oxygen is made available to the bacteria for aerobic breakdown of the effluent content substances.

An interesting variant of the immersion filter system is a system in which a hollow body (cellular wheel), which can rotate about its axis, not only serves as an incrustation surface, but also draws air into the vessel as it rotates. The air then rising from the lowest point also supplies oxygen to the freely suspended activated sludge, increasing the efficiency of the system as a whole. Immersion filters can be employed to advantage with concentrated effluents, since the oxygen supply is good even at high consumption rates. Moreover, by positioning the immersion filters in series, the most favourable biocoenosis can always be established in every case. The immersion filter energy requirement is low, as only the friction loss and the difference in weight between emergent, water-laden disks and the lighter dipping disks has to be overcome.

The suspension filter process, also called the fluidised bed technique, can also be regarded as a special form of biological filter medium. Biological filter media, on which the biomass is fixed, serve as suspension media. Not too heavy granulates, in the 1–4 mm diameter granule size, of plastic, sand, light expanded clay aggregate, pumice stone and activated charcoal come into consideration for this purpose. It is important that the filter media put into the reactors are uniformly fluidised over the reactor volume. As a rule, the up-current (bubble column) technique is used when the filter medium is heavier than the medium to be treated – effluent in this case – or the loop principle (circulating fluidised bed).

Suspension filters offer two important advantages: the inert filter medium offers a large specific surface due to its granulate form, and consequently adequate room for colonisation. To this is added, in the case of so-called active filters (e.g. → Activated charcoal), the geometric factor of the inner surface, and, particularly, a synergetically amplifying and accelerating power, thanks to the qualitative surface nature of specific carbons. The use of activated charcoal as the suspension filter medium in fluidised bed reactors has been familiar for approx. 15 years in the Katox system developed by Krupp.

Biological oxygen demand → Biochemical oxygen demand.

Biological tower Atmospheric oxygen is introduced in increasing quantities in the activated sludge process of biological → Waste water treatment. Micro-organisms convert degradable pollutants into carbon dioxide and water, building up a bacterial mass. Aerobic bacteria require a supply of oxygen to this end. The micro-organisms multiply rapidly in the presence of biologically acceptable substances to form a large quantity of activated sludge, sludge return maintaining the particularly beneficially high sludge concentration. This is followed by accelerated breakdown, so that, in comparison with the simple oxidation ranges, the time required is reduced to approximately one hundredth, and is then only 4–12 hours. In the activated sludge process, the constructional and operational methods mentioned in the list can differ. The most widespread is single-stage biological basin which exists in numerous variants. For example, the type and method of effluent feed and mixing in activated sludge tanks and the type and method of oxygen introduction can be modified, e.g. by means of surface ventilators or nozzles.
Activating process:

- single-stage biological basin (→ activated sludge process),
- multi-stage biological basin,
- biological filter media (Katox, Biokop),
- high-load activated sludge process (compact reactor, turboplan reactor),
- Bayer biological tower,
- Biohoch reactor (Hoechst),
- deep shaft reactor (ICI).

The supply of pure oxygen instead of air (see Table) is variable or the method of construction, e.g. biological tower version. The advantages of the biological process are the mainly low cost, the extensive dispensation with auxiliary agents and the low sludge quantities. The disadvantage lies particularly in the larger space requirement. The chemical or chemical/physical purification processes are extensively independent of quantity and concentration variations and of the presence of bacterial toxins. In addition, the biological degradability of the effluent content substances plays no part. The ratio between BSB$_5$ and CSB, i.e. between the easily degradable proportions and the total pollution, is approx. 2:1 in domestic waste water, while the ratio is less favourable in industrial effluent; typical effluent from textile finishing plants has a BSB$_5$/CSB ratio of 4:1–6:1.

Specific disadvantages of the classic biological basin are also recognisable on account of their widespread distribution: the large space requirement, which is the limiting factor, especially with restricted space conditions, plus aerosol formation, i.e. the occurrence of fine water droplets, accompanied by gaseous emissions of liquid substances, which result as a rule in odours in the clarification plant vicinity. The third disadvantage is the low atmospheric oxygen utilisation factor. Depending on the type of air introduction system, e.g. nozzle introduction or surface ventilation, the utilisation factor lies only between 5 and 10%. In order to cover the necessary oxygen requirement therefore, a larger air supply is necessary, which means a high level of expenditure on electrical energy together with increased aerosol and possibly also foam formation. The above-mentioned disadvantages are avoided by the biological tower. High containers, of steel as a rule, which have a fluid level of 10–25 m, are used instead of the usually flat basin construction. With identical volumes, the base of a 20 m high water level is only 1/5th of that of one with a height of 4 m. The small base also facilitates tank covering, by means of which aerosol and odour problems are solved. The exhaust gases can be cleansed of the stripped, easily volatile substances by suitable methods, e.g. biology, activated charcoal or by combustion.

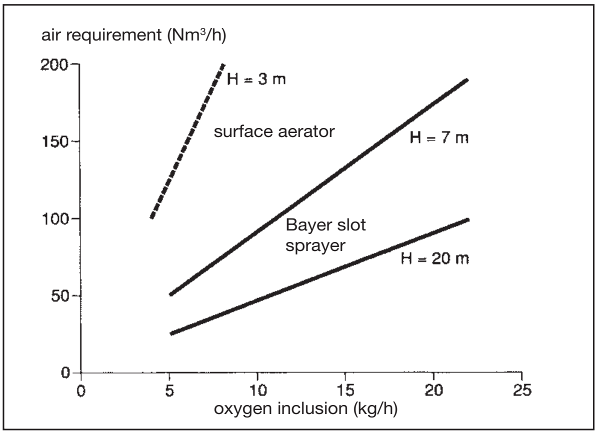

Fig. 1: Air requirement as against oxygen inclusion with various water level heights.

Another advantage of the biological tower is better atmospheric oxygen utilisation in the deep water column. The route of the air introduced through the water is longer, and more oxygen is dissolved under the pressure of the water (Fig. 1). This means approximately double the oxygen yield, which is approx. 3 kg of oxygen/kWh instead of approx. 1.5. The residual oxygen content of the exhaust gas is therefore significantly less than in conventional processes. Air has an oxygen content of 20.95 vol.%. For the usual basin construction, the oxygen concentration in the exhaust air is 19–20%, which means 5–10% oxygen utilisation as against a concentration of 5–8%, i.e. 60–75% utilisation for the biological tower (Table).

	Bayer biological tower	biological basin
oxygen demand (tonnes/day)	45	45
gas absorption	Bayer injector	surface aerator
depth of water	17-24	4
O_2 yield (kg of O_2/kWh)	2,7-3	1,5
air requirement (m^3/h)	10 800	70 300
O_2 in the exhaust gas (% vol.)	5-8	19-20
O_2 utilisation (%)	60-75	5-10

Tab.: Biological tower and biological basin oxygen inclusion.

With comparable oxygen demand, the necessary air requirement is reduced to almost one seventh (Fig. 1). This has positive effects on the energy requirement, on the stripping effect, and (in the event of any exhaust gas cleansing necessary) on the downstream treatment stage.

A relevant gas absorption system has to be developed at the same time in order to be able to utilise to the best effect the advantages of the deep water column for oxygen inclusion. Finely distributed gas bubbles are produced, and the effluent thoroughly mixed at the same time (Fig. 2) by special injectors located flush with the bottom of the activating tank. This also effectively prevents biological sludge sedimentation.

The long injector service life and the absence of moving parts in the activating tower lead to a high degree of processing reliability, ease of maintenance and operating reliability on the part of the air inclusion system. Due to the height of the unit, it is possible to create an additional buffer system, enabling an additional upstream balancing basin to be eliminated in specific cases (Fig. 3).

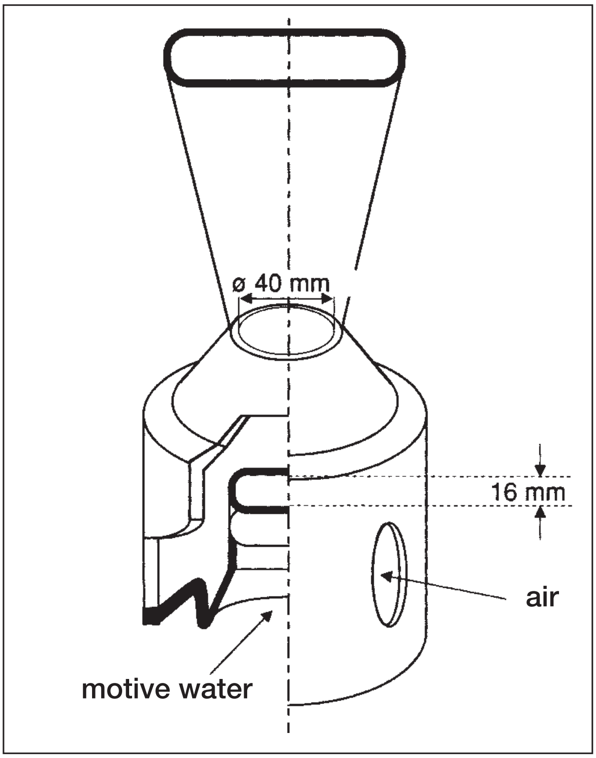

Fig. 2: Bayer injector slot sprayer model.

To the activating stage is connected a biomass separation process in the sedimentation stage. Depending on sludge settling behaviour, sedimentation or gas absorption flotation is suitable to this end.

With sludge separation by sedimentation, cyclones must be incorporated between the biological tower and the sedimentation stage (Fig. 4) in order to degas the gas-enriched water/sludge mixture, so that the sedimentation process can proceed undisturbed. If flotation

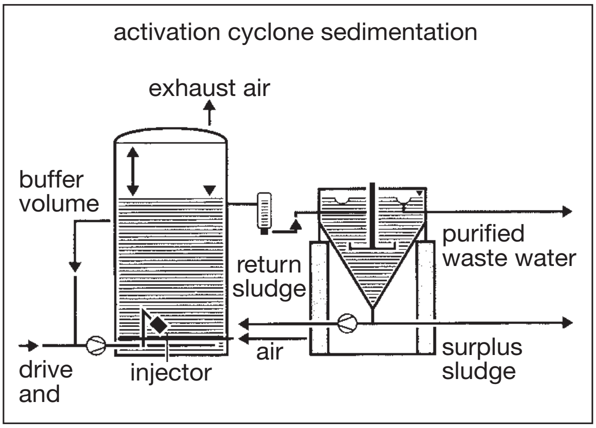

Fig. 3: Bayer biological tower with integrated buffer volume.

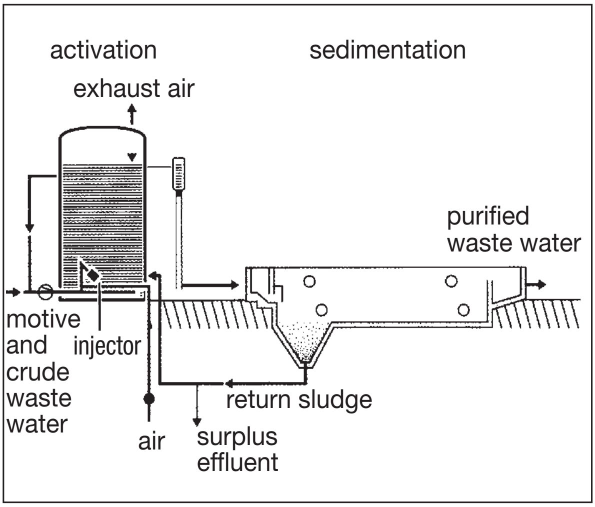

Fig. 4: Sedimentation tanks behind the biological tower.

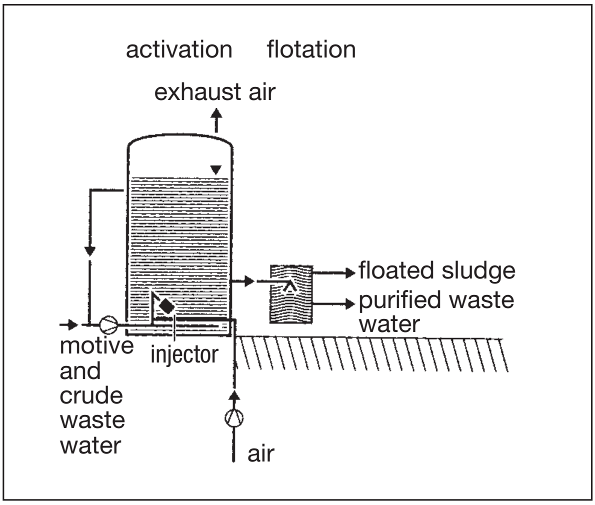

Fig. 5: Biological tower with flotation.

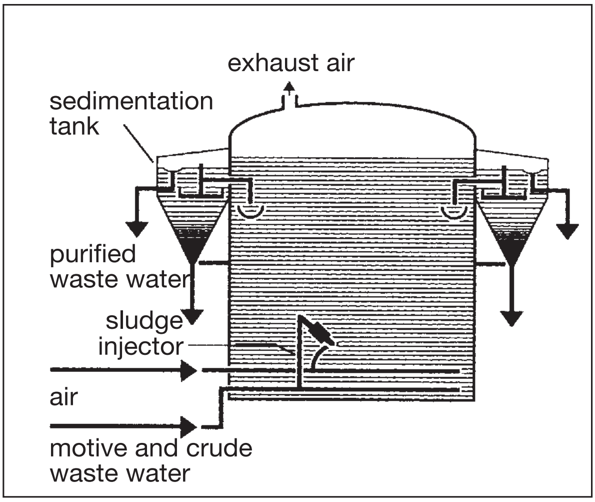

Fig. 6: Bayer biological tower with integrated sedimentation.

is selected for sludge separation, cyclones are unnecessary, since the gases have an additional positive effect (Fig. 5). Flotation is particularly suitable where there is a tendency for the sludge to float (Fig. 6).

An effluent treatment plant suitable for use in textile finishing has a precipitation stage, a subsequent presettling stage, a total of three activating tanks in parallel, each of 1200 m^3 capacity and approx. 12 m high water level, a reduced height sedimentation stage and a sand filter (Fig. 7).

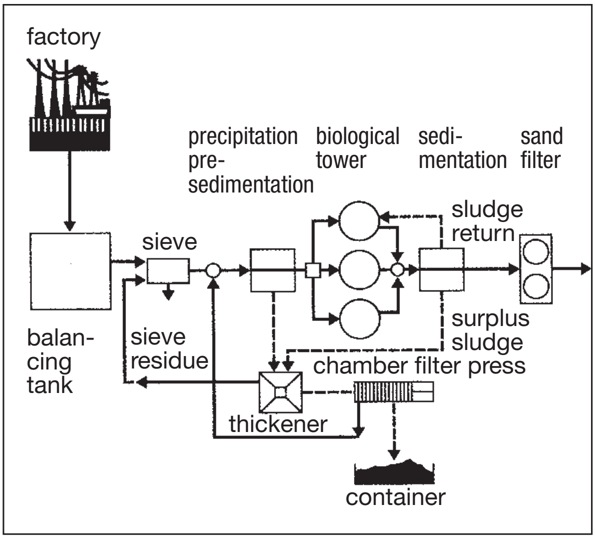

Fig. 7: Flow diagram of a biological tower with physical and chemical pre-purification.

The sludge-containing water from the biological tower must be drained free of pressure and foam, and degassed to the level of the sedimentation tanks in order to effect quiet, foam-free effluent introduction. A plant was designed for a capacity of 7700 m^3/day; the waste water accumulation over a nine month observation period was approx. 150 m^3/h (according to Sewekow and Diesterweg).

Biological waste water treatment This stage of waste water treatment is based on natural self-purification processes. In order to accelerate aerobic degradation, however, the water is enriched with oxygen artificially. The most frequently used treatments are the percolating filter and → Activated sludge processes.

I. Percolating filter. This consists of a vessel containing a bed of filtering material such as broken stone, lava or pieces of plastic covered with a so-called biofilm of algae, bacteria and other microorganisms. The mechanically cleaned waste water is sprayed with a rotating sprinkler above the contact bed whereby falling drops of water absorb oxygen from the air. The waste water seeps slowly downwards between the stones which are colonized by microorganisms. These micro-

Next Page

organisms extract organic pollutants from the waste water by absorbing them, breaking them down with oxygen, and multiplying. The percolating filter thus replicates, in the smallest space and under accelerated conditions, the self-purification processes which occur in flowing water courses.

II. Activated sludge process. In this process, a mixture of protozoa and bacteria (activated sludge) is added to aerated waste water to break down organic matter. As the microorganisms use this organic matter for food they multiply, producing more activated sludge. In practice, a brown-grey sludge is kept under constant movement in an aeration tank by surface ventilation or compressed air. If a small sample of this activated sludge is allowed to stand for just a few minutes in a glass cylinder, a grey-brown sludge settles out and the water lying above it is clear. Under the microscope it can be seen that this sludge is composed of countless microorganisms, such as bacteria, funghi, protozoa, etc. This mass is referred to as activated sludge to distinguish it from digested sludge. In an accumulation such as this, all the organisms consume a large quantity of oxygen which must be constantly replenished. This is achieved either by sprinkling or by passing compressed air or oxygen beneath the sludge. These purifying organisms must, however, be retained in the treatment plant and the waste water passing from the aeration tank or the exit from the percolating filter enters a secondary sedimentation tank for this purpose. As in mechanical clarification, the sludge (activated sludge in this case) settles out from the still water in a relatively short time. Whilst the treated waste water then flows from the outfall into a stream, river or the sea, the so-called returnable sludge is pumped back into the aeration tank. This large bacterial culture is therefore in a state of constant circulation. When the mass of activated sludge becomes too great, a part of it can be returned as excess sludge to the preliminary sedimentation tank. There the sludge, together with the coarse pollutant particles which have settled out, reaches the digester and is thus finally removed from the waste water. As a result, pollutants absorbed by the microorganisms are removed from the waste water. → Waste water treatment; Methanation in biogas processes.

Biomass The available biomass is the total quantity of organic substance in the form of living organisms in a given unit of area or volume at time t. The simplest reaction scheme for the photosynthesis (P) of biomass producers and the respiration (R) can be represented by the following chemical equation:

$$CO_2 + H_2O + E \underset{R}{\overset{P}{\rightleftharpoons}} \langle CH_2O \rangle + O_2$$

E = Energy conversion, mainly in the form of sunlight for P and mainly in the forrm of heat for R;

P = Primary productivity through assimilation by means of photosynthesis: i.e. the synthesis of organic material from inorganic compounds;

R = Respiration: the decomposition of organic material by oxygen to inorganic compounds (mineralization);

$\langle CH_2O \rangle$ = Organic material (biomass) which, on average, is composed of the elements C:H:O in a 1:2:1 ratio.

Biopolishing Enzyme finishing treatment for cellulosic fabrics. → Biofinishing.

Biosensors for environmental analysis Enzyme reactions are particularly suitable for the selective determination of environmentally-relevant substances. Thus, for the analysis of e.g. urea (in swimming pool water) the enzyme urease can be used, and for the detection of insecticides the enzyme acetylcholinesterase (AChE) can be employed. In both cases the enzyme is immobilized on the surface of a single stick pH electrode (Fig. 1) by crosslinking with beef albumin.

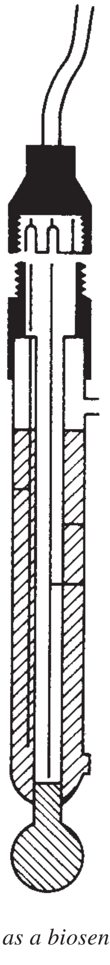

Fig. 1: Enzyme electrode as a biosensor for environment analysis.

The simplest reaction scheme for the photosynthesis (P) of biomass producers and the respiration (R) can be represented by the following chemical equation:

$$CO_2 + H_2O + E \underset{R}{\overset{P}{\rightleftharpoons}} <CH_2O> + O_2$$

E = Energy conversion, mainly in the form of sunlight for P and mainly in the forrm of heat for R;
P = Primary productivity through assimilation by means of photosynthesis: i.e. the synthesis of organic material from inorganic compounds;
R = Respiration: the decomposition of organic material by oxygen to inorganic compounds (mineralization);
$<CH_2O>$ = Organic material (biomass) which, on average, is composed of the elements C:H:O in a 1:2:1 ratio.

Biopolishing Enzyme finishing treatment for cellulosic fabrics. → Biofinishing.

Biosensors for environmental analysis Enzyme reactions are particularly suitable for the selective determination of environmentally-relevant substances. Thus, for the analysis of e.g. urea (in swimming pool water) the enzyme urease can be used, and for the detection of insecticides the enzyme acetylcholinesterase (AChE) can be employed. In both cases the enzyme is immobilized on the surface of a single stick pH electrode (Fig. 1) by crosslinking with beef albumin.

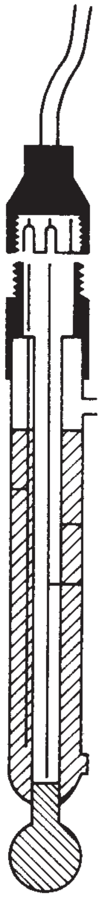

Fig. 1: Enzyme electrode as a biosensor for environment analysis.

A simple screening procedure for residues of crop protection agents is of great interest in environmental analysis. In this context, a rapid test for the presence of insecticides makes use of the fact that the enzyme reaction (catalysis of acetylcholine to choline and acetic acid) is inhibited by these substances. Thus the higher the insecticide concentration in a sample, the lower the decrease in pH (due to the formation of acetic acid). For the practical application of this enzyme single-stick pH electrode (i.e. biosensor technique) a simple analytical scheme including electrode reactivation has been developed to differentiate between insecticides based on phosphoric acid esters, thiophosphoric acid esters and carbamates (Fig. 2).

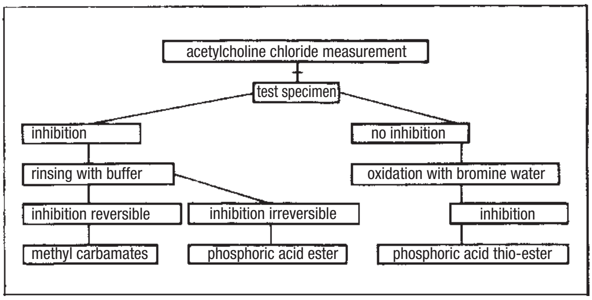

Fig. 2: Analysis plan for the differentiated determination of pesticides by means of the acetylcholine esterase enzyme electrode as a so-called biosensor.

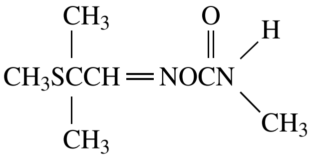
Carbamate insecticides (Fig. 3) cause a reversible inhibition of the enzyme. By contrast, the inhibition caused by phosphoric acid ester insecticides is irreversible and can only be eliminated by a special electrode treatment (reactivation). Thiophosphoric acid ester insecticides inhibit the enzyme reaction only after oxidation to phosphoric acid esters. Even concentrations of a few micrograms per litre (ppb range) of phosphoric acid ester insecticides can be detected with the aid of this biosensor, e.g. in drinking water, ground water and surface water.



$$\mathrm{CH_3SC(CH_3)_2CH{=}NOC({=}O)N(H)CH_3}$$

carbamate insecticide

Fig. 3: Carbamate insecticide for biosensory analysis.

Bioses → Sugar.

Biotechnology At the present time, biotechnology is understood to involve the utilization of biological processes within the framework of technical operations and industrial production. Biotechnologies, in fact, exploit the use of bacteria, yeasts and animal and plant cell cultures for the manufacture of specific substances which depend on the metabolism and biosynthetic capacity of the former. According to the definition adopted by the European Federation of Biotechnology, created in 1978, biotechnologies make it possible through an integrated application of knowledge and techniques of biochemistry, microbiology, genetics, and chemical engineering, to draw benefit, at the technological level, from the properties and capacities of microorganisms and cell cultures. Biotechnology always deals with reactions which, in principle, are of a biological nature. These reactions are performed either by living microbial cells or plant and animal cells and their tissues, or by enzymes from cells or parts of cells. The production of biomass from the organisms or parts of organisms mentioned is also an area of biotechnology.

Applied at the industrial level, these biotechnologies constitute bio-industry. Bio-industry includes, on the one hand, industrial activities where biotechnologies can replace technologies generally or currently in use and, on the other hand, industrial activities where biotechnologies play an essential driving role. In the first instance they include, in the area of chemical industry, the synthesis of flavourings and artificial seasonings, plastics, and products for the textile industry; in the area of energy, they include methanol, ethanol, biogas and hydrogen production; in the area of biometallurgy, they include extraction of certain metallic elements. In the second instance biotechnologies extend to the food industry (mass production of yeasts, algae and bacteria) with a view to providing proteins, amino acids, vitamins, and use of enzymes; to the increase of agricultural productivity (cloning and selection of plant varieties from cell and tissue cultures, bio-insecticides); to the pharmaceutical industry (vaccines, synthesis of hormones, interferons and antibiotics); to environmental protection and abatement of pollution (treatment of sewage, transformation of domestic wastes, composting and the manufacture of biodegradable compounds).

Microorganisms are not only capable of synthesizing very specific molecules but are also capable of making large quantities of simple molecules. Dyestuffs, or at least their building blocks, are structurally relatively simple molecules. The complexity of a biological process is often greater than that of a chemical process. This sophisticated character not only applies to biosynthesis but likewise to the isolation of biosynthesized products and product purification.

The product yield in a bioreactor consists mainly of a solid phase (cells, possible solid fractions from the nutrient solution) and a liquid (aqueous) phase. The target product may be present either in the solid and/or the liquid phase. In some cases the solid phase itself may represent the product (e.g. yeast cells for forage purposes).

At the outset of every biotechnological process is the search for a suitable biological system. This system must (like a catalyst) possess a genetic potential which is capable of promoting the desired biosynthesis. The search for a suitable biological system can involve at least two different aspects. In the first case (a traditional approach), an unknown microorganism population is confronted *a priori* with a problem.

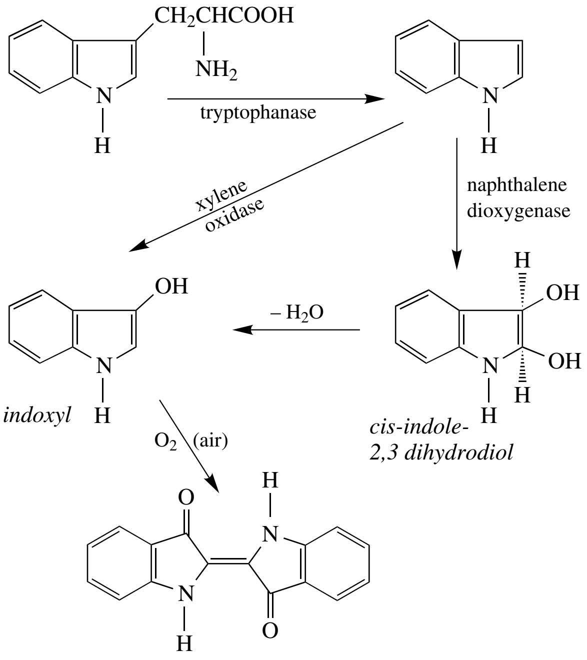


Fig.: Indigo biosynthesis.

Biotechnology is an interdisciplinary science at the frontier between several biologically, biochemically and technically oriented disciplines. At the centre, however, is the application of biological processes to industrial production. The objective of all biotechnical processes is to make use of certain metabolitic-physiological and biochemical capacities of biological systems for technical purposes, i.e. for production purposes. Suitable biological systems are based primarily on microorganisms, i.e. bacteria, yeasts or funghi, occasionally also algae and recently, on an increasing scale, cells of higher plant species, mammals or even human tissues. The potential of these cells for biosynthesis can thus be harnessed to make technically interesting products or convert certain substances into others. The spectrum of these biosynthetic products is very wide and includes foodstuffs, pharmaceutical products and other biologically active materials as well as fine chemicals or new raw materials. By way of example, a carbon source intended to be converted or broken down is brought into contact with different microorganisms. If, amongst these countless microorganisms a subpopulation exists which can break this carbon source down, then this species will start to multiply. The isolation of this specific species no longer stands in the way. This methodology which, in most cases, has emerged after an intensive screening program has produced many of the microorganisms used in technical processes today (see Fig.).

Biotope A small area or habitat of a particular type in a large community defined by the organisms (plants, animals, microorganisms) that typically inhabit it. All organisms are dependent for their life requirements on specific habitats providing the necessary environmental factors for their existence and needs. Compared to its surroundings, a biotope is a habitat which has certain environmental peculiarities that are specific to itself and relatively well characterized. It is the habitat of a → Biocoenosis.

Bipolarity → Dipole.

Bipolymeride Polymeride from 2 types of basic components.

Bird's eye (peacock's eye) Pattern is produced by regular bird's eye type weave effects. Worsted or worsted ply yarns, as far as possible of pure wool or of 70–90% wool content, are used exclusively. There are several types of weave, an eight-shaft crêpe weave being predominantly used. The yarn sequence for warp and weft is 2 dark, 2 light. Finish character: napless.

Birefringence Characteristic of the splitting of light waves in a crystalline mineral. Splitting occurs into two waves of different speeds and vertically opposed directions of oscillation. Thus, with transparent Iceland spar (potassium carbonate) for example, the image appears doubled, for which reason this spar finds use in polarisation equipment (→ Polarized light).

Bis (Old Lat.: *duis* = twice) Prefix meaning "twice" or "again". Used in chemical nomenclature to indicate that a chemical grouping or radical occurs twice in a molecule, e.g. Naphtol AS-BR (Hoechst) is a bis-2,3-2´-oxynaphthoic acid-dianisidide. A bis-azo compound contains 2 azo groups in the molecule and is also indicated in a disazo dye (such as e.g. → Congo red).

Bisage (French, English) Twice-dyed fabric.

Bis-aziridinyl chloromethyl phosphine oxide (BACPO) Flame retardant agent for cotton, applied in accordance with the dry cross-linking process.

BISFA (Fr.) Bureau International pour la Standardisation de la Rayonne et des Fibres Synthétiques (International Bureau for the Standardization of Man-made Fibres), Basle. Since 1928 (analogous to the → RAL in Germany) it has been concerned with drawing up internationally recognized guidelines for the standardization, description and sales of man-made fibres.

Bis (β-hydroxyethyl) sulphone (BHES), β,β′-dihydroxydiethylsulphone, HO–CH$_2$–CH$_2$–SO$_2$–CH$_2$–CH$_2$–OH. A vinyl sulphone used as a reactant resin for wash-and-wear finishes.

Bismarck Brown FR extra A cationic dye used for the differentiation of various textile fibres and fibres which have been subjected to different treatments (according to Herzog-Koch). Similar to the → Methylene blue test.

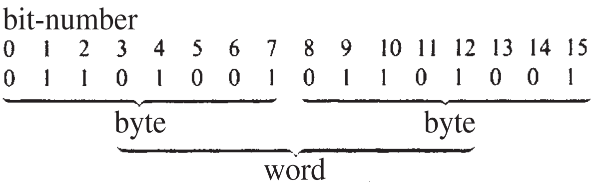
Bismuth (Bi) Brittle, crystalline heavy metal with a slightly reddish sheen. Atomic weight 209; melting point 269°C; density 9,78. Attracts oxygen only on the surface. Compounds: bismuth mainly trivalent. Salts chiefly colourless. Mainly severe hydrolysis in aqueous solution (turbidity, precipitates). Use: alloyed (with lead, tin, cadmium) as low-melt solder for self-acting fire extinguisher closures. Constituent of Wood's and Lipowitz's. alloy.

Bismuth-active substance (BiAS) Term for nonionogenic surfactants, the microbial decomposition of which is of monitoring interest in test on biological decomposition (→ Surfactant biodegradability, evaluation of); supplementary to → MBAS for anionic surfactants. Method of determination (Wickbold method) ion aqueous solution by precipitation with $KBiI_4 + BaCl_2$ and subsequent determination in the spectrophotometer or potentiometrically.

Bisphenol Starting material for the manufacture of → Epoxy resins. Bisphenol A = p,p´-isopropylidenediphenol $HOC_6H_4{-}C(CH_3)_2{-}C_6H_4OH$.

Bisulphites, are acidic → Sulphites resp. salts of sulphurous acid (H_2SO_3) (→ Sulphur oxyacids). Readily soluble reducing and bleaching agents (action of sulphur dioxide).

Bit A contraction of binary digit, in computer technology and information theory, the smallest conceivable unit of information, representing a choice between only two possible states: the presence or absence of a single pulse; + or –; 0 or 1; a switch being off or on. If the letters of an information alphabet are represented by binary characters (e.g. with 0 = no or "off", 1 = yes or "on") then the information content of such a binary character is equal to 1 bit. For simplification a fixed number of bits are grouped together. Thus a unit of information consisting of 8 bits is referred to as a byte (a term in common useage in electronic data processing). Example for large groups of bits with varyious numbers of compositions:



The general term is "word" which is why a "byte" is also a "word" in this context. The capacity, i.e. the number of bits which can be processed by a computer is expressed in kilobytes (kbyte or K). One kbyte corresponds to 2^{10} = 1024 bytes. The likewise frequently used term "megabyte" (mbyte or M) corresponds to 1 million bytes (2^{20}).

Bitumen A term for:

I. A black or brown solid to viscous semisolid liquid meltable mixture of hydrocarbons obtained from crude oil as a distillation residue.

II. The constituents of natural asphalt which are soluble in carbon disulphide.

Biuret (ureidoformamide, allophanamide, carbamylurea) $H_2N{-}CO{-}NH{-}CO{-}NH_2$. Formed by the action of heat on urea (elimination of ammonia). A water-soluble substance which, in alkaline solution, gives an intense violet colour with copper salts. The reaction occurs with all substances containing 2 or more amide groups ($-CONH_2$). → Biuret reaction.

Biuret reaction A simple test for the presence of proteins (e.g. glue), peptides and damage to wool. If urea is heated to temperatures of 150–160°C ammonia is split off and biuret is formed as an intermediate product:

$$\underset{\textit{urea}}{H_2N{-}CO{-}NH_2 + H_2N{-}CO{-}NH_2} \longrightarrow \underset{\textit{biuret}}{NH_2{-}CO{-}NH{-}CO{-}NH_2} + NH_3$$

In alkaline solution this forms a violet-coloured copper complex with copper sulphate. The reaction is characteristic for all substances which contain several peptide bonds. The reaction therefore serves as a test for biuret, oxamide, peptides and proteins.

Bivalent (or divalent). Chemically capable of combining with 2 atoms of hydrogen or their equivalent (→ Valency). Also having an oxidation state of two.

The term has also been applied to bivalent systems as in e.g. compact energy converters with a heat pump and a heating system (solar energy).

Bk, chemical symbol for berkelium (97).

Black component (Black content, blackishness, blackness value), the black component of an object colour of a lower degree of lightness detectable in the sense of the so-called degree of greyness (→ Grey series). The 0–100% black component is equivalent to a blackness value (form differentiation → Lightness) of 0–10 .

Black content → Black component.

Black denim This term has been reserved for → Blue denim which has been overdyed black in contrast to the fast-dyed classical qualities of → Denim, produced by yarn or piece dyeing methods which remain deep black after repeated washing. Black denim becomes blue-grey in colour after washing and may also be given a stonewashed finish. Denims which have been dyed with black indigo dyes have an attractive blue-grey appearance after a stonewash treatment.

Black mordant,

I. A term used for stock preparations of → Aniline salt used in the impregnation of cotton fabrics for the production of oxidation black (aniline black).

II. Also a mordant for logwood black → Pyrolignite of iron and iron (III) sulphate.

Black-out cloth Different types of woven fabric, mostly highly calendered, sometimes raised on one side, dyed to a dark shade (possibly → Camouflage dyed). Also coated as black-out curtain (a carbon coating).

Black-out curtains Roller blinds made from fabrics composed of synthetic fibres to which one coat of carbon black is applied between two polymer coatings thereby producing a virtually total lightproof material.

Blade squeegee The classical shape of → Squeegee in contrast to a roll squeegee.

Blanc fixe → Barium sulphate.

Blank bleach The operation of a bleaching plant with all the chemicals but no textile material in order to check the equipment, controls, etc.

Blank dyeing A "dyeing" carried out on a specific textile material with the omission of dye from the usual recipe. By this means it is possible to check the influence of actual dyeing conditions on the material in the absence of dye which could otherwise, e.g. hide any yellowing or other non-dye-related problem.

Blanket manufacture The so-called pile blanket is woven as a double blanket, the pile yarn connecting the top and bottom fabrics. After the weaving process, the pile ends are cut in the middle on the loom (Fig. 1), simultaneously producing two woven fabrics. It is important that the pile yarn is very firmly anchored, so that the fabric does not break up. Two fabrics (each raised on one side) can be made up side by side to produce high quality blankets.

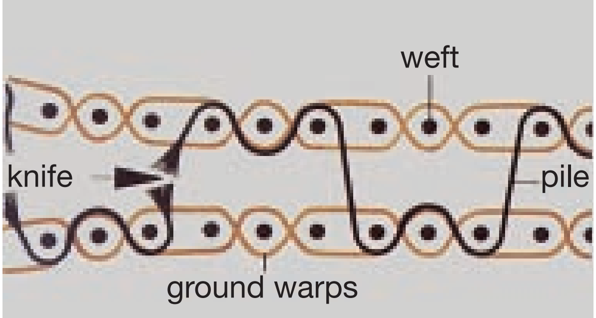


Fig. 1: Separation of top and bottom fabric in blanket manufacture.

The teddy velour process is a patented technology (Fig. 2) which has been extended by a new process (teddy velvet). The pile yarn (which can be raised) is firmly anchored on both sides by the ground warp and the weft. The pile loops on both sides offer the largest possible raising surface. In raising, part of the loop is anchored in the ground weave, producing a firmly set velour which cannot lint. Advantages: high pile, good stability and excellent heat retention.

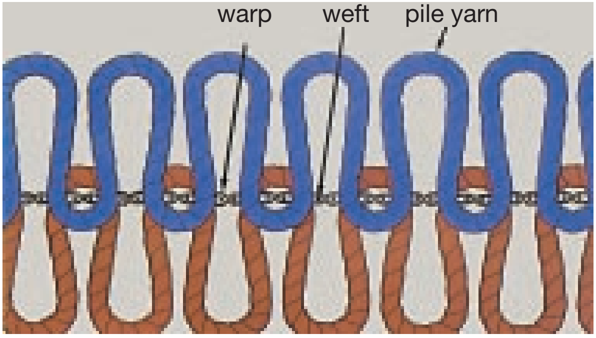

Fig. 2: Teddy velour blanket.

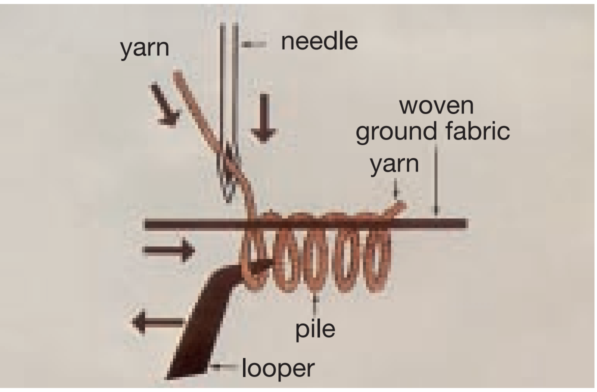

Fig. 3: Blanket tufting.

Strongly patterned, multi-coloured blankets are produced on the jacquard machine. In tufting, there is neither warp nor weft. The pile ends are needled into a ready-made woven ground fabric (Fig. 3). Many hundreds of needles pierce the ground fabric, while grippers take down the ends fed through the yarn eye in the needle. The needle moves back, threading up for the next stitch, while the ground fabric runs through the machine at the same speed. The pile end is secured only by the raising process.

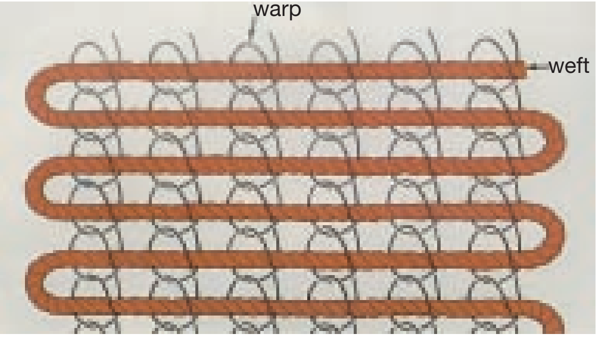

Fig. 4: Raschel blanket.

The Raschel process is based on warp knitting technology with weft insertion (Fig. 4). The warp yarn is very fine, the weft yarn very lofty. The weft is securely anchored by the warp stitch. The weft arches like a cord during fulling; in this way, it can be particularly well raised to produce high long pile bulk.

Blanket finishing comprises the following processes:

1. The controlled grey fabric is fulled and scoured, for the grey fabric has to felt in order to be raised.
2. Piece-dyeing takes place at this point if necessary. Dyeing can be effected in the loose stock state (raw material), in the hank (yarn), after spinning or in the piece (woven fabric).
3. The blanket appearance, i.e. the pile, is produced by raising, the grey blanket running through various passages on the raising machine. The surface, highly felted by scouring, is opened up, and the fibre ends teased out.
4. On the raising machine, the thick, lofty pile is brought to uniform height, levelled, and cut. The fibre material is then stretched and polished on the Polrotor in order to reproduce the hair lustre lost in the numerous operations.
5. The blanket batch is now cut to single blanket dimensions. The current standard size is 150 x 200 cm. There is no standard European dimension.

Blanket seam A printing fault in roller printing characterized by a light-coloured, widthwise stitching mark appearing on the face side of the printed fabric caused by the seam in the rubberized blanket beneath.

Blanket washer A special compact washing machine used in roller printing for continuous washing of the printing blanket during running. It is usually located immediately behind the printing machine.

Blank print A print produced on a textile substrate with a print paste that contains all the necessary chemicals and auxiliaries except the dye and which has been processed in the normal manner. This procedure is often used to check the influence of printing conditions where the presence of dye would interfere with the result.

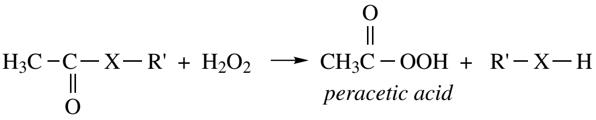
Blank screen A non-engraved screen (i.e. with no design) in rotary screen printing fitted with a squeegee but without print paste supply. It is used either in the "first hand" position to improve adhesion of fabric to the blanket adhesive before reaching the printing zone or in the "last hand" position to level out any unevenness in the print.

Blank vat An alkaline solution of sodium dithionite as used in vat dyeing but without dye. Uses: for stripping and levelling vat dyed materials, and for the development of vat dyeings produced by the pigment-pad process or other two-phase dyeing method.

Blazer Sports jacket. In its original form a fairly lightweight jacket, often striped or in the colours of a sports club, school, etc. with decorative buttons and a badge bearing a coat of arms. In recent years it has also developed into a more anonymous style in plain colours usually without a coat of arms but often still with quilted seams.

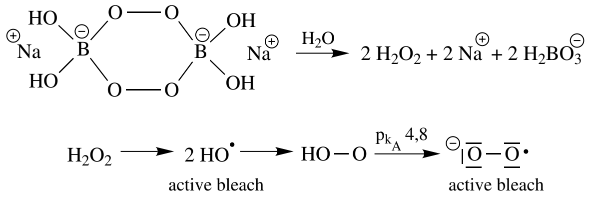
Bleachability In → Bleaching, this represents the optimum degree of whiteness achievable with minimum chemical damage to the fibre (in the case of cotton the → Cuprammonium fluidity should not be higher than 3–5).

Bleach activators (perborate activators) Acetyl compounds which have the capacity to form peracetic acid with H_2O_2 donors in the liquor as an intermediate stage of the bleaching reaction. The reaction is virtually independent of the washing and reaction temperature, and proceeds preferentially at pH 9–12 at significantly lower temperatures than usual:

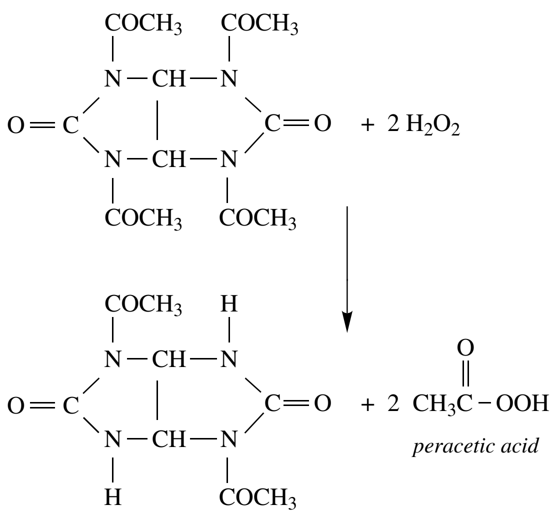


$$H_3C-\underset{\underset{O}{\|}}{C}-X-R' + H_2O_2 \longrightarrow CH_3\overset{\overset{O}{\|}}{C}-OOH + R'-X-H$$

In accordance with this principle, functional bleaching systems are developed with combinations of sodium perborate and bleach activators which (e.g. in the case of heavy-duty detergents) are capable of giving bleaching effects at < 60°C comparable to those obtained at 95°C with sodium perborate alone. Tetraacetylglycoluril (TAGU) is a bleach activator of this type (besides the tetraacetylenediamine types in washing agents) which, with the H_2O_2 donor formed on solution of the heavy-duty detergent,



functions as a bleach activator:



Bleach decomposition When hydrogen peroxide is used as a bleaching agent, the bleaching liquor can spontaneously decompose if it becomes too alkaline due to the inclusion of inadequately washed-out residual alkali from the preceding scouring stage. The practical finisher says “the bleach is decomposing”.

Bleached denim, often garment-washed, i.e. made up → Jeans are washed and bleached. A precisely calculated quantity of a bleaching agent, frequently chlorine-based, is added to the wash liquor in the prewash which bleaches out some of the indigo dye. The garments are finally rinsed with a special softener so that the denim remains soft and without a boardy handle.

Bleaching Chemical treatment of textiles in order to lighten or remove by means of suitable bleaching agents the tinting contained in the grey fabrics due to growth (natural fibres) or production (man-made fibres). In the grey state, textiles generally have a yellowish (sometimes also grey-brown) tint which has a detrimental effect for white or light shades on specific batches. Whilst lightening was effected in the past by natural (meadow) bleaching (particularly with linen and linsey-woolsey, and sometimes with cotton too), stripping is carried out today by chemical processes. The natural dyestuff can be destroyed both oxidatively (→ Oxidation bleach) and reductively (→ Reductive bleaching) and also by a combination of those two processes, where maximum fibre protection is the prerequisite. Sometimes bleaching is combined with other finishing stages like scouring, desizing or dyeing. In order to assist the bleaching effect, particularly with white fabrics, → Fluorescent brightening agents are used additionally. Bleaching is effected either in a long bath (high liquor ratio) or by impregnation bleaching, i.e. the fabric is steeped in the bleach liquor, left to dwell with or without squeezing, and/or exposed to heat. Generally, bleaching is mainly carried out in the pretreatment department; in order to obtain a clear pastel shade or a clear print, the preceding bleach can be regarded as pretreatment for example. Nevertheless, white colouration is principally associated with affecting the sensation of “colour”, for which reason bleaching is also regarded as colouration.

Bleaching agent, hydrogen peroxide Hydrogen peroxide bleaching, particularly of cotton, has gained in importance in view of the effluent problems (AOX) caused by hypochlorite bleaching. Hydrogen peroxide is a chemical compound which reacts as an oxidising agent in most cases. Hydrogen peroxide can also have a reducing effect only against very powerful oxidation agents such as potassium permanganate for example. This reaction is used for determining hydrogen peroxide content. The bleaching action of the H_2O_2 in the liquor on the other hand is causally connected with the oxidation potential of the compound. Various chemical equilibrium reactions are illustrated in Fig. 1 (→ Peroxide bleach process; hydrogen peroxide bleaching).

$$H_2O_2 \xleftrightarrow{K} HO_2^- + H^+$$

$$K_{298K} = \frac{(H^+) \cdot (HO_2^-)}{(H_2O_2)} = 1{,}78 \cdot 10^{-12}\ [\mathrm{mol/l}]$$

$$H_2O_2 + NaOH \rightleftharpoons H_2O_2 + Na + HO_2^-$$

$$2\ HO_2^- \rightleftharpoons O_2 + 2\ OH^-$$

Fig. 1: Chemical equilibrium reactions in the bleaching liquor (Degussa).

As a weak acid in aqueous solutions, hydrogen peroxide itself dissociates into ions in only a very low ratio. We know that the free acid has a very weak bleaching action only, and consequently has to be activated in order to be able to produce an adequate bleaching effect from the economic standpoint. For this reason, hydrogen peroxide bleaching is carried out exclusively in the alkaline range. The activator which is to be employed in the individual case, and the strength in general of the alkalinity of the bleaching liquor to be reached, depend on the type of textile raw material and the pretreatment it has already received. For vegetable fibres (like cotton for example), a caustic alkaline bleaching liquor is preferred. In the case of alkali-sensitive animal hairs (wool), only mild alkaline bleaching conditions can be used. With cotton, sodium hydroxide - in the case of linen also sodium carbonate - is used almost exclusively as the alkali source on cost grounds. On the other hand, buffer systems are often employed when bleaching animal fibres. The well-known tetrasodium pyrophosphate should be mentioned at this point. In addition to the bleaching chemical H_2O_2 and the alkali as activator, the hydrogen peroxide bleaching formulation basically also contains a scouring and wetting agent for improving liquor penetration capacity and also a stabiliser. Stabilising the hydrogen peroxide in the bleaching liquor is of fundamental importance to a uniform bleaching result and largely gentle treatment of the textile raw fibre material. The type and quantity of the stabiliser selected are consequently quite important, since hydrogen peroxide bleaching liquors are not adequately stable under practical conditions for a satisfactory bleaching result without this auxiliary agent. We know that the decomposition rate of H_2O_2 rises sharply with temperature particularly in the alkaline range, and any desire to save stabiliser in the formulation is therefore ruled out for this reason. Stabilisers must be added to the liquor in order to prevent H_2O_2 decomposition in the liquor under textile bleaching

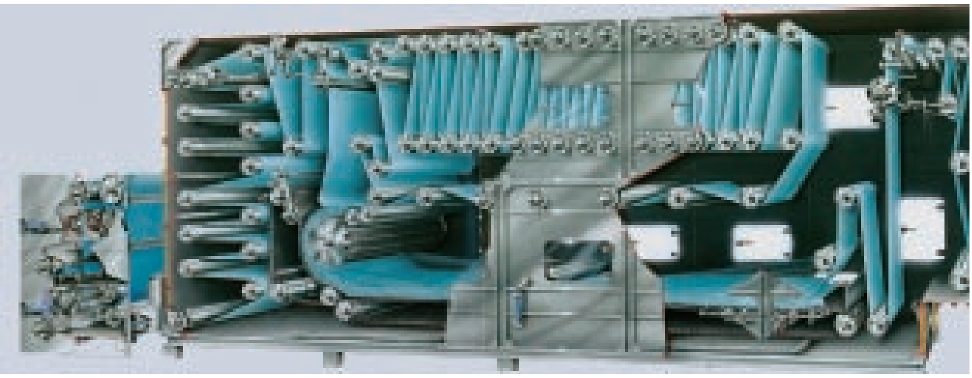


Fig. 2: Brugman bleaching line for the single-stage hydrogen peroxide bleaching of woven cotton fabrics.

conditions (particularly with increased temperature and alkaline activation).

The most important, very frequently used stabiliser systems are organic stabilisers based on phosphoric acids, aminocarboxylates and sodium silicate (waterglass) in combination with alkaline earth metal ions, particularly magnesium ions. Waterglass itself has a stabilising effect only in the presence of alkaline earth metal ions, which are in addition mainly responsible for water hardness. In the bleaching liquor, sodium silicate and magnesium ions form colloids, which act as buffers, and keep liquor alkalinity constant. This is important for a uniform bleaching result. Not to be forgotten is the anticatalytic effect of this classic stabiliser, which is based on the fact that H_2O_2 decomposition catalysts are incorporated in the waterglass colloids, and are chemically inactivated. The stabilising effect of this system as against the H_2O_2 in the liquor is based on colloid chemical processes. This empirically constantly confirmed fact is of great importance in practice. A typical single-stage woven cotton fabric bleach with hydrogen peroxide is shown in the plant in Fig. 2 (with prescouring section for desizing) (Weck).

Bleaching agent, sodium chlorite This is a very gentle oxidative bleaching agent for fibres, particularly for cotton, which, in a long liquor, does not chemically damage the cellulose structure, even with moderate overdosing and fairly lengthy contact times. The reason for this is to be seen in the relatively moderate oxidation potential of the agent regarded as an effective bleacher - chlorous acid ($HClO_2$). Removal of the seed husks and the other coloured impurities of cotton follows, as chlorite bleaching is carried out in the moderately acid zone at an approx. pH of 3.7–4.0. Thus, → Sodium chlorite enables numerous products, which, along with cotton, have alkali-sensitive fibre constituents, such as polyacrylonitrile or regenerated cellulose for example, to be bleached. In addition, various man-made fibres produced from natural polymers, like viscose, acetate or modal for example, are also suitable for bleaching with sodium chlorite. Polyester, polyamide and polyacrylonitrile are to be mentioned in the case of synthetic fibres. With all the above-mentioned textile fibres, chlorite bleaching results in a degree of whiteness which cannot be achieved with hydrogen peroxide in a single stage process.

Sodium chlorite is not suitable for bleaching animal fibres such as wool and silk for example, as the protein structure of these fibres is oxidatively attacked, and irreparably damaged under the conditions existing in chlorite bleaching liquors. Since chlorite bleaching is carried out in the acid pH range, very little swelling occurs with cellulosic fibres, for which reason fabrics sensitive to creasing and folding are preferably bleached with sodium chlorite. Furthermore, this bleaching agent is decidedly less sensitive to heavy metal ions than hydrogen peroxide. For this reason, sodium chlorite is preferred to hydrogen peroxide for bleaching products like poplin for example (catalytic decomposition of the H_2O_2 and fibre damage has to be reckoned with in the presence of specific heavy metal ions in the H_2O_2 bleaching liquor). A further advantage of the chlorite bleaching of cotton or products containing cotton is also to be seen in the fact that, by bleaching in the weak acid range, fewer fats and waxes are dissolved out by soaping vegetable fibres than with alkaline hydrogen peroxide bleaching. On the one hand, this has of course an advantageous effect on the CSB content of the bleaching department effluent, and, on the other, a fabric optically whitened with sodium chlorite has a soft handle.

A glance at the comparatively complicated chlorite bleaching chemistry (Fig. 1) shows where some potential disadvantages of this bleaching agent lie. Chlorite bleaching is carried out as a rule at temperatures of 80–95°C and in pH ranges between 3.7 and 4.0, for sodium chlorite, reacting strongly alkaline in aqueous solution, must be activated with acid in order to enable its bleaching action to be fully developed. The problems begin of course with activation and the formation of complicated chemical equilibria in the liquor due to it (Fig. 2).

$$\begin{array}{ll}
ClO_2^- + H_2O & \rightleftharpoons HClO_2 + OH^- \\
ClO_2^- + H^+ & \rightleftharpoons HClO_2 \\
5\,NaClO_2 + 4\,HCl & \longrightarrow 4\,ClO_2 + 5\,NaCl + 2\,H_2O \\
3\,ClO_2^- & \longrightarrow 2\,ClO_3^- + Cl^- \\
4\,ClO_2 + 2\,NaOH + H_2O_2 & \longrightarrow 2\,NaCl_2O + 2\,H_2O + 4\,O_2
\end{array}$$

Fig. 1: Chemical reactions of sodium chlorite or chlorine dioxide.

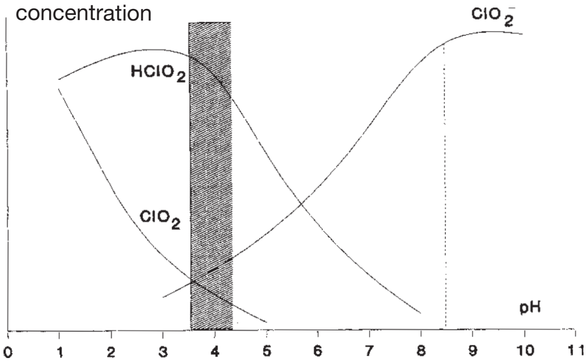

Fig. 2: Reactive intermediate in chlorite bleaching relative to the pH.

The concentration of the chlorous acid ($HClO_2$) acting as the bleaching agent reaches its maximum in the 2.5–3.5 pH range. Below pH 3.0 however, fibre damage becomes noticeable due to cellulose hydrolysis. In addition, the disproportionation of the chlorous acid into chlorine dioxide and hydrochloric acid in an excessively strong acid range, which has a further fall in pH as a consequence, has always to be taken into account. Chlorine dioxide is also very toxic as a gas. In the weakly acid or neutral or alkaline range on the other hand, only the non-bleaching action ClO_2 chlorite anions are dominant. For these reasons, the optimum reaction conditions lie in a comparatively narrow pH range between 3.5 and 4.5, in which relatively mostly activated $HClO_2$ molecules are present in equilibrium. These complicated and outwardly easily affected chemical equilibria are graphically illustrated in Fig. 2. A chlorite bleach does in fact produce a lower AOX content in the effluent, but partial flows can exceed the permitted limits (according to Weck).

Bleaching agent, sodium hypochlorite Bleaches cotton in particular cost-effectively and to a high degree of whiteness, but the AOX value as a measure of organic halogen compounds (accumulation of NaOCl on cotton impurities) exceeds the permitted effluent pollution. The quantities of → Sodium hypochlorite used in textile finishing as compared with the paper industry are in fact small, but are also the cause of critical action on the part of the authorities. Sodium hypochlorite is a powerful oxidising agent with a correspondingly high redox potential. Since hypochlorite consequently reacts relatively unselectively with the fibres, the danger of fibre damage with this bleaching agent is much greater as compared with the others. For this reason, the bleaching processing parameters, particularly the pH value, must be exactly adhered to. Due to its high oxidation potential, hypochlorite bleaching is carried out only in the cold state. Hot bleaching is ruled out on account of the equilibrium displacement in the direction of hypochlorous acids or active chlorine, which would result in drastic fibre damage. For this reason, it is essential to monitor the pH during bleaching, since the active bleaching species, the hypochlorite anion and hypochlorous acid, are present beside each other in the chemical equilibrium. Practical experience confirms that sodium hypochlorite bleach liquor has a preferential bleaching action in an alkaline medium, but is increasingly fibre damaging in the neutral range. The reason for this, that hypochlorite bleaching can be effected only in a narrow pH range (hatched in the Fig.), is attributable to the fact that, with very high concentrations of chlorous acid in the neutral range, they not only react with the natural impurities in the vegetable fibres but also with the polymer structure of the fibre material.

The actual bleaching reactions run more or less parallel to fibre damage therefore, and the question as to what different extent these two parallel reactions take place can only be answered via the pH value. In the 9 to approx. 11 pH range, the active bleaching species concentration and the free molecules of hypochlorous acid are high enough to react preferentially with the natural impurities in the fibre, thanks to the high oxidation potential. At the same time however, the danger of elementary chlorine release does not arise, while an adequate reservoir of still inactivated hypochlorite anions is available. In the higher pH range, the HOCl molecule concentration is so low that this is unacceptable in practice. With the liberation of oxygen during the decomposition of hypochlorous acid, HCl is produced, which then releases elementary chlorine to an increased extent (according to Weck).

Bleaching and catalytic damage The presence of metals in trace amounts, especially iron, manganese and copper, cause the spontaneous release of oxygen in peroxide baths which results in local destruction of cellulose (formation of holes). When traces of such metals are present in cellulosic textiles a preliminary treatment with oxalic acid or complexing agents is necessary. This pretreatment can, however, be omitted if diethylenetriamine pentaacetic acid (DTPA) is used as a stabilizer in the bleach bath instead of silicate.

Bleaching auxiliaries Products designed to improve the reliability of bleaching, accelerate bleaching

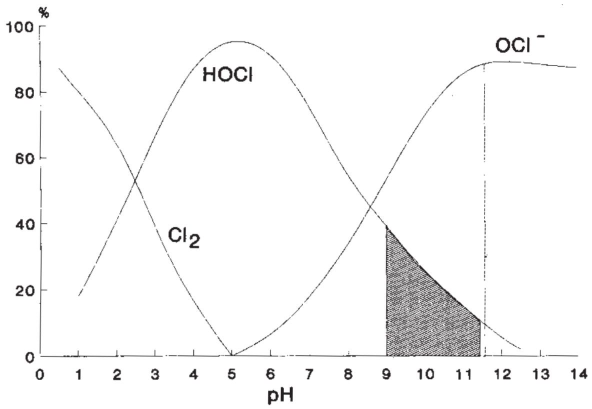

Fig.: Intermediate products with and without bleaching action with the use of sodium hypochlorite solution relative to the pH.

action (especially for peroxide and sodium chlorite bleaching), and provide protection against fibre damage.

1. Wetting agents: these are mainly alkylnaphthalene sulphonates, sulphonated oils, fatty alcohol sulphates, and fatty acid condensates. Wetting agents for bleaching can also contain solvents.
2. Stabilizers: very important for bleaching with hydrogen peroxide. Suitable products include: sodium silicate (water glass), phosphates, organic complexing agents, protein fatty acid condensates, phosphoric acid esters.
3. Activators: for bleaching with sodium chlorite. Suitable products include: inorganic and organic acids, phosphates, nitrates, esters and ammonium salts.
4. Corrosion inhibitors for sodium chlorite bleaching: fatty acid condensates, nitrates, nitrites and phosphates.

Bleaching catalysts → Catalysts which function as oxygen carriers are used in bleaching to activate the bleaching process and achieve savings in the quantities of bleaching agents required.

Bleaching chemicals

I. Chlorine-based products: e.g. chlorine dioxide, chloride of lime, sodium chlorite, sodium hypochlorite.

II. Oxidative products: ammonium persulphate, potassium permanganate, potassium persulphate, sodium perborate, sodium percarbonate, sodium pyrophosphate peroxide, sodium persulphate, sodium peroxide, hydrogen peroxide.

III. Reductive bleaching agents: sodium bisulphite, sodium dithionite, sodium pyrosulphite, sulphurous acid.

Bleaching chemicals, automatic For monitoring and controlling (potentiometric titration principle) the chemical content of impregnating liquors.

Bleaching, degree of → Whiteness, degree of.

Bleaching/dyeing combined process Combination of bleaching and dyeing for cellulosic fibres. The process is restricted to the use of hydrogen peroxide as bleaching agent. Applicable for direct, vat and vat leuco ester dyes.

Bleaching earths (active earths) are colloidal magnesium aluminium silicates with varying iron contents, used as filtering auxiliaries for decolorizing dark mineral oils, fatty oils and fats and similar very finely divided substances. The raw materials are clays which are opened up (activated) by heating or chemical treatment (mineral acids, alkalies). Activation with acids breaks the crystal lattice by dissolving out $Al(OH)_3$, which opens the inner capillary structure and so increases the effective surface area. The activity is connected with direct bonding of OH ions to silicon and the content of water bound to the mineral is mainly responsible for the decolorizing effect, so that combined physical and chemical actions are required for the adsorbing effect with bleaching earths. The earths can however vary considerably depending on their activation. As water is also adsorbed, gels are formed (which do not pass through filters). Today they have no practical significance.

Bleaching fastness →: Colour fastness to bleaching agencies: hypochlorite, peroxide, sodium chlorite.

Bleaching fastness of coloured wovens Colour fastness of → Coloured woven articles to processing. Requirements for cotton are: colour fastness to soda boiling, kier boiling, hypochlorite bleaching, chlorite bleaching and peroxide bleaching. Requirements for viscose are: colour fastness to hypochlorite, chlorite and/or peroxide bleaching. With combined chlorine-peroxide bleaching processes, the order in which both these bleaching chemicals are applied has an influence on the fastness of some vat dyes (black brands).

Bleaching of animal fibres Cold bleaching for dark animal hairs at a liquor ratio of 20:1, pH of 9,2–9,5 and a temperature of 20–25°C in soft water containing 2 g/l sodium pyro- phosphate, 30–40 ml hydrogen peroxide 35% and 20–25 g potassium or ammonium persulphate. The bleaching treatment is carried out for 18–24 hours followed by a final rinse and, if necessary, a reductive aftertreatment. The bleach bath can be reused after freshening with appropriate chemical additions.

Bleaching of coir It is not possible to achieve a white with this fibre. An effective brightening can be obtained, however, with hydrogen peroxide and an afterbleach with sodium dithionite.

Bleaching of coloured woven goods Bleaching carried out on coloured woven goods in accordance with the practical requirements of the → Bleaching fastness of coloured woven goods.

Bleaching of cotton Has the function of removing the dyed impurities which cannot be removed by scouring or kier boiling, particularly the natural dyestuffs of the cotton fibre and also the residual husks. The fibre material is bleached by means of sodium hypochlorite, sodium chlorite or hydrogen peroxide baths, in many cases in a sequence of these bleaching methods in a combination process (hypochlorite-peroxide). The question as to which process has preference depends on various factors, particularly the demands which are made on the bleached fabric. A so-called "semi-bleach" is adequate for batches destined for dyeing or printing. The cellulose is more or less broken down by each bleaching process. This is expressed by a reduction in the average degree of polymerisation (DP). Here, the bleacher must take into account the fact that the loss is to a certain extent permanent. Comprises are inevitable in selecting time, temperature and chemical concentration relative to degree of whiteness and fibre damage and also to environmental protection.

The intensity of bleaching required depends particularly on the inherent colour of the cotton. It is impossible to obtain a uniform white on cottons of different natural colours by bleaching. Shade differences are visible even after bleaching. Pretreatment has a bearing on this. If one is unwilling to scour intensively, bleaching must be correspondingly intensive, increasing the danger of fibre damage. On economic grounds, attempts are made to shorten all treatment processes, and to cut out individual stages wherever possible. In treating woven fabrics, desizing, scouring and bleaching and also optical whitening in the case of white fabrics, are frequently combined into a continuous process.

All bleaching processes, particularly peroxide processes, can be catalytically affected. From this, it follows that cotton must contain no metals prior to bleaching. It must, if necessary, be pretreated or acidified beforehand with complex formers. Bleaching equipment must consist of corrosion-resistant material. Pumps, piping, valves and other fittings must also contain no catalytically active metals like iron, copper, manganese or unsuitable alloys. Stainless steel and earthenware can be used for hypochlorite and peroxide; special alloys, possibly titanium, and earthenware or plastic are recommended for chlorite. Bleaching baths, especially peroxide liquors, must be heated by indirect heating by means of preheaters or closed steam coils.

Cotton can be bleached in various make-up forms, i.e. also in different processing stages:

I. Loose stock: the bleaching of cotton in loose stock form is of subordinate importance, and is carried out in pack equipment with liquor circulation (e.g. the Krantz radial bleaching machine) using peroxide, with hypochlorite in addition in the first stage if necessary. If a fully enclosed unit (HT equipment) is available, scouring and bleaching can be effected in a single stage in a highly alkaline peroxide bath. Waterglass is replaced by an organic stabiliser in order to ensure good spinnability.

II. Card sliver: treatment in bundle form in a pack cylinder has been abandoned in favour of wound batches. A complete card sliver bleaching plant consists of a winding machine, warp beam material carriers, HT bleaching unit and beam centrifuge. The bleaching conditions themselves are the same as for loose stock. For the continuous bleaching of large batches, units have been produced which are similar to those of continuous woven fabric bleaching. After impregnation with the bleaching agent and heating comes steaming, where the material is carried forward by perforated cages or conveyor belts.

III. Yarn: yarns are bleached in cross-wound packages or warp beams in circulation-type equipment, mainly in two stages for full white, first with hypochlorite and then peroxide. In the case of yarns containing few husks, a highly alkaline peroxide bleach alone is sufficient under HT conditions in order to obtain an acceptable white without special scouring processes.

IV. Fabrics: the great majority of cotton is bleached in woven or knitted fabric form. The processes are based closely on those of scouring; bleaching is effected either in rope or open-width form, in batches or continuously, and in the same equipment. Production quantities and fabric quality determine the choice.

Fabric bleaching in rope form:

a) Batch processes: only lightweight qualities with no tendency to crease are suitable for this. Small batches can be bleached in the winch. Liquor circulation vessels are employed for large batches. This bleaching process is called "kier bleaching", and is generally carried out in two stages with a sodium hypochlorite pre-bleach and a hydrogen peroxide after-bleach. A single bleaching stage can be used depending on the quality of the fabric to be bleached and relevant local factors.
b) Continuous processes: the equipment used for continuous rope bleaching is the J box with upstream impregnating section. Hypochlorite bleaching can be effected in an unheated J box. In the bottom of the J box is a bath (sump) which contains approx. half the chemical concentration of the impregnation section (wet J box). Impregnation with the bleaching solution is effected in an impregnation section (saturator). With peroxide and chlorite bleaching, heated J boxes are employed, or the impregnated fabric is steam heated prior to entry into the J box. Depending on the bleaching agent used, the J box consists of stainless steel, titanium, ceramics or plastic (polyester/glass fibre). U-shaped containers with nozzles at inlet and outlet are available for full-bath bleaching. Liquor and fabric run parallel at the entry end, and opposite to each other at the outlet end.

Bleaching fabrics in open-width form: this method is suitable for all woven fabric qualities.

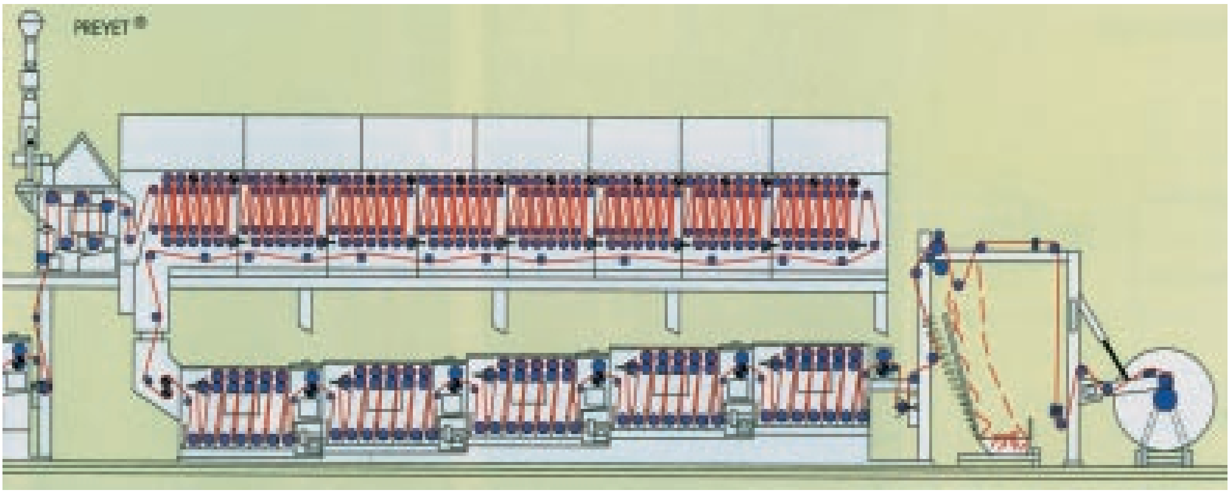

Fig.: One-step continuous bleaching unit for woven fabrics using the Preyet-spray-system, a roller steamer and a roller washing unit from Kleinewefers KTM.

a) Batch processes: batches scoured in a jigger are subsequently bleached in the jigger, hydrogen peroxide being almost exclusively employed. The second possibility of batch bleaching is offered by the “pad-roll”, pad mangle-dwell or batch bleaching process. A batch bleaching line comprises a pad mangle – or better, an impregnating section – a heating unit (steam, air, infra-red) and a dwell chamber. The heater unit can be located inside or outside the chamber. When perforated rollers are employed for batching, scouring can follow in the batch after bleaching. At the end of the bleaching process, the roller is connected to a rinsing water supply. Cold dwell processes are of interest from the energy saving standpoint. All temperature variants are suggested for peroxide. The lower the temperature the longer the dwell time. Practical operation assesses the degree of whiteness obtainable with a single stage peroxide bleach and the fabric wettability differently. Average degrees of whiteness are obtained with the BASF extraction cold bleach. Persulphate ($Na_2S_2O_8$) can also be used for cold dwell bleaching.

b) Continuous processes: these processes are of great importance. The equipment used in them is the same as for the alkali stage in scouring. Continuous process monitoring and a constant quality standard is ensured by using measuring equipment and multi-component bleaching agent dosing units. The processes comprise impregnating the fabric with the bleaching liquor (under certain circumstances in → High wet pick-up system), heating by steam and dwelling in a steam atmosphere with subsequent washing off. One processing variant is dwelling prior to steaming. Qualities which do not tend to crease can be plaited down in J boxes or on to conveyor belts or roller beds. The other qualities are fed in open-width over roller systems (at least in the initial stage) before being plaited down. A batching box is suitable for batches of over approx. 20 000 m of uniform width. Less room is taken up by HT or pressure steamers, in which the bleaching process is carried out within 45 to 120 secs at 130–140°C. Medium term bleaching processes with steaming times of 10–20 mins are more usual. Short bleaching times of 1–3 mins can be achieved with hydrogen peroxide in open steamers with the use of superheated steam (see Fig.). Scouring and bleaching each take 2 mins. In addition to waterglass as a stabiliser, sodium tetraborate or sodium pyrophosphate are to be added to the peroxide bath.

Bleaching of furs →: Fur bleaching; Bleaching of animal fibres.

Bleaching of jute This fibre is difficult to bleach. Hydrogen peroxide or sodium chlorite are used, preferably chlorite first followed by peroxide. A rapid after-yellowing occurs, however, following exposure to light.

Bleaching of knitgoods The processes are closely allied to those for woven fabrics, treatment in rope form being of greater importance than open-width bleaching. Knitgoods are particularly elastic, and do not tolerate lengthwise traction. Installations must be designed for this (see Fig.). Good raw material quality with no husk residues is generally selected for cotton knitgoods, so that the chemical concentrations can be reduced accordingly. Waterglass is only reluctantly used (handle impairment) as a peroxide bleach stabiliser; organic stabilisers in combination with magnesium sulphate are used instead.

Bleaching of linen With flax, the non-cellulosic constituent content, at 25–30%, is significantly higher than with cotton. In order to obtain a full white therefore, intricate treatments are necessary. The loss of weight occurring in scouring and bleaching can be as high as 40%. The old grass bleaching method is very

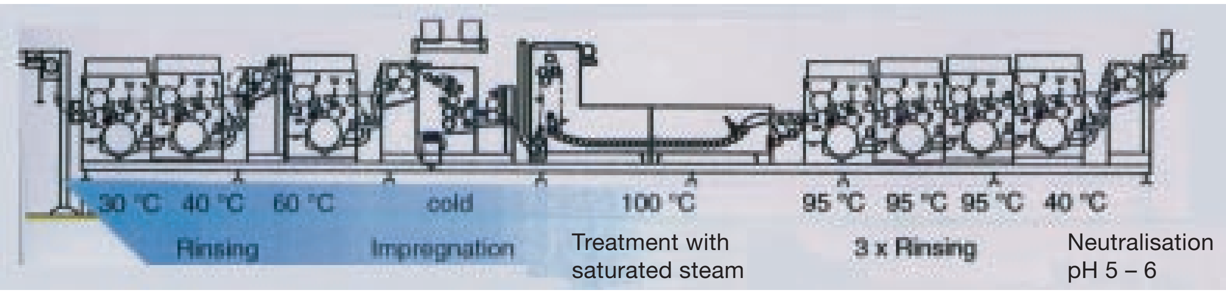

Fig.: Bleaching of knitgoods according to BTM with the Spray-Flour-Unit for rinsing without tension.

rarely used now. This previously widespread bleaching method comprises a sequence of alkaline scouring operations (hot liquors) and hypochlorite baths. 4 sequences (called rounds) were necessary in order to obtain a full (4/4) white. Lower degrees of whiteness are designated 1/4, 2/4 and 3/4 whites; the treatment required consequently comprised 1, 2 or 3 rounds. Attempts were made at an early stage to obtain a full white without the time-consuming 4 rounds. A "short" process is still occasionally used, the principle of which is to destroy the lignin, after scouring, in an acid hypochlorite bath at pH 4–4.5, and then pre-bleach in an alkaline hypochlorite bath, and post-bleach in a hydrogen peroxide bath. In the Ravensberg process, bleaching is effected after scouring with an aqueous chlorine dioxide solution, followed by a bleaching stage with hydrogen peroxide, and, finally, one with hypochlorite. The "LOK" process (Degussa) is carried out without pre-scouring, bleaching first with sodium chlorite and then with hydrogen peroxide. Another process also operates without scouring, first of all pre-bleaching with hypochlorite at pH 11.5, and, following the addition of sodium chlorite to the same bath, post-bleaching at pH 5.5 at 65°C. In practice, a 4-stage combination bleach is widespread: alkaline scouring, alkaline hypochlorite bleaching, chlorite bleaching and peroxide bleaching follow one another.

Bleaching of man-made fibres In contrast to natural fibres, man-made fibres contain no coloured attendant substances. They are already white when put on the market; optical whiteners are sometimes added to the spinning material. For full white, bleaching cannot of course be dispensed with, particularly where yellowing occurs due to the use of heat-stabilisation. Bleaching is mainly restricted to woven and knitted fabrics. Yarns are more seldom bleached, and loose stock rarely. Bleaching chemicals have to be adapted to the different fibre materials. Reducing agents are not damaging to the fibres, and are universally applicable in this regard. Sodium dithionite and also sodium and zinc formaldehyde sulphoxylate are used. Of the oxidative bleaching agents, sodium chlorite is universally employable except for polyurethane fibres. Hydrogen peroxide on the other hand is not suitable for all synthetic fibres. Polyamide in particular is sensitive to active oxygen. Polyvinyl alcohol is a protective agent. Unsuitable too is hypochlorite, which forms chloramine with polyamide, while potassium permanganate is also fibre-damaging. Man-made fibres are bleached in the full bath; the impregnation process, as employed with natural fibres, is unsuitable. J-box equipment is a possibility for continuous bleaching. In the case of synthetic fibres, the delustring agents, stabilisers, optical brighteners and UV absorbers (light protection agents) present in the spinning mass can, under certain circumstances, lead to difficulties in bleaching with sodium chlorite. Thus, the manganese salts contained in polyamide fibres as light protection agents cause pronounced yellowing of stilbene-based optical whiteners when exposed to light in the wet state. Fully delustered polyester fibres, also tend to yellow, and are therefore better bleached with hydrogen peroxide. In chlorine bleaching, some non-delustered polyester fibres acquire a strong red cast, which can be prevented by adding hydrogen peroxide or sodium perborate to the chlorite bath. Acetate and triacetate fibres persistently retain chlorine, for which reason they should be treated with sodium disulphite or sodium dithionite after chlorine bleaching. In bleaching polyamide fibres with sodium chlorite, it can occasionally be observed that the uptake of fluorescent whitening agents is blocked. Elastane fibres are difficult to bleach; the permissible bleaching agents have a negligible effect.

Bleaching of silk Oxidative and/or reductive bleaching processes can be used for brilliant and bright shades. Bleaching generally follows degumming. As a rule, mulberry silk generally already reveals a light colour after degumming, and bleaching is consequently necessary only for a full white. On the other hand, bleaching is almost always necessary for obtaining brilliant shades with degummed tussah silk owing to its inherent colour. Depending on tussah quality, a full white can be obtained only with difficulty, if at all. For full white, optical whiteners can be added to the subsequent reduction bleach bath after oxidative pre-bleaching.

Silk is bleached for example in accordance with the following processes:

1. Oxidative bleaching with 35% H_2O_2 and $Na_4P_2O_7$.

2. Reductive bleaching with stabilised sodium dithionite.
3. Bleaching and brightening (full white): optical brightening is mainly effected after oxidative pre-bleaching in the reduction bleaching bath.

Bleaching of wool Natural wools have a more or less strong inherent colour, which can be bleached out by reductive or oxidative treatments. The two processes are to be employed one after the other for a full bleach. The targeted white is however, even after the best of bleaches, unstable to exposure to light and washing. Yellowing occurs in the course of time. The cause of this is not yet known, and there is no product which can prevent this fault. It has been observed that many optical brighteners act as sensitisers, accelerating yellowing. Yellowing can be delayed by thiocarbamide and formaldehyde. Wool is sensitive to chemical effects, for which reason batches which have been subjected to anti-felt finishing for example should be bleached particularly gently, or it is recommended that bleaching be carried out prior to felt-free treatment. The lowest possible wool residual grease content – approx. 0.1–0.2% for worsted yarns, and 0.2–0.3% for woollen yarns – is important to the bleaching effect. The duration and temperature of the bleaching process have a great deal of influence on the quality of the wool. It is bleached in all processing stages: as loose stock, tops, yarn, fabric, in the full bath or by the impregnation process, continuous or in batch form. Under some circumstances, piece goods are dyed in pastel shades in the presence of bleaching agents.

I. Oxidative bleaching processes: hydrogen peroxide is generally used. Up to now, the waterglass used as a stabiliser in the cotton bleaching process has been found unsuitable for wool, and has been replaced by sodium pyrophosphate or one of the commercially available stabilisers. The pH is set with ammonia (provided that no silicate is employed). 50°C is the optimum temperature, with a duration of 3–4 hours. Cold storage bleaching with peroxide is possible with the aid of specific auxiliary agents. With the sensitivity of wool to alkali, peroxide bleaching in an acid medium is suggested. One such process is the “Prestogen W” process (BASF). Opinions as to the effect of acid peroxide bleaching as against the alkaline method differ. In the latter case, the white should be better and more stable with no greater fibre damage. Wool with a strong inherent colour is treated first of all in a solution of iron sulphate, centrifuged, and then bleached (natural hair depigmentation) in a hydrogen peroxide bath with complex formers added (for removing the iron). With such qualities, the finisher hesitates to use the catalytically intensified peroxide process.

II. Reductive bleaching processes: these are unsatisfactory for a full bleach, and are used only for brightening or as the 2nd stage of a full bleach. Many of the commercially available reductive bleaching agents are provided with an added fluorescent whitening agent.

With all processes, bleaching must be followed by a good rinsing process. Wool stubbornly retains hydrogen peroxide, a fact which can lead to dyestuff damage in the subsequent dyeing process. A reductive bath frequently follows for safety purposes. In a 2-stage bleach therefore, the reductive stage is carried out as the final process.

Bleaching powder vat → Chlorate discharges.

Bleaching soda A term which has a double meaning:

I. → Sodium dithionite.

II. A mixture of sodium carbonate and sodium silicate for water softening capable of binding traces of iron. Used in laundries, etc.

Bleaching stabilizers In hydrogen peroxide bleaching the effect is dependent on the controlled release of oxygen. Fibre damage is likely to occur if oxygen is released too rapidly. Besides the well-known sodium silicate (water glass) stabilizers which exhibit an optimum effect, other stabilizers based on polyorganosiloxanes, sodium borate and magnesium silicate are also used. The disadvantages of silicate stabilizers include difficulty in removal during washing, formation of deposits on the fibre and on processing machinery, harsh handle etc. No fully effective substitute for sodium or magnesium silicate has yet been found, however. If bleaching is carried out over a relatively long period of time (e.g. the cold pad batch process) it is particularly difficult to find an effective substitute for sodium silicate. When sodium orthosilicate is used, a combination of phosphate and a magnesium salt is recommended as a stabilizer. → Bleaching auxiliaries; oxidative bleaching processes.

Bleaching with hydrogen peroxide under acidic conditions In hydrogen peroxide bleaching it is usual for peroxide baths to be maintained under alkaline conditions since the release of oxygen proceeds too slowly in acidic media. However, Degussa has developed a product, Activator SF, which permits bleaching to be carried out at pH 5,5–7,0.

Bleach liquor → Sodium hypochlorite.

Bleach-related fibre damage → Vat dyes and fibre damage.

Bleeder styles Prints with indistinct outlines (→ Flushed prints). Print pastes for this style of printing contain two or more components. One of these components ensures a faithful reproduction of the engraved areas whilst the other components, because of their special properties, flow beyond the confines of the engraving into the unprinted areas where they give mainly contrasting colours at the edges of the printed motifs. Example: cotton fabric prepared with a naphthol and printed with diazo fast colour bases or salts in combination with reactive dyes to give bleeding effects. A two-phase fixation process is used for the reactive dye components.

Bleeding This problem occurs mostly with textiles which have been dyed in deep shades with dyes of poor wet fastness properties. When such materials are washed, or subjected to a wet treatment, the dye bleeds out into the liquor resulting in a lighter shade. In printed goods, dye can bleed into the white (unprinted) areas of the design causing staining of the whites. Bleeding can also give rise to problems in subsequent wet finishing treatments. Causes:

1. dyeings or prints produced with dyes of inferior wet fastness properties,
2. inappropriate washing conditions.

Blending weigher Used in colour kitchens for the preparation of individual print pastes. The system, which consists of both a fixed and a movable concentric dial scale, permits individual taring with the movable scale for the weighing of each component whilst the total quantity can be read off the fixed scale. Weighing errors are largely eliminated by this means.

Blister crêpe → Cloqué.

Block copolymer → Block polymers.

Block cutting Production of the → Hand for block printing. Pattern production by woodworking in accordance with pre-print blocks with fine contours by driving in pins and sheet metal strips. The latter are detailed in a lime wood block by means of red hot punches and babbitting with white metal alloy which serves as a printing knife when nailed on.

Blocked fatty acid groups Masked fatty acid and → Fatty acid condensation products.

Blocking effect in the dyeing of polyamide Mutual displacement of individual acid dyes in the dyeing of polyamide materials within the range pH 3–6. The effect is dependent on dye constitution, dye concentration, fibre saturation value and the dyeing auxiliaries used. The dye constitution is of decisive importance here since, as a rule, polysulphonated dyes are blocked by monosulphonated dyes and, depending on the degree of saturation of the fibre, dye concentration and auxiliaries concentration, are partially or completely displaced thereby preventing them from exhausting on to the fibre.

Blocking filters are used in → Spectrophotometers for → Colour measurement of fluoresecent white samples. This sort of equipment enables the effects of the substrate and brightening agents to be separated. The excitation of the brightening agent can be removed to a large extent with a variable u.v. filter (the measured colour values are those of the unbrightened substrate). On the other hand, with blocking filters for visible light or with a u.v. source, the values for the brightening agent alone are obtained. In this case the apparatus operates as a spectofluorimeter. Complete separation of the two types of light is not possible because optical brightening agents are excited to some extent by short wavelength light in the visible region.

Block polymers (block copolymers). These high polymers are formed from chains of different → Copolymers whereby individual units are joined together in relatively long alternating sequences (see Fig.). An example could be blocks of polyvinyl chloride interspersed with blocks of polyvinyl acetate. Such polymer combinations are made synthetically. They depend on the presence of an active site on the polymer chain which initiates the necessary reactions. Branched copolymers of this type are graft copolymers.

Block printing The oldest printing process – block printing – is mainly of historical interest today (→ Hand block printing). This is operated with so-called blocks which have been produced by striking brass pins and strips into a front bar, forming the pattern in this way. This process has been retained in developing countries, and also finds use in roller production for relief printing machines.

Blocks for printing (printing blocks) For hand block printing the blocks are cut from wood which are then infilled with felt and, where necessary, copper strip and pins (depending on the intricacy of the design) are also incorporated. Fairly hard woods are used for all printing blocks, e.g. ash, box, lime, sycamore, holly and particularly pearwood. To facilitate registration in hand block printing, brass pins are driven in at the corners of the block to indicate the position of the next repeat (→ Block cutting).

Blood alcohol, is measured as a percentage and arises after imbibing alcoholic drinks (ethanol). Blood alcohol has only a very tenuous connection with the states of intoxication induced by the inhalation of solvent vapours (hydrocarbons, chlorinated hydrocarbons, etc.) although it increases considerably if accompanied by the consumption of alcohol as well.

Blood, detection of Important in forensic medicine. Well-known methods include:

I. Benzidine test: involves making a clear extract of the blood stain with a 0,85% sodium chloride solution, then observing the reaction with some benzidine + acetic acid + hydrogen peroxide. Positive result = blue-green coloration.

II. Fluorimetry: blood does not normally fluoresce and appears black. After removal of iron from the haemoglobin and overstaining in haematoporphyrin with sulphuric acid = red fluorescence of high intensity; after removal of the acid with strips of filter paper and spotting with strong ammonia = crimson red fluorescence. Practical procedure: A platinum needle is moistened with conc. sulphuric acid and used to draw a fine line on the stain which is immediately neutralized with ammonia = fluorescent crimson red stripes on the wetted fibres under UV light. After separation of the caked blood which is optically “dead”, blood serum exhibits a weak bluish fluorescence.

Blood stains Red or brown in colour. When fresh, the stains are paler with a sharp boundary. Since the composition of blood varies, stain removal is very difficult and in some cases impossible, especially if the stains have become fixed by the action of heat. Removal: treatments are best carried out as soon as possible under essentially cold to lukewarm conditions; a prebleach with some ammonia and soap as well as diastase solution is useful: (a) bleaching with a 3% hydrogen peroxide solution, if necessary at increased temperature, (b) diastase solution (together with glycerol and possibly some ammonia). Yellow residue = iron (→ Rust stains).

Bloom,

I. In deep dyeings, the fullness or toning with a red, yellow, or blue cast, e.g. “bloomy black”. → Blue brushing.

II. The colour of foam in vat dyeing baths which, in contrast to the generally quite different colour of the vatted dye, appears closer to that of the finished (fully oxidized) dyeing.

Blotch design A single or multicolour printed design in which up to approx. 80–90% of the fabric surface is printed in one colour.

Blotch print In direct printing, a printed design of high coverage. Also used to substitute dyed grounds for discharge printing in cases where no dischargeable dyes are available with adequate fastness properties or where technical problems are encountered in coloured discharge printing.The degree of cover of a blotch print may be low, medium or heavy.

Blotch printing (cover printing). This type of printing is used to provide a background to a design which, unlike the white grounds in normal direct printing, or the plain coloured grounds in discharge printing, consists of a distinct pattern effect. It is produced with a special printing roller either simultaneously, before or after production of the main design, e.g. for imitation weave effects, fine dots, lines, etc. It may be visible over the entire surface of the printed fabric or limited to areas falling over other colours by resist or discharge printing.

Blotch printing machine (cover printing machine). A roller printing machine set up to print the entire surface of a fabric with print paste or a thickened chemical solution by means of, e.g. a completely engraved blotch roller (cover roller).

Blotch roller (1000 point roller), pad mangle roller engraved with recesses, for transferring softening agents and possibly dye solutions during → Nip padding.

Blotting paper effect → Capillary fabric-liquor interchange.

Blouson (Fr.). A short jacket or top having the shape of a blouse reaching to the waist, with either a buttoned or zip front and ample sleeves. The sleeve endings are finished with elastic material.

Blowdown of boilers A cleaning procedure for the removal of solid substances which have settled in the water reservoir of a boiler used for steam raising purposes. The procedure is often carried out with an automatic valve operating at working pressure.

Blown oils Thickened →: Semi-drying and drying oils (especially linseed oil, as well as castor, rapeseed and fish oils) which are already partially oxidized by heat and agitation produced by a current of hot air at 70–120°C. As a consequence of this treatment, drying is more rapid when used as oil sizes. They form reasonably stable light soapy emulsions in water without the need for emulsion-promoting additives.

Blow ratio Can be varied by the quantity of dispersed air brought in during foaming. If for example 1 kg of liquor is foamed to 10 l of foam, this is equivalent to a 10:1 blow ratio, or the foam has a litre weight of 100 g. → Foam application.

Blow test for dye homogenicity The simplest test to determine whether a dye in powder form is a homogeneous dye or a mixture. A small speck of the dye is blown across a piece of filter paper (approx. 10 x 20 cm) which has been completely wetted with warm distilled water, alcohol, benzene or conc. sulphuric acid. A homogeneous dye will produce uniformly coloured dots on the wet surface whilst a mixed dye will produce two or more different colours.

BLRA, abbrev. for (the former) British Launderers’ Research Association (now → FCRA); → Technical and professional organizations.

Blue brushing Surface brushing of the pile in black piece-dyed cord and velvet fabrics with a mixture of linseed oil and Berlin blue to achieve a more intense bloomy black shade.

Blue cast in bleached goods This effect is the result of excess → Blueing of bleached goods to compensate for yellowness. The resultant blue tint or cast manifests itself as an increase in whiteness only up to a certain level.

Blue deficiency A substrate which reflects the incident light falling on it uniformly and to a high degree at all wavelengths appears white to the eye. In general, however, fibres absorb more light in the blue region of the spectrum due to the presence of impurities (natural pigments) than in other regions of the visible spectrum (the effect is more pronounced with natural fibres and is usually less with synthetic fibres). The prevailing yellowish cast in bleached goods is referred to as blue deficiency and appears unattractive to the human eye. In order to achieve increased whiteness, therefore, the blue deficiency of a textile fabric can be cancelled out by applying compensatory measures and/or by increasing the amount of reflection. Both effects are obtained to a certain extent in bleaching. The additional application of a fluorescent brightening agent leads to further compensation of blue deficiency due to a simultaneous increase in lightness thereby producing a more brilliant white. A further improvement in whiteness by compensation which involves the application of very small amounts of suitable blue or violet dyes in the → Blueing of bleached goods is also possible.

Blue denim Strong woven cotton fabric with a warp twill construction, dark coloured warp and light (undyed) weft. Classical fabric for → Jeans. → Denim.

Blue "eating" dye combinations Catalytic fading caused by the action of light on the blue or blue-green components in combination dyeings with yellow and orange dyes which results in preferential and accelerated fading of the former. The problem occurs chiefly with vat dyes.

Blue "eating" yellow dyes These are yellow vat dyes which accelerate the photodegradation of blue (or blue-green) vat dyes. For this reason, they can only be used in combination with blue dyes up to a certain maximum concentration for the production of green shades. → Catalytic fading.

Blueing agents for bleached goods Blue dyes which are generally known as → Tinting dyes (or tints) for bleached goods.

Blueing of bleached goods As a supplementary treatment to correct the yellowish cast of bleached textiles the process is often referred to as the → Tinting of bleached goods.

Blue jeans →: Jeans; Denim.

Blue scale A standard comparative scale from 1 to 8 which is used for assessing the → Light fastness of dyed or printed textiles (1 = very poor, 8 = excellent). It consists of 8 standard blue dyeings on smooth wool fabric with varying degrees of sensitivity to the action of daylight or artificial light. In order to eliminate uncertainties in the evaluation of exposed blue standards and a test specimen, attempts have been made to obtain more precise ratings by colorimetric measurements. It has been found that to achieve the same degree of colour difference from daylight exposure different amounts of light are necessary depending on the season of the year. Use of the present blue scale as a standard comparative scale for light fastness tests has been subject to increasing criticism in recent years, particularly in the USA, where a polyester fabric dyed with a violet disperse dye has been recommended as a substitute.

Blue stone → Copper sulphate.

Blue vitriol → Copper sulphate.

Blue water phase Blue (or green) dyeing of the water phase of dry-cleaning in the water trap after the distillation of tetrachlorethylene. Is caused by copper corrosion.

Boarding The heat setting of hosiery and socks made from polyamide fibres to stabilize the knitted construction and confer a desired shape or size on the entire article. Depending on the type of hose and the stage of finishing, a distinction is made between

a) preboarding: a process carried out as the first stage of finishing at a temperature which is approx. 20°C higher than temperatures employed in subsequent finishing treatments and which are likely to be encountered in use (e.g. 115–130°C, 1,7–2,7 bar with saturated steam for 90–120 s);

b) postboarding: a treatment carried out after dyeing at 115–130°C with saturated steam for 60–90 s in order to achieve the desired shape of the articles.

Pre-setting or presteaming (not identical with preboarding) is carried out at 95–108°C for 10–20 min. Hosiery which has been presteamed is easier to process in subsequent finishing treatments.

Boarding of hosiery → Hosiery setting.

Boardy A subjective term used in the sense of a "boardy handle" for fabrics with very tightly woven and knitted constructions. The term is also used to describe finished fabrics that are excessively stiff or firm and lack suppleness.

Bobbin cleaning device Mechanically or pneumatically removes fibres remaining on the cores.

Bobbinet (English: bobkin = bobbin, net = tulle), so-called English tulle, net curtains and laces with at least 3 yarn systems. Binding or bobbinet ends, which spirally wrap round warp and patterning ends, are characteristic. For distinguishing purposes, mechanically produced English tulle is described as bobbinet tulle, the simplest version of which is so-called honeycomb – also called plain sexangular or hexagonal tulle. It is produced from two yarn systems, warp and weft systems. The warp system runs in the vertical direction in the fabric, with the weft system in the diagonal direction, each weft or bobbin end of the course looping once after each warp end on its diagonal path. Each bobbin end works first on the fabric face rising from left to right, then rising from right to left on the fabric back, forming the honeycomb openwork which is typical of sexangular tulle.

Bobbin lace Net-like openwork fabrics produced with fine threads (by hand or machine) that are fed from bobbins and worked into a pattern by the twisting together and crossing of strong ply yarns. Tulle and net backgrounds are also encountered. Bobbin lace galloons in different widths can be used as edge trimmings.

Bobbin length Length of the thread to be wound.

Bobbin packing machines Automatically pack the individual (yarn) packages in sheets in order to protect the yarns during transport.

Bobbins In worsted spinning these are yarn packages from the ring spinning machine. In carpet weaving they are flanged bobbins or spools.

Bobtex yarns Simulated spun yarns produced by embedding individual staple fibres in a thermoplastic or adhesive coating on a filament yarn. In principle, a thermoplastic polymer is applied to a filament yarn (as the strength component) and coated with staple fibres before the polymer sets in order to improve bulk and textile appearance. Yarn consolidation is achieved by means of false twist. A composite yarn produced in this way does not necessarily have to be twisted after heat setting/cooling thereby giving a flat hairy yarn. Bobtex yarns can be produced automatically and continuously at high speeds (300–600 m/min.) in any desired composition to meet specific requirements.

BOD → Biochemical oxygen demand.

Body and border carpet Wall-to-wall carpeting supplied in widths up to 5 m which is laid up to the wall skirting boards.

Body, climate, clothing In German the so-called 3-K system (Körper, Klima, Kleidung) which forms the basis of investigations in clothing physiology. → Clothing physiology.

Boiler, automatic Fully automatically controlled → Steam boiler. This term says nothing about type of construction, but is applied both to flame tube, smoke tube and Benson boilers.

Boiler feed water → Water requirements for steam raising boilers.

Boiler scale A more or less hard deposit which results from the use of untreated or inadequately treated boiler feed water. Boiler scale adheres firmly to the surfaces of plates and tubes in contact with water in steam boilers. If excessive, it leads to overheating of the metal and ultimate failure. Boiler scale is composed principally of (→ Water hardness salts), calcium carbonate and sulphate (gypsum boiler scale), some magnesium salts and (particularly dangerous) silicates.

Boiling out Unwanted → Kier boiling. Unwanted kier boiling during cotton textile washing occurs as a consequence of vat dyed effects in alkaline oxygen-depleted washing agent at high temperature (boiling) in the presence of reducing substances and under densely packed conditions. Under such conditions, even wash-fast vat dyeings/prints vat into soluble dyestuff/leuco compounds which easily leave an imprint on other articles, and stain them. Remedy: steep/prewash starched vat dyed articles prior to washing in order to remove natural starch as far as possible.

Boiling point All boiling points quoted in the literature, etc., relate to standard atmospheric pressure (1,0133 bar). When a liquid is subjected to increasing heat, a continuously increasing development of vapour on the surface is first observed together with the release of bubbles of vapour which rise from within the liquid. From this point onwards, the temperature of the liquid rises no further; this temperature is referred to as the boiling point. On further heating, the entire liquid is transformed gradually into the vapour state, i.e it evaporates. A pure liquid has a boiling point characteristic for that liquid whilst mixtures of liquids boil in specific sequence one after the other according to the typical boiling points of each component of the mixture, i.e. they are transformed successively into the vapour state (fractional distillation for the separation of mixtures). Thus special boiling point spirits (SBP), formerly known as benzine, is a mixture of different hydrocarbon homologues with no fixed boiling point but a boiling range of 60–120°C which indicates the boiling limits. A clear sharply defined boiling point indicates the presence of a pure liquid of uniform composition, whilst an indistinct boiling point is indicative of a mixture or impure liquid.

Boiling range In contrast to liquids of uniform composition with characteristic → Boiling points (e.g. pure benzene, water, glycerol), liquid mixtures (e.g. special boiling point spirits) have a well defined boiling range which extends from the lower to the upper boiling limits of the components.

Boiling water test (for dyeings) → Dye class identification tests on fibres.

Bolt A roll or piece of textile fabric of varying length.

Bolting cloth (→ screen mesh/gauze). This term covers a variety of lightweight open fabrics characterized by their fine and uniform mesh used for sifting flour and semolina (miller's bolting cloth), voile fabrics, window gratings, etc. as well as screen gauze or silk gauze for screen printing. Both warp and weft threads are accurately spaced and are woven in simple leno or other non-slip construction in order to maintain the mesh size. Bolting cloth contains 50–200 mesh openings/cm in coarse qualities, 200–400 in medium qualities and up to 3 000 in fine qualities.

Bolting silk → Bolting cloth of tightly twisted silk ply yarn, but also of other fibre materials, like cotton, flax and wool for example.

Bombyx mori (Lat.). A species of moth, the cultivated silkworm of which feeds on mulberry leaves and produces the finest quality of natural → silk.

Bond

I. → Chemical bonds.

II. Woven fabric structure, the method of yarn crossing (pattern draft) which forms the fabric. It determines stability, pattern and also external appearance. We differentiate between the following basic bonds (Fig.):

a) Plain weave, calico, tabby weave, taffeta weave, the simplest and shortest types of construction. On both sides of the fabric lie alternately warp end 1 over the weft end, warp end 2 under it, 3 over it etc. The name plain weave is generally used for cellulose

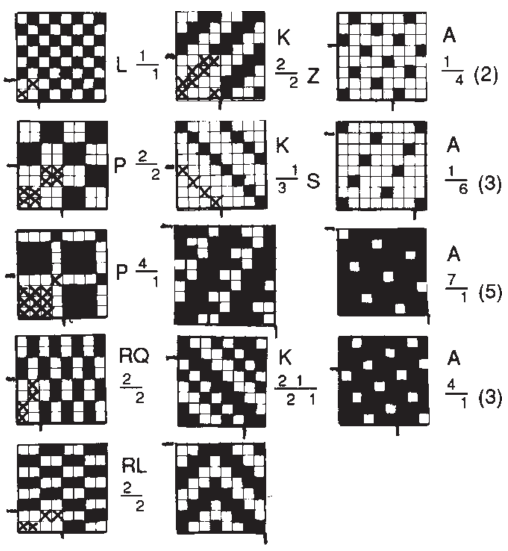

Fig.: Types of ground weave and some derivatives. Left: plain weaves: basket weave, Panama, patterned Panama, warp ribs. Centre: twill weaves: twill of uniform line, weft twill, steep twill (gabardine), stitched twill, zigzag twill. Right: atlas weaves: two weft and two warp atlases.

fabrics, calico is becoming obsolete for cotton fabrics, tabby weave for wool fabrics and taffeta for silk fabrics.

b) Twill weave, reveals diagonal stripes, and also called rib or twill rib. Fainter or more pronounced twills are produced by predominant warp ends on the fabric face = warp twills, or predominant weft ends on the fabric face = weft twills. In the case of right-hand twills, the twill runs from bottom left to top right, and the other way for left-hand twills. Broken or zigzag twills are produced by alternating stripe direction.

c) Atlas weave has uniformly scattered crossing points, where the other yarn crossing points lying between the visible crossing points are more or less covered by the ends lying on top (called floats). There are also (similar to twill) warp and weft atlas constructions, 3, 5, 8 and 10 construction etc.

d) Derived weaves, all other weaves which are derived from a) to c) or are combined from these derivatives; from plain weave e.g. basket weave/hopsack (panama), (longitudinal and transverse) ribs and leno weave; from twill weave e.g. cross, herringbone, wave, fancy twill and honeycomb weave; from atlas weave e.g. double atlas, crêpe and shadow weave.

Bonded fabrics (nonwovens) (Fr.: Tissus non tissés). Generic term for nonwoven and nonknitted bonded textile fabrics produced from fibres (fibre composites), yarns (yarn composites) or fabrics (laminates). They are subdivided into the following categories →: Yarn composites, Fibre composites, Stitch-bonded composites, Swell process nonwovens, Fused bonded nonwovens, Spunbonded nonwovens, Extruded composites, nonwovens, Milled composite fabrics, Knitted composites.

Bonded pile carpets → Pile carpets produced by adhesive bonding a folded material of yarns, webs or fibres to a substrate. Processing possibilities:

I. Single-stage process: simultaneous feeding and adhesive bonding of the pile material to 1 or 2 substrates (textile or plastic), or adhesive bonding two substrates together with pile material and separating them by cutting, so as to produce two identical fabrics.

II. Two-stage process: pile layer is formed in itself, adhesive bonded to a substrate, and then separated by cutting, again producing two identical fabrics.

III. Three-stage process: for colour patterned fabric. The pile material (tow, yarns, webs etc.) is compressed into a block (by freezing for example), cut into sheets across the longitudinal axis in a thickness equivalent to the required pile height, and adhesive bonded to the substrates.

Bonding agent In screen printing, a bonding agent is applied to printing blankets on flat-bed and rotary screen printing machines before coating with a thermoplast adhesive in order to ensure satisfactory bonding of the latter.

Bonding of textiles In order to reflect recent technology, bonding is defined as: the bonding of two textile materials by means of locally applied adhesives (Fig. 1) in contrast to → Laminating which involves the uniform distribution of a binder over the entire surface. Bonding thus represents a technical variant of laminating (Fig. 2). A typical bonding process is the front fusing of outerwear materials with fusible interlinings (point-bonded nonwovens). After both textiles have been joined together in the ironing press or setting press in garment making, the polymer spots applied to the fusible interlining melt and bind both textiles together on cooling into a "sandwich"-like composite. Such fusible interlinings are made by joining several carded webs together by needle punching followed by a

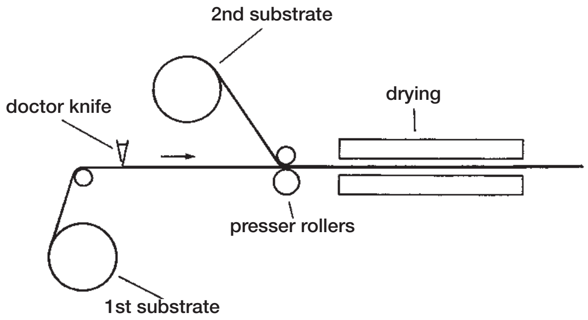

Fig. 1: Schematic bonding process.

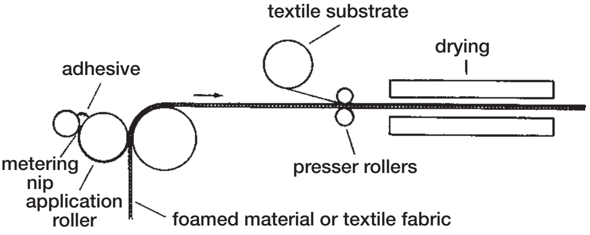

Fig. 2: Bonding/laminating process.

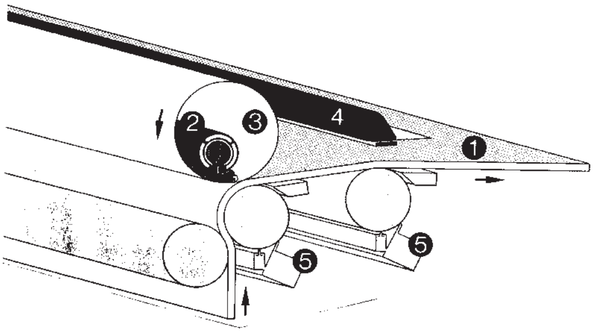

Fig. 3: Stork CT-IV dot coating for bonding setting interlinings.
1 = finished setting interlining; 2 = paste feed; 3 = rotary screen; 4 = infrared drying; 5 = pressing systems.

final chemical bonding with a foamed binder (synthetic resin dispersion). Coating is carried out by powder spray methods or rotary screen printing.

By dividing up the adhesive layer into numerous individual and discrete areas (Coin process) a softer handle and better drape is achieved. The size of the points or pattern and its distribution is variable. Opinions differ as to whether adhesive areas of the same size or different sizes with a uniform distribution are better.

Various methods are used to apply the binder:

1. Roller application: engraved rollers are used for this purpose, i.e grooved rollers for application in lines, thousand point rollers for spot bonding, as well as rollers with engraved designs. Excess binder is removed with a doctor blade.
2. Rotary screen application: this process involves rotary screen printing with a binder dispersion. Heavy gauge rotary screens engraved with a series of dots are used (Fig. 3).
3. Thermobonding: polyethylene powders of different particle size are applied by the spray or powder dot process. The binder melts in a heat zone after which both materials can be bonded together. Meltable binders are also used for nonwoven interlinings in shirt collars and cuffs.

A process known as “Chem-Stich” can likewise be described as a bonding technique. In this process shrinkable and unshrinkable fabrics are used to produce cloqué type effects. A solvent-based adhesive is applied with a design roller to a polyamide fabric which has not been heat-set. After a light drying treatment, a heat-set outer fabric is brought into contact with it by adhesion. A final heat treatment in the stenter (approx. 180°C) causes the base fabric to shrink and the outer fabric takes on a blistered appearance.

Bonding unit For → Bonding and also for → Laminating foamed materials. The application roller is engraved with stripes, dots or other figures.

Bondi process Method of producing textile floor coverings. Yarn sheets or loosely woven fabrics are layered in zigzag form into a low stack, which is stuck on to a backing material, and cut.

Book-fold processing Procedure used in crêpe finishing. Fabrics of e.g. viscose or silk are reeled or plaited into book-form with laps of 90–100 cm; the book of fabric is then sewn with loops of twine through the selvedge on one side of the book only. The loops are about 25 cm long. The fabric is then suspended from a horizontal pole which passes through the loops, so that the weft direction hangs vertically in the soap bath into which the fabric is lowered until it is completely immersed. In this manner, the liquor is able to circulate freely between the folds of the cloth, which is free from creases during the crêping treatment. Excellent crêpe effects are produced in this way. The procedure is also used in the degumming of silk piece goods for subsequent weighting (lightweight georgette and crêpe de chine fabrics).

Booster → Wet steamer.

– (dry-cleaning) → Dry cleaning detergent.

– (laundry) → Detergent booster.

Booster boxes American system of small boxes containing cooled blank vat solutions as built-in units to steamers, e.g. in the pad-steam process. The method has not proved popular in practice. A further development of this principle is the → Wet steamer process of Gerber.

Borassus piassava → Palm fibre.

Borates Salts derived from metaboric acid HBO_2 and polymeric boric acid $(B_2O_3)_x \cdot H_2O$ but generally not from normal boric acid (H_3BO_3). Alkali salts (e.g. → Sodium borate) are water-soluble with an alkaline reaction (hydrolytic cleavage); other borates are generally either insoluble or sparingly soluble.

Borax → Sodium borate.

Bordered fabrics Woven or knitted fabrics with designs running parallel to the selvedge; printed, embroidered, open-work effects, etc. Used for blouses, dress fabrics, home furnishings and household textiles.

Boric acid, H_3BO_3. Salts = borates. Colourless, smooth, flake-like crystals; sparingly soluble in cold water (40 g/l at 20°C), readily soluble in hot water (approx. 290 g/l at 100°C) and in alcohol (1:25) and glycerol (1:5). Volatile in steam. Solutions have a very weak acidic reaction. Uses: As a preservative for textile finishes (inhibits bacterial growth in 1–3% solution but does not destroy bacteria); flame-retardant finishes; tanning, etc.

Boric acid, identification test, e.g. as foreign matter or residue on the fibre:

I. Ash the specimen, mix with calcium fluoride and moisten with conc. sulphuric acid. Heat in a Bunsen flame; presence of boric acid = green flame.

II. Soak the ash with dil. hydrochloric or sulphuric acid. Moisten a piece of turmeric paper with the mixture and dry; presence of boric acid = red-brown coloration (titanium, molybdenum and zirconium salts also give a brown coloration).

III. Mix the ash with a little conc. sulphuric acid and a little methanol. Heat in a test tube and ignite the escaping vapours; presence of boric acid = intense green flame.

Boron fibres Industrially manufactured mineral fibres of the following types:

I. Boron fibres: vapour-deposited filaments made by depositing vapour phase boron from a boron halogen compound on a heated tungsten wire. Tensile strength 100–200 cN/tex, E modulus 370–450 kN/mm^2. These fibres have been developed for use in aircraft and space applications; for rotors, turbines, etc. The fibres can also be woven into fabrics.

II. Boron carbide fibres: manufactured by the reaction of boron chloride and hydrogen with carbon fibres at high temperatures whereby a layer of B_4C is formed immediately on the carbon surface (conversion of approx. 50% of the carbon to B_4C). Tensile strength 80 cN/tex, E modulus 340 kN/mm^2, stable to temperatures up to 2200°C, high conductivity. Uses: protective clothing against radiation, heat insulation, etc.

III. Boron nitride fibres: derived by reaction of boron oxide fibres with ammonia through several intermediate stages of increasing temperature (up to 1800°C); they consist of up to 99% BN. Tensile strength approx. 100 cN/tex, E modulus 28–90 kN/mm^2; short-term temperature resistance up to 3000°C; better corrosion resistance than carbon or glass fibres, high electrical resistance. Uses: aircraft and space applications; heat and electrical insulation; protective clothing against atomic heat flows, etc.

Bottom hair Short, fine animal hairs in the hair undergrowth, generally without any medulla, supple, elastic, high crimp, good felting properties.

Bouclé (French = loop),

I. Clothing and overcoat fabrics with a curly, knobby surface due to incorporated fancy burl, kink and loop ply yarns. The name indicates the rough granulated surface of the fabric. The typical bouclé character is produced by so-called loop ply yarns (mostly three-ply) of worsted or woollen yarn, which can be found both in the warp and the weft, but are generally present only in the weft. With high qualities, the loop-forming end consists of mohair, achieving a particularly beautiful lustre effect. Bouclés are woven in simple ground constructions, predominantly tabby weave. Lighter-weight fabrics (in all colours) as dress fabrics, heavier fabrics (mostly in darker shades) as winter overcoat fabrics. The latter are usually reinforced by ground picks, or even have ground warp and ground weft. Despite the rough fabric surface, bouclés are included among napless finish fabrics. The winter overcoat qualities are mostly raised on the back in order to improve heat insulation. So-called bouclé imitations have no loop ply yarns, but only a construction with a consciously rough accent. Bouclé fabrics are generally classic, reasonably hard-wearing dress, costume and overcoat fabrics. Because of their loops, admittedly somewhat sensitive in contact with metallic, rough or sharp objects. Loop fabrics are similar, but not identical with them.

II. Weft and warp knitted fabrics with a structured surface.

Bouclé carpets Carpets with uncut pile loops (loop pile carpets). Since, up to approx. 1960, the pile material in loop pile carpets mostly consisted of hair yarn, bouclé carpet was often, but incorrectly, used as a synonym for hair yarn loop pile carpets (→ Brussels carpets).

Bouclé-ondulé process (Reinhard system) carpet-producing process in which undulated yarns, fabrics or webs are laminated on to a backing fabric. → Bonded pile carpets.

Bouclé yarn Compound yarn produced from coarse wool as well as cotton or man-made fibres comprising a twisted core with an effect yarn wrapped around it so as to obtain wavy projections on its surface.

Bougran (bougram, bougrassin, bugram, tailor's canvas) Gauze-like cotton or spun viscose interlining, grey or black in colour, mostly flat in shade. Preferably used instead of excessively thick and heavy → Buckram.

Bourette (Fr.: *bourette*, *bourré* = full hair or fibre). Yarn produced from (silk) waste and combing noils in schappe spinning which is interspersed with knots and slubs. → Flock silk, frisons.

Bow distortion, correction of Occasionally rollers are used for passive correction of bow distortions in the fabric as it leaves the stenter. These rollers, which do not take up the fabric but merely have an idler function, are less suitable for fabric straightening (with some exceptions). In principle, they also cause a deviation in cloth run similar to the straightening method using bow rollers. A dry fabric, however, is not easily straightened in this way, because it is often comparatively stiff. Moreover, often the distortion cannot be permanently rectified (e.g. with heat-set fabric), and the distortion recurs as soon as the fabric is released. Hence, it is preferable to apply other methods to draw out the lagging middle section of the web by increasing the traction at the stenter exit. This can be adequately achieved by means of the normal take-up or draw rollers, the surface of which should, however, provide a suitable coefficient of friction. If the take-up roller is entirely smooth, it will not have an adequate draft action. On the other hand, if the surface grip is too extreme, i.e. no slippage at all is possible, the straightening effect will also be inadequate, because the fabric edges are pulled along with the middle section. With a medium coefficient of friction, however, the centre of the web is properly transported, and a certain degree of slippage is possible at the edges, as required; the fabric is delivered well aligned. Another option is to use a take-up roller with a variable diameter. Contrary to passive straightening, slight changes in diameter are already sufficient to significantly increase the peripheral speed of the roller centre in relation to the roller edges. A higher peripheral speed, however, means that the web is transported faster at the centre than at the edges; thus the lagging bow is brought forward.

The correction of bow distortions by means of either of the two methods described can be automated by an appropriate system. However, should there be a prominent leading bow, properly aligned fabric delivery will be virtually impossible. This state of affairs is, however, relatively seldom. To meet high accuracy demands, a fully automated weft/course straightening unit in front of the entry is frequently combined with automatically controlled chain/draw roller correction by means of scanners at the stenter exit. This combined straightening system is a necessity, because only minor distortions can be corrected via chain and draw roller control alone, so that it is not possible to dispense with straightening at the entry.

There is a popular straightening option that is often applied in the USA: at the delivery end of the stenter only the lagging bow is measured and corrected, thus reducing the expense for electronic measuring and control systems, as opposed to straightening via stenter chain with differential drive. The question is often raised whether the method of correcting residual distortions by means of the stenter chain and take-up roller can ever be advocated. Experience has shown that the answer must be in the affirmative. When the centre web is drawn forward, this means that with most fabrics the straightening action is not limited to the last few decimetres – which would be tantamount to localised elongation – but that the effect of straightening at the exit extends right into the stenter. Here, however, the fabric is not completely dry and/or not yet heat-set, i.e. it is still ductile. But once the fabric is entirely dry or has completely cooled down after heat-setting, it is virtually impossible to permanently rectify distortions.

The straightening effect is calculated according to the following formula:

$$R = \frac{r \cdot i \cdot L}{v}$$

R = straightening effect in cm,
r = straightening effect per pulse in cm,
i = no. of pulses/min., set with specific v (dependent on the controller, the no. of pulses changes proportional to the change in speed),
L = stenter length in m,
v = basic speed in m/min.

Bow straightener Device for the correction of bow distortion in fabric webs, e.g. with curved rollers.

BP,

I. abbrev. for: British Patent.

II. abbrev. for → Benzoyl peroxide.

BPC, abbrev. for: British Productivity Council.

BPI, (Ger.) abbrev. for: Bekleidungsphysiologisches Institut Hohenstein (German Institute for Clothing Physiology); → Technical organizations.

Br, chemical symbol for bromine (35).

Braid Narrow fabric produced by (→ Braiding); used for trimmings, etc.

Braiding (braided goods). Textile materials produced by interlacing three or more threads in such a way that they cross one another in diagonal formation. A distinction is made between flat braids (→: Braid, gimp), tubular braids (→ Cords) and openwork goods (braided lace).

Braiding fibres The following types of fibre are mainly used in the production of → Braids: palm fibre, leaf fibres, pandanus fibre, straw fibres and bast fibres.

Braids plain or figured narrow fabrics with woven-in velour; also conically woven. Used as velour or clothing (seam) protective edgings.

Bran A waste product from the milling of grain into meal; still occasionally used as a component in fermentation vats (soda vat, woad vat, bastard vat).

Brandom process An English dyeing system for the production of multicoloured yarns. Principle: local dyeing of yarn in the package. The effect is similar to that obtained in → Yarn printing.

Brandon process Pile yarn is wrapped spirally around rectangular metal rods to produce an adhesive bonded carpet. The rods are then pressed into a substrate provided with adhesive. After the windings have been cut, and the metal rods removed, a velour fabric is obtained.

Brazing The process of joining two pieces of metal with the aid of:

a) a low melting point metal (→ Brazing solder) applied between the adjoining surfaces,
b) a soldering flux (zinc chloride-ammonium chloride solution) or sodium tetraborate,
c) ammonium chloride,
d) soldering copper or a gas flame.

Brazing solder Metal alloy used for → Brazing which has a lower melting point than the metal to be brazed; e.g. tinman’s solder (tin-lead solder), spelter or hard solder (copper-zinc, possibly including silver).

Break-even analysis The differing cost behaviour of the cost centres has to be clearly expressed in the costing. It is not always possible to differentiate in terms of cost behaviour when the costs are recorded. In production, there are costs which can only be clearly attributed to the cost unit after they have been incurred, when cost unit rates have been drawn up accordingly. For internal profit and loss accounting, the costs must be shown separately according to their behaviour and their cause. This is only possible if costing and profit and loss accounting have the same structure. In order to assess the behaviour of the costs, a reference point is required – turnover. The question which is always in the foreground is: How do the company’s costs in question as a whole (not those for an individual article) change if the turnover (production) increases or decreases in terms of quantity? Three different behaviour types can be clearly established:

1. Turnover-dependent expenditure (Fig. 1): There are various expressions for this: variable, performance-related, turnover-proportional, production-dependent. What these terms all indicate is that the expenditure is directly dependent on turnover (= direct costs). There is not just a dependence in terms of quantity here, where the costs change if the amount sold changes, e.g. the cost value of the goods sold, in the production, the material consumption, energy, etc. There is also a dependence in terms of value: If the selling price is altered, this gives a different turnover figure for the same quantity, with certain costs also being changed as a consequence. The turnover-dependent costs all have a striking feature: they automatically change necessarily, with any change in turnover. If the turnover increases or decreases by a single unit, the total of these costs changes accordingly in the corresponding period. If one unit more has to be produced, then more raw material is required for this additional unit. At the level of the article, the turnover-dependent costs correspond to the so-called price floor. If the article is sold at the price floor, then the net operating results are not altered, since the revenue is just as high as the costs incurred directly by this article.
2. Expenditure for infrastructure (Fig. 2): Infrastructure includes what a company needs in order to be able to achieve its sales performance (with production), e.g. premises, installations, staff, etc., before sales (turnover) activity and production can be started. All these parts of the infrastructure have a particular capacity. The costs of the infrastructure only change when new components have to be “fitted in”. This adaptation is always carried out gradually. For example: Additional machines increase depreciation, and may even require new premises; wages change as a result of new appointments or redundancies. A feature of these costs is that they are not caused directly by the change in quantity of turnover or production, but by the decision to change the capacity of a part of the infrastructure.

   An additional module of capacity or infrastructure does not come automatically, but always requires a decision by the responsible management. Thus the infrastructure costs are not caused by the turnover. Rather, it is the case that the turnover uses or makes a demand on the existing infrastructure. The various infrastructure modules have differing turnover or

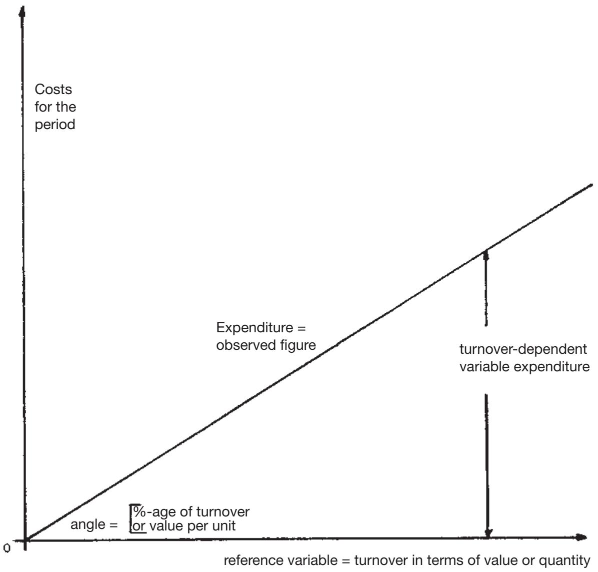

Fig. 1: Graphic representation of turnover-dependent expenditure.

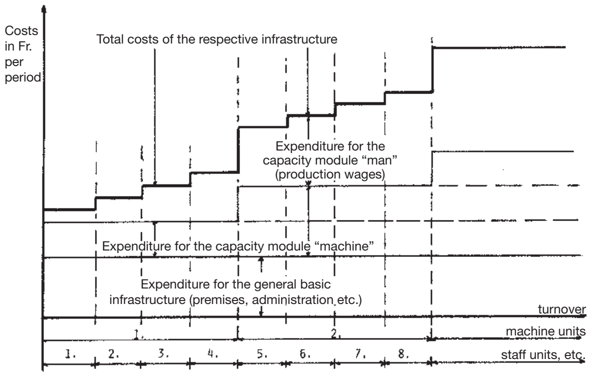

Fig. 2: Graphic representation of the expenditure of the infrastructure (in development).

production capacities. They have to be supplemented accordingly for differing increases in turnover. The supplementation of an infrastructure module leads to cost jumps in the cost profile. This is the peculiarity of fixed costs. We therefore do not have fixed costs and leaps in fixed costs. All infrastructure costs increase in jumps, in contrast to the continuous increase in turnover-dependent costs. Only the range of the individual modules varies.

3. Elective expenditure: There are also costs which are not dependent on turnover, but neither can they be associated with capacity. They have one feature in common with the infrastructure costs, which distinguishes them from turnover-dependent costs. This also has to be decided. Whereas in the case of infrastructure costs, the decision creates costs which recur regularly (e.g. wages, depreciation, rent etc.), with this expenditure group, in the absence of any explicit renewal these costs are incurred only once. They are valid as a one-off event. Examples: Advertising costs, staff training, projects and investigations, which as a rule always relate to the future.

With this clear allocation of costs (1 to 3), the contribution margin can be defined simply: Revenue less turnover-dependent costs equals contribution margin. Or to put it another way: Revenue less all costs incurred directly when one additional unit is produced and sold. These costs are equal to the price floor. The contribution margin is thus always a balance. The term originates from the fact that with this difference, a contribution must be made which covers the infrastructure costs and the elective expenditure. If anything is left over, that is profit.

Separation of costs according to how they behave allows a simple graphic representation of the benefit threshold or break-even point (Fig. 3). Whereas elsewhere the equation “turnover equals total expenditure” was taken as a basis, the break-even analysis (contribution margin calculation) now represents that with the formula “contribution margin equals infrastructure costs plus elective expenditure” (source: Issler).

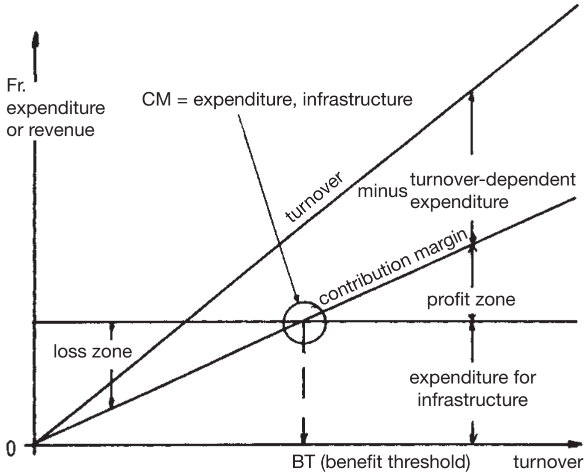

Fig. 3: Benefit threshold (BT), graphic representation according to break-even analysis (contribution margin calculation) (benefit threshold where CM = infrastructure expenditure).

Break even point (BEP) A traditional break even chart shows revenue and costs as a linear function of output or production. As illustrated in the Fig. the total cost is the sum of fixed costs and total variable costs for each level of production indicated along the horizontal axis. Revenue is the product of selling price and the number of units made and sold. If the production output per unit time is represented along the horizontal axis of a graph (see Fig.) with the corresponding costs as well as earnings along the vertical axis, then the BEP is the intersection of the two lines which can be taken as the profit or loss threshold, i.e. the point at which neither a profit nor a loss is made.

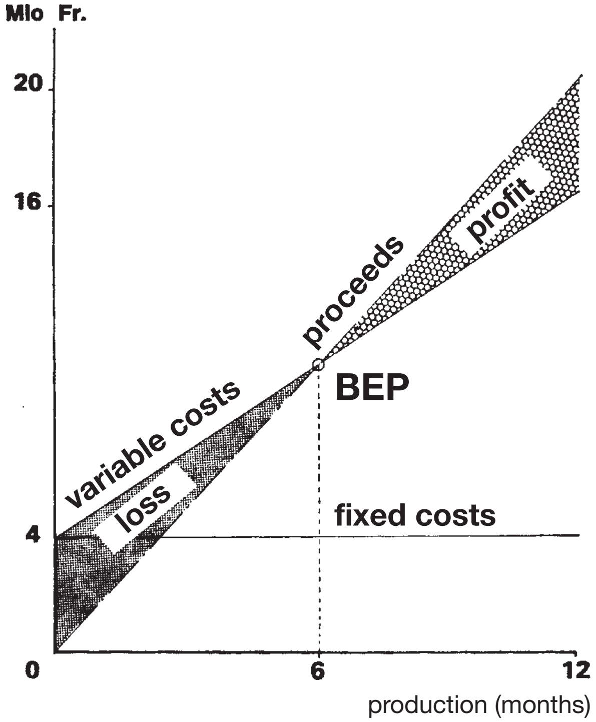

Fig.: Break even point

Breaking force The → Tensile strength test measured immediately prior to complete parting of the test specimen in simple tensile strength testing; it is consequently always somewhat lower than max. tensile load.

Breaking length Dimension (no longer used) for the → Tensile strength of a material. The breaking length denoted the length of a test specimen (fibre, yarn), the dead weight of which was equal to the →

Breaking load, and was indicated as length in kilometres at break.

Breaking load → Tensile force.

Breaking strength → Tensile strength.

Breaking strength in bending → Flexing fatigue limit.

Breaking stress (cross-sectional breaking strength), in the → Tensile strength test, the quotient of the breaking force and the initial cross-section of the test specimen.

Breaking weight → Tensile strength.

Breathability The concept embraces a number of characteristics. Thus, it is used to describe water vapour permeability, waterproofness or water pressure resistance and windproofness or air permeability. The result is an overall picture of heat-regulatory processes which describes the wear comfort of clothing textiles.

The multitude of "breathable" textiles and their different production processes make unambiguous description difficult. The artefacts of end-user advertising reinforce this impression still further. The conceptuality loses further in terms of unequivocalness in the transition of the processes describable as "high-tech" development into the technical textiles application field with sometimes completely different requirements, and it therefore makes sense to segregate the characteristic profile. Only → Water vapour permeability is to be understood by breathability. The parallel testing of water pressure resistance continues however to be indispensable, as there is no utility value without adequate waterproofness. Precisely this interrelationship between waterproofness and water vapour permeability, which appears first of all to be a contradiction, establishes the attraction of these products. In contrast, air permeability or windproofness can be left out of consideration, since it is practically zero in the case of coatings. Thus, ventilation in these types of textiles, e.g. in the case of sportswear or tents, is conditional only on cutting technology, and must be taken into account in model design. Water vapour permeability and air permeability are completely different physical properties, and are not dependent on each other. The latter is not important for moisture conveyance; air movement can of course change the climatic conditions, and consequently indirectly affect breathability too in the individual case.

The development of "breathable" textiles is closely associated historically with a desire for leather-like properties. Synthetic leather production is therefore responsible for the emergence of numerous production methods. A large proportion of water vapour permeable materials, the so-called poromers, work on the leather principle, i.e. water vapour is conveyed by a microporous foam structure. Extended development in the field of breathability also permits other fields of application. To some extent, the now numerous processes represent innovations which are far superior in their requirement profile to the impregnation process employed for many years. They can be subdivided into the following groups, where technology and characteristics can vary greatly relative to the field of application:

- microfibre woven fabrics,
- microporous coatings,
- laminates with microporous membranes,
- laminates with compact membranes,
- compact, hydrophilic coatings.

Breathable coatings Unscientific term for porous coatings which are permeable to air and water vapour. They are produced by various methods: e.g. through the addition of water-soluble salts to the coating compound followed by subsequent dissolving out, or by mixing indifferent solvents with the aqueous coating compound, or through the addition of gas-releasing substances to the coating compound. In another process, nonwoven fabric is coated with a solution of polyurethane in dimethyl formamide followed by subsequent dissolving out of the latter with a non-solvent for polyurethane. → Microporous coatings.

Bridging oxygen → Fatty sulpho acid esters.

Brightening acid A mixture of lactic and tartaric acids. Excellent scrooping agent (no fibre damage) especially for the achievement of a scroopy silk handle (treatment with 1–2 g/l soap followed by 2–6 g/l brightening acid without intermediate rinsing and final drying at low temperature.

Bright radiator drier → Infrared predrier capable of reaching temperatures up to approx. 1950°C.

Brilliancy

I. Physical dimension of → Brightness or the impression of brightness (→ Colorimetry).

II. SI unit derived from candela per square metre (cd/m^2).

$$\text{brilliancy} = \frac{\text{light intensity of a light source}}{\text{luminous area of this light source}}$$

The range of brilliancy runs from the luminophores (→ Fluorescent substances) with approx. 1 mcd/m^2 to the xenon high pressure lamp with 10 Gcd/m^2.

Bristles,

I. Natural bristles: white to grey, coarse, stiff hairs of the domestic and wild pig. Used for brushes, paint brushes and brooms.

II. Synthetic bristles (DIN 60 001): coarse, chopped, synthetic monofilaments which, depending on stiffness and length, are suitable for the manufacture of brushes, paint brushes, brooms, etc. Synthetic bristles produced principally from polyamides, polyurethane or polyvinyl chloride are not only considerably stronger than natural bristles, but are also more resistant to water (as well as rotting) and chemicals.

British gum Roasted maize starch (maize dextrine). Excellent thickening agent for textile printing, especially for vat dyes. Other roasted starches, even including those derived from potato starch, are occasionally marketed as British gum.

British Textile Technology Group (BTTG) An independent British textile research and technology organization formed in 1988 as a result of a merger between the former Shirley Institute and WIRA textile research organizations. → Technical and professional organizations.

Brittleness → Flexibility.

Broadloom,

I. Descriptive term for wide carpeting produced in widths of 6 feet (180 cm) and above.

II. In the USA, a statistical term for → Roll carpets.

Brocade A figured heavy fabric often with elaborate large area designs produced on a jacquard loom. Basic weave is satin. The design, on the surface only, often produced with yarns in contrasting colours, may also contain metallic threads. Brocades are made with any major textile fibres and normally include a lustrous fibre (e.g. silk with cotton, viscose, etc.). Used for evening wear, ball gowns, theatre fabrics, furnishing fabrics, upholstery, etc.

Brocade (découpé), An additional effect thread is inserted into the ground weft (→ Lancé). If the structures are far apart from each other due to the pattern, the floats are cut (cropped). This makes it more difficult to extract the floats on the back; the fabric weight is also reduced. Lancé découpé is also referred to as imitation → Broché.

Broché (= interweaved). Fabrics with patterns that look as they have been embroidered on. Genuine broché is produced on swivel looms. Besides warp and weft, these looms have a third thread system which inserts small shuttles controlled by a jaquard loom. The swivel embroidery stay serves to guide and drive the broché shuttles distributed over the width of the fabric. The broché weft is firmly interweaved together with the ground weft. The figuring threads are reversed in accordance with the patterning contours (as opposed to: → Lancé). When the patterns are a short distance apart, the broché thread runs to the next figure; with a greater pattern spacing the thread is cut off on the reverse side of the fabric.

Broken bast-soap Acidic dyebath for natural silk containing the original → Bast soap from degumming which has beneficial levelling properties in silk dyeing.

Broken ends Are promoted by the high productivity of modern weaving machines and the introduction of new products by other production processes (fast spinning etc.). In weaving (see Fig.), warp ends are subjected to high loadings, the physical mechanisms of which are extremely complex. Sizing is necessary for preventing warp fatigue, particularly due to repeated extension.

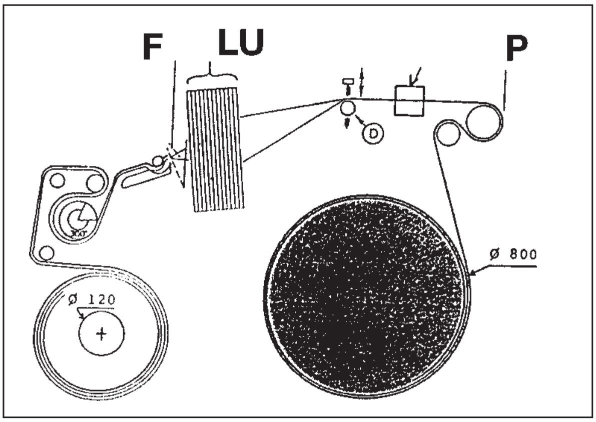

Fig.: Warp yarn path in classic weaving.
F = woven fabric start; LU = heald stafts; P = back rest roller.

The warp sheet is systematically divided into two yarn sheets in order to form the shed and enable the weft to be inserted. After every pick, the position of the ends is reversed so that a cross-over takes place. Each warp end runs through the eyelet of a heald which correctly positions it. The elastic property of the yarn is used to open the closed shed, the result being yarn tension changes in every cycle. Dynamic fatigue phenomena (not static) result in ends breaking in their weak places. For identical max. tension, the fatigue phenomena and the number of yarn breaks is the higher the greater the tension differences between low and high tension. The higher the degree of elongation with identical basic tension, the sooner the yarn breaks.

Broken twill A strong cotton fabric with a warp cross twill weave. The fabric has a high resistance to slippage and is characterized by a particularly “full” handle. Used especially for leisure wear.

Bromate discharges Oxidative discharges, e.g. as coloured discharges on indigo by printing a mixture of sodium bromate or bromite and chlorate of alumina (aluminium oxide), followed by subsequent steaming, washing off and dyeing (with alizarin). Nowadays of relatively minor importance.

Bromelia fibres Leaf fibres of the *Bromeliaceae* family which are indigenous to the tropical and subtropical regions of South America. They form a subgroup of the → Hard fibres and include, e.g. pineapple fibres, caroa fibre or so-called silk grass. In contrast to the agave fibres, they are easily extracted from ripe leaves which have a high fibre content and a low amount of leaf flesh. The fibre strands are approx. 1,5 m long with a tensile strength of up to 60 cN/tex. The better qualities are processed into fine spun yarns and silk-like fabrics in their countries of origin. Coarser and more highly lignified fibres are processed into ropes, braids, etc.

Bromite desizing Process for desizing cotton fabrics by the oxidative degradation of starch with sodium bromite.

Bromothymol blue (BTB). Used as an indicator in desizing with diastases for pH control within the optimum specified range.

Bronze An alloy consisting principally of copper and tin, possibly also containing other metals. Bronze for bearings generally contains up to 84% copper. Phosphor-bronze, which is malleable and can be drawn, generally contains 0,1–0,3% phosphorus, and is used where resistance to corrosion and wear is required. Bronze can be readily melted, it is harder and more elastic than copper and produces a crystalline or granulated fracture. Uses: fittings, machine components (bearings, toothed gears, worm gear drives, etc.).

Bronze pigments These are manufactured from metal granules in special ball mills in the presence of lubricants to prevent cold bonding of the particles. The following types are available:

I. Leafing pigments: so-called leaf-forming "fat-rich" pigments which float on the liquid surface and orientate to give a highly reflecting film.

II. Non-leafing pigments: "low fat" pigments which are completely wetted out and therefore do not float but orientate within the binder film.

III. Special pigments:

a) water-dispersible pigments for aqueous binders,
b) surface-coated pigments (for coating powders),
c) pigment pastes for special applications in plastics,
d) pigment pastes containing printing oils for the graphics industry.

Lubricants in leafing types: saturated fatty acids; lubricants in non-leafing types: unsaturated fatty acids and alkylamines. → Bronze printing.

Bronze powder → Metal powders.

Bronze printing Although described as "bronze" printing, gold-bronze pigments are used which consist almost exclusively of copper/zinc alloys (brass) whilst real bronze is, in fact, an alloy of copper and tin. The gold-bronze pigments are subdivided into the natural colours dependent on their alloy composition:

copper	containing 100% copper
pale gold	containing approx. 90% copper
vivid pale gold	containing approx. 80% copper
deep gold	containing approx. 70% copper

In addition, pure aluminium powder is also available as silver bronze. → Metal powder printing.

Bronzing of dyeings Dyeing fault manifest as a metallic iridescent appearance which is associated with poor rubbing fastness. There are a number of possible causes, i.e.: inadequate pretreatment (wax or oil residues), dye precipitation (e.g. in hard water), over-saturation (excess dye) of dye on the fibre, and the premature oxidation of sulphur and vat dyes during dyeing.

Brown coal Mainly brown to black-brown in colour, seldom black. Brown coal extracted from mines contains 40–50% water and approx. 6% ash components. It is rich in bituminous products and is therefore graded according to increasing bitumen content (benzene-soluble) into fire coal (dark brown) and extraction lignite (light brown). Brown coal briquettes consist of compression-moulded comminuted brown coal with a water content of 15–17%.

Brownian movement The phenomenon of erratic random movements performed by molecular particles of like electric charge therefore preventing collisions (water drop test under the microscope). Law of "ideal disorder". This constant random movement triggers an osmotic pressure causing the migration of e.g. dye particles from areas of high concentration to those of lower concentration thus initiating the diffusion of dye particles within the fibre.

Brushed denim Velvet-like emerized (sanded) cotton twill fabric with a light fluffy surface and soft handle for fashion jeans available in different colours and raw white besides blue. →: Jeans, Denim.

Brushed fabric The name refers to the finished character of the material. Fabrics with brushed finishes may be roughly categorized into a) fabrics with a short close lying pile (e.g. eskimo, doeskin, fine-ribbed woollens) often associated with an enhanced lustre, and b) fabrics with a long loosely ordered pile (e.g. mohair fleece fabrics, brushed loden). These fabrics are predominantly woollen articles and, less frequently, worsted articles in plain-weave, warp cross twill weave, warp satin weave and tricot weave constructions. To achieve the brushed effect, the goods are raised and (wet) brushed. It is important that the brushed effect is adequately set - this applies particularly to those fabrics in category (a) above.

Brush furnisher rollers Used in roller printing machines to transfer print paste to engraved printing rollers: They perform two functions, i.e. to furnish engraved printing rollers with print paste and clean out the engraved areas at the same time. They are chiefly used for print pastes which tend to build up deposits in the engraving ("sticking in"), e.g. pigment colorants, certain vat dyes, as well as discharge print pastes con-

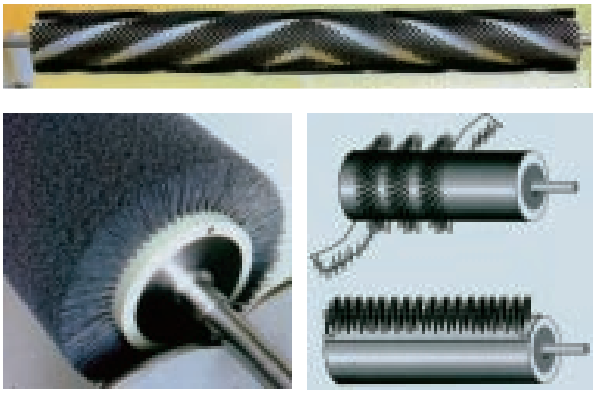

Fig.: Examples from TSI for different brushing rollers for dry and wet brushing taining white pigment. Brush furnisher rollers of a different type were used in a patented process of the now defunct company Kekko for so-called "waste water-free" dyeing (see Fig.).

Brushing

I. An operation in dry finishing which serves particularly the cleaning of woven wool fabrics, but also those produced from other fibres, when fibre fly, dust or threads have to be removed. Furthermore, the raising effect can be affected by brushing, in fact, in such a way that the raised hairs point in a specific direction, or become entangled with each other. Brushing is carried out on so-called → Brushing machines, before or after shearing and before pressing, mostly simultaneous with steaming. Brushing units are also employed between singeing and desizing or dyeing and printing. In the first case, severe contamination of the scouring liquor is prevented, while, in the second, fibre deposition on the roller printing machine roller is avoided. Brushing is of by far the greatest importance in the production of woven pile fabrics, e.g. cord and velvet.

The Fig. shows various brush combinations:

a) blowing, brushing, suction: recommended for removing all kinds of adherent dust;
b) brushing, suction, blowing, suction: recommended for removing imprinted dust from fibre plates, waffle floor coverings, artificial leather etc with a very deep action;
c) beating, suction, blowing, suction: treatment of etched out products; the residues are practically completely removed, and the bath contamination for washing-off reduced to a minimum;
d) suction, blowing, suction: recommended for the contact-free removal of fine and very fine dust from warp knitted fabrics, braided fabrics, muslin; tulle, paper, artificial leather, foils, films, glass etc.

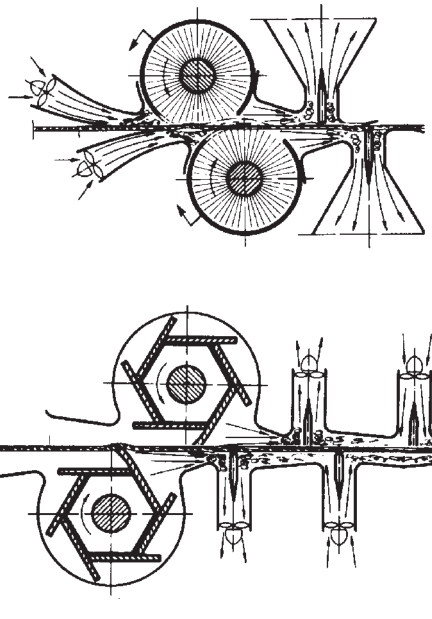

Fig.: Kälin system brush combinations.
top: for removing dust; bottom: for burn-out patterns.

The beating and brushing machine (van Wyk) is of a design similar to a cyclone type beating and brushing machine, but furnished with an incorporated fan with a dust filter bag instead of the cyclone.

II. Felt hats are brushed in the warm, wet state in order to fix the nap in the case of long-haired surfaces, to produce a silken lustre and to improve handle with hair hats. To this end, the hat is placed on a rotating cone, and processed by brush pressure. Felt hat brushing generally follows fulling after the dyeing process, and can take 30–90 mins with interruptions. Brushing and shearing also serves to eliminate the pilling prerequisites.

Brushing machines (brushing and steaming machine) (see Fig.) for the finishing of napped fabrics. The main unit is a large brush-covered drum which rotates against the fabric run in contact with the fabric back. The brushing effect is not only dependent on roller speed but also on the actual clothing material (→ Brushing rollers). A wide steaming table is generally located upstream for simultaneous steaming.

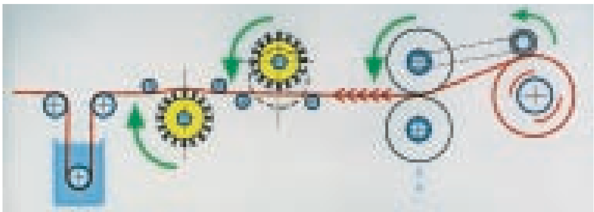

Fig.: Wet brushing machine for pile fabric (TMT).

Brushing rollers Components of brushing, longitudinal shearing, card roller, special wet brushing machines etc. Brushing rollers should run absolutely concentrically so that the brush pressure on the fabric (see Fig.) remains constant, i.e. unchanging.

In the case of the still very commonly used brushes with wooden cores (bristle tufts pressed in or held in by wire), gradual warping or distortion of the wooden core occurs under the influence of varying room humidity, with consequent loss of brush concentricity and disadvantageous effects on brushing process quality. This does not occur with brushes in which the brush material is pressed into a U-sharped spiral metal band, and in which the mounting base is secured by wire. These types of endless brush spirals are slid on to a special iron core to the required length, pressed together at both ends by means of ring nuts, and shorn down to working diameter. With these types of brushes, the brush material can be renewed quickly at any time by replacing the worn spiral.

Fig.: Brushing roller clothing.

Brush pile finishing Analogous to → Lustring. A finishing process given to pile fabrics (cord fabrics, velveteen) to improve lustre and appearance of the dried and finished pile face by treatment in a → Brush pile finishing machine (application of lustre-enhancing products combined with beating, brushing and steaming).

Brush pile finishing machine (waxing and lustring machine). Pile fabrics are run though the machine with the back side against a heated cylinder and the pile side is pressed against polishing rollers rotating at higher speed in the counter direction to the fabric passage, as a result of which a sustained ironing effect is imparted to the pile (see Fig.). The polishing rollers consist of steel centres covered with wool felt. The polishing effect can be varied by the application of lustre-enhancing products (molten wax or other finishing agents) before entry to the polishing rollers. Pile alignment is achieved in the final treatment by steaming or beating. Because of the risk of fabric deformation with pressure-sensitive materials, cord fabrics should be rolled up immediately after cooling and carefully stored.

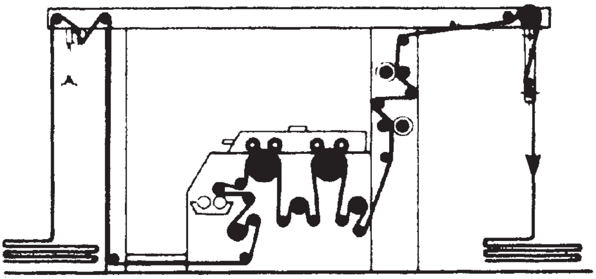

Fig.: Typical twin finishing roller brush pile finishing machine.

Brush roller application Application of finishing liquors, usually in concentrated form (liquor pick-up < 40% = low pick-up system) to textile fabrics by spraying from a brush roller. Liquor is transferred from a roller partially immersed in the finishing liquor to the rotating brush from which it is thrown by centrifugal force on to the fabric in droplet form.

Brush stencil print A cheaper Japanese imitation of a → Yuzen printing which can easily be distinguished from the latter due to the absence of small irregularities and crossovers which are so characteristic of a genuine Yuzen printing as a result of the many repeating stencils used.

Brussels carpet A loop-pile carpet, woven on a Wilton loom, over unbladed wires (i.e. when the cutting blade of the metal strip is absent); originally manufactured in Brussels. Depending on type of pile material, these carpets are described as hair or wool Brussels.

BS,
I. Bachelor of Science (USA), academic degree.
II. British Standard.
III. benzene-soluble (chem.)
IV. binary state (comp.)

BSI, abbrev. for: British Standards Institution. → Technical and professional organizations.

BTTG Abbrev. for: British Textile Technology Group, → Technical and professional organizations.

Bubble coloration process Non-repeating patterned effects in polygon or ring shapes (from burst bubbles) as well as grape-like motifs are produced on textile fabrics from dye-containing bubbles (produced by blowing air through a pad liquor containing surfactant and thickening agent). The bubbles are allowed to impinge on the back side of the fabric or they can float on to the fabric surface (including carpeting materials). Discharge effects, as well as designs produced by the application of Fast Colour Salts on naphtholated grounds, are also possible.

Buckram A → Stiffened fabric, generally linen or cotton, usually of natural colour, with good elastic resilience produced by impregnating a plain-weave opensett fabric with fillers and stiffeners. Its uses include linings, millinery, waistbands and bookbinding.

Buckskin A suiting fabric similar in handle and appearance to, but heavier than, a doeskin fabric, made from fine merino wool, wool/cotton union, closely sett, heavily milled, lightly raised and closely sheared on the face. A distinction is made between summer and winter buckskin depending on fabric weight (the latter is often produced as a double fabric).

Buffer → Buffer solution.

Buffer solution A general term for a solution containing a mixture of an acid reacting salt and a base or an alkaline reacting salt and an acid. The pH of such solutions is not significantly changed on dilution or the addition of H^+ or OH^- ions (acids and bases). The action of buffer solutions is based on the formation of weak acids or bases from intercepted H^+ or OH^- ions. Thus, solutions of weak acids and their salts with strong bases, e.g. acetic acid/sodium acetate (CH_3COOH/CH_3COONa), usually in equivalent ratio or other suitable mix ratio, are used for the buffering of H^+ and/or OH^- ions. Acidic reacting hydrogen salts can also be used instead of weak acids. The same applies to mixtures of weak bases and the salts of strong acids, e.g. ammonium hydroxide/ammonium chloride (NH_4OH/NH_4Cl). The capacity of the system to buffer H^+ and/or OH^- ions is based on the example of acetic acid and the following two reactions:

$$CH_3COO^- + H^+ \rightleftharpoons CH_3COOH$$

$$CH_3COOH + OH^- \rightleftharpoons CH_3COO^- + H_2O$$

Buffer solutions of known pH value can also be used as comparative solutions for measuring the pH of unknown solutions. Commercial standard buffer solutions suitable for the calibration of pH meters are available which cover a range of pH values. Relevant tables of suitable buffer mixtures for the preparation of buffer solutions are also readily available. Mixtures of the following compounds are particularly suitable as buffer solutions:

- sodium dihydrogen phosphate NaH_2PO_4/disodium hydrogen phosphate Na_2HPO_4,
- boric acid H_3BO_3/sodium perborate $Na_2B_4O_7$ and
- citric acid/sodium citrate.

Such solutions possess the characteristic property of changing only very slightly in pH on addition of strong acids resp. strong alkalies since, e.g. the strong acid is "neutralized." An example in dyeing is the use of sodium acetate which can buffer hydrochloric acid:

$$CH_3COONa + HCl \rightleftharpoons NaCl + CH_3COOH$$

or

$$H^+ + Cl^- + Na^+ + CH_3COO^- \rightleftharpoons Cl^- + Na^+ + CH_3COOH$$

Even the dilution of a buffer solution with water, e.g. by a factor of 10, causes no change in the pH value. Comparative buffer solutions are required in pH measurement determinations, e.g. standard acetate solution prepared from 350 ml distilled water, 100 ml of 1N acetic acid and 50 ml of 1N sodium hydroxide: pH value of this solution = 4,62. In a similar manner, amphoteric substances (protein, glue, amino acids) as well as, in a wider sense, protective colloids, e.g. as used in the dyeing of wool with acid dyes, in wool chlorination, bleaching, etc., may also be regarded as buffers. Finally, levelling agents with fibre or dye affinity also offer buffering effects to some extent. → formaldehyde/ammonium salt reactions.

Builders Substances which increase the effectiveness of soaps or synthetic detergents (→ Syndets) by acting as softeners and sequestering or buffering agents. They help to retain dispersed soil in the wash liquor and prevent redeposition. Phosphate-silicate formulations, once widely used, have now been restricted for environmental reasons (→ Eutrophication). They have been largely replaced by → EDTA or → Zeolites, sometimes combined with nitrilotriacetic acid. Certain starch derivatives may also be used as builders.

Build-up behaviour of dyes A distinction is made between build-up behaviour of dyes in printing and in dyeing. In printing, the fact that the effective quantity of dye applied per unit surface area can only be determined approximately is a great handicap and often leads to the application of excess dye. Each application of excess dye is indicative of inefficient working practice since, on the one hand it is a cost factor, and also has a negative influence on subsequent processes such as dye fixation and afterwashing on the other. With the knowledge of dye-specific build-up curves obtained by colour measurement techniques, a step towards the better control of applied print paste quantities has been made (Fig. 1).

The build-up behaviour of dyes is greatly influenced by the:

- substrate,
- substrate pretreatment,
- print paste composition,

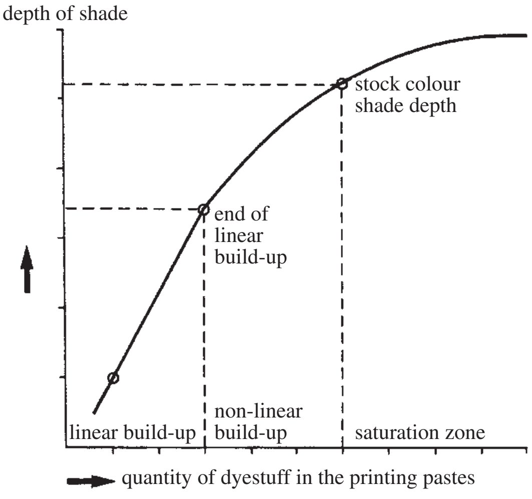

Fig. 1: Example of a dye build-up curve.

- print paste application,
- drying,
- fixation,
- afterwashing of printed goods.

If these parameters are kept constant, build-up curves are an ideal tool for the evaluation and comparison of different dyes. From these curves it can be seen that, in the main, dye build-up may be subdivided into 3 zones:

1. Linear build-up zone: this zone allows reliable strength comparisons to be made between dyes. The end-point of linear build-up provides an indication of build-up behaviour but gives no information on the economic build-up limit achievable.
2. Non-linear build-up zone: this zone begins with a flattening of the build-up curve and extends to the point where an additional quantity of dye is no longer worthwhile from a technical and economic standpoint. The end-point of this zone is called the “stock colour depth.”
3. Saturation zone: this zone begins at the point where dye is applied in quantities above the stock colour depth. It poses high risks with regard to, e.g.:
   - poor reproducibility,
   - loss of economy,
   - afterwashing and colour fastness problems,
   - poor product comparability in terms of strength, shade and application behaviour.

Build-up curves provide a means for the technical and economic evaluation of dyes. Optimum stock concentrations are dependent on local conditions and these should be established accordingly.

In the exhaust dyeing of polyamide fibres for the carpet sector, dyeing equilibrium changes as shown in Fig. 2 if the dyeing temperature is reduced.

A comparison of the build-up behaviour of different dyes as a function of dyeing temperature at a constant pH of 6,0 and a constant dyeing time reveals important differences in the behaviour of dyes with medium, high, or very high neutral exhaustion properties and migration properties which are corresponding very good, average or moderate. Whilst metal-complex dyes require temperatures near to the boil for optimum build-up because of their high molecular weight, acid dyes already exhibit rapid build-up behaviour from 40°C which, from 80°C, can already change gradually into a desorption phase. The well-known pH-selective behaviour of acid dyes is exploited in the controlled pH process; and is especially pronounced with dyes of medium neutral exhaustion properties. Build-up behaviour shifts considerably if the pH is reduced from pH 6 to pH 4; a property which is exploited in the sliding pH process.

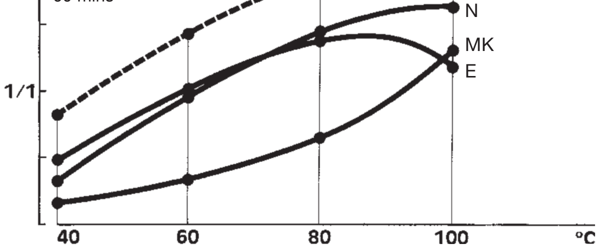

Fig. 2: Effect of dyeing temperature on dye build-up.

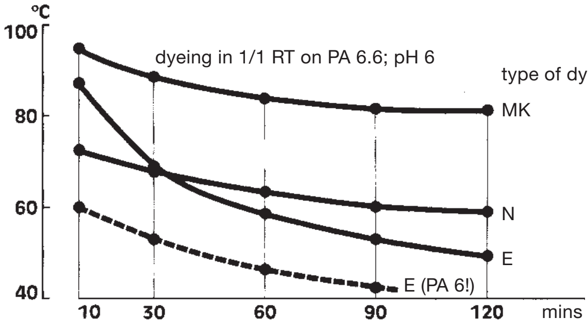

Fig. 3: Effect of dyeing temperature on dye build-up.

As shown in Fig. 3, the conditions required to achieve a 1/1 standard depth are different for the 3 types of dye selected. The E-type dyes, with medium neutral exhaustion properties, require a dyeing time of 60 min. at 60°C, whilst the N-type require 120 min. and the metal-complex dyes can only be applied in practice at temperatures of 80°C and above. The situation changes if polyamide-6 is used as substrate instead of polyamide-6.6; in this case, exhaustion increases so that, e.g. the E-type dyes build-up to 1/1 standard depth within 10 min. at 60°C.

Built soaps → Syndets.

Bukhara carpets Extremely fine hand knotted carpets made chiefly by nomads of the Turkoman tribe of the Tekkeh who live on the Trans-Caspian steppes. The motif used for Bukhara carpets is by far and away the best known of all those used for decorating oriental carpets, i.e. the Gul, which means rose in Persian. It is an octagonal motif with slightly rounded angles. Typical motif colours are blue, black or, more rarely, green with red and orange. The band between the outer edge and the central motif is wholly in ivory or alternating ivory and light red. The ground and border colour is almost always red, but in different shades, ranging from violet to orange. Wool warp and weft. The weft thread is very fine and is invisible even when used double. The pile is also in wool of excellent quality; soft, silky and hard-wearing. The quality of the wool is, in fact, one of the reasons why Bukhara carpets are so famous. The Persian knot is used with a very high density of between 350 000 and 600 000 knots per m^2.

Bulk development The development of bulk in

HB yarns (→ Textured yarns) of polyamide, polyester and polyvinyl chloride fibres either continuously, in hank form, super packages or as knitted fabric. The aim is to produce maximum bulk in textured or latent crimp yarns or in fabrics made therefrom. The essential conditions are heat, lubrication, movement, and the absence of tension. Bulk development may be accomplished during wet processing or may be a separate operation such as hot air tumbling, steam-injection tumbling or drycleaning.

Bulked Yarns → Textured yarns.

Bulking plants Used for the continuous bulking of HB yarns (high-bulk yarns). Bulk development is achieved by means of saturated steam, superheated steam or hot air.

Bulk/volume in textured yarns Filling capacity of a → Textured yarn per unit of weight (mass) measured under defined conditions.

Bulletproof vests Intended to provide the wearer with protection against small arms fire. They are of lightweight construction to afford maximum wearing comfort over long periods and provide protection against small to medium calibre bullets. Fabrics made from aramid fibres are mainly used, which offer the greatest degree of safety and the possibility of joining fabric layers together and producing combinations with thin sheets of hard material to give flexible laminates combined with the water repellency of aramid fibres.

Bump yarn Coarse, thick cotton yarn (sized) produced from cotton waste by the condenser yarn process. Frequently used for ground warps in carpet manufacture.

Buna rubbers Synthetic rubbers developed originally by Harries resp. Mathews and Strange as far back as 1910 and manufactured (at first in Germany by BASF) by polymerization of butadiene with finely divided sodium as catalyst (hence the name Buna, derived from the abbrev. of *Bu* + *Na* used as a trademark) for which the viscosities were given as attached numbers (so-called “number buna”). Further development by Bayer and the introduction of emulsion polymerization (1929, Bock and Tschunkur) led from these types to so-called “letter suffix buna”, i.e. Buna S, SAR (→ Styrene-butadiene rubber) a copolymer of butadiene and styrene as well as Buna N, NBR, GR-N (→ Butadiene-acrylonitrile rubber), or nitrile rubber, a copolymer of butadiene with acrylonitrile. As a result of further process modifications, e.g. the development of Ziegler-Natta catalysts and the use of other monomers for copolymerization (e.g. isoprene) etc., a whole variety of buna types (also in latex form) became available with optimum suitability for different applications. Uses: similar to natural rubber; especially for container linings; seals; swell-resistant printing rollers; protective coatings etc.; laminating; coating; foam rubber, etc.

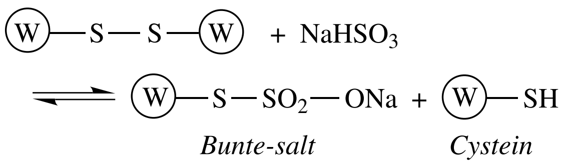
Bundesmann test A test used to determine the water repellency of fabrics by means of the Bundesmann Water Repellency Tester in accordance with DIN 53 888. → Water sprinkling apparatus Pfersee.

Bundle pack Method of packing yarn in hank form. In the English numbering system, 1 bundle = 10 lbs (10 English pounds = 4.536 kg). In metric numbering, 1 bundle = 5 kg. (→: Skein, Hank). Bundle pack variant units are usual to some extent. Bundle packs are produced in a bundle press.

Bunsen burner (chem.) A gas burner consisting of a tube with a small gas jet at the lower end, and an adjustable air inlet by means of which the heat of the flame can be controlled (air/illuminating gas mixture); used as a source of heat for laboratory work.

Buntal This → Palm fibre is made from stalks of the unopened leaves of the Buri palm of the Philippine Islands. It is a light fibre used to make hat braiding.

Bunte salt Formed by the sulphitolysis of cysteine in wool:



Bunte salt dyes, are a special group of sulphur dyes which, due to transformation of the mercapto groups into thiosulphato groups, are converted into a soluble form which has no affinity for cellulose. However, the addition of barium hydrosulphide during dyeing causes a gradual reverse transformation to take place into a form having affinity for cellulose.

The term has also been applied to a type of reactive dye for wool, which contains alkylthiosulphato groups. It has been postulated that these dyes attack cysteine groups when applied to wool and the asymmetrical disulphide formed largely disproportionates into symmetrical dye disulphides which are relatively insoluble.

Bunting A soft, flimsy, loose-textured, plain-weave cloth most frequently used in flags. Bunting was originally made from cotton or worsted yarns, but today’s flags are made primarily from polyamide or acrylic fibres.

Burette Apparatus for measuring the quantity of a liquid or gas in a chemical operation. In volumetric analysis the burette generally consists of a vertical transparent glass tube graduated in fractions of a millilitre provided with a glass stopcock or rubber tube pinch-cock at the lower end, by means of which the amount of liquid which is allowed to flow from the graduated tube may be controlled. Used for → Titration.

Burette test Used for testing small fabric specimens to determine the effect of waterproof/water-repellent finishes. The lower end of a → Burette, or metal cylinder is sealed with a small specimen cut or stamped out of the fabric to be tested. A water column of predetermined height is then allowed to act on the test specimen for a specified period of time.

Burgundy pitch → Colophony.

Burling iron Tweezers used in → Slubs.

Burning A → Combustion related process. → Burning behaviour of textiles.

Burning behaviour of textiles → Pyrolysis, i.e. the destruction into breakdown products by heat, is the first stage of every burning process. Not only does the fabric itself burn but so too do its pyrolysis products, and this determines the burning behaviour. The oxidation of these products develops either sufficient or insufficient heat to pyrolyse more of the material, i.e. to support the burning or to allow it to die out, i.e. the endothermic pyrolysis needs to be supplied with heat from the exothermic oxidative burning. Volatile flammable gases are produced on pyrolysis of the substrate and they rise into the flame through the preheating zone and provide new fuel for the flame (Fig. 1).

The energy balance for the burning process (Fig. 2):

1. Energy is required for
   - heating the fibre to the pyrolysis temperature (melting processes with thermoplastic fibres),
   - the pyrolysis reaction,
   - evaporation of the pyrolysis products,
   - heating the breakdown products to the ignition temperature,
   - compensation for the heat lost to the surroundings.

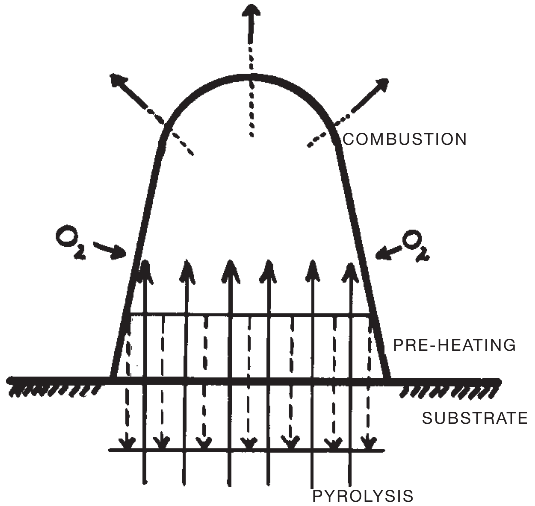


Fig. 1: Model of the stationary state of burning and pyrolysis in the burning process of textiles. The endothermic pyrolysis is supplied with energy in the form of heat from the oxidative exothermic combustion. In pyrolysis of the substrate volatile flammable gases are produced which rise into the flame through the pre-heating zone and provide new fuel for the flame.
——→ = combustible gases; - - -→ = heat transfer.

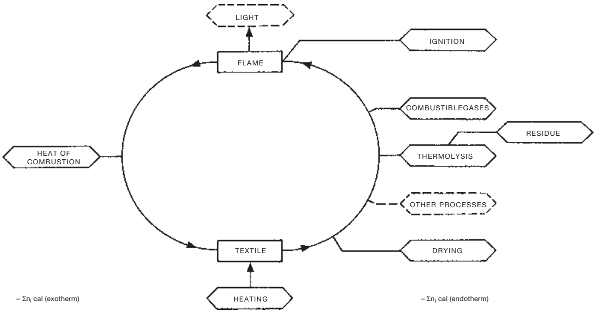

Fig. 2: Diagram of ignition of textiles (steady state).
Sn_i cal = total of the heat energy taken up or given up in the individual phases.

2. Energy is produced by
   - exothermic reaction of the breakdown products.

If the heat of combustion of the fibre is compared with this energy balance, the value obtained relates to the rate of propagation of combustion in this system. (see Table).

fibre material	combustion heat (kJ/g)	max. flame temperature (°C)	pyrolysis temperature (°C)
cotton	16,3	860	350
wool	20,5	680	325
polyamide	33,1	875	390
polyester	23,9	700	390
polyacrylonitrile	31,8	850	250
polypropylene	46,5	840	375

Tab.: Burning behaviour of textiles.

Factors which promote the rate of propagation of combustion of textiles:

- rate of the pyrolysis reaction,
- the melting behaviour of the fibre material,
- the oxygen requirement of the decomposition products during burning,
- the weight per unit area of the material,
- the nature of the surface,
- the fit of clothing (tight or loose),
- the number and nature of the layers of under and outer clothing,
- finishes (e.g. oil-containing preparations).

The effect of dyes is of minor importance in this connection. It is possible that they (e.g. metal complex dyes) may occasionally have a significant wicking effect, which does not significantly increase the rate of propagation however.

Burning properties

If an organic material is heated, it decomposes at a definite temperature into gases that burn, i.e. combine with the oxygen of the air with a flame, if they ignite spontaneously or a source of ignition is available. Thus cellulose decomposes into low boiling flammable alcohols and ethers which are oxidised in the presence of oxygen (from the air) to carbon monoxide and/or dioxide and water. This releases energy which heats up more cellulose and the process is continued. If the amount of energy released in this process is greater than the energy necessary to heat and destroy, the burning accelerates. On the other hand, if it is smaller the flame goes out. In the first case the material is readily combustible and in the latter case it is difficult to burn. If the combustion proceeds uniformly, the material burns normally. The change in burning behaviour of a particular material is obviously blurred. Division of materials into different grades of combustibility applies only at normal ambient temperatures i.e. for burning the original phase. If the temperature of the surroundings increases sharply all the combustible (organic) material is destroyed and a flammable gas mixture is formed. Fire spreads rapidly in this phase, flashover occurs. The rate of combustion of a flat textile material increases with:

- alteration of the spatial disposition from horizontal to vertical,
- increase of the inner volume,
- change in construction from single layered to multi-layered (particularly with thermoplastic fibres).

Below, several variables are set out that have been found from experience to affect the burning behaviour of textile products:

- the structure and the nature of the surface,
- the fibre material,
- preparation, finishing, dyeing,
- soiling,
- arrangement in use,
- combination of textiles,
- the ambient conditions,
- heat conduction.

Properties that characterize the burning behaviour of products can be listed:

- flammability,
- the rate of spreading of flames,
- the development of heat,
- shrinkage and melting,
- the development of smoke,
- the formation of toxic gases.

In testing and evaluating the burning behaviour of textiles, the following variables are important:

1. Minimum ignition time: the time that is required to ignite a test sample of the textile material under defined conditions, i.e. to produce persistent self-supporting combustion.
2. Burning time: also known as the after-burn time or the after-burn period, i.e. the time over which the test sample continues to burn independently after ignition and removal of the source of ignition.
3. Rate of flame spread: the distance that the flame travels on the burning test sample in unit time. It should be noted that this variable depends largely on which section the burning is timed over.
4. Glow time: also known as after-glow time or after-glow period, i.e. the time over which the material continues to glow after the the flame goes out or the source of ignition is removed.

During the burning process an equilibrium (steady state) is set up between oxidation (combustion) at the solid/gas phase boundary and pyrolysis (in the solid textile material). Oxidation with a supply of air is exothermic and supplies heat energy into the textile material among others, during which endothermal pyrolysis (destruction in the absence of oxygen) produces flammable gases (and tarry residues). These gases rise into the flame and feed it with flammable material.

Burning properties These include all the physical and chemical changes which take place in materials subjected to the action of fire. The most important burning properties of a selection of textile fibres are listed in the Table in the order of their limiting oxygen index (→ LOI value) and corresponding heats of combustion which are relevant to the important maximum flame temperatures and pyrolysis temperatures.

fibre material	limiting oxygen index	combustion heat (kJ/g)	inflammation temperature (°C)	melting point (°C)
polyacrylonitrile	18,2	31,8	465-530	235-320
cotton	18,4	16,3	255	does not melt
triacetate	18,4	–	450-520	293
2.5 acetate	18,6	–	450-540	255
polypropylene	18,6	46,5	570	164-170
viscose	19,7	16,3	420	does not melt
polyvinyl alcohol	19,7	–	–	does not melt
polyamide	20,1	33,1	485-575	160-260
polyester	20,6	23,9	485-560	252-292
wool	25,2	20,5	570-600	does not melt
modacrylic	26,8	–	–	160-190
aramids	30,0	–	–	soft from 316
polyvinyl chloride	37,1	21,4	–	100-160

Tab.: Properties of various fibres relative to burning behaviour.

Burning tests for fibre identification A qualitative analytical scheme (according to Agster) for the identification of unknown fibrous substrates by observing their burning behaviour, having regard to flame, smell and residue (see Table).

odour	burning behaviour, residue	fibre material
odourless	asbestos remains unchanged, glass fibre melts to form pearls	mineral fibres (asbestos, glass fibres)
like burning paper	quickly burns away, whitish grey ash	vegetable fibres (cotton, flax, hemp, viscose and cupro fibres)
like burning hair	slow burning, ash first of all bubbly-coal-like, later whitish grey; ash skeleton with weighted natural silk	animal fibres (wool, natural silk, regenerated protein fibres)
acidulous (vinegar)	burns rapidly, first of all small molten balls, later whitish grey ash	acetate
pungent, irritating to the point of provoking coughing (HCl)	liquates, does not continue to burn outside the flame, smoky, white smoke drifts after quenching, black, brittle residue	polyvinylchloride
faintly like burning hair, not pungent	liquescent at first, then burning, continues to burn outside the flame, not smoky, vitreous, yellow to brown thready melt	polyamide
unpleasant, like mouse droppings	liquescent and burning, continues to burn outside the flame, not smoky, hard, brown residual melt	polyurethane
sweetish and aromatic	at first liquescent, then burning, continues to burn rapidly and smokily outside the flame, black, brittle residue	polyacrylonitrile
sweetish and aromatic, not pungent	at first liquescent, then burning, smoky flame, does not continue to burn outside the flame, vitreous, yellow-brown, thready melt	polyester
like burning paraffin candles	at first liquescent, then burning, continues to burn outside the flame, light brownish, brittle residue	polyethylene
like burning paraffin candles	liquescent, does not burn, white smoke drifts, yellowish brown melt	polypropylene
like burnt sugar	liquescent, then rapidly burns away even outside the flame, not smoky; light brownish brittle residue	polyvinyl alcohol

Tab.: Burning tests for fibre identification.

Burning time → After-burn time.

Burn out lace → Burn out styles.

Burn out printing (devoré printing) The process of printing a design on flat fabrics composed of different fibre types with a paste containing chemicals capable of dissolving or destroying one of the fibre components. Fabrics resembling lace have been produced in this way for shirtings and other fashion articles.

As shown in the Table, sodium dihydrogen phosphate is a virtually universal burn out agent for fabrics containing fibre mixtures with polyester. Aluminium sulphate also gives good results when favourable conditions exist with regard to the substrate structure and composition. The considerably more aggressive sodium dihydrogen phosphate can even be used successfully on woven and knitted fabrics produced from yarns composed of intimate fibre blends. Sodium dihydrogen phosphate cannot be used on fibre mixtures containing polyamide, however. In these cases, aluminium sulphate must be used, preferably on core-spun yarns. Sulphuric acid is used as an extremely aggressive burn out agent (for the all over process). Sodium hydroxide solution is used to burn out the wool/silk components in mixtures with polyester or polyamide; protein fibres are broken down hydrolytically under conditions of high pH which results in their complete removal.

	aluminium sulphate	sodium hydrogen phosphate	caustic soda	benzoic peroxide
cotton	+	+	–	–
viscose	+	+	–	–
linen	+	+	–	–
polyester	–	(–)	(–)	–
polyamide	–	+	(–)	–
triacetate	–	+	(–)	+
acetate	–	+	(–)	+
wool	–	–	+	–
silk	–	–	+	–
fibre is: + destructible, - resistant, (-) partially resistant				

Tab.: Burn-out agents and fibre materials.

Burn out styles (devoré styles, à jour effects, chemical embroidery). These styles are produced on fabrics composed of different types of fibres by the (local) action of chemicals capable of destroying a selected fibre followed by its subsequent removal. The effects include all-over or printed open-work designs on blend fabrics or burn out lace produced by machine embroidery on a subsequently burnt out base fabric of a different fibre type and → Burn out velvet effects. The simplest example is a mixture of silk and cotton or viscose. In this case, aluminium sulphate or chloride is used to carbonize and dissolve out the latter component (by saturation, mild drying, heating, final brushing out). With acetate/viscose mixtures the latter is dissolved out by boiling alkali. A treatment in cold 70% sulphuric acid can be used to dissolve out the cotton in polyester/cotton fabrics (with no effect on the polyester).

Burn out velvet (velours dévorant). Velvet fabric with designs produced by fibre-selective chemical burn out action. → Burn out styles.

Burnt alum → Aluminium potassium sulphate.

Burnt farina (roasted starch) → Dextrine.

Burnt gas fumes, colour fastness to → Colour fastness to atmospheric contaminants; burnt gas fumes.

Burnt magnesia Magnesium oxide.

Burnt-out embroidery A machine embroidery technique producing fabric comprising embroidered motifs in accordance with DIN 6000. This embroidery technique creates simulated true lace. Embroidery is applied to a base material (paper or linen cambric). The embroidered motifs are linked by the required number of cross-over stitches so that the subsequent burning-out of the base material produces lace material (or motifs) in the form of piece goods. The embroidery machines are of the two-thread type and the density of the stitches determines the nature and plasticity of the lace.

Burr removal → Carbonizing.

Bursting strength Defined as the multi-directional resistance to rupture of a circular fabric specimen. Testing of flat materials (textile fabrics, paper, films, etc.) is carried out under two-dimensional stress by applying a load perpendicular to the test surface. Both the effective pressure at the moment of bursting in N/cm (bursting strength) and the bulge-height in mm (bursting distension) are measured.Test specimen sizes are 10 or 100 cm^2. The test gives a useful indication of material serviceability with regard to wearing performance resp. wear and tear.

Bursting strength tester Apparatus or instrument for the determination of → Bursting strength.

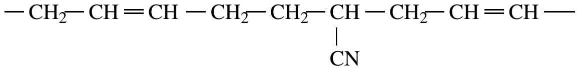
Burst stitch damage Faults occurring in making-up (significantly more serious in the case of solvent cleaned fabric) especially with wool and wool/synthetic double jersey fabrics. Cause: fibre puncturing by needle points during sewing, stitches bursting due to the use of needle sizes unsuitable for the fabric density, or synthetic fibre yarn melting. Soft finishes (solvent type) are suggested as an effective countermeasure.

Butadiene, represents the simplest example of the → Dienes:

$$CH_2{=}CH{-}CH{=}CH_2$$

Butadiene is the starting material for the manufacture of butadiene rubbers (→ Buna rubbers).

Butadiene-acrylonitrile rubber, synthetic rubber consisting of a copolymer of → Butadiene with → Acrylonitrile:



$$-CH_2-CH{=}CH-CH_2-CH_2-\underset{\displaystyle CN}{\underset{|}{CH}}-CH_2-CH{=}CH-$$

Properties: Shore hardness range 40–95, good adhesion to fabrics and abrasion resistance, good stability towards acids, solvent resistance is excellent (aliphatic hydrocarbons) to poor (aromatic hydrocarbons), good resistance to oxidation (moderate to ozone), poor stability to sunlight and fire. In contrast to natural rubber that starts to soften at high temperatures, butadiene-acrylonitrile rubber hardens because of further polymerization. Tends to distort permanently under tension. Machinability is more difficult because of somewhat poorer abrasion of the material and this also applies to adequate adhesion to fabrics. Uses: container linings, non-swelling pressure rollers, protective clothing, thickeners, oil-resistant hose pipes etc.

Butadiene-sodium rubber → Buna rubbers.

Butane → Saturated hydrocarbons.

Butanol (butyl alcohol), C_4H_9OH. Generally available as the primary or normal butanol. Density 0,8; b.p. 114–118°C. Colourless highly refractive liquid with an alcoholic odour. Flammable (very luminous flame). Miscible in 12 parts of water, readily miscible with ethanol, ether, etc. Uses: excellent solvent for dyes (especially in printing), resins and lacquers (spotting agent); also used as a defoamer in dye liquors, etc.

Butene (butylene) → Olefins.

Buttons Depending on the material concerned, buttons can cause various dry cleaning problems. Some certain types of buttons can be very expensive; damage or loss due to dissolution can be prevented by prior knowledge of the material composition, or by removing before dry cleaning. The most important types:

I. Buttons of mineral origin:

a) Glass buttons: resistant to all types of treatment, but are easily damaged by knocks or blows (e.g. in a tumbler).

b) Mother of pearl buttons: similar characteristics to Ia; a misted appearance which may develop as a result of redyeing processes can be rectified by polishing.

c) Metal buttons: usually made from non-ferrous metal, galvanized to protect from corrosion. Very susceptible to stripping prior to dyeing and to acid dyeing (liable to turn black or stain due to oxidation). Prior removal is advisable.

d) Fabric-covered buttons: often with metal base, sometimes with cardboard insert. Show similar reaction to Ic. High risk of damage during wet treatment (oxidation stains); fabric-covered buttons should, therefore, be removed before redyeing processes, unless they are sewn onto separate fabric patches.

II. Buttons of vegetable origin:

a) Wooden buttons: are easily recognized. Dry cleaning can cause the surface to dull; washing often causes marks resulting from the wood stain; redyeing almost always causes a loss in lustre. Removal is, therefore, advisable.

b) Ivory nut buttons: used almost exclusively on men's outerwear, usually with artificially structured surface, harder than IIa (ringing sound when knocked together; strong impact will cause the buttons to shatter). Surface colouring often achieved with direct dyestuffs (light ground visible when back of button is cut and dampened). Are considered to be resistant to washing and dry cleaning.

III. Buttons of animal original:

a) Bone buttons: used on overalls, for example, generally very robust.

b) Buffalo horn buttons: can be recognized by the coloured annual rings or layers and transparency to light; stability generally very good, however, the buttons are easily deformed during dyeing.

c) Cornungula buttons: light coloured horn, bleached and often dyed (often irridescent) transparent, seldom seen these days. Characteristics similar to IIIb.

d) Leather buttons: usually very sensitive to moisture and heat (mark off onto light fabric), often also affected by dry cleaning (chlorinated hydrocarbons), often resulting in fabric staining or marking; thus removal (or preliminary testing) is always advisable.

IV. Plastic buttons: made from various synthetic resins, such as → Casein plastic (Galalith). Usually good imitations of IIc und IIIc (recognizable by the ringing sound when knocked together). Likely to become slightly deformed and porous and lose their lustre in redyeing processes. There are buttons of this type on the market that are resistant to dry cleaning and others that are freely soluble in solvents. The dissolving tendency can be tested by rubbing the buttons with a rag soaked in solvent. Experience has shown, however, that this precautionary measure is unreliable, because during dry cleaning the buttons are subjected to the solvent in question for a much longer period, during which time dissolving and stickiness of the surface (so-called syrupy buttons) may occur . In case of doubt, therefore, removal is advisable.

Butt seam sewing machine Serves to compensate differencies in elongation (= smooth seam), chiefly used in front of the entry of stenters, calenders, padders, raising and shearing machines, and also for stitching fabric into a tube for washing and dyeing. Industrial sewing machines for butt sewing of fabrics without overlapping. The seam is flat and can be undone by simply pulling the thread.

Butyl → Alkyl.

Butyl alcohol → Butanol.

Butyl benzyl phthalate (BBP) → phthalates.

Butyl cellosolve → Ethylene glycol monobutyl ether.

Butylene → Olefins.

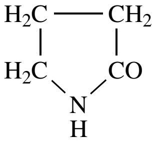
Butyl glycol → Ethylene glycol monobutyl ether.

Butyl rubber (isobutylene-isoprene rubber). Synthetic rubber obtained by copolymerizing isobutylene and isoprene. Properties: good fabric adhesion and abrasion resistance. Good to excellent resistance to acids but generally poor to solvents. Excellent resistance to atmospheric ozone and good resistance to sunlight. Poor fire resistance. Uses: for seals and coatings. Less permeable than natural rubber and used in tyre inner tubes.

Butyric acid (n-butyric acid; butanoic acid; ethylacetic acid; propylformic acid) C_3H_7COOH. Occurs as an organic fermentation product of butter and animal milk fats. Colourless liquid with a penetrating and obnoxious odour. Strong irritant to skin and tissue.

Butyrolactam (2-pyrrolidone). Uses: a monomer for the manufacture of polyamide-4, starting material for → Polyvinylpyrrolidone (dye-stripping agents, adhesives, binders).

Butyrolactone A → Lactone (intramolecular cyclic ester) used as an intermediate in the manufacture of textile and dyeing auxiliaries.



Bw → Cotton, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988. From 1991 → CO.

By-pass A system for directing flow around a fixture, vessel, connection or pipe, instead of through it, controlled by means of valves. In stenters e.g. (see Fig.), the overdrying or oversetting of fabrics as a result of short duration stoppages can be prevented by a by-pass control system. In the event of a machine stop, the air flow is immediately diverted from the fabric to the heat exchanger without interrupting the air circulation cycle. On restarting the machine, full air flow and temperature conditions on the goods are immediately restored.

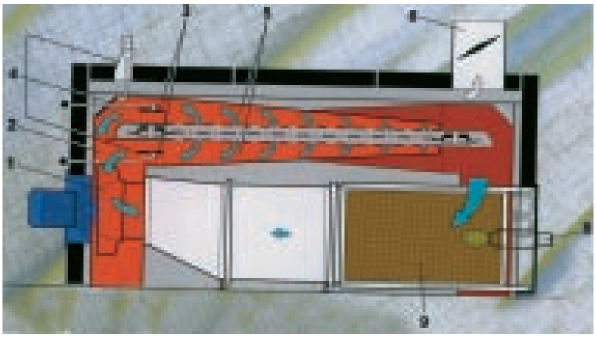


Fig.: By-pass (no. 4) in the classic-flow-stenter from Brückner
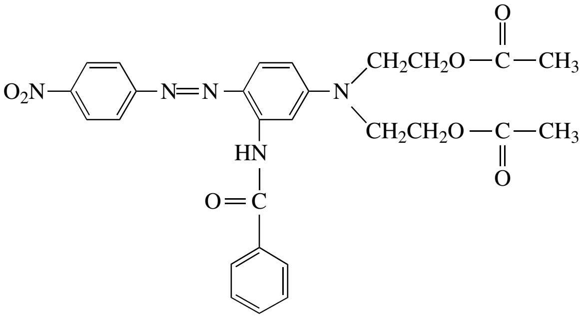
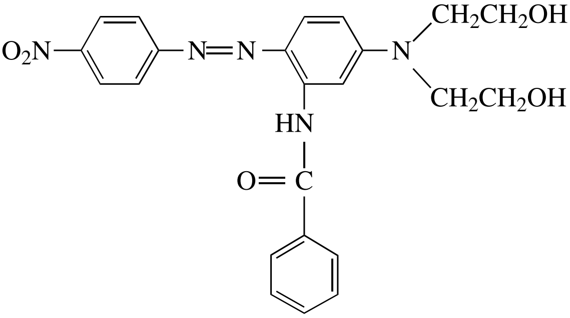
1 = fan; 2 = distribution of air to upper and lower nozzle; 3 = throttle valve; 4 = by-pass-system; 5 = nozzles; 6 = exhaust air out-let; 8 = gas burner; 9 = filter screen.

By-product level In dye synthesis, by-products are formed in addition to the desired dye. If these are not removed before sale of the finished product, the resultant by-product level can give rise to problems in subsequent dye application. Example: the following disperse dye



has a rating of 5 in the multifibre strip wash test (at 1/1 standard depth). However, if the dye contains only 0,4% of the following by-product based on 100% of dye exhausted from the bath,



which actually corresponds to a 0,008% dyeing of this product, the wash fastness of the entire dyeing at 1/1 standard depth is then reduced to a rating of only 1–2.

Byssinosis An industrial respiratory disease among workers in the vegetable fibre industry (principally cotton) which takes the form of a feverish bronchitis, often characterized by chest tightness on returning to work after a period of absence. It is not the fibre itself which is responsible for Byssinosis but the → Endotoxins contained as impurities in the fibre dust. Attempts to free the raw cotton of endotoxins before spinning by washing or lye treatment have proved to be uneconomic and spinnability is considerably impaired. Similarly, attempts to remove the endotoxins by treatment of the cotton with steam or various chemical vapours have met with little success.

Byssus silk → Mussel silk.

Byte A fixed number of bits (now almost always 8 bits) that can be handled and stored as a single unit of data in a computer.

C

C,

I. abbrev. for Celsius, as in temperatures expressed in °C (degrees Celsius).

II. symbol for → Carbon.

c, prefix for → Centi (hundredth), or 10^{-2}, e.g. as in cN/tex.

CA,

I. → Acetate fibres ($2^{1}/2$), → Textile fibre symbols according to DIN 60 001 T4/08.91.

II. → Hemp, standard abbrev. according to the → EDP Code (→ Textile fibre symbols).

CA^{+} → Acetate fibre deacetylated (saponificated).

Ca, symbol for → Calcium.

Cabinet steamer A cabinet-type steamer set up in various ways for the steaming a) of vigoureux or tops printing (in steam boxes or drawers, max. 1.25–1.5 bar); b) when pleating (material hanging).

Cabinet steam finisher Steam finisher for the batch steam treatment of outerwear in textile cleaning.

CAD in textile printing The colour management in a print shop consists of the engraving section and the coloration section (Fig. 1).

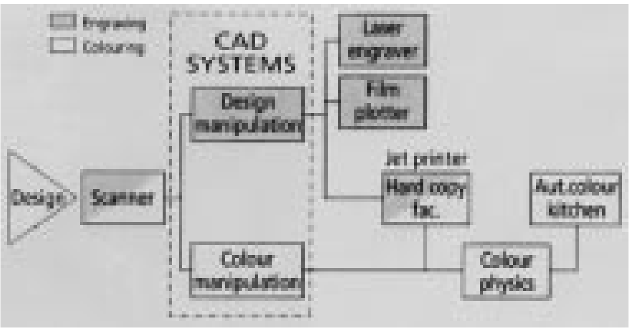


Fig. 1: Processing a design scanned on to a monitor screen (CAD) and printing screen (laser) and printing paste creation (Stork).

A CAD system (Computer Aided Design; → Computer application in textile finishing), with the help of a scanner, takes in the design which is to be modified in terms of shape and colour, to enable on screen working. The laser engraver and the colour kitchen are then also connected to the CAD system. However, this requires a special system configuration in textile printing. Here, the route of on-line printing is being developed by all suppliers, i.e. computer-controlled patterning and colouring, including colour formulation and printing of patterns and colour designs on paper or fabric, automatic colour kitchen, pattern printing units equipped with production parameters, right down to reproducible production on the printing machine.

With the CAD system, two fundamental aims are pursued:

- supporting the patterning and design department in the development of fashionable designs, and
- providing design and production data for faster conversion of production for designs which have been developed.

The aim is to support the pattern designer and to reduce the number of rejections. The representation of draft designs on screen or by means of printouts allows early submission to the client, and agreement with the partners on the fine details of the draft designs. The following factors have a positive effect on the design and production process:

- reduction of routine activities,
- shortening of planning and processing phases,
- easier execution of modifications,
- utilisation of older designs with new colour schemes,
- faster realisation of customers' wishes and ideas,
- faster presentation and market presence with fashionable designs,
- archiving of patterns and colour designs which have been used and designed,
- comparison and pre-selection of draft designs without production on the sampling table,
- automatic creation of technical documents and production specifications,
- better monitoring,
- cost reduction in the design department and in the production of colour designs,
- consideration of in-house specifications and standards in the development process.

In order to achieve these aims, a program package with the following modules is required:

- colour management,
- management of stencils and designs,

- coloration,
- processing of models and studio pictures,
- production of design and production documents including control data for textile machines.

Since CAD systems are intended to achieve not just a visual support in pattern design work, but also to address extensive administrative work, aspects of quality assurance and presentation tasks, the choice of a robust hardware platform with connection options to existing data processing facilities, connection options for standard peripherals and a step-wise construction of the system is necessary. In order to store large amounts of data, such as is generally necessary with the various stencils of a pattern design or numerous pattern designs which are in production or development, large storage capacities are required, in particular also to enable storage of older collections.

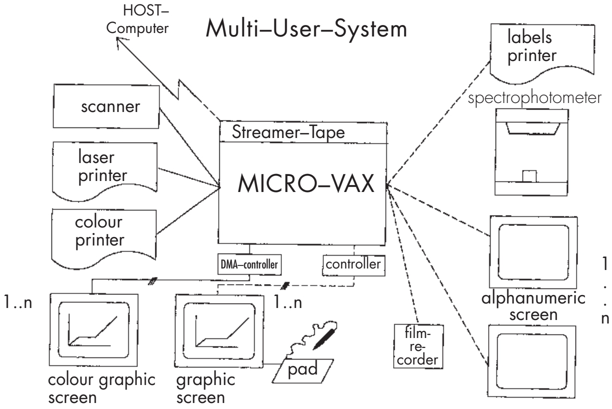

Fig. 2: System configuration CAD textile printing.

Fig. 2 illustrates a typical system configuration. With this, the print sequence of colour separations can be displayed, taking into account the current colour of the respective stencil. Within the program module, different colour designs of the same pattern design can be coloured in. Up to 9 colour designs can be shown on the screen simultaneously, depending on the size of the pattern design or the pattern repeats, in order to construct harmonious colour sequences or colour-matched colour designs on the screen. The pattern designs can be laid over different fabrics. The structure of the woven fabric, which has been built-in or read-in via a scanner, appears clearly, so that for example the effects of fancy textures or jacquard weaves become visible as part of the design. After completion of the various colour designs, production documents can be printed out on a laser printer for the sample table. The colour designs themselves can be printed on a colour printer. The article master data can be sent to the computer. Coloured samples can be scanned in with the aid of a scanner and displayed on the monitor. Via an automatic colour reduction program, the multitude of colours can be reduced to a number of printable colours. In stages, the user can examine at what number of colour separations an interesting, graphic motif can be obtained. At the same time, the results of different reduction stages can be shown on screen.

Cadoxen solution contains 5% cadmium, 28–30% ethylene diamine and 0.5 mole caustic. Uses:

1. Determination of → Fluorescent brightening agents on cellulosic materials.
2. Determination of the cellulosic content in cellulose/synthetic fibre mixture yarns (especially cellulose/polyvinyl alcohol).

Cake dyeing Dyeing of synthetic, viscose, acetate and triacetate filaments on → Pack system dyeing machines with cylindrical material carriers or creel system dye tubes. Problem: levelness, through-dyeing; partly due to swelling of the material. Cake dyed material is usually made into multicoloured products; high wet-fastness requirement.

Calcined Synonymous with anhydrous. Salts designated as “calc.” (e.g. sodium sulphate and sodium carbonate) have lost their pure water content through heating or roasting (calcining). For practical applications, this results in correspondingly greater efficacy with the same salt amounts for the “calcined” salt quality, i.e. smaller amounts of this are required. Comparison ratios are usually stated for the individual salts.

Calcite Chemically pure → Calcium carbonate in the form of sharp-edged crystals. When deposited on textiles they exert a destructive “abrasive” action.

Calcium (Ca), a soft, silvery-white metal, stable in air, very reactive, most important member of the → Alkaline earth metals with their typical properties; atomic weight 40. In water the calcium ion forms salts which are soluble (bromide, chloride, iodide, nitrate), sparingly soluble (sulphate) and insoluble (phosphates, with decreasing hydrogen ion concentration resp. increasing pH).

Calcium acetate (acetate of calcium), $Ca(CH_3COO)_2 \cdot H_2O$; MW 176. Uses: for silk dyeing (addition to calcium-deficient water, freedom from iron is required) and water-repellent impregnations.

Calcium carbonate (carbonate of lime, chalk), $CaCO_3$; white crystals or powder; MW 100; density 2,72. It is very slightly soluble in water containing carbon dioxide (0,14 g/l at 25°C). It acts (as a “base”) by neutralizing acids with the formation of water-soluble calcium salts. Uses: in wool dyeing (production of pastel shades), alizarin red dyeing, naphthol dyeing (neutralization of acidic baths), removal of hair from leather skins, building industry, cleaning agents, chalk, putty, etc.

Calcium content of cotton This results from compounds which are stored during fibre growth. Depending on the provenance, the calcium content of the ash fluctuates between 1.18 and 3.99%, which corresponds to 0.06–0.24% calcium in relation to the cotton. Higher values can be attributed to artificial irrigation, the use of fertilisers containing calcium (e.g. lime-nitrogen), treatment of the cotton with herbicides or defoliants containing calcium. An increase in the calcium content due to defoliants based on calcium cyanamide ought to be low these days, since the cultivated areas treated thus are small (<3.5%). It is not known to what extent the emulsifier calcium dodecylbenzol sulfonate, which is frequently used in plant protective agents, contributes towards an increase in the calcium content of the cotton fibre.

In the case of mature seed capsules of cotton plants which have been treated with herbicides and artificially irrigated in greenhouses, it has been possible to determine 0.13% calcium. Calcium content of various cotton qualities:

Flock, raw	0.09%
Yarn, raw	0.06%
Yarn, bleached	0.02%
Fabric, raw	0.06%
Fabric, bleached	0.04%
Tricot, raw	0.04%

Calcium hardness → Water hardness salts.

Calcium hydrogen sulphite $Ca(HSO_3)_2$; colourless or pale yellow solution, smelling of sulphur dioxide. Used as a bleaching agent, e.g. for sponges.

Calcium hydroxide (Slaked lime), $Ca(OH)_2$; → Calcium oxide.

Calcium hypochlorite (Chlorinated lime, bleaching lime), $Ca(OCl)_2$, salt of the hypochlorous acid (HOCl), MW 127. White, loose powder (no lumps), typical chlorine smell, avidly attracts carbon dioxide from the air (under decomposition, runs into a greasy mass; store dry, cool and well sealed). Good calcium hypochlorite contains 75.8% activated chlorine. Soluble in cold water (large residue). Used for: bleaching cellulose fibres (sodium chlorite and chlorine bleaching processes); chlorination of wool (reduced felting and shrinking properties, increased dye affinity, silky handling, silky lustre) and carpets (carpet antique effect).

Calcium oxide (Quick lime, caustic lime, unslaked lime), CaO, MW 56. White (grey-yellow) porous mass, hygroscopic (with heat generation) and strongly attracting carbon dioxide (conversion to calcium carbonate, therefore store well sealed). With water, with intense heating (up to approx. 450ºC), forms highly alkaline calcium hydroxide $Ca(OH)_2$: $CaO + H_2O \rightarrow Ca(OH)_2 + 63.69$ kJ. However, calcium oxide is only slightly water-soluble (at 15ºC 1.3 grammes per litre, 100ºC 0.65 grammes per litre) to form "lime water"; under the action of water, "slaked lime" results (calcium hydroxide); the watery white, milky suspension is called "milk of lime". Used for kiering agents, boiling agents (cotton), vat dyeing (zinc-lime vat), calcium mordant in dyeing (cotton); water purification (lime-soda process); construction engineering, furnace lining, reference value for calcium hardness etc.

Calcium sulphate → Gypsum.

Calcium sulphate hardness → Water hardness.

Calender bowls, commissioning of → Conditioning of calender bowls.

Calender coating Method used when coating the 4-roller calender with rubber, etc. To obtain good rubber coatings the rubber sheet is pulled into two rolls by calender rollers running at the same speed, and then on the last calender roller fabric is pressed onto the rubber sheet by means of a rubber roller.

Calender crease Typical crease which appears on both sides of tubular knitted fabric which has been passed in the flat state through a calender. The calender crease, like the ladder, can be used as an orienting line for slitting.

Calender felt Technical endless wool felt compound fabric approx. 7–9 mm thick as a continuous back grey for felt calenders etc.

Calendering Important finishing operation for most types of woven fabric (except wool), narrow fabrics, etc. Treatment of open-width fabric with pressurized bowls or rollers on the → Calenders to influence the surface appearance, pore density, smoothness, lustre/matt effects, handle and, if required, produce additional patterning effects (embossing, moiré, chintz, etc.).

Calenders A multi-roll machine (2–16 rollers or bowls) for → Calendering. The bowls rotate under adjustable mechanical, pneumatic or hydraulic pressure. The principle of operation is based on at least two adjacent calender bowls, one or more being a) a metal bowl (usually steel or chilled iron), the surface of which (ground, polished, chromium-plated or engraved) can be heated if required (steam, gas, electricity), with b) resilient bowls (one or more). To prevent damage to the surface of the resilient rolls when particularly thick seams pass through, "seam detectors" are provided, which effect instantaneous pressure relief = "skying" (e.g. air cushions). Calendering effects are varied by various factors (Fig. 3)such as number of bowls, arrangement of the bowls, bowl material (e.g. a + b), bowl pressure (varies according to fabric type and width, usually up to approx. 50 tonnes; can be over 100 tonnes), metal bowl temperature (up to 300°C depending on fabric and effect), rotational speed and the degree of friction (e.g. up to 300 per cent friction by having an inclined fabric-filled bowl or faster running metal bowl), fabric state (dry, damp, wet), cloth run and number of passages.

Fig. 1 shows typical calender bowl configurations: On the 3-bowl rolling or swissing calender (configuration B, C, D) all rollers have the same rotational speed

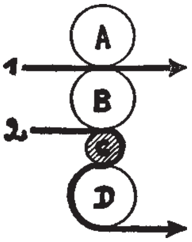

Fig. 1: Bowl arrangement options on calenders.
A, B, D = resilient rollers; C = heatable metal roller.

and create a rolling pressure. In this example, the heatable metal bowl (C) is positioned between the two fabric-filled bowls (B, D). Besides a smooth finish, a cloth run as shown in configuration 2 produces a semi-glaze (without heating) or a high lustre (with heating) on one side of the fabric. The → Friction calender (glazing calender) operates according to the same arrangement (B, C, D), with the difference that the middle, heated metal roller runs at a higher adjustable speed, thus producing a high lustre (for satin and chintz) by means of frictional pressure. On the rolling and friction calender, both effects can be achieved alternatively by shifting the metal bowl (C) to the bottom {delustring calender (configuration A, B, C)}, and a matt effect can be achieved on one side by having the cloth run between the resilient bowls only, according to configuration 1. To suit higher demands, multi-bowl rolling and delustring calenders as well as combined rolling, delustring and friction calenders with a 4-bowl arrangement are available (configuration A, B, C, D).

The → Chasing calender has an additional guide roller system (so-called chasing unit, e.g. 6–12 rollers), through which several layers of fabric are guided, resulting in the beetle effect (the fabric surface is closed, the threads retaining their rounded structure), as is usual on cotton and linen fabric (white goods, damast, bed ticking, shirt fabrics, lining fabrics). → Embossing calenders serve to produce various embossed effects on grey cloth (crepe calender), and on finished fabrics (embossing calender). The latter usually has two or three bowls, the heatable engraved embossing bowl being located above the resilient bowl. This group includes the ciré calender, the moiré calender and the → Schreiner calender (silk-finish calender). All the above embossing functions can be achieved on multi-purpose embossing calenders by changing the bowls, with an additional drive for the lower bowl to achieve high-lustre effects (chintz finish), too. All calendering effects can be achieved on 5-bowl universal calenders (up to 50 t pressure, operating speed max. 100 m/min.), which are available as swissing, delustring, friction, chasing and embossing calenders. For glazing damp cotton fabric, the calender for simili mercerizing is used, whereas the so-called water calender serves to express liquids (max. 45 per cent) from cotton and linen fabrics suitable for this process, at the same time achieving a certain surface sealing effect. The latter (usually 3-bowls = configuration B, C, D), e.g. with 2 jute-filled bowls (B, D) between which is a heatable, chromium-plated steel or bronze roller (C) (alternatively a non-heatable steel roller with hard rubber covering). Normal pressure up to approx. 30 tonnes (with hydraulic system up to 60 tonnes), operating speed approx. 50–100 m/min. and more. Water calenders with more than 3 bowls help to even out the effect and increase the throughput speed. The design of the felt calender, which is used for drying light-weight cellulosic fibre and union fabric blends as well as tricot fabrics, deviates from that of the above mentioned constructions. First of all, the fabric passes through an expander unit for weft stretching (so-called Palmer unit) consisting of two wheel rims which can be skewed in relation to the cloth passage (with combined holding devices to obtain the required tentered width independent of the entry width), on which the fabric selvedges are held fast by endless rubber or leather straps, prior to fabric feed on a felt backgrey to the rotary drying drum and subsequently to the plaiter or batching unit. The felt backgrey causes the liquid that is evaporated during drying to stay in contact with the fabric longer, resulting in the typical felt calender finish, e.g. a pleasant, natural lustre and soft, full finish on wool fabrics. In order to increase performance, a predryer in the form of a cylinder drying machine can be fitted between Palmer and felt calender. A further special type of calender worth mentioning is the so-called rubber coating calender (3–4 chilled iron rolls with heating and cooling facility, synchronized or with friction) used for coating and laminating of extremely long production runs requiring a heavy coating (industrial fabric, rainwear and protective clothing fabrics, etc.) and serving to calender-on the rubber layer (coating; skimming). On the “doubling” calender (steel and paper-filled or rubber roll) duplex fabrics, for example, can be produced by pressing two webs together with the rubber layers facing.

On their 2-bowl, all-purpose calender, Küsters use their “swimming roll”, while on their 3-bowl calender

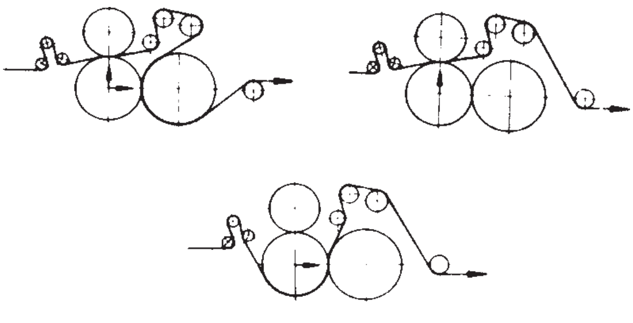

Fig. 2: L-shaped bowl arrangement on calenders with Nipco roll from KTM Kleinewefers.

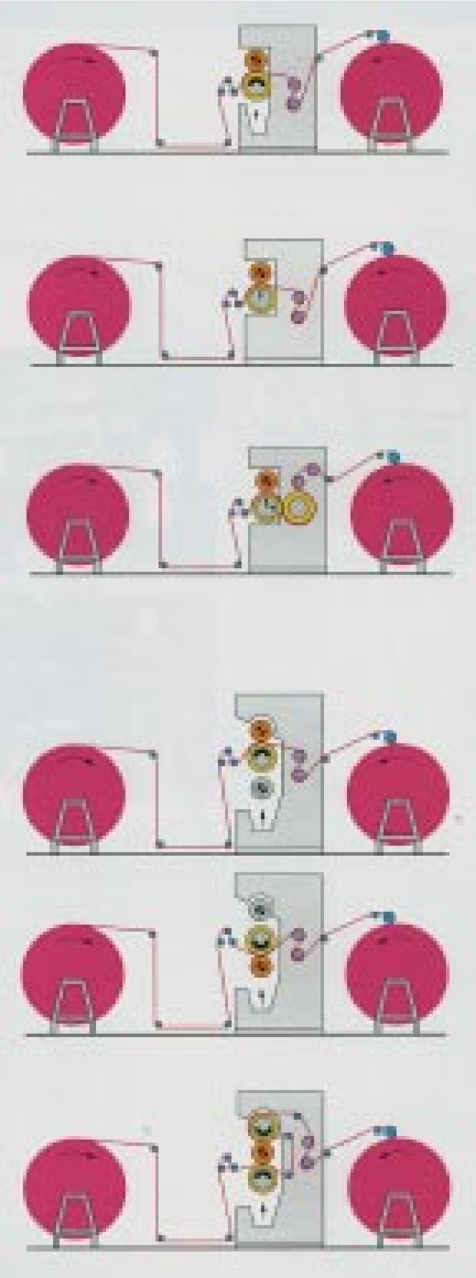

2 roll textile calender with S-Roll
- steel roll, heated
- swimming roll Küsters

Effects: gloss, smoothness, condensing

2 roll textile calender with hydro flex roll
- steel roll, heated
- hydro flex roll

Effects: gloss, smoothness, condensing

3 roll textile calender with hydro flex roll
- steel roll, heated
- hydro flex roll
- elastic roll

Effects: gloss, smoothness, condensing, handle, matt

3 roll textile calender with S-roll
- engraved roll heated f. e. Schreiner
- swimming roll Küsters
- steel roll, smooth, heated

Effects top nip: Schreiner, embossing
Effects bottom nip: gloss, smoothness, condensing

3 roll textile calender with two S-rolls
- swimming roll Küsters
- steel roll, smooth, heated
- swimming roll Küsters

Effects: high gloss, smoothness, high density

Fig. 3: Calendering.

KTM Kleinewefers have incorporated a “Nipco” bowl as the middle roller, which adjusts to the deformation of conventional mating rolls. On this universal calender, the 3 bowls are arranged at an angle of 90° to each other forming an L-shape; at the top an oil-heated steel roll, in the middle a Nipco roll with its special cover, behind which is a special cotton-filled bowl. The hydraulic pressure application is effected by means of supporting or pressure elements pressing against the inside of the Nipco bowl sleeve and acting on the heated steel roller on top and independently on the cotton-filled bowl behind. The pressure elements follow the flexion line of the mating rollers, so that cambering is unnecessary. With this arrangement, typical calendering effects can be achieved by means of the various bowl combinations (Fig. 2).

Calibration curve A measuring curve which is recorded for comparison with a reference curve.

Calico,

I. (Calicut). Printed → Plain weave cotton fabric or percale (highly finished = bookbinder’s calico) produced from grey, plain (e.g.) woven cotton fabrics; named after the East Indian city of Calicut (today Calcutta).

II. Plain weave cotton fabric, single-colour or printed. Is the finest of the three grey cloth qualities with an average in each case of 15–28 ends/cm (warp and weft) from Nm 50–70 (20–14 tex) cotton yarn. → Plain weave cotton fabric.

Calorie (thermal unit), quantity of heat required in order to heat 1 g (“small” or “gramme calorie” = cal) or 1 kg of water (“large” or “kilogramme calorie” = kcal) from 14.5 to 15.5°C. Replaced as a unit in the SI system by → Joule: 1 cal = 4.1868 J.

Camayeux effects Light and dark effects in the same shade which are achieved at the same time in one dyebath, on the same fibres with a different affinity for dyestuffs (→ Tone-in-tone dyeing). This can be achieved by processing untreated wool with treated wool, e.g. unchlorinated/chlorinated and non premordanted/mordanted, to make yarn, woven and knitted fabrics, followed by dyeing with selected chrome dyestuffs. The chlorinated and premordanted wool has a much higher dye affinity than the untreated wool, thus producing the light-dark effect. On silk, the same effect can be achieved by processing degummed, unweighted silk yarn with mordanted, degummed, unweighted silk yarn, which is dyed with chrome dyes.

Cambium (sapwood layer). So-called growth tissue, also called growth layer (→ Procambium), by which is understood the layer in the process of lignification in wood (cambium rings = annual growth rings) and also with bast fibres (→ Flax stem structure), lying, in the latter case, between the bast and wood layers, producing bast outside and wood cells inside. In retting, the cambium is the layer separated from the stem wood.

Camel hair Fibres in the → Natural protein fibres group coming from the Bactrian or two-humped camel or sometimes also from the dromedary (Africa, Asia, Australia). The hair of the camel, moulted in clumps, is collected and the guard hair is combed out. The annual yield per camel is around 3–4 kg. The guard hair is classed as a coarse animal fibre and is smooth, stiff and lustrous, about 50–60 mm long and of 70 µm average fineness. The undercoat which is classed as a fine animal fibre consists of soft, slightly lustrous, crimped fibres of characteristic “camel” sandy to light brown colour or occasionally dark brown to black. They are about 60–100 mm long and of fineness 14–26 µm. Camel hair is usually processed in its natural colour as it is difficult to overdye. In unblended form it is mostly used in the worsted sector (knitwear and thermal underwear). Blended with sheep’s wool, alpaca, cotton and synthetic fibres, it is used predominantly for fine soft woollen-spun yarns with brushed or hairy effects (blankets, loden cloth, ladies dress goods, coatings) and for thermal underwear. Camel hair with guard hair intact is often used in slipper cloth. The guard hairs which are difficult to spin are used in coarse blankets, felts and coatings.

Camel hair cloth Because the hair of the camel, especially the fine undercoat, is of higher quality and more expensive than sheep’s wool it is often imitated using wool dyed to camel shades. Wool fabrics dyed to camel shades are piece-dyed with a solid-shade appearance whilst genuine camel hair cloths can be distinguished by their slightly mottled appearance which has high fastness, especially to rubbing and to light exposure, and they also withstand standard dye stripping tests. A camel hair cloth must therefore always consist of original camel hair. Camel hair fabrics are virtually all made with woollen-spun yarns. Finishes include velour (upright napped or laid pile) or as a pilot cloth with long brushed pile. Weight between 450–750 g, providing good thermal insulation. Used in high quality outerwear.

Camlet A fine lustrous yarn resembling camel hair or a corresponding plain-weave fabric made from linen or cotton with worsted or silk plied yarns.

Camouflage dyeings and prints have to meet the strictest requirements for military equipment (uniform fabric, tent awnings, camouflage nets, vehicle paints and so on), not only to prevent them from being visible to the naked eye but also from being detected by technical equipment. Camouflage and deception systems have been developed intensively over the last 50 years:

- camouflage nets,
- u.v. reflecting winter camouflage,
- radar scattering nets (Fig.),
- computer controlled mosaic printing,
- thermal winter camouflage,
- wide-band radar camouflage,
- radar winter camouflage,
- multispectral camouflage.

Effective camouflage dyeings must have reflectances that correspond to the natural surroundings for every colour in the visible and invisible regions. Multi-coloured patterns corresponding to natural colours provide camouflage for normal vision. It is considerably more difficult to meet the wider requirements of effective camouflaging against i.r. observation at the same time.

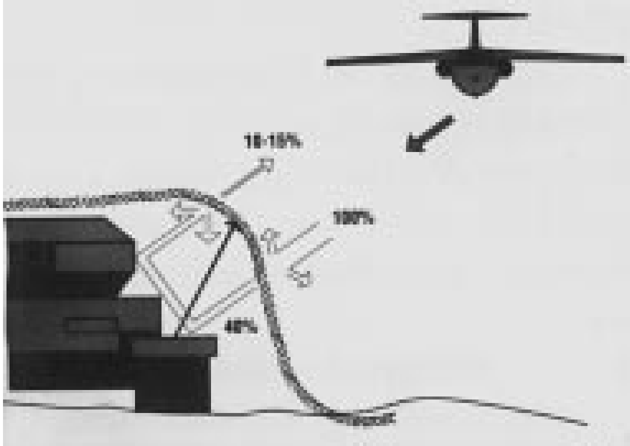

Fig.: The principle of radar scattering.

The object of camouflage against i.r. radiation is the same as it is for visible light: avoidance of contrast and elimination of contours by patterning. For this purpose, it is necessary to know how the i.r. reflectance of the camouflage dyeings/prints compare with the natural background in the spectral ranges of the three types of i.r. observation. These have different i.r. ranges: i.r. photography 800–850 nm, i.r. night vision searchlights 900–1000 nm, i.r. camouflage glasses (red filters) for visual observation 700–730 nm. The effectiveness of i.r. camouflage also depends on the contrast between the spectral characteristics of the camouflaging material and those of the natural surroundings. The i.r. reflectance of natural objects is strongly affected by the moisture content: bright yellow sand has a moderate i.r. reflectance when it is dry but it absorbs just like soil when it is damp. The reflectance of green foliage has a maximum at around 550 nm and a sharp increase around 700 nm; meadows and deciduous trees appear bright in an i.r. objective; conifers appear much darker.

If the reflectance curves of camouflage dyeings match the curves of the natural objects, unwanted contrasts will be eliminated for all modes of observation. However the reflectance curves of most organic dyestuffs are quite different: the sharp increase at 700 nm that is desirable for green shades is almost always missing, and most dyes do not absorb strongly enough in the long wavelength region. Hence it is necessary to use combinations of several dyestuffs (for the colour in the visible region, application properties and especially fastness properties) to get the required reflectances for all modes of observation.

The i.r reflectance of textile materials is greatly affected by bleaching (i.r. reflectance of bleached goods is 70–90%, falling to 50–30% for unbleached goods). The i.r reflectance is increased by titanium white and decreased by carbon black. Aftertreatments and finishing can also affect the i.r. reflectance. Requirements (% reflectance and the range of wavelengths over which these reflectances are to apply) vary according to which military service has placed the order, e.g. 25–30% reflectance at 900–1000 nm for night vision equipment, 35–60% for green or 35–35% for brown in the 800–850 nm wavelength range for i.r. photography.

Camphor $C_{10}H_{16}O$. Molecular weight 152; density 0.98–0.996. Colourless or white, granular, crystalline or powder. Only slightly soluble in water; good in alcohol, acetone, chloroform, fatty oils etc. Gradually vaporises at room temperature. Burns easily. Use: especially for the celluloid industry, for moth protective finishes (toxic fumes) etc.

Candela (cd), formerly called "standard candle". Photometric unit of intensity of light: a black body at the temperature of solidifying platinum (2042.5 K) emits, in a perpendicular direction, a light intensity I of 60 cd per cm+ flat surface. This unit of measurement (basic unit of the SI system) was introduced internationally in 1948. Conversion of the outmoded terms HC and IC: 1 cd = 1.107 HC (Hefner candle) = 0.981 IC (international candle).

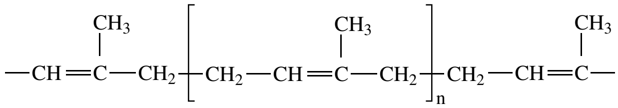
Candle filter → Sewerage-filter-system.

Cannetilles spirally wound → Fancy metal yarns.

Cantala fibre Agave fibres (Philippines, Indonesia, Mexico) similar to → Sisal, but softer and more elastic.

Canvas (duck). A strong firm fabric (flax, cotton, viscose) woven with square interstices using hard-twist warp and weft threads. Used as ground for embroidery, carpet knotting, tapestry and suchlike and as a stiffening material.

Caoutchouc Milky juice of tropical Hevea varieties (density = approx. 0.93), which is in the trade as → Latex, and produces the solid so-called raw rubber by coagulating agents (acetic and formic acid), which is more or less free of water, dark coloured or bleached, mostly in the form of rolled out, rolled up "fleeces" or as fine powder. Caoutchouc is a polymerisation product of isoprene:



$$-CH=\overset{CH_3}{\overset{|}{C}}-CH_2-\left[CH_2-CH=\overset{CH_3}{\overset{|}{C}}-CH_2\right]_n-CH_2-CH=\overset{CH_3}{\overset{|}{C}}-$$

Properties: lighter than water, almost odourless, outstandingly elastic and very extensible, poor conductor of heat and electricity. Paracaoutchouc is brittle at 3–4°C, sticky at 145°C, deliquescent at 170–180°C, and burns with a very smoky flame. Soluble in ether, benzol, petroleum ether, oils and fats, carbon bisulphide, carbon tetrachloride, turpentine oil etc, mostly undissolved residues remaining. Diluted alkalis and acids bring about no change. The effects of light and air lead to considerable changes. The natural stickiness is eliminated by masticating with sulphur and the like (→ Vulcanize, to), by which means the familiar rubber is made, abrasion resistance, insensitivity to heat, electrical data etc. This lies in the peculiar nature of the formulation, i.e. variations in softeners, filling agents, sulphur, accelerators, ageing agents, dyes, carbon black etc. Use: the production of rubber yarns, foam rubber, for covering textile yarns (latex too), impregnating woven fabrics (laminating), coating applications, as an adhesive for leather and synthetic leather, as a rubber solution (dissolved in benzol) etc.

Cape gum South African. Vegetable type rubber with a high arabin content, which has only limited uses on account of its poor quality and inadequate water solubility.

Capillaries → Individual fibrils.

Capillarity Generic term for all physical phenomena which occur in consequence of the → Surface tension of liquids in capillaries and cracks and in porosity.

Capillary activity (interfacial activity, surface activity). The ability of adsorbent substances to reduce interfacial or surface tension in the dissolved state, and, in fact, with a simultaneous concentration increase at the surface. Relative to fibres, capillary activity causes displacement of the air in the macroscopic and submicroscopic fibre capillary spaces (water conductors) which is extremely important for numerous finishing operations (scouring, bleaching, dyeing etc), providing for the wetting out and penetration of dissolved, adsorbent substances (dyes and auxiliary agents with scouring, wetting, dispersing and emulsifying properties). Ionogenic products (anionic soaps, cationic soaps) and, quite particularly, nonionogenic products come into consideration for this purpose.

Capillary analysis In dyestuff levelness tests, an approximately 20 cm long strip of filter paper is suspended from a stand, and 1.2 cm of the bottom end immersed in the dye solution. Assessment in terms of relevantly differently dyed strips and zones of the faster and slower rate of rise of individual dyestuffs at issue. Improvement of this method by paper chromatography. Separating processes for colloids of variously high degrees of adsorption on porous masses (→ Chromatography) are described as capillary analysis, different colloid charges also being capable of determination.

Capillary dehydration According to Messik, a wet and a dry woven fabric are brought in close contact in a relevant device (Fig.) by means of a capillary squeeze roller so that moisture is exchanged between the fabrics in consequence of capillary forces. Dehydration effect of up to 10% of water content possible, dependent on fabric type and number of passages (→ QS-process).

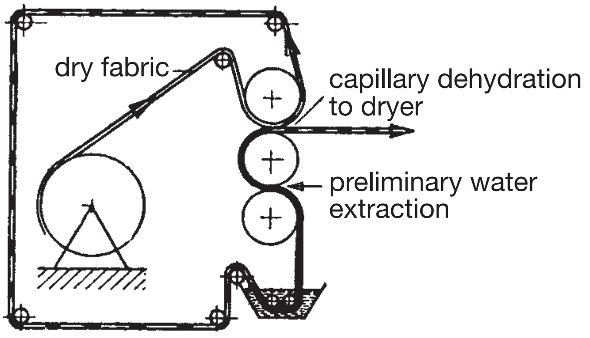


Fig.: QS (squeezing-suction) capillary dehydration according to Messik.

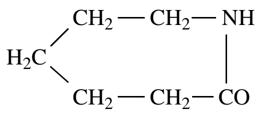
Capillary fabric liquor interchange Exchange of moisture through the contact of 2 fabrics with different moisture contents, blotting paper effect (→ QS-process).

Capillary viscometer → Viscometers.

Capillary water Water held in capillaries (→ Water of crystallization), which is present as a natural water content in fibres, and which has to be protected in drying in order, as far as possible, to retain the natural fibre characteristics (handle, appearance, strength, elasticity etc).

Caproic acid (hexanoic acid, hexylic acid, hexoic acid), $CH_3(CH_2)_4COOH$; oily, colourless or pale yellow liquid with an unpleasant rancid sweat-like odour. Glycerides of the acid occur naturally in cow and goat milk in small amounts and in some vegetable oils, e.g. coconut oil; it is also formed in the fermentation of butyric acid. Uses: manufacture of textile auxiliaries.

Caprolactam Starting product for the manufacture of polyamide-6 (nylon 6) obtained commercially by various methods from aromatics (benzene, toluene). All methods of caprolactam manufacture result in the production of ammonium sulphate as a by-product.



Caprolactam melt process in dye identification Melt sample (polyester or polyamide) with approximately 3 g caprolactam in a porcelain crucible. Allow to cool, stirring continuously, add a little ether, stir and filter. Filter residue is tested using vat dye, filtrate is tested using a different dye group.

Caprylic acid (octanoic acid), $CH_3(CH_2)_6COOH$; clear, colourless liquid fatty acid with a slight, unpleasant, rancid odour and burning taste. Occurs free in sweat, as esters in fusel-oil, from which it is most easily prepared, and as glycerides in the milk of cows and goats and in coconut and palm oils. Used in the manufacture of textile auxiliaries.

Caracul Asiatic variety of the broad tail sheep which owes its name to the town of Kara Kul in eastern Bokhara, but which is not only raised in that region but also in Persia for example. The caracul sheep has also found a new home in Southwest Africa. Apart from a very coarse wool, caracul sheep provide the familiar Persian lambswool.

Carbamates Systematic term according to IUPAC regulation C-431 for esters and salts of carbamic acid, which therefore includes the group $H_2N–CO–O$. The esters are frequently still called by their historic name → Urethanes, and the term → Polyurethanes has also become generally prevalent for polymer carbamates.

Carbamic acid Can be described as a "half amide" of carbonic acid (HO–COOH). Like this, it does not exist free, but only in the form of salts or esters. Example: Ammonium-carbanide ($H_2N–CO–O–NH_4$), which is present in technical ammonium carbonate

$[(NH_4)_2CO_3]$ as an equilibrium component, and is associated with a proportion of the wool protection effect in dyeing and washing.

Carbamic acid esters → Urethanes.

Carbamide → Urea.

Carbamide group (carbonamide), –NHCO–. The typical grouping in proteins, polyamides, urea, polyureas etc.

Carbamide peroxide Solid hydrogen peroxide, urea peroxide, contains 16% active oxygen. White, easily water soluble crystals, which decompose at 50°C in the presence of moisture: When dissolved, neutral peroxide solutions are formed. Application: as bleaching and oxidizing agent.

Carbamide resins (urea resins) → Urea-formaldehyde compounds.

Carbanions Anions with carbon atoms as the carrier of the negative charge (cf. example formula under → Carbenium ions). Carbanions are intermediate stages in many electrophilic substitution reactions. Due to the negative charge their structure is influenced by cations, by substituents and, in particular, by solvents.

Carbazole → Heterocyclic compounds.

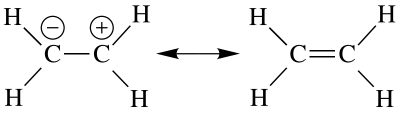
Carbazole-sulphuric acid reaction is used for

I. Formaldehyde detection: Dissolve 1–2 granules of carbazole in 2 ml concentrated sulphuric acid, add the solution under investigation drop by drop. Carbazole-sulphuric acid solution is stable for a maximum of 30 min. Dyeing: a) Formaldehyde = deep blue; b) Acetaldehyde = greenish blue; Glyoxal = green.

II. Anti-crease finish detection: Boil fabric sample in test tube with 5% sulphuric acid. After cooling the solution is poured off into another test tube and freshly prepared solution of 0.1% carbazole in concentrated sulphuric acid is added drop by drop. If blue colouring, or later a cornflower blue deposit occurs, this confirms anti-crease finishing.

III. Casein fibre detection, Undyed casein fibres do not result in staining with acidified water: Boil out sample in test tube and perform reaction with watery extract.

Carbenium ions Cation with a positive charge on a carbon atom. If we take as an example a mesomeric resonance formula of ethers



then this materializes because a C atom also takes on the π electron of the other (“carbenium-carbeniate” formula). Therefore, according to Dilthey and Wizinger, triphenylmethane dyes can also be interpreted using the carbenium formula: $(H_2N–C_6H_4)_3≡C^{\oplus}$. The presence of an unsaturated system (→ Chromophore) is the prerequisite for the presence of mobile π electrons, i.e. for the occurrence of mesomerism, which is encouraged by auxochrome (electron donor) on the one hand and by antiauxochrome (electron acceptor) on the other (–E or +E effect). The elimination of such functional groups has a shortening or interrupting effect depending upon this, which either causes colour change or the complete disappearance of the colour.

Carbides (acetylides). They are compounds of carbon with metals (e.g. calcium carbide), boron or silicon (→ Carborundum). Carbides formed with elements close to carbon in the periodic table, e.g. SiC, B_4C, are essentially covalent and are generally extremely hard and infusible (→ Boron fibres).

Carbinol Synonym and obsolete term for → Methanol.

Carbinol group $R–CH_2OH$, is the typical group in e.g. → Fatty alcohols.

Carbocyclic Any organic compound whose “skeleton” is in the form of a closed ring of carbon atoms. This includes both alicyclic and aromatic structures. → Cyclic hydrocarbons.

Carbohydrases Group of carbohydrate splitting → Enzymes belonging to the main group of hydrolases. They also split di- and polysaccharides and glycosides. According to this we differentiate between a) polyases and b) glucosidases.

Carbohydrates This large and important group of organic vegetable products was given its name at a time when, of the chemical construction of these substances, virtually only the total formula $(C_x(H_2O)_y$ was known, which is invalid for all carbohydrates in the light of current knowledge, and, incidentally, also covers other compounds which do not represent carbohydrates, e.g. acetic acid $(C_2H_4O_2)$, lactic acid $(C_3H_6O_3)$ etc. Today, we also know that carbohydrates are not hydrates (and should therefore be more correctly defined) but the primary oxidation products of polyhydric alcohols. Included among the carbohydrates today are not only so-called simple sugars (like grape sugar) but also higher molecular sugars (like cellobiose, cane sugar and the like). The fact alone that cellulose is the most frequent organic compound in the world, and occurs in cotton and viscose, the textile fibres most produced, indicates the importance of the carbohydrate types:

I. Monosaccharides (grape sugar type): subdivision in each case in accordance with the number of available O atoms in bioses (two O atoms, like glycoaldehyde $CH_2OH-CHO$), trioses, tetroses, pentoses, hexoses (six O atoms, like grape sugar/glucose) etc. (polyoses).

II. Oligosaccharides: produced from 1–4 monosaccharides with elimination of water, e.g. disaccharides, which also almost always contain hexoses (c.f. above); these include for example cane sugar (of glucose and fructose), malt sugar (maltose), milk sugar (lactose, of glucose and galactose) and cellobiose.

III. Polysaccharides: constructed of many monosaccharide residues like dextrin, starch, agar-agar, chitin, pectins and especially cellulose of 1000–3000 glucose residues. This group is no longer classed with the so-called sugars.

Carbohydrazides → Hydrazides.

Carbol fuchsin, Ziehl's stain is used in microscopic work for staining bacteria directly (in concentrated form) and in → Gram stain (diluted 1 : 4). Consists of 1 g of fuchsin + 5 g phenol dissolved in 90 ml of distilled water and made up with 10 ml of 95% alcohol. Before use, the sediment is filtered off as it interferes with the microscopy. Depending on their state and form, most bacteria can be shown up with carbol fuchsin solution (400–600 fold increase); there is a smaller increase for mould fungi.

Carbolic acid → Phenol.

Carbon (C). Atomic weight 12. Non-metalloid, free element as diamond, graphite and amorphous coal, odourless/tasteless. High melt point metals are the sole solvents. With air admission, burns to carbon dioxide (with insufficient air: to carbon monoxide with soot separation), with sulphur to carbon bisulphide, with nitrogen (under relevant conditions) to cyanogen. Almost reactionless at temperatures below 500°C. Amorphous coal is already reactive below 100°C (activated charcoal). Extraordinarily capable of transformation (approx. 300 000 known compounds) in chemical compounds; basic element of all organic compounds. Compounds: with oxygen = carbon monoxide CO and carbon dioxide CO_2, which produces carbonic acid with water; with nitrogen = cyanogen CN (prussic acid HCN); with sulphur = carbon bisulphide CS_2; with metals = carbides (calcium carbide CaC_2); with hydrogen = coal gases and heating gases, motor vehicle fuels etc.

Carbon, activated → Activated carbon.

Carbonate of lime → Calcium carbonate.

Carbonate of soda → Sodium carbonate.

Carbonates Salts of → Carbonic acid H_2CO_3: so called "acid" salt (Sodium hydrogen carbonate) and normal salt (ammonium, calcium, potassium, sodium carbonate). Only alkaline salts are easily soluble (hydrogen carbonates more difficult), remaining slightly soluble in a solution strongly alkaline (hydrolysis). Decomposition involving the generation of CO_2 is caused by acidification.

Carbonato chelate is a term for CO_2 in complexes.

Carbon black is the product of thermal decomposition of acetylene or the residue from burning coal tar, tar oils, naphthalene, natural gases, and from combustion engines etc. It is deep black, very fine carbon in the form of graphite crystals (2–6 nm in diameter) (Fig. 1). It is completely insoluble in water and is used as black pigment for mass coloration, Indian ink, typewriter ribbons, leather etc. Carbon black is used in elastomers as a pigment and filling agent (motor vehicle tyres, rubber conveyor belts and so on) for bonding the elastomeric material, and also for making it cheaper.

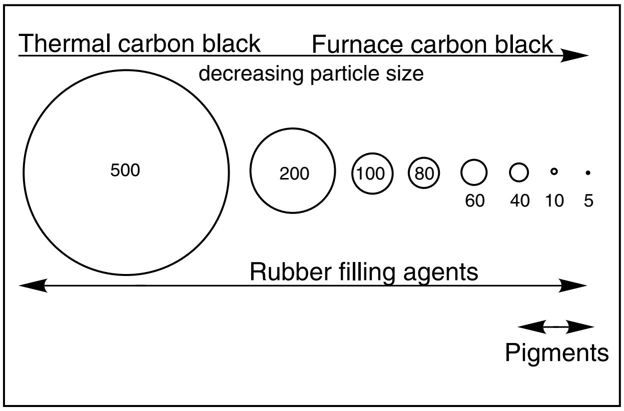


Fig. 1: Particle sizes of carbon black in mm with application areas.

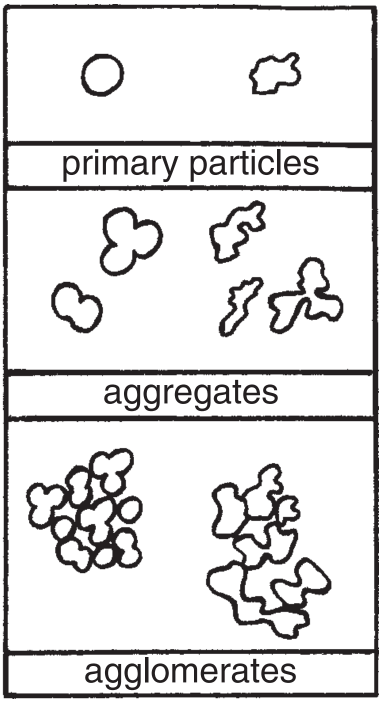

Fig. 2: Carbon black: primary particles, aggregates and agglomerates.

As increasing amounts of synthetic carbon black are added, the network of carbon becomes more continuous (Fig. 2) until electrical charges can be conducted. The electrical conductivity as a function of the filler concentration drops sharply at the percolation point (Fig. 3).

Apart from high concentrations of 10–20 weight-%, the carbon black can accumulate in definite tracks, e.g.

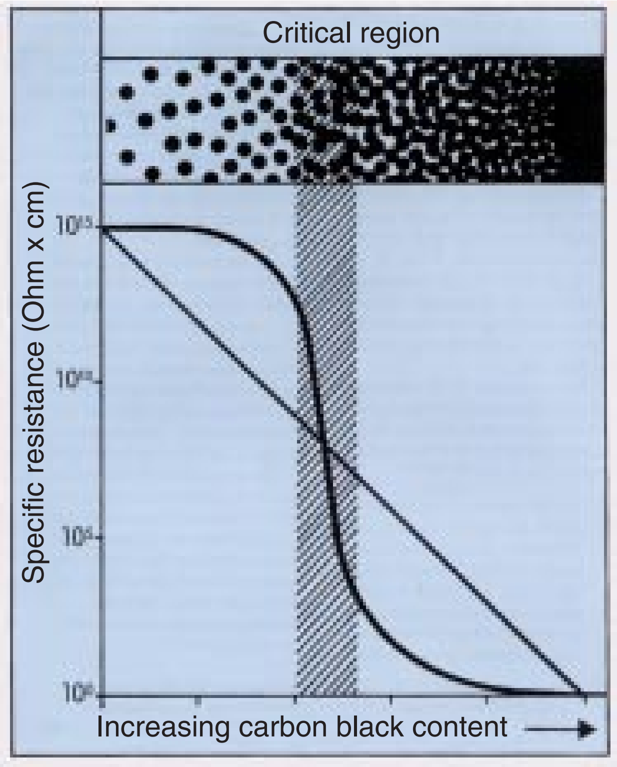

Fig. 3: Change of resistance of rubber with increasing carbon black content.

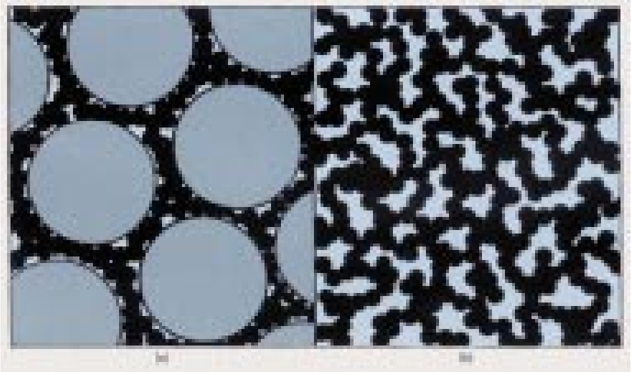

Fig. 4: Diagram of the distribution of carbon black in conductive rubbers (a) with core/shell structure, (b) with homogeneous carbon black distribution.

along the granule boundaries in pressed discs, so that continuous networks may form even with less than 1% of carbon black (Fig. 4) (contributed by Zeppernick and also by Röttgers).

Carbon-chain fibres Synthetic fibres having only carbon atoms in the main chain of the macromolecule such as polyacrylonitrile, polyvinyl chloride, polyvinyl alcohol, polyolefin and fluorine-containing (polyfluorinated) fibres.

Carbon dioxide (CO_2). Molecular weight 44.01. Colourless gas with a slightly acid odour (anhydride of → Carbonic acid), water soluble, non-combustible in air, heavier than air. Compressed under pressure at 0°C, forms commercial "liquid carbon dioxide" (in steel cylinders: for refrigerators, fire extinguishers, fireproof tank loading), from which comes flocculent, white "carbon dioxide snow" by pressure removal and under latent heat. This is pressed under pressure into solid blocks (so-called "dry ice").

Carbon dioxide, supercritical Diverse liquid extraction methods are employed for producing natural substances or for separating out undesirable attendant substances from natural substances, carbon dioxide in the supercritical (liquid) state being enlisted to an increasing extent. The technically favourable position of the critical point (Fig. 1) of CO_2 at $p = 7.3858 \pm 0.005$ MPa and $T = 304.20 \pm 0.05$ K favours industrial use.

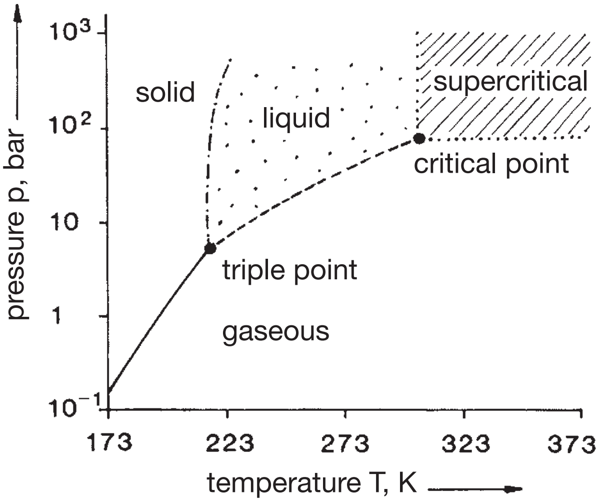

Fig. 1: Carbon dioxide phase graph.

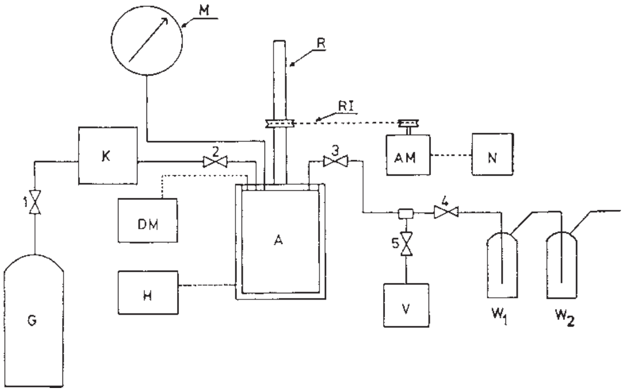

Fig. 2: Schematic view of static high pressure equipment (Schollmeyer).

With liquid CO_2, extraction can be carried out easily in an autoclave (Fig. 2) in which the liquid is periodically extracted on the Soxhlet extractor principle (Schollmeyer).

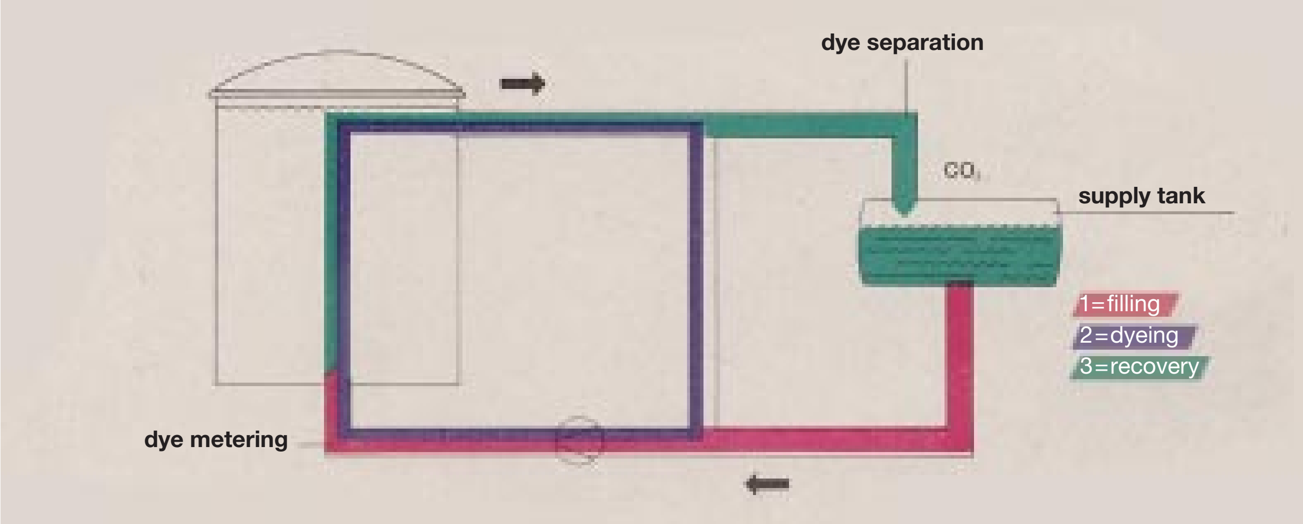

Fig. 3: Circulation in dyeing with supercritical CO_2 (Jasper).

For particular emphasis is the ability of supercritical carbon dioxide to dissolve disperse dyes, which is not the case with hitherto used aqueous dye liquors. It can be handled despite the high pressure, from which it can be seen that coffee or hops for example have been extracted with it on the industrial scale in the food industry for years. Ciba-Geigy has developed polyester dyes suitable for dyeing in supercritical carbon dioxide. As another partner, Jasper has built an engineering concept for a 3 kg sample machine with a liquor volume of 20 l. This design (Fig. 3) provides for putting the material to be dyed into a dyeing autoclave, and pumping the supercritical carbon dioxide required into the dyeing machine from a CO_2 supply tank. The dye is added via a metering lock. The supercritical carbon dioxide is transferred back into the supply tank after passing through the fabric for approx. 10–20 min in a specified pressure/temperature programme. The dyeing machine is ventilated, and the fabric can be removed.

Practical laboratory trials at Ciba-Geigy reveal that a degree of dye exhaustion of up to 98% can be reproducibly achieved. CO_2 losses may lie in the 2–5% range. This means that only minimal quantities of the CO_2, taken from the atmosphere anyway, and approx. 2% of the originally used dyestuffs occur as waste in powder form, and can therefore be easily disposed of or reused.

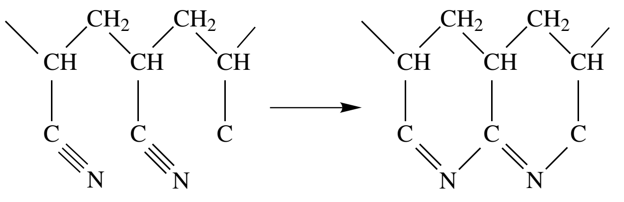
Advantages of this process:

- no effluent, since CO_2 is reused; residual dyestuff occurs in concentrated form as powder; no dispersing and levelling agents;
- approx. 80% less energy requirement for heating up the liquor; fabric drying eliminated;
- higher investment cost for the dyeing machine, but saving on the investment cost of dryers;
- reduced personnel costs, since no drying.

Carbon disulphide CS_2; mol. wt. 76.12; density 1.262. Water white liquid, colourless to slightly yellow (especially under the influence of light), very mobile, highly refractive, very volatile (should be stored under water); the smell is aromatic in the pure state, but is usually repugnant and penetrating (impurities); inhaling leads to symptoms of poisoning; on contact with skin, it penetrates into the blood stream (later: neuralgia, loss of appetite, trembling etc.); extremely flammable (boiling point 46.2°C; auto-ignition temperature about 235°C), forms explosive gases; even radiant heat from a near-by beaker of boiling water can cause ignition, a flame 5 m away can ignite air/vapour mixtures; burns with a blue flame (to give sulphur dioxide). Insoluble in water, soluble in alcohol, ether, chloroform. Uses: cleaning agent (for all kinds of fats, spots of asphalt, varnish, resin, rubber, paraffin, pitch, sulphur, sealing wax, tar and wax etc.).

Carbon-fibre-reinforced plastics (CFRP). Plastics with interpolated carbon fibre woven fabrics, nonwovens or ropes for technical use in stringent requirements. They have high specific strength, stiffness, resistance to fatigue, high thermal resistance, low coefficients of friction. Use: in ultra-quality construction (jet motive power units, rocket construction, space ship construction etc.). For the purpose of internal bonding between fibre and plastic (mostly 50 : 50), the fibre surface is refined by acid oxidation (chemical activation), plasma treatment or by polysiloxane treatment.

Carbon fibres (C fibres). Starting basis (Fig. 1) from regenerated fibres (viscose filaments with/without drawing) and synthetic fibres (polycarbonate, polyamide, polyacrylonitrile, polyvinyl alcohol), which are first of all oxidised by pyrolysis (Fig. 2), and then, with drawing (in nitrogen), are carbonised (Fig. 3), and "graphitised" at 1500–3000°C. The carbon fibres so formed consist of 80-90% carbon, C atoms forming ribbon-like C hexagonal planes, e.g:



ring formation in "graphitisation"

C fibre

Production of carbon fibres:

1. Stabilisation (180–300°C): oxidative and/or chemical treatment with or without fibre drawing as a precondition for solid phase pyrolysis.
2. Carbonisation (300–1600°C): thermal decomposition of the stabilised, unmeltable fibre intermediate product.
3. Graphitisation (1600-3000°C): high temperature treatment with or without fibre drawing.

So-called HS carbon fibres and isotropic carbon fibres are obtained as products of the second stage. The third stage produces HM carbon fibres.

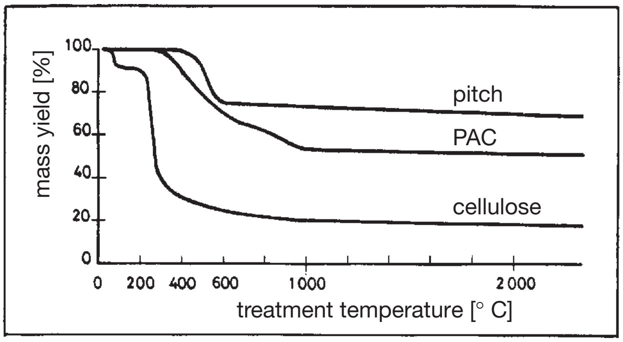


Fig. 1: Pyrolysis behaviour of different starting materials for carbon fibres.

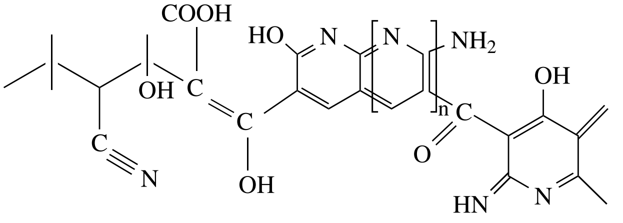

Fig. 2: Reaction of polyacrylonitrile with oxygen.

One imagines linear thread molecules from 2 atom chains occurring, connected by main valency bonds, forming superimposed graphite-like structures in the form of layer lattices (mutually displaced) in a polycrystalline structure. In addition to greater thermal stability (fireproofness, infusibility), such structural systems (Tab. 2) also have higher strength (Tab. 1), i.e. approximately 3 times the strength of glass fibres and steel (and tear strengths, starting from polycarbonates, up to 2500 N/mm^2, starting from viscose filaments even up to 3000 N/mm^2), and also absolute chemical resistance and hydrophobic characteristics.

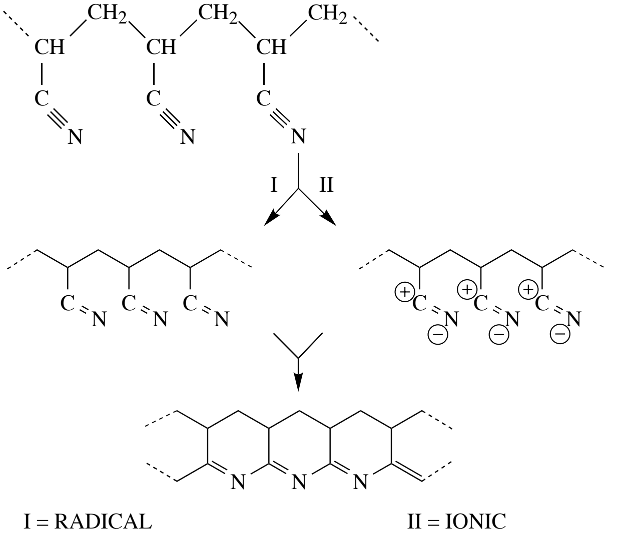

Fig. 3: Mechanism of the ionic and radical cyclisation of polyacrylonitrile-based carbon fibres.

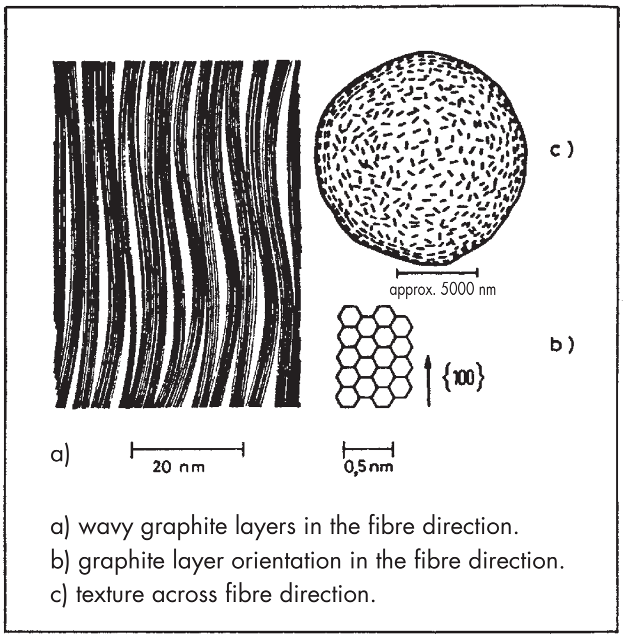
	C fibres	Glass fibres	Steel fibres
Density g/cm^3	1.6-1.8	2.54	7.9-8.1
Strength cN/tex	120-180	36-90	30-35
E-modulus kN/mm^2	220-500	45-75	140-200
Elongation %	0.5-1.3	3-4	1.0-1.8

Tab. 1: Characteristics of carbon fibres in comparison with glass and steel fibres.

Structural features	Fibre type
Layer planes predominantly parallel with fibre axis little long-distance arrangement	High strength (HS) C-fibre
Layer planes predominantly parallel with fibre axis good long-distance arrangement	High modulus (HM) C-fibre (graphite fibre)
No recognisable first draw orientation very poor long-distance arrangement	Isotropic C-fibre

Tab. 2: Classification of carbon fibres on their structural basis.



a) wavy graphite layers in the fibre direction.
b) graphite layer orientation in the fibre direction.
c) texture across fibre direction.

Fig. 4: Model of the structural build-up of anisotropic carbon fibres (W. Ruland).

Highly interesting from the fibre technology standpoint in the case of viscose filament origin is the extensive retention of the microfibrillar structures of the cellulose structure, despite the extraordinarily high pyrolysis temperature.

Appearance: black, lustrous, slippery handle, greater stiffness than glass fibres. The most important textile technological characteristics result from the typical structures of the fibres (Fig. 4). Use (in the textile sector): production of fireproof woven fabrics, filter cloths, electrically conductive woven fabrics for heating, thermally insulating felts, composites (CFK).

Carbonic acid (H_2CO_3). Unknown in the free state. Combined in nature as → Carbon dioxide (CO_2) in the form of carbonic acid salts (→ Carbonates), e.g. in calcium carbonate ($CaCO_3$). From this production by conversion with acids:

$$CaCO_3 + 2\ HCl \rightarrow CaCl_2 + H_2O + CO_2$$

The hydrate of CO_2 (+ H_2O = H_2CO_3) is the true carbonic acid. A bivalent weak acid (blue litmus slightly reddened), weakly ionised.

Carbonizing Employed for removing vegetable fibres and impurities (burrs, straw fragments etc) from wool. Wool may be carbonized in the form of fibre stock, piecegoods or rags/shoddy. Procedure: Treat the wool with carbonizing liquor, remove water by squeezing, suction extraction or centrifuging, dry, bake, crush/shake and neutralize.

1. Carbonizing liquor: Generally sulphuric acid (up to approx. 7%), less commonly hydrochloric acid (up to approx. 4.7%) or aluminium or magnesium chloride solution (7–11%). By adding an acid-resistant wetting agent it is possible to reduce acid concentrations to half. Aluminium or magnesium chloride is less harmful to the wool.
2. Centrifuge at constant speed (fibre stock, shoddy, rags) or squeeze out (fibre stock, shoddy, rags, piecegoods) or suction extract (piecegoods) to approx. 40–50% moisture content.
3. Dry at 140°C.
4. Bake in the dryer at 140°C.
5. Shake, i.e. mechanically remove the baked (carbonized) cellulosic fragments (hydrocellulose) in a beater-opener (fibre stock, shoddy, rags) or in a milling machine fitted with flanged rollers (piecegoods). It is relatively easy to remove carbonized matter here.
6. Neutralize (eliminate the acid present in the material) in a scouring machine (fibre stock, shoddy, rags) or a dolly (piecegoods).

Mistakes and damage may be avoided by taking care with the factors critical to the result. Irregular carbonizing becomes evident in piece dyeing in the form of skitteriness. Differences in dye affinity occur from one lot to another and therefore different batches should not be mixed together. The thorough rinsing out of the sulphuric acid requires large volumes of water. An alternative method is to pad first with tetrachloroethane and then with dilute sulphuric acid, dry and bake (Sperotto Rimar). The CSIRO method of carbonizing is a controlled sulphuric acid process. The card sliver is soaked in sulphuric acid at room temperature, dried at 80°C and baked at 130°C. A specially designed stuffer device which avoids damage to the wool is used for releasing the vegetable matter. The sliver is finally rinsed, neutralized with ammonia and again rinsed.

In principle, wool textiles of any kind can be carbonized as fibre stock, yarn or fabric before and after dyeing. However, in the carbonizing process the wool protein undergoes such severe chemical modification that the interrelationships of the functional groups and the corresponding reactivity of the protein can be modified. This phenomenon is very important when carbonizing is to be followed by dyeing since the presence of a certain number of acid or basic groups in the wool protein relative to the dye used is one of the factors governing the quality of a dyeing.

The following reactions have an influence on the basic and acid groups in carbonizing with sulphuric acid:

a) Peptide chains are broken, crosslinking occurs and isopeptide bonds are split during the carbonizing process.
b) The sulphatization of serine, the N to O peptide shift in the carbonizing-drying phase.
c) The hydrolysis of serine-O-sulphate during the dyeing process.

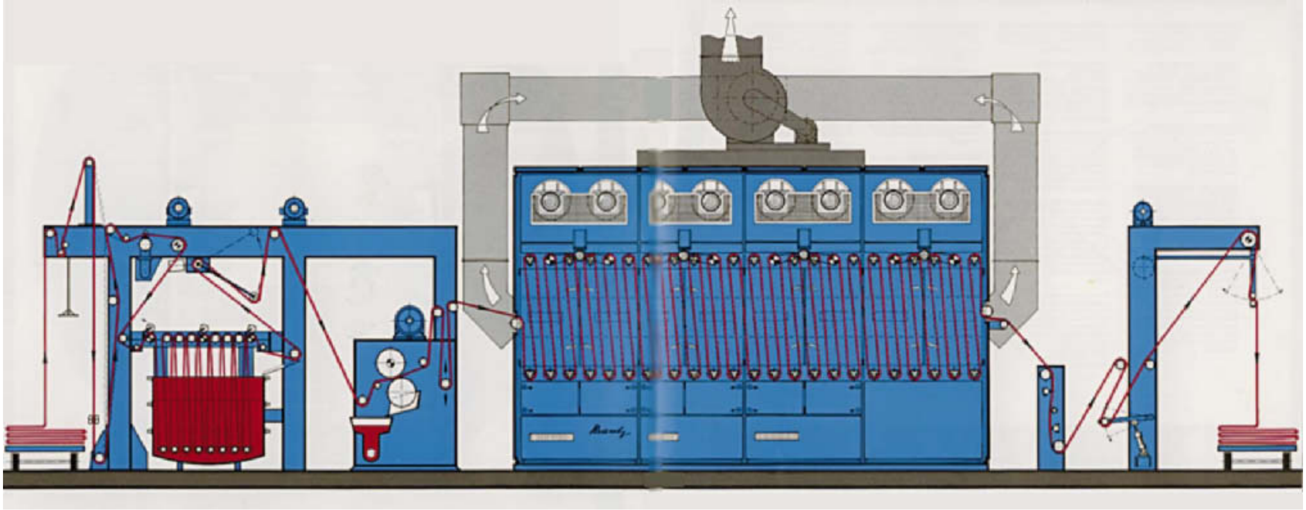


Fig. 1: Carbonizing line (Krantz) with sulphuric acid roller vat and hotflue drying/carbonizing range.

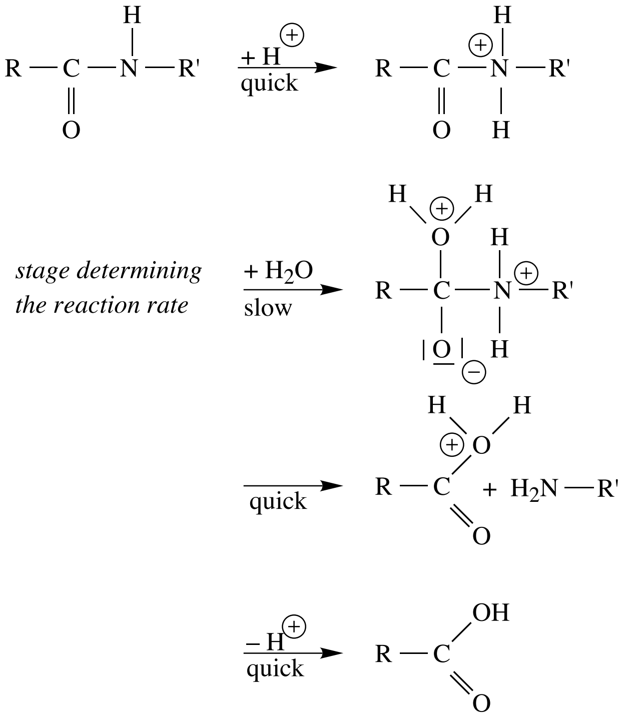
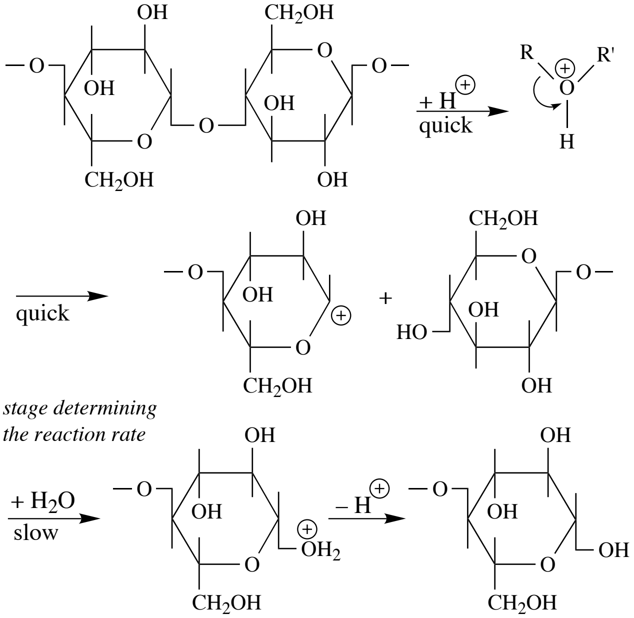
All these factors include a change in the balanced acid and basic groups, with the formation of sulphate groups regarded as predominant, thus affecting the dye affinity of wool. If for economic reasons it is decided to carbonize before dyeing then the above factors may be regarded as critical. Major defects will occur especially if there is an irregular distribution of acid on the material and the drying process associated with carbonizing is not correctly performed, all of which can represent a variable degree of "damage" to the material. However, carbonizing after dyeing (post-carbonizing) has the following disdvantages:

- unavoidable shade variations in post-carbonizing;
- further acidity emanating from dyeing is introduced into the carbonizing process, making it difficult to neutralize to tolerable residual acid levels (below 1%),
- wool already degraded by dyeing appears to be especially susceptible to further damage in post-carbonizing,
- lower economic viability due to high chemical consumption,
- fabrics with a high burr content must be milled between baking and neutralizing, interrupting the continuity of the process,
- maximum speed is approx. 10 m/min.

In carbonizing by chemical routes hydrolytic degradation of the vegetable matter (cellulose) occurs, whilst if





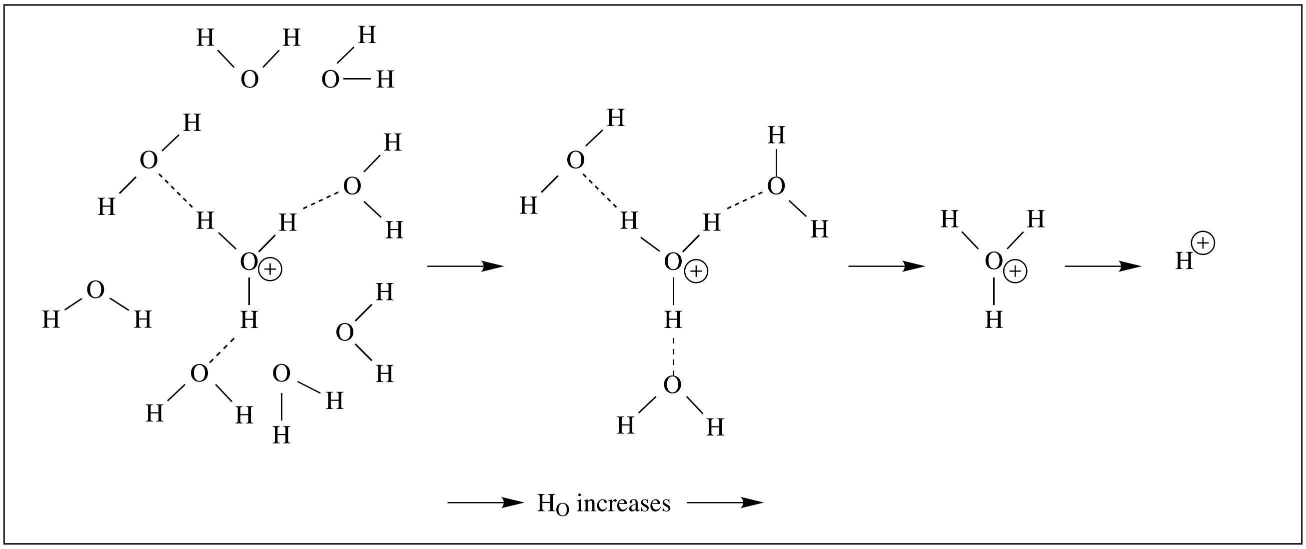


Fig. 2: Effectiveness of protons of conc. mineral acids according to Hanna et.al.

the procedure is correct the wool is protected from hydrolytic damage by its different reaction mechanisms. The R–NH–CO–CHR group of wool created by polycondensation represents an amide group. The following conditions apply for the hydrolysis of amides (and for the wool proteins also):

a) The rate of the acid hydrolysis with acid of moderate concentration is proportional to [amide] · $[H^+]$.
b) There is steric hindrance by groups of bulky configuration.
c) Hydrolysis oocurs as an A-2 mechanism.

In concentrated acid solutions the rate of hydrolysis of an amide passes through a maximum (the hydrogen ion concentration corresponding to this maximum is different for every amide). Further addition of concentrated sulphuric acid then only causes water molecules to be bound in the solvate sheaths of the protons and anions, so that the amount of “free” water capable of attacking the carbonyl-carbon atom declines. Consequently concentrated acids have a damaging effect on wool proteins only when water is present, i.e the principal duty of a good carbonizing plant is to impede the reaction rate limitation phase by rapid drying. The glucosidic bond of cellulose is an acetal bond which reacts especially sensitively to hydrogen ions. The hydroxyl groups of cellulose together form strong hydrogen bonds and a large number of cellulose molecules are densely packed together into a larger unit by crystallographic aggregation. It is difficult for chemical reactions to occur because the supermolecular structure of the cellulose first has to be loosened in order that the reaction can continue through to the innermost chain molecules. The periodic loose spots are preferentially split by the action of mineral acids and also statistically the β-glycoside bonds. In the course of the reaction the degree of polymerisation declines considerably. The homopolymer series of hydrocellulose is created. Of the reaction equilibrium of the hydrolysis process it is only possible to express the view that at a first approximation the course of the reaction is dependent on the number of bonds available for splitting in the easily accessible zones. As far as these are concerned a reaction of the first order in terms of time takes place. Once these reactions have taken their course, further reaction in the still difficult access zones is governed largely by diffusion processes. It has been established that the diffusion processes come clearly to the fore when a weight loss of approx. 5–10% has occurred. The mechanism of chain splitting in acid hydrolysis is the consequence of a hydrogen ion catalysis process.

The technological consequence of this is that because in the case of wool, water participates in an early rate-determining reaction stage but does much later do so in the case of cellulose, to prevent unwelcome wool damage drying of the sulphuric acid soaked goods must be implemented as quickly as possible. Earlier carbonizing systems (hot-flue with several successively hotter chambers) did not permit such a procedure. Today there are high-performance dryers for this purpose (Fig. 1). These machines represent the only means of substantially restricting the action of the hydroxonium ions to the cellulose in the hydrolysis context, with the water being removed from the reaction system as quickly as possible. In the absence of water the hydrolysis of wool is suppressed and the H_0 function (Fig. 2) of the sulphuric acid is simultaneously increased to such an extent that the cellulose is quickly and substantially degraded.

For economic reasons it would be meaningful not to neutralize pre-carbonised wool before dyeing but to perform the dyeing with the sulphuric acid present. This can cause the dyeing process to be uncontrollable because more and more acid gets into the dyebath with increasing dyeing temperature. Despite carefully conducted pre-carbonising providing appreciable cost advantages, the risk of skittery dyeing or “marbling” detracts from the process reliability in some cases.

Carbonizing agent In accordance with TEGEWA nomenclature, those textile auxiliary agents which facilitate and accelerate penetration of the carbonising acid into the vegetable impurities in the wool, promoting destruction of the vegetable impurities. Carbonizing agents also enable the quantity of acid and the duration of carbonizing to be reduced, thus protecting the wool fibre. Furthermore, nonionogenic surfactants also have a protective action on the wool. Prerequisite: maximum acid and heat resistance in the case of aluminium chloride impregnation, otherwise relevant resistance. For consideration: nonionogenic products.

Carbonizing chamber Part of the drying device for temperatures above 100°C used in carbonisation.

Carbonizing, fastness to Assessment of the effect on the shade of a dye by the carbonizing process, by which foreign vegetable fibres are removed from wool by means of diluted sulphuric acid and aluminium chloride solutions. When acetate or polyamide fibres are to be removed from wool, carbonising must be effected with aluminium chloride. Test implementation: 15 mins at room temperature with
a) 60% sulphuric acid solution,
b) 60% aluminium chloride solution,
with a 20 : 1 liquor ratio, squeezing/centrifuging to 80%. Drying: approx. 30 mins at 60°C. Carbonizing: 15 min at 105 °C for the sulphuric acid process, and 15 min at 115°C for the aluminium chloride process, rinsing test specimens in cold flowing water for 5 min. Then dry half at 60°C in hot air, and neutralise the other half – with sodium carbonate in the case of the sulphuric acid process, and with ammonia after using the aluminium chloride process. Rinsing, drying. Grey scale assessment of the two halves.

Carbon monoxide (carbon oxide, CO). Molecular weight 28.01. Hardly water-soluble, colourless, tasteless and odourless poisonous gas: lethal dose approx. 1 g (= less than 1l); 0.3% in inhaled air = death after approx. 15 mins. Occurs for example in coal combustion (even with excess air) as the first stage:

$$2\,C + O_2 \rightarrow 2\,CO + 2 \times 109\ \text{kJ},$$

similar to coal gas, oil, motor vehicle fuel (as exhaust gas from the Otto motor approx. 5 vol% CO). Burns from approx. 700°C with a bluish flame to carbon dioxide:

$$2\,CO + O_2 \rightarrow 2\,CO_2 + 570\ \text{kJ}.$$

Use: including for synthesis (hydrocarbons, alcohols) and heating fuels (producer gas, mixed gas, water gas) and the like.

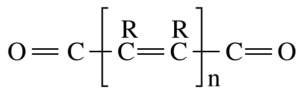
Carbon oxo-acids,

– H_2CO_3 = carbonic acid; salts = carbonates.
– H_2CO_4 = percarbonic acid; salts = percarbonates (Na_2CO_4 sodium percarbonate)
– $H_2C_2O_6$ = peroxycarbonic acid; salts = peroxycarbonates ($Na_2C_2O_6$), oxidising agents.

Carbon oxychloride → Phosgene.

Carbon tetrachloride (Tetrachloromethane), CCl_4. Colourless liquid, water-clear, neutral, without free chlorine, non-combustible, sickly sweet smell, highly narcotic. → Chlorinated hydrocarbons.

Carbonyl dyes Large class of dyes which have at least two carbonyl groups standing in conjugation with one another (>C=O):



$$O{=}C-\left[\overset{R}{C}{=}\overset{R}{C}\right]_n-C{=}O$$

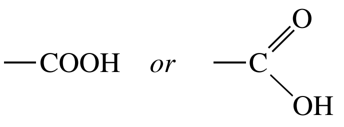
These include in particular indigo (thioindigo) and anthraquinone compounds as vat dyes. Also, higher anellated carbonyl compounds, which are exclusively vat dyes (e.g. acyl amino anthraquinone). Other carbonyl dyes refer to, amongst others: quinacridones (pigment dyes), benzo- and naphthoquinone derivatives (vat and dispersion dyes), and perylene carbonic acid derivatives (vat dyes). Classification by application: ionic carbonyl dyes (with water-solubilising substituents of an anionic or cationic nature); a large number of wool, polyacrylonitrile and acetate dyes; dispersion dyes (dispersion dyes used these days are mostly anthraquinone-carbonyl dyes), also some reactive dispersion-complex-forming carbonyl dyes (mordant dyes); reactive dyes; vat dyes; vat leuco ester dyes.

Carbonyl group The >C=O group in such compounds as aldehydes, ketones, metallic carbonyls and phosgene. In most cases identical with the → keto group.

Carborundum (Silicon carbide), SiC. Manufactured at above 2000°C from carbon and quartz. Characteristics: Multicoloured (reddish, greenish blue, black) crystals, extremely chemical and heat resistant, similar hardness to diamonds, density 3.2. Application: As grinding and polishing material, for the manufacture of fire resistant bricks and electrical resistors.

Carboxyl extra group produces ∅ amino acids e.g. in keratin molecules. The carboxyl extra group determines the behaviour of wool and silk towards alkalis, by reacting as acids.

Carboxyl group Monovalent typical acid group:

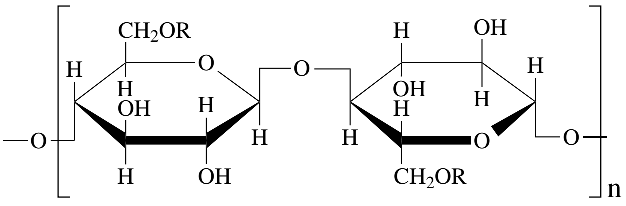


which is represented in organic acids and transfers its marked acidic character to the remaining compound (carboxylic acids, fatty acids), and to the textile assistants (fatty acids-carboxyl group), dyes (auxochrome), etc. The ionizable H atom can be exchanged for a metallic cation, creating salts of the carboxylic acids, or can be exchanged for organic radicals, which leads to the formation of esters. If, instead of the acid H, the OH group is composed differently , then the entire remaining residual acid R–CO is transferred to the new compound as so-called → Acyl.

Carboxylic acids Carbonaceous organic acids, which are made up of → Alkyls and the characteristic carboxyl group –COOH, e.g. CH_3–COOH (acetic acid), derived from the hydrocarbon CH_4 (methane), also as → Polycarboxylic acids. Mono, di-, tri- etc., aliphatic, aromatic, saturated and unsaturated carboxylic acids exist. Opposite → Mineral acids.

Carboxymethylcellulose (CMC). CMC is generally understood to mean sodium carboxymethyl cellulose (carboxymetholcellulose-sodium salt, in technical language also abbreviated to NaCMC). This is a colourless, water soluble cellulose ether, which swells and forms a gel when stirred into water and forms a viscous colloidal solution. The viscosity can be altered by reducing the molecular weight of the alkali cellulose in the reaction. CMC reacts as a polyelectrolyte and can be precipitated from watery solution in flakes by multivalent metal ions, e.g. Cu^{2+} and Al^{3+}. The addition of mineral acid causes free water insoluble cellulose glycol acid (commonly abbreviated to HCMC) to form. CMC is largely stable in an alkaline environment. Due to the manufacturing process, technical CMC contains sodium chloride and sodium glycolate, washing out with a weak alcohol yields cleaned products with a salt content below 0.5 %. Manufacture: In the treatment of cellulose with caustic soda liquor. Reaction with chloroacetic acid or its sodium salt at increased temperature (possibly in the presence of an organic solvent) yields CMC in addition to sodium glycolate and sodium chloride. Depending upon the intended application the end products are neutralised and cleaned.

Application: As water soluble thickener, suspending assistant and protective colloid in the dyeing industry, in washing agents and soaps as an antiredeposition agent, in the textile industry as chemical finishing, in filtering, sewerage and flotation processes, as a printing assistant and for thin-layer and ion exchange chromatography. The greying inhibiting effect of CMC is only limited on hydrophilic fibres, e.g. cotton, i.e. it is inferior to that of cellulose mixed ethers, e.g. Methylhydroxypropylcellulose.



alkalicellulose: R = Na
carboxymethyl-cellulose sodium salt: R = CH_2COONa
cellulosexanthogenate: R = CSSNa

Carboxymethyl starches Important starch ethers as reaction product of starch with chloroacetic acid (in the presence of alkali), also mixed ether with other etherification substances (dimethylsulphate, ethylene oxide or propylene oxide). Substitution or etherification degree 0.3–0.5. Cold water soluble carboxymethyl starches are generally highly substituted, so-called cooking types, on the other hand, are rarely substituted.

Carcinogenic (Gk.: karkinos = cancer, genan = cause). Cancer-causing → Carcinogens.

Carcinogenic substances → Carcinogens.

Carcinogens (Gk.: = cancer-inducing; equivalent to the Latin cancerogen). Cancer-inducing substances; very heterogeneously composed group of substances which can cause cancer in animal experiments and/or in human beings. To be considered here for example is interaction between cancer-inducing working materials and nucleic acid (constituent of cell nuclei), where, by triggering mutations, a defective information chain can form in cell division. Cancer-inducing working materials include in particular so-called alkylating compounds (cross-linking chemicals), condensed aromatic hydrocarbons and numerous, very different types of organic and inorganic compounds. There is no parallel between cancer-inducing working materials and general toxicity and also intensity, which can be regarded as still completely harmless, can be indicated for substances, the effect of which, according to the current state of knowledge, means unequivocal danger of cancer for human beings. Such lists therefore contain no TLV values for safe carcinogenic working materials for humans. All new carcinogenically suspect substances included in the TLV list have no TLV value. Since 1976, there have been groups A1, A2 and B for cancer-inducing working materials, and, since 1980, a quantitative danger classification in groups I-III as a yardstick for differentiated protective measures in practice, out of which bottom threshold values are available for cancer-inducing working materials. (Especially → dangerous substances). In the Federal Republic of Germany, Technical Guidelines have been cited by way of a supplement in order to reduce as far as possible the risk of health impairment in the production/processing of cancer-inducing working materials. Furthermore, not all carcinogenic substances can be predicted from animal experiments. In the case of substances recognised as highly cancer-inducing in humans, it is necessary to eliminate these substances as working materials or to change over to other non-dangerous substances. In the Federal Republic of Germany, the latter consideration has led to the disappearance from the market of a whole range of dyestuffs for the production of which benzidine or 2-napthylamine were necessary. On the other hand, strong measures are required for protecting employees against starting and intermediate products regarded as cancer-inducing; the technical expenditure necessary for this increases sharply with the danger of the substance. This applies even more to safety conscious behaviour/methods of operation in laboratories, where operations are carried out with chemically cancer-inducing working materials; this applies for example to laboratory clothing (do not enter dining rooms, monitored clothing), laboratory premises, laboratory waste, general cleanliness checks, liquid pipetting (never with the mouth), weighing out, working under extraction hoods, spills/residues, glass apparatus cleaning (chromic-sulphuric acid mixture as an unspecified oxidation reagent should inactivate practically all organic carcinogens by decomposition). Basically, do not eat, drink, smoke or store any foodstuffs in laboratories. Constantly bear in mind: even one-off contact can result in tumour formation; no limit dose can be set. The effects of different carcinogens can add up/multiply, and resorption through the skin is to be reckoned with in addition to oral and inhalatory intake.

Dangerous working substances include:

butyrolactone
DDT
diazo compounds
expoxy
hydrazine sulphate
nitrosamines
phosgene
carbon tetrachloride
resins thiourea
thionyl chloride.

Analysis of the currently available data, e.g. in accordance with IARC (International Agency for Research in Cancer) criteria, shows that adequate experimental proof of carcinogenic effect on animals is available for approx. one dozen dyestuffs. For a number of colouring agents, principally dyestuffs, there is evidence of a justified suspicion of a carcinogenic effect, e.g. certain azo dyes, for which it can be shown that they can be metabolised in a substantial quantity in the organism into proven carcinogenic aromatic amines (like for example benzidine dyes into benzidine). The use of such colouring agents in areas with greater and not easy to control exposure, e.g. hair dyeing, finger nail colouring, home dyeing, and also in industrial areas with inadequate work hygiene, can result in increased risk. No benzidine nor its primary metabolites (N-monoacetyl and N,N'-diacetyl benzidine) were detected in the urine of exposed workers when good work hygiene was implemented. In contrast, these metabolites could be detected in the urine of workers in poor work hygiene conditions. These potential risks were the occasion for the decision of the leading dyestuffs manufacturers to remove these dyes from their ranges at the beginning of the seventies. In general, it can be concluded that azo compounds, which, in reductive metabolic splitting, can form carcinogenic amines which are suspect in the absence of relevant experimental data, also have carcinogenic potential.

Card,

I. The seed head of the teazle plant or more commonly an assembly of wires protruding from a base structure, both used for raising or napping the surface of a cloth, generally a woollen cloth.

II. Distinction is made between the flat card (short-staple system) and the roller card (worsted and woollen systems). In the former the prepared cotton lap is opened up to single-fibre state, the fibres extended and assembled into the → Card sliver.

Cardboard tubes (winding tubes). Used for the crease-free batching of pressure-sensitive fabrics (velvet, imitation furs etc).

Card clothing Used to clothe the flats of cotton cards and the rollers of woollen and worsted cards and also as card fillet for the rollers of napping or raising machines. Pins are set to protrude from one face of a fabric foundation. This foundation is a composite multi-ply structure consisting of a woven cotton back with maximim stability and a pliable rubberized blanket face. The flexible ply ensures that the tips of the heavily stressed pins always return to their initial angle.

The fabric plies are bonded to form the multi-ply cotton foundation by rubber macerated with toluene. The isoprene rubber compounds dissolved with toluene in agitating mixers are spread onto the fabric. In the heater duct following the applicator head the toluene present in the compound is evaporated off and subjected to a solvent recovery process with the recovered toluene being largely recycled. The rubber remaining on the fabric is substantially the same as that in the original recipe. Dissolving in toluene is solely for the purpose of applying it in controlled amounts onto the fabric. The procedure is repeated for the required number of fabric plies (on both sides of the inner plies and on one side of the outer plies). Singly or doubly rubberised fabrics are produced which are cold-laminated on the calender, i.e. pressed together adhesive-to-adhesive. The rubber solution is likewise applied to a substrate fabric by the same procedure, but in this case the compound recipe and the nature of the blanket produced differ. In the preparation of the rubber solution acrylonitrile-butadiene or styrene-butadiene rubber is used because an oil-resistant surface is essential for fillet to be used in the spinning process (the oils used in spinning would soon destroy an isoprene rubber blanket). The recipe is prepared in a compounding room. The rubber is worked by the rubber mill and the vulcanizing agents added to the compound which is then dissolved with toluene in a kneader to form rubber solution. The subsequent spreading process is a fabric bonding proc-

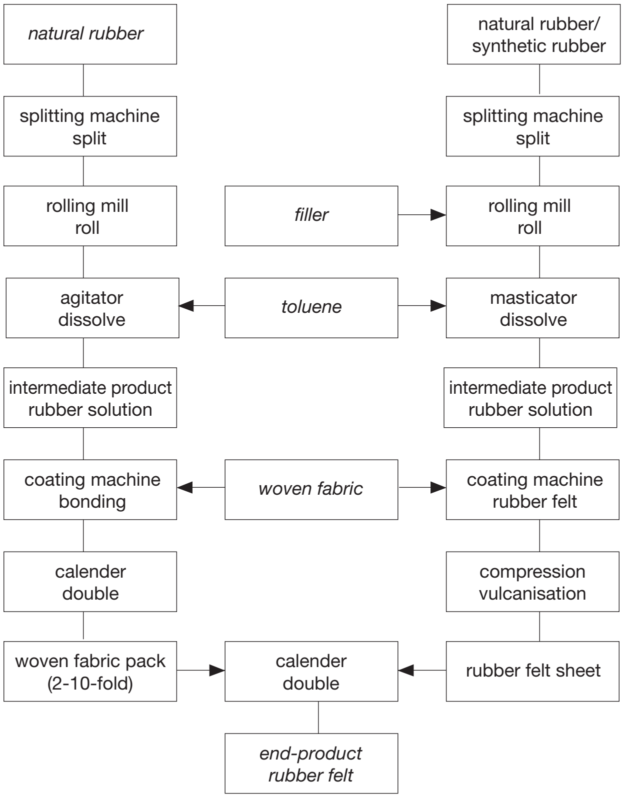


Fig.: Schematic representation of the card clothing production process.

ess. The painted blanket is vulcanized on a vulcanizing press at 120–170°C. Incorporation of a blowing agent has the effect of distending the compound to provide higher bulk and softness. The final vulcanized blanket has rubber painted on the back. Finally the assembly of fabric plies and the rubber blanket are bonded together on the calender (Fig.).

Increasing the degree of crosslinking in the flexible ply enables the following properties to be improved:
- permanent elongation,
- permanent compressive set,
- dynamic damping at high temperature,
- resistance to expansion,
- breaking extension,
- tensile stress,
- tear strength,
- fatigue resistance,

With less improvement in:
- resistance to abrasion,
- vapour permeability,
- electrical resistance,
- cold flexibility,
- breaking strength.

The following vulcanizing agents and fillers are used in the vulcanizing process:

a) Masticator for the rubber milling process: to impart good pliability and absorbency to the types of rubber.
b) Plasticiser: to obtain a high degree of softness in the finished blanket and a high plasticity factor in vulcanizing.
c) Sulphur: the actual vulcanizing process is brought about by chemical crosslinking with sulphur.
d) Chalk: filler for increasing the bulk.
e) Carbon black: filler, colorant, and to increase the abrasion resistance of the face.
f) Benzene-sulphohydracite: blowing agent for increasing bulk and adjusting the softness of the rubber.
g) Tetramethyl-thiuran disulphide: vulcanizing agent (semi-accelerator).
h) Mercapto-benzthiazyl disulphide: vulcanizing agent (super-accelerator).
i) Triethanolamine: vulcanizing agent (super-accelerator).
k) Various fillers.

The interaction between vulcanizing agents, sulphur and fillers enables vulcanizing times to be specified precisely. It is thus possible with carefully planned recipes to cover all required end-uses and card clothing specifications.

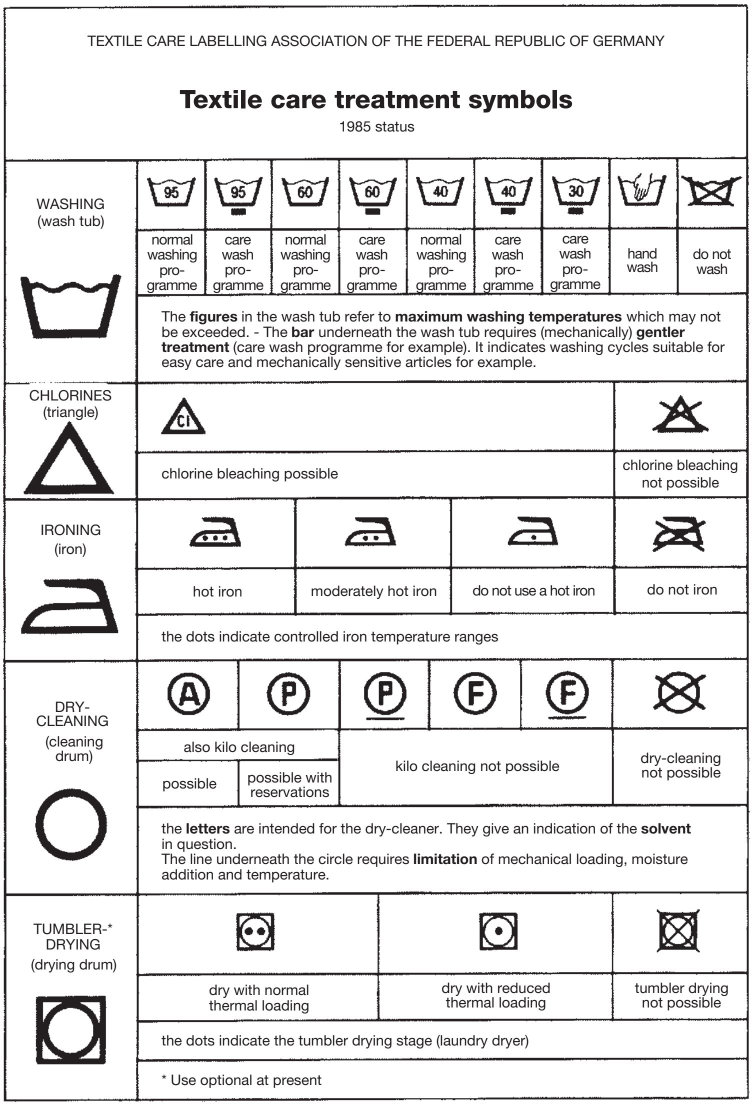
Carded yarn Manufacturing term for yarns produced by woollen spinning system, characterised by their bulkiness and a more or less hairy surface. The fibres are not fully parallellised, but only carded (carded without the additional combing process as with → Worsted yarns), then spun by means of web formation, twisting etc. (not drafted). The process is suitable for almost all fibre types, from the shortest waste materials to medium-length, fine crimped fibres (particularly strongly crimped wool, good felting properties), and used in a variety of blends (mixture or melange effects) for cheap to good quality end products. Mainly for ladies and mens outerwear fabrics, uniforms, blankets, carpets, etc.

Card lap winding machine Winds card lap on to perforated beams for dyeing and bleaching.

Card raising machines Rod and roller card raising machines using teasels as raising tool. → Raising machines.

Card sliver Semi-manufacture in the spinning of cotton and viscose. A web of fibres in ribbon form comprising fibres in parallel alignment (similar to top on the worsted spinning system). Card slivers are for example dyed (→ Pack system dyeing machines) packed into compact balls or wound onto beams in dyeing machines. Card sliver passes via drawframe and speedframe before being spun into yarn.

Care labelling of textiles The purpose is to provide the end-user and purchaser of a textile product with information on the fibre composition and care of the textile. This is contained on two sewn-in labels or frequently one joint label. If any of this information is absent, caution is advised or even non-purchase recommended. Raw materials labelling and care labelling dif-



The **figures** in the wash tub refer to **maximum washing temperatures** which may not be exceeded. - The **bar** underneath the wash tub requires (mechanically) **gentler treatment** (care wash programme for example). It indicates washing cycles suitable for easy care and mechanically sensitive articles for example.

the dots indicate controlled iron temperature ranges

the **letters** are intended for the dry-cleaner. They give an indication of the **solvent** in question.
The line underneath the circle requires **limitation** of mechanical loading, moisture addition and temperature.

the dots indicate the tumbler drying stage (laundry dryer)

* Use optional at present

Fig. 1: Textile care labelling symbols.

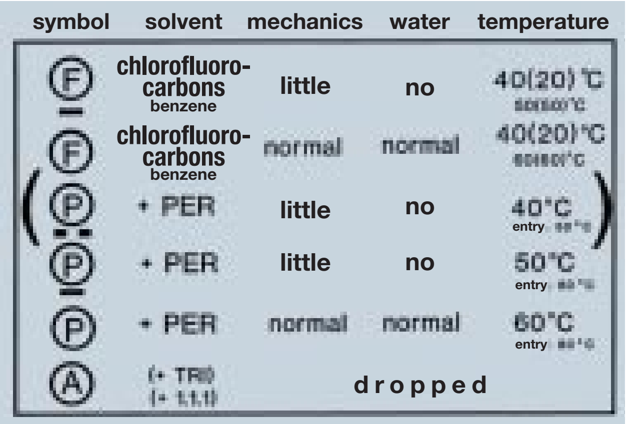
fer both in principle and legal basis. Raw materials labelling must conform with the legal obligations of → Textile labelling regulations (in Germany and Britain for instance) whilst care labelling is undertaken on a voluntary basis. The consumer who regards the absence of care labelling as unimportant does so at his own peril. Nor is care labelling entirely above the law. The copyright of the symbols used is held by the "Groupement International d'Etiquetage pour l'Entretien des Textiles" (Ginetex) in Paris. The trademark rights for Germany for example are in turn held by the Arbeitsgemeinschaft für Pflegekennzeichen für Textilien, a Ginetex member which comes under the auspices of Gesamttextil, the leader association in Frankfurt/M, and similar arrangements exist in other member countries. A number of trade and commercial bodies operate within the working group, including a consumer organisation and various research institutes.

Fig. 1 summarises the care labelling code for textiles. The system is generally available free from licence fees but three conditions are attached to its use:

1. The symbols must be depicted exactly in their original form.
2. They must not be associated with arbitrary symbols.
3. With the exception of the optional tumble-dry, there must be a full set of symbols.

The label must give information on the wash method and on the ironing temperature and also indicate whether dry cleaning is possible. Composition and care labels are no less important than the maker's brand as a medium for manifesting the integrity of the producer. As the nature of the textile trade becomes increasingly global, the fibre composition is generally stated in a number of languages. This is unnecessary for care symbols which have international recognition (ISO 3758:1991, EN 23758:1994). However, care labelling does not represent a quality mark.

Fig. 2 describes procedures defined for dry cleaning. The care symbol not only describes the nature of the cleaning medium (solvent, added water) but at the same time it defines the severity of the cleaning action, cleaning and drying temperatures and the maximum permitted treatment times for avoiding irreversible damage. For instance "F" not only indicates the use of a very mild solvent, but at the same time also low drying temperature and because of the high volatility, short drying time and consequently low mechanical action.



symbol	solvent	mechanics	water	temperature
F	chlorofluoro-carbons benzene	little	no	40(20) °C [illegible]
F	chlorofluoro-carbons benzene	normal	normal	40(20) °C [illegible]
P	• PER	little	no	40 °C entry [illegible]
P	• PER	little	no	50 °C entry [illegible]
P	• PER	normal	normal	60 °C entry [illegible]
A	(• TRI) (• 1.1.1)	dropped		

Fig. 2: Dry-cleaning symbols and technical content of the basic processes, in which chlorofluorocarbons are prohibited in the Federal Republic of Germany, and are replaced by benzene in special machines (PER = tetrachloroethylene; TRI = trichloroethylene; 1.1.1 = trichloroethane).

With the exception of “A” which for ecological reasons will probably no longer have any future significance in Europe, for each basic symbol there are in principle two stages of treatment for textiles of different sensitivities, or in the case of “P” in future with the demise of the fluorinated hydrocarbons as many as three stages.

The “F” symbol is important not just due to the use of fluorinated hydrocarbon but because of the flashpoint (flashpoint for Stoddard solvent = white spirit). The drying temperatures also given apply to the use of white spirit.

Care of textiles Necessary care taken to guarantee → Wearing comfort over a period, in fact in the sense of work simplification and reduction. Simple washing by hand or machine, easy dirt, stain and skin grease removal. Most possibly bacteria eradication too by washing and dry cleaning; centrifuge, and hang on the line without having to be afraid of dimensional changes. Quick drying (therefore fresh daily).

Carmine azurol Colour reagent for differentiating between fibre materials in the textile, chemical pulp and paper industries. As a supplement to → Neocarmine, particularly for protein and synthetic fibres. Implementation: free test specimen of adherent foreign matter, perfuse with carine azurol solution, dye for 15 mins at 80–90°C in a water bath, rinse. Findings:

stained grey = polyamide 11, polyester, polyvinylidene copolymers
pale greenish blue = modacrylic
pale blue = triacetate, polyvinylchloride (post-chlorinated = stronger), polyacrylonitrile
light medium blue = capok, polyamide 6 and 6.6, wool
dark blue = jute
dark blue-violet = silk, wild silk, polyvinyl alcohol, casein fibre
reddish violet = copolymer
dark red = natural and man-made cellulose fibre (excepting capok, jute, acetate, alginate).

Carnauba wax (palm wax). Most important vegetable wax, which is obtained from the surface of the Carnauba palm leaf (South America). Brittle, fragile, greyish yellow, slight lustre. Types: fatty grey, refined (paraffin additive), also bleached and brightened. Melt point 80–86°C, light qualities lower, refined 70–72°C. Difficult to saponify, necessary to emulsify. Soluble in benzine, benzol, xylol, chloroform, turpentine oil, chlorinated hydrocarbons etc. Used for sizing and chemical finishing for example.

Caroa fibre (craua, croa, coroa). Source: a fibre from the leaf of the plant *Neoglazovia variegata*, indigenous to Central and South America, grows wild in Brazil in large quantities. The Brazilian plant yields a fibre that can be used for suitings and coatings in tropical countries, as well as for rugs, paper, light rope and twine. The fibre is creamy white in colour, strong, flexible and fairly soft to touch. It contains a high proportion of lignin. Compared with jute, caroa is 3 times as strong, and fabric, sacking or twine made from it is about half as light as similar articles made from jute. → Bromelia fibres.

Carob is the active content of → Locust bean flour (the fruit of the locust or carob tree). Contains high molecular weight carbohydrates and hemicelluloses, principally → Galactomannan (mannogalactan).

Caro’s acid (peroxysulphuric acid, sulfo monoper acid, persulphuric acid), H_2SO_5 or $HO–SO_2–O–OH$. In its pure state, white crystals, soluble in water as strong, monobasic acid with slow decomposition (develops ozone-rich oxygen even at room temperature). In the presence of larger amounts of sulphuric acid, rapid splitting into sulphuric acid and hydrogen peroxide, according to the following equation:

$$H_2SO_5 + H_2O \leftrightarrow H_2SO_4 + H_2O_2$$

Caro’s acid is to be regarded as a hydrogen peroxide whose H atom is replaced by the SO_3H group; it thus has the structure: $HO–O–SO_3H$. Caro’s acid oxidises aniline into nitrobenzene, and it instantly releases iodine from potassium iodide solutions. Used for making wool shrink-resistant.

Caro’s acid process for anti-felting finish Experience gained from the CSIRO wool research laboratories has demonstrated the connection, shown in the table, between processing method and wool area shrinkage.

Working method	Wool area shrinkage
untreated	40 %
5% solution	21 %
5% solution, previously neutralised to pH 6-7	11 %
5% solution, pH 6-7, saturated with sodium sulphate	4– 5 %

Table: Relation between processing method and wool area shrinkage when given an anti-felting finish using Caro’s acid.

In the last case, the oxidation reaction appears to be limited specifically to the outer cortex cells of the wool, and is therefore suitable for print pre-treatment of the wool fabrics.

Carousel centrifuge Used on the carousel principle for centrifuging individual cross-wound packages creeled on special spindles.

Carousel motif printing machine Circular screen arrangement with fully rotating printing tables, central drive and fully pneumatic control. Easily interchangeable printing tables for printing different sizes of motifs. - producer Maag Flockmaschinen GmbH.

Carousel printer Screen printing machine for the automated printing of finished textiles, carousel system.

Carousel screen printing machine Semi-automatic screen printing machine, on which the screens are accommodated in a rotating frame, which runs between two short tables, so that two fabrics can be printed next to each other by two printers by swinging in the screens.

Carpet ageing Artificial ageing of carpets, achieved by chlorination, which brings about an intensification of the appearance of colour, pile and lustre, usually associated with simultaneous damage to the fibre.

Carpet back coating → Back coating of carpets.

Carpet back singeing Carpets are singed before foam application, allowing the primary coat to be reduced by 10% (with improved tuft anchorage) and the foam application by as much as 35% to approx. 1.5–2 mm thickness (= shorter cure time, faster production speed, better final quality). The carpet back singeing unit in a continuous carpet backing line is situated between the entry and the primary coating module.

Carpet base material → Carpet primary backing.

Carpet beating and dust extraction machines With suction, working area adjustable to carpet width, up to 4 m working width. Mechanical action by vibration causing beater waves; dependent on the manufacturer may be fitted with metal tappets, metal sprung plates, plastic or leather plates, brushes.

Carpet beetles Beetles whose larvae feed on and cause damage to wool carpets. → Textile parasites (see Fig.).

Fig.: carpet beetles with larvae (enlarged) (source: Bayer).

Carpet binding machine Used especially for the edge-binding of cut, tufted floor coverings which are laid “wall-to-wall”.

Carpet cleaning Process:
- dust removal (vacuum cleaning),
- dry process (e.g. powder),
- hot water/steam vacuum cleaning,
- shampooing (pile wash, foam cleaning),
- wet wash,
- solvent process,
- special process (stain removal, disinfection, etc.)

Depending on the type of carpet, suitably adapted processes should be selected or combined.

Carpet comfort →: CF-value; Tread comfort value.

Carpet – contaminant tested The registered quality mark of the “Association of Environmentally Friendly Floor Coverings” (GUT: Gemeinschaft umweltfreundlicher Teppichböden), which was established by reputable European carpet manufacturers. Carpets and floor coverings of GUT members have displayed this quality mark since autumn 1991. GUT certifies that the carpets awarded this mark are tested for the presence of contaminants (“schadstoffgeprüft”), i.e. only raw materials are used which contain no health-threatening pollutants such as pentachlorophenol, formaldehyde, asbestos, vinyl chloride, CFCs or pesticides. The carpets are also manufactured under the most environmentally friendly conditions. Routine monitoring by the Carpet Research Institute at Aachen (TFI: Teppichforschungsinstituts Aachen) help to guarantee this.

Carpet continuous dyeing plant For the dyeing of carpet lengths of up to 5 m in width, with running speeds of 5–20 m/min. Pad-steam processes are separated by the method of application of the dye liquor. Continuous carpet dyeing plant can be fully integrated, i.e. to contain pretreatment, dye liquor application and fixing, as well as washing off (Fig. 1).

The additional pretreatment wetting system, “Fluicon II” (Fig. 2), with integrated vacuum extraction removes finishes, spinning oils and fugitive dyes, and enables the extracted washing solution to be reused at the final washing off stage. The presteamer gives the carpet the required volume.

The “Quick-Change” dye liquor application system (Fig. 3) is used for both for plain colours and for rinsing after printing for light to heavyweight carpets. Changing from one colour to the next requires less than 0.5 m without stopping. The “Quick-Change” colour change is carried out without stopping the dyeing or rinsing process and with a minimum of lower quality production.

In the “Cloud” steamer (Fig. 4), a steam volume control delivers the correct amount of steam fixing the dye. This control leads to a substantial reduction in steam consumption. The washing stage after fixation

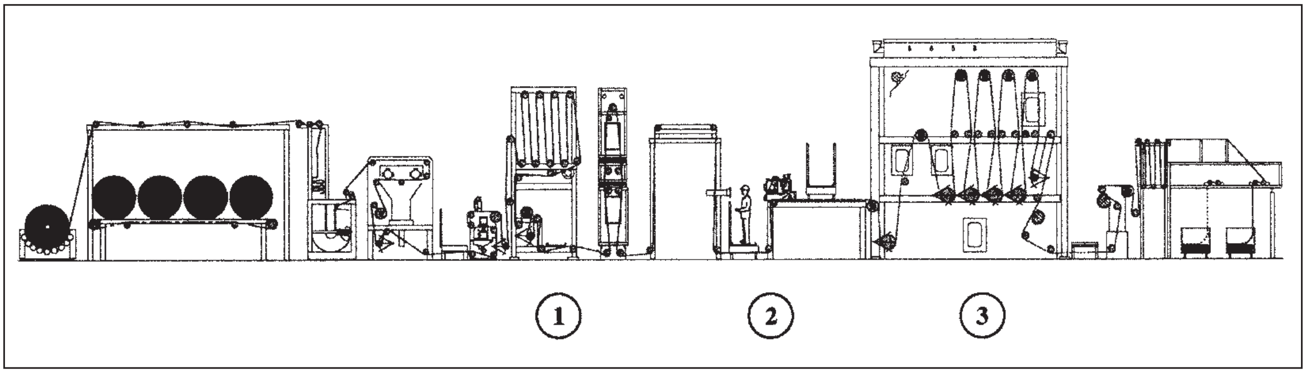


Fig. 1: Example of a continuous carpet dyeing plant (Küsters).
1 = pretreatment with "Fluicon II" application system; 2 = "Quick-Change" dye liquor application system; 3 = "Cloud" loop steamer.

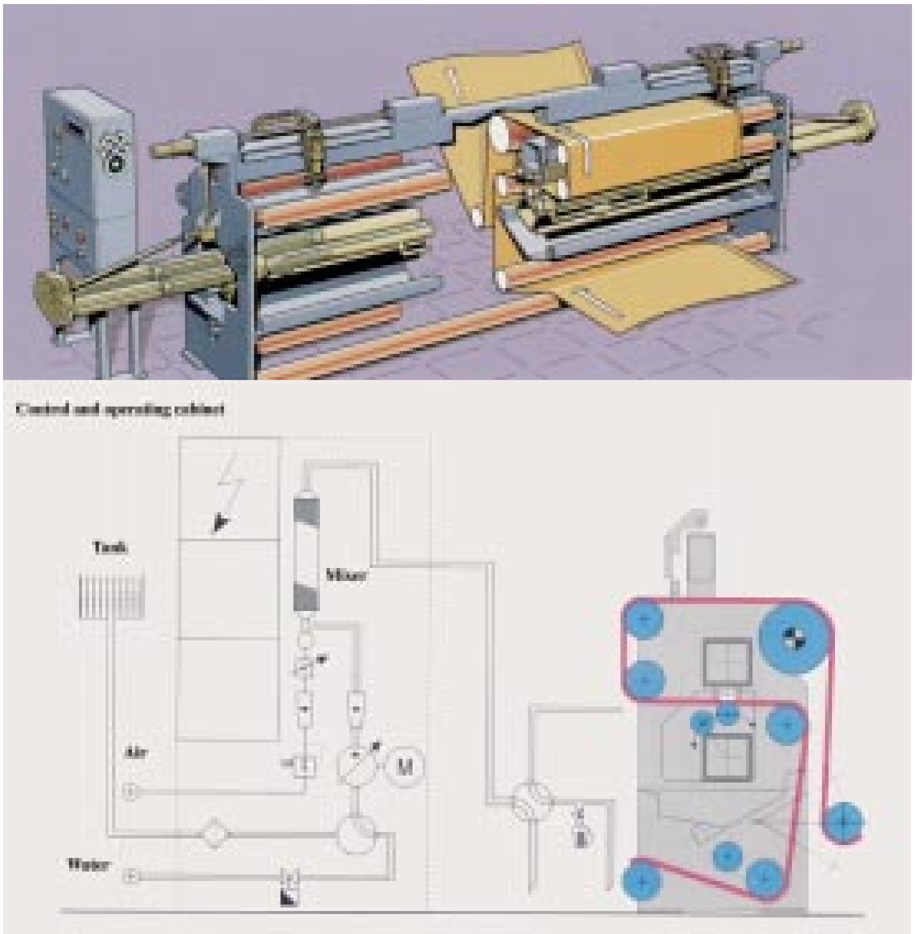

Fig. 2: Fluicon application system for carpet pretreatment (Küsters).

has been optimised for economic and ecological performance. At the exit from the steamer, residual liquor is extracted from the carpet at boiling temperature by a suction system without the addition of cooling water.

Carpet drying machines Automatic through-feed and festoon machines, with forced hot air circulation for drying washed, rinsed and dewatered carpets.

Carpet dust and water extractor Transportable vacuum cleaner, normally combined for dry and wet application, especially for extracting dry foam. → Foam cleaning.

Carpet dyeing Apart from carpet piece dyeing, materials which are to be made into carpets can in principle be dyed at all processing stages (spun dyed, as tow, loose stock, tops or yarn). Carpet piece goods are dyed batchwise or continuously (see Fig. 1: carpet dyeing plant from Mitter). Discontinuous processes include the dyeing of small carpets (e.g. bath mats, toilet sets) using paddle or drum dyeing machines; carpet pieces up to 5 m in width are dyed using carpet winch dyeing machines, beam dyeing machines and carpet continuous dyeing plants. Needle pile carpets and espe-

1 = moving platform; 2 = unrolling mechanism; 3 = sewing machine; 4 = extraction; 5 = J-box; 6 = prewashing; 7 = steamer; 8 = central conveyor; 9 = dyeing or printing zone; 10 = horizontal steamer; 11 = festoon steamer; 12 = washing off; 13 = weft straightening device; 14 = dryer; 15 = compensator; 16 = goods inspection; 17 = winding mechanism; 18 = dye kitchen.

cially those with a polyamide or polyester pile are well suited to piece dyeing; those of polyacrylonitrile and wool less so.

The demand for better control of the environmental impact dyeing of carpets has lead to the optimisation of the dyes and auxiliaries used with regard to their biodegradability and the processes used with regard to water and energy consumption, thus minimising as far as possible consequent environmental impact. Disperse dyes were mainly used for the dyeing of polyamide carpets. This resulted in low exhaustion levels and heavy coloration of effluent. The development of suitable acid dyes has satisfied a substantial proportion of the environmental demands. A balanced range of dyestuffs with high exhaustion rates, good levelling and migration properties, suited to both batch and continuous applications, has brought about the required improvements in quality for production and commercial demands.

However, a high exhaustion rates with acid dyes requires a suitable auxiliary/chemical application system. Correct pH control including the use of buffer systems and minimal levels of auxiliaries with fibre affinity is needed to achieve the lower effluent loading in terms of colour content. Further improvements can be made e.g. by replacing phosphate buffer systems with ammonium acetate/aAcetic acid systems although this raises the TOC content. An initial step in the direction of this aspect of the more environmentally friendly dyeing of carpet piece goods is represented by the DOSACID system (controllable bath exhaustion by pH control and acid dosing) for winches with liquor circulation. Rationalised working procedures and larger dye batches were the original reasons for the increase in use of continuous dyeing machines. Earlier machines with the so-called uncontrolled liquor pickup (500–700%) were further developed to liquor pickup of 350–500%, with required suitable pumps with controls and dosing. This control and reduction of the application volume led to a reduction in effluent loading by excessive use of dyes and auxiliaries.

The oil crisis induced further developments aimed at energy savings as well as reduced effluent loading. In this context, 1979 saw the introduction of foam application, which enables processing with dye application volumes of 150–350%. Development is not yet complete (see Fig. 2), as the following examples relating to the production of more efficient continuous plant show:

- Modification to improve penetration (Fluidyer),
- Reduced liquor loss on colour changes (Quick Color-Change),
- Steamer with reduced energy consumption

(source: Bouwknegt).

Carpet finishing may be undertaken at the end of the carpet manufacturing process or together with other finishing or manufacturing processes. Its purpose is to improve the carpet and give an increase in quality. Carpet finishing is varied due to the varied types of carpet

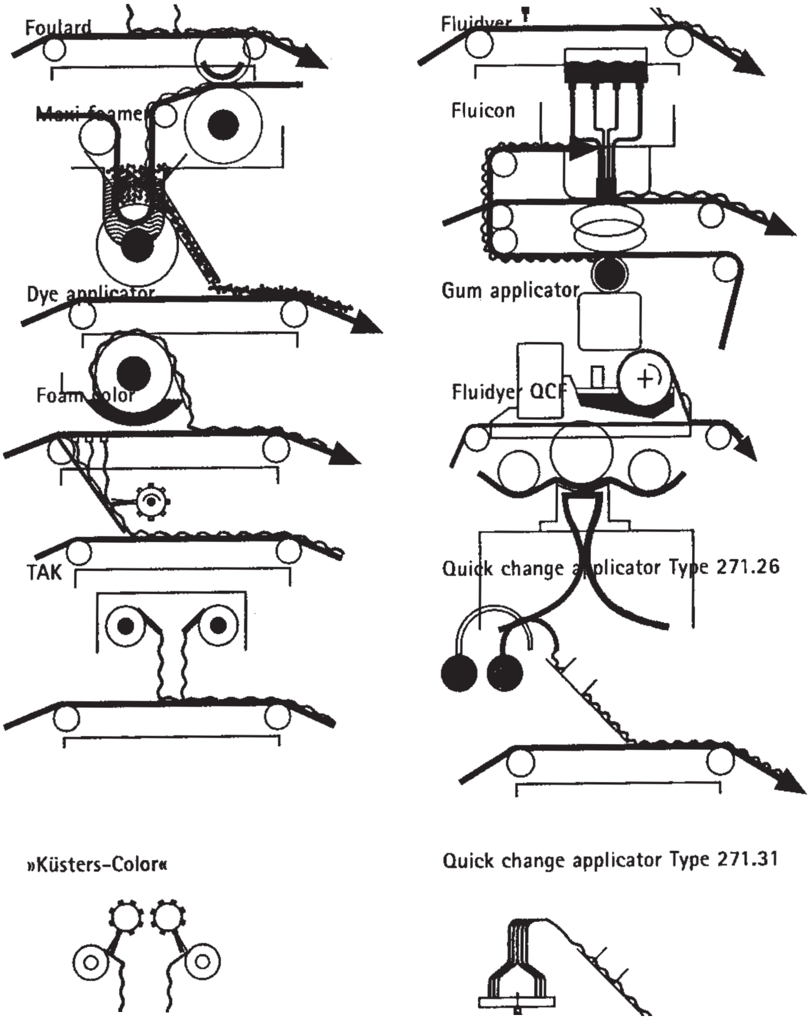

Fig. 2: Carpet dyeing systems from Küsters.

manufacture and design. The different finishing methods are:

1. Dry finishing processes: brushing, shearing, backcoating.
2. Wet finishing processes: antimicrobial, antisoiling, antistatic, flame-retardant and softening finishes.

The desirable properties for a carpet finish are:

– simple application,

- no effect on coloration,
- temperature resistance,
- high abrasion resistance,
- no increase in the soiling tendency of the textile floor covering in comparison with goods without an antistatic finish.

The following aqueous application processes are used: spraying, roll-transfer coating and padding. Application by spraying is the most common method. If the solution, e.g. of an anti-electrostatic is sprayed on to the pile side, it is essential to run the goods over a roller or rounded edge at the point of spraying (Fig. 1). This opens the pile, so that the product can penetrate down to the base material rather than merely reaching the upper surface of the pile. When spraying from the backing, the concentration must be selected so that sufficient product penetrates to the pile. A decrease in concentration towards the upper surface cannot be avoided, but does not affect the antistatic effect (Fig. 2). It is essential when using this working method to ensure that the effectiveness of subsequent coatings for securing the pile is not affected.

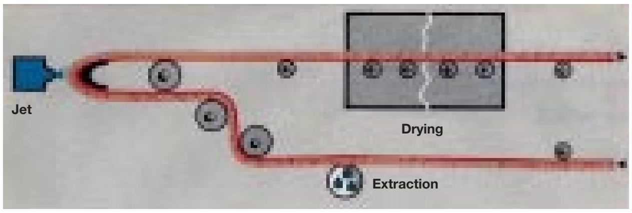

Fig. 1: Carpet finishing: Spray application on the pile side (Reich).

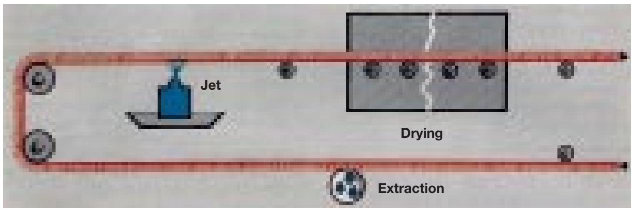

Fig. 2: Carpet finishing: Spray application on the backing side before the backcoating (Reich).

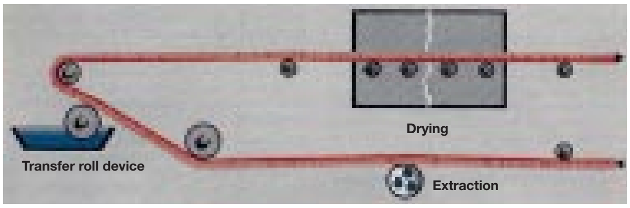

Fig. 3: Carpet finishing: Transfer roll application on the pile side (Reich).

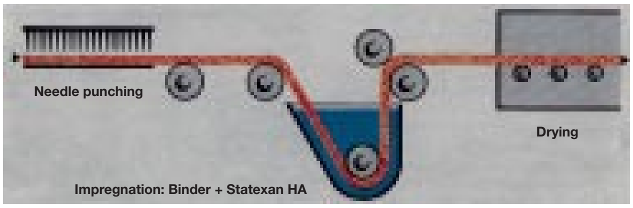

Fig. 4: Antielectrostatic finish of needle-punched floor coverings (Reich).

Transfer-roll application (Fig. 3) can be applied from the pile or reverse. Inconsistent deposit levels caused either by poor quality or deficiencies in the spray equipment can be avoided by using this method.

Pad application is only used for pile goods in exceptional cases, as the pile can be damaged by the pressure of the mangle. This method is extensively used for needle-punched floor coverings. For technical and commercial reasons it is necessary for the product to be brought together with the binder (Fig. 4). Good compatibility of applied finishes with the binder is necessary. Flooring materials must have a long life and great importance is attached to the fastness of the dyeing. Any finishing products applied must not affect this fastness, nor the quality of the colour.

Textile floor coverings are exposed to considerable temperatures during the production process, e.g. when vulcanizing the back coating. Applied products must not decompose, volatilize nor diffuse into the fibres under these conditions. A finish for textile floor coverings must not affect the abrasion resistance of the carpet, nor the soiling behaviour of the carpet. Many finishing agents can be oily or viscous substances which bind dust and dirt particles, thus leading to more rapid soiling.

An antistatic coating of 0.4–0.5% (Figs. 5–7), based on the pile weight of the carpet material, reduces possible personal electrostatic charges even at relatively low humidity (say 30%). The low add-on rate also reduces the effect on shade or soiling behaviour of the floor covering.

The abrasion resistance of the finish is surprisingly high. After five hours' abrasion in a friction charging apparatus an increase in the surface resistance of max. half power of ten resulted. For this test rubbing cloth sample, made of a knitted fabric of the same fibre type as the floor covering to be tested, is rubbed against a test piece at a force of 100 N. The rubbing cloth sample is renewed every 5 mins during the first half hour, and every 15 min thereafter for the remainder of the test, in order to prevent the accumulation of finishing agents on the rubbing cloth sample, which would lead to a state of equilibrium between the test piece and rubbing cloth sample. The high resistance to abrasion is confirmed by usage under real use conditions. The explanation for this behaviour should lie in the fact that after the abraiding of the upper layer of the pile, enough product remains in the deeper layers of the pile to ensure sufficient conductivity, i.e. transverse conductivi-

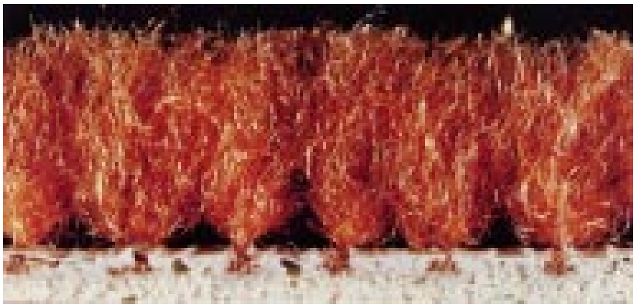

Fig. 5: Untreated, polyamide cut-pile carpet with backcoating after use (Reich).

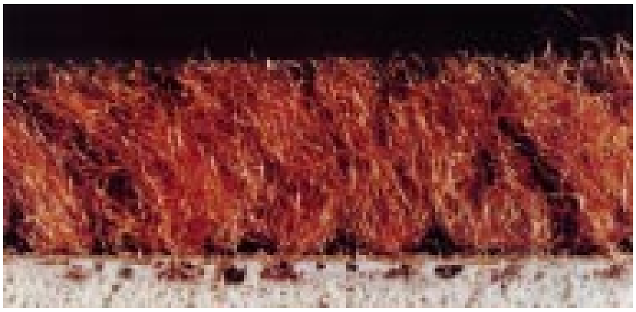

Fig. 6: antielectrostatic finished carpet subjected to wear (Reich).

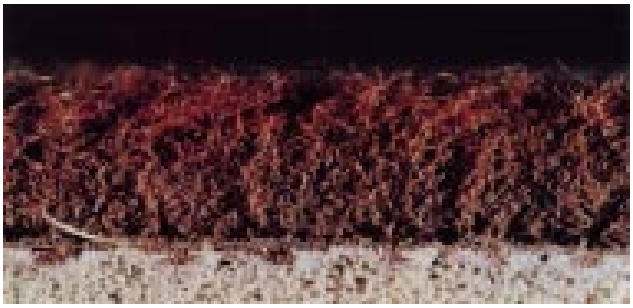

Fig. 7: Carpet without finish, subjected to wear (Reich).

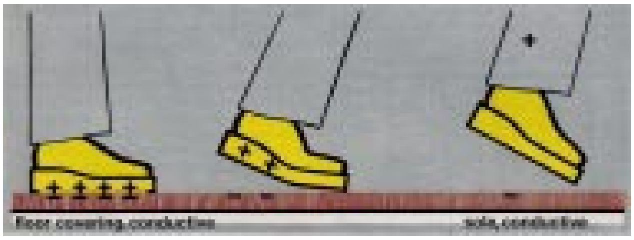

Fig. 8: Electrostatic behaviour when walking on textile floor coverings (Bayer).

ty. By treating with an effective antielectrostatic agent the surface resistance of textile floor coverings is reduced to such an extent that the electrical charges generated by walking are dispersed in a sufficiently short time. The floor covering can no longer be regarded as an electrical isolator. Account must be taken of the fact that when walking, in contrast to running, at least one foot is always in contact with the floor. When raising a shoe, if all the charge generated cannot be dispersed through the last point of contact, then in the case of conductive footwear, a charge interchange may take place through the body and the other shoe which at that moment is in contact with the floor covering (Fig. 8). The charge generated in a person by electrostatic induction after raising the shoe is therefore neutralized. Charges on the underside of the shoe are neutralized at the next step by the charges flowing from the conductive floor covering by adjustment of the state of equilibrium referred to above. By determining the friction charge, and as a result the traffic test, it can be shown that by means of surface conductivity to the extent mentioned above, an effective electrical short circuit exists between floor covering and person, and thus the conditions for the build-up of problematic electrical charges when walking on a textile floor covering are not present (Reich).

Carpeting → Fitted carpets.

Carpet mark Quality mark registered by the European Carpet Association for Germany (ETG: Europäische Teppichgemeinschaft für Deutschland e.V., Wuppertal) in conjunction with the manufacturer's brand/trademark or company labelling of carpeting in regard to their fibre composition under the Textile Labelling Act (TKG: Textilkennzeichnungsgesetz) and their end-use suitability symbols (divided into three areas of use: bedroom, living and working environments plus additional attributes: wheel-chair suitability, usable in damp areas, suitable for stairs). Carpet squares require only fibre composition. Licence for use issued by Carpet Research Institute (TFI: Teppichforschungsinstitut, Aachen) on behalf of the ETG.

Carpet pile → Pile layer.

Carpet presteamer Used for tufted carpet in continuous printing and dyeing lines to relax the cloth and to maintain volume after pretreatment in the prewash (→ Carpet prewashing and bulking unit). Vertical construction enables large fabric capacity and maintenance of an uncontaminated steam atmosphere. With automatic steam volume regulator. After leaving the steam atmosphere still in the hot state, mechanical pile finishing by beater roll Machine maker: Fleissner.

Carpet prewashing and bulking unit Compact unit designed for continuous treatment of tufted carpet comprising perforated drum wash bath and an annular arrangement of baffle plates with slits across their effective width for directing jets of the controlled circulation liquor onto the pile surface of the carpet before final through-flow washing of the fabric (see Fig.).

Suction-slot extractor arm at the delivery end. Optional jet application of hot liquor promotes bulk in the carpet pile and allows tensions in pile yarn and substrate to relax. With special water/lint separation be-

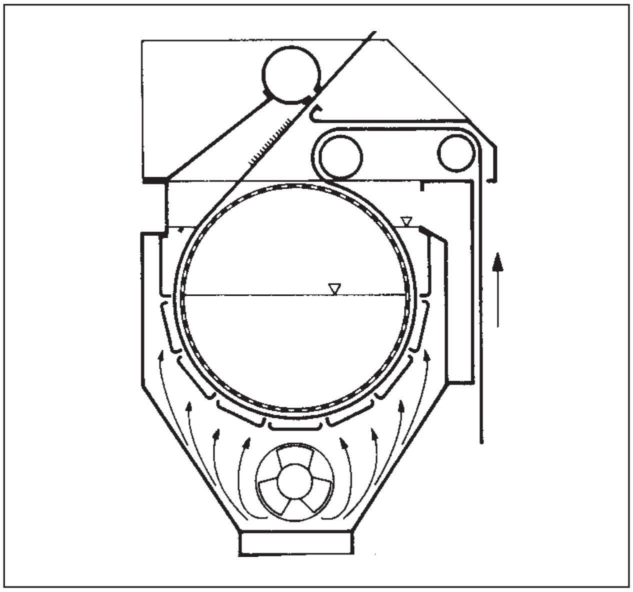

Fig.: Carpet pretreatment machine by Fleissner.

tween suction slot and pump. The short distances travelled by the fabric result in linear, low-tension and crease-free fabric transport. – Manuf.: Fleissner.

Carpet primary backing According to DIN 61151: the primary carrier for the pile or surface layer. Formerly almost exclusively of woven jute, today made of polypropylene and polyester, woven or bonded-fibre nonwoven.

Carpet printing Printing, especially of → Tufted carpets with dyestuff classes determined according to the fibre content by screen-printing tables or special → Carpet printing machines, with the objective of dyeing the pile down to the backing material. The principal difference from conventional printing processes lies in the fact that a printed carpet is continuously coloured without intermediate drying, with washing immediately afterwards. The following basic carpet printing techniques are defined (see Fig.):

I. Direct printing: This comprises the printing of all colours contained in the pattern. Printing is carried out on white goods using large-area or rotary printing machines.

II. Applied printing/overprinting: This is similar in its application to direct printing. Not all colours in the design are printed, but dependent on the process are present either as a result of previous dyeing (applied printing on a previous dyeing) or by means of the wet-on-wet method using dye liquor application equipment such as the pad, Fluidyer, sprayer, applicator or all-open screen. With this process, dyestuffs are not destroyed as is the case with discharge printing, nor is their fixing impeded as is the case with resist printing. Light displacement effects may arise with the wet-on-wet process.

III. Discharge printing/Discharge resist printing: Discharge printing involves removing the dye from a previously dyed layer in the places to be printed. The

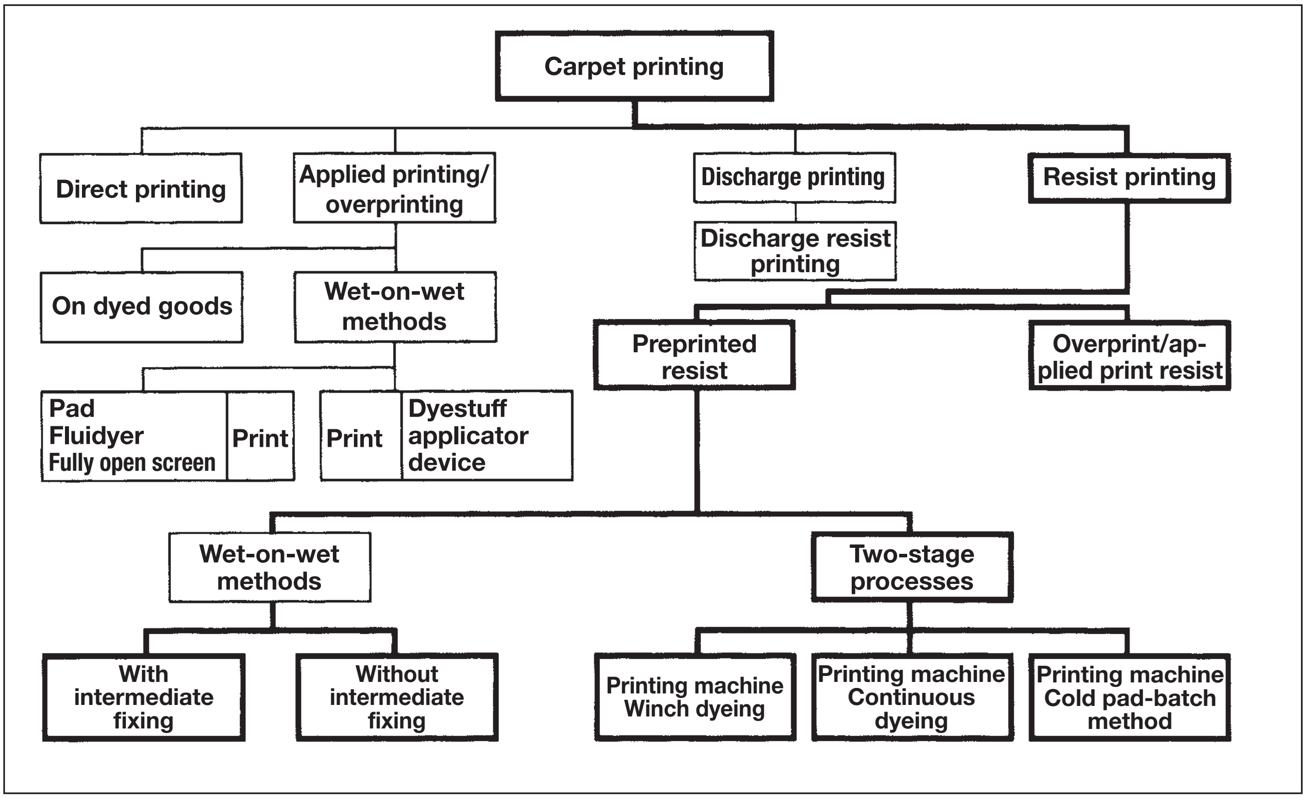

Fig.: Types of carpet printing (Bayer).

term discharge resist printing is applied to the technique whereby dyes are locally removed prior to fixing, so that they are not present on the fibre at the fixing stage.

IV. Resist printing: This method used to have a high prominence in the field of textile printing (e.g. batik-bandanna method), but now has only limited application.

V. Pre-printed resists: After application of the resist printing pastes, the printed places accept little or no dye from the liquor at the subsequent dyeing stage. The methods can be subdivided into single-stage wet-on-wet processes with or without intermediate dye fixing and two-stage processes, by which printing is carried out first, and the goods are subsequently continuously or batch process overdyed.

VI. Overprint/applied print resists: this refers to the removal of a dye previously mechanically applied to the fibre by the subsequent application of a printing paste. These may be viewed as chemically-enhanced "displacement prints"; it is not only a mechanical displacement which takes place, which at best gives rise to tone-in-tone brightening. Special chemicals or auxiliary agents, which possess dye or fibre affinity, given the relevant pH, may in addition prevent the fixation of the dye of the previously applied background dye. The background can hereby be applied using a pad or Fluidyer, 100% or using a blotch printing template if required. The resist printing technique uses practically all the methods already referred to. New developments are heading in the direction of pre-printed resists using fibre reactive auxiliary agents (source: Wirtz).

Advantages for carpet printing:

- Independence in coloration of substrate and carpet structure, giving rise to independence of the pre-dyed yarn and no limit to the pattern in production.
- Enhanced profitability due to restricted types of grey goods.
- Quick, easy production of similar patterns in different colourways.
- Printed pattern means less visible soiling sensitivity of the floor covering.
- Possibility of overprinting second-class quality carpets, thereby improving their quality.
- Fast adaptation of pattern and colourway to suit customer requirements and fashion trends.

Disadvantages/difficulties for carpet printing:

- Printing plants are generally set up for large-scale production; this requires substantial investment and possibly under-utilisation of capacity.
- Substantial possibilities for variation in the colourway conceal greater risk of fragmentation of tasks into different processes.
- Material consumption in patterning, commencement of printing and change of pattern may be considerable, both in terms of goods and dye paste.
- Machine set-up times may be quite lengthy, especially for designs involving several colours, and can only be shortened as a result of high investment costs.
- Under certain circumstances print penetration problems causes coloration or technical printing problems material qualities.
- It is difficult to design continuous carpeting which may be adapted for the production of tiles.

Carpet printing machines Special printing machines for → Carpet printing (Fig. 1), e.g. the following types:

- Aljaba carpet printing machines: constructed on the principle of conventional roller printing machines with rotary screens made of rounded bronze wire with internal squeegees, in place of normal copper rollers. – Manuf.: Aljaba.
- BDA carpet printing machines: This carpet printing system involves the application of the dye paste using sponge or twin squeegees, whereby printing paste can be sucked up from below by means of a vacuum, giving good pile penetration. – Manuf.: Singer-Cobble.
- BTM carpet printing machine (by British Tufting Machinery Co.): Works with surface printing rollers (patterns embossed on the printing roller), whereby the patterns to be printed are also given a foam coating, which after the passage of a press roller soaks up a new charge of low-viscosity print paste from the dye paste trough. – Manuf.: Singer-Cobble.
- Deep-Dye printing machines: restricted single-sided dip dyeing process, whereby the pile is repeatedly brought down into contact with a dye paste trough divided up to form the pattern. – Manuf.: Deep-Dye Processes.
- Stalwart carpet printing machine: Printing by passage between an embossed dye paste application roller (several in the case of multi-coloured designs) and a driven counterpressure roller. – Manuf.: Pickering.

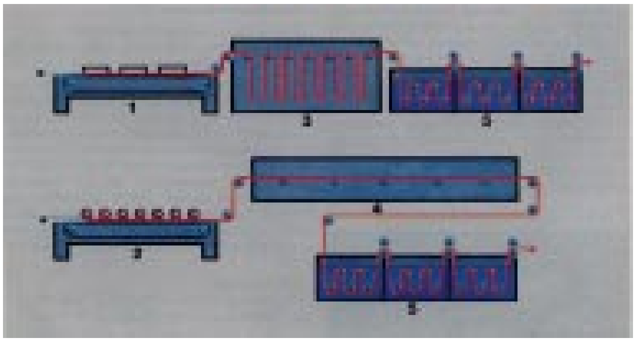

Fig. 1: Carpet printing process (by Bayer).
1 = flat bed printing machine; 2 = rotary printing machine; 3 = loop steamer; 4 = horizontal steamer; 5 = washing machine.

- P. Zimmer flat bed carpet printing machine, TDA 62, 74: works with magnetic contact pressure of a roller squeegee or double roller squeegee application system. – Manuf.: Zimmer, Kufstein.
- Mitter rotary carpet printing machine: dye paste is applied by friction (2–15%) between a rotary screen and rotary squeegee. – Manuf.: Mitter.
- J. Zimmer rotary carpet printing machine: works by means of a magnetic rotary squeegee. After intermediate drying it is overprinted with colourless or lightly coloured dye paste, in order to achieve the final penetration. – Manuf.: Zimmer, Klagenfurt.
- Carpet spray printing plant → Millitron process. Manuf.: Deering Milliken.

The designer of a carpet printing machine has to solve a number of technical problems specific to carpets:

- Large working widths (up to 5 m) and large repeats. This has resulted in special screens (Fig. 2) and complicated mechanisms for screen changing (Fig. 3).

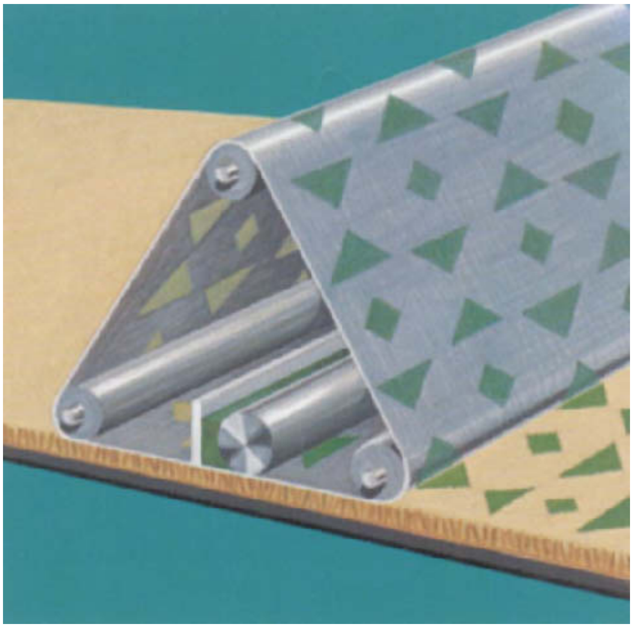

Fig. 2: "ROTAFILMPRINT" device for repeats of up to 4m (Mitter) (source: Bayer).

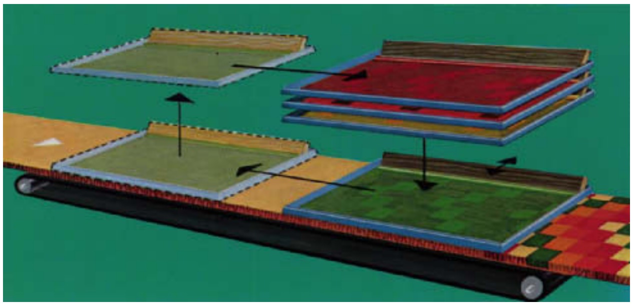

Fig. 3: "SEMIMATIK" compact flat bed carpet printing machine (Zimmer).

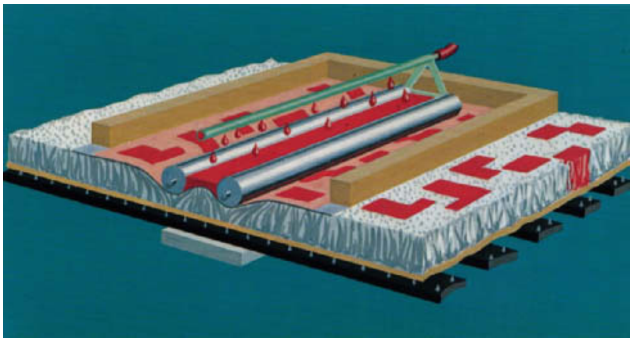

Fig. 4: Zimmer TDA carpet printing machine.

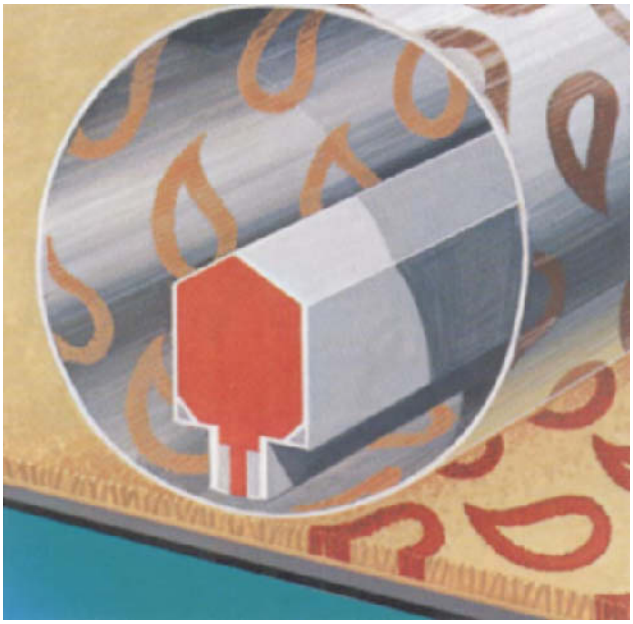

Fig. 5: TRSDM (1) rotary screen carpet printing machine with HYDROSLOT (Zimmer).

- The presence of the voluminous and pressure-sensitive pile requires a special roller squeegee using magnets with pressure control for flat bed printing. (Fig. 4) or a slot squeegee with vacuum suction from the reverse of the carpet. The adoption of magnetically-operated systems have also proved useful in rotary printing with large widths and the pile problem (Fig. 5) for the precise positioning of a slot squeegee within a rotary screen, using two or three rollers of standard size in one colour giving partial repeats which are brought together (intermittent printing) to give the desired large repeat.
- Several stage processes seek to enhance the pile penetration by carrying out the dye paste application and penetration stages separately (Fig. 6).
- Spray printing involves computer-controlled dye paste application from microjets (without screens or print rollers). The pattern to be reproduced is input and (controlled via a colour display screen) saved

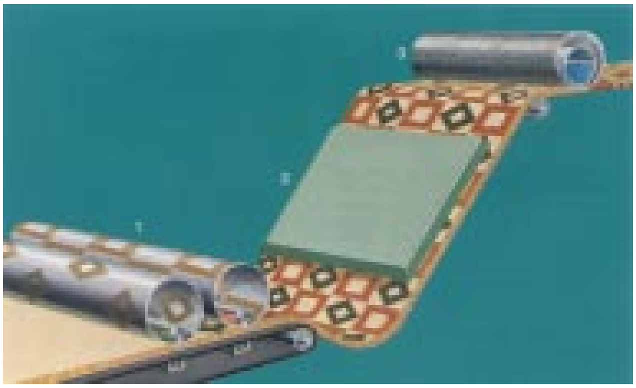

*Fig. 6: Rotary screen printing machine for carpets (3-stage process) (source: Bayer).
1 = Printing machine; 2 = Infrared heater; 3 = Penetration screen.*

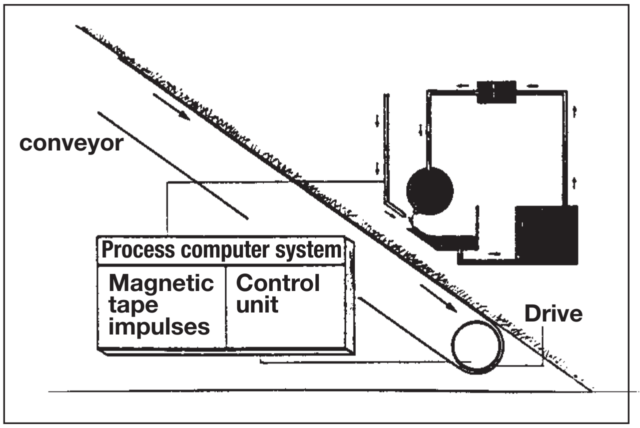

Fig. 7: Millitron spray printing: by applying the dye liquor jet using compressed air the liquor is deflected to the collecting basin, so that the pile is not patterned.

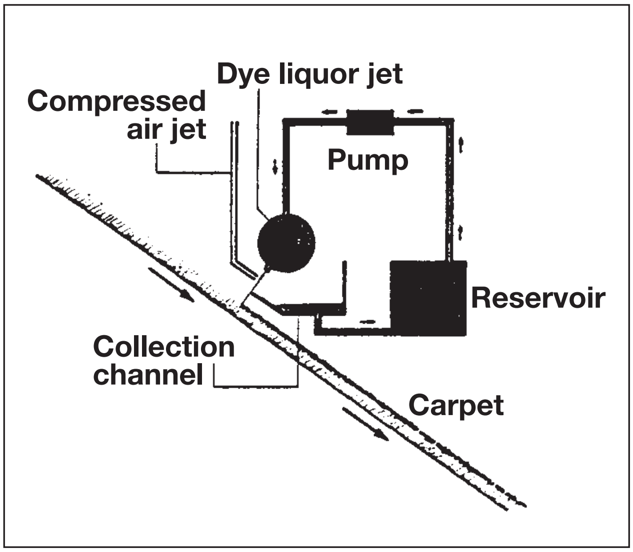

Fig. 8: Millitron spray printer: The pattern is formed as the carpet pile absorbs the thickened dye liquor jet.

on magnetic tape. The tape is used to control the printing machine, the main component of which is the system of jets extending across the whole width of the machine (Figs. 7 and 8); the carpet passes beneath these at a rate of 6 m/min.

Carpet quality labels The individual designation and marking of textile floor coverings. Carpets must contain a certain amount of pile fibre per unit area and have a specified resistance to wear. E.g.: DuPont 501 label; Enkalon; Monsanto-A (Acrylan) label; Bayer-Dralon label. Similar quality labels are also offered by carpet yarn manufacturers and also those awarded by consumer advice bodies, e.g. British Consumer Council swing-ticket, and by carpet manufacturers, e.g. → Carpet mark of the TFI or GUT environmental label.

Carpet raschel knitting machine Knitting machine used in the manufacture of → Raschel carpet. Integral backing comprising cotton, viscose, jute, paper or synthetic yarns is knitted simultaneously with the pile surface.

Carpet roll paternoster Storage and display apparatus for carpet rolls.

Carpets Textile floor, wall or ceiling coverings. According to DIN 61 151, the following features are used for classification: type of manufacture, manufactured controlled surface dimensions, material in the pile or surface layer, surface form, colour, carpet backing material.

I. Type of manufacture: knotted, woven, knitted, stitch-bonded, tufted, needle-felt, flocked, bonded carpet.

II. Surface: flat, pile, bouclé (loop pile), velour (cut-pile) carpet.

III. Colour: plain, multi-coloured carpet.

IV. Supply form: rugs, roll goods, carpet tiles.

V. Origin: Oriental, Balkan, Bavarian, Dutch carpets. Certain marks of origin have become generic names.

VI. Application: bedroom, living room, workplace; indoor, outdoor, contract, automotive carpets.

Carpets, dust extraction Mechanical beating, suction or brushing, possibly both sides of the carpet, in order to remove as much loose dirt and dust as possible.

Carpet shampooing (Carpet pile wash), as defined in RAL 991-A is customarily applied to fitted carpet. Comprises mechanical dust removal and subsequent treatment of the pile surface with a carpet detergent which is stable in hard water, can be converted into dry foam without wetting out the carpet foundation (substrate fabric) and leaves behind non-sticky residue that is easily removed by vacuuming. There then follows quick extraction of foam and moisture, drying (suction drying), brushing, etc. for finishing → Foam cleaning.

Carpet shearing machine Is suitable for shearing soft velour carpets. Up to 6000 mm working width.

Carpet singeing Modifying the pile of oriental carpets using a flame or chemical agents in order to harmonize the overall colour impression. → Carpet ageing.

Carpet spray printing Process in which print solutions are applied to pile fabric, not by means of stencils, but in a diluted form by spray jets. Typical examples: Chromojet (Zimmer), Millitron (Milliken); → Spray printing.

Carpet squeeze rollers Squeeze rollers for removing the water from washed, wet carpets. Working width approx. 3.5–4 m. With rinsing facility.

Carpets, static charge A separation between two nonconducting materials gives rise to an electrical charge, this also applies to carpets with normal usage. Under certain circumstances → Static charge may build up which are so great that discharge between 2 surfaces occurs with a spark; this is felt as an unpleasant shock (see Fig.). With a relative humidity of > 50%, however, most carpets have a very low tendency to build up static charges. The shock sensitivity limit for most people lies in the region of around 2000 V.

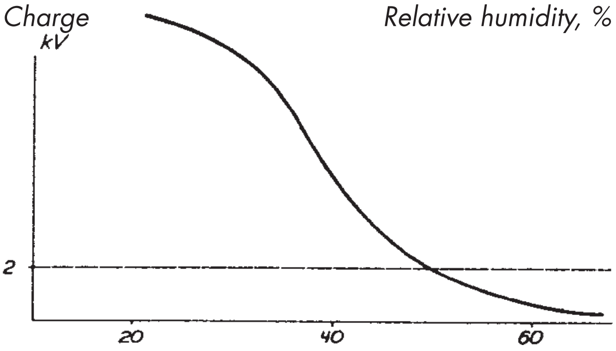

Fig.: Carpet charge in relation to the relative humidity.

Carpet steamers,

I. Steaming machine for continuous dye fixation when dyeing carpet lengths using the pad-steam process.

II. Plant for the stretching and steaming of carpet lengths to improve the appearance (flattening the pile, bulking).

Carpet steamers in continuous plant must be designed in accordance with the process, i.e. printing, dyeing or a combination of both, product speed and fixation times. Combined carpet steamers consist of standard, horizontal and loop compartments running together as individual units with automatic steam volume control.

Carpet suitability for underfloor heating In order to be suitable, a floor covering should not alter quickly under the influence of heat (backcoating) and should only emit a low level of odour. The degree of heat stability must be suited to the heating system, underfloor temperature, efficiency, heating requirements and must be made with suitable stability.

Carpets, walk test → Walk test.

Carpets, weft-patterned Machine-woven carpets, the pattern of which is produced by the relevant insertion of coloured weft yarns.

Carpet testing Testing textile floorcoverings for construction and suitablity for use, including:
- determination of weight and thickness,
- pile density,
- reduction of airborne and impact noise,
- sound absorption,
- thermal conductivity,
- fastness to light, water and rubbing,
- thickness loss under compression,
- dimensional stability,
- resistance to dynamic loading,
- resistance to wear by a walkwheel,
- resistance to wear by a steel ball in a rotating drum,
- resistance to wear by castor chair,
- burning characteristics and
- electrostatic characteristics.

Carpet transfer printing → Transfer printing of floorcoverings.

Carpet washing Comprises mechanical dust removal, washing of the pile surface and underside of the whole carpet with carpet detergents (→ Shampoos) followed by final thorough rinse.

Carpet washing machine Continuously operating open-width washer for carpets up to 5 m effective width.

Carpet winch dyeing machines Stainless steel equipment for the dyeing of carpet in piece form of 100–250 m in length, up to 5 m in width. The open width carpet is loaded via the winch roller into the winch vessel containing 20–30 l liquor and the ends sewn together. It is dyed during 3–6 hours at up to 98°C, during which time the carpet is constantly run over the winch in open width or rope form. Modern carpet winch dyeing machines have dye circulation systems with heat exchangers outside the dye bath. For carpets with polyester pile, pressurised winches are used up to 140°C.

Carpet yarns Filament yarns for the carpet sector are produced manily by the BCF process, which produces in one operation from the granulate via extruder spinning, drawing, texturing, interlacing and winding (Fig.). The crimp structure is obtained by braking the filaments in a heated chamber (stuffer box), producing yarns in the 500 to 4000 dtex count range. Maximum production speed is 4000 m/min (polyamide) and 3000 m/min (polypropylene).

Great efforts has been made to improve quality, and there is a continuing development target of increasing dyeing uniformity in such a way that stripe-

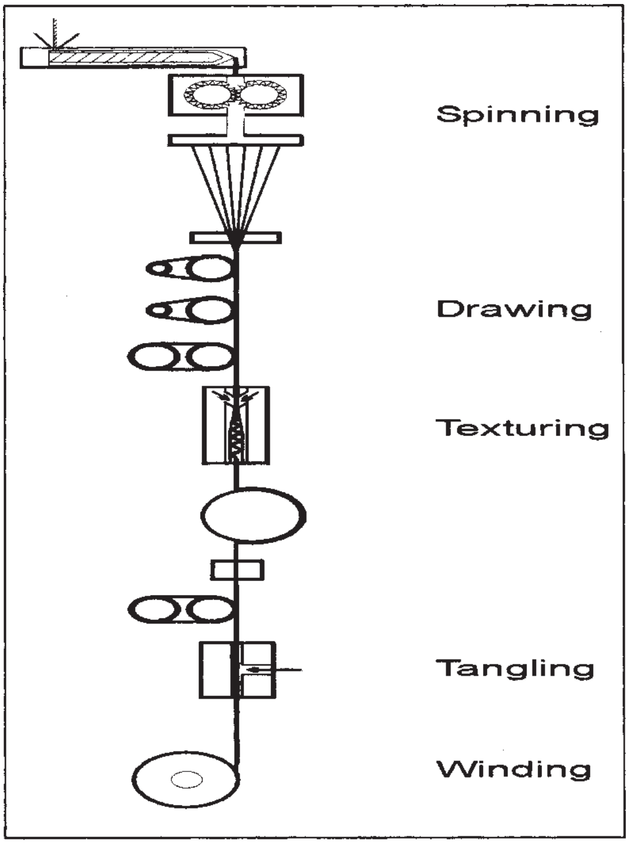

Fig: BCF process.

free cut loop carpets can be produced from BCF carpet yarns.

Carpet yarns, setting The twist of wool carpet yarns can be set with sodium bisulphite in a continuous process; for polyamides: → Heat setting of carpet yarns.

Carragheen (Irish moss, pearlmoss, kelp). Dried seaweed (North Atlantic), negligibly or extremely ramose, wide and narrow, pointed, with fine fibres, 7–15 cm long, bleached, hard and cartilaginous, almost odourless, reddish blue to violet, bleached yellowish and browned. Approx. 80% mucilaginous substance content; since it is used as a handle finishing agent, no incrustation should occur. May not react acidically when bleached. Swell in cold water, and then dissolve by boiling. Solutions: 25 : 1 still jelly-like, 30:1 stiffening mucilage (does not colour blue with iodine solution as does Iceland moss; produces sugar-like compounds when boiled). Use: as a chemical finishing agent ("natural finish" for cotton = supple-voluminous stiffness, with no real hardness; also for wool), used as a clarifying, stiffening or gelling agent.

Carrier (Dyeing accelerators, accelerators, carrier substances, carriers). Chemical compound for increasing the dyeing speed and the thorough dyeing properties of synthetic fibres (particularly polyester, triacetate, PVC) at or below 100°C. Numerous theories exist concerning the mode of action, of which the following are the most likely:

1. Carriers act as dye solvents: a strengthening of the dye occurs at the fibre/liquor phase interface.
2. Swelling action of the carrier: loosening of the van der Waals forces or hydrogen bonds between the fibre chains.
3. Lubricating action by the carrier on the dye and the fibre.
4. Vein or hole formation in the fibre structure (supporting the formation of free volume).

X-ray investigations showed that even with water treatment at 100°C, a noticeable rise in the degree of crystallinity occurs. In the presence of carriers, this increase is even more significant. It was also possible to establish structural improvements in the crystalline areas. The increase in the degree of crystallinity appears to take place, to a considerable extent, at the expense of the originally present mesomorphic areas which were poorly or moderately organised. The remaining amorphous areas thus become more accessible, and the dye uptake capacity increases.

From infra-red spectroscopic measurements made on polyester, it can be concluded that the pre-diffusing carrier is absorbed by the material, but above all (insofar as it is constitutionally capable of this) it is relatively strongly bonded to the polyester molecule through hydrogen bonds. This is apparent from the OH valency variation band, which displaces itself after the longer frequency range. The pre-diffusing dye displaces a more or less large proportion of the bound carrier. A requirement for this is that the dye itself likewise carries groups which, possibly more strongly than the carrier, are capable of hydrogen bonds or dipole interaction with the polyester. The dye molecule will penetrate deeper (possibly also faster) into the material the less the dye is held up on its diffusion path by polar centres or by dye/polyester hydrogen bond interaction. The pre-diffusing carrier has the task of blocking the bond-ready centres of the polyester molecule to a certain extent. The dye is thus not hindered on its diffusion path, or only slightly; it penetrates faster and more deeply. At the same time, it makes way more quickly for post-diffusing dye molecules; the dye uptake is increased.

The following requirements are made of carriers: cheap, effective at low concentrations, easy and safe to use, low odour, colourless, neither toxic nor skin-irritant, no effect on fastnesses and nuances of the dyeing, not sublimable out of the liquor bath, not very soluble in water and with good emulsifying properties, not too strongly bound to fibres (see Fig.), ecologically justifiable.

Main groups of carriers (Tab. 1):

I. Hydrophobic swelling agents, e.g. benzene, chlorobenzene, diphenyl, o- and p-phenyl-phenol, m-cresol: due to their good affinity to fibre, these products have excellent swelling action and can be effectively applied even in small amounts. A disadvantage in most

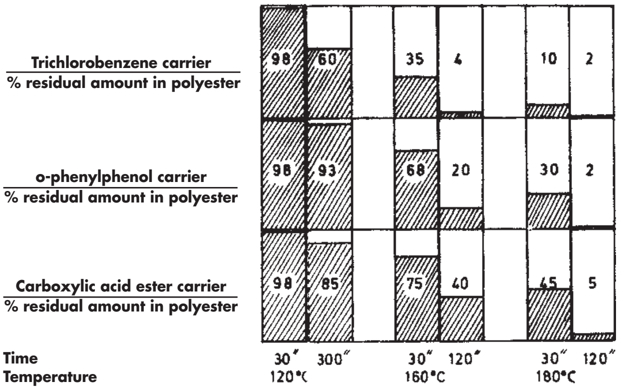

Fig.: Removability of carriers from polyester textiles in drying and thermofixing (shaded area: amount of carrier taken up by or remaining on the fibre).

Di-phenyl, type b o-phenylphenol methyl naphthalin	30–60	10–20	60–30
Ester carriers	40–70	10–20	40–20

Tab. 2: Examples of carrier formulations.

of these substances is their toxicity and carcinogenicity, as is the poor lasting properties of the emulsion (forms a cream after boiling for a longer period).

II. Hydrophilic swelling agents, e.g. benzoic acid and its esters, benzyl alcohol: these substances are usually only effective when larger amounts are used, but have the advantage of being less toxic and, as a consequence of their simple emulsifying properties, they do not lead to drop formation even in open equipment.

For even distribution in the liquor bath, carriers mostly contain various added emulsifiers, and very often also other additives as well as solvents, in order to improve the emulsification behaviour, including storage stability (Tab. 2).

Carrier compounds Basic compounds or chemicals used as vehicles for other active substances performing a specific function (e.g. hydrogen peroxide on pyrophosphate = perpyrophosphate). They serve as a basis for certain compositions (e.g. in → Fragant finishes).

Carrier-free dyeable polyester fibres As is well known, the normal polyester fibre (polyethylenterephthalate) can be dyed at boiling temperature and normal pressure only if prior to that, carriers have facilitated the penetration of the dispersion dyes by loosening the fibre structure. After dyeing, these auxiliaries disperse partly into the air, partly into waste water, and can cause environmental problems. The remedy of reducing the amount of carrier, or eliminating it entirely, by using higher dyeing temperatures is precluded for sensitive fibre blend components. The obvious solution was therefore to develop a polyester fibre which already has the loosened structure, which can be created by carriers, to start with.

Polyester is a condensate of terephthalic acid and ethylene glycol. Of the numerous possibilities for increasing its dye affinity by incorporating additional components, the condensing of polyethene is of particular interest. Copolymers are created with statistically distributed polyalkylene oxide blocks, whose length and concentration determine the effect. Both the composition of the polymer and its processing into fibre must be carefully balanced in order to obtain the maximum advantageous characteristics. With the loosening of the polyester structure, there is the risk that valuable properties of the fibre which determine the good processing and performance behaviour are reduced. The desired high dye affinity of the fibre is to be achieved without seriously impairing important properties, such as e.g.

- modulus,
- fibre strength,
- shrinkage,
- fixability,
- dyeability in all shade depths,
- good light fastness and wet fastness of the dyeings.

The processing properties of the fibre, as well as the quality, e.g. wear resistance, shape retention, crease recovery of the resulting article must be preserved.

Carrier residues, removal Since residues of carriers can impair the light-fastness of dyeings, particularly on polyester, they are best removed through reductive final scouring with soda lye and sodium dithionite.

Carrier rollers Provided in order to prevent slippage of the rollers.

Carrier stains When working with carriers, darker dyed stains (carrier stains) can occur on the textiles to be dyed. These stains can be difficult to remove, and are due to inexpert working practices. Causes:

- poorly dissolved or poorly dispersed carrier;
- carrier is volatile in steam, condenses on colder dyeing unit parts and drips back onto the textile material;
- in the case of poorly cleaned dyeing units, the carrier dissolves out residues of grease, dirt and dyes, which end up on the textile material.

Carrier stains are hard to remove, particularly in goods of polyester/wool. In some cases, stripping helps removal of carrier residues.

Carrier system Relates to yarns (dyeing machine suspension system) for ladies' hose, which are treated in specific hose dyeing machines suspended over sticks in bundles. Sometimes also usable for hank yarn.

Carrotting The steeping of hare and rabbit hair in mordant. A term from the hat-making industry. The best mordant for this is the mercury nitrate mordant, where mercury is not released (incorporated into the hair keratin). Consequently there is an increase in weight and stable setting. No pre-treatment is required for dyeing, since the material is kneaded for several hours at 90°C with sulphuric acid (pH 3). All peroxide mordants damage the material; this results in weight loss, unstable setting, carrotted material is not stable in storage, felts lose stability, i.e. become loose over time.

Cartridge filter Consists of fine-pored, specially impregnated paper with activated charcoal additive (for tetrachlorethene, on account of the greater danger of marking off) or without activated charcoal. Cartridge filters differ from precoated filters particularly in dispensing with filter powder (this eliminates a precoating operation). Cartridge filters are used for dry-cleaning machines up to 18 kg charge weight (minimum throughput of 1500 kg of normally soiled fabric per pair of cartridges). → Sewerage-filter-systems.

CAS, abbrev. for: Chemical Abstracts Service. → CAS Index Number.

Case cord Continuous filament case cord yarns and steel cord yarns are woven to form the load-bearing plies forming the carcass or body of a vehicle or aircraft tyre or heavyweight conveyor belting, drive belts etc.

Casein Protein product of animal (milk) or vegetable (legumes) origin. Powder and small granules, horny, almost white to dull yellow. Water-soluble (if necessary with the addition of sodium tetraborate, ammonia, soap and the like). No coagulation when heated, cold coagulation by mineral acids. Solution: gelatinous, slightly foaming (prevented by glycerine, turpentine oil, Turkey red oil). Conservation necessary (formaldehyde). Precipitation by acetic acid (soluble in excess), hydrochloric acid (soluble in excess of diluted casein solution, greater excess = renewed precipitation), decomposition by tannic acid, metal salts, enzymes. Use: as size and print thickener.

Casein fibres → Man-made protein fibres of animal origin (milk protein). The casein is separated from the whey, dissolved in caustic soda, and spun in a precipitating bath with sulphuric acid, sodium sulphate, sodium chloride and, if necessary, formaldehyde (harden in formaldehyde). Casein fibres were the most important regenerated protein fibres, as they have a certain similarity to sheep's wool, and are consequently particularly suitable for blends with it. Use is limited however due to their rather moderate strength and elongation values (8–11 cN/tex, 50–70%), and their high strength loss and plasticity in the wet state.

Casein plastics (Galalith). Horn-like plastic of paracasein hardened with formaldehyde, which is used mainly for buttons. Density 1.32; burns with difficulty. Yellowish white and dyed in the mass or later (in the latter case, white ground visible on scratching with a knife) also coloured in layers, marbled, low lustre (sprayed with cellulose lacquer) or high lustre (bleach liquor process). Properties: insoluble in water, acids, alcohol, benzene, chlorinated hydrocarbons (cellulose lacquer is soluble); thermoplastic. Subsequent dyeings are often brightened in a soap wash; shade loss mostly with hot alkali treatment. Casein plastic buttons should be detached prior to wet treatment and redyeing.

Cashgora Although fine animal hair makes up only about 0.11% of the total world production of textile fibres, due to their high raw material price these fibres (see Tab.) have attained particular economic importance. In general parlance, no distinction is made between wool and fine animal hairs; nevertheless the German Textile Labelling Act provides for "wool" to mean the fibres of the coat of the sheep. Fine animal hair types are named with or without the suffix "wool" and hair. Animal hair fibres.

Cashmere means the fine bottom hair of the cashmere goat, which is separated out from the bristly hair by combing. Mohair means the hair of the angora goat, which consists of long, glossy, wavy fibres and which is obtained by shearing. Both types of goat were intro-

Fibre	Fineness (µm)	Length (mm)	Price level (£/kg)	Producing countries
Mohair	24 - 40	75 - 100	6 - 18	South Africa, Texas, Turkey, Australia
Cashgora	19 - 22	50 - 60	8 - 20	New Zealand, Australia
Cashmere	15 - 19	25 - 90	35 - 70	Tibet, China, Mongolia, Iran, Afghanistan, Australia, New Zealand
Camel hair	18 - 26	29 - 120	10 - 12	China, Mongolia
Alpaca/llama	22 - 25	75	12 - 15	Peru, Chile
Vicuna/guanaco	10 - 20	30 - 50	150 - 200	Peru, Chile
Angora	11 - 15	25 - 50	20 - 30	China, South America, France
Yak	19 - 21	30 - 50	15	Tibet, China, Mongolia

Tab.: Characteristics of fine animal hair fibres.

duced into New Zealand from Europe and Asia. Cashgora means the fine bottom hair of the cashgora goat, which is the result of cross-breeding female cashmere goats and male angora goats in New Zealand. It was only in the 19th century that the finest bottom hair was discovered in some of these wild goats. Cross-breeding trials of these animals were first undertaken in order to reduce the proportion of coloured bottom hair, since it is with the genes of the male angora goats that the feature "white colour" is passed on to descendants.

Cashgora goats have a thick, white coat of a coarse coat and fine bottom hair, which is obtained by shearing. The cashgora quality can be divided into three categories, depending on the degree of cross-breeding, with the first cross yielding the finest fibres. Each further cross with angora goats leads to a coarser quality, similar to mohair. Classification is thus according to fineness, which lies between that of cashmere and mohair, at 17-23 μm. Like all keratin fibres, fine animal hair fibres too have all structural elements such as cuticula, matrix fibrils and microfibrils; although their proportionate distribution differs.

A comparison of the dyeing behaviour of cashmere and cashgora shows that both animal hair types can be dyed with the most conventional wool dyes, under corresponding dyeing conditions, in the same manner. There are no significant differences with regard to evenness, shade, depth and fastnesses. The changes in properties which the fibres may suffer during dyeing or in subsequent processes depend, amongst other things, on pH and temperature, and as a result of the attack on the fibre lead to substance losses, loss of strength and yellowing. In the changes in properties, detected by the usual analytical methods, in each case it is shown that the change in property depends more clearly and starkly on the treatment conditions than on the animal species. Greater differences do occur in individual values, but these cannot be interpreted in the form of a clear demarcation between cashmere and cashgora. The heavily deviating ratio of matrix-forming to helix-forming protein components between the Mongolian cashmere and cashgora from New Zealand does not have any consequences for practical dyeing, whilst the differing structure of the scale layer and the fibre finenesses becomes apparent in the differing felting behaviour.

Cashmere Goat hair, belonging to the group of natural protein fibres, from the cashmere goat, which is native to the Kashmir mountains and which these days is also bred or lives wild at great altitudes and in extremely cold conditions in northern India in the Himalayan region, southern Russia and Asia Minor. The cashmere hair is obtained at the time of moulting by pulling, combing out or shearing. It is subsequently sorted and classed. The fleece weight per goat per annum is about 0.3–0.6 kg downy hair, which usually has to be washed. The bristly hair (50–75%) is up to 300 mm long, coarse and smooth, and is separated from the valuable bottom hair by combing. The downy hair has a silky lustre, and is wavy and soft. The colour is rarely white, usually grey, brownish and blackish. The length is 40–90 mm, the fineness 10–20 μm, which corresponds to the finest merino wools. The tensile strength is relatively low. The handle is particularly soft and pleasant. The quality is determined by the colour (the lighter it is, the more valuable), and by the proportion of bottom hair. Cashmere is spun in pure form and in blends, primarily of finest merino wool, natural silk, cotton and synthetics. Worsted yarns are used for knit goods, necktie fabrics and hand-woven shawls; carded yarns are more frequently produced and used for fine cloths and fabrics for ladies' wear, with a napped or fleece-like surface. Animal hair fibres.

Cashmere wool → Cashmere.

CAS Index Number Chemical substance identification number according to CAS (Chemical Abstracts Service). It is used in virtually all international chemical documentation systems and affords quick access to further data on the respective substance.

Caster chair test → Castor test.

Casting resins → Polyester resins.

Cast iron → Iron.

Castor oil Viscous oil from the castor bean, light yellow to brown, odourless. Dries slowly in air, transparent alcohol soluble. Contains the triglyceride of ricinoleic acid: $C_{17}H_{32}(OH)COOH$. Density 0.960–0.964. Use: production of soaps, Turkey red oil and as an additive to printing pastes.

Castor oil soaps Use as an auxiliary agent product, e.g. hard soaps and for brightening and chemical finishing.

Castor test Mechanical carpet testing machine for investigating whether carpets are suitable for being subjected to office chairs with wheels. Changes in visual appearance are graded 1–5. In the course of this, the carpet backing can be damaged. In the case of high-filled foams (up to 300%), the foam strength is too low (foam is loosened from the carpet). Fundamentally, castor-proof carpets have to be glued over the entire area; wheeled chairs should contain rollers in accordance with DIN 68 131 (other rollers can cause considerably more damage).

Casual wear Synonymous with → Leisure wear, progressing in the mid 1970s to cover unconventionally more flamboyant garments combining greater comfort with more youthful style features, being lighter in weight and more yielding to the body, with highlighted stitching (of collars, pockets, belts etc.) and above all easy-care properties.

Catalysis (Gk.). Accelerating a chemical reaction by reducing the activating energy with the aid of catalysts. The reaction rate is changed. Types of catalysts:

I. Homogeneous catalysts: the catalyst has the same state of aggregation as the reacting substances.

II. Heterogeneous catalysts: the catalyst is generally solid, and the reaction partners are liquid or gaseous.

Many processes take place in nature in the form of catalysis, enzymes acting as catalysts (biocatalysts). Catalytic processes play an important role in industry.

Catalyst There are chemical processes which have states of equilibrium which lie largely on the product side; but as they reach equilibrium only very slowly, they are of little practical value for substance synthesis. In many cases however, the time required for reaching a state of equilibrium can be greatly reduced by the addition of a substance which in fact participates in the reaction but is not consumed in it. These substances are called catalysts. The way in which a catalyst participates in the mechanism of a reaction remains unknown in some cases, but the following generalised statements can be made as regards its action: a catalyst reduces the activating energy of the reaction process, a much larger proportion of the molecules participating in the reaction achieving the necessary energy E_a.

In this way, the reaction rate increases under otherwise unchanged conditions. The activating energy of the opposed reaction – the so-called back reaction – is also reduced. As both the rates of the reaction and the back reaction are affected by the catalyst in the same way, the time required for establishing equilibrium is reduced (Fig. 1).

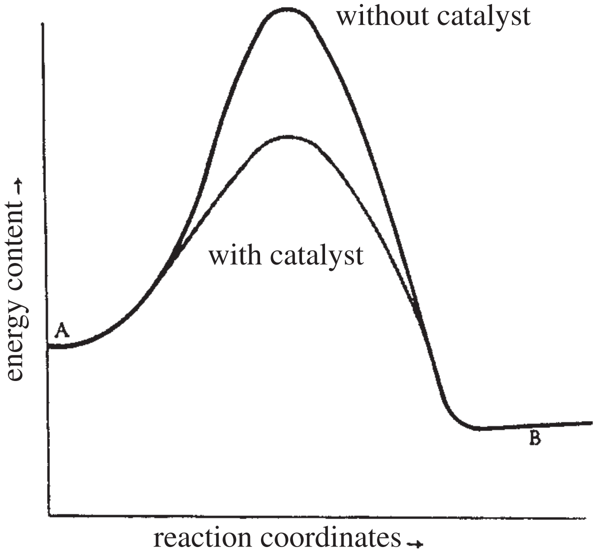

Fig. 1: Energy profile of a catalysed and a non-catalysed reaction.

Conversely, there are also substances which, when added to a reaction mixture, slow down the reaction by increasing the activating energy; they are known as negative catalysts or inhibitors. A catalyst can be a solid metal surface on which the reaction takes place, a hydronium ion (H_3O^+) in aqueous solution or any other substance.

Catalytic processes can be divided into four groups:

1. Catalysis in the flame, particularly thermal catalysis.
2. Homogeneous catalysis in solutions, particularly acid or base catalysis.
3. Heterogeneous catalysis, particularly with redox systems on large surfaces.
4. Enzyme catalysis, particularly on the key/lock principle.

Catalytic exhaust air purification is a process that is applied when catalyst poisoning can be excluded (Fig. 2). A new generation of catalysts expand the industrial field of application. In spite of the high resistance to catalyst poisons, no heavy metals should be contained in the exhaust air, as this would substantially reduce the normally very long lifetime of the catalyst.

Dürr Ecopure-KAR units can be applied for low pollutant concentrations, and they achieve excellent combustion efficiencies. The raw gas is pre-heated to the catalyst start-up temperature by a heat exchanger tailored to the specific application, and subsequently ducted through a high-performance precious metals catalyst. At temperatures between 200°C and 350°C the hydrocarbons are oxidized and are transformed into harmless H_2O and CO_2. A catalytic system is only suitable when pilot tests have shown successful results. For such tests Dürr has several different compact pilot units.

Catalysts for resin finishing The cross-linkers commonly used in resin finishing are used only with the addition of catalysts, which act as cross-linking reaction triggers and as reaction accelerators. The action of these catalysts is based on the freeing of hydrogen ions. Catalysis (acid), breaks the carbon/oxygen linkage of the N-methylol groups, and a reaction takes place with the hydroxyl groups of the cellulose with the discharge of water. The catalyst has three basic functions:

1. Establishing equilibrium between the N-methylol compound and the formaldehyde split off from it.
2. Dispensation of the formaldehyde consumed by cross-linking.
3. Catalysation of the cross-linking of the N-methylol compounds and the formaldehyde with the cellulose.

The reaction mechanism should be in accordance with the following diagram.

The catalyst increases the hydrogen ion concentration during condensation, increasing the reaction speed. All catalysts used in the resin finishing of cellulosic fibres in combination with N-methylol compounds are either latent or potent acids. The latent catalysts develop their acidity (acid content) only when heated (condensing); the potent acid catalysts already

Catalyst for resin finishing

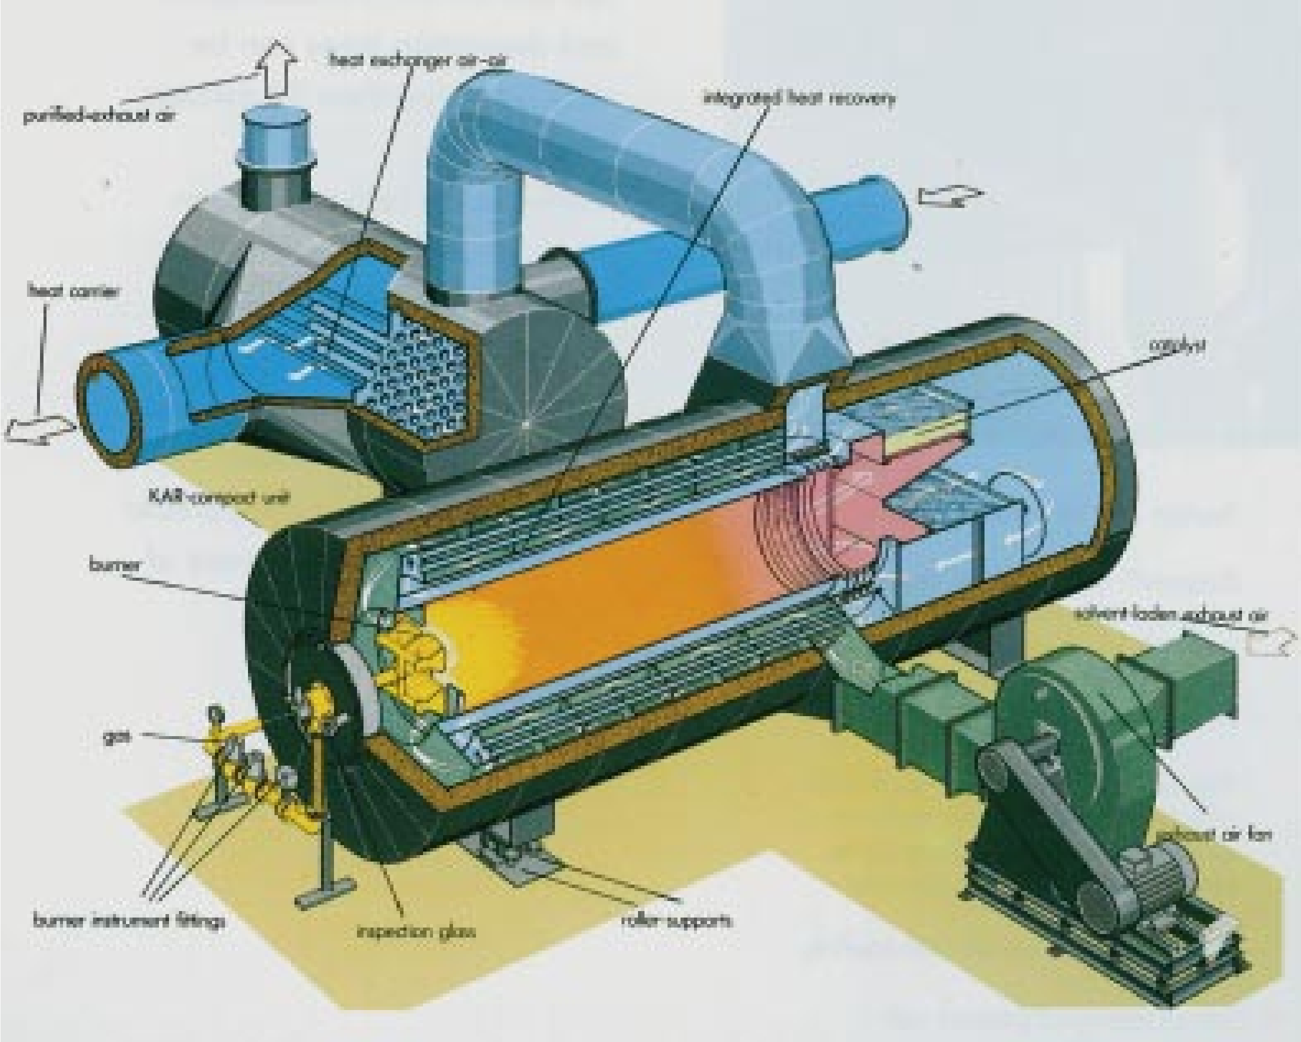

Fig. 2: Catalytic exhaust air purification.

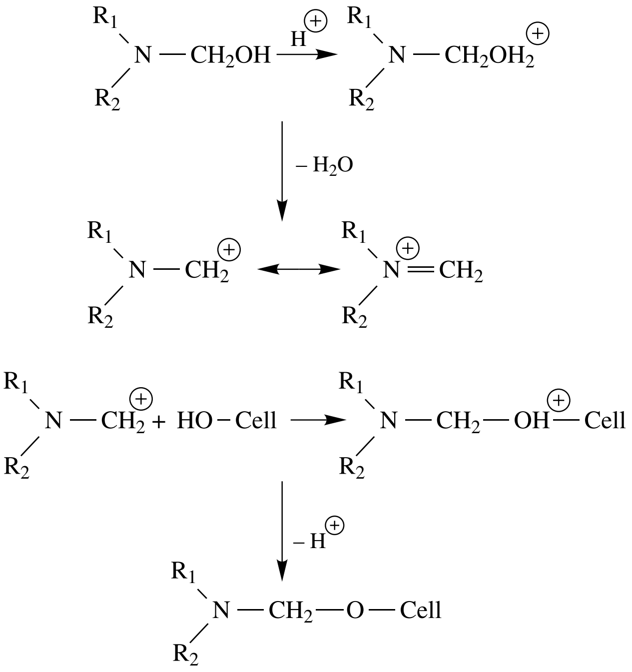


react acid in the bath. In order to obtain optimum finishing effects, the type of cross-linker, the type of fibre to be finished, the condensation conditions, the requirements on the finished fabric plus possible fabric shade changes should play a part in catalyst selection. From the technical processing standpoint, the catalysts, like the cross-linkers, are divided into three groups:

Type of finishing (Fibre swelling state)	Type of catalyst	pH
Dry cross-linking (not swollen)	metal salts ammonium salts	3– 6
Moist cross-linking (partially swollen)	mixed catalysts free acids	1– 2, 5
Wet cross-linking (swollen)	free acid free alkali	0– 1,5 10– 12

Tab.: Common catalysts for dry, moist and wet cross-linking.

1. Catalysts for dry cross-linking,
2. Catalysts for moist cross-linking,
3. Catalysts for wet cross-linking.

Important for catalyst selection is the technical processing implementation of cross-linking and the state of fibre swelling (Tab.).

In addition to so-called complex catalysts, metal salt catalysts or ammonium salt catalysts are predominantly used for dry cross-linking. These types develop their full effectiveness only when heated or condensed.

Complex catalysts	high reactivity
Ammonium nitrate	
Ammonium sulphate	
Ammonium chloride	
Zinc nitrate	
Monoammonium phosphate	
Diammonium phosphate	
Ammonium oxalate	
Zinc chloride	
Magnesium chloride	lower reactivity

a) Complex catalysts are mixtures of metal salts of strong acids with complex-forming hydroxycarbonic acids (tartaric or citric acid). Small additions of these medium strength organic acids have a great effect, since the hydrogen ions are distinguished from the metal ions by their “minuteness” and great mobility. The organic acid (citric acid) is also catalytically active on its own, and one cannot therefore use the term synergism with this catalyst combination; added effectiveness on the part of the two components is involved here.

Complex catalysts are used mainly for cross-linking N-methylols with cotton and natural cellulose fibres. Fast reaction times and high temperatures can be selected owing to the high degree of acidity of these catalysts; moreover, loss of material tear strength due to hydrolysis is not to be excluded.

b) Ammonium salt catalysts are used predominantly for bathotonic resins on regenerated cellulose woven fabrics. With the use of these products, care should be taken to ensure that liquor stability is delimited, since the ammonium salts change the liquor pH, and condensation can therefore be triggered in the liquor. If the particle size of these precondensed contents has increased to such an extent that it can no longer penetrate the fibres, so-called deposition occurs. This leads to detrimental effects, to brittleness, and consequently to reduced abrasion resistance. Liquor stability decreases from ammonium sulphate, via ammonium chloride and ammonium nitrate to ammonium oxalate. The pH can change from pH 6 to pH 3.5 within a few hours when using ammonium chloride for example.

The reaction method of the ammonium salt catalysts is based on the following principle:

$$6\ HCOH + 4\ NH_4Cl \rightleftharpoons (CH_2)_6N_4 + 6\ H_2O + 4\ HCl$$

Formaldehyde reacts primarily with the ammonium ions to methenamine (hexamethylenetetramine, urotropine), releasing the relevant acid (hydrochloric acid). On the other hand, the ammonium salts split off in heating ammonia (NH_3).

– Ammonium nitrate NH_4NO_3: due to the high degree of reactivity, there is a danger of shade changes with dyeings which are oxidation sensitive. Optical whiteners can be impaired in terms of their light fastness. Fibre damage may be caused in addition if excessive condensation conditions are selected.

– Ammonium chloride NH_4Cl and ammonium sulphate $(NH_4)_2SO_4$: the two are about equally reactive, and are used in finishing polyamide/cellulose blends. They can replace ammonium nitrate owing to their low “aggressivity” levels.

– Monoammonium phosphate $(NH_4)H_2PO_4$: used for cotton, regenerated cellulose and their blends with polyester and polyacrylonitrile fibres. Also suitable for obtaining wash resistant calendered and pleated effects on cotton.

– Diammonium phosphate $(NH_4)_2HPO_4$: a buffer action catalyst which is frequently used in finishing cotton or regenerated cellulose with dimethylol urea.

– Ammonium oxalate $(NH_4)_2C_2O_4$: for special finishing processes such as stiff finishing on white polyamide fabric. Owing to its low reactivity, there is no yellowing.

c) Metal salt catalysts are used for preference in the finishing of cotton and its blends with synthetic fibres; in general linguistic usage, metal salts are also termed substances which give off acid. The action of most metal salt catalysts develops only on heating to above 100°C, i.e. in the unswollen state of the cellulose fibre. Magnesium chloride ($MgCl_2$) and zinc chloride ($ZnCl_2$) require condensation temperatures > 140°C; zinc nitrate ($Zn(NO_3)_2$ already reacts from 130°C. In decreasing activity sequence:

$$Zn(NO_3)_2 > ZnCl_2 > MgCl_2$$

The catalytic effectiveness of the salts is a complex result of different factors, and the acidity of the cation plus the nature of the anion are equally relevant. If one varies the cation within a group of the periodic system, e.g. of group 2a, with Mg, Ca, Sr, Ba with the same anion, e.g. the chloride, one observes decreasing effectiveness with increasing atomic weight.

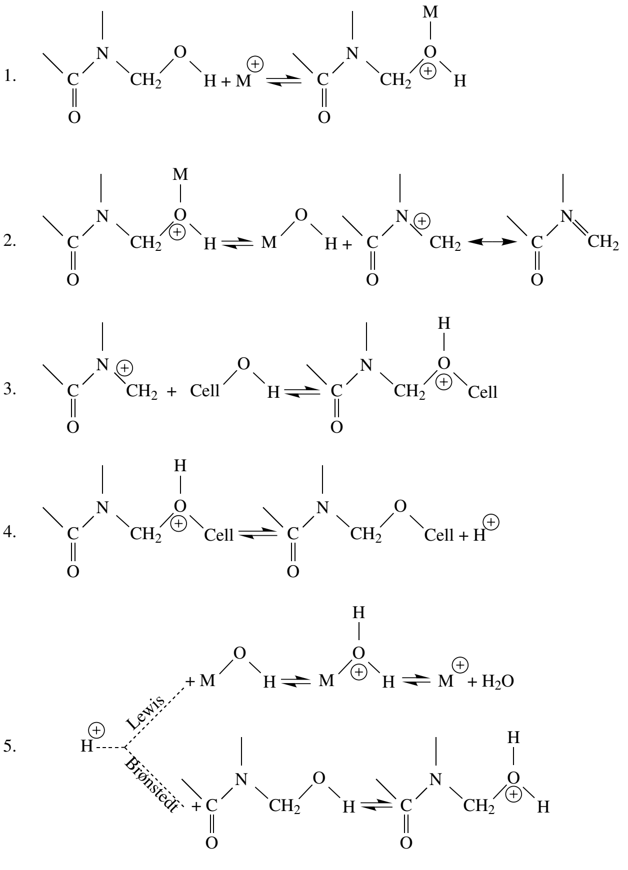
$$Mg^+ > Ca^+ > Sr^+ > Ba^+$$

This could be based on the fact that, with increasing atomic weight and presupposing the same anion, the acidity, i.e. the electron affinity, decreases, and mobility is also reduced due to the increasing ion size. The importance of the anion in the case of metal salt catalysts is revealed by magnesium and zinc salts in the following sequence of effectiveness:

$$NO_3^- > Cl^- > SO_4^{2-}$$

It should be noted with regard to the action method that magnesium chloride for example decomposes into magnesium oxide and hydrogen chloride only at temperatures above 800°C (conditions which do not in any case occur in dry cross-linking). Catalysis via self-forming acid (hydrochloric acid) is improbable therefore for metal salts. The salts must be catalytically effective in another way. Basically, one starts from the fact that metal salt catalysts catalyse cellulose cross-linking with N-methylols in the first place in accordance with the Lewis acid mechanism. Lewis defined the acids generally as molecules or ions which are capable of coordination with solitary pairs of electrons. He defined bases as molecules or ions which make solitary pairs of electrons available for coordination.

In principle, this mechanism is the same as in normal acid catalysis. The difference lies in the fact that the N-methylol-oxygen is protonised on the one hand by metal ions instead of hydrogen ions, while, on the other, metal hydroxide and not water is split off with the formation of the ureidomethyl ion (carbonium-immonium ion) stabilised by isomerism. The next step is the reaction with nucleophile hydroxyl groups of the cellulose to protonised cellulose ether.



The ureidomethylation reaction is concluded by hydrogen ion loss. The split off hydrogen ion can now either protonise the next methylol group directly in accordance with Brønsted catalysation, or, in accordance with Lewis, react with the metal hydroxide to form metal ions and water.

- Zinc nitrate $Zn(NO_3)_2$: is the most effective metal salt catalyst of the metal salts used. It is suitable for natural cellulose fibres and their blends with synthetics. Shade changes and the impairment of optical whiteners are possible.
- Zinc chloride $ZnCl_2$ and magnesium chloride $MgCl_2 \cdot 6H_2O$: predominantly for cotton and its blends with synthetics for low-crease finishing. Both are suitable for white fabrics and chlorine-fast finishes; the light fastness of optical whiteners is not affected.

Catalytic damage Oxidative changes or cellulose destruction (hole formation) caused by catalysts, thus reducing textile product service value. This fibre damage is attributable to the local enrichment of iron-containing compounds. If, e.g., cotton contaminated by minerals containing heavy metals is processed into yarn in the OE spinning process, it can become enriched due to the centrifugal forces of the mineral dust in the rotor, falling back from there as small compact particles on to the yarn as it forms. The high degree of punctiform enrichment has concentrations which amount to a multiple of the total iron compound content. It is not the total content therefore which is decisive, but the distribution and frequency of the catalytically acting particles in the textile product. Local enrichments are predominantly found in uneven distri-

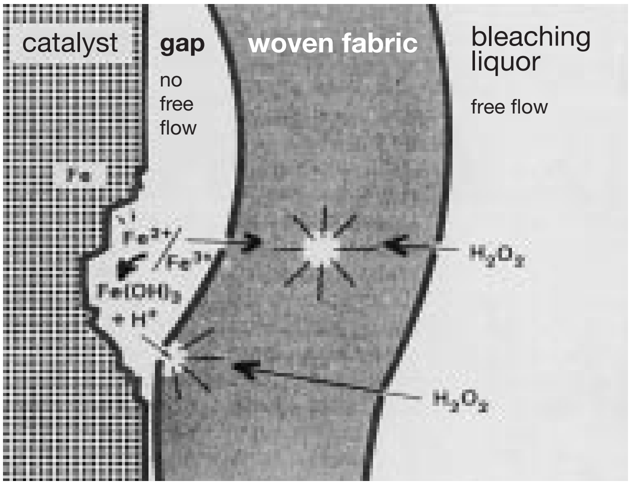


Fig.: Schematic diagram of catalytic damage occurrence (Meyer).

bution in rotor yarns, whilst an almost uniform distribution of iron compounds is present in ring yarns.

Catalytic damage in the bleaching process (→ Bleaching and catalytic damage) occurs in that, in addition to a local drop in pH due to the release of protons in the conversion into iron hydroxide, dissolved iron salts are formed. The prerequisite for catalytic damage is particles which quickly destroy either the fabric itself (e.g. protons, oxidising agents) or the peroxide, e.g. due to the meeting of iron ions (Fig.). This occurs when the active particles are locally present in a higher concentration, and the damage point of the fabric can be reached without difficulty.

It is difficult to imitate catalytic damage in the laboratory, since the severe catalytic corrosion of iron presumes first of all rust formation. Rust is formed in accordance with the formula

$$Fe + {}^{1}/2\, O_2 \rightarrow FeO$$
$$2Fe + {}^{3}/2\, O_2 \rightarrow Fe_2O_3$$

This is equivalent to an iron tube which decomposes after a few weeks in a moist atmosphere. Rust formation passes through the following phases:

- adsorption of oxygen (from the air) to the metal surface,
- migration of iron atoms with oxide formation at the surface, which leads to gaps in the molecular lattice of the metal,
- migration of iron atoms to deeper layers,
- further rust formation on the surface.

In this way, the initially compact crystalline structure gradually disintegrates.

Peroxide disintegration is accelerated by a multitude of substances and substance mixtures. The presence of such so-called catalysts in the bleaching liquor and/or in the textile product leads to spontaneous bleaching agent decomposition. Associated with this is extreme fibre damage which is expressed in such a way that the cellulose is oxidised to oxycellulose, and subsequently depolymerised. In peroxide decomposition, the peroxide is split into the radicals:

$$H_2O_2 \rightarrow HO^{\cdot} + HO^{\cdot}$$

due to the considerably reduced activating energy.

In addition to enzymes, bacteria, the textile substrate and dirt, heavy metals in particular, which occur in a number of valency stages, iron, copper, manganese, chrome and nickel for example act as catalysts. Iron compounds represent the largest proportion in cotton attendant materials. Heavy metals can make their way into or on to the textile product and/or the bleaching liquor in various ways. This happens mainly:

- due to the cultivation, growth and harvesting conditions of the different cotton sources,
- during textile material transport and storage,
- due to metal abrasion during production of the yarn and its processing into fabrics,
- due to corroding steam and water pipes,
- due to the feeding of technical chemicals,
- due to corroding stainless steels with locally damaged surfaces.

As regards catalyst action, a distinction is drawn between two types:

1. Contact catalysts.
2. Transfer catalysts.

Type 1 acts mainly by adsorption (chemisorption) of the peroxide on to active surfaces or centres. In the case of type 2, a distinction is drawn between: a) a catalyst which forms an unstable intermediate product with no change in valency, and which decomposes again with catalyst regeneration (with the splitting off of oxygen in the case of peroxide); b) a redox mechanism, i.e. the catalyst has two or more valency stages (e.g. iron), and is transferred by the peroxide from a lower to a higher valency stage, which then decomposes the peroxide by the splitting off of oxygen when the catalyst recovers its initial form.

The radical chain reaction can be explained by the Haber-Weiss mechanism with the example of bivalent iron:

Start: $Fe^{++} + HOOH \rightarrow Fe^{+++} + {}^{\cdot}OH + OH^{-}$

Chain: ${}^{\cdot}OH + HOOH \rightarrow H_2O + HOO^{\cdot}$

$Fe^{++} + HOO^{\cdot} \rightarrow Fe^{+++} + HOO^{-}$

$Fe^{+++} + HOO^{\cdot} \rightarrow Fe^{++} + O_2 + H^{+}$

End: $Fe^{++} + {}^{\cdot}OH \rightarrow Fe^{+++} + OH^{-}$

This mechanism applies to both iron(II) and iron(III) ions.

For the activity of a catalyst, i.e. for the quantity of peroxide decomposed in the unit of time, not only the type, the surface, the particle size and its structure are of prime importance, but also the pH of the liquor, its temperature and the dilution of the peroxide. The presence of a number of catalysts frequently results in the rate of decomposition being considerably greater than is equivalent to the sum of the individual components or partial reactions. This effect is described as a catalyst promoter effect or as a synergetic effect. A mixed hydroxide of copper, manganese and iron results for example in a hundred times quicker decomposition of peroxide. On the other hand, there are also substance combinations which depress peroxide decomposition. The reaction processes are much more complex in the case of a mixed catalyst, and sometimes are not precisely explained.

Promoter effect with the example of iron and copper ions:

$$Cu^{++} + HOO^{\cdot} \rightarrow Cu^{+} + O_2 + H^{+}$$

$$Cu^{+} + Fe^{+++} \rightarrow Cu^{++} + Fe^{++}$$

The $HOO^{\cdot}$ radical formed in accordance with the Haber-Weiss mechanism reacts with copper(II) ions with the formation of oxygen, the copper(I) ions occurring reducing iron(III) ions to bivalent iron on their part. This again triggers the radical chain reaction. In connection with mixed catalysis, even inactive substances or substances with very little activity, such as alkaline earth hydroxides for example, are of interest, becoming highly active catalysts through adsorbing metal ions. An example of this increased activity is the calcium, iron and copper(II) hydroxide three-substance system, where the calcium hydroxide itself is inactive. There is also the possibility, in the presence of alkaline earth ions or hydroxides, of reducing the activity of the mixed catalyst in terms of peroxide decomposition, e.g. in conjunction with silicate ions.

Catalytic damage in bleaching → Bleaching and catalytic damage.

Catalytic fading Mutual negative influence on the light-fastness of dyes in combination dyeing. The light-fastness of the combination dyeing is less than that of the components. Above all with some vat dyes, but also with some substantive and dispersion dyes (Blue eaters). A marked catalytic fading effect is present when for example two dyes with light fastnesses of 7 fall to grade 3–4 when combined. Occurs particularly with azo blue; less strong with anthraquinone blue dyes when combined with azo yellow, azo orange, azo brown, azo red brands. In the case of anthraquinone dyes, between them one finds no mutual reduction in light fastness, or only a very slight one. The impairment varies according to the proportion of the components.

CATCC, abbrev. for: Canadian Association of Textile Chemists and Colorists.

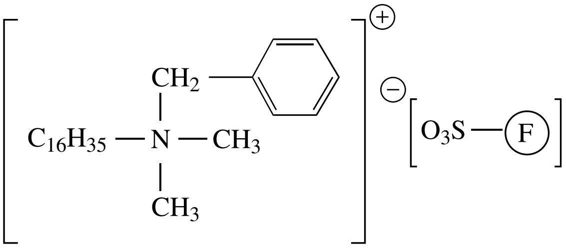
Catechu (cachou). From the Indian “Kati” plant and “chuana” = distil. Extract of the aqueous extract of the Indian tanner’s acacia. No longer used brown dye, formerly used for tent and covering fabrics, as the fabric was simultaneously endowed with natural waterproofing, increased weight and a fuller, harder handle.

Cathode (Gk.: kathados = a downward path). Derived term for the negatively charged → Electrodes (negative pole), through which the negative current in the electrolytes emerges (into which the positive current from the electrolytes enters). During current passage, the cations move to the cathode, and are charged there, cathodic reduction processes etc possibly taking place. Working materials frequently used in cathode technology are precious metals, iron, copper, zinc, aluminium, lead, cadmium, titanium and graphite.

Cation exchanger → Ion exchanger.

Cationic General term in the surfactant field for positively charged, surface active, hydrophobic carbon compounds with ionically reacting groups. Antonym: anionic.

Cationic aftertreatment The most important method for improving the fastness of dyeings made with direct and union dyes and which can have a very considerable effect on fastness to water, washing, perspiration, wet ironing and cross-dyeing (usually by 1–3 fastness ratings). Principle: conversion of the anions of the dyestuff on the fibre into sparingly soluble or insoluble salts of the dyestuff acid, e.g.



Although the principle applies to all anionic dyes, the improvement in fastness differs to some extent, depending on the molecular weight of the dyestuff and the number of sulpho groups. In addition, a definite minimum amount of the cationic product is required, which may vary according to the product, so that specified average amounts should be used in all cases. Cationic products are therefore fastness improving agents.

Working method: after dyeing, rinse well, apply 1–4% for an exhaust process, 5–20% for a continuous process, at pH 5–6 for 15–30 min at 20–60°C, according to the cationic product. Rinsing is usually required. Processing faults: use of too little product, insufficient rinsing after dyeing (poorer rubbing fastness), sometimes the water used for rinsing is too hard (reduced fastness to rubbing and washing; for this reason it is better to rinse with soft water at first and, if necessary, add hard water gradually). It must also be taken into account that different products have different sensitivities to sodium sulphate and hard water and will have a greater or lesser effect on the shade of the dyeing and may possibly lead to poorer light fastness. With products that affect the light fastness, combining aftercoppering with the cationic treatment can often compensate because of their opposing effects on the light fastness. The same idea lies behind the cationic resin-metal salt aftertreatment for simultaneously improving the fastness to light and wet treatments.

Cationic polymers react with anionic dyestuffs to form salts, so-called polymer salts. The primary driving force is purely electrostatic in nature, with binding forces of 30–60 kJ/mol. This type of polymer salt is insoluble in water as well as in organic solvents, and it is primarily this insolubility that produces the good contact fastnesses of dyeings after fixation. Apart from the pure electrostatic interaction, however, when two molecules approach one another sufficiently closely, other binding forces also come into play; these are hydrogen bonding, van der Waals' attractive forces and above all hydrophobic interactions. Hydrophobic forces have a significant effect on the washing fastness of dyeings. If the aftertreating agent has other functional groups apart from the quaternary ammonium groups, e.g. –OH; =NH; $–NH_2$; –C≡N or guanidine groups, a complex can be formed with metal-containing anionic dyes. This type of bond is very stable, hardly affected by external variables and leads to very high contact and washing fastnesses with metal-containing reactive or substantive dyeings. Atomic bonds can also be formed between the aftertreatment agents, the dyestuff and sometimes the fibre as well. The binding forces in these cases are 3–4 kJ/mol. This sort of bonding can take place when the aftertreating agent is modified with reactive groups and the dyestuff and fibre also have functional groups such as –OH or $–NH_2$. This type of bonding can produce high fastnesses, up to being fast to washing at the boil. It can be a serious disadvantage that this type of product cannot be removed from the fibre in practice and cross dyeing is extremely difficult. However, reactive products are being used increasingly in sulphur dyeing where they react mainly with the –SH groups of the dyestuffs and there is scarcely any reaction with the cellulose.

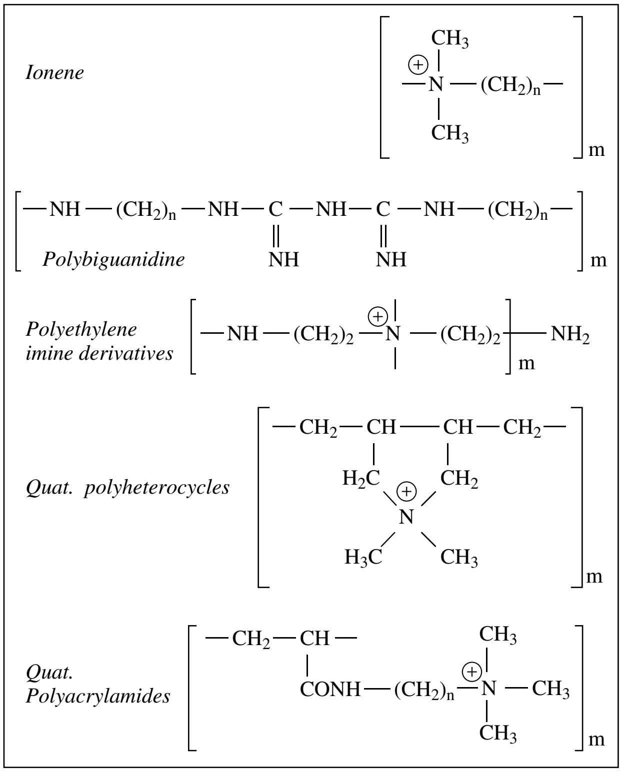


Fig. 1: Structural features of some aftertreatment agents.

A common feature of all cationic aftertreatments is the presence of at least one quaternary ammonium group in the molecule; this gives affinity to the fibre as well as reacting with the dyestuff. Apart from these, other polar or even reactive groups, the molecular weight as well as the supramolecular structure of the cationic polymer play a role.

Fig. 1 shows structural features of some of the aftertreatment agents that are in current use. The list is not complete as many variations with heteroatoms such as oxygen and sulphur are possible within these basic structures.

The quaternary ammonium groups give the affinity for the fibre as well as reacting with the anionic dyestuffs. Cellulosic fibres have a negative zeta potential, so that positively charged ions are attracted to the surface of the fibre. This takes place very rapidly. The positive ions neutralize the negative charge centres at the fibre surfaces and can even lead to an inversion of the charge to a positive zeta potential.

Fig. 2 shows zeta potential measurements on cotton fibres in the presence of cationic polyelectrolytes.

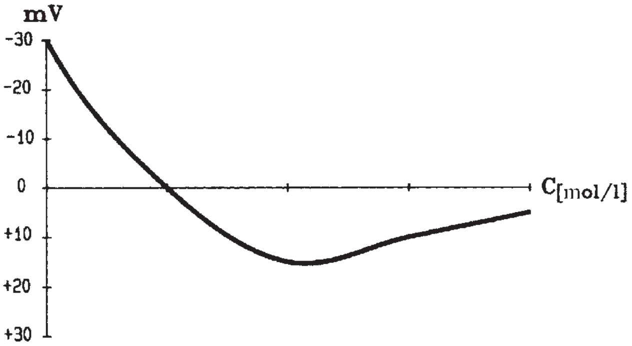

Fig. 2: Dependence of the zeta-potential of cotton fibres on the concentration of cationic polyelectrolyte.

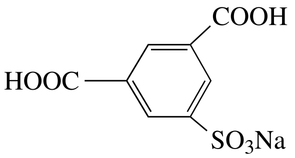
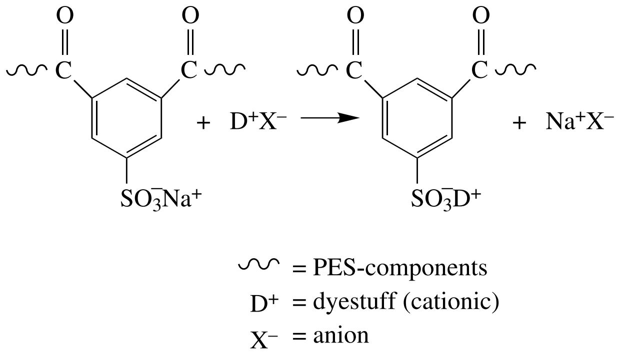
This situation however means that only a limited amount of cationic polymer can be bound to the fibre surface, as the change in potential of the cellulose fibre surface very quickly leads to repulsion of subsequent cationic molecules. The amount that is bound is almost independent of the structure of the compound and of other parameters, such as time, temperature or pH. The saturation value depends on the fibre and is reached quickly, assuming that diffusion into the interior of the fibre does not occur or only occurs very slowly (Contributed by Fischer).

Cationically dyeable polyester fibres Polyester fibres can be modified into cationically dyeable polyester fibres by the copolycondensation of terephthalic acid and 5-sodium sulphoisophthalic acid with ethylene glycol.

Cationic-dyeable polyamide



Dyeing mechanism:

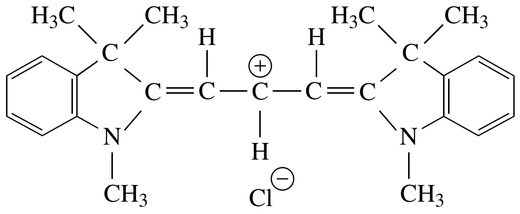


Cationic-dyeable polyamide → Differential dyeing polyamide fibres.

Cationic dyes (basic dyes). Included here are all salts of organic dye cations applicable in accordance with an ion exchange mechanism. They belong among the oldest synthetic dyes, can be fixated on practically all natural fibres, and were therefore of great importance in earlier days. The most important textile application field today is polyacrylonitrile dyeing and, to a lesser extent, anionically modified polyamide dyeing. Among the cationic dyes strongly represented are anthraquinone and azo dyes with quarternary ammonium or phosphonium groupings, plus cyanine and hemicyanine dyes, the methine groups of which are partially or completely substituted in the cyanine chain by nitrogen. Cationic metal complex dyes have been suggested in the patent literature for dyeing polyacrylonitrile fibres. Anchoring principles on polyacrylonitrile and anionically modified polyamide: the anionic nature of polyacrylonitrile fibres is based to some extent on the sulphuric acid semi-ester groupings which are derived from the persulphates used as starters in polymerisation. To this are added sulphonate groups of comonomers which substantially improve the dyeability of the polymerisate. These ionic substituents will not be associated with protons, even in a strongly acid medium. Ion exchange, i.e. the absorption of the cationic dye, cannot therefore be controlled by dyebath pH. In the interest of levelness therefore, one operates in accordance with the principle of "concurrence around the bonding points" with cationic retarding agents (retarders). Anionic retarders, which the dye cations virtually freeze in the form of difficult-to-dissolve finely distributed salts in the presence of dispersing agents, operate on the opposite basis. Of advantage for most cationic dyes is the conspicuous brilliance due to a narrow, steep absorption band, which goes along with high colour intensities and favourable production costs. The disadvantage is unsatisfactory light fastness, which impairs finish dyeing particularly on hydrophilic fibres.

Dyes, the total molecule of which is positively charged in dissociation in water, qualify as cationic. Typical representatives are:

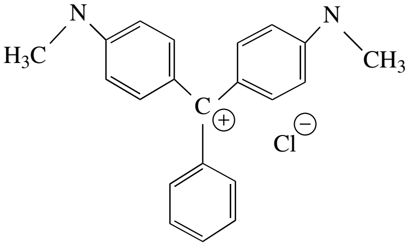
1. Cations in carbenium structure form:
   - Polymethine dyes as cation cyanines.



Carbenium structure

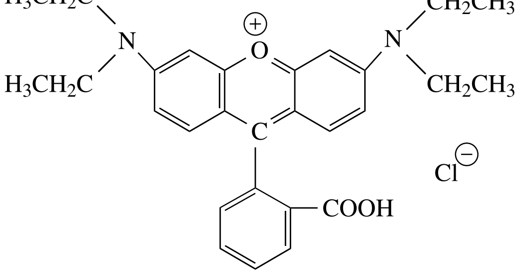
   - Triphenylmethane dyes, e.g. malachite green.

Carbenium structure



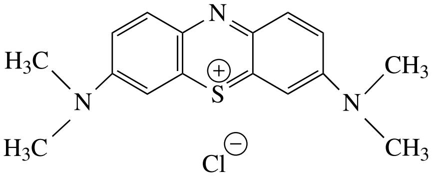
2. Cations in oxonium structure form:
   - Xanthene dyes, e.g. Rhodamin B.

Oxonium structure

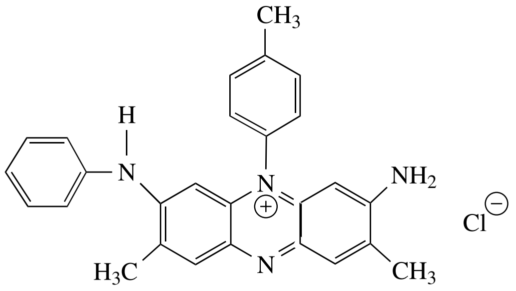


3. Cations in sulphonium structure form:
   - Phenthiazine dyes, e.g. methylene blue.

Sulphonium structure

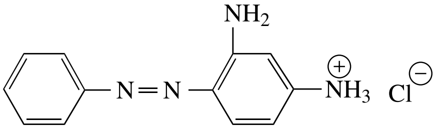


4. Cations in ammonium structure form:
   - Phenazine dyes, e.g. mauvein



Ammonium structure

or chrysodine.



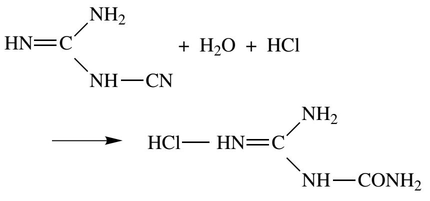
Cationic pretreatment This treatment – also called mordanting – is used with cellulose fibres in order to make them absorptive to cationic dyestuffs. Such mordants are tannin, sulphuretted phenols etc.

Cationic protein derivatives Quarternary "Croquats" for hair care cosmetics with polypeptide chain and fatty alkyl groups are also interesting from the textile chemical standpoint. 3 types of different alkyl groups:

Type L: contains the $C_{12}H_{25}$ alkyl group;
Type M: contains the $C_{10}H_{21}$-$C_{18}H_{37}$ alkyl groups;
Type S: contains the $C_{18}H_{37}$ alkyl group.

Have marked surface activity properties (wetting, foaming), biocidal activity (slightly germicidal), and at the same time are much more substantive than conventional protein derivatives.

Cationic resin Salt-type but high molecular condensation product synthetic resins of similar construction to cationic textile auxiliary agents, which are more or less water-soluble despite a high degree of cross-linking, have available adequately salt-forming groups with acids, and are therefore split into ions to some extent in aqueous solution, the resin-forming components being present as cations. Thus for example, dicyandiamide can be condensed with formaldehyde in the presence of hydrochloric acid, part of the dicyandiamide becoming saponified to dicyandiamidine salt:



$$\mathrm{HN{=}C(NH_2)(NH{-}CN)} + \mathrm{H_2O} + \mathrm{HCl} \longrightarrow \mathrm{HCl{-}HN{=}C(NH_2)(NH{-}CONH_2)}$$

The condensation product obtained is water-soluble. Through suitable mixing of the amine salts of more strongly basic amines in acid condensation with formaldehyde one obtains the most favourable proportions in terms of solubility and cross-linking. Such cationic resins also react on the principle of → Cationic aftertreatment as compared with anionic dyestuffs, insoluble salts forming from the resin cation and the dyestuff anion. Tendency to a lower degree of shade change than with cationic textile auxiliary agents, the softness of which is achievable with a small addition of cationic softener. With relevant dye selection (copper after-treatment dyestuff and sulphur dyes too in part), cationic resin combination products with copper salt provide good light fastness in addition to very good fastness to washing up to 60–75°C in the dyeing of spun glass yarns, in wet and dry strength improving preparation for glass fibres, in washing and cross-dyeing fast delustring, and with water-repellent agents, flame retardant agents (phosphoric acid counterions) etc.

Cations → Ions.

Cat's eye resin → Dammar resin.

Cattle hairs (cows' hairs). The most valuable from the technical spinning standpoint is the tail hair, similarly also curry comb hairs. In contrast is tannery waste hair, which is mainly used for felt and cheap coverlets etc., highly enriched with lime salts which have to be removed prior to finishing (dyeing etc.).

Cause and effect diagram Work analysis tool that enables the systematic structuring of problems. If, for example, the question is asked: what are the influences on achievable production results? the answers can be structured and organised with the aid of this tool. It is best to divide problems roughly as a first step. This can be done under the headings as shown in the Fig.:

- people (knowledge, training),
- methods (processes, recipes),
- materials (consumables),
- machines (equipment, tools),
- standards (specifications, instructions),
- information (what has changed).

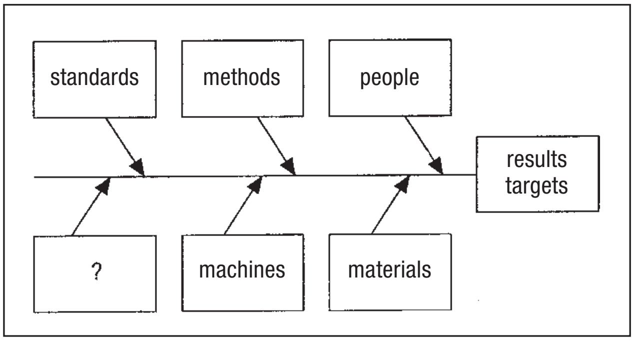


Fig.: Cause and effect diagram.

Additions or deletions can be made at any time. It is also possible to single out an individual point and to divide it up again. The advantages of this method of working are:

- contributions of individual colleagues can easily be classified,
- gaps in the collection of materials are recognised more rapidly,
- allocation to the individual points of view invites further contributions,
- the diagrammatic presentation facilitates communication.

Causticaire method is used for assessing the ∅ ripeness of cotton by treatment with alkalis of different concentrations.

Caustic alkalies → Alkalies; Caustic soda; Potassium hydroxide.

Caustic ammonia → Ammonium hydroxide.

Caustic discharges → Alkaline discharges.

Causticizing Treatment of cellulosic fibre woven fabrics with approx. 15–30°Baumé caustic soda without tension. The lye temperature is kept low to advantage – approx. 10–20°C. Causticizing shrinks and compacts the woven fabric, and increases dye uptake in dyeing and printing. Special machines (Fig.) of any make are used for this purpose. There are also special causticizing machines, comprising a padder and a short expander roller unit. The fabric, impregnated with lye, remains in the roll for some hours, and is then rinsed off. For regenerated cellulose fibres, the treatment is carried out in open width and without tension. Lye concentration moves between 2 and a maximum of 10°Baumé at a temperature between 15 and 25°C. Cotton fabrics are impregnated with lye on a padder, rolled up, left to dwell if necessary, then washed and neutralised. Lye concentration 10–30°Baumé. Used for example for producing imitation suede leather on warp knitted fabrics (described as “Limbach products” or “simplex”), and also in the chemical finishing of woven cotton stretch fabrics and → Crêpe prepared by steeping in caustic soda (crêping).

Causticizing number Test process which is based on the differing affinity of a mixture of green and red substantive dyes for untreated and causticized or mercerised cotton. Cannot be used in the presence of unripe fibres. The difference can be determined in figures by colorimetry.

Caustic potash solution → Potassium hydroxide.

Caustic printing process → Crêpe prepared by steeping in caustic soda.

Caustic recovery plants For recovering lyes from used liquors, increasing processing efficiency, and reducing effluent loading.

Caustic shock process Wet fixation process for reactive dye prints. Principle: print fabric with printing paste, dry, pass for 20–60 s in open width through a strong, boiling alkali bath containing electrolytes (roller vat), and then wash off. Variants as steam-wet fixation processes for viscose: brief presteaming for 3–5 min before the caustic shock process produces a deeper shade on viscose.

Caustic soda → Sodium hydroxide.

Caustic soda liquor → Sodium hydroxide.

Caustic soda, soda process for water softening A simpler process than the Lime-soda water softening process (i.e. without lime saturators), but involves higher costs for chemicals. Here, the principle used is that of calcium exchange through caustic soda (sodium hydroxide), which during softening to some extent forms soda (sodium carbonate), and consequently requires a lower addition of soda.

Caustic soda solubility test Test used for chemical fibre differentiation. Action of caustic soda (sodium hydroxide) 1 : 10. Result: insoluble = viscose, slightly

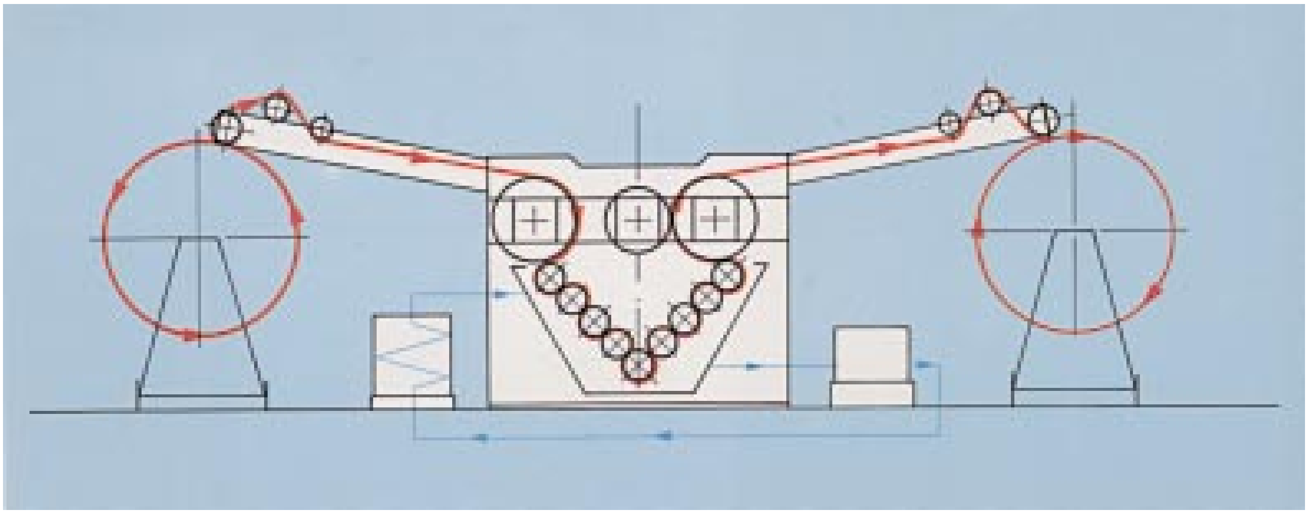

Fig.: Cibi causticizing machine.

yellowed; acetate somewhat swollen; cotton, flax = yellow; jute = brown; soluble in a cold medium = wool and soluble in a hot medium = silk.

CAV, abbrev. for: critical add-on value.

Cavitation (Latin). Hollow space formation, e.g. as a wear phenomenon due to the hollowing of material components (wood, metal, masonry) by liquid droplets like pitting etc. Cavitation is also familiar in dye liquor, where for example vapour pressure at 85–100°C increases so quickly that normal centrifugal pump action is no longer guaranteed. On the suction side, i.e. in the low pressure zone, liquid vapour tension can then result in the formation of vapour bubbles, reducing pump efficiency, which can fall to zero. This cavitation is encountered in HT dyeing.

Cb, former symbol for the element Columbium which is now known as Niobium (Nb).

Cb fibre (chemical bonding fibres) → Binder fibres.

CC,

I. → Coconut fibre, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

II. → Cupro fibres, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988. From 1991 → CUP.

cc, abbrev. for: cubic centimetre.

CCC, abbrev. for: Central Classification Committee/NL, The Hague, Holland (FID/CCC-UDC) = international Central Classification Committee of the FID (Fédération internationale de documentation); → Technical and professional organizations.

CCM, abbrev. for → Computer colour matching.

CCol, abbrev. for → Chartered Colourist.

CCS, abbrev. for: Comisiade Standardisonea; Rumanian Standards Institute; → Technical and professional organizations.

Cd, symbol for cadmium.

Ce, symbol for cerium.

Ceiba fibre It is a yellowish, silky, seed hair of the South American bombax tree, also known as silk cotton. Mainly used as a stuffing material. → Fruit wall hairs.

CELAC, abbrev. for: Centre de Recherche et de Contrôle Lainier et Chimique, Verviers, Belgium (Belgian Research and Testing Centre for Wool and Wool Chemistry); → Technical and professional organizations.

Cellobiase An enzyme occurring in malt, germinating spinach, oats etc., which degrades → Cellobiose to glucose. It is encountered *inter alia* as a secretion of certain bacteria particularly in fish nets, etc. (→ Microbial damage to textiles).

Cellobiose Disaccharide produced on partial hydrolysis of cellulose, made up of two glucose units joined by a β,1,4 linkage. → Cellulose.

Cellophane (Cellulose skin, cellulose film). Transparent cellulose film. Practically impermeable for air, bacteria, organic solvents, grease, etc. Application: as packaging, bottle tops, adhesive tape, as safety glass, textile fashion material and basketwork, etc.

Cellosolve (ethylene glycol monoethyl ether), $C_2H_5O(CH_2)_2OH$, colourless liquid, practically odourless, miscible with hydrocarbons and water. Combustible. MW 90, density 0,93, b.p. 130–138°C, flashpoint 40°C, evaporation number 43. Does not dissolve acetate fibres. Uses: solvent in dyeing and printing for cationic, acid and indigo dyes, solvent for nitrocellulose, natural and synthetic resins.

Cellular Resembling or consisting of cells; multicellular = having many cells.

Cellulase is an enzyme (polyase) that degrades cellulose to cellulose dextrins. It is extracted from certain bacteria, among others, and together with → Cellobiase leads to fibre damage in cotton (→ Microbial damages to textiles). Cellulose is the most commonly encountered compound in the biosphere and more than half of the total organic carbon is held in cellulose. Cellulose is an unbranched polymer of glucose units that are joined to one another by β-1,4-bonds. Mammals do not produce cellulase and so they cannot digest wood and vegetable fibres. However some ruminants have cellulase-producing bacteria in their digestive tracts and can therefore digest cellulose.

There are several micro-organisms that can grow using cellulose as their only source of carbon and energy. Apart from certain bacteria, e.g. cellovibrio, cellulomonas, pseudomonas, actimycetes and some anaerobic strains, these are mainly fungi that produce mycelia. The most active cellulose-degrading strains of fungi known to date are trichoderma viride (reesei), trichoderma lignorum, trichoderma koningii, penicillium funiculosum, penicillium iriensis and fusarium solani. These micro-organisms play an important role in the Earth's carbon cycle.

Investigations into enzymatic cellulose hydrolysis, mostly carried out with certain strains of fungi, show that there are at least the following three enzyme systems involved in the process (Fig. 1):

1. Endo-β-1,4-glucanases split the chains of native cellulose in the middle. Structures with lower degrees of crystallinity are destroyed in the process and a lot of free chain ends are formed.
2. Exo-β-1,4-glucanases (cellobiohydrolases) split cellobiose units from the ends of the cellulose

A natural cellulose $\xrightarrow{\text{endoglucanase}}$ cellulose*
B cellulose* $\xrightarrow{\beta\text{-glucosidase}}$ cellobiose
C cellobiose $\xrightarrow{\text{exoglucanase}}$ 2 glucose

Fig. 1: System of cellulases for cellulose decomposition. (with numerous free chain ends).*

chains and hence work in synergically with the endoglucanases.

3. β-1,4-glucosidases hydrolyse the cellobiose to glucose.

The endocellulases produce amorphous cellulose from crystalline cotton.

If an enzymatic degradation of the cotton chains is being considered, it has to be noted that the activity of cellulases falls with increasing lignin content (Fig. 2) (contributed by H. Sahm).

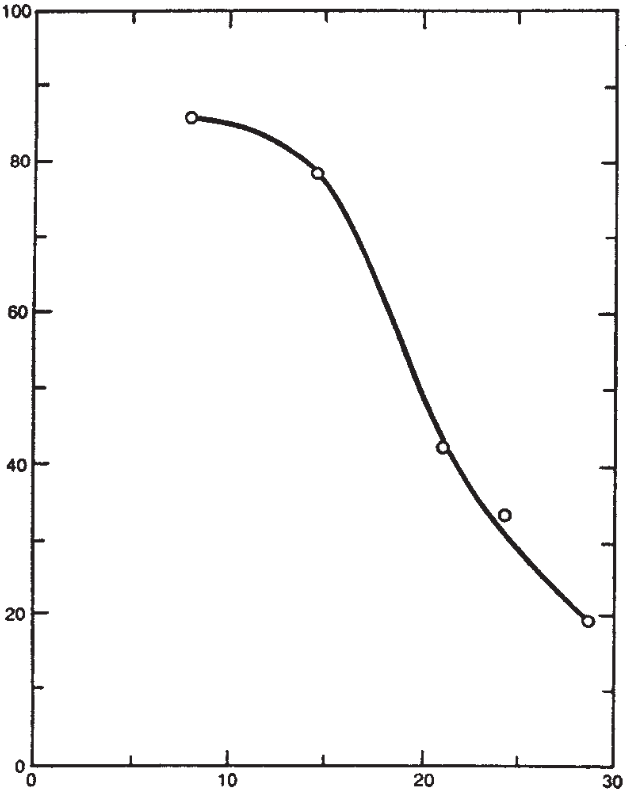

Fig. 2: Prevention of the cellulose decomposition of wool burrs with cellulase (of T. viride) in the presence of lignin. ordinate = cellulose splitting [%]; abscissa = lignin in the cellulose material [%].

Celluloid is a “solid” solution of → Camphor and → Collodium cotton. Glassy, transparent, strong and elastic in the pure form, softening at 80°C, often coloured (moulded products). Highly flammable. Uses: moulded articles of all types (as a substitute for horn, tortoise shell, ivory). In the textile sector used for buttons, washable glazed clothing (celluloid collars), oilcloth and so on; also in bronze printing (e.g. in so called zapon varnish).

Cellulose is the most important component of plant cell walls. The term “cellulose” has different meanings in the various branches of science. In 1847, the botanist Payen originally called the main component of plant cell walls cellulose. Botanists still use the word in this sense, no matter whether the plant is a flowering plant, a fern or an alga. Fibre technology understands cellulose to mean the material that can be isolated from a small number of plants by definite chemical processes. For chemists, celluloses are high molecular weight substances made up of D-glucose residues, joined together in the β-position. Finally crystallographers use the word cellulose to describe a crystalline substance with a well defined unit cell.

Only a few celluloses fulfil all these definitions. If the non-cellulosic components of the cell wall are removed one after the other by boiling with water, hypochlorite (to give halocellulose) and treatment with 4N caustic potash, so called α-cellulose can be obtained as microfibrils with the minimum loss of weight. The microfibrils are long, fine fibres with diameters of about 10–20 nm. The α-celluloses are made of pure glucose units only in very rare cases, e.g. in the algae valonia and cladophora. All other α-celluloses contain small amounts of other sugars. For example, apart from 1.5% xylose, cotton contains smaller amounts of mannose, galactose and arabinose. The α-cellulose of the red alga rhodymenia palmata on the other hand contains 50% of xylose. Even in this case the x-ray pattern is exactly the same as that of the α-cellulose from valonia. There must be a paracrystalline layer of the other sugars surrounding a crystalline core of eucellulose (100% glucose).

Cellulose is found in a fairly pure form in the seed hairs (cotton) and stems or leaves (flax, hemp, ramie) of many plants. As only mechanical separation is needed for technological purposes, such processes have been used for thousands of years. In more recent times cellulose has also been obtained from hard and soft wood as well as from the stems of annual plants using non-mechanical separation processes. Cellulose is found with non-cellulosic components, making up up to 40% of lignified cell walls. These non-cellulosic components consist of up to about 70% of lignin and up to about 30% of the so called hemicelluloses (short chain polysaccharides made of non-glucose sugars such as mannose, galactose, xylose, arabinose, uronic acid). Cellulose is built up from D-glucose residues (→ Glucose). D-glucose is one of the $2^4 = 16$ possible hexoses. The aldohexose group consists of the sugars allose, altrose, glucose, mannose, gulose, idose, galactose and talose.

The constitution of cellulose was proved by total hydrolysis, which gave more than a 95% yield of glucose. When the cellulose is permethylated with dimethyl sulphate before the hydrolysis, 2,3,6-trimethyl glucose is obtained. The glucose residues must therefore be joined in the 1,4-positions. Cellulose is degraded enzymatically only by β-glucosidases: the bonds are therefore β-glucoside. The optical rotation of the disaccharide cellobiose also supports the presence of β-glucoside bonds. Cellobiose is obtained by de-

Modification	Source (natural)	Production (synthetic)
Cellulose I (native cellulose)	Cellulose-containing algae	From III with H_2O under pressure
Cellulose II (cellulose hydrate)	Helicystis algae	Dissolution and reprecipitation of I; mercerized fibres
Cellulose III	–	Careful decomposition of cellulose-ammonia
Cellulose IV	Coltsfoot	Heating II in glycerine to 290°C

Tab.: Cellulose modifications.

grading cellulose with acetic anhydride. The specific rotation of cellobiose is + 35º, compared with + 136º for the diglucoside maltose. In the D-series, the rotation of the α-form is always more positive than that of the β-form. For example the rotation of α-methyl-D-glucoside is + 159º compared with – 34º for β-methyl-D-glucoside. In addition, x-ray analysis also shows β-glucoside bonds.

The molecular weights of native celluloses are very high. If cotton is harvested before the capsules have opened and is kept away from light and oxygen, the degree of polymerization, DP = 13 000. Cellulose is not soluble in water. The reasons for this are intramolecular hydrogen bonding as well as the high x-ray crystallinity of about 60% and the consequent high enthalpy of melting. However, cellulose can be dissolved in metal complexes such as cuoxam ($[Cu(NH_3)_4]^{2+}$), cuen ($[Cu(H_2NCH_2CH_2NH_2)]^{2+}$) or sodium iron tartrate (a complex of $[(C_4H_3O_6)_3Fe]Na$ with HOOC–CHOH–CHOH–COOH). This is less sensitive to oxidation than are cuoxam and cuen. Hydrate complexes of cellulose may be present in this solvent.

Cellulose can occur in various crystal modifications that have different dimensions and angles of the unit cell (see Table). The exact positions of the hydrogen bonds in the various modifications are not known. Both the glucopyranose residues in cellobiose are in the chair form and all the OH and CH_2OH groups are directed equatorially. There is an intramolecular hydrogen bond between carbon atoms 3 and 5 and there are also 7 intermolecular hydrogen bonds. Two fibre molecules are present in the elementary cell of cellulose I. They probably run antiparallel as both ends of the microfibrils reduce silver ions.

A density of 1.59 g/cm^3 is accepted for the closest packing. However because of the volume fraction between the micelles, cellulose fibres have densities of only 1.50–1.55 g/cm^3. The density of native fibres in much lower because of this intermicellar volume. For cotton, it is only 1.27 g/cm^3.

The different methods for determination of the crystallinity give different values for cellulose. The differences are due in part to the different ways in which the methods take averages and in part to the fact that when chemical methods are used, the original physical structure can be altered to some extent (swelling and so on). The crystallinity of cotton cellulose is 60–70% (contributed by Elias).

Cellulose acetate (Acetate cellulose, acetyl cellulose, cellulose esters of acetic acid). Differentiated according to the number of bonded acetic acid residues, into diacetate and triacetate (see Table).

Structural principle: → Cellulose derivatives. In chemical terms, the so-called diacetate, the raw material of the acetate fibre, is a chemical $2^1/2$-acetate, which is to be regarded as a mixture of various esterification stages between di- and tri-acetate. In terms of manufacture, there are close connections between both cellulose acetates. → Acetate fibre.

	Triacetate (primary acetate)	2 1/2-acetate (secondary acetate)
Formula	$[C_6H_7O_2(CH_3COO)_3]_n$	$[C_6H_7O_2OH(CH_3COO)_2]_n$
Acetic acid content	60–62%	53–56%
Typical solubility:		
org. solvent	rather insoluble	rather soluble
acetone 80%	insoluble	soluble
acetone	partially soluble	immediately soluble
glacial acetic acid	only soluble when boiling	soluble even when cold
Used for (e.g.)	triacetate silk, fibre foils lacquers raw materials for drive belts	acetate silk, fibre foils films, lacquers for paintwork fixing agents for bronze-and pigment printing

Tab.: Comparison of cellulose $2^1/2$-acetate and triacetate.

Cellulose acetate in textile printing As thickening agent and substance carrier (→ Metal powders) which is fixed by heat (steaming), e.g. in → Pigment printing.

Cellulose combustion It takes place in 3 main phases of pyrolysis:

1. Formation of → Laevoglucosan.
2. Formation of volatile gaseous or liquid decomposition products.
3. Combustion/afterglow of the resulting carbon residue.

Cellulose, degree of polymerization The → Average degree of polymerization of various cellulosic fibres is as follows:

Cotton approx.	3000–6500
Ramie	(>) 2700
Flax	2500–9200
Hemp	2200

Cotton, spun	approx. 1200
Wood pulp	700–3000
Cupro filament	400–600
Viscose filament	(>) 200–460
Acetate filament	175–360

It should be noted that, in the case of regenerated cellulosic fibres, chain lengths above DP = 800 are no longer capable of being spun. The DP values of cellulosic fibres decrease rapidly as a result of strong oxidation and hydrolytic action, together with the tensile strength. Thus hydrocellulose for example rapidly reaches values of 300–200; below 150–100 disintegration to powder already occurs.

Cellulose derivatives These include cellulose ethers and cellulose esters. The Fig. shows a schematic comparison of the structural principle.

I. Cellulose ethers: created through the exchange of the H or OH group with → Alkylenes, therefore alkyl cellulose. Characterised by evenness and purity, resistance to temperature, fermenting, moulding etc. Depending on the degree of alkylation, excellent stiffening agent for sizes, finishes, print thickeners, also emulsifiers, etc. →: Methylcellulose; Oxy ethylated cellulose; Carboxymethylcellulose. Also serves as a water repellent.

II. Cellulose esters: derivatives with substituted → Acyclic compounds. Inorganic cellulose esters are best known as → Nitrocellulose for collodion cotton, nitrocellulose lacquers, artificial leather and wax cloth manufacture. Organic cellulose esters are very important for the manufacture of chemical fibres, monofilaments and foils, such as e.g. acetate cellulose and triacetate fibres; for the production of immunised, passive and amine yarns (immunisation); more important as wash-resistant water-repellent effects; for permanent finishes; also for lacquers, finishing agents (formerly for coatings), print thickening agents, and binding and fixing agents for pigment printing.

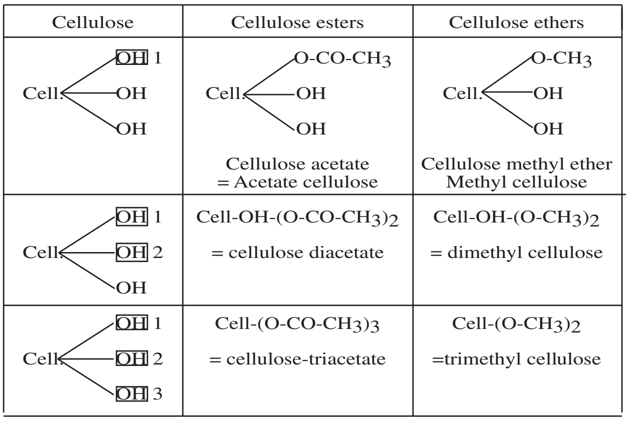

Fig.: Structural principle of cellulose ethers and cellulose esters.

Cellulose diacetate →: Cellulose acetate; Acetates.

Cellulose dyeings, identification tests → Dye class identification on fibres.

Cellulose dyes An overview of the relative market shares for various dye classes suitable for cellulosic fibres is given in the figure. The areas occupied by the respective dye ranges correspond to sales volumes converted to quantities of comparable effect. The centre point of each area corresponds to the assumed average costs along the horizontal axis. The shape of the areas has been estimated. The value of these comparisons can be demonstrated by taking direct dyes as an example. At the lower left of the figure are pale dyeings for which dyestuff costs can be ignored since, for practical purposes, only the process costs need be considered here.Towards the middle of the area there is an upwards protrusion which represents the area occupied by aftercoppering dyes. At the far right of the area are deep dyeings involving an aftertreatment.

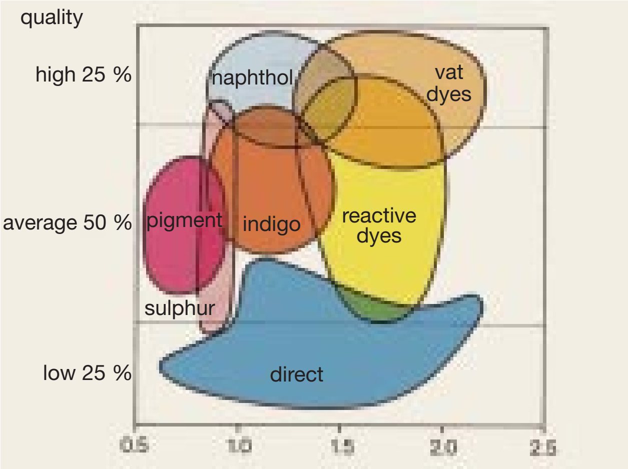

Fig.: Cellulose dyestuffs 1983.

The overlapping zones are clearly recognizable. In these areas there is intense competition. A typical example here is the transition zone from medium to high quality where, in the main, reactive or vat dyes are used which also provide an alternative to naphthol dyes. Pigment colorants are a cost effective choice for the medium quality zone but only if they meet the specified quality criteria. When additional criteria such as, e.g. fabric handle, are involved, the relative positions may change (Christen and Horstmann).

Cellulose esters → Cellulose derivatives.

Cellulose esters of acetic acid → Cellulosic fibres, regenerated, e.g. acetate and triacetate fibres (cellulose ester fibres).

Cellulose ethers → Cellulose derivatives.

Cellulose fibre creasing behaviour → Creasing behaviour of cellulose fibres.

Next Page

Cellulose glycol ether → Oxyethylated cellulose.

Cellulose glycolate → Carboxymethylcellulose.

Cellulose methyl ether → Methylcellulose.

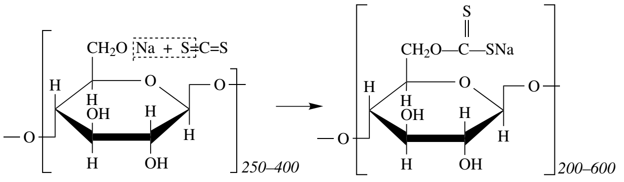
Cellulose nitrate → Nitrocellulose.

Cellulose, oxyethylated → Oxyethylated cellulose.

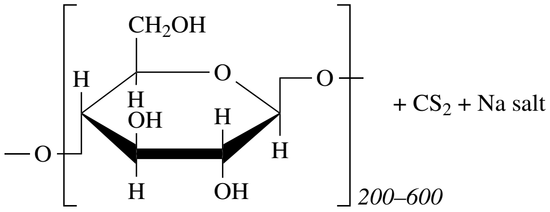
Cellulose synthetic fibres, old term for → Cellulosic fibres, regenerated.

Cellulose triacetate →: Cellulose acetate; Triacetate fibres.

Cellulose xanthate is formed as an intermediate product in the manufacture of viscose by the action of carbon disulphide on alkali cellulose (soda cellulose):



It is an orange-yellow, sulphur-containing, cellulose intermediate product and is dissolved in caustic soda to give the highly viscous viscose solution. During subsequent spinning through spinnerets and coagulation in a sulphuric acid bath the sodium cellulose xanthate is converted back into cellulose:



Cellulosic fibres Consist predominantly of → Cellulose and can be divided into:

I. → Natural cellulosic fibres;

II. → Cellulosic fibres, regenerated;

III. modifications, such as e.g. → Modal fibres.

Cellulosic fibres – latent damage Oxidation processes that cause an increase in the instability of the 1,4-bonds amount to latent fibre damage. These bonds are sensitive to alkali and can be broken in alkaline processes (including alkaline washing). The capacity for taking up dyes and the mechanical properties deteriorate. Measurement of differences in → Chain length is suitable for estimating this alkali sensitivity.

Cellulosic fibres, regenerated The group of → Man-made fibres includes textile fibres made of natural plant polymers. Classification (see Tab.):

I. Regenerated cellulosic fibres: →:Viscose fibres, Cupro fibres, newer regenerated cellulosic fibres, spun with the aid of newer types of solvent.

II. Cellulose ester fibres: →: Triacetate fibres, Acetate fibres, Alginate fibres, Rubber fibres.

III. Vegetable protein fibres: →: Zein fibre, Arachin fibre, glycine fibre.

Cellulosic man-made fibres are jet-spun, silk-like fibres made of regenerated or esterified cellulose, i.e. made of chemically soluble cellulose (cotton linters, straw, wood), which is extruded through jets and obtained as a solidified fibre structure by precipitation or evaporation,. They are used as filaments (including monofilaments such as artificial horsehair), or cut (staple fibre).

CEMATEX, abbrev. for: Comité Européen des Constructeurs de Matériel Textile (European Committee of Textile Machinery Manufacturers), Zürich. Founded in 1953. The main body is the Central Committee composed of delegations from associate members of 8 countries.

Amongst other functions, CEMATEX is responsible for organizing the ITMA international textile machinery exhibition.

Centi- Unitary prefix for one hundredth = 10^{-2}; e.g. 1 cm = 0.01 m.

Central atom → Complex compounds.

Central cylinder,

I. A smooth hollow roller, sometimes covered with wool or wool felt material (→ Printing cylinder) used in roller printing. Driven by contact pressure with the printing rollers.

II. The central main cylinder of raising machines and spinning machines (carding, combing machines).

Centre drive batcher Compared with a → Rising roll batcher, the batching roller on the centre drive batcher is powered, so that the batch in fixed bearings is driven at a variable speed. It is important for the tensile stress to remain constant, this being achieved by special drives. →: Batch drives; Hydraulic batch drive.

Centre lamella →: Flax long-fibre structure; Flax cell structure; lamella.

Centrifugal damping machine Centrifuge in which the material is pre-wetted or wetted during running, and where the wetting fluid is collected once more.

Centrifugal pumps (→ Pumps). Centrifugal pumps draw liquor from a horizontal intake into the pump casing (Fig. 1) from where it is discharged into circulation by an impeller mounted on a horizontal shaft which rotates at high speed. In a typical centrifugal pump, the liquor enters the pump axially into the centre of the eye of the rotating impeller and is discharged tangentially upwards into the outlet of the casing. As the liquor moves progressively from the eye to the periphery of the impeller, its velocity, and hence kinetic energy, is continuously increased by centrifugal forces. The pump and motor together form an integral block (Fig. 2).

Fig. 1: Cross section of a centrifugal pump.

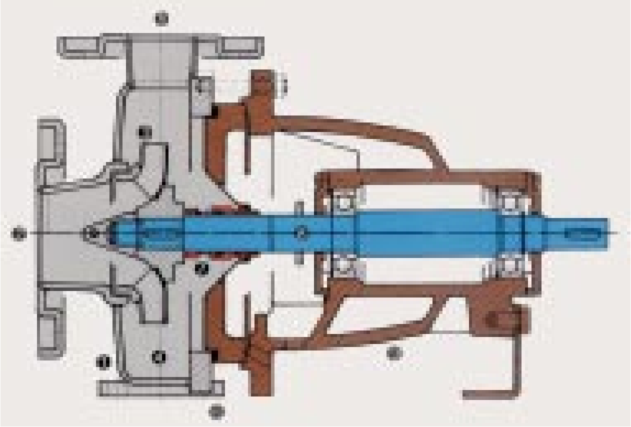

Fig. 2: Block construction of centrifugal pump and motor (Hilge).
6 = pump base; 7 = axial face seal; 8 = short shaft;
9 = three-phase A.C. motor and motor base.

For dye liquors containing dispersal particles which are likely to undergo irreversible changes under excessively high shear forces (e.g. disperse dyes), impellers with a special geometry are necessary so that contact between the walls of the pump and the liquor is minimized (Fig. 5).

To achieve a more gentle liquor transport, impellers with several curved blades are used so that the fluid particles in the rotating impeller zone are more loosely associated (Figs. 3 and 4).

Due to the nature of centrifugal pumps, the direction of liquor flow (Figs. 8 and 9) cannot be changed by changing the rotational direction of the motor. The characteristic curve of a Krantz centrifugal pump (Fig. 6) can be changed over a wide range by altering the

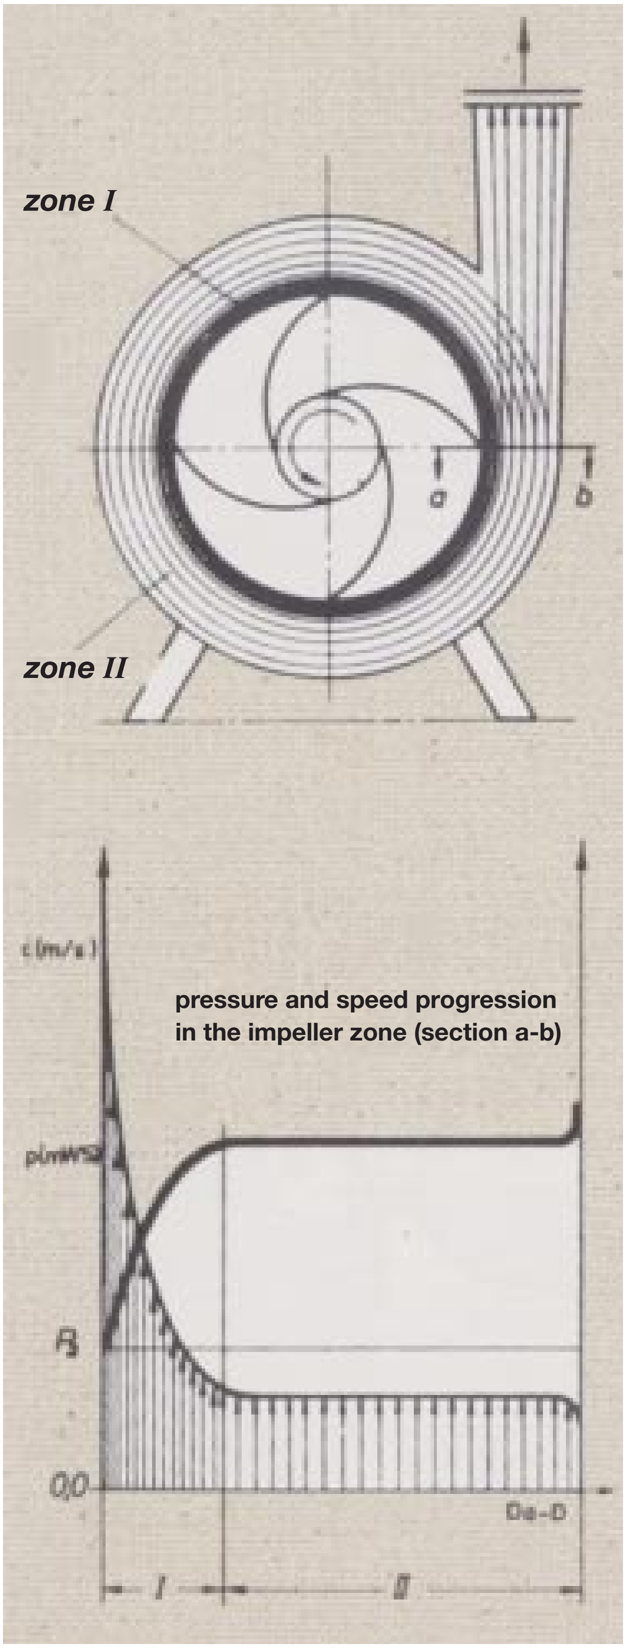

Fig. 3: The fluid particles are loosely associated in a rotating ring of liquid (Hilge).

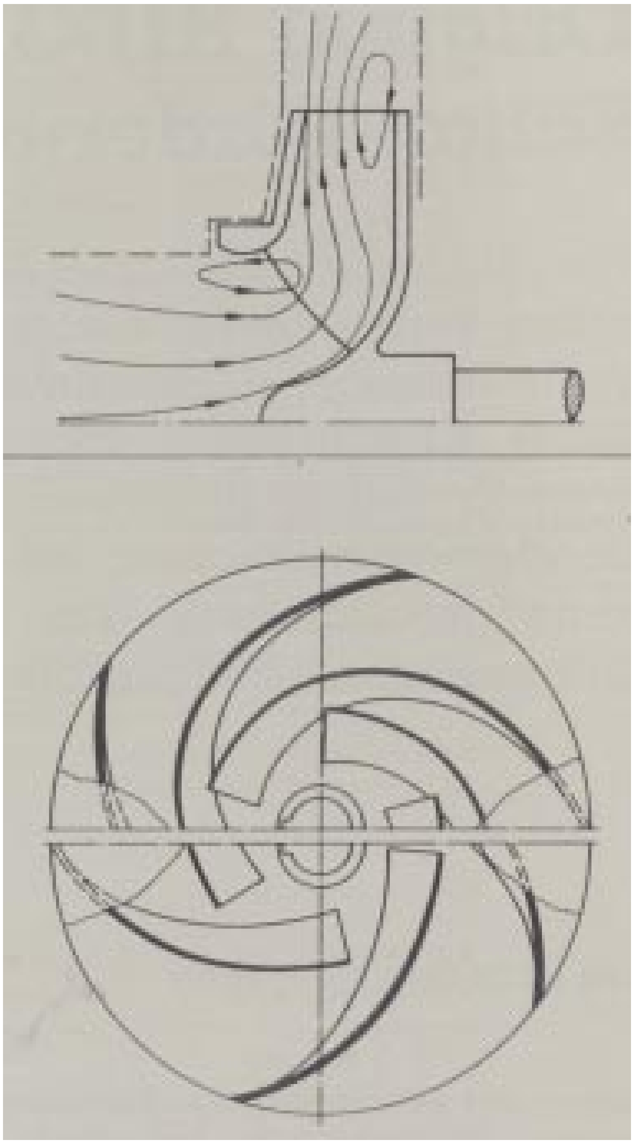

Fig. 4: Flow curves in a centrifugal pump (Hilge).

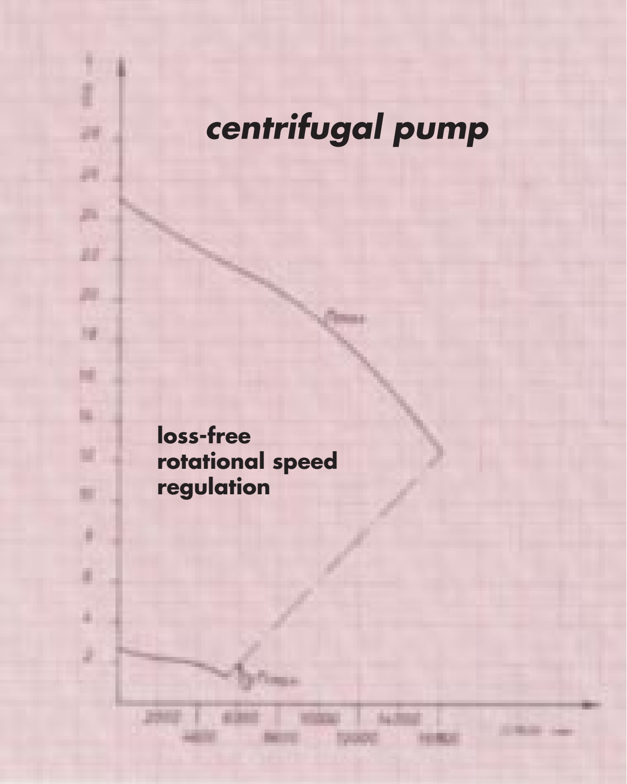

Fig. 6: Characteristic curve of a centrifugal pump.

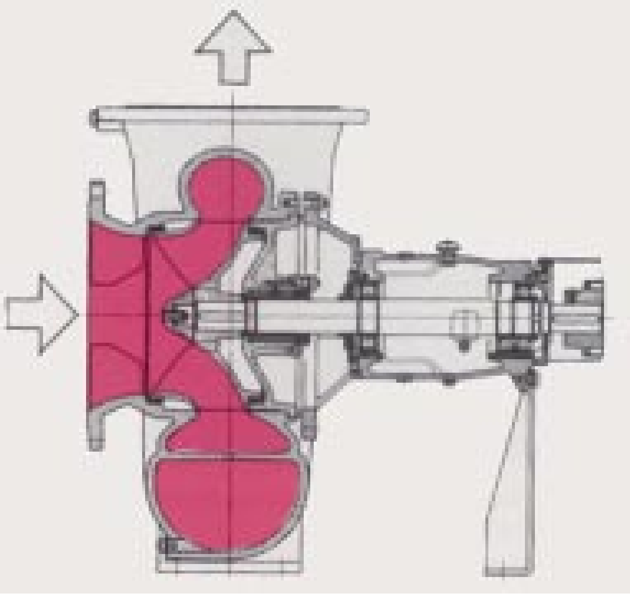

Fig. 7: Centrifugal pump for large volumes of liquor.

speed of the motor (an almost parallel shift is achieved) so that even very large volumes of liquor can be handled. Constructions in the periphery of the pump chamber are available to vary the direction of liquor flow without changing the rotational speed of the pump (Figs. 8 and 9). The liquor is fed e.g. to the suction side of the impeller via a hinged elbow. Several curved guiding vanes are arranged concentrically at the outlet. With this type of arrangement, the axial loads on the pump shaft counterbalance each other which is particularly important for trouble-free performance of the axial face seal and considerably reduces the load on the pump shaft bearings. Depending on the position of the elbow, which is driven by a servomotor, the illustrated functions (Fig. 9) are put into effect.

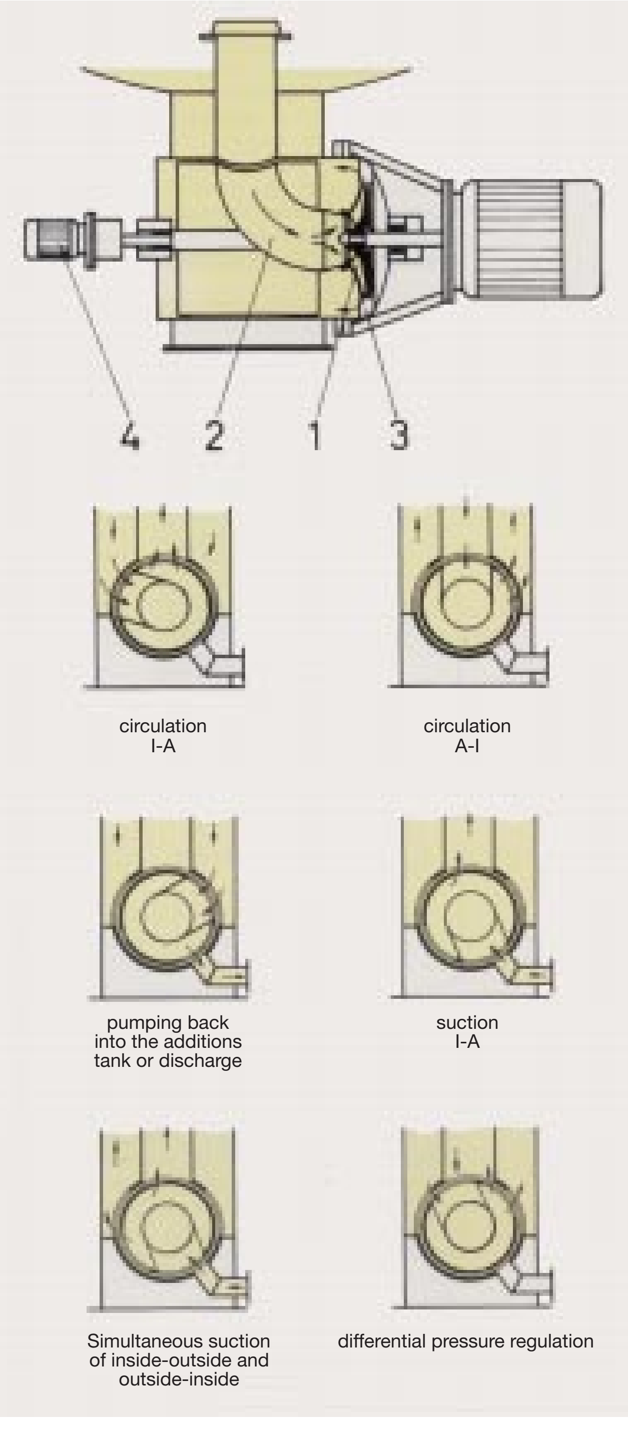

Fig. 8: Arrangements for changing direction of flow (Jasper).
1 = impeller; 2 = elbow; 3 = guide vane; 4 = servomotor.

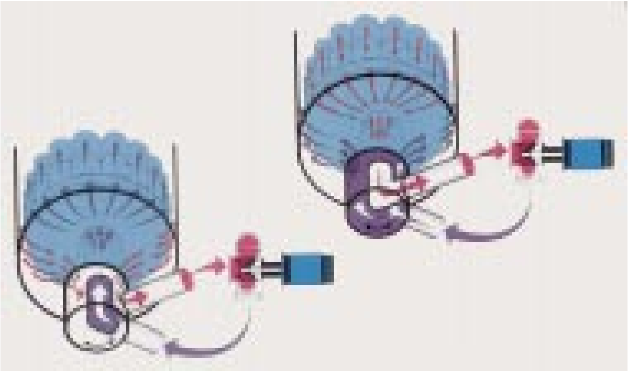

Fig. 9: "Alterator" of Krantz for change of liquor flow direction.

Centrifuge dyeing A new process for dyeing, bleaching, washing, softening and centrifuging in one machine (Fig.) , is possible. The centrifuge, which was jointly developed with the assistance of practical dyers from the textile industry, is suitable for the treatment of loose fibres (loose stock) as well as hanks of yarn in processing liquors. Most types of fibres in common use can be dyed by this process.

The machine layout of the centrifuge is represented schematically in the Fig. The Centri-Dye consists of the following components: dyeing centrifuge, preparation tank with pump, addition tank for the liquor and liquor pump, filter, heat exchanger, all necessary valves and other essential parts. The control system for the dyeing and centrifuging process is built into a floor-mounted service cabinet which is equipped with a frequency converter, an energy restorage unit for the braking operations as well as a programmable logic computer (PLG) for the running program which includes a monitor screen on which the actual state of the process is displayed.

In order to dye loose fibres they must first be press packed resp. wet stamped into cakes and lifting frames as for dyeing in conventional dyeing machines, after which they can be loaded, together with the lifting frames into the dyeing drum of the centrifuge. Hanks of yarn for dyeing can be loaded into the dyeing drum of the centrifuge in loose layers. Compared to the combination of conventional dyeing machine and centrifuge, considerable savings of water, dyes and auxiliaries, as well as energy, are achieved when dyeing is carried out in the Centri-Dye due to the lower liquor ratio and the smaller liquor pump which is only required to supply liquor to the centrifuge. These savings amount to: 30 to 40% of water, up to 50% of dyes and auxiliaries, 20% of energy and 20% dyeing time. Moreover, the transfer of material from dyeing machine to centrifuge is eliminated with this system.

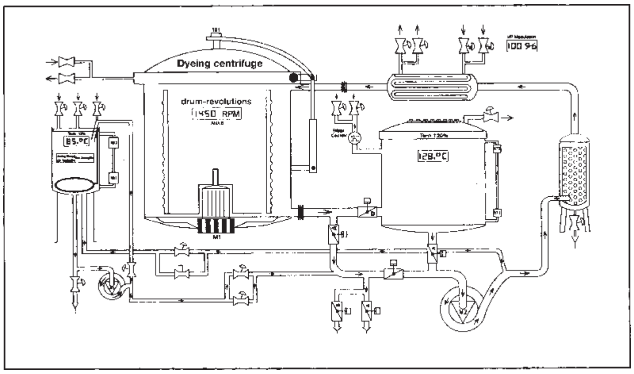

Fig.: Schematic representation of the dyeing centrifuge Centri-Dye from E. Mühlmann GmbH.

In the dyeing operation, liquor is pumped through the filter and heat exchanger into the dyeing drum of the centrifuge, where it is forced through the loose fibres/hanks of yarn by centrifugal force, then hydro-extracted from the drum to the additions tank from where it again circulates through the filter and heat exchanger back to the centrifuge. A level dyeing is also achieved due to the uniform centrifugal force produced in the centrifuge. A further advantage is that the drum does not need to be fully loaded. Good dyeing results are still achieved even when the centrifuge is only 20% full. Consequently, this centrifuge is also flexible for small batchers without the need to use liquor displacing elements. Also of advantage is the fact that the price of the Centri-Dye is lower than a combination of centrifuge and conventional dyeing vessel. Moreover, the pay-back period is quite short due to the high savings of water and energy. At present, this newly-developed dyeing centrifuge is available for 100 to 500 kg of loose fibre and 50 to 200 kg of hanks.

Centrifuge hydro-extraction → Water extraction.

Centrifuges (hydro-extractors). Centrifuges are used for → Water extraction (dewatering, pre-drying) of textile materials. Values of approx. 15% for residual moisture content can be achieved depending on the type of textile fibre. Centrifuges with perforated drums or baskets (Ø up to approx. 2000 mm) which oscillate vertically in ball-and-socket joints suspended on three points are produced in various designs as pendulating, suspension, cage and vertical centrifuges, also with so-called gliding support bearings as gliding support centrifuges or in horizontal resp. vertical arrangements as open-width, horizontal and warp-beam centrifuges, etc. Most centrifuges have electric drives for speeds of approx. 750–1200 rpm and are generally provided with automatic control over various ranges. For safety reasons, an interlocking lid is essential on a centrifuge so that the motor cannot be started until the lid is locked, nor the lid raised until the basket is stationary again after the machine has been stopped.

When used for dewatering loose stock, the cake of loose fibres is transferred from the dyeing machine to the centrifuge and hydro-extracted before it is run into

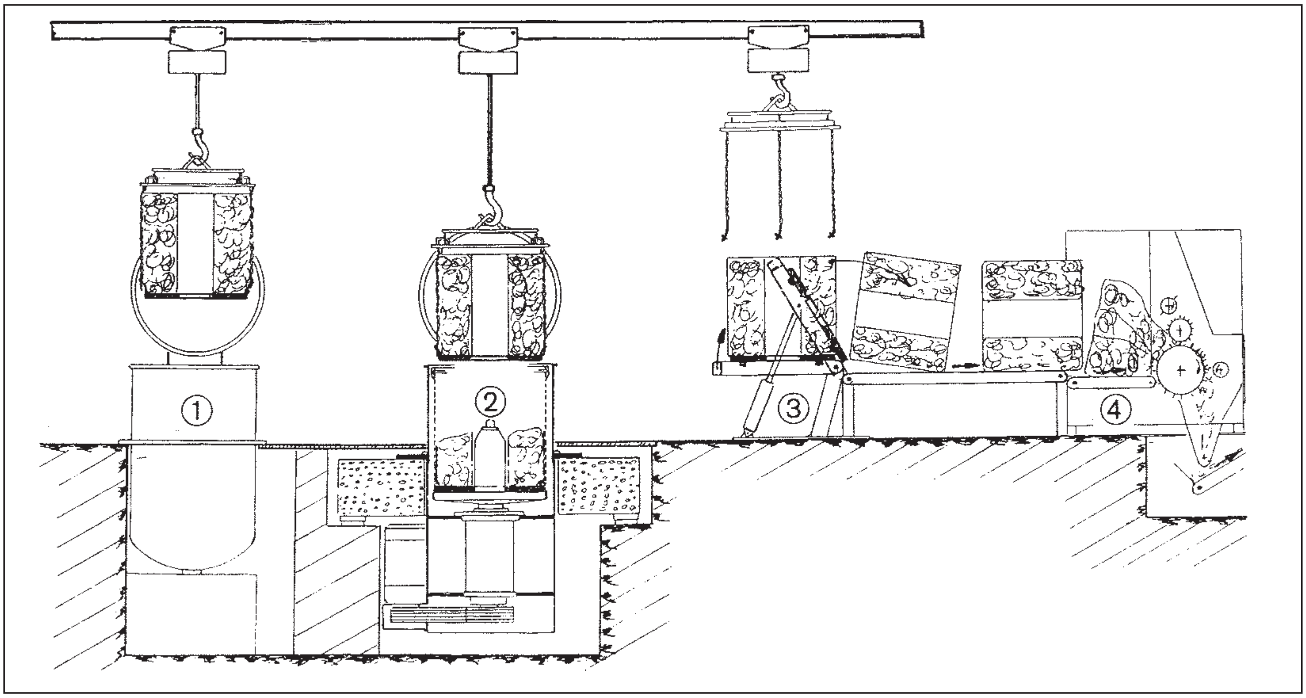

Fig. 1: Incorporation of a centrifuge in a working procedure for the treatment of loose fibres.
1 = bale removal from dyeing machine; 2 = hydro-extraction in centrifuge; 3 = removal of material carrier; 4 = bale opening.

the fibre opener as a preliminary stage of drying in a perforated drum drier (Fig. 1). If an immersion centrifuge is used, impregnation of the loose fibres with a spinning lubricant is also possible. In this case, the material is loaded into the centrifuge, liquor is then pumped in (until it covers the material), and the goods are finally hydro-extracted. The advantage of such a procedure lies in the fact that a separate treatment of the textile material in an impregnation vat and the reloading of wet goods into the centrifuge are eliminated (Fig. 2).

Impregnation of textile material in the impregnation basket of a centrifuge is generally quicker and more effective for all processes than in a vat. The centrifugal force which drives the liquor through the goods during centrifuging accelerates penetration. It is possible to carry out several processes one after the other in an immersion centrifuge. In this case, however, separate drain channels and liquor tanks must be provided. The basket of an immersion centrifuge has an outer casing without perforations which surrounds the cylindrical basket of a normal centrifuge (extended conically at the top). By this means, it is possible to fill it with liquor to the level of the upper rim. Only when the basket is set in motion does the liquor, which is driven outwards by centrifugal force, rise up the basket casing and run over the upper rim. Such impregnation processes can also be carried out on columns of yarn packages with the Krantz spray dosing system (Fig. 3).

Centrifuges for yarn packages

Fig. 6: Dyeing centrifuge (OBEM).

Loose fibre material (loose stock) can also be centrifuged continuously (Figs. 4 and 5).

For the dewatering of yarn packages, other possible options besides the asymmetrical dewatering of columns of yarn packages in suitably shaped compartments of the centrifuge (Fig. 6) include symmetrical dewatering by the rotation of individual packages (Fig. 7) or columns of yarn packages (Fig. 8) which involves less risk of package deformation.

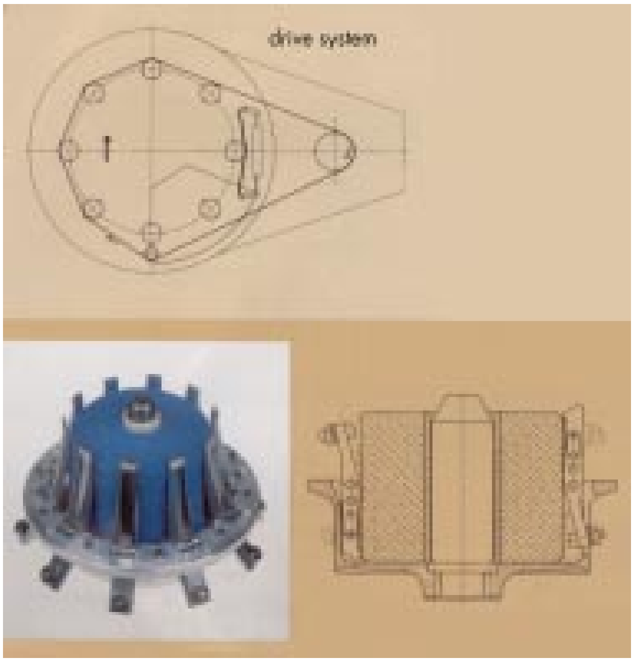

Fig. 7: Centrifuge for individual yarn packages (Frauchinger).

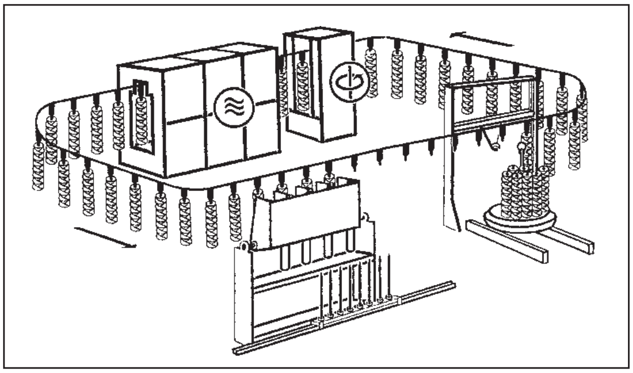

Fig. 8: Centrifuging system for columns of yarn packages (Thies).

Centrifuges for yarn packages,

I. → Centrifuges for removing water from cross-wound yarn packages on individual heads.

Centrifuges swelling The weight of water retained after centrifuging by a textile sample which has been impregnated with a swelling agent and centrifuged under standard conditions expressed as a percentage of the weight of material.

Centrifuging (printing paste). Are a → Print paste sieving machine in which the application of centrifugal forces enables impurities to be separated out of the print paste (clearing, separating and emulsifying cylinders).

Centring device An electronic device installed at the fabric entry of a flat-bed screen printing machine to balance out any irregularities in the dimensions of woven patterns for printed hand towels, neckwear and headscarves by the formation of transverse folds in the border separation areas before the fabric is glued to the printing blanket.

Centripetal action A developmental action (e.g. force, acceleration) starting at the outside and working towards the centre (i.e. the opposite of centrifugal force), e.g. flow phenomena in vortex or whirlpool formation. Centripetal filter → Filtration plants.

Ceramic fibres Industrially produced organically based fibres; artificial → Mineral fibres. These include silicium oxide and silicium carbide fibres, and aluminium oxide and aluminium silicate fibres for example. They are all resistant to high temperature, and find use in special technical fields.

Cerasin (Latin: cerasus = cherry; also metarabin). Cerasin is named after the source of this polysaccharide component in cherry tree gum (35–50%), but it is also found as at least α of the water insoluble fraction of normal rosaceous gums. The chemical composition should correspond largely to → Bassorin. However with nitric acid less mucic acid is produced than with bassorin. Solutions are produced after prolonged boiling, probably as a result of degradation of the material. It is known that with cerasin, as with arabic acid, the viscosity gets higher with increasing pH and then goes down again with excess alkali.

Ceresin wax (ozokerite, earth wax, mineral wax). Wax-like hydrocarbon mixture, mostly paraffins, high boiling point petroleum fractions and resinous substances. The wax is only of commercial value after purification. White or yellow waxy cake with a fine-grained fracture, virtually odourless and tasteless. The purified wax has a melting point of 60–85°C. Ceresin wax is not saponifiable. Uses: waterproofing textile fabrics, production of batiks, textile sizes, substitute for carnauba and beeswax.

Ceric sulphate (cerium IV-sulphate), $Ce(SO_4)_2 \cdot 4H_2O$. Water-soluble, yellow, crystalline powder. Density 3,91. Strong oxidizing agent in acidic solutions (similar to potassium permanganate). It is even stable to heating in solutions of sufficiently strong acidity. Uses: for volumetric analysis as a substitute for $KMnO_4$ in potentiometric tritrations (“ferroin” indicator). Occasionally used in dyeing aniline resp. diphenyl blacks.

Certification Certification in accordance with DIN ISO 9000 provides evidence that a company is capable of meeting consistent quality standards. This commitment to quality must be supported by following an effective quality assurance system. Certification and quality management (→ Quality assurance) are additional elements (Fig. 1).

The requirements for a particular product are set out in specifications which the producer undertakes to comply with. Agreement on specified requirements is mainly necessary in problem cases and can only be

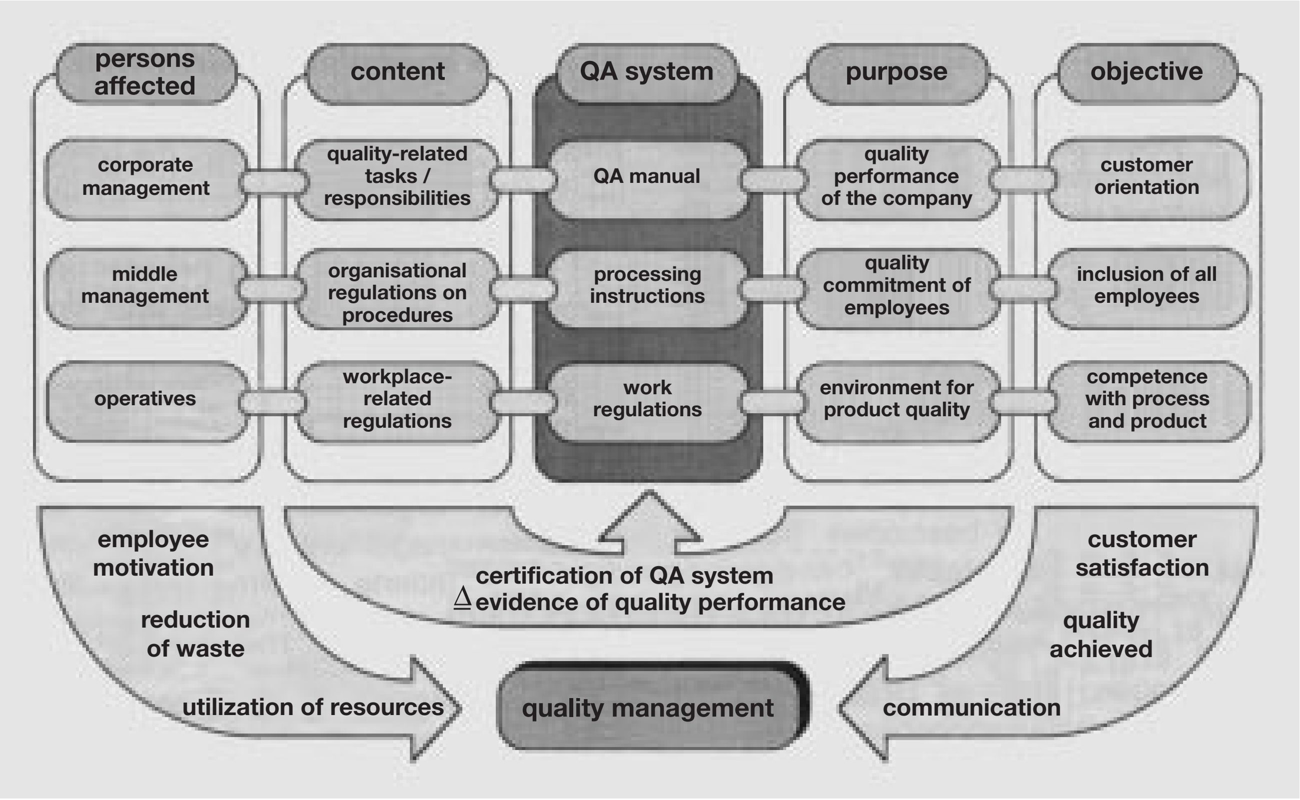

Fig. 1: Relationship between certification and quality management.

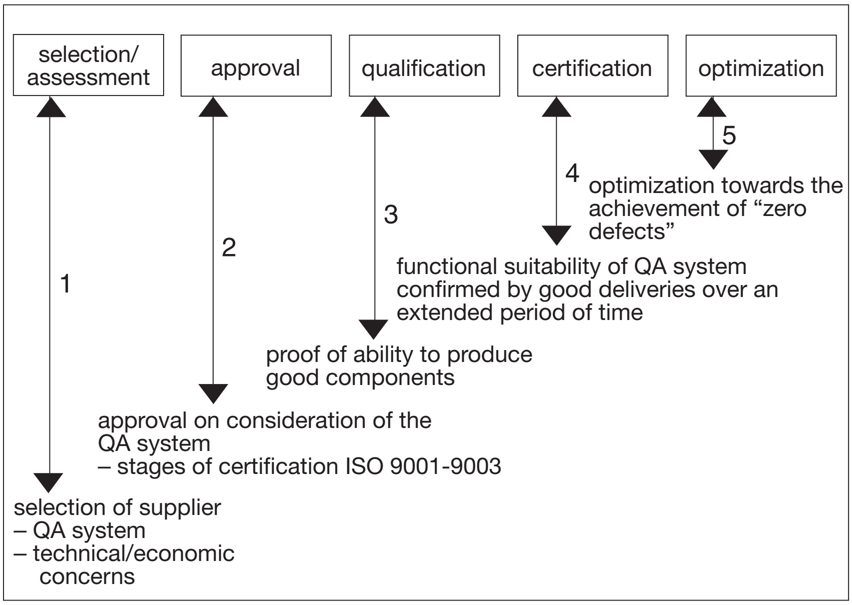

Fig. 2: 5-phase concept for quality assurance (IBM).

achieved through an intensive dialogue and exchange of information between customer and supplier.

The supplier is primarily assessed as to whether or not he meets the requirements of DIN ISO 9000. To this end, he must guarantee that he is applying the necessary quality standards at all levels and in all fields of his production. He is then in a position to transpose the customer’s requirements into his manufacturing operation and, by virtue of his technical competence, produce and supply routinely inspected goods of faultless quality. The procedures are thoroughly documented in written form, e.g. in a quality assurance manual and are subject to scrutiny at any time.

Accreditation to DIN ISO 9000 provides no guarantee of fault-free goods. As a qualification, therefore, evidence is given that the manufacturing operation is capable of producing goods of consistent quality.

A qualification plan includes these requirements which must be complied with:

- processing competence and process control on the part of the supplier,
- workmanship in manufacturing,
- reliability and reliability record.

The objective of qualification is also to determine and evaluate the interaction of all components in a manufacturing operation such as the materials, processes, machines, etc. as well as their compatibility at all stages of production. The data obtained is documented in writing and forms the basis for the product qualification. The supplier then has an obligation to inform the customer of any modifications to his processes such as optimized procedures, relocation of processing, etc. as well as any organizational changes which could have a negative impact on the function of the quality assurance system. After qualification, the capability of the supplier is assessed over an extended period of time. Particular attention is paid here to translation of the established quality assurance system into the current manufacturing operation.

A positive evaluation of the following criteria is decisive for certification of the supplier:

- delivery according to specification,
- quality,
- quality performance,
- processing competence,
- workmanship.

A summary of the 5-phase concept from selection of supplier to optimization is given in Fig. 2.

After the certification stage, the company undertakes to optimize the process in such a way that an ongoing increase in quality is possible. This is achieved by:

- continual checking of processing competence,
- audits (both external and internal),
- statistical process control techniques.

(source: Hein).

CETIH, abbrev. for: Centre d’Etude Technique de l’Industrie de l’Habilement, Paris and Lyon (French Centre for Technical Studies of the Clothing Industry); → Technical and professional organizations.

Cetyl pyridinium chloride (1-hexadecylpyridinium chloride, CPC), white powder, soluble in water (neutral reaction), alcohol, chloroform. Typical → Pyridinium compounds. Used in, amongst other things, 0.1 and 1% aqueous solution for titration (methylene blue method) of the content of anionic-active substances in dry cleaning liquors which contain cleaning promoters.

Cetyl trimethyl ammonium bromide (CTAB), $[C_{16}H_{33}N^+(CH_3)_3]Br^-$, white, powdery, voluminous, foam-forming, cleaning and disinfectant cationic surface-active agent. Water soluble 1 : 10 (= pH 5–7). Used as: antiseptic (0.2–1% solution) and dyeing auxiliary (e.g. retarder, stripping agent, white resist in printing).

CF, → Carbon fibres, → Standard abbrev. for textile fibres, according to DIN 60001 T4/08.91.

Cf, symbol for Californium.

CFC, abbrev. for: chlorofluorocarbon. A type of compound in which some or all of the hydrogen atoms of a hydrocarbon (usually an alkane) have been replaced by chlorine and fluorine atoms. Most chlorofluorocarbons are chemically unreactive and are stable at high temperatures. They have been used as aerosol propellants, refrigerants and solvents, and in the manufacture of rigid packaging foam.

Because of their chemical inertness, chlorofluorocarbons can diffuse unchanged into the upper atmosphere where photochemical reactions cause them to break down and react with atmospheric ozone causing → Ozone layer depletion. For this reason their use has been discouraged.

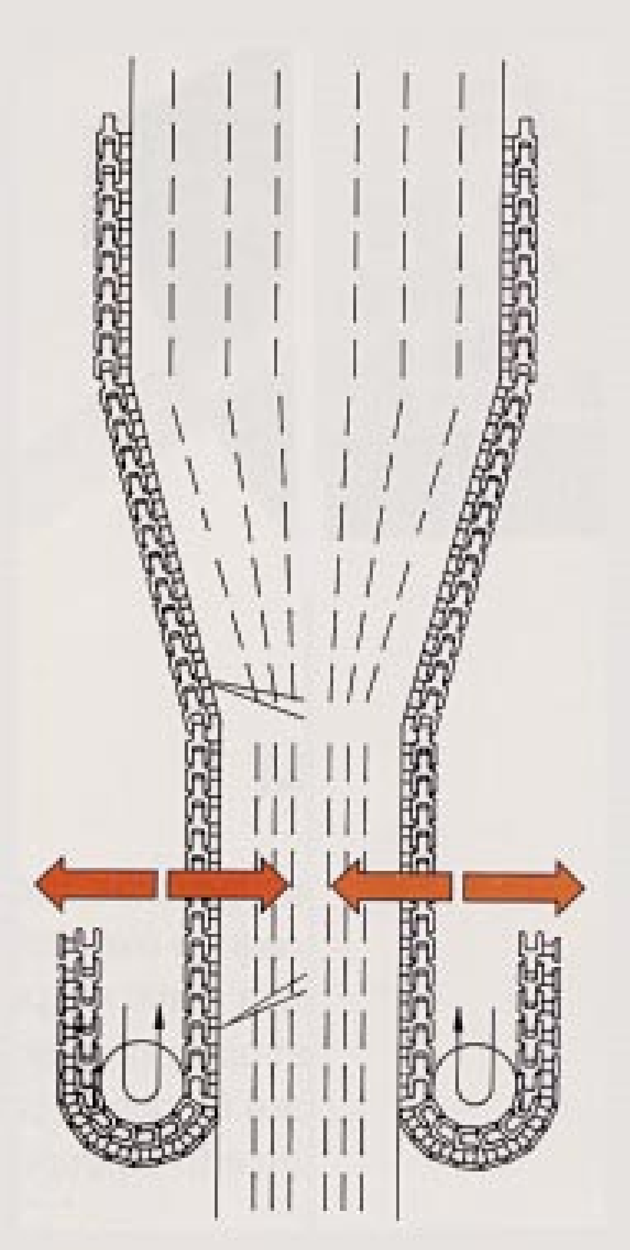

Fig. 1: Stenter chain guiding (US patent).

CFS value, abbrev. for: “Cycle Felting Severity”, an IWS Standard for the felting of wool in washing.

CF value → Comfort factor.

CG Plastic White Scale → Ciba-Geigy White standard.

Chafer fabric External strengthening of the shoulder of car tyres, where the tyre and the wheel rim come into contact. In tyres with inner tubes flexibility, (shear) stability and adhesion are required; with tubeless tyres air has also to be prevented from escaping between the tyre and the wheel rim. Fabrics with coatings of adhesive applied to them are used.

Chagrin fabric is a description for:

I. strongly grained leather, hides from horses, camels, sharks etc.

II. embossed material, e.g. from an embossing calender.

Chagual gum Vegetable gum from Chile and Peru with a high content of → Bassorin. It is found in various forms: voluminous pieces, crystalline, cylindrical and hollow, up to 15 mm in thickness. Chagual gum is only partly soluble in water. The insoluble component swells to form a crystal-clear gel with high refrangibility and low adhesive properties.

Chain On stenters: pin links are linked together into an endless chain for fabric transport purposes. Two chains (vertical or horizontal return) take up the fabric by means of pins or clips, passing it through the stenter processing zone (Figs. 1–4).

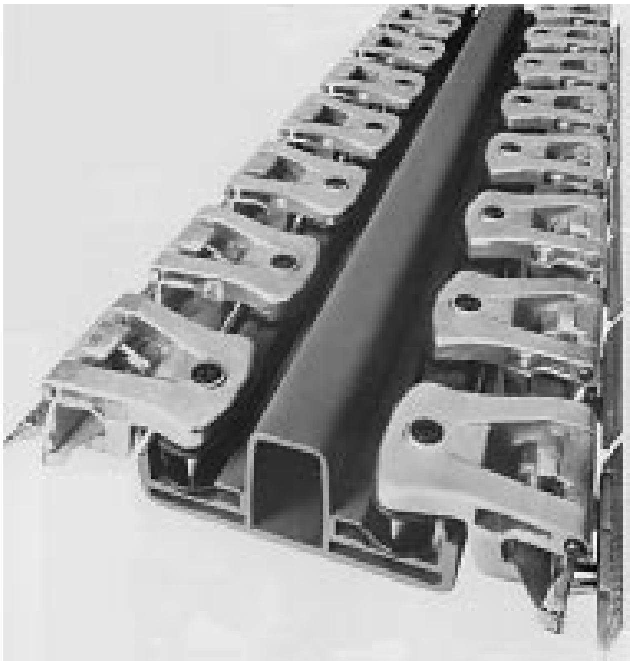

Fig. 2: Horizontal chain guiding (Babcock).

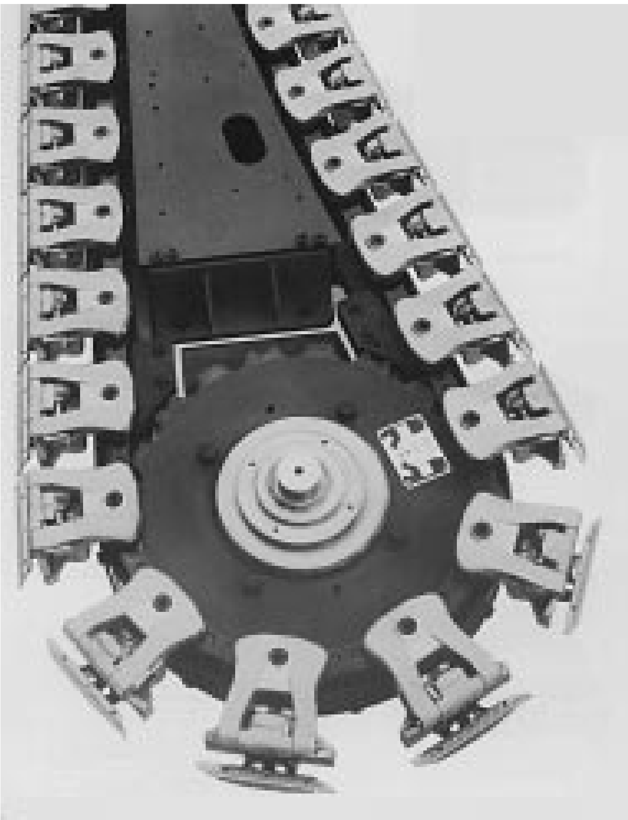

Fig. 3: Horizontal chain return (Babcock).

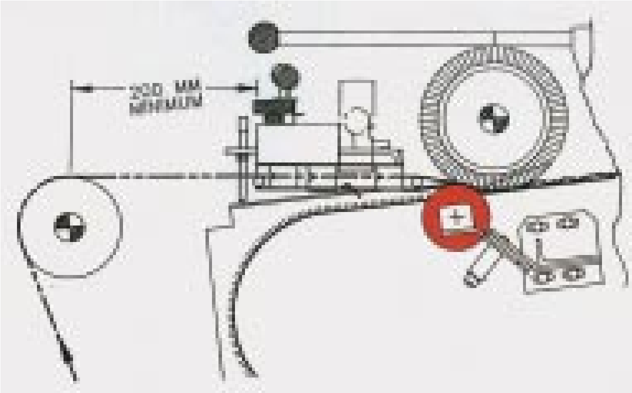

Fig. 4: Vertical tenter frame chain.

Chain adjuster Tensioning unit which is adjusted in the event of slack running transmission chains.

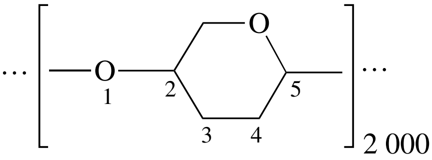
Chain lattice → Pleated sheet structure.

Chain length The greatest molecule length produced with the greatest possible extension of the macromolecule (zig-zag chain) whilst maintaining bond angle and the atom spacing.

Chain length difference in cellulose The values for the → Average degree of polymerisation DP are different depending on the measuring process. The nitrate values (decomposition by nitration) are almost always 10% higher than the cuoxam values (decomposition by solution in cuoxam). Staudinger described this phenomenon as chain length difference CLD, and suggested the following simplified formula:

$$\mathrm{CLD}\ [\%] = \frac{\mathrm{DP}_{\mathrm{nitrate}} - \mathrm{DP}_{\mathrm{cuoxam}}}{\mathrm{DP}_{\mathrm{cuoxam}}} \cdot 100$$

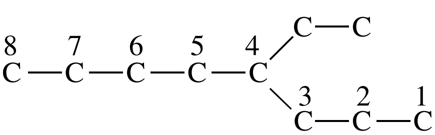
Chain link number According to Staudinger, the number of atoms in a principal valency chain. Since each glucose ring in a cellulose chain molecule consists of 5 primary valency type concatenated chain links,



one obtains the cotton cellulose chain link number by multiplying the degree of polymerisation by 5 = 10 000, viscose cellulose 300 x 5 = 1500.

Chain molecules Like filamentary molecules or linear molecules, this is a collective term for molecules (mostly of a high molecular weight) with a chain structure, with or without branching. The diameter of the chain molecules (calculated from the axis of the stretched chain) is only about 1 molecule dimension, and is minuscule compared with the length. The chain molecules can occur in fully stretched form, but the non-stretched forms, particularly in solutions, are much more frequent; the deviations range from a simple kink through a helix to a random ball. →: Chains; Macromolecules; Polymers.

Chains, chemical combinations of atoms (chain atoms or chain units) covalently bound together in a row, and which are the basic structural elements of a series of molecules (→ Chain molecules). Such chains usually consist of the same or similar building units; they can be "open" or "closed" depending on whether the end units are free or joined to one another. The chain is said to be branched when an atom that is part of the chain is also the starting point for one or two new chains. The most important chains consist exclusively of carbon atoms. They are found e.g. as open (linear) chains of the form -C-C-C-C-C- in, among others, the n-alkanes, alkenes and so on. Branched chains have the form:



In this case the ethyl group (as the shorter chain) substituted on the C-atom in position 4 is also described as a side chain of the n-octane; the numbering is in accordance with IUPAC Rule A-2. Lengthening the chain by adding further chain units is called homologization. Closed chains are present in e.g. cyclic compounds and these may also be branched. This sort of chain where the chain units are atoms of one and the same type, as shown above, are often described as iso-chains in distinction to hetero-chains, which have hetero atoms in the chain. In general use the term "chain" is usually limited to molecules with open chains; this applies above all to macromolecular chain molecules. The characteristic quantities in this case are the number of chain atoms (→ Chain link number) and the chain length.

Chain stitch Ornamental stitch made by connecting loop stitches to form a distinct line resembling the links in a chain. Used especially to edge and join braids as well as for elastically joining up knitted goods.

Chair leg test A serviceability test for textile floor coverings that imitates the load from chair legs. A statistical pressure test in accordance with DIN 54 316. Measurement of impression depths in mm and appearance in grades 1–5.

Chalcogens The elements oxygen, sulphur, selenium, tellurium, polonium of group VI. Their compounds are known as chalcogenides.

Chalk → Calcium carbonate.

Chalking Usually goods which have been treated with excessive quantities of filling agent (kaolin etc.). Textile surfaces (woven and knitted fabrics) display light markings to the surface, often when the material is creased (hand testing or wearing), folded, or pressure is applied by a hard object, from a measuring wheel or the foot of a sewing machine to a fingernail; the material is said to display a writing or chalking effect. Generally, this writing effect is a concealed and therefore undesirable quality defect. It may become apparent during the finishing of goods, thus immediately following dyeing, but also after finishing. To a limited extent this writing effect may show more or less strongly dependent upon the moisture content of the fabric. The main fabrics affected are those with relatively even surfaces and of uniform shade, in mid to deep tones; less susceptible are prints and heavily structured fabrics. Woven fabrics and knitted goods are equally susceptible. Essentially, investigations show up two different causes. Common to both is the fact that mechanical changes to the surface cause a change in the refraction of light thus giving rise to line markings. Line-type, localised destruction of threads or fibres on the surface, e.g. as if caused by a pin or needle, give rise to bearding-type cracking which leaves a single sided mark (chafe marks). The cause of the removable fault in a fabric displaying the chalking effect is caused by a possible superficial thread or fibre displacement. The diffuse reflection of the light from the normal threads is suddenly transformed into directional reflection due to surface flattening resulting from mechanical causes and the line shines. The textile is marked by lines that stand out clearly from the surrounding fabric surface. If this affects several threads in a direction diagonal to the weave, it is known as lateral yarn displacement, or mesh displacement in the case of knitted goods (see Fig.). The surface relief and thus the reflection of light are changed. The displaced fibres or threads remain deformed and do not return to their original positions. Such a fabric is too strongly susceptible to plastic deformation due to its structure, yarn twist, yarn lie, yarn stiffness, inner inelasticity, fibre softness and insufficient internal lubrication, sometimes also dependent on the finish.

Fig.: Surface-sensitive, relatively hard, plasticizable knitted fabric. Threads and meshes are permanently displaced by mechanical influences, causing a change to the reflection of light. Flattened areas shine, the surrounding surface gives a diffuse reflection (top = right side; bottom = reverse side) (source: Steinbrecher).

The deformability of the surface is a clear characteristic specific to each material type and does not independently correct itself. In the second case, generally found in finished textile goods, usually with a discontinuous surface film (finishes rarely form a fully-enclosed film on the threads and fibres), the thin patchy film areas of the finish break, and the breaks reflect the relatively directional light diffusely, causing a matt line. Such faults are not essentially typical of certain finishing products or types; they may arise following any application methods and in practically any product category. On the contrary, the formation of the effect and thus the appearance of the fault is dependent on the qualities of the partial film, thus the finish or product add-on. If this film is easily broken or splintered by localised, mechanical influences, a number of small breaks are formed. The straight-line, mechanical influence causes the stripe-like formation of numerous small particles that reflect the light in a diffuse manner, giving a line that is usually matt in appearance. Such effects can be avoided or removed during finishing; both knitted and woven fabrics affected can be repaired. In the case of the first type of fault referred to, the deformability (plasticizability of the material) must be removed by increasing the "inner" softness, lubrication and flexibility or elasticity. This should result in the material returning to its original condition quickly, preferably spontaneously. In successful cases the lie of the fibres or threads return immediately to position due to the elasticity obtained. This is possible using a flexible soft finish, smoothing finish to increase the internal lubrication, or mechanically by tumbling. In the latter case a possible solution lies in standardising the reflection of light by breaking up the isolated areas of film equally, therefore spreading the breaks evenly over the whole surface of the fabric. For this purpose, calenders, felt calenders or tumbling may be used. The surface film coating is evenly broken giving equally diffuse light reflection from the numerous small breaks. The isolated areas of film-like finish must be as flexible and thin as possible whilst avoiding brittleness as much as possible. The film builds up on the surface to a minimum extent if the application method gives good penetration into the thread giving as low surface coating as possible. This depends on the "impregnation" strength, the absorptive capacity of the finishing agent, the wetting capacity of the finishing liquor and not least the volume, concentration and composition (proportion of film former). The addition of action-enhancing wetting agent (n-alkyl phosphate) may help (source: Steinbrecher).

Chamber acid → Sulphuric acid.

Chambré fabrics are made of 50:50 polyester/cellulose in which the warps are made of cellulose and the wefts of polyester. They are dyed with reactive dyes first, the polyester remaining undyed, and then printed with disperse dyes.

Chamfering Removing the edges of cross-wound bobbins before dyeing in order to avoid dark patches. Done by hand or using chamfering machines.

Changeant (glacé, shot silk). Fabrics made of natural silk or synthetic fibres, in which the warps and wefts are different colours. Filament yarn fabrics are usually piece dyed in a single bath process, viscose or cupro being the first fibre and acetate filament the other. The changeant effect is most effective in plain weave fabrics when the moving light-dark contrast of the individual components effectively enhances the changing colour effect to give an attractive interchange when the angle of incidence of the light changes. Used as clothing, overcoat or lining material.

Change in colour Device for assessing the degree of change of colour by → Grey scales for colour fastness testing (change in colour).

Change of state in textiles From the point of view of thermodynamics, textile material is in a state of equilibrium.

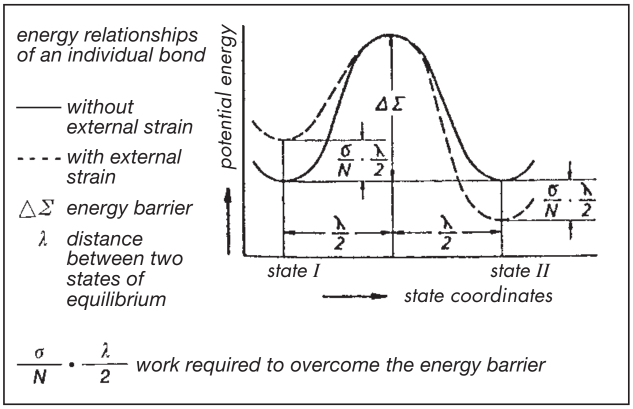


Fig. 1: Principle of stable states and associated changes of state through the "rearrangement" of bonds between cellulose molecules (source: Rüttiger).

If the material changes into a different state of equilibrium (Fig. 1) as a result of certain external influences (tensile stress, heat, swelling), then the progression of this change of state takes place over a period of time because of the necessary activation energy barrier, i.e. the rate of "rearrangement" determines the time for the mechanical progression (e.g. the breakdown and reformation of hydrogen bonds (Fig. 2).

Compared to processes from derived but often readily accessible variables, states are to be regarded as kinetic, which is an essential characteristic:

a) states: equation of state, state variables. Typical examples for indications of states in practice: textile material is finished, bleached, calendered, afterwashed, dried as a final stage, conditioned, made-up, etc.
b) processes: transitory change of state variables, i.e. changes of state as kinetic and/or physico-chemical processes. Typical examples for processes in practice: textile material stretches, shrinks, swells, wets, dries, or is cured, heat-set, embossed, ironed, broken, steamed, stretched, relaxed, sanforized, etc.

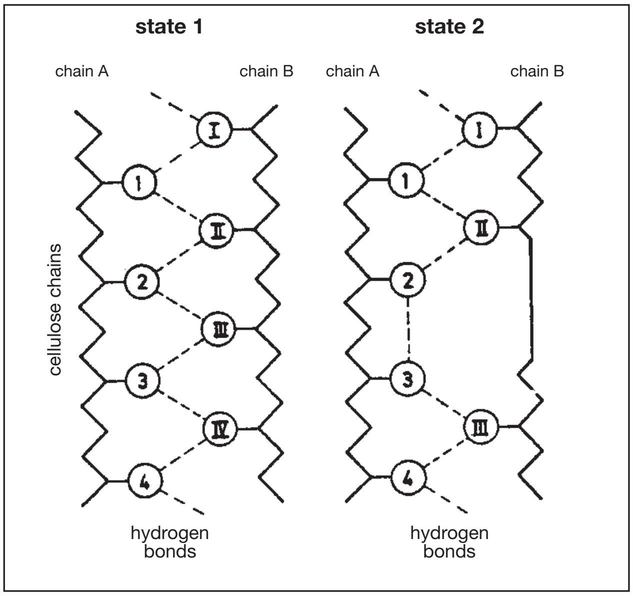

Fig. 2: Hydrogen bonds between the –OH groups of cellulose for different arrangements (states) of the chains. Air-dried cellulose contains one water molecule for each 3rd hydrogen bond which can facilitate the "rearrangement" from state 1 to state 2 (source: Rüttinger).

Important changes of state which occur during practical textile finishing:

1. Modulus of deformation through variations of
   - stages of stress,
   - rates of stress,
   - states of swelling,
   - degree of crosslinking.
2. Recovery, contraction after mechanical stress has ceased:
   - spontaneous: amount, modulus, (elastic resilience),
   - delayed: amount, rate.
3. Elongation after a tensile stress:
   - f (stress, time, swelling, temperature),
   - creep, relaxation of deformations,
   - permanent (creeping) and pseudo-permanent component.
4. Manifestations of rupture:
   - tensile stress,
   - abrasive stress.
5. Stretching-setting processes:
   - relaxation of tension
   - retardation of tension
   - equilibrium point,
   - release of "frozen-in" internal tensions.
6. Shrinkage processes (thermal and swelling contraction):
   - washing shrinkage,
   - pressing shrinkage,
   - processing contraction (free, and with counter tension),
   - max. swelling contraction (free, and with counter tension),
   - inversion effect on mercerizing.
7. Thermal and swelling changes (reversible components only):
   - heat expansion,
   - swelling dilatation, de-swelling contraction.
8. Transitions, 1st and 2nd order:
   - crystalline – amorphous,
   - crystal type I – crystal type II,
   - glass-like – rubber-elastic state.

During the tensile stress of fibres, the following changes of state can occur: firstly, deformation of the fibres takes place mainly due to bending of the bond angle, strain on the loops without opening them, and other reversible processes. This is also accompanied by strain on, and partial breakdown of, the → Tie molecule which is joined to each other in the crystalline regions via the non-ordered (amorphous) regions. For each step of elongation, the number of additional unstretched loops decreases. With an increasing rate of elongation, a few chains (those participating in reversible deformation) can reach their state of equilibrium. More force strands therefore participate in the elongation which results in a steeper rise in the stress-strain curve. In the middle region, irreversible deformations are also involved such as disentanglement, drawing, unhooking, i.e. transposition processes. Large forces are necessary for this. In the end region, the chains are so highly stretched that flow processes take place, as a result of which the macromolecules lose their role as tension carriers, e.g. by displacement, folding, withdrawal of chains from the crystallites, and the scission of crystallites so that molecules, and molecule segments, which have not yet been subjected to strain up to now, are included together in the transfer of energy. As a result, the number of chains participating in the transfer of energy is only slightly increased.

For processes and states involved in tensile stress and recovery, as well as the analogous relationships in creasing, the micro-states and changes associated with them are explained in the Table. They reveal the relationships between the individual variables and the means of determining them. Determination of material-specific constants from derived functions of the state parameters for the complete characterization of a textile material is the purpose here (source: Rüttinger, Beier and Schollmeyer).

Characteristic Statistical concept for a characteristic property which makes the evaluation of units possible (→ Statistical analysis).

Chardonnet, H. (1839–1924). A native of France, he has been called the father of rayon because of his successful research in producing what was then called artificial silk from nitrocellulose.

Charge (batch). The total quantity of a product

	Textile process	*Representation by the relevant equation of state*
Tensile stress (crease formation)	Sample history (drawing, conditioning)	Determined by n_F, n_U, n_S as long as the sample is in a state of equilibrium.
	Clamping length	The length of the calculated example is in the ground state ($n_S = 0$) due to the selected standardization $L_0 = 10$ cm. For comparison purposes, conversion to the effective clamping length must always be carried out. Real samples have the length for calculation $L_0 = (1\,000 + n_S) \cdot 10^{-2}$ [cm].
	Deformation (crease formation) up to a certain extension or tensile stress with different rates of deformation	The main characteristic is the extension of the free segments and the modulus of deformation (M_D); For the constants n_F, and n_S, the following equation applies as a first approximation $M_D = \frac{E_0}{n_F}(1000 + n_S)$. Second criterion; The increase of n_S which, after extension beyond the elasticity limit (yield point), no longer completely recovers even if an equilibrium has been established. As n_S begins to increase: applies; $\sigma_a \approx E_0$. The time-dependent factors are determined by dn_F/dt; dn_S/dt and dn_U/dt; Fine adaptations are possible by applying *Eyring's* three-element model.
	Tension or deformation relaxation (creep)	A) Reduction of external tensile stress with constant length of sample due to increase of n_F. As a result, there is a reduction in the extension of the F-segments and consequently the tensile stress. B) Increase of sample length with stress time due to an increase of n_S. The equilibrium is determined by: $\frac{dn_S}{dt} \approx K \cdot \Delta n_S$
Mechanical recovery (crease recovery)	Spontaneous contraction (elastic recovery)	The rate is primarily dependent on the sample's mass inertia (characteristic oscillation) and the extent by n_F. The modulus of contraction is characteristic. As a first approximation, applies where n_F and n_S are constant; $M_K = \frac{E_0}{n_F}(1000 + n_S)$
	Delayed contraction (creep recovery)	Δn_S determines the extent of creep recovery. The time progression with constant temperature and swelling is given by: $-\frac{dn_S}{dt} \approx K' \cdot \Delta n_S$. Normally , the further the sample has been deformed beyond the elastic region, the greater the value of Δn_S.
	Tension retardation	The tension which builds up in a sample relieved of stress up to $\sigma_a = O$ over time is mainly limited by Δn_S and E_0. The amount is calculated from Δn_S, E_0, n_F and λ. If a blocked segment under tension is released (S→F) then a corresponding (blocked and frozen-in) tension is also released.
	Permanent extension (elongation, crease angle)	The permanent extension is given by that component of n_s which remains constant after tensile stress. The greater Δn_S was after tensile deformation, then the greater the permanent extension.
	Swelling recovery (washing shrinkage)	Swelling recovery occurs in relation to the extent that n_s is converted by swelling processes into n_F, or n_U.The resultant swelling contraction tension is determined by Δn_S (swelling), n_F and E_0.The reversible change in the length of l_0 during swelling is superimposed on this process.

Tab.: Relationship of micro-states with changes of state in textiles.

manufactured under specified conditions which is understood to be of homogeneous composition.

Charged system → Batch system.

Charge reversal The ability of ionic colloidal electrolytes in aqueous solution to transfer their electrical charge, e.g. to fibres with the opposite charge (negative charge on protein and cellulosic fibres) or to chemicals adsorbed by the fibre (auxiliaries for improving fastness).

Charging of machines In industrial production, a distinction is made between when a machine is running and non-running times. During the latter period, the

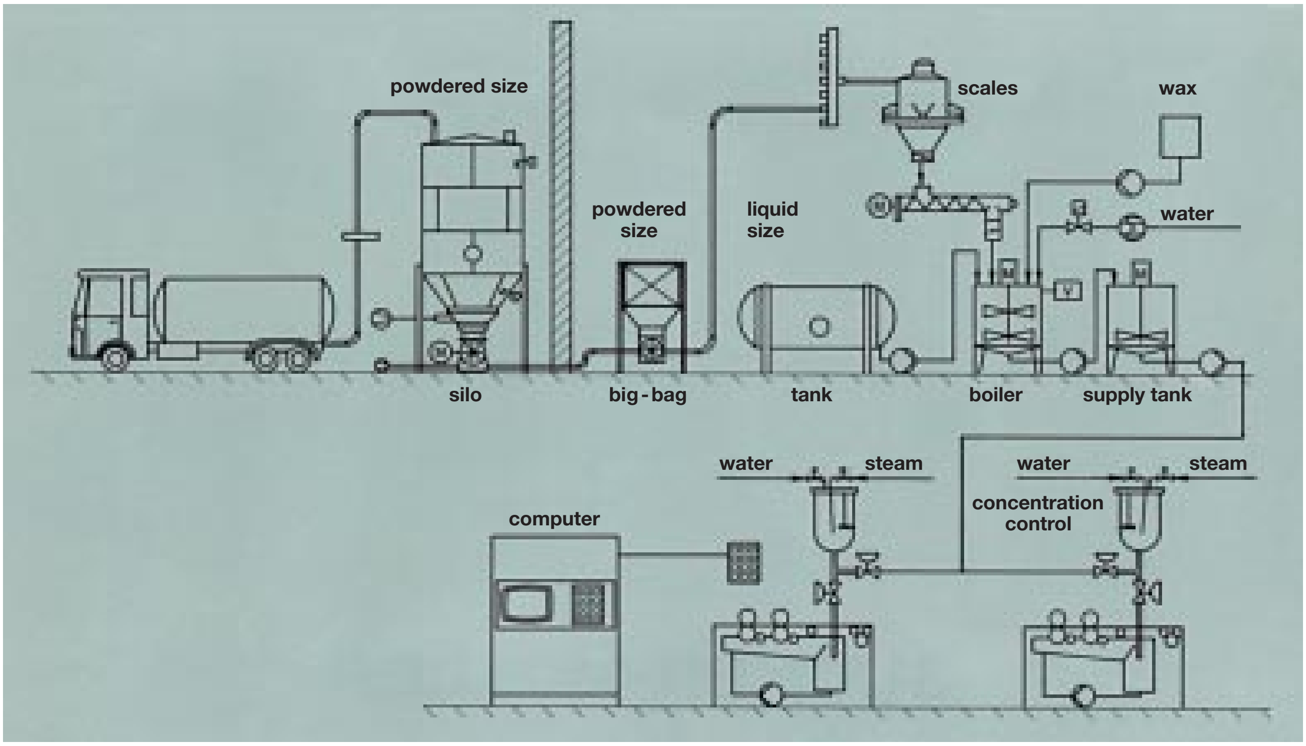

Fig.: Charging of a sizing line.

machine is unloaded and loaded for the next process cycle. This process is known as charging. It also includes charging the machine with the necessary auxiliaries, chemicals and dyestuffs. Every textile finishing plant which for example applies finishing products to textiles must be logistically organised including outside supply of raw materials to reduce any standing time to a minimum (see Fig.).

Char length Length of the torn, carbonised area in → Flammability testing (vertical test). It is determined after the recorded afterglow period on the same test sample. 89 mm is the required average limit value for textiles with flame retardant finishes (mean value of 10 measurements); the max. individual value is 114 mm.

Charly is a → Copper man of size 50 at the Hohenstein clothing physiology institute and can imitate the temperature regulation of a person (→ Clothing physiology): the legs can be moved at the hip and knee joints and the arms can be moved at the shoulders and elbows, it can sit, lie, stand and also imitate walking and running movements. It is heated by warm water (pipe system). External evaporation can be measured with water (body cooling, sweat evaporation). A complex control system is used for comparative clothing studies, physiological work measurements etc.

Charmeuse Fine, soft warp-knit in silk, viscose or polyamide filament yarn, finely corded, very fine-meshed, invariably two-threaded and run-resistant, generally having more lustrous face and crimped back. Tricot charmeuse has a face of tricot character, used for underwear.

Chartered Colourist Technical qualification of the → Society of Dyers and Colourists, Bradford, England.

Chasing calender The fabric is fed in a spiral through the calender by a roller device. The goods are arranged in 7 layers one above the other in the roller system, and are led over a board into the middle of the calender. The goods run spirally towards the outside, so that the last outer layer leaves the upper nip and is led to the winding up (Figs. 1 and 2).

The goods are compressed in the circulation

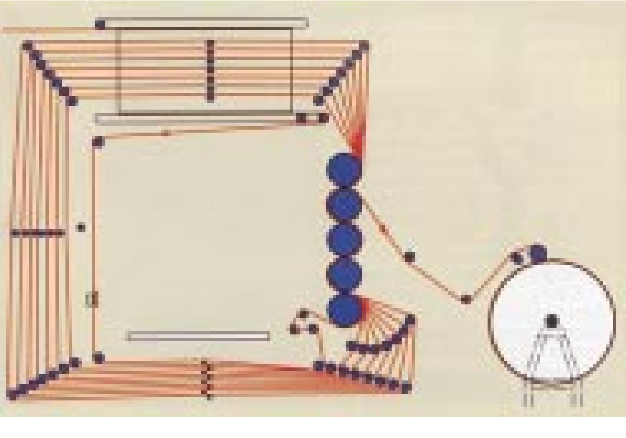

Fig. 1: Fabric control in a chasing calender (KTM Kleinewefers).

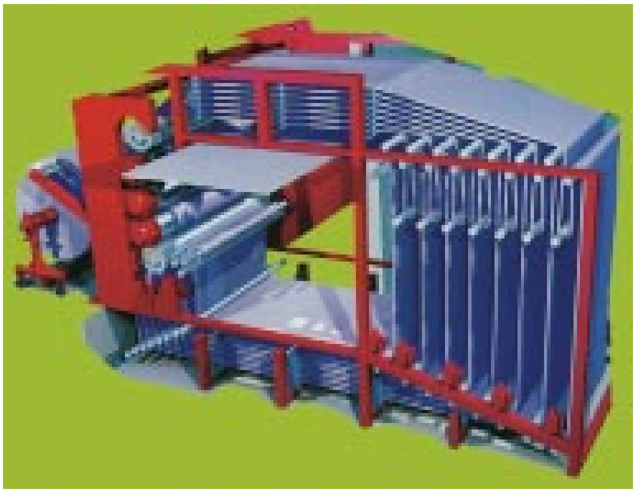

Fig. 2: Chasing calender for high-quality bed and table cloth made of cotton and linen (Küsters).

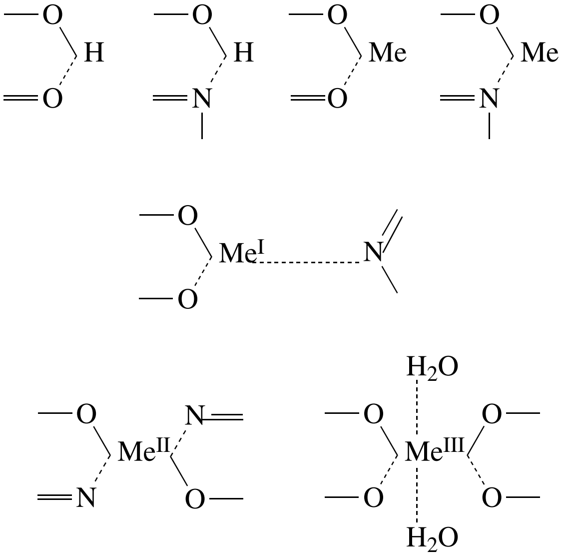


through the chasing calender. The aim of the treatment is to get the required density and air permeability at the same time. Because there are multiple layers of fabric in the press the fibres remain round and bulky.

CHC process (Calendered Heat-Set). Caustic soda treatment for polyester knitgoods to improve the surface characteristics.

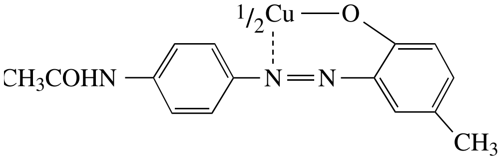
Check list A statistical registration and evaluation system for counting and measuring results, with headings such as the following: size classification, absolute frequency, % frequency, % frequency total. Each individual value, assigned in advance equidistantly to a pre-determined size classification, is marked in the relevant row by a vertical mark. The ultimate count of the check marks enables immediate conclusions to be drawn on frequency distribution.

Cheese cloth Lightweight cloth of open structure in plain weave. The net appearance is created by the very open interlacing of warp and weft. The fabric has low structural stability and an appropriate finish is generally necessary to prevent warp/weft slippage.

Chelate An inorganic complex in which a ligand is coordinated to a metal ion at two (or more) points, so that there is a ring of atoms including the metal, i.e. a metal-complex. The process is known as → Chelation.

Chelate bond, complex (Latin: chelae = claws). Chelation arises from an → Atomic bond as primary valence and a → Coordinate atomic bond as the secondary valence, so that a metal or hydrogen atom is joined to two positions in an inner complex compound.

Such bonding (semi polar) plays an important role, e.g. in deactivating water hardness, very frequently in various metal complex dyestuffs, in phthalocyanine ring systems as well as extremely numerous textile chemical processes in the form of hydrogen bonds. In the case of chelated metal atoms, the terms metal-, copper-, chromium chelate etc. are used. For reserving disperse dyes in reserve printing on polyester disperse, dyes that are suitable for chelating with metals are used; they form complexes and lose their affinity for polyester. Suitable metals are copper, chromium, cobalt, iron and aluminium. In practice, copper acetate or copper formate are used according to the principle:



Chelate resist printing A process for the production of resist prints on polyester whereby functional groups such as –OH, –NH, –COOH, >C=O or >NH in disperse dyes are able to form chelates with heavy metal cations such as Cu, Cr, Co, Fe or Al from the corresponding heavy metal salts. Penetration of disperse dyes into the polyester fibre is prevented by chelate formation. The best results are obtained with copper compounds in the following order: copper acetate, formate, sulphate and phosphate.

Chelation Formation of metal-complexes in which a metal cation is held by coordinate bonds within one or more molecules containing several electron-donating groups in a closed ring structure. → Chelate bond.

Chemical affinity is the driving force behind chemical reactions that results in mutual absorption and reactivity, such as e.g. between a fibre and a dyestuff or textile auxiliary (→ Affinity, dye affinity). The affinity between reactants generally increases with differences in the electrochemical characteristics (→ Electrokinetic interfacial potential). According to Pauling, affinity is a question of the energy differences and the probability of the state (entropy). A system in equilibrium has no driving force, i.e. it has no inclination to react in one direction or the other. However, if e.g. the concentration of one of the substances or the temperature is increased, a force is created which drives the system towards a new equilibrium for the reaction. If the substances on both sides of the reaction have the same heat content (equal enthalpy), the reaction goes in the direction of the greater probability (entropy). On the other hand, the reaction goes in the direction in which heat is liberated if the substances on the left and right of the equation have the same entropy. At equilibrium, the driving force arising from the change in heat content (change in enthalpy) in the course of the reaction is exactly balanced by the driving force arising from the change in probability (change in entropy).

Chemical bonding fibres (cb fibres) → Binder fibres.

Chemical bonds Electrical bonding forces between atoms and molecules which can have very different types and effects, depending on the state and structure of the molecule. The following principal types are distinguished:

I. → Ionic bond (electrostatic, polar, heteropolar bonds, electrovalency).

II. → Atomic bond (electron pair, homopolar, covalent, unitary, non-polar bonds) as the principal valence bonds.

III. → Coordinate atomic bond depending on → Secondary valence forces in the form of dipole moments, hydrogen bonds, van der Waal's forces, induction forces and dispersion forces (sometimes without secondary valence forces). In the majority of cases one type of bond predominates although transitions to other types of bond have certainly been observed, just as forces of different natures can be present at the same time, as in e.g. → Chelate bond (atom and co-ordination bonding).

Chemical characteristics of wool Because the chemical nature of wool is that of a protein, it can be characterized with simple, rapid tests and can also be analysed exactly with more expensive methods, to detect any alterations in the fibre caused by finishing treatments. The amino acid composition is characteristic for a given wool; the compositions of an individual fibre can be different at the root and the tip, e.g. from weathering. In tips that have been weathered, the content of histidine and tyrosine is lower as a result of photooxidation (Table).

The cysteine content also changes along the length of the wool fibre (Fig. 1), partly from a break down of cystine by weathering at the tips, and partly by incomplete keratinisation in the root.

amino acid	tip	root
tyrosine	3,66	4,19
histidine	0,72	1,02
lysine	2,99	2,90
proline	7,72	7,58
serine	11,42	11,07
glutamine	13,07	12,47
asparagine	7,23	6,92
leucine	7,87	7,56
isoleucine	3,10	2,93

Tab.: Effect of exposure to weather on the characteristic amino acid content in defined fibre sections of Cape wool (data in mol %) (Klee).

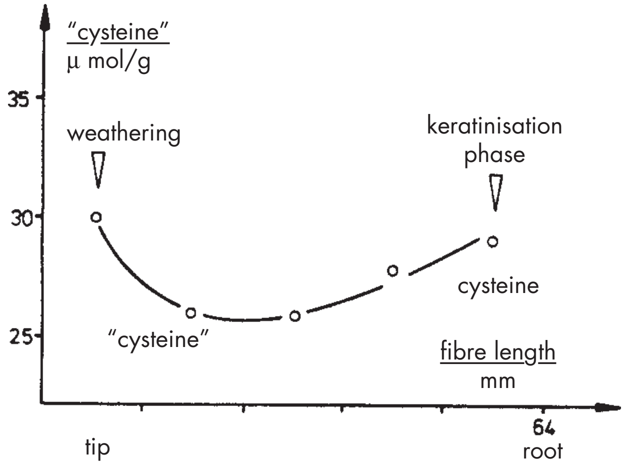


Fig. 1: Effect of weathering and the keratinisation phase on the "cysteine" content of fibre sections of an Australian wool (medium fibre diameter 18.8 mm)(Klee).

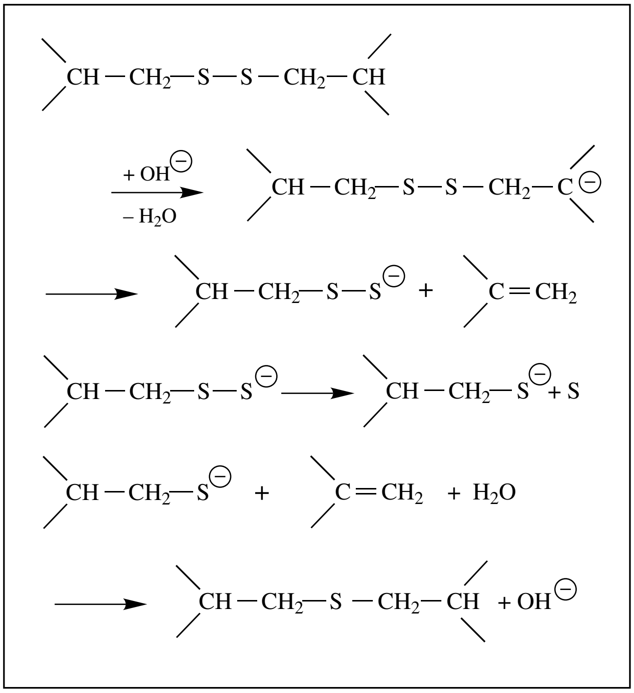

Fig. 2: Lanthionine occurrence in an alkaline medium.

Chemical characteristics of wool

The lanthionine content is a characteristic product of certain cystine degradation processes (Fig. 2).

On oxidation of wool, the cystine content decreases in favour of cysteinic acid (Figs. 3 and 4).

Apart from the carboxyl and amino end groups, the amphoteric character of the keratin molecule depends on the side chain functions. The side chains are characterized by their content of bifunctional acidic and basic amino acids. At the isoionic point, the carboxyl groups in the protein have donated protons to the amino groups so that exactly equal numbers of anions and cations are present. The isoionic point was found to be pH 4.9 by Elöd. The value measured by electrochemical methods is called the isoelectric point and is only slightly different from the isoionic point.

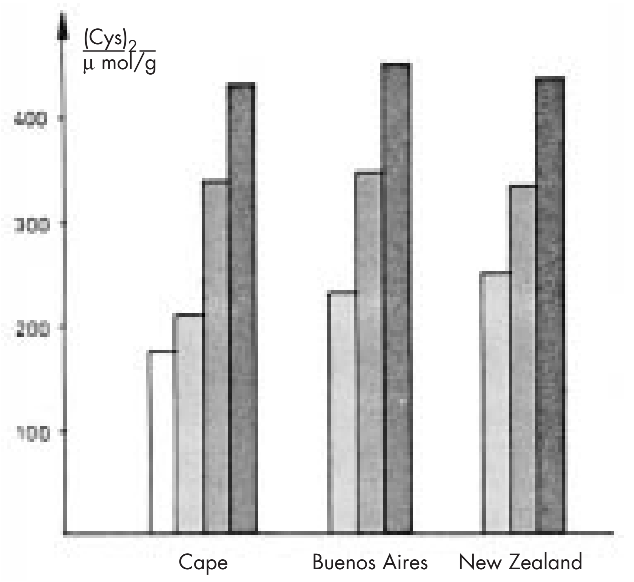

Fig. 3: Cystine content of fibre sections of Cape, Buenos Aires and New Zealand wool (bar graph explanation in Fig. 4).

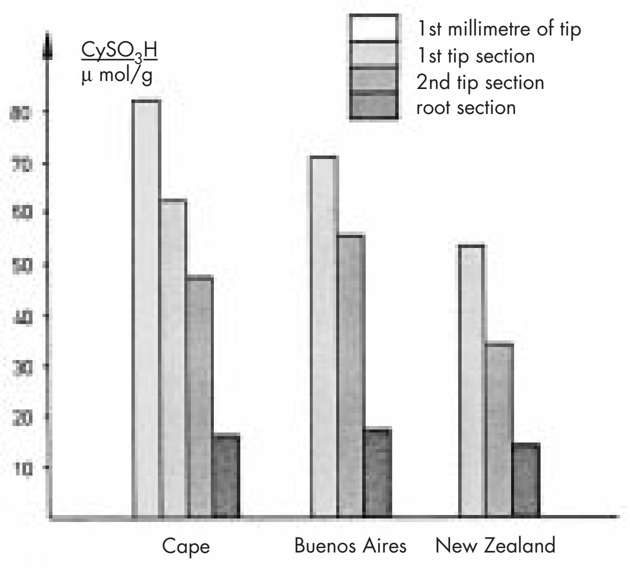

Fig. 4: Cysteic acid content of fibre sections of different wools.

Wool fibres are stabilized by salt bridges as well as by disulphide bridges (Fig. 5).

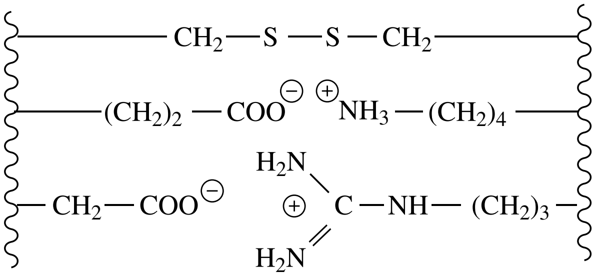

Fig. 5: Salt bridges in undamaged wool at the isoionic point.

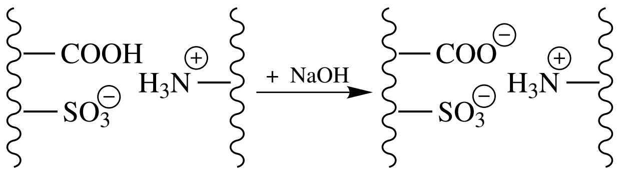
Wool oxidized by bleach still shows good stability but, in the test for solubility in alkali, the osmotic pressure is higher because of the new charge distribution, so that the solubility in alkali is high (e.g. 70% with bleached wool compared with 20% for dyed wool). Normally high values for the solubility in alkali (over 30%) indicate acid damage (at the peptide links), whereas the solubility in urea-bisulphite shows alkali damage. However, the increase in the solubility in alkali and also the decrease in the solubility in urea-bisulphite (from about 60% for untreated wool to 0–10% for alkali damaged wool) can also be associated with decreased stability (Fig. 6).



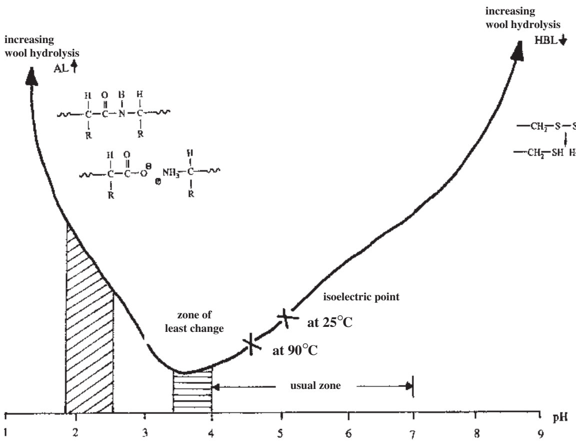


Fig. 6: Wool hydrolysis and zone of least wool change relative to dyebath pH at 100°C.

Chemical compounds Substances formed by the combination of → Elements in fixed proportions. The smallest typical unit of a compound is the → Molecule. Chemical compounds are subdivided into inorganic and organic compounds.

Chemical decatizing Finishes of a chemical nature to impart form retention, in contrast to normal decatizing which involves mechanical and/or physical treatments.

Chemical detergents Incorrect term for → Synthetic detergents.

Chemical displace technique for reserve printing of carpets Chemical blockers affect the fixation of selected acid dyes on polyamide fibres or wool and on cellulosic fibres, so that white, tone-on-tone and contrast dyed or printed effects can be achieved.

Low-affinity dyestuffs should be used for background dyeings. Their affinity is further reduced by the blocking agents. For cross dyeing, dyes with good build-up and fixation characteristics should be chosen so that they are not displaced by the blocking agents or by the alkaline application conditions. It is possible to apply the blocking agent first and then overdye or vice versa. The first method gives less sharp colour definition than the second.

With the blocking technique many design ideas and colour effects can be achieved, e.g.:

- tone-in-tone effects on polyamide or woollen carpets in carpet printing or space dyeing, and also on pile goods made of cellulosic fibres;
- negative space effects on polyamide fibres and wool;
- light contrasting effects on a dark background, both in carpet printing and in space dyeing on polyamide, wool and cellulosic fibres.

Chemical embroidery → Burn out styles.

Chemical engineering A scientific engineering discipline concerned with the techniques for carrying out processes in which substances are changed by variety, property or composition. The main application is in the chemical industry (hence the name chemical engineering), but it also applies to all industrial fields which involve chemical, thermal and mechanical conversion of inorganic/organic substances and supplying the necessary equipment and machinery. The function of chemical engineering is to set up industrial scale processes in which the properties of the substances that are being treated are changed. This can be contrasted with mechanical processing of workpieces in the solid state to alter the exterior form of the articles (mechanical engineering). The following are examples of objectives for individual processes in textile dyeing and finishing, e.g.:

- The objective of washing is separation of materials, i.e. an alteration of the interior structure by extraction and by desorption of contaminating substances, possibly coupled with chemical breakdown reactions. In some cases so-called structural development can take place at the same time by changes in the physical macro- and microstructures.
- In weight reduction of polyester fibres the objective is a chemical reaction at the fibre surface and subsequent removal of material. The result is a change in the macrostructure resulting from the increase in surface area.
- The objective in drying is separation of materials. However there is also a change in the physical micro- and macrostructures which may be desirable or undesirable.
- In thermofixation, there is an alteration of the physical properties by recrystallization of the fibre material.
- Dyeing is a mixing of materials, sometimes with additional chemical reactions.
- Similarly, finishing is a combination of mechanical effects with chemical reactions with the aim of altering the physical and chemical properties.

Model representations of material, heat and mechanical transformations in textile dyeing and printing systems are important prerequisites for technical descriptions of processes and for operating dyeing and printing processes. It is still not possible to describe any system in textile processing completely quantitatively by direct relationships. Control of a system is performed (if not by hand) by adjusting devices (e.g. adjusting motors, regulating transformers, potentiometers). To provide the control signals needed, a parameter must be measured with a sensor and used to generate information about the course of a transformation from knowledge of technical relationships. Hence, from the point of view of textile production with its many and diverse property transformations, measuring and control technology is a vital auxiliary science. It can however only become effective if there is at least a model concept and the dominant parameters that affect the transformations in a system are known (contributed by Schollmeyer).

Chemical finishing Textile finishing gives a textile its final commercial character with regard to appearance, shine, handle, drape, fullness, usability etc.; takes place in a wet state as → Wet finishing or in a dry state as → Dry finishing. Nearly all textiles are finished. The finishing auxiliaries are applied using finishing machines, padders or mangles with one- or two-sided action or by impregnation. Altering the composition, rheology and viscosity of the finish applied can vary effects.

Finishing includes all processing stages such as bleaching, dyeing and printing (especially fabrics), that contribute to the final appearance and handle that convert the textile into a saleable article (aftertreatment). In a wider sense, processes that occur before dyeing such milling, carbonising, mercerising etc. are also regarded as finishing processes since they also have a fundamental effect on the final appearance of the textile (preparation). Few fabrics come directly from the loom ready for sale. After weaving they are simply examined and knots and loose yarns are removed. Special finishing effects may be given to such coloured goods in a finishing process. For both yarn and piece-dyed fabrics the dyeing must withstand the finishing treatment without bleeding or change of shade (process fastness). The final result of the finishing process is dependent upon the prior processing stages. Previously unnoticed faults may become apparent at this stage. It is extremely important that woollen materials are well shrunk and enter the finishing process with their natural moisture content. The success of the English woollen finishing process was not so much in the machinery as the individual work processes because the material had time to "recover" between the individual stages, i.e. to absorb moisture and "relax".

The individual finishing processes are many and varied. Their order and detail will not be described at this point. In general it can be said that during the finishing of synthetic fibre fabrics, difficulties arise due to the material's low moisture regain. Processes used for natural fibres will not necessarily give good results on synthetic because it is often impossible to apply sufficient product to the fabric or achieve the desired effect.

The finishing department includes a finish preparation kitchen that should be separate to the dye house kitchen. This is where the finishing formulations are prepared, and is equipped with storage tanks, measuring devices, scales, heated mixing tanks with stirrers and transport containers. In large-scale systems the formulations can be fed directly to the machines by pipes. Otherwise closed mobile vessels made from stainless steel or plastic are suitable.

Yarn finishing is less important than piece goods finishing. In particular sewing thread made from mercerised cotton, linen and mixtures with synthetic fibres and silk require finishing. These yarns must have a low-friction character. To achieve this they are impregnated with wax, paraffin or silicone derivatives and also undergo mechanical treatment by means of stretching and brushing (polishing). The treatment takes place in thread form, in batch or continuous processing. The machines used to stretch or polish the threads consist of pairs of heated and polished rollers that act on the threads. They are enclosed in a chamber that is supplied with steam. During stretching the rollers rotate slowly so that no deposits occurs. This process is also known as brillianting.

In order to make dyed silk threads easy to unwind; the hanks must held in a straight and untangled form. This takes place between the individual finishing stages and as a final treatment. Hanks are suspended from a horizontal bar and then stretched with another bar. This hand process can be performed by a machine. During silk finishing, lustring also takes place, whereby the silk threads pulled with a stick whilst hanging from a pillar and twisted alternately to the left and right. Machines are also available for this treatment. Cracking (crunchy handle, Craquant) handle treatment of natural and regenerated cellulose fibres and polyacrylonitrile fibres is also considered to be yarn finishing. Oil emulsions and organic acids or ethoxylated derivatives of saturated fatty acids or fatty alcohols are used.

Finishing is intended to guarantee perfect processing of materials, above all sewing capability during clothing manufacture. The high speeds of modern sewing machines generate more needle friction, which can lead to local fabric damage. A suitable softening finishing provides help. Another process is to re-align the weft, which may become distorted during processing and no longer runs at a right angle to the warp or may be bowed (curved across the width of the fabric). The dyed material should be checked prior to each finishing process, particularly if the finish is to be permanent. Correction of faulty processing can be difficult or even impossible.

Chemical finishing auxiliaries Auxiliaries combined with → Chemical finishing agents in formulations to improve compatibility and bath stability and to modify the finishing effect in a particular way. Special fats, waxes, sulphated oils and compounds on a similar basis. The additional use of non-ionic or anionic detergents assists in penetration of the textiles. Included are organic and inorganic humectants; and also products for improving the water repellency of finishing agents that are not resistant to wetting, such as urea- and melamine-formaldehyde compounds, formaldehyde-releasing products and the like.

Chemical fixation Stabilization of a polymer state by crosslinking with bifunctional reagents.

Chemically-embossed floorcoverings Continuing developments in printing techniques as well as the patented Kongoleum process have made it possible to produce an extremely wide range of imitations of all sorts of tiles as well as novel designs for floor coverings (Fig.). Glass fibre non-woven fabrics or mineral papers as used as the backing material onto which a polyvinyl chloride plastisol is applied together with a foaming agent, and is set below the activation temperature of the foaming agent. Then it is printed in the required colours (usually a multiple intaglio printing) with or without the addition of an inhibitor, and a coating layer of compact plastisol is applied after a short exposure to air. The whole construction is then fixed at a higher temperature, so that the agent in the foaming layer decomposes and creates foam. Trimellitic acid anhydride (TMAA) is predominantly used as the inhibitor in concentrations of about 10–20% on the weight of the print paste.

For high production rates, equipment up to 4 m wide is used, often using an in-line process. This process runs continuously, from the backing material, through

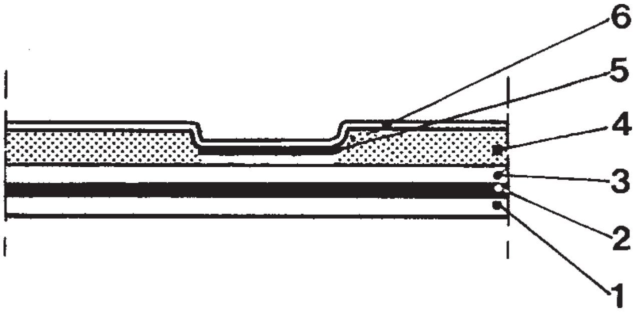

Fig.: Drawing of a structured floor covering.
1 = back coating; 2 = substrate; 3 = ground coat; 4 = foam coat; 5 = print colour coat with inhibitor; 6 = top coat.

the coating and the printing and the application of the covering layer, to the final ready-for-sale rolls.

Equipment of this type has the disadvantage of being less flexible in the type of product that it can produce than are off-line processes, in which the coating and printing are carried out in different units.

Chemically pulped waste jute material is a jute wool.

Chemical/Mechanical finishing of textiles General name for piece goods finishing. Includes all textile material processing procedures after the fabrics leave the weaving, hosiery or knitting mill until finishing is complete. In most cases the raw goods will need to have their final characteristics applied or developed to suit further processing and eventually make goods that are ready for sale. This includes all the work remedy faults from the fabric forming process and/or to give the goods the required characteristics of handle, lustre, weight, surface structure or reduce susceptibility to creasing, shrinking, sensitivity to water etc. The finishing works must give the goods mechanical and/or chemical treatments that maintain the characteristics of the textile fibres, and to provide added value to the goods suitable to the intended end-use.

Textile finishing is widely varied from the mechanical and chemical aspects and requires good knowledge of the raw material and fabrics. It is not possible to draw up a general finishing work plan because the processes depend on the raw material, the origin of the fabric and the desired effect. Wet finishing consists of individual wet finishing processes (bleaching, mercerising, carbonizing, milling, dyeing etc.); dry finishing consists of dry handling processes (decatizing, calendering, pressing, roughing, shearing, singeing etc.

Whereas fashion changes have dominated by colour changes in the past, current fashion is mainly characterised by finishing effects. The finisher must pay attention to two main items of surface finishing:

- using mechanical means such as emerizing, raising, crushing and creasing, chintzing, calendering, pressing, milling, crinkling and crêping.
- using chemical means such as cross-linking, setting, thermosetting, softening, glazing and providing a handle.

In the TEGEWA sales statistics (1988), the main materials used were softeners with 12 500 tonnes, followed by fillers, stiffeners and weighting agents (8500 tonnes). This means: 20 000 tonnes/annum of handle adjusters are used in the Federal Republic of Germany. Approximately 10 000 tonnes/annum of resin finishing agents clearly indicate the importance of low-creasing, swell-resistant and crush setting finishes.

Approx. 2000 tonnes/annum of hydrophobic auxiliaries based on paraffin products, silicones and fluorochemicals. 2000 tonnes/annum of flame retardant auxiliaries show that consumer protection is important, particularly in the use of textiles in the public sector (public transport, public buildings). Sewing thread lubricants (500 tonnes/annum), anti-electrostatic agents (500 tonnes/annum) and antimicrobial auxiliaries are intended for special purposes, but still constitute 2000 tonnes/annum. Light fabrics and knitwear (less than 200 g/running metre) require more and more use of antislip and ladder resistant auxiliaries (1000 tonnes/annum). Because of environmental problems during finishing and the new requirements for biodegradable textiles, enzyme-based finishing is becoming increasingly important. Electrical-based finishing (high-frequency drying, plasma and corona treatment) will be used more frequently in the future.

Chemical metering for fully automatic dyehouse Liquid chemicals are metered directly into the mixing hoppers or chemical tanks of the machines from stock tanks through metering equipment that consists of several groups of dosing units, the number depending on the number of associated dyeing machines. A dosing unit consists of n chemical valves, 2 dosing pumps, 2 electronic counters, 1 feed distributor with a regulating motor and 1 valve for rinsing water. The dosing program is started from the process controller when a chemical is required. If the dosing group for a required apparatus is occupied, the demand is put into a

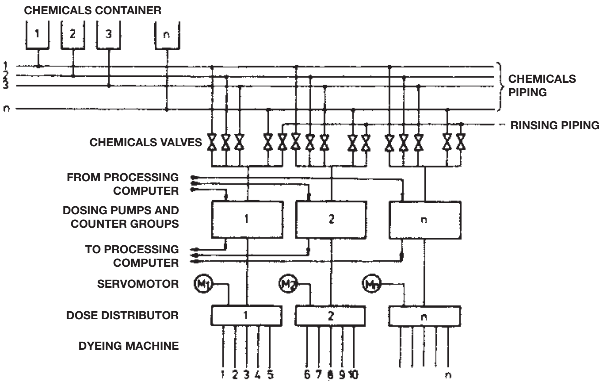

Fig.: Dyehouse dosing unit.

waiting queue. On the other hand, if the particular dosing group is free, the appropriate chemical valve is opened by the dosing program and the feed distributor is put into the correct position. Then the number of strokes for the 2 dosing pumps involved is calculated from the amount of chemical to be dosed, these values are fed into the appropriate electronic counter and the dosing pumps are started. When the last chemical for a unit has been dosed, the dosing program runs a rinsing program for this unit. The amounts are determined and used in the final program exactly as for the dyestuff dosing program (Fig.).

Chemical metering station Modern measuring and control techniques enable processes to be supervised and controlled. In most cases a simple and safe dosing system is required for economical operation. A possible arrangement of a chemical dosing station for feeding bleaching chemicals is illustrated in the Fig.

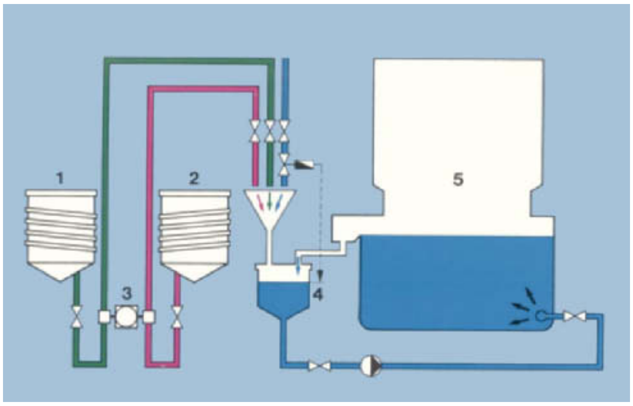

Fig.: Bleaching chemicals dosing station.
1 + 2 = chemicals containers; 3 = dosing pump; 4 = level control; 5 = impregnating section.

To avoid premature reaction, the components are prepared separately in vessels (1 and 2). The concentrations correspond to the ratios that are to be mixed in the recipe. The required amount is then delivered by a two channel pump (3) so that the amounts of the chemicals put into the impregnating unit (5) are adjusted according to the weight of the goods and the speed. The bath is circulated by a chemical pump and is then kept at the required level by an automatic feed of fresh water. The float regulator (4), outside the impregnation unit, works through a magnetic valve.

Chemical oxygen demand (COD), is determined as a → Summation parameter. COD determinations are generally used for assessing effluent as well as water in exhaust air scrubbers, to determine the COD for an effluent stream, and to estimate the loading of the scrubbers and hence prevent possible over-saturation or to check the efficiency of its operation. To determine the COD of all oxidizable organic components, the sample is boiled in a strong sulphuric acid medium with an excess of potassium dichromate ($K_2Cr_2O_7$). After 120 min. under reflux, the solution is cooled and back titrated with ferrous ammonium sulphate ($(NH_4)_2Fe(SO_4)_2$) solution. The amount of potassium dichromate consumed is proportional to the amount of oxidizable organic material in the sample.

The COD value is the formal oxygen requirement in the reaction with the strong oxidizing agent, potassium dichromate.

COD (Chemical Oxygen Demand)

$$3\ H_3C\text{–}COOH \xrightarrow[\substack{-\ 4\ Cr_2(SO_4)_3 \\ -\ 4\ K_2SO_4}]{\substack{+\ 4\ K_2Cr_2O_7 \\ +\ 16\ H_2SO_4}} 6\ CO_2 + 22\ H_2O$$

The BOD value (→ Biochemical oxygen demand) is the oxygen required in an oxidation that is similar to the processes that take place in aerobic clarification plants.

BOD (Biochemical Oxygen Demand)

$$H_3C\text{–}COOH + 2\ O_2 \xrightarrow{enzyme} 2\ CO_2 + 2\ H_2O$$

In determining the COD, the acetic acid is reacted with chromium in the hexavalent state and the chromium(VI) is reduced to chromium(III). The chromium(VI) required is determined and converted to the equivalent amount of oxygen. The summation parameters of the various measurements cannot be converted from one process to another; this is illustrated in the three examples in the Table.

Acetic acid contains organic carbon and can be oxidized both by chemical and by biochemical methods; therefore there are values in all three columns of the table. As biochemical degradation takes significantly longer than oxidation with dichromate, the COD is larger than the BOD. Urea also contains organic carbon, however it cannot be oxidized either chemically or biochemically. Sodium sulphide contains no carbon; as this substance is toxic, a BOD value cannot be measured; on the other hand, chemical oxidation is possible.

	total organic carbon [mg C/g]	biological oxygen demand [mg O_2/g]	chemical oxygen demand [mg O_2/g]
acetic acid CH_3COOH	400	720	1060
urea $O{=}C(NH_2)_2$	200	0	0
sodium sulphide Na_2S	0	(tox.)	820

Tab.: COD, BOD_5 and TOC compared in examples.

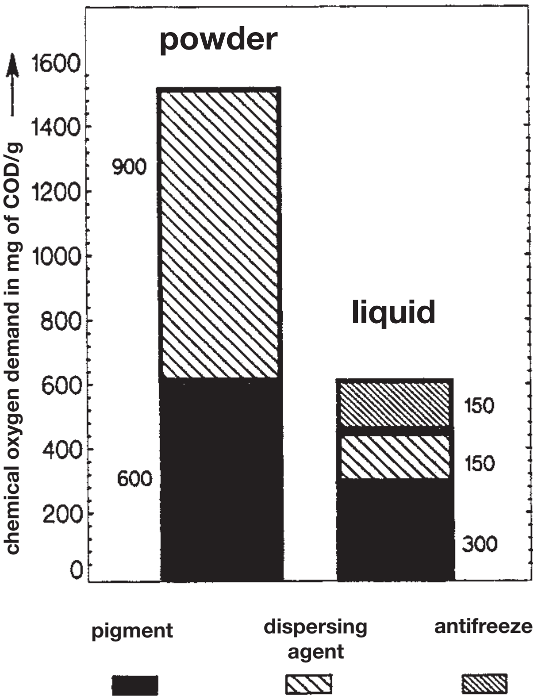

Fig. 1: Disperse and vat dyestuffs and their effect on COD.

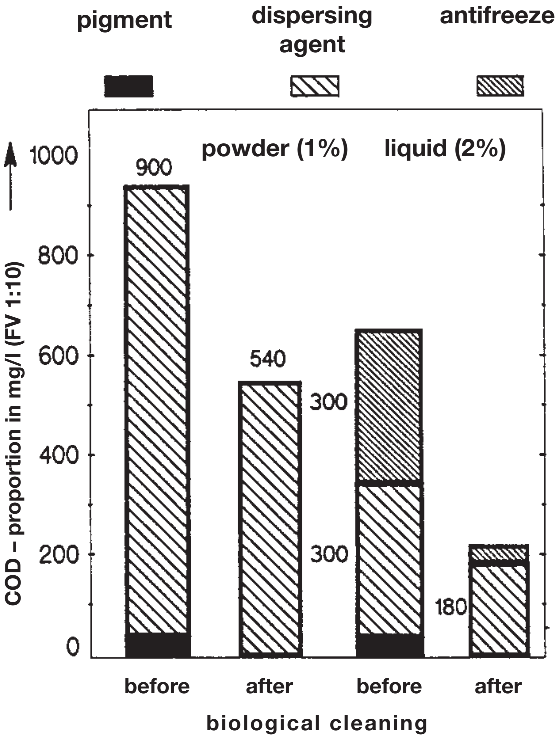

Fig. 2: COD pollution of effluent due to dyestuff after the dyeing process.

In the German environmental regulations, the COD is usually taken as the summation parameter for the organic loading and used as a limiting value for permitted discharge and also as a measurement for calculating effluent charges. The majority (up to 60–70%) of the COD loading in the effluent from textile processing is due to sizes and preparation chemicals. However dyehouses and printworks can also make a significant contribution to the COD loading. In dyeing with disperse and vat dyes, not only the choice of auxiliary but also the choice of the form of the dye is significant (Figs. 1 and 2).

Powder dyes have COD values from about 1500 mg/g, of which only about 40% comes from the dyestuff itself and about 60% from the dispersing agents. With liquid dyes, the average COD value is around 600 mg/g, of which about half comes from the dyestuff and 25% each from the dispersing agent and the antifreeze. If equally strong dyeings are made with a powder dye and with a liquid dye that is half the strength, the following results are obtained: the actual dyestuff in both cases is practically all taken up by the textile material, the dispersing agents and antifreeze on the other hand remain completely in the bath. Because of the higher content of dispersing agent, the COD loading of the exhausted dyebath is significantly higher when the powder dye is used; after a biological effluent treatment the difference is even more pronounced as the antifreeze used in the liquid dye is biodegraded very easily.

Ratio of BOD/COD: the BOD shows how readily a substance can be degraded biologically (e.g. in a clarification plant) under given conditions (free of heavy

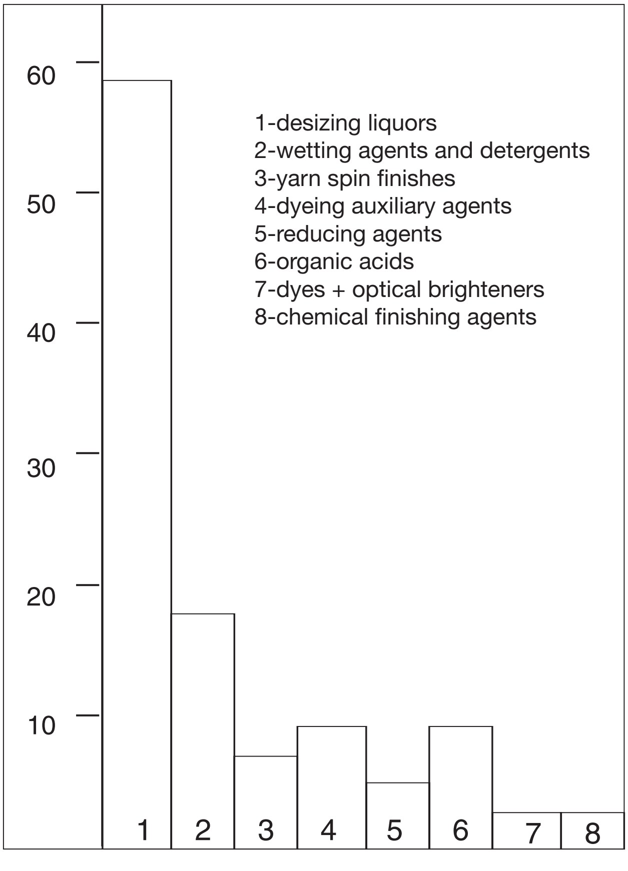

Fig. 3: Diagram of COD pollution in dyehouse effluent from woven fabric finishing.

metals and so on). However the ratio of COD/BOD is more meaningful, as it can be estimated from the COD how high the ultimate BOD must be. In domestic effluent, the ratio is about 2 : 1; in effluent from the dyeing and finishing industry it is around 4 : 1 or 5 : 1, sometimes even worse. The aim is to get the ratio down to about 2 : 1 (ideally 1 : 1). However, a lot of the polluting substances removed in textile processing come from previous textile preparation processes. About two thirds of the effluent loading for which the textile processors are responsible to an increasing degree is size, preparation agents, spooling oils and spinning auxiliaries that are necessary for washed and wetting (Fig. 3). Up to the present time, the most important factors in the development of textile auxiliaries have been the effects of assisting the processes with regard to quality and yield. In the future biological degradability or eliminability of these materials will be demanded, and this will in turn require changes in spinning and weaving.

Chemical pad Padder used exclusively for the application of chemicals.

Chemical products Generic term for all technical materials obtained by the chemical modification of natural raw materials or pure synthesis.

Chemicals. Chemicals manufactured for industrial or laboratory use as →: Fine chemicals; Heavy chemicals; Textile chemicals.

Chemicals, sampling of (Sampling). They must correspond to the average of the whole or a specific part in accordance with DIN 50 001. To this end, dependent on the substance type, thorough shaking, stirring, grinding or similar is essential. Organisation: Specialist Committee for the Taking of Specimens in the Association of German Engineers Process Engineering Section.

Chemiluminescence → Luminescence.

Chemisches Apparatewesen (Ger. association for) → Dechema.

Chemistry (Gk. *kemia* = transmutation). The branch of physical science concerned with the composition (→ Analysis), structure (→ Synthesis), properties, and reactions (→: Elements; Atoms; Molecules; Chemical compounds) of substances. The main branches of chemistry are →: Inorganic chemistry; Organic chemistry; Physical chemistry. For the textile technologist, the chemistry of dyes, fibres, colloids, textile auxiliaries, etc., are also important. According to classical definition, a chemical reaction occurs when a permanent change in the state of a substance takes place, e.g. by pouring dilute sulphuric acid on zinc whereby a new chemical substance, zinc sulphate (a salt), is formed from a metal and an acid.

Chemosensors are used to identify chemical substances and determine their concentrations. The imperfect selectivity of the currently available chemosensors is a significant disadvantage; apart from the sensitivity to the required substance, they also respond to other substances. An example of an electronic sensor is ELECOS (Electronically Controlled Sensitivity) in which the multi-dimensional signals from arrays of sensors are evaluated by the mathematical methods of pattern recognition so that an "electronic sensitivity" is reached. In contrast to the conventional gas measuring techniques, in which the analysis of complex atmospheres is carried out by determining the individual components, in electronic selectivity with arrays of sensors, a complex mixture is correlated to a signal pattern (finger print), in the same way as the sense of smell works. If this pattern is stored in a teach-in process, gas mixtures can be analysed without having to analyse each of the components individually.

Chemothermal is a term for the combined effect of chemicals and heat; e.g. → Chemothermal disinfection of clothing.

Chemset process for wet treatment of carpet yarn (washing, mothproofing etc.) with integrated fixing, drying and winding. Carpet yarn is normally delivered on bobbins. Before further processing on tufting machines, it must be washed (freed of spinning oils and contaminants) and set (twisting). If these wet treatments can only be carried out in hanks, preliminary unwinding and subsequent rewinding are necessary. In the Chemset machine (Fig.) from Andar (Annett & Darling Ltd) and Wronz, the yarn is taken from up to 24 bobbins in 2 "levels" (coilers), passed through the required wet treatment, dried and then wound up again in a 12 spool winding machine. Without the labour intensive hank handling, the process can be controlled better and the treatment is more even. A further advantage is that a mothproofing treatment can be integrated with the washing.

A definite yarn twist is a prerequisite for the surface appearance of the yarn. The bending and torsional tensions produced in the sheet of yarn are released in the setting process. This involves a reordering of the molecular structures of the individual fibres. In the Chemset process, the relaxation of tension comes principally from breaking disulphide bonds of the cystine in the wool by the nucleophilic attack of the hydrogen sulphite anion. The equilibrium reaction is shown by the following simplified equation:

$$\textcircled{W}-S-S-\textcircled{W} + HSO_3^- \rightleftharpoons \textcircled{W}-SH + \textcircled{W}-S-SO_3^-$$

Breakage of the disulphide bond accelerates with increasing temperature in hot water or steam and also with increasing pH. From the equilibrium equation, the cystine bond can be reformed (thiol exchange reaction) by an oxidative treatment, and the stability of the molecule is restored. This can be done simply by rinsing the yarn in a warm water bath.

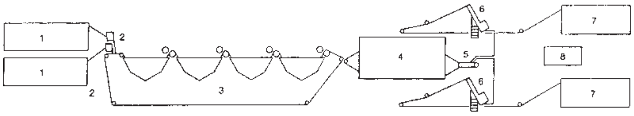

Fig.: Functional diagram of the Chemset machine.

The Chemset machine (Fig.) consists of (1) a double sided creel with 24 spindles and a rotating bobbin holder for 3 bobbins per spindle; (2) Gilbos bobbin winders with a normal working speed of 300 m/min, which set a 250 mm ceiling on the width of the output sheet; (3) baths for the wet treatment with efficient nips (washing, setting and rinsing); the first two baths have integrated liquor suction with a controllable liquor recycling through heat exchangers; (4) an Andar high efficiency drier; (5) a short run of yarn from the output of the drier where the yarn is split into two bands for storage and winding up; (6) Superba MAT yarn storage to allow spindling and repairing without any breaks; (7) 12-bobbin winding machine (Gilbos TU 1) with automatic bobbin winding; (8) a process regulator for automatic control with fault indication and process supervision

Chenille (Fr. = caterpillar),

I. Yarn with projecting fibres resembling a caterpillar. Yarn produced by first "weaving" in plain gauze or cross-weave interlacing and then cutting up the fabric warp-way. Distinction is made between flat chenille which is cut longitudinally on the chenille cutting machine, and scroll chenille which is produced as a plied yarn on chenille machines. The core generally consists of a plied wool or viscose yarn and the pile for example of silk, wool, cotton or viscose. End-uses: for (Axminster, chenille) carpets, apparel, upholstery, furnishing fabrics, scarves etc.

II. Woven velvet-like fabric the weft of which consists of chenille yarn. Multicolour, fancy or hollow chenille may be produced depending on the design. With this form of manufacture colour combinations are limitless. On shuttle and rapier weaving machines as many as thirty or forty different colours can be used. The characteristic features of chenille velvet are the high bulk and soft handle. This is why chenille fabrics resemble terry fabrics. Because of the complex time-consuming manufacturing technique these fabrics are relatively expensive.

Chenille Axminster carpet Chenille is the most expensive of the machine-woven Axminster carpets, and it offers the widest range of possibilities with respect to depth of pile, design, colourings, and width. Chenille may be constructed as wide as 9 m without a seam, and can be made as a single unit to fit irregularly-shaped areas. It can be produced with a pile up to 25 mm in height. This height, when supported by a heavy cushion back, gives a luxuriously soft and resilient quality to the carpet as well as excellent durability. The woven chenille construction requires two separate weaving machine operations. First, soft or hard-twisted yarns are woven in a blanket containing cotton warp threads with leno crossings. This blanket is composed of soft or hard-twisted weft yarns bound together by the cotton warp. Another machine cuts this weft halfway, producing furry strips that are held together by the cotton yarns in the centre. This strip, which resembles a caterpillar, is pressed into a V-shaped form, and the separate ends are tied together forming a continuous chain. This chain is subsequently used on the second weaving machine as a weft for the final weaving of the chenille carpet. A well-constructed chenille uses a fine-quality yarn and a densely-packed high pile, which results in the high durability of this weave.

Cherry gum → Rosaceae rubber.

Cheviot Term used originally for long, coarse and lustrous wool from Scottish Cheviot sheep. Nowadays the term also applies to lowland and → Crossbred wools.

Cheviot fabrics Named after Cheviot wool but today mostly made from crossbred wools, in other words wools of a relatively coarse nature. Cheviot fabrics are made from either worsted or woollen yarns. The worsted forms have a clear finish and are mainly sold in piece-dyed form. The woollen forms are frequently in lively designs and have a somewhat "woolly" cover. Weaves: twill, zigzag twill, plain and fancy weaves. Because of the relatively coarse strong wool these fabrics are substantially wrinkle-resistant. With their naturally harsh handle Cheviot fabrics are primarily used in menswear. A particular advantage of crossbred and Cheviot wools is their high resistance to pressure, creasing for example, but these wools withstand mechanical abrasion less satisfactorily than the fine merino wools, so taken as a whole their wear characteristics are not especially good.

Chicopee non-wovens Stabilization of nonwoven fabrics by water jets (making holes); a binder is also necessary.

Chiffon Transparent sheer fabric produced from fine highly twisted yarn in a plain-weave construction (e.g. cotton chiffon, mostly bleached with a matt finish, silk chiffon is generally similar to voile). Extremely lightweight but very strong. Used for evening dresses, lingerie, blouses and scarves. Chiffon velvet is a very lightweight silk velvet.

China clay → Kaolin.

Chiné printing → Warp printing.

Chinese rugs Antique Chinese rugs were made with the Persian or Senna knot, making possible a large number of knots per cm and a close shearing of the pile. Later, rugs were made with large, coarse designs and a deep pile. In more recent years, Chinese rugs have been made in plain colours as well as in the floral and dragon patterns characteristic of Chinese design. The pile of

Chinese rugs is unusually deep, making these rugs remarkably durable.

Chintz (Hindi, *chint*, from Sanskrit *citra* = gaily-coloured). A plain-dyed or printed cotton or viscose plain-weave fabric with a highly glazed finish produced by friction calendering (→ Chintz finish). Used for draperies, slipcovers, upholstery.

Chintz calender A → Calender for the production of high gloss and closing of fabric yarns. The finish effect is produced by bringing the cloth into contact with a heated, polished, chilled-iron bowl which is travelling at a faster speed than the cloth itself. Three-bowl heavy friction calenders are suitable for highly glazed finishes. The bottom bowl is usually made of close-grained cast-iron, the middle bowl of cotton (which is of greater diameter than the others to allow for wear; the top, or glazing bowl, is made of highly polished chilled-iron and is heated by steam or gas. An arrangement of spur wheels enables the top bowl to achieve a friction ratio of up to approx. 300%. The cloth enters the calender through the bottom nip and passes round the middle bowl (which is revolving at the same surface speed as the bottom bowl) and the friction effect is produced by the top bowl with its higher surface speed which imparts a high polish.

Chintz finish High glaze finish produced by friction calendering cellulosic fabrics previously impregnated with wax or paraffin emulsions, dried, and adjusted to an appropriate residual moisture content. Permanent chintz effects are produced on fabrics to which resin finishes (mainly melamine-formaldehyde compounds) have been applied prior to friction calendering, followed by subsequent curing. The finishing procedure is similar to → Embossing. Nowadays, depending on market requirements, higher demands are placed on the wash fastness of chintz finishes; in these cases, reactant resins are applied together with fluorocarbon or silicone derivatives.

Chintz prints (partial or local chintz). Localized glazed effects produced by screen or roller printing, e.g. single, multicolour or non-coloured designs with high glaze on white, black or multicoloured grounds without glaze. Pigments are used as colorants. The chintz effects are resistant to washing up to 40°C.

Chip,

I. Commercial form of plastics and fibre polymer starting materials (granules).

II. Electronic component as, e.g. a tiny wafer of semiconductor material, such as silicon, processed to form a type of integrated circuit or component such as a transistor.

Chip coloration → Mass coloration.

Chips Chips of synthetic fibre polymers (polyamide, polyester). Produced by shredding tapes of the polymerisate melt/polycondensate melt, to reduce to the required size. Undyed or dyed (chip dyeing), they are re-melted and extruded during spinning (known as the chip-melt-spin method).

Chitin (Gk. *khiton* = shell), $(C_8H_{13}O_5N)_n$. A polysaccharide comprising long chains of N-acetylglucosamine, a derivative of glucose. Chitin is structurally very similar to cellulose and serves to strengthen the supporting structures of various invertebrates being the principal constituent of the shells of crabs, lobsters and beetles. It is also found in some fungi, algae and yeasts. It is used as a raw material in the manufacture of → Man-made protein fibres of animal origin.

Chloramine bleach → Chlorine-peroxide bleach.

Chloramines In → Chlorine bleaching processes, protein impurities in the cotton and chlorine from the hypochlorite solution combine to form greenish yellow chlorination products (chloroproteins of the type R–NH–Cl). They are soluble in alkalis and precipitated by acids; hence they are not removed by acidification after bleaching but remain on the fibre and can lead to fibre damage on drying (release of hydrochloric acid).

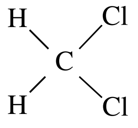
Chloramines become pale yellow during storage. For this reason they must be destroyed. This can be done effectively with an → Antichlor. On the other hand, chloramines (and proteins) act as stabilizers in alkaline hydrogen peroxide solutions; many combination bleaching processes have been based successfully on this principle (chlorine oxygen bleaches, → Chlorine-peroxide bleaches).

Chlorate of alumina → Aluminium chlorate.

Chlorate-steam process Steaming process for the development and fixation of vat leuco ester dyes in direct printing. The print pastes contain an addition of sodium chlorate as oxidizing agent.

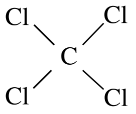
Chlorides Metal salts of hydrochloric acid and chlorine compounds of nonmetallic elements or organic radicals, a typical chloride is → Sodium chloride (common salt). Properties: mostly crystalline compounds which are water-soluble (except the chlorides of silver, mercury, lead), and colourless (except the chlorides of chromium, cobalt, copper, iron, nickel, etc., which are coloured).

Chlorinated hydrocarbons (CHC's). Chlorine substituted → Hydrocarbons of the dichloromethane type,

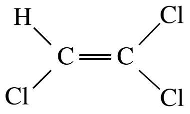


which play an important role in degreasing, dry cleaning, detergents, fat solvents (soaps) etc. High mol. wt. members (e.g. polyvinyl chloride, polyvinylidene chloride) are used in the production of thickening agents, plastics, synthetic fibres etc. A more important chlorinated hydrocarbon in textile chemistry is tetrachloroethylene, which is used for dry cleaning. 1,1,1-trichloroethane is used in white board cleaners. Because of its higher toxicity, carbon tetrachloride is no longer permitted in textile cleaning/textile industry.

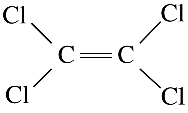
Chlorinated hydrocarbons: comparison of structures:



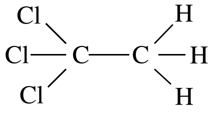
Carbon Tetrachloride



Trichloroethylene



Tetrachloroethylene



1.1.1-Trichloroethane

Chemical properties: the chlorine in tetrachloroethylene, carbon tetrachloride and trichloroethylene (that were the most used at one time), is in neutral bonds, but they are not completely stable. For this reason suppliers provide so called stabilizers to increase the stability. Decomposition can occur in the presence of moisture (especially with carbon tetrachloride: after prolonged contact with undissolved water and in the presence of oxygen, there is a gradual release of phosgene and hydrochloric acid [metal corrosion]; tetrachloroethylene and trichloroethylene are practically unaffected by undissolved water), light (storage in dark rooms or opaque glass bottles; solvent vapour continuously removed from the air in the room, or else unprotected iron and steel articles will rust very quickly), elevated temperatures (decomposition starts about 30–40°C above the boiling point; carbon tetrachloride and trichloroethylene above 110ºC, tetrachloroethylene above 140–150ºC). Contact with heated surfaces at these temperatures must be avoided also in indirect distillation (vapour pressure of carbon tetrachloride and trichloroethylene above 3 bar, of tetrachloroethylene above 6–7 bar) and traces of acid. More severe decomposition is evident from the pungent smell from the release of hydrochloric acid (test: shake with distilled water, blue litmus paper should not turn red; aqueous solution + several drops of nitric acid + silver nitrate solution should not give a white precipitate of silver chloride; nail test). Decomposed chlorinated hydrocarbons can be regenerated by filtering slowly through calcined, pulverized sodium or potassium carbonate.

Chlorinated hydrocarbons – neutralization No matter how CHC's have become acidic, they can be neutralized by bringing the pH back to 7.4–7.8 (e.g. with alkanone) by distillation with an addition of calcium carbonate, calcium hydroxide or 2% sodium carbonate solution. In no case can sodium or potassium hydroxides or calcium oxide be recommended: they can lead to the formation of chloroacetylene, which reacts vigorously on contact with air.

Chlorinated hydrocarbons – physiological effects Most chlorinated hydrocarbons evaporate quickly. Their vapour-air mixtures act to a greater or lesser degree as narcotics. At the beginning there is merriment and intoxication, fatigue and unconsciousness follow and can lead to death. Prolonged inhalation, even of small amounts, can lead to chronic damage to the nervous system and other organs. Symptoms of acute carbon tetrachloride poisoning are: dazed state, vomiting, coughing, irritation of the mucous membranes, belching, diarrhoea, in severe cases unconsciousness, convulsions, pulmonary bleeding, kidney damage, serious liver damage, jaundice, death. Warning symptoms are fatigue, drowsiness, sleeplessness etc. Trichloroethylene poisoning acts insidiously, often only after a long time, e.g. nervous illness, visual impairment, loss of teeth, trembling, loss of smell and taste etc. Tetrachloroethylene is counted as the "most harmless" , but the symptoms of poisoning are similar to those of trichloroethylene, although not nearly so severe. The highly toxic CHCs are carbon tetrachloride, tetrachloroethane and especially pentachloroethane.

With CHCs, the human skin loses its lipids and becomes dry, brittle and then cracked and very susceptible to infection, which can lead to inflammation and even to extensive skin disease. The protective measures must be strictly observed and the precautionary measures recommended by the suppliers should be checked constantly.

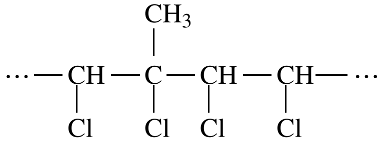
Chlorinated hydrocarbons – solvent monitoring CHCs straight from the factory are stabilized (→ Chlorinated hydrocarbons – solvent stability), but they can be contaminated by additions that get in while they are being used. The solvent should be checked at least with universal indicator paper (the solvent is shaken vigorously with an equal amount of distilled water and the separated water tested) or with Bromothymol Blue solution (0.05% alcoholic solution) in a test tube (fitted with a clean stopper): 5 ml of solvent + 2 ml of distilled water (must be neutral i.e. pH 7) + 2 drops of Bromothymol Blue indicator solution is shaken well and the upper aqueous layer examined: factory fresh solvent = strong blue (pH above 7.5); usable: = colour towards a light green (pH above 6.4) shows that the solvent is still free of impurities; when the colour changes over a short time from green to yellow: the cause of the fall in pH must be identified before it is stabilized again with fresh solvent. The causes could be: introduction of acids from outside or localized overheating with unsuitable stabilizers.

Chlorinated hydrocarbons – solvent stability Chlorinated hydrocarbons are decomposed by the action of light, air, heat and moisture, depending largely on the molecular structure (polar/non-polar). The stability decreases from tetrachloroethylene through trichloroethylene to 1,1,1-trichloroethane; because of their unsaturated character the first two are more prone to an oxidative attack, whereas 1,1,1-trichloroethane is more susceptible to hydrolysis. Stabiliszer combinations (corrosion inhibitors) overcome these different instabilities very effectively. Because of these considerations, only stabilized CHCs are available commercially: up to 0.02% by weight in tetrachloroethylene, somewhat more in trichloroethylene, and up to 6% by weight in 1,1,1-trichloroethane. Testing of factory fresh tetrachloroethylene sometimes gives pH values of almost 9, i.e. definitely alkaline (with a consequent risk of corrosion to copper and tin), although pH 7.5 would be enough. In modern dry cleaning equipment the pH of tetrachloroethylene can at times move slightly into the acid range, and this can promote corrosion. These difficulties can be eliminated by using combinations of kieselguhr and special silicates as the filtering agent.

Chlorinated hydrocarbons – storage CHCs are stored for long periods in storage tanks made of sheet iron, steel or galvanized iron. Rusting is prevented by application of a CHC resistant coating. Tanks made of V4A steel are especially suitable. Aluminium tanks are not suitable for trichloroethylene and 1,1,1- trichloroethane (alloys). The rule of thumb for the storage capacity of a tank is: capacity at least 50% greater than the anticipated volume to be stored. Larger tank installations require sealed take off points. Every CHC tank must be clean, dry and free from contamination.

Chlorinated paraffins Chlorination products of → Paraffins resp. high boiling point synthetic hydrocarbons or petroleum fractions. They are nonflammable and function as excellent wash-resistant flame retardants which also prevent after-glow. Chiefly available nowadays in the form of emulsions (more favourable effect on handle).

Chlorinated rubber $(C_5H_6Cl_4)_x$, density 1.66. Produced by chlorination of over-milled, irradiated, oxidized or vulcanized natural → Caoutchouc:



$$\cdots-\underset{\text{Cl}}{\text{CH}}-\underset{\text{Cl}}{\overset{\text{CH}_3}{\text{C}}}-\underset{\text{Cl}}{\text{CH}}-\underset{\text{Cl}}{\text{CH}}-\cdots$$

or also from synthetic material (e.g. from → Buna). White to pale yellowish substance (granules, powder or emulsions of different viscosities), with 60–68% chlorine content, with no taste or smell, non-flammable, insensitive to water, alkalis, acids, salts, petrol etc.; decomposes above 130ºC losing chlorine and turning brown. Soluble in benzene, hydrocarbons, carbon tetrachloride, trichloroethylene, chloroform, methyl-, ethyl- and butyl acetates and so on, partially soluble or swellable in acetone and ether. Uses: → Chlorinated rubber paints, for protective coatings of various types, protective coverings, flame resistant impregnation, for thickening and fixing (with softeners) in pigment and metal printing, laminating fabrics etc.

Chlorinated rubber paints Used as fixing agents in bronze printing (with the addition of plasticizers, as they would otherwise be too brittle) and as universal protective coatings against all kinds of corrosion for iron, metal or wooden constructions, walls, coverings, walls, concrete bases, pipework etc. They are (→ Chlorinated rubber) free of oil, available in any colour, harden quickly, stable to temperatures up to 100ºC (up to 60ºC when wet) resistant to bacteria, insulating, non-toxic, mechanically more resistant than red lead coatings; easy to clean by spraying with soap and water and similar solutions.

Chlorinated water fastness assesses the resistance to chlorinated water. A sample is wet out in distilled water, dewatered to 100% water content and placed in an aqueous solution containing 20 mg/g of active chlorine (from sodium hypochlorite) at a liquor ratio of 100 : 1 for 4 hours at 20ºC. Assessment with the grey scale.

Chlorination of wool leads to an increase in swelling and wettability, dyestuff affinity, lustre and to reduction in the felting and shrinkage (anti-felting and shrink resistant finishing). The principle is: the action of aqueous solutions which develop “active chlorine”, e.g. sodium hypochlorite, hypochlorous acid and chloraminated compounds. Uniform chlorination of wool requires control of the chlorination of the wool and careful supervision of the process. Increasing the temperature or reducing the pH accelerate the reaction and lead to irregular, unlevel, treatment. Temperatures below room temperature and higher pH’s slow the chlorination reaction. However the latter is associated with increasing damage and yellowing of the fibres. Slow and level chlorination is achieved with compounds like chloramines, e.g. with alkali metal salts of di- or trichloroisocyanuric acid.

No striking differences can be seen in an electron microscope between alkaline chlorinated wool (pH 9) and untreated wool. However, large parts of the exocuticle are removed from wool that has been chlorinated at pH 1, and the endocuticle, which is susceptible to hydrolysis, becomes part of the wool surface (Fig.). The fraction of liberated wool gelatine in the acid chlorinating liquor (exocuticular protein) is about ten times as great as the protein liberated from the inside of the fibre during alkaline hydrolysis. In addition, similar amounts of keratin proteins are liberated in acid chlorination but remain held in the wool in the form of salts, and are only liberated on alkaline treatment. The chlorinated, soluble wool protein increases the AOX content of the effluent.

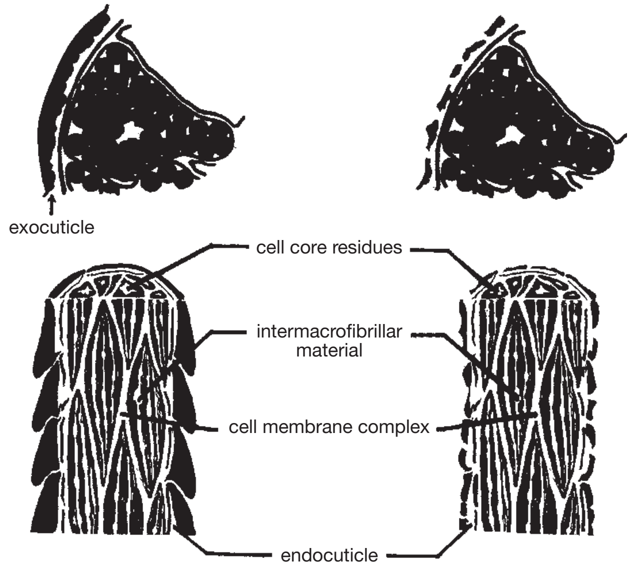


Fig.: Schematic diagram illustrating the morphology of not very cross-linked non-keratin proteins (shown in white) in wool and chlorinated wool, which can be preferentially weakened in subsequent hydrolysis (dyeing conditions, fastness tests), and can be released as wool gelatine. The hydrolytically resistant keratin proteins are shown in black (Baumann).
Top: cross-sectional sector of wool according to Mercer et al.
Bottom: longitudinal view of the bond structure of wool.
Left: untreated wool and alkali-chlorinated wool. No significant morphological differences visible in the electron microscope.
Right: pH 1, chlorinated wool. After a large part of the exocuticle has been removed, the hydrolytically more easily corrodible endocuticle is part of the wool surface.

Differences between wool fibres that have been chlorinated to different degrees are shown up sharply in subsequent dyeing processes. The lightly crosslinked, non-keratin proteins (endocuticle, cell membrane complex, residues of the cell nuclei and intermacrofibrillar material) are the reason that wool is so susceptible to hydrolytic attack in all practical dyeing processes at the boil or under HT conditions. Part of the morphologically specific non-keratin proteins liberated will remain in the bath as wool gelatine in a combination that is characteristic for the particular dyeing conditions. Another part will remain held in the wool and only be freed by a change in pH. Apart from the oxidatively loosened keratin proteins, in dyeing chlorinated wool, non-keratin proteins (weak spots) are also liberated. Acid chlorinated wool has an open structure (the endocuticle is part of the surface); the surface of alkaline chlorinated wool is largely intact, similar to that to untreated wool. For this reason, it is understandable that the dye fastnesses of untreated wools are generally 1–2 points better than those of acid chlorinated and wool that has had an antifelting finish and been dyed. Possible applications:

1. Increasing the dyestuff affinity and wettability: 1–1.5% of active chlorine (calculated on the weight of fibre) in a weakly acid liquor below room temperature for about 20–30 min, then anti-chlored and bleached in a fresh bath with 1–2 g/l sodium dithionite. Liquor ratio about 30 : 1.
2. Anti-felting and crease resistant finishing: 1.5–3.5% active chlorine is used as described in 1.
3. This treatment can produce a significant increase in the lustre.
4. Giving carpets an antique appearance: intensive surface treatment with chloride of lime solution (8 g/l active chlorine) for 30 min, intermediate rinsing, then another surface treatment with 0.6% caustic solution. The carpet is left in the alkaline solution for 20 min, then well rinsed and dried.

The process requires a lot of experience and has also become something of a problem from the ecological point of view.

Chlorination/resin finish → Antifelting finish of wool on the base of synthetic resins which is preceded by a chlorination.

Chlorine (Cl), atomic weight 35,5. Nonmetallic halogen element. Dense greenish-yellow poisonous gas with a pungent, very irritating odour, soluble in water. Forms explosive mixtures with hydrogen, especially in sunlight (chlorine detonating gas). Chlorine is a very reactive element and combines directly with most other elements. It is noncombustible, but supports combustion (strong oxidizing agent). Compounds include hydrochloric acid HCl, and chlorides as salts. Compounds with oxygen include monoxide, dioxide and heptoxide (Cl_2O, ClO_2, Cl_2O_7) which form → Chlorine oxoacids with water. Characteristic (for analytical chemistry): silver chloride is insoluble in water and dilute acids but soluble in dilute ammonia solution. Calcium chloride is readily soluble. Uses: as a disinfectant (water sterilization) and oxidative bleaching agent for textiles. Its salts are used in bleaching, carbonizing, delustring, dyeing (sodium chloride); as oxygen carriers in dyeing and printing; dye mordants; chemical analysis, etc.

Chlorine bleaching, → Oxidative bleach for cellulosic fibres, chiefly used on natural cellulosic fibres such as cotton and linen (→: Bleaching; Bleaching agents).

I. → Hypochlorite bleach: calcium hypochlorite $CaOCl_2$ (bleaching powder); sodium hypochlorite NaOCl.

II. → Chlorite bleach: sodium chlorite $NaClO_2$.

III. → Chlorine dioxide bleach: ClO_2.

Chlorine carriers for dry bleaches Organic chlorine compounds which, e.g. split off available chlorine resp. hypochlorite at elevated temperatures. They find application in bleaching detergents, wool detergents, sterilizing washing agents, antifelting finishes for wool, etc. Examples →: Chloramines; Chloroisocyanuric acids.

Chlorine/chlorate discharges These are examples of oxidative discharges:

I. Acid-chloride of lime process for discharging Turkey red and indigo.

II. Chlorate-red prussiate of potash process for discharging indigo, indigoid vat dyes, cationic dyes and mordant dyes.

Chlorine content of bleach liquors → Available chlorine.

Chlorine dioxide bleach Bleaching with an aqueous solution of chlorine dioxide which, during the process, is freshly prepared on a continuous basis in special equipment. It finds only occasional application, e.g. in the Ravensberg linen bleaching process. A chlorine dioxide bleach process on the cold pad batch principle has been used in France.

Chlorine fastness → Hypochlorite bleach fastness.

Chlorine generators They are used to ensure the controlled → Chlorination of wool. They are able to bind free chlorine initially in the form of a buffered chlorine carrier, e.g. alkali-metal salts of dichloroisocyanuric acid (DCCA).

Chlorine-Hercosett process Antifelting finish for wool based on the application of synthetic resins to prechlorinated wool, e.g. → Hercosett process.

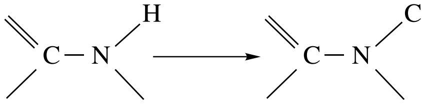
Chlorine oxoacids are a series of very weak to very strong acids: hypochlorous acid (HClO), salts: hypochlorites, strongly oxidising bleaching agent; chlorous acid ($HClO_2$), salts: chlorites (sodium chlorite bleach); chloric acid ($HClO_3$), salts: chlorates; perchloric acid ($HClO_4$), salts: perchlorates ($NaClO_4$).

Chlorine-peroxide bleach (Ce-Es bleach, chloramine bleach). "Ce-Es" is the abbreviation (from Böhme) for a combined chlorine peroxide bleach. This process was originally developed to avoid bucking. As compared to the old → Kier boil-chlorine bleach, in site of the satisfactory full white, there are significantly lower losses in weight and stability. Principle: pre-wetting, impregnation with hypochlorite solution, squeezing, layering in a peroxide bleaching unit and (without intermediate rinsing) peroxide bleaching. The term "chloramine bleach" comes from the chloramines that are formed with chlorine and which act as stabilizers in the subsequent peroxide treatment. Use: only sporadically for cotton workware.

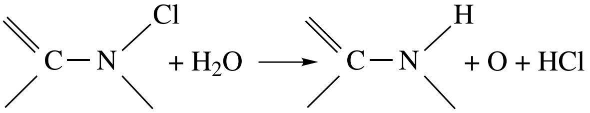
Chlorine products → Bleaching chemicals.

Chlorine resistance of resin finishes The resistance of resin finished textiles to available chlorine , e.g. in bleaches (→ Chlorine retention) is largely dependent on the chemical type of resin finish applied. Finishes based on e.g. DMPU, are resistant to chlorine.

Chlorine retention The capacity to hold chlorine; the behaviour of finished textiles towards baths that contain active chlorine (so-called chlorine washing, usually as an addition to the actual washing process to improve the whitening effect or to disinfect; the requirements for industrial laundries differ in different regions, e.g. in USA and Spain, and also in domestic washing). Depending on their chemical constitutions, the finishing agents fixed on the fibre combine to a greater or lesser extent with chlorine to form chloronitrogen compounds,



which, in subsequent heat treatments (e.g. ironing, steam pressing), damage the goods by oxidative and hydrolytic decomposition: more or less intense yellowing or browning, reduction in the tensile strength. Testing normally by AATCCC 92-1971.



In finishing with nitrogen-containing finishing agents, urea-formaldehyde derivatives, such as DMEU, DMDHEU, are particularly prone to chlorine retention; dimethylol compounds, such as propylene urea and DMPU and carbamates, such as dimethylol methoxyethyl carbamate, do not retain chlorine. There is no loss in strength when methoxy melamines are used in finishing, only possible yellowing; hence they are used as a buffering addition to other finishing agents, such as DMEU. Nitrogen free finishing agents do not retain chlorine.

Chlorine, test for → Potassium iodide starch paper.

Chlorine test for dyeings on cellulosic fibres Procedure: the dyed or printed textile specimen is placed in sodium hypochlorite solution (7–8 g/l available chlorine) acidified with a little dilute hydrochloric acid. The nature, intensity, and speed of bleaching are observed.

a) Substantive dyes (including aftertreated dyeings): bleaching is generally complete; original colour no longer returns on rinsing. Certain yellows are chlorine-resistant.
b) Cationic and sulphur dyes: the colour is likewise completely bleached out and is no longer restored on rinsing. Certain sulphur dyes are fast to chlorine.
c) Vat dyes and naphthols: no change. Indigo dyeings are bleached to a slight extent.
d) Reactive dyes: slight to complete bleaching occurs; original colour is no longer restored on rinsing.

Chlorite bleach (→ Chlorine bleaching). The reaction mechanisms involved are well known. According to Agster the following processes take place:

1. liberation of the bleaching agent:
   $NaClO_2 + HCOOH \rightarrow HClO_2 + HCOONa$
2. bleaching reaction:
   $HClO_2 \rightarrow HCl + 2\,(O)$
3. decomposition of the bleaching agent:
   $5\,HClO_2 \rightarrow 4\,ClO_2 + HCl + 2\,H_2O$
   $2\,ClO_2 + H_2O \rightarrow HClO_2 + HClO_3$
   $3\,HClO_2 \rightarrow 2\,HClO_3 + HCl$

The concentration of the effective bleaching agent, chlorous acid, reaches its maximum at pH 2.5–3.5. Below pH 3.0, fibre damage becomes very noticeable. The decomposition of the weak acid, $HClO_2$, generates the strong acids $HCl + HClO_3$, which hydrolyse the cellulose. Hence the optimum conditions are in the range of pH 3.0–4.0. To buffer the reaction medium against becoming too acidic, phosphate buffers are used as stabilizers, so that no more chlorous acid is liberated than the goods can use. Otherwise the treatment is unlevel and there is more decomposition of the bleach liquor with all its consequences (Fig.).

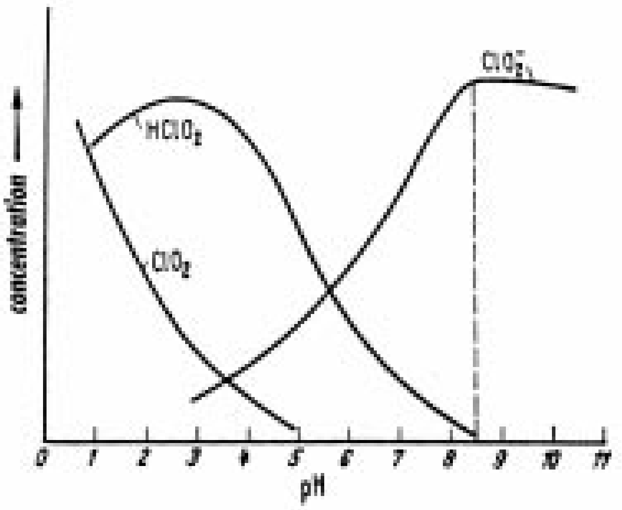


Fig.: Products of decomposition in chlorite bleaching relative to pH.

Chlorite bleach fastness assesses the stability to sodium chlorite bleach solutions.

I. Light: treatment with 1 g/l sodium chlorite (80%) at pH 3.5 (addition of acetic acid) for 60 min. at 80ºC, liquor ratio 50 : 1. Subsequently rinsed for 10 min. in running water.

II. Severe: with 2.5 g/l sodium chlorite (80%).

Assessment with the grey scale.

Chlorites Salts of chlorous acid $HClO_2$ → Chlorine oxoacids. Properties: on heating they undergo sudden or explosive decomposition; in solution they are strong oxidizing and bleaching agents, e.g.→ Sodium chlorite.

Chloro-, prefix for compounds with complex bound chlorine.

Chlorobenzene (monochlorobenzene, phenyl chloride), C_6H_5Cl. Colourless volatile liquid with unpleasant almond-like odour. Toxic (avoid skin contact and inhalation, good ventilation necessary). Density 1,1, b.p. 132°C. Insoluble in water but soluble in alcohol, ether, benzene. Uses: as a solubility reagent for synthetic fibres (soluble cold = polyvinyl chloride including post-chlorinated types; soluble at the boil = polyethylene); formerly used as a carrier in the dyeing of polyester textiles with disperse dyes.

Chloro(-fibres) is an incorrect abbreviation for chlorinated polyvinyl fibres. →: Polyvinyl chloride fibres; Polyvinylidene chloride fibres.

Chlorfluoroalkane → Chlorofluorocarbons.

Chlorofluorocarbons (CFCs), best known as derivatives of methane or ethane, where the hydrogen is wholly or partially replaced by fluorine or fluorine and chlorine. With a low boiling point, non-flammable and of relatively low toxicity, chlorofluorocarbons are used as coolants, propellants for aerosols and blowing agents for foams, degreasing agents and formerly as solvents in special dry cleaning plant for furs, leather and delicate articles. The gentle action of CFCs made them suitable for: maintaining colour brilliance, increasing the range of items which can be cleaned and reducing the risk to delicate items (reduction in the rate of damage); official directives have forbidden the establishment of CFC plant in Germany.

CFCs for dry cleaning: there are certain requirements that must be fulfilled by a dry-cleaning solvent. It must be capable of cleaning textiles well without damaging them. It must be economically efficient to use; when used correctly it should not decompose, nor should it endanger the health of people or pollute the

solvent	time	problem
turpentine oil	1825–1840	hardly volatile strong smell
benzene	1830–1860	cancer-inducing
petroleum ether	1850–1950	combustible
heavy benzine	1925	combustible
carbon tetrachloride	1900–1950	toxic
trichloroethylene	1925	restricted
tetrachloroethylene	1930	restricted (ground water danger)
1,1,1 trichloroethane	1965	restricted
fluorocarbon 113	1960	reactions in the stratosphere
fluorocarbon 11	1970	

Tab.: Historical development of dry-cleaning agents.

environment. These requirements have become so stringent over the years (see Table) that the use of CFCs has now been forbidden in Germany. CFCs are highly volatile, evaporate into the atmosphere, and there decompose. According to current knowledge, a large proportion of tetrachloroethane (hexachloroethylene) is decomposed in the troposphere, the lowest atmospheric layer. It is assumed that the chlorofluorocarbons or at least a part thereof, penetrate undecomposed through to the layer above, the stratosphere, and reach the ozone layer (see Fig.). The effect of the ultra-violet rays which are strong at this level is thought to cause chlorine atoms to separate off from the fully halogenated chlorofluorocarbons (i.e. those without hydrogen atoms), which then break down the ozone molecules to leave molecular oxygen. Thus the ozone layer is reduced and its effectiveness as a filter against UV radiation is weakened. Consequently, UV radiation to the earth's surface is stronger, which could cause biological changes. CFC 11 (trichlorofluoromethane) and CFC 113 (trichlorotrifluoroethane) are thought to pose particular risks as chlorine-containing and fully halogenated CFCs.

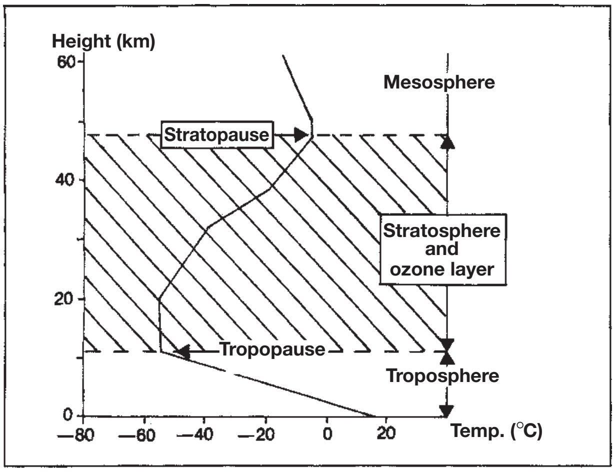

Fig.: Division of the atmosphere. Chlorofluorocarbons penetrate the stratosphere where they reduce the ozone content.

Chloroform ($CHCl_3$). Colourless fluid, mobile, volatile, sweetish smell (anaesthetizing), can cause blistering of the skin, suspected of being carcinogenic, noncombustible, gradually decomposes in the presence of light and air (store in brown bottles). Slightly soluble in water, easily miscible with alcohol, ether, petrol etc. Dissolves acetate fibres, rubber, fats, oils, resins, tar and suchlike. Used as: solvent and stain remover (stains of light fats and oils, dried-on oil paint, varnish, lacquers, resins, rubber, tar, iodine; in difficult cases mixed with ether); tends to leave a mark at the edge (rework with petrol) in the case of lacquers, glues, etc.

Chlorohydrins Organic compounds containing one or more C(OH)·CCl groups. Reactive group for crosslinking reactions, e.g. with cellulose in the presence of alkaline catalysts (sodium hydroxide solution) with at least 2 functional groups. Used *inter alia* as resin finishes, e.g. →: Dichlorohydrin, Epichlorohydrin.

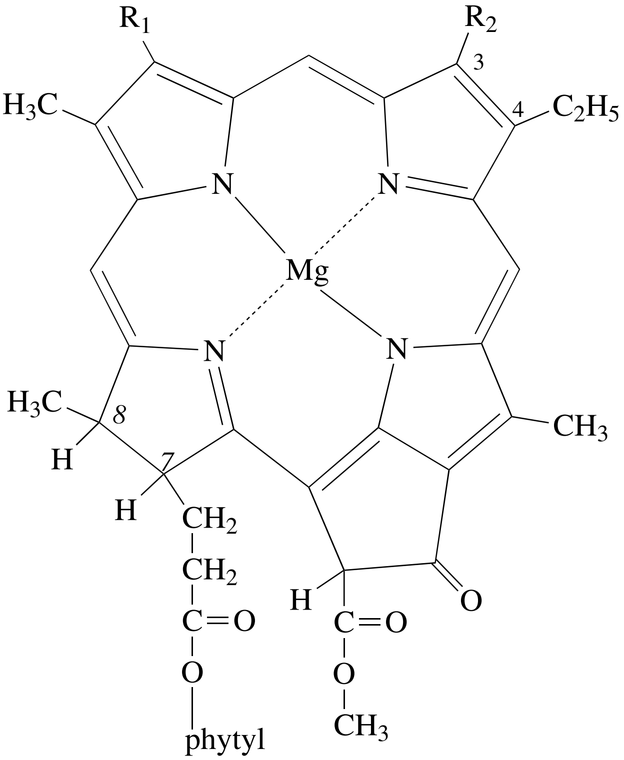
Chloroisocyanuric acids In the form of the tri- and dichloroisocyanuric acids, as well as sodium and potassium dichloroisocyanurates, they are important as chlorine generators in cleaning detergents and antifelting finishes for wool. Chloroisocyanuric acids are formed by the chlorination of isocyanuric acid resp. cyanuric acid whereby both tautomeric forms are present in the chlorination products with the iso-form predominating.

Available chlorine content in comparison with other chlorine generators:

Eau de Javelle, conc.	149–159 g/l
Chloride of lime (bleaching powder)	365–390 g/l
Trichloroisocyanuric acid	850 g/l
Dichloroisocyanuric acid	700 g/l
Potassium dichloroisocyanurate	600 g/l
Sodium dichloroisocyanurate	590 g/l

Advantages compared to other chlorine bleaching agents: higher available chlorine content, readily soluble, bleaching action already effective at low temperatures. The stability of chloroisocyanuric acids increases with decreasing chlorine content.

Chlorophyll is obtained by extraction of ground leaves. It is a mixture of the blue-green chlorophyll a and the yellow-green chlorophyll b:



chlorophyll a:	R_1: $CH=CH_2$, R_2: CH_3
chlorophyll b:	R_1: $CH=CH_2$, R_2: CHO
bacteriochlorophyll a:	R_1: $CO–CH_3$, R_2: CH_3; hydrated in 3.4 position
chlorophyllide a:	R_1: $CH=CH_2$, R_2: CH_3; H instead of phytyl

Both types of chlorophyll contain complexed magnesium (they are structurally similar to the red colouring in blood, haemoglobin, an iron complex). They consist of a coloured component (chlorophyllide) and a high mol. wt. alcohol (phytol). Chlorophylline is produced on saponification. This is the cause of the spontaneous deodorizing effect originally ascribed to chlorophyll. The deodorizing effect of chlorophyll is only significant with butyric acid; with other strongly smelling substances, there is no or only a slight effect. Use → Chlorophyllines.

Chlorophyllines are the coloured acids or their water-soluble salts produced on saponification of → Chlorophyll. General name for mixtures of different composition, with complexed magnesium, more usually however with copper (commercial preparations have 0.8–4.7% copper) to increase the greenness and the light fastness. The deodorizing properties of the various chlorophyllines differ in intensity, occurrence of the optimum effect and duration of the effect. The copper complexes seem to be rather less effective. Use: colouring soaps, oils, cosmetics; as deodorants and textile odour improvers.

Chlorovinyl fibres → Polyvinyl chloride fibres.

Chlorzyme process is a special chlorination process for crossbred wool to give it a soft structure like merino wool. Treatment with dry chlorine gas and subsequently with the enzyme, papain. The scale structure is eliminated, leading to a flat, silk-like handle. As the chlorination does not reach the inside of the fibre, the fibre is not thinned.

Chol- (Gk. *khole* = bile or gall). Prefix as a combining form before a vowel, e.g. as in choline, cholesterol, etc.

Choli Short-sleeved bodice, usually of silk, as worn by Indian women. Frequently decorated with embroidery and mirror appliqué work.

Cholic acid → Gall extract.

Choline is an organic base, deliquescent crystals, strongly alkaline, readily soluble in water and alcohol, absorbs considerable amounts of carbon dioxide from the atmosphere. Component of lecithin. Produced synthetically by the action of ethylene oxide on trimethylamine. Betaine is produced on mild oxidation. Interesting textile auxiliaries of the fatty acid-choline ester type are obtained by esterifying the alcoholic hydroxyl group with a fatty acid. Solutions of these esters foam like soap solutions; they are fairly resistant to sodium carbonate (but not to strong alkalis) and acids in the cold (hydrolysis takes place at higher temperatures). Alkylene or aralkylene substituted cholines and their derivatives are used as pasting and auxiliary agents in vat printing.

Chromate discharges → Oxidative discharges for the production of coloured discharges on indigo grounds. The discharge print pastes contain sodium bichromate and alkali.

Chromate dyeing process Single bath chroming process for chrome dyes.

I. Wool: selected chrome dyes (mordant dyes) are dyed together with a chromium salt in the same bath. This process is used especially in cases where iron or copper is present in the water or in the dyeing equipment.

II. Wool/cotton unions: special dye mixtures (wool/cotton chrome dyes) are dyed together with a chromium salt in the same bath.

Chromatic Relating to, or characterized by a colour or colours; monochromatic = one hue or colour, trichromatic = three colours, polychromatic = multicoloured.

Chromatic adaptation Adaptation of the sensitivity of the retina to the predominant colour in the → Field of vision. Has a large effect on the judgement of → Colour and leads to the colour of an object being perceived very differently, e.g. according to which other, interfering colours there are around the sample. This effect is at its greatest when the second, interfering colour is in the centre of the field, i.e. directly surrounding the sample in question, and decreases the further the second colour is from the centre of the field of vision. When an original and a reproduction dyeing with the same colour are being compared, chromatic adaptation plays no role because it changes the character of the perception of the colour, but does not affect the equality of the two colour sensations. When there is a colour difference between the two samples, however, difficulties arise with the introduction of a second colour into the surrounding field of vision of the observer. The second colour affects identification of the direction of the variation, so that mistakes in the selection of the dyes needed for correction arise: for this reason it follows that an inspection table that is completely free of other samples of every type is essential for comparing samples (→ Adaptation).

Chromatic circle This is a circular representation of the → Hue of so-called chromatic colours which are formed by combining additive colour mixtures. The chromatic circle is restricted to a maximum of 200 different pure shades which can be produced e.g. using perceived equal saturation and brightness values. The commonly used 24-section chromatic circle contains 8 principal colours each in 3 levels (light, saturated/full, dark) and each ordered with the so-called colour coefficient (also referred to as a colour point), starting with yellow (colour coefficient 1, 2, 3) through orange (4–6), red (7–9), violet (10–12), ultramarine blue (13–15), ice-blue (16–18), sea-green (19-21) to leaf green (22–24). The complementary colours of the first order are located 180° opposite each other in the circle (e.g. yellow 2 and ultramarine blue 14). These always give black when mixed subtractively. Complementary colours of the second order are understood to be trichromatic groups which are always located at 120° to each other (e.g. yellow 2, violet 10 and ice-blue 18). Subtractive mixtures also give black here (photographic principle), whereas additive mixtures give white (→ Colorimetric measures). The colour coefficients of the chromatic circle and the letters of the grey series give the Ostwald standard code for the colour (→ Pure spectral colour).

Chromaticity coordinate Normal chromaticity coordinates (x,y) are values that define a colour without reference to the lightness (→ Colorimetric measures).

Chromaticity diagram (CIE colour diagram, colour triangle). Geometric representation of colour in its various mixtures derived from the → Colorimetric measures. The Ostwald colour triangle is determined from the three triangular points white (a), black (p) and pure spectral colour (pa). According to standardised international representation (DIN 5033 and 6164) as per the CIE or IBK triangle, a right-angled form of an open triangle is used with x as the abscissa and y as the ordinate (→ Colorimetry). Within the triangle is the bell-shaped curve of the so-called spectrum locus of the monochromatic light wavelengths, beginning at 400 nm (= violet blue) to 520 nm (= green), 575 nm (= yellow), 600 nm (= orange) up to 700 nm (= red). The trace of the curve closes at the bottom between 700 nm and 400 nm with the so-called purple boundary with the purest possible purple colours, i.e. mixtures of red-violet-blue (Fig.). The achromatic point E lies at the lower centre (for equi-energy light; $x, y, z = 0.333\overline{3}$), which must be fixed here as normal white C. As the curve therefore clearly shows all pure shades, all standard colours must fall within the area enclosed within the curve, any colour therefore will be on the straight line between point of illumination C and the corresponding spectral colour, a colour mixture will be on the straight line between these two components. Complementary colours consequently lie on either side of the connecting line, spectral colour/point of illumination. If the 24 shades of the Ostwald chromatic circle are sequenced according to the corresponding shade wavelengths, then the colour lines 1–24 radiating outwards from the centre C are formed, e.g. yellow 1 at just 575 nm would represent the homochromatic range from outside to inside from the pure spectral colour to white with the relevant blue complementary colour on the other side of C. Lines S 1–15 which are similar to the annual rings of a tree are the saturation curves which represent all shades (1–24) from 1–7. After determining the colour measures for a specific colour by colorimetry, the chromaticity co-ordinates y (green fraction) and x (red fraction) are entered in this co-ordinate system and thus the so-called colour point or colour location which uniquely defines the colour is obtained as z (the blue fraction) follows from the equation: $z = 1 - (x + y)$. The latest trend in colorimetry is to shift the achromatic point by illuminating from standard illuminant A to illuminant D_{65}.

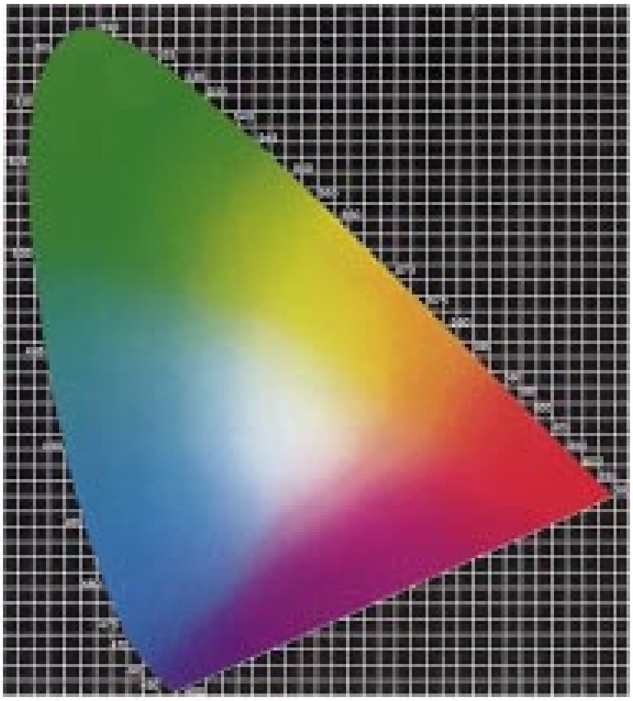


Fig.: Chromaticity diagram.

Chromatic colours According to Ostwald, so-called pure spectral colours in yellow, red, blue, green and intermediate → Shades; in practice mostly mixed with white and/or black. → Chromaticity diagram.

Chromatin → Protoplasm.

Chromatogram A graphical record of a completed chromatographic separation by paper, thin-layer or gas chromatography. The Figure illustrates examples of chromatograms produced from extracts of mercerized cotton dyed with a (monofluorotriazine) reactive dye as a function of fixation times from 0–28 min. (pH 11, 40°C, 200 g/l Na_2SO_4).

The chromatograms clearly show that, under the given fixation conditions, the concentration of intact reactive dye on the fibre decreases rapidly whilst that of the hydrolyzed dye, on the other hand, only increases very slowly. This indicates preferential reaction of the dye with the fibre.

Chromatography (Chromatic adsorption analysis). Separation procedure for isolating individual com-

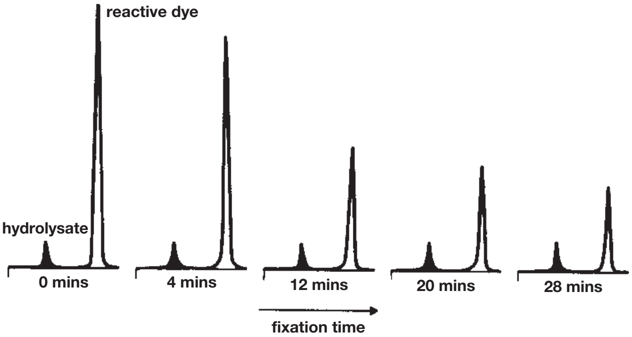

Fig.: Demonstration of the reaction of a reactive dye with cellulose by chromatography of a respective fibre extract on paper.

ponents from mixtures of substances with similar constitutions (related derivatives, isomers and the like) but having different adsorption power. First used by Tswett in 1906 in the analysis of mixed dyestuffs. A distinction is made between different kinds of chromatography depending on the physio-chemical basis of the method.

Method and classification in accordance with separation function:

I. Adsorption chromatography: an equilibrium occurs between the molecules adsorbed on the solid surface (powder or fibre) and those that are present in the flow of solution or gas. The separation function is nonlinear (result: diffuse stain edges).

II. Separation chromatography: based on the distribution of mobile and stationary liquid phases (whereby the fixed carriers may not react with the phase). The substance is dissolved in both phases. Stationary phase: usually water or polar organic solutions, including gel with enclosed liquid. Advantage: linear separation function (the distribution coefficient is independent of the concentration of the substance dissolved in both non-mixable liquids). → Paper chromatography usually means distribution chromatography.

III. Chemical chromatography: extremely stable bond between the carrier and the solids that are to be separated. The position of the bonding zone is extremely dependent on substance concentration.

IV. Column chromatography: special case of III where substances that are to be separated come into contact with the adsorbent that is fixed to the carrier. Example: silver salt fixed in the column, dissolved in a flowing solution of sodium chloride and potassium chromate, forming a silver chloride zone (top) and a silver chromate zone (bottom).

V. Ion exchange chromatography: normally using resin columns that exchange ions with the solution.

VI. Salting-out chromatograph: salting out with electrolyte reduces solubility in the mobile phase.

VII. Electrochromatography: substances are separated by means of differing mobility in the electrical field and different adsorption capacity. Also called paper electrophoresis if paper is used.

VIII. → Thin layer chromatography: same method as paper chromatography regarding the introduction of the mixture of substances to be separated, the use of the carrier and the way in which the separated substances are made visible, but the adsorbent sensitivity is considerably greater. The individual components separate much more rapidly and the process is therefore more practical.

Adsorption chromatography exploits the edge zone appearance of the adsorption of constituents of a liquid solution into a solid surface. The accumulation of a substance on the solid edge zone of a solid/liquid system is based on the reaction between the molecules adsorbed from the solution and the solid surface. The forces occurring between the particles in the liquid and those in the solid substance determine this reaction. For any given solid this force depends on the structure of the molecules in the solution and the solvent, whereby differing degrees of adsorption may occur and affect the separation of the dissolved substances. In this case, minor structural differences are often enough to create different adsorption behaviour. A general quantitative description of this phenomenon is difficult, since it is extremely dependent on the respective experimental conditions. It must also be taken into consideration that as well as the desired differing adsorption of the dissolved substances the solvent is also frequently adsorbed. However, empirically gained experience is usually enough to solve many separation problems using chromatography.

Chromatographic analysis is usually divided into 3 stages. First the substances to be examined are separated. These substances are then dissolved in a suitable solvent. The solution is allowed to flow through a vertical tube that is filled with the adsorption agent. This is where the dissolved substances accumulate in various places in the column as per their respective adsorption behaviour. A so-called → Chromatogram forms that is visible if the substances have different colours. Nonpolar substances such as ether, n-alkanes, carbontetrachloride, benzene etc. are normally used as solvents. Sugar, aluminium oxide, calcium carbonate, silica gel etc. are often used as adsorption agents. In the second stage the substances on the adsorption agents in different zones of the column are removed again. A suitable elution agent is run from the top to the bottom of the column in order to do this, causing the individual substances to leave the separating column one after the other, allowing them to be collected individually. This process is called the development of the chromatogram. Polar solvents such as methanol, ethanol, acetone etc. are used as elution agents. The final stage is the quantitative analysis of the individual materials gained in the previous stage, whereby normal physical methods are used.

Dye mixtures can usually be easily and reliably detected and isolated from the different coloured zones using the described method. Only a few products have proved themselves to be effective adsorption agents for dye identification, since neutral, aqueous dye solutions have to run through quickly but still provide wide, clearly separated adsorption zones. According to Schaeffer, this requirement is efficiently fulfilled by an extremely homogeneous mixture of aluminium oxide and talc, in a ratio of: a) 80 : 20 for most cationic and acidic dyestuffs, b) 90 : 10 for non-levelling acidic and chrome complex dyestuffs; c) 95 : 5 for direct dyestuffs. Mixtures of amino acids, plastics, carbon hydration products, sugars, fats, oils etc. are also chromatographed, whereby other adsorption agents and solvent are normally used.

Chrome alum → Potassium chromium sulphate.

Chrome development of dyes → Chroming of dyes.

Chromed wool Stabilisation of woollen yarn against fungus and bacteria by blind chroming using the single-bath chroming process. The same applies to an even greater extent to afterchromed wool, which has shown a resistance after 75 days during a soil burial test. By taking electron microscope pictures of chromed wool (ultra-thin layers) it was proven that most of the chromium moves into morphological wool areas that are rich in carboxyl groups and basic groups, i.e. endocuticle, cell core residue, cell membrane complexes and intermacrofibular cement. A direct comparison of chromed wool that has been previously enzymatically treated using pronase it was found that pronase treatment only as an effect on the endocuticle.

Chrome dyeing Afterchrome dyes are still widely used in wool dyeing in all stages of wool processing. The benefits are good to excellent colour fastness in all process and wet fastness requirements, good levelling and a low price level. Traditionally, dark shades are dyed, particularly black and navy blue. When dyeing wool with afterchrome dyes, acidic dyes with groups that can be sequestered are applied and aftertreated using potassium dichromate. After Cr^{6+} has been reduced to Cr^{3+} by the functional groups of the wool it is probable that a 1 : 2 metal-dye complex is formed. A final chroming liquor can contain tri- or hexa- valent chromium, whereby the latter represents the most problematic component because of its cellular toxicity. For this reason, hexa valent chromium compounds are replaced by tri valent chromium compounds in leather dyeing. In wool dyeing this is not possible, since the salts in tri valent chromium do not absorb or only absorb to a limited extent under the weak acidic application conditions.

Afterchrome dyes have come under pressure because of the increased stringency of the effluent laws. This is even more of a problem because no suitable alternative has been available to date, particularly in cases where a high degree of fabrication fastness is required. The terms of the effluent anti-pollution legislation (38th administration regulation) specify an extremely low total chromium level (old 38th administration regulation: 2 mg/l; new 38th administration regulation: 0.5 mg/l) for effluent discharges to the sewage system by wool dyeing companies that use chromium dyes. The threshold values for having to treat partial current effluent as required by the authorities may be as much as 5 times greater than the required general value for collected mixed water when entering the public sewage system (chromium (III) 2 mg/l; chromium (VI) 0.5 mg/l).

As far as treating a liquor containing chromium is concerned from a chemical point of view, with a daily total of 1000 m^3 of effluent in the mixing lagoon, a chromium content of 0.5 mg/l is much more difficult to treat than 10m^3 of partial flow effluent with 5 mg/l (both total: 50 g chromium) because the chemical balance is much easier to move to the right. However, chromium also occurs in the effluent when using metallic complex dyes.

Comparison of residual chromium content in sewage:

– traditional afterchrome dyeing	20–150 mg/l
– theoretical chromium factor (i.e. in relation to the stoichiometric dye quantities for binding to wool)	1–6 mg/l
– 1 : 1 metallic complex dyeing	3–13 mg/l
– 1 : 2 metallic complex dyeing	< 13 mg/l

Chromium dye binding via the chromium probably takes place in the low-sulphur range during afterchrome (microfibrous surface) and the non-keratin range (see Fig.).

The residual chromium quantities in the sewage from chromium dyeing can be reduced as follows:

- increase the bath exhaustion.
- adsorb excess chromium (III) from the dye solution on the wool.
- the optimum pH of 3.5 cannot be achieved using

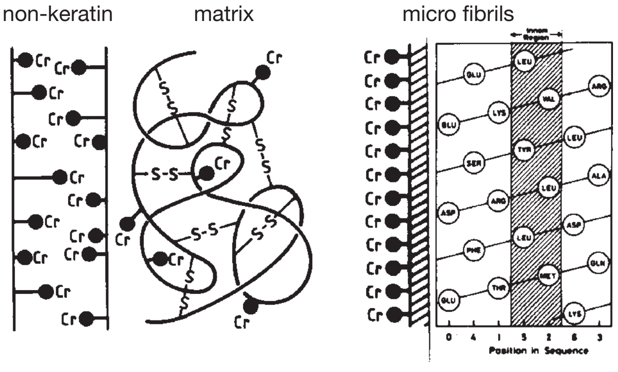

Fig.: Chromium dye binding from a chromium dyeing in morphological consistuents of wool (according to Fraser).

normal dyeing methods as the pH drifts towards 4.5. This means that formic acid can be used as a replacement using (using pH controlled dosing if possible).

- sulphate has a detrimental effect. In the "Glauber's salt" process sodium sulphate is therefore added at a later stage.

Chromium dyeing on loose wool leads to poor running characteristics in the spinning process. In order to optimise the original damage to the fibre and the loss of surface friction, dyeing can take place as follows: a) use chromium dyes at 80º with Baylan NT (special product made by Bayer AG); b) afterchrome in a fresh vat with theoretical chromium factor level; c) aftertreat with thiosulphate according to the relevant IWS method.

If possible, the loss of surface friction can be reduced using the soft flow technique (Wronz) by using less fibre flow during flock dyeing. An alternative to chromium black dyeing is dyeing with metal-free, dual-function bromo acrylide-based reactive dyes. This kind of dyeing is three times as expensive as chromium dyeing (excluding effluent costs) because two or three times as much monofunctional or dual-function reactive black is required to match chromium black dyeing.

Chrome dyes Chrome dyes are acid dyes with a complex-forming group, normally 2 OH groups on aromatic ring in an o-position to an azo-group (Fig.). With transitional metal ions, particularly chromium or cobalt, this produces a stable dye complex (dye pigment) with the fibre, which considerably improves the durability of the dye and the fastness of the dyeing (→ Chroming of dyes).

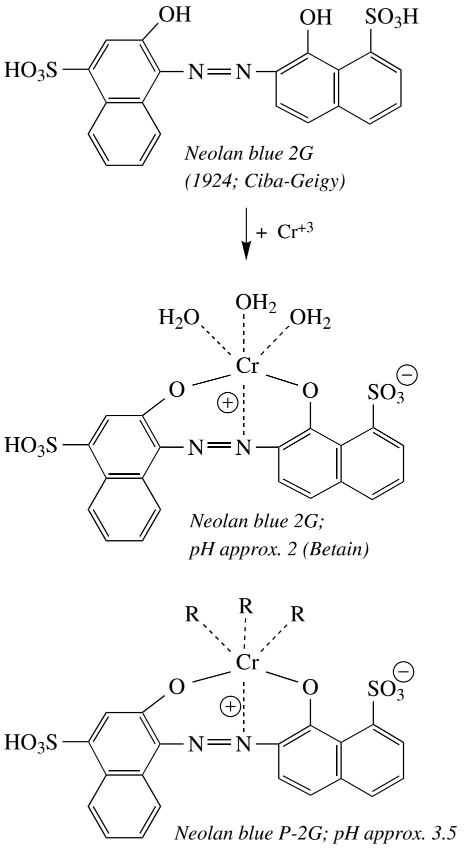

Fig.: Structural formula of a chrome dye.

After chromium salt treatment has taken place, a distinction is made between:

I. Pre-chroming process (wool): pre-chroming with potassium dichromate/acid, 1–1.5 hours at the boil, rinse; apply acid dyes suitable for chrome dyeing in a fresh bath.

II. Single-bath chroming process (wool): simultaneous dyeing and developing (chroming) in a slightly acidic bath. Suitable chrome dyes are applied together with special chromium mordants or potassium dichromate so that the slowly forming chromic acid pigment is absorbed into the fibre.

III. After-chroming process (wool, silk, polyamide): the chrome dye is applied to the fibre similarly to an acid dye. Add potassium dichromate to the depleted dye bath, whereby the chromium lacquer forms on and in the fibre. The most commonly used dyeing method for practically all chrome dyes.

Chrome dyes are seldom used on silk and polyamide.

Chrome gelatine Used in the manufacture of film printing screens using the photochemical process. It is used in the coatings in which light energy is used to trigger chemical reactions that lead to property changes and allow roller markings to be fixed. When mixed with chromium salts and illuminated for a long period, gelatine turns into an insoluble mixture called chromium gelatine. This knowledge is exploited and a carrier layer is applied onto the gauze of the screen, containing both gelatine and a chromium salt. After drying and illuminating through a partially covered transparent positive or negative, the non-illuminated parts can still swell, whereas the illuminated parts harden and are therefore no longer soluble during subsequent rinsing in water.

Chrome leather → Leather.

Chrome photoprinting Under diffuse light (using an opaque glass filter) fabric made from viscose filaments is impregnated with a solution such as 5% potassium dichromate for 20 minutes at room temperature, squeezed out, dried in the dark, exposed through a photographic negative, thoroughly rinsed (diffuse light) and then dyed using chromium mordanting dyes. Some of the dye is fixed to the illuminated, prechromed areas of the fabric. This has a certain wash-resistance, and the positive appears in its shading, naturally in a single colour only. Finished by thorough rinsing and drying.

Chrome tanning Animal hide is tanned into "wet blue" after cleaning by cross-linking the collagen chains with chromium. The expression describes wet, swollen leather that is subsequently dyed and re-fatted. The tanning serves to convert rot-susceptible hide into rot-resistant leather, so that the hide fibres no longer swell or shrink due to the absorption or loss of water, and become more temperature resistant and more resistant to the effect of chemicals.

Only the tri-valent salts in the chromium have a tanning effect, such as chromium (III) chloride and chromium (III) sulphate; e.g. $[Cr(H_2O)_6]Cl_3$ hexaquochromium (III) chloride (cationic). Chromium is in a position to form complexes using 6 coordinative binding options (Fig. 1).

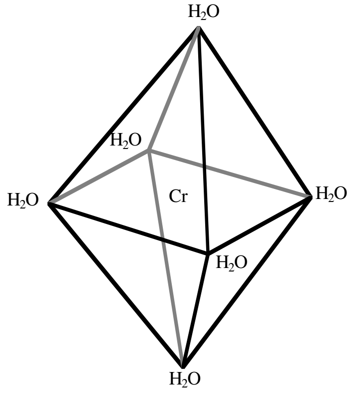

Fig. 1: Chromium complex octahedron.

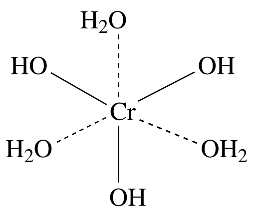
The hydrolysis of hydrated cations in the chromium salt produces basic complexes and may result in insoluble chromium hydroxide.

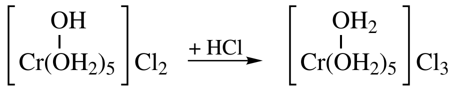
$$[Cr(H_2O)_6]^{3+} \longrightarrow [CrOH(H_2O)_5]^{2+} + H^+ \longrightarrow$$

$$[Cr(OH)_2(H_2O)_4]^{+} + 2\,H^+ \longrightarrow [Cr(OH)_3(H_2O)_3] + 3\,H^+$$

as a complex chemical structural formula:

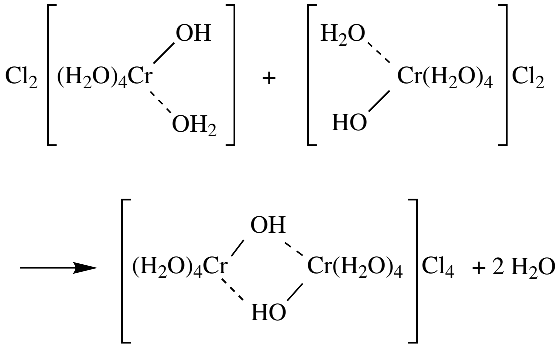


The solution itself becomes more acidic because of the release of H⁻ ions. Hydroxy compounds only form from chromium salts that can coordinatively bind water. This formation is prevented by adding acid and the old hydrous compounds are formed again.

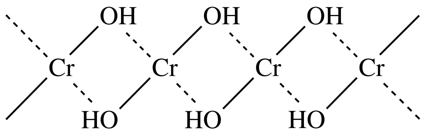


$$\left[\overset{OH}{\overset{|}{Cr(OH_2)_5}}\right]Cl_2 \xrightarrow{+\,HCl} \left[\overset{OH_2}{\overset{|}{Cr(OH_2)_5}}\right]Cl_3$$

Hydrous compounds tend to condense into multinuclear complexes. The prerequisite for this is the presence of a hydroxy group and a water group in the participating mononuclear components. The procedure takes place as shown in the following diagram:



As long as free OH groups are available, growth continues until polyhydroxyl compounds are formed during olating.



A certain degree of basicity must be guaranteed for such polyhydric alcohol compounds to occur. Increasing the temperature, adding alkali and ageing the solution lead to the formation of polyol compounds with an increase in molecule size leading to a colloidal state. Adding concentrated acids and boiling has the reverse effect called de-olating.

During chrome tanning an attempt is made to allow small molecule and low basicity cationic chromium complexes to diffuse into the hide, which allows the tanning conditions to be adjusted so that binding with

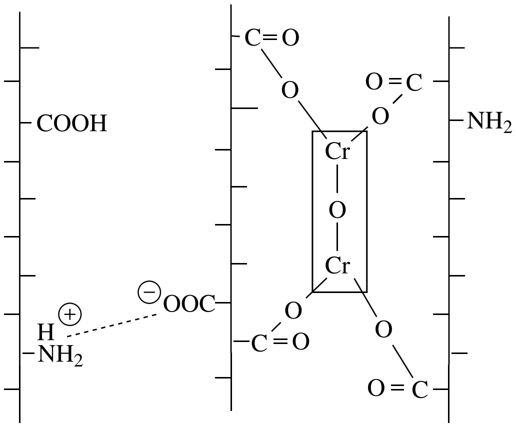


Fig. 2: Cross-linkage diagram of collagen chains caused by chrome tanning.

collagens can take place after previous olating, without scar tanning or surface cross-linkage occurring. The chromium complexes must be linked to the carboxyl groups (–COO⁻) in the collagen slowly in order to guarantee that the hide is tanned evenly (Fig. 2).

Tanning is an endothermic process and is assisted by heating, since a limited number of dissociated carboxyl groups are present in collagen at a pH of 4.5 to 5.0. Anionic tanning substances can be used, but only on a small technical scale, and do not provide any shrinkage values.

Many chromium complexes are technically masked in order to counteract precipitation during neutralization. The ligands are occupied by acid groups with complex affinity and therefore compete with the groups in the hide with complex affinity.

Chrome test for dyeings,

1. Ash the fabric to be tested (ash colour yellowish-green to black-green ash), and then melt the ash in a porcelain crucible with a 1 : 2 mix of sodium carbonate and potassium nitrate - produces a yellow liquid (aniline black; chromium mordant dyeing or chromium after-treatment; catechu brown or mineral colours such as chrome yellow to orange).
2. Liquefy the ashes of the fibre sample in 5 times the quantity of sodium carbonate/potassium nitrate (1 : 1) = chromium colours the melt green. Dissolve part of the melt in acetic acid and add lead acetate = yellow deposit of lead chromate. Dissolve the second part of the melt in dilute sulphuric acid, add a layer of ether and add a few drops of hydrogen peroxide. Chromium = blue perchromic acid, which dissolves into the ether layer when shaken.

Chroming The coating of copper print rollers with a layer of chrome to protect against damage and chemical influence.

Chroming of dyes Used to form chromium complexes in the fibre, which develops the final shade and improves light-fastness, especially wet fastness. A prerequisite is the presence of complex-forming groupings in the dye molecule, mainly OH- and COOH-groups in the ortho position. Most → Chrome dyes are soluble in water. These are azo dyes, which have OH-, COOH- or NH_2-groups in ortho position to the azo group, and azo and triarylmethane dyes with salicylic acid groups and anthraquinone dyes with OH- groups. Dyes with these groupings form complexes with trivalent chrome, with the displacement of the H atoms in the complex-forming groups (Fig.).

The chrome atom can form 6 saturated bonds building stable rings with 5 or 6 atoms.

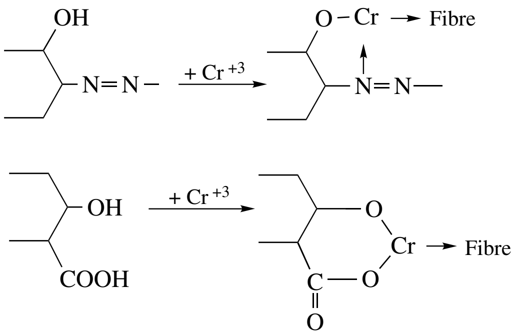

Fig.: Dye molecule structure.

I. Pre-mordant process: with wool (mordant dyes; chromium dyes) the application of the dye onto the premordanted wool provides immediate permanent colouring and therefore makes shading easier. However, only a relatively small number of dyes are available for this process. The process is fairly time consuming, provides little fibre protection and is hardly ever used.

II. Single-bath chrome dyeing process: the simultaneous application of dye and chromium salt to wool, and therefore the dyeing and development of the shade is made possible in a slightly acidic bath. Here also dyes with the most rapid complex-forming are selected, having good levelling and similar exhaustion properties from a slightly acidic bath. Special chromium mordants or potassium dichromate and ammonium sulphate is added. The process is important because of the relatively short dyeing time, good fibre protection, low sensitivity to the presence of other metal ions in water, equipment etc. The dyes have good balance and extremely good process and end-use fastness. With dark colours there is a tendency for the dye liquor to show lower exhaustion, which often results in poor rub and wet fastness. Colour levelness is much more difficult for slightly damaged wool. Union fabrics are dyed using union fabric chromium dyes in the single-bath chroming process. These are dye mixtures made from substantive dyes, using chromium dyes in the single-bath chromium process. Union fabric chromium dyes are only of minor significance.

III. After-chroming dyeing process: achieves the good process and end-use fastness for wool. Dyeing takes place in a slightly acidic bath. After complete exhaustion of the bath, a hexa-valent chromium salt is added (usually potassium dichromate), and the chromium pigments build up on the fibre during the rest of the dyeing process. The final colour is only seen after successful chroming, which makes shading more difficult. Before adding the chromium salt the dye bath must be extremely well exhausted so that only the dye that has been absorbed into the fibre is complexed. Before chromium salt is added, the dye bath is cooled to 80°C, brought to the boil again after adding the chromium salt and, depending on the darkness of the colour and the ease of development of the dye, treated by boiling for 30–40 min. until complete shade development has taken place. During the after-chroming process the dye may be more sensitive to metal, particularly iron (colour dulling). Adding sequestering agents to the dye bath can compensate for these metal-influencing effects. After-chrome processes are no longer used for polyamides (with the exception of black).

Chromium (Cr), very hard, brittle, silvery metal; atomic number 52,01, m.p. 1530°C. It readily forms alloys with other metals, e.g. with iron to give chrome steel with increased hardness, tenacity and corrosion resistance. Chromium can form bi-, tri- and hexavalent compounds. Chromium (II) hydroxide is a typical base, chromium (III) hydroxide is a weak base, whilst chromium (VI) hydroxide is a strong acid after water has been split off. The → Chromium salts are mostly coloured. Uses: for the production of numerous important chrome dyes having exceptionally high light fastness, chrome dyeing, important oxidizing, mordanting and tanning agents.

Chromium-complex dyes → Metal-complex dyes.

Chromium complexes Chromium compounds in which the element chromium is present as the central atom.

Chromium oxide, Cr_2O_3, MW 152,2. Starting product for chrome mordants.

Chromium (III) potassium sulphate (Chrome-alum, potassium chrome-alum), $KCr(SO_4)_2 \cdot 12H_2O$, molecular weight 499.4; dark violet crystals or light violet powder; soluble in water, violet-coloured solution, colour changes to green when heated. Usage: dye mordanting (particularly with some acidic dyes for increasing washing and bleeding fastness); manufacture of chromium mordants; waterproofing impregnation; lime insolubilization; KS colour delustring (transformation using alkali molybdate or wolframate solution); leather tanning. No longer used.

Chromium salts Compounds of 2, 3 and 6-valent chromium in a great variety of colours (white, green, violet, yellow, red, blue). The colour is dependent on the mode of attachment of the anions, as well as water molecules, to the chromium atom. Thus complex ions exhibit different colour reactions to the same individual ions outside the complex. Examples:

chromium (II) chloride $CrCl_2$
= white, blue when dissolved in water,
chromium (II) acetate $Cr(C_2H_3O_2)_2H_2O$
= red,
chromium (III) acetate $Cr(C_2H_3O_2)_3$
= green, solution turns violet later,
chromium (III) chloride $CrCl_3$
= violet,
potassium chromate K_2CrO_4
= yellow,
potassium dichromate $K_2Cr_2O_7$
= orange-red.

Chromium salts are highly toxic in waste water. Fish toxicity is detectable in the presence of very small amounts.

Chromium salts in dyebaths, colour fastness to →: Colour fastness; Chromium salts.

Chromium, test for on chromed wool Procedure: approx. 0,5 g of the textile material is ashed and the ash melted with 4–5 times its quantity of a mixture composed of equal parts soda ash and potassium or sodium nitrate. A yellow coloration of the melt indicates the presence of chromium. On dissolving the melt in approx. 3 ml of 30% acetic acid and adding a few drops of lead acetate solution, a yellow precipitate is likewise indicative of chromium.

Chromogen → Chromophore.

Chromogen black Specific indicator for → Complexometry.

Chromojet printing of carpets Polyamide pile goods can be sprayed with dye liquor in patterns so that printing is possible without using screens. The dye liquor, which is under pressure, is injected into the carpet pile via valve and jet systems. The valves are mounted on a movable slide block which, controlled by computer, moves to and fro cross-wise to the run of material (pile tiles). The colour change takes place outside the spraying area. The spraying area can be extended to 120 x 120 cm^2. Up to 8 colours are available. The pattern resolution is 600 dots per metre. Designing proceeds as follows:

The designs can be produced interactively by means of design computers (see Fig.). This makes it possible to respond quickly to customers' wishes. Similarly, keeping finished goods in stock becomes superfluous, as production is only to order. The patterns are stored on conventional diskettes, so no screens are required. Patterns can be changed in the space of seconds. Pattern repeats are possible with runs of up to 30 metres. Registering the colours to one another is not necessary. Colour printing can be controlled to a great extent, ensuring full penetration in all standard qualities. Directly

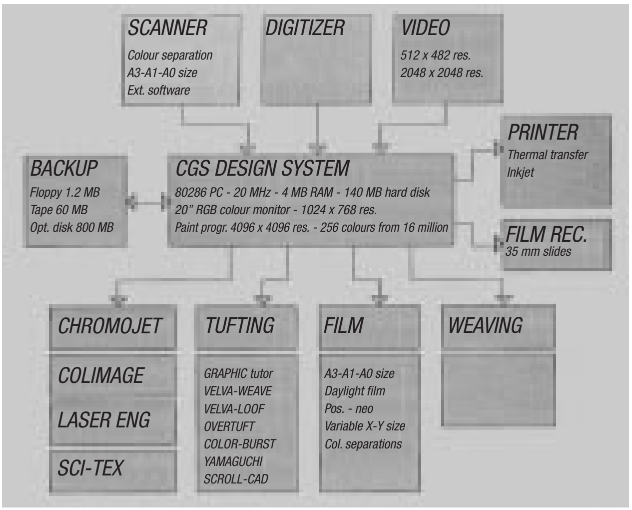

Fig.: Chromojet printing of carpets (Zimmer).

timed valves (jets) are used, which perform up to 400 opening and closing movements per second, so that optimum pattern sharpness and colour separation (weaving effect) is ensured. The pattern fineness is limited due to the digital system: half-tones and colour runs can be simulated to a limited extent.

The mechanical system is effected in a modular construction method, so that the correct plant can be optimally designed for each application purpose. Variable widths, numbers of colours, pattern resolutions and production outputs are possible. The production output is less than for rotary printing. Spray printing is suitable for patterning goods for the contract carpeting sector, where what matters is an individual design and good penetration, and not the yardage output. In contrast to screen printing, with spray patterning the problem is rather that too much dye liquor is applied. For this reason, a lower limit is set for the pile weight used. In practice, carpets and tiles from a weight of about 400 g/m^2 and upwards are patterned. The range has been tested at up to 1800 g/m^2. Thus for the textile area, it can be economical to use.

Chromophore Colour carrier or colour-carrying group in dye molecule = electron acceptor. Important as a link, bridge or corner pillar. The presence of chromophores in chemical compounds produces colour (chromogen = colour producer). Important chromophores are a) double bonds (–C=C–C=C–N=N–, –N=O), the accumulation of which gives the dye substantivity; b) so-called intersections of forking or branching double links, the accumulation of which leads to colour shifts in the direction of yellow - red - violet and causes the colour to shift darker to black as the molecules become larger.

Examples:

1. Azo group (–N=N–); identifier for azo dyes, represented in direct, acid, cationic, mordant dyes etc. Frequent occurrence affects colour intensity: chrysoidine (1 double bond between 2 benzene nuclei), Bismarck brown (2 double bonds, 3 benzene nuclei), naphthylamine black D (2 double bonds, 6 benzene nuclei).
2. Azine group (+N–N=): present in safranine and azocarmine, for example.
3. Nitro (SO–) group (–N=O) or $-NO_2$; represented in Oxford blue R, naphthol green B, naphthol yellow S, for example.
4. Carbonyl group (>C=O): characteristic of anthraquinone and vat dyes, alizarin etc. (present at least two times).
5. Other groups: >C=NH, typical for cationic dyes (auramines): C-bonded benzene nuclei, typical for cationic (fuchsines, malachite green) and acidic dyes (brilliant indo cyanine 6 B, patent blue A); –CO–C=C–OC–, typical for indigo and indigoid vat dyes (indanthrene brilliant pink R, Ciba violet B, Algol scarlet GG); –S–S, the typical disulphide group for sulphur dyes etc.

Principle:

hydrocarbon + chromophore = chromogen

C_6H_5 + $-NO_2$ → $C_6H_5-NO_2$

benzene (residual) *nitro group* *nitrobenzene*

colourless pale yellow

Chromotropic acid (1,8-dihydroxynapthalene-3,6-disulphonic acid). Intermediate for azo dyes and analytical reagent. As the latter it forms the basis of a very sensitive test for formaldehyde (limit concentration 1 : 500 000). Procedure: 1 drop of the test solution, 1 ml of 72% sulphuric acid and a few grains of solid chromotropic acid are heated for a short time in a test tube over a naked flame. The presence of formaldehyde is indicated by a red-violet colour.

Chundri (Chunsi). (Indian) same as → Bandhana. Red fabric with extremely coarse, mainly white, yellow and green scattered patterns.

Churning effect → Orthinetic coagulation.

Chuzen Japanese process for manufacturing reserve dyeings with indigoid vat dyes or naphthols on folded woollen fabrics that are printed with a reserve paste, compressed into a block and have dye liquor poured over them. Used as Kimono materials.

C.I., abbrev. for → Colour Index.

CIA, abbrev. for: Instituto Agronomico, Secão de Tecnologia Fibras, Campinas, São Paulo, Brazil (Brazilian Agricultural Institute, Section Fibre Technology); → Technical and professional organizations.

Cibafast W Brand name of a UV absorber for photochemical wool protection developed by CSIRO, IWS and Ciba-Geigy. It gives wool a more resistant basic whiteness, makes dyed materials more stable to light (1–2 grades) and slows down the photochemical degradation of wool. Cibafast W is a sulphonated o-hydroxyphenylbenzotriazol derivate; soluble in water, excellent (hot) light stability, dye bath stable, colourless on wool; maximum absorption at approx. 335 nm. It is used as a “colourless, acid dye” and can be applied directly from the dye liquor; only used for aftertreatment in exceptional cases, e.g. for reactive dyeing; solubility in water approx. 10 g/l at 40ºC; approx. 80 g/l at 85ºC. The application quantities are 1–2.5 percent by weight; good absorption capability at a pH of 3–5 (yield approx. 85–95%). If dyeing takes place at a higher pH, the addition of acid is recommended. Has good levelling and migration capability and good wet, hand washing, shampoo and dry cleaning fastness. Combination with selected dyes recommended. UV absorbers are becoming more important in this area, where textiles and skin are increasingly under threat because of the destruction of the ozone layer; this mainly concerns Australia and South Africa at present.

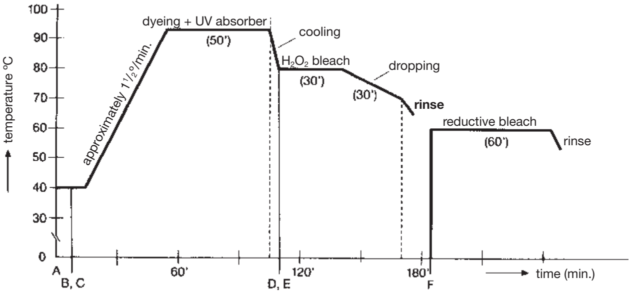

Fig.: Acidic single-batch dyeing/bleaching process with reductive aftertreatment using Cibafast W.
A = 2% acetic acid, 80% concentration (pH 5.2), 1 g/l sodium acetate. 1% Albegal A; B = selected dyes; C = 2% Cibafast W; D = Bleach activator; E = 25 m/l hydrogen peroxide, concentration 35%; F = 2% sulphuric acid, concentration 96%, 2.5 g/l Erioclarit B (or 1.5 g/l sodium metabisulphite).

Ciba-Geigy white standard Tool for the visual or instrumental assessment of white samples. Interpolation is possible and, in the case of instrument evaluation, extrapolation. The Ciba-Geigy white standard is used in the textile and washing auxiliary industry.

The Ciba-Geigy white standard for wool is mainly used in the paper and plastics industry. The white standard is made using cotton cretonne, bleached and brightened in a washing bath with an alkyl aryl sulphonate-based detergent. Consists of 18 visually equidistant grades of 10 units each, with a whiteness scale of 70–240 units, i.e. mainly extends on the yellow-blue axis in the colour space, whereby the differences in nominal degree of whiteness must correspond with the visually discernible differences using average daylight illumination (standard light type D_{65}). A finely graduated scale is required for visual assessment; a few grades suffice as the calculation basis for instrumental assessment.

The Ciba-Geigy plastic white standard (CG plastic standard, plastic white standard) for determining whiteness consists of 12 one-sided matted plates made from compressed melamine resin. Plates 1–4 contain decreasing concentrations of a yellow pigment and do not fluoresce. On the other hand, plates 5–12 contain increasing concentrations of an optical whitener. Grades 1–12 cover the whiteness scale of 20–210 Ciba-Geigy units. As well as whiteness, colour (green or red layers) can also be assessed. Can be cleaned using lukewarm water. Application: in the paper and plastics industry and in the manufacture of less resistant white standards made from textiles and paper.

CICS, abbrev. for: Committee for Index Cards for Standards, Holland; → Technical and professional organizations.

CID, abbrev. for: Comité International des Dérivés Tensio-Actifs; Secretariat: Paris, France. (International Committee on Surfactants); → Technical and professional organizations.

CIE, abbrev. for: Commission International d'Éclairage (International Commission on Illumination), with headquarters in Paris, France.

CIELAB Colour difference units (evaluation) obtained from colour measurement procedures and calculated with the aid of → Colour difference formulae are generally expressed in CIELAB units today. According to the CIELAB system, the CIELAB coordinates L, a, b, are represented in colour space as mutually perpendicular axes with L representing lightness (from white to black) with a and b representing red/green and yellow/blue colour differences respectively. → Colour measurement.

CIETEX, abbrev. for: Conference Internationale de l'Enseignement Textile (International Conference on Textile Education), Villeneuve d'Asq-Flers, France. A permanent international conference of textile teaching and training establishments which has achieved great importance for management trainees and advanced vocational training across the entire textile sector. Objective: the further development of teaching methods at all levels within the textile sector.

CIE whiteness formula → CIE recommendation for standard identification of the degree of whiteness. The formula should only be used for a relative comparison of similar samples measured at the same time on the same device because of the technical difficulty in measuring fluorescent dyes (absolute precision, precision of adapting the sample lighting to the spectral distribution of daylight). In relation to D_{65}, 10 degrees, the CIE whiteness formula is:

$$W = Y + 800 \cdot (0.3138 - x) + 1700 \cdot (0.3310 - y)$$

As well as the whiteness formula, a formula for identifying the tint of white samples is recommended:

$$T = 900 \cdot (0.3138 - x) - 650 \cdot (0.3310 - y)$$

T is positive for samples with a green tint, and negative for samples with a red tint.

Cigarette test → Flammability testing.

CIM (Computer Integrated Manufacturing). Full integration of the data from all systems involved in industrial manufacturing, i.e. measuring data is not just recorded but also processed and used for process control. The associated software must be extremely user-friendly in order to do this when an individual department such as colour metrics is to be integrated into the CIM network. To begin with there will only be isolated cases of CIM factories, such as a fully automated cotton combing plant where many spindles are operated by just a few employees. Quality and material flow will be monitored by a central computer station. → Computer applications in textile finishing.

Circular dichroism Light contains left and right rotating components that are absorbed to differing degrees by optically active compounds (→ Optical activity). The dependence of wavelength on the varying absorption of right and left polarised light (ΔE) is called circular dichroism. For example, it can be used as a measure of the degree of correctness of amylose iodine associates, which reaches an extremely high value with an average degree of polymerisation (DP) of 50 and drops off again towards longer chains. When the solutions are left to stand after adding iodine, there is considerable increase in dichroistic absorption over a standing period of 2 hours (Fig.).

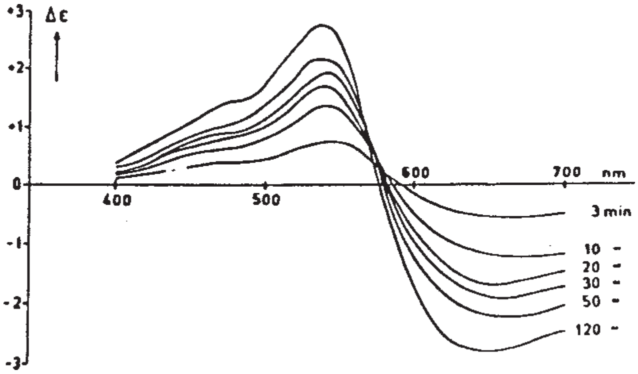

Fig.: Circular dichroism of amylose iodine solutions: temporal increase of the solutions by standing (DP 47).

Circular knife cutting machine Unit with which printed fabrics etc, particularly printed nonwovens are cut or parted to a specified width.

Circular knit goods Fabric knitted in tubular form, which is mostly also finished in this form, and only afterwards slit open.

Circular-knit pile fabric (Nicky) → Plush cloth, of smooth or textured yarns, with closed loops (plush loops), similar to → Terry fabric. If the loops are cut, → Cut-pile plush is obtained. The ground of the fabric is usually cotton, possibly reinforced with polyamide or polyester yarns, the pile of cotton. Loop size 3–4 mm. Special shearing machines are used to cut the pile (loops). Before shearing, the goods are tumbled. Different finishing processes for circular-knit pile fabric:

I. Piece-dyed goods:	II. Yarn-dyed goods:
Dye,	Scour and soften,
Hydroextract,	Hydroextract,
Slit,	Slit,
Tumble dry,	Tumble dry,
Precrop,	Precrop,
Soften,	Steam and tumble dry,
Hydroextract,	Final crop,
Tumble drying.	Stenter finish (stenter frame).

Circular-knit pile fabric finishing Circular-knit pile fabrics are generally finished by cutting the loops to give → Cut-pile plush, with the majority of articles piece dyed. In the case of yarn-dyed articles (usually of polyester), the tube is cut open, tumbled dry (to open up the pile) stentered, cropped and heat set. In the case of piece dyed articles the necessary processing stages must be adapted to the material (usually cotton/polyester). Pre-treatment and dyeing take place on the winch (to avoid permanent creasing). The pre-treatment for cotton consists of the boiling process, possibly followed by peroxide bleaching. After dyeing the goods are centrifuged to physically remove water. In order to raise the loops the goods are tumble dried, stentered and in the case of cut-plush fabric, cropped. Polyester or polyester/cotton qualities are steamed (pre-setting) after cutting, followed by precropping and scouring (winch), centrifuging and drying. Before dyeing, heat setting must take place at 185–190°C. After winch dyeing the goods are tumble dried; wet shearing then takes place to make the pile stand up and become more even. Variations of the sequences described above are possible. Circular knit pile fabric finishing is complicated and requires a good deal of experience. Its cost may represent up to 40% of the value of the fabric.

Circular singeing → Singeing machine for tubular knitgoods.

Circulating air drier → Drying systems.

Circulating hot oil unit (Circulating oil thermal unit, oil heat transfer boiler, forced oil-circulation boiler, thermal oil boiler, heat transfer plant, in accordance with DIN 4754), Heating process using a closed oil-circulation system. Heating below boiling point, therefore no pressure. Heating medium in tube boiler (vertical or horizontal). Source of heat provided by burners in which fuel oil or gas is burned, occasionally also electrical energy. Heater must be fitted with all control and safety devices. Heat transfer medium conducted by circulation pump (centrifugal pump) from the heater to the points of use and back. Heating time according to size of plant and volume of heat transfer medium minimum 15 mins. No acceptance or inspection obligations for heat transfer heating systems. A full load of thermal oil lasts some 4–5 years or more in a well-built plant; after this reclamation and where applicable topping up should be carried out as necessary. Installation costs are higher for larger diameter pipe systems and more complicated control mechanisms (3 distributing valves). For closed dyeing machines, specifically suited programmable controls are necessary. With in-between switching of a circulating hot oil unit-steam converter, additional steam is made available (up to 20 bar) with good overall efficiency (in comparison with simple steam boiler operation, no loss of condensate, no loss of heat, no operating personnel, no corrosion in the pipework and boiler installation, no water treatment). Application: wherever heat is required (heat exchangers) where automatic, maintenance-free operation is required. Operating range starts at heat transfer medium temperature of 130°C, main range 150–300°C, in exceptional cases up to 320°C. Specifically for steam/hot water heating systems, for dyeing machines (e.g. beam, winch, HT becks), for air heaters, for stenter frames, for drying or fixing machines, etc.

Circulating liquor machine It is necessary to differentiate between types of textile processing machinery. A distinction can be made between textile machines and machinery for processing textiles. Textile machinery can carry textiles on a fabric carrier in a horizontal or vertical manner and liquors flow through stationary fabric.

Circulation drying Principle of solvent regeneration in the case of dry-cleaning machines and solvent degreasing and finishing machines, where air is blown by fans in a circle over a cooler, a heater and through the solvent-containing machine section (e.g. drum). The heated air evaporates the solvent on the textile material. In the cooler, the absorptive capacity of the air is reduced as against the solvent gas contained in it, and the gas is therefore condensed into liquid solvent, which flows through the water trap into the clean solvent tank.

Circulation machines → Dyeing machines.

Circulation of dye liquor As a result of rationalization in yarn preparation and coning, larger and larger yarn packages, and therefore higher package weights than hitherto, are now being dyed although demands on the technical quality of the yarn and the levelness of dyeing have not been lowered. This requirement can only be satisfied by employing an alternating circulation of liquor for yarn packages of this type (Fig. 1) which commences immediately after filling the dyeing vessel. The alternating circulation, achieved with liquor reversal systems which do not require the liquor pump to be switched off, ensures level exhaustion of the uniformly distributed dye within the yarn package from the beginning of the dyeing process. This type of circulation also ensures a uniform supply of dye in both flow directions with a short fixation phase.

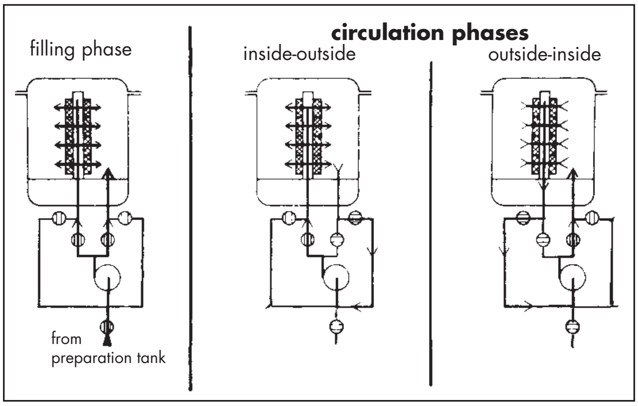

Fig. 1: Liquor flow in the Rapidcolor process (Hoechst/Then).

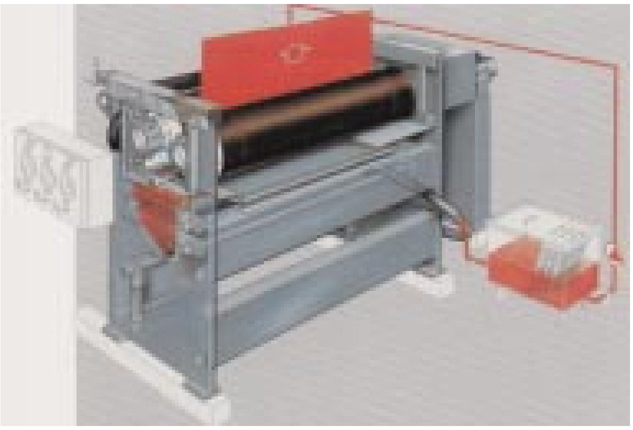

Fig. 2: Unipad dye padder for dyeing pile fabrics with liquor circulation to remove lint by filtration (Ramisch-Kleinewefer).

Liquor circulation may also be necessary on dye padders (Fig. 2) in continuous dyeing processes so that the dye liquor in the pad trough can be constantly filtered when, e.g. pile fabrics are being impregnated with dye liquor (lint separator).

Circulation pump A pump used to circulate dye liquor in dyeing machines for cross-wound yarn packages (see Fig.).

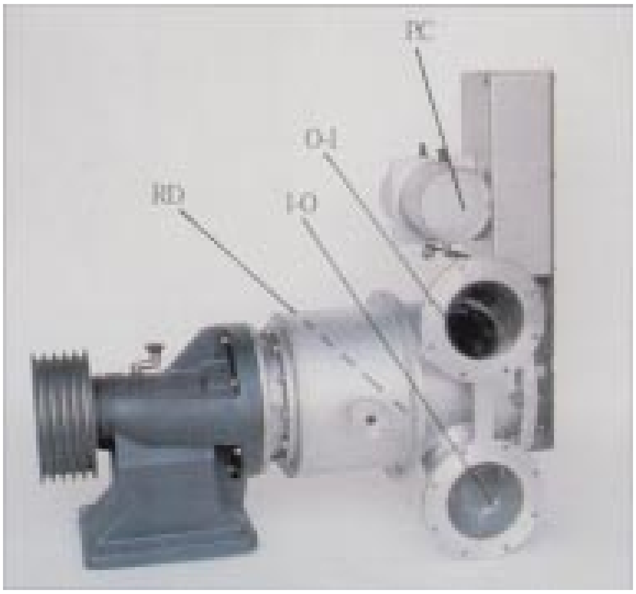

Fig.: Electronically-controlled circulation pump from Bellini with changeover of liquor flow direction from inside/outside (I/O) to outside/inside (O/I) without changing the rotational direction of the motor and without stopping the motor. This is achieved by means of a special liquor reversal valve (RD).

Ciré (Fr. wax, waxed; also oilskin rainwear). A brilliant patent leather effect produced by the application of wax, heat and pressure. Fabrics are mostly impregnated with paraffin or wax emulsions followed by a passage through the → Friction calender. The result is a supergloss almost metallic in appearance. (A shiny surface given by a hot calendering alone to a fabric made from thermoplastic fibres is also called ciré).

Ciré calender Crêpe calender with lightly engraved embossing bowl.

Ciré effects → Embossing.

CIRFS, abbrev. for: Comité International de la Rayonne et des Fibres Synthétiques (International Rayon and Synthetic Fibres Committee), Paris, France; → Technical and professional organizations.

Ciselé A grainy plain-colour silk crêpe fabric with a scroopy handle and good draping properties, not unlike a → Moss crêpe in appearance. Shrink-resistant, crease-resistant and water-repellent characteristics are imparted by the finish.

cis-form (Syn-form) (lat: this side), isomer structural form of chemical compounds where the radicals in the spatial molecular arrangement are "neighbouring on the same side", as opposed to the trans-form (anti-form), where the radicals are "spaced out, alternately to the right and left" (see Fig.).

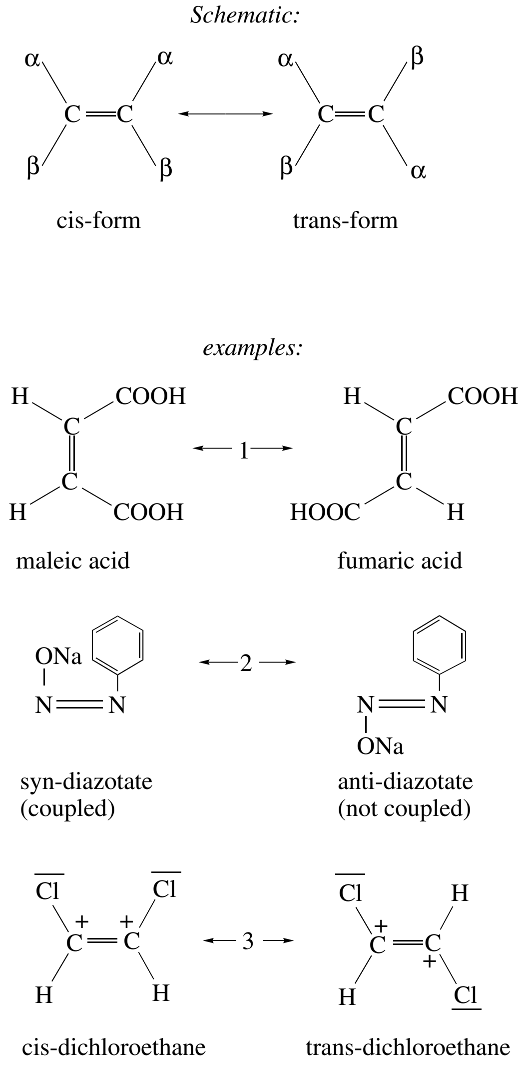

Fig.: Cis-form.

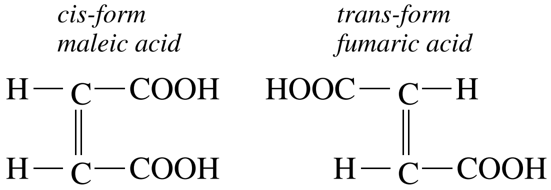
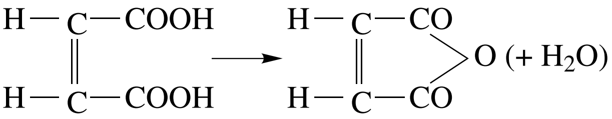
The compounds in examples 1–3 are used frequently in textiles and each have special significance. For example, they play a part (Type 2) in certain azo dyes. Example 3 is even more significant. This is the type of chemical compound that has a clear dipole moment in the syn form (1.8) but not in the trans form (dipole moment = 0).

Cisterns (tiled pits). Open pits (usually rectangular) constructed of brickwork or concrete, faced with ceramic tiles, used in wet processing as temporary storage units for piling down cotton fabrics in rope form between the individual process stages of alkali scouring and bleaching. Cisterns are occasionally provided with a liquor circulation system.

cis-trans isomerism Concerns → Cis-form and trans-form isomerism, a phenomenon that is widespread in organic chemistry and always occurs when the two atom groups linked to each of the two carbon atoms in a carbon double bonding C=C are different (see diagram example under → Cis-form). This isomerism, which is based on various spatial molecular arrangements, is defined in maleic and fumaric acid by the two C atoms that can no longer be freely rotated against each other, whereby the two carboxyl groups only lie on the same side (cis) of a plane or at opposite sides (trans).



Both forms can be mutually transposed. Both turn into Bernstein acid when catalytic hydration occurs, but only maleic acid produces an internal hydride when heated (as proof of the cis-form):

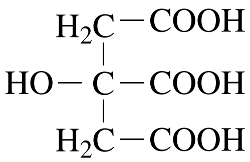


whereas fumaric acid also turns into a maleic acid hybrid if subjected to considerable heating over a long period of time. Because of the two neighbouring carboxyls the double bonding of this anhydride is strongly activated, meaning that it can easily splice into cyclic polymers with dienes. The cis-trans isomerism is not restricted to unsaturated compounds but also occurs in many different forms in cyclically created compounds.

Previous Page

CITEN, abbrev. for: Comité International de la Teinture et du Nettoyage (European Professional Organization of Dyers and Drycleaners); → Technical and professional organizations.

Citric acid (citric acid, ß-oxitricarballyl acid), $C_6H_8O_7$; salts = citrate. Occurs as a water of crystallisation free, light powder and (usually) as colourless crystals (+ 1 Mol H_2O; mol. wt. 201; density 1.542). Surface decomposes to white power at 30–40ºC when water is added. Odourless, sour taste and acid reaction, citric acid is considered to be a strong acid that attacks cellulose fibres when it vaporizes. Soluble in water (approx. 1.350 g/l of crystallised acid dissolve at approx. 20ºC), soluble in 80% alcohol and ether.



$$\begin{array}{rcl} & H_2C & -COOH \\ & | & \\ HO- & C & -COOH \\ & | & \\ & H_2C & -COOH \end{array}$$

Nitric acid oxidizes citric acid into oxalic acid. Usage: lubricant for viscose and silk (seldom); in acidic discharge printing; with antimony salts for resisting cationic dyes; as a scouring aid (5% solution); removal of berry stains, ferro-gallic ink stains, coffee stains, red wine stains, tea stains etc.; may be damaging to dyes, has tendency to form stubborn yellow stains on white materials.

CL → Polyvinyl chloride fibres, standard abbrev. according to the → EDP Code (→ Textile fibre symbols); → CLF.

Clarification temperature With nonionogenic surfactants with → Turbidity point, the temperature below which the mixture of the two liquid phases has become homogeneous due to cooling.

Claws → Clips.

Cleaning → Washing. Also as a widespread abbrev. for → Dry cleaning.

Cleaning ability Expression of the behaviour of textile material against → Dry cleaning. Assessment and recommendation by → Care labelling of textiles (textile care symbols).

Cleaning action of dry-cleaning detergents With the dirt removing mechanism of organic solvent drycleaning detergents, the method of operation covers more or less the following functional system of compounds, depending on the type of dirt:

a) solvent soluble/water insoluble or water emulsifiable (e.g. oils, fats, waxes and tar);
b) solvent insoluble/swelling in water (e.g. starches, pectins and some types of protein);
c) solvent insoluble/water soluble (e.g. salts, sugar, urea and dyeing auxiliary agent residues);
d) solvent insoluble/water insoluble (e.g. pigment dirt).

Cleaning activity Functional principle of → Drycleaning detergents.

Cleaning and shearing machines Used for removing yarn residues prior to fabric finishing.

Cleaning cloths Different types find use in the home:

- high quality, random web type floor cloths for long-term use in the 100–400 g/m² weight range.
- 10–100 g/m² longitudinally laid web dishcloths for short-term use (disposables).
- spunbonded or wetlaid disposable cloths.
- multi-purpose or dry webs of regenerated or natural cellulose in the 40–80 g/m² range.
- cross-laid, synthetic, nonwoven dusters approx. 100 g/m² in weight.
- approx. 50–80 g/m² mop cloths for floor cleaning.
- cellulose fibre or polypropylene polishing and cleaning cloths for furniture, upholstery, shoes, metal components etc.

Cleaning performance test American soil test of the IFI.

Clean room clothing This, which has to be worn at specific work stations for protecting sensitive products from contamination by fluff or skin particles, has hitherto predominantly been developed in accordance with this protective function standpoint. The routes followed to this end however have frequently led to textile and clothing constructions which are to some extent at variance with physiological requirements. Under the physiological aspects of clean room clothing, a distinction is to be drawn basically between outerwear and under clothing and between clean room clothing systems, operative job difficulty and environmental climate. With clean room clothing, physiological requirements with simultaneous protection for the product can be very extensively met with the right construction, although certain guidelines should be followed as regards both textile and clothing construction. In the case of clean room outerwear, the problem, when worn in direct contact with the skin, of its adherence to the skin on perspiring due to the smooth surface caused by the synthetic filament yarns employed, has not yet been completely solved. With many products, this results in the wear comfort being impaired or even the occurrence of an unpleasant skin sensation. The climatic conditions set up in the clean room must be absolutely adapted to the clothing in order to create a physiologically good situation for employees. At 22°C and 35% relative air humidity, and with an airflow speed of 0.3 m/sec, the majority of clean room clothing systems is capable of providing good physiological wear comfort in terms of the job difficulty obtaining in practice.

Clean room clothing should therefore act as a barrier against particle-form contamination given off by human beings (including fibres and fibre fragments). As long as porous material, preferably woven fabrics, are

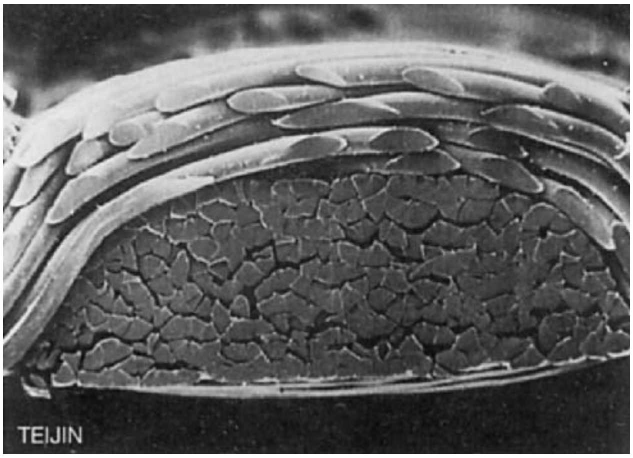


Fig.: Compactness of a clean room clothing woven fabric.

used for the task, it must be assumed that particles will penetrate this barrier. The hitherto usual concept of barrier action is based on the assumption that airborne particles may be involved. From the textile standpoint, this assumption is not quite correct in two respects:

- from experience, clean room clothing has some residual contamination even in favourable washing and decontamination treatment conditions, i.e. in the fabric are lodged particles which can be released by movement.
- when a clean room coat or overall rubs against underclothing due to movement, it must be assumed that particles on the underclothing will penetrate into the pores of the outerwear fabric, and will pass through the pores mechanically on further movement.

These migration effects also occur in the case of padded outerwear and beds.

Clean room clothing fabric (Fig.) also functions as an accumulating barrier against particles. This has a

Tab.: Construction of different clean room clothing fabric qualities (Novitex).

limited effect; in addition to small, airborne particles, large, mechanically transported particles also undoubtedly penetrate this layer. As regards airborne particles, the fabric behaves like a surface filter (caking). The particles at first retained in filter cakes can be mechanically transported through the fabric. As an accumulating barrier, the fabric has characteristic properties which depend on its porosity. In comparison with a porous fabric, a dense fabric is difficult to decontaminate and has a high degree of residual contamination after washing or decontamination treatment. Based on these findings, particularly dense fabrics cannot be recommended without qualification for stringent clean room clothing requirements.

From both the aspect of filter capacity and the standpoint of clothing physiology therefore, it is advisable to take a targeted requirement profile as a basis (Tab.).

Clear Ready-to-use pigment print paste based on kerosene emulsion or synthetic thickener which contains all the necessary auxiliaries except pigments.

Clear colour In contrast to → Dull colours, contains, in addition to colour contents, either just white (light clear range) or just black (dark clear range). Details: → Pure spectral colour.

Cleavage of dyes involves the following:

I. The readiness of azo dyes to split at the azo group, for which reducing agents, such as e.g. sodium dithionite, are required. Two cleavage products are formed from splitting the dyestuffs, both of which are amines and each one of which has a nitrogen atom from the original azo group. The cleavage of dyestuffs is often the basis of discharge and resist printing.

II. The possibility of hydrolysing an ester group in a dyestuff molecule into the corresponding carboxylic acid by using acid or alkali. This is made use of in alkaline discharge resists of disperse dyes on polyester.

Cleavage products result from cleavage of chemical compounds. So, e.g. azo dyestuffs are broken at the azo group, in several reaction steps, by reaction with strong reducing agents into two compounds that contain amino groups (→ Cleavage of dyes). In discharge and reserve printing processes, it is important that the dyestuff cleavage products are readily removable. The structures of dyestuffs can be elucidated by isolating and identifying the cleavage products.

CLF → Polyvinyl chloride fibres, → Textile fibre symbols according to DIN 60 001 T4/08.91.

Cling propensity of textile fabrics End-use property. In wearing all-silk and synthetic garments for example, clinging to the body can occur as a result of electrostatic charging, a phenomenon that may sometimes give rise to complaints. Clinging of textiles to damp skin may inhibit the transmission of perspiration.

Cling property (F_K), The force expressed in cN required to detach a textile from a water boundary surface. Relates to the subjective sensation of a textile worn next to skin bathed in perspiration, the discomfort becoming greater with higher cling properties. Skin model measurements produce the following F_K comfort indices:

< 25 cN = very good
25–50 cN = good
> 50 cN = unsatisfactory.

Cling test Measuring instrument which measures the adhesion of a test fabric charged with static electricity by friction to a metal plate. The time taken for the test specimen to fall is measured. AATCC Test Method 115-1965, 115-1969.

Clingy A term used in the USA for undesirable adhesion of textile materials to the body during wear. It occurs, eg. with garments made from unweighted pure silk as well as polyester. → Cling test.

Clip marks Defective lighter or darker marks on the fabric when heat setting synthetic piecegoods, due to subsequent variable dye absorption, caused by → Clips.

Clips Continuous holding devices for anchoring woven fabric selvedges (stenters) during drying, heat setting, shrinking, mercerising etc, enabling fabric to be tensioned or relaxed as necessary

Classification:

I. Clips: generally preferred for lighter-weight woven fabrics which pass quickly through the stenter, the fabric being tightened in the clips by the wedging action of a flap, the light-tight fit holds the fabric without damage, and all the clips in the chain clamp uniformly. Speeds over 200 m/min. They are distinguished as follows, depending on design: a) hammer clips, which operate by means of a simple slamming mechanism. b) feeler clips have feelers on their flaps (in the case of mercerising machines, with iron flaps, possibly also with a hard rubber cover etc), which release the fabric selvedge at a specific distance from the flap knife edge, enabling uniformly wide edge clamping to be achieved. Malleable cast iron or light metal alloy is used as clip body material. Clamping edge and table consist of rustproof steel. The clamping edge almost always has but one knife edge; fluted knife edges are also used in special cases. With later clips, attention is paid to ease of fitting, and flaps and chain bolts are detachable (use of circlips, spring washers, clamps etc. rather than rivets). Krantz has designed a “two-storey” double clip, by means of which two fabrics can be fed through the machine one above the other in the case of mercerising machines and stenters. Air Industries has developed a clip in which the mass is reduced and the surface enlarged by ribs, providing for quicker heating up and improved selvedge drying.

II. Pin links: are preferred for operating with overfeed (max. tension-free drying and shrinking, in the heat setting of synthetic woven fabrics), especially in order to prevent glazing due to clip marking; the woven fabric selvedges are pinned on by separate brushes. Pin size and numbers are oriented to the nature of the fabric. The pins, made of hardened standard or rustproof steel, are set in pin bars (brass), in part surface protected (chrome or nickel plated), and screwed on to pin links (malleable cast iron) for ease of replacement, which, on their part, are linked together by bolts and bushes (hardened steel). Roller link connections are rarely encountered, as pin chain speeds do not generally exceed 100 m/min.

III. Combined clips: are used to provide the two functions of pins and clips in one clip. There are fixed and movable types. In the case of fixed combinations, a pin bar is screwed on in front of the clip. There is another design for vertical return chains, on which the pin bars are located behind the flaps. Movable combinations can be designed in various ways, either the pin bars being swung out of the way in principle, or clip operation can take place. Special devices on the stenter serve to actuate these combinations. They are designed in such a way that the pin bars can automatically be swung in or out while the chain is running. Such clip/pin combinations identify machines which have to combine high fabric speed (approx. 200 m/min) with high performance.

CLOC Concentration of Limit of Oxygen for Combustion = minimum oxygen concentration above which a fibre will burn. Values usually lie between 18 and 28%; higher in polyamidimides at 31.9% and polyvinylchlorides at 37.1%. Other methods produce similar values. The behaviour of fibre mixtures is often unpredictable, since they may be easier or harder to burn; each fibre mixture should be treated as an independent system.

Cloqué A blister effect crêpe fabric woven in double-cloth construction with a thin crêpe georgette-type base and a generally plain-weave face having blister-like relief effect (woven or embossed). Distinction is made between the following forms:

I. Woven cloqué: Unshrunk or minimum-shrunk weft yarns are woven grouped in a particular order with a warp consisting of either shrunk or unshrunk yarns or alternatively a combination of the two. The differences in shrinkage characteristics are obtained by pre-setting the yarns at different temperatures. Yarns with different rates of drawing are also woven to achieve the same result. It is also possible to use yarns of different twist characteristics in warp and weft. Another method of weaving cloqué fabrics is to employ polyamide threads having different shrinkage potential. The cloqué effect, resembling the crêpe finish produced by caustic soda printing, is created in subsequent setting and other finishing processes. It is also possible to produce woven fabrics similar to sand crêpe and other relief effects. Although the effect in woven cloqué does not offer such a wealth of options as II., it is the most popular in terms of the amount of fabric produced.

II. Chemical cloqué: Created by the action of chemicals on polyamide fibres. The polyamide fibre can be caused to shrink by the action of swelling agents (e.g. phenolic substances, organic acids, calcium thiocyanate, aliphatic alcohols). Resorcinol and phenol in 20–25% solution are applied, usually thickened with Senegal gum or gum arabic (also in combination with glycerine), by machine printing. Film printing allows appropriate breaks to be made. The durable cloqué finish is produced by subsequent tensionless steaming for 5–10 minutes or by briefly heating up to relatively high temperatures (e.g. 2–3 minutes at 130°C) in a fixation machine. If required the finish is capable of effectively withstanding a subsequent dyeing process and with careful treatment will adequately withstand ironing. An advantage that a chemically produced cloqué finish on polyamide has over the crimp in a caustic soda produced crêpe on cotton is that here it is possible to apply any desired pattern, i.e. not only stripes, since in the swelling and shrinkage processes involved both warp and weft react virtually equally.

III. Bonded cloqué: An imitation of woven cloqué. It is produced by spot adhesive-bonding unfinished viscose or cotton georgette with a smooth dense fabric, e.g. taffeta. Two plies of fabric are thus bonded together, one of which must be very lightly constructed and also have shrinkage potential, for which purpose the unbleached high-twist georgette crêpes mentioned earlier are suitable. The taffeta on the other hand needs to be the densest possible so that the adhesive applied cannot strike through. The adhesives are usually applied by printing using zinc screens, in dots of variable size or in patterns which then determine the appearance of the cloqué finish. It is important for the adhesive paste to be of the correct viscosity. It must not be so thin as to strike through the taffeta, nor so thick as to risk clogging the screens. The substances applied must possess good adhesive power combined with adequate durability and the dot-printed sites must retain satisfactory elasticity in the finished fabric.

Closed loop control → Automatic control systems.

Cloth beam Serves as a take-up device on the loom (→ Weaving) for the finished woven textile.

Cloth guides Fixed guiding apparatus, which operates on a length of fabric passing over it. There are retarder guides, expander guides or deflector guides, depending on use.

Clothing felt → Felt fabric.

Clothing physiology Physiology is the science of the functions of living organisms. Clothing physiology is defined as the science of those phenomena involving mutual interaction between body and clothing and manifested in the comfort, efficiency and health of the wearer. It involves aspects of physics, chemistry, medicine, physiology, psychology and textile technology. The generic term → Clothing technology is used by some authorities.

The expression “physiologically engineered clothing” is meant to imply that the clothing performs to best advantage whilst an activity is being pursued. This function represents the sum of all properties influenced by fibre composition, spinning and weaving or knitting history, by thickness, density, weight, coloration and finish, and also by garment fit and make-up technology and by clothing systems.

Clothing physiology is based on the three basic criteria of body, climate and clothing which must be intercompatible, but which in turn are each made up of a large number of separate factors:

1. Body:
   - skin type and skin temperature,
   - release of heat and moisture,
   - activity level,
   - health status and standard of nutrition,
   - psychosomatic stress,
   - body weight and body size.
2. Climate:
   - air temperature and relative humidity,
   - air movement,
   - solar irradiation and moisture factors,
   - effects of other substances (dust, liquids).
3. Clothing:
   - thickness and density,
   - air retention, air permeability,
   - water vapour or humidity permeability,
   - moisture absorption and transport properties,
   - waterproofness,
   - thermal insulation,
   - skin compatibility,
   - elastic properties,
   - electrostatic characteristics,
   - fit and make-up,
   - number of textile/garment layers worn.

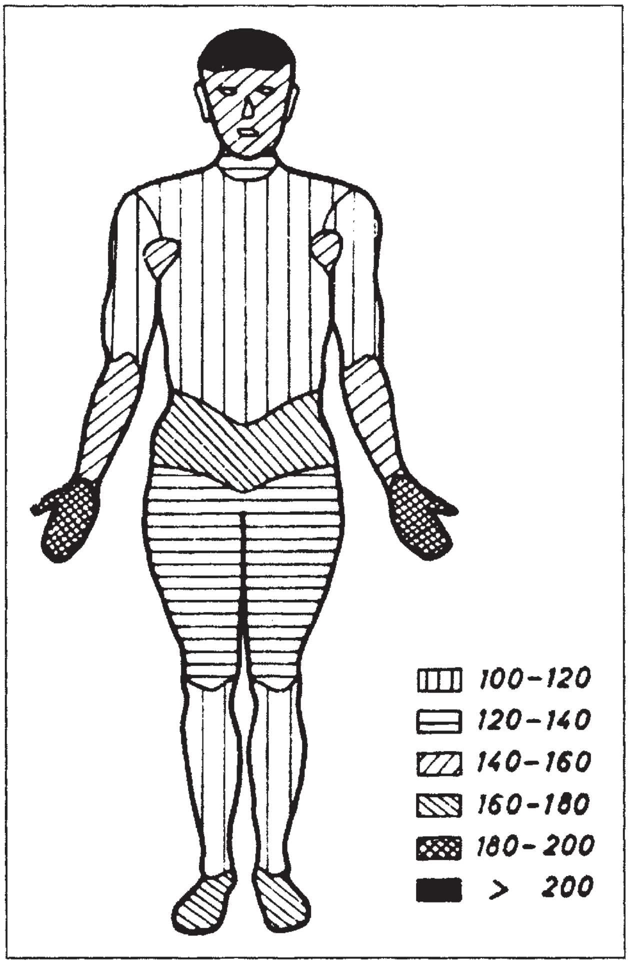

Fig. 1: Distribution of active sweat glands per cm^2 in an adult person of middle age.

The function of clothing is to assist the body’s inherent thermal control processes and thus relieve the circulatory system and maintain efficiency in mind and body, including under adverse environmental climatic conditions. Wearer comfort must also be maintained with the clothing worn in rapidly fluctuating climatic conditions, in other words with changes in temperature, humidity and air movement, and equally with the body at rest and in movement, or during heavy manual activity. Nevertheless it does not suffice for clothing to be suitable only for one type of climatic condition and only one particular activity, since body activity as well as weather and climatic conditions vary within a wide range. Physiologically efficient clothing must be capable of coping with these variations within reasonable limits, i.e. it must cover a wide thermophysiological control range. Clothing must furthermore undertake ergonomic functions. i.e. it must not hinder movement of the wearer and in the case of protective clothing must be capable of adequately protecting the wearer from certain hazards. The wearer also expects his clothing to have adequate mechanical strength, satisfactory resistance to cleaning and care processes, and to be colourfast and fashionable.

Through its basal metabolism and work metabolism the human body produces excess heat depending on the level of activity. This is dissipated via the breath and via the skin. Production of perspiration (Fig. 1) maintains the cooling threshold temperature at about 37°C. Heat production in the following activities, expressed in Watts is:

sleeping	85 W
standing speaking	165 W
jogging	480 W

Maximum variation: basal metabolic rate:work metabolic rate = 1 : 10.

Heat release M is obtained from:

- breathing (approx. 10 %) as H_{res}
- dry heat flow as H_c
- vaporisation heat flow as H_e

H_c and H_e jointly account for 90%.
These indices inter-relate in the following manner:

$$M = H_{res} + H_c + H_e \pm \frac{\Delta s}{\Delta t}$$

$$= H_{res} + \frac{(T_{skin} - T_{outside}) \cdot a}{R_c} + \frac{(p_{skin} - p_{outside}) \cdot a \cdot d}{R_e} \pm \frac{\Delta s}{\Delta t}$$

d = discomfort factor
R_c = thermal insulation
R_e = vapour permeation resistance (must be sufficiently low)
Δt = time segment
Δs = heat content
T = mean temperature
p = mean water vapour pressure

Since H_c does not vary much, heat release is flexibly controlled mainly by R_e. Moisture dissipation as a means of regulation occurs in this context via five routes:

1. Water vapour diffuses through pores in the clothing.
2. Swellable fibres in the clothing absorb liquid perspiration which diffuses slowly via the hydrophilic fibres and finally desorbs at the outer surface of the garment.
3. Fibres that are capable of being thoroughly wetted-out (microfibres with large surface area) adsorb liquid water on their surface. This migrates by wicking action to the outer surface of the textile article and there desorbs.
4. Capillary condensation occurs in the random fibre assembly with outward dissipation by capillary forces. Good wetting-out characteristics are necessary for this purpose.
5. Fifty percent of water vapour released by the skin can be dissipated via convection by a good rate of air exchange if the clothing is suitably constructed. Clothing construction (Fig. 2) is therefore a factor of greater influence than type of fibre.

Clothing comfort is expressed particularly effectively by the "discomfort factor" d. If the skin is dry d approaches zero; if the skin is wet then d = 1. Comfort occurs at $d \approx 0.3$ and $T_{skin} \approx 32–29°C$. If it is not possible to achieve thermal equilibrium, the heat content Δs changes with time Δt, which is possible to a limited extent by adjusting the extremity temperatures and the core temperature.

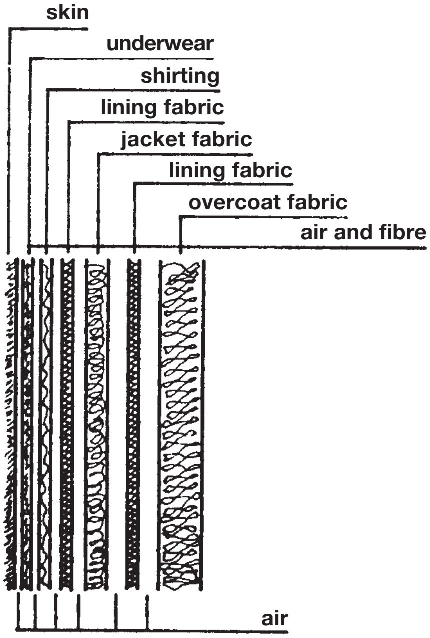

Fig. 2: Engineered clothing construction with adequate space between the various layers.

Apart from having good thermophysiological wear characteristics, the physical sensorial reaction to textiles worn next to the skin must be satisfactory. This involves the sensations aroused by the contact of textiles with the skin, for example softness or suppleness. There can also be unpleasant sensations such as scratching and stinging, or the adhesion of textiles to skin wet with perspiration. Skin irritations of this kind, often mistaken for allergies, can be eliminated by the right surface characteristics in next-to-the-skin textiles, controllable by adopting appropriate fibres and fabric or garment structures and assemblies (spacers). The following rules apply to the "engineered" design of physiologically correct clothing:

a) Thermal insulation, moisture transport and air exchange (convection and ventilation) of a clothing system are influenced both by the characteristics of the textile materials and by the fit of the garments.
b) The actual thermal insulator is the air trapped in the clothing, i.e. the more is trapped the higher the thermal insulation.
c) Moisture transport and moisture permeability are critical in the case of variations in the environmental climate or the work level of the wearer across the full span of the thermophysiological control range.
d) The control range or the end-use range of a clothing system is all the greater when none of the garments worn lie close to the skin.
e) Water-repellent textile layers within a clothing system should be thin so that sufficient water vapour can permeate by diffusion.
f) Air permeability in textiles need not necessarily also imply good moisture permeability.
g) Good skin compatibility in materials is important. It prevents skin irritations which are otherwise caused by mechanical irritation or by moisture build-up.

Application of this system permits logical selection of textile materials under consideration and of clothing systems. Laboratory tests performed in stage 1 on the skin model (thermoregulatory model of human skin) with pieces of fabric and in stage 2 on a manikin with made-up garments produce indices characterising the fabric or garment. Computed predictions provide information on the probable wearer comfort of a particular clothing system under different conditions of climate and activity of the wearer which also need to be taken into account.

The clothing systems selected in these two initial stages are then examined in stage 3 (wearer trials in a climatic chamber) mainly for the performance of the clothing and wearer reaction with regard to moisture dissipation. It is closely examined whether certain clothing parameters in stages 1 and 2 have been correctly assessed in respect of actual wear. Wearer tests in the field in stage 4 (restricted practical test) and stage 5 (test marketing) are as a rule limited to a few already optimised clothing systems which have been systematically selected in the preceding stages. (Source: Mecheels).

Clothing technology Term used by some authorities as an alternative to → Clothing physiology. Self-explanatory generic term covering the physical, chemical and medical aspects of clothing having the following functions:

- Research of the relationships between the human body, its clothing and the environmental climate.
- Determination of the influence of the variables involved in the manufacture of clothing, such as type and form of fibre, and yarn and textile construction.
- An aid to ascertaining the optimum clothing for different end-uses, for example leisure and occupational clothing, sportswear, uniforms.
- Improvement of man's lifestyle, giving particular consideration to health, hygiene and comfort.

Cloth make-up Textile finishing includes the treatment

- of loose fibres (e.g. flock dyeing in Fig. 1),
- of yarn package (e.g. cheese and cone dyeing in Fig. 2),
- of hank yarn, warp beams and continuous yarns (in continuous operation),
- of fabrics such as nonwoven fleece, knitted goods or woven fabric (e.g. piece dyeing on the hank, as depicted in Fig. 3, or on the beam, as depicted in Fig. 4)
- of ready manufactured parts (fully-fashioned finishing, such as stonewashed jeans).

Textile finishing therefore treats textiles in any type of cloth make-up.

Cloth press Special padding mangles for wool and wool blend fabric for impregnating and dewatering, e.g. when acidifying (carbonising), finishing (e.g. weighting), etc.

Cloudpoint Refers to the temperature at which liquids, oils, solutions become visibly cloudy. Impor-

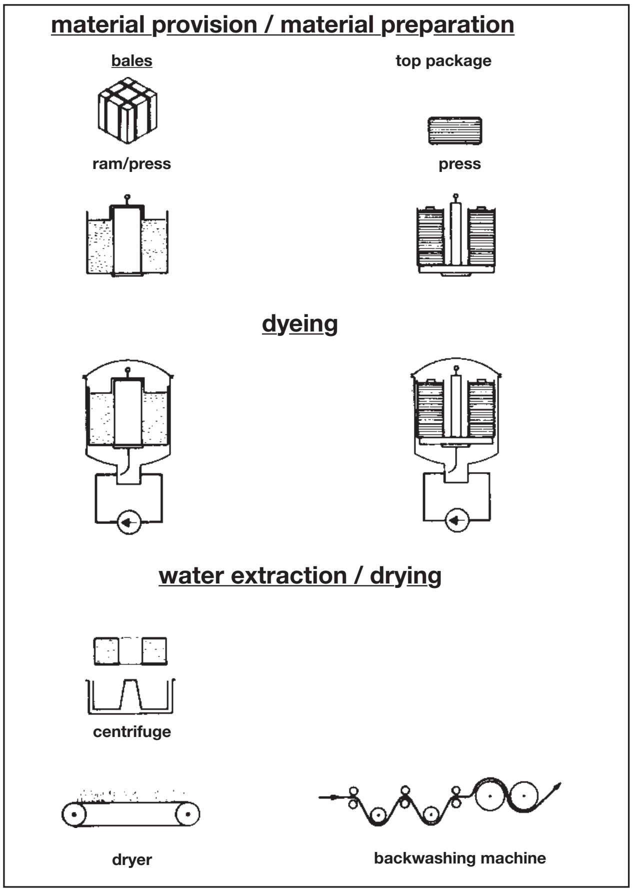

Fig. 1: Loose stock and top dyeing (Quas).

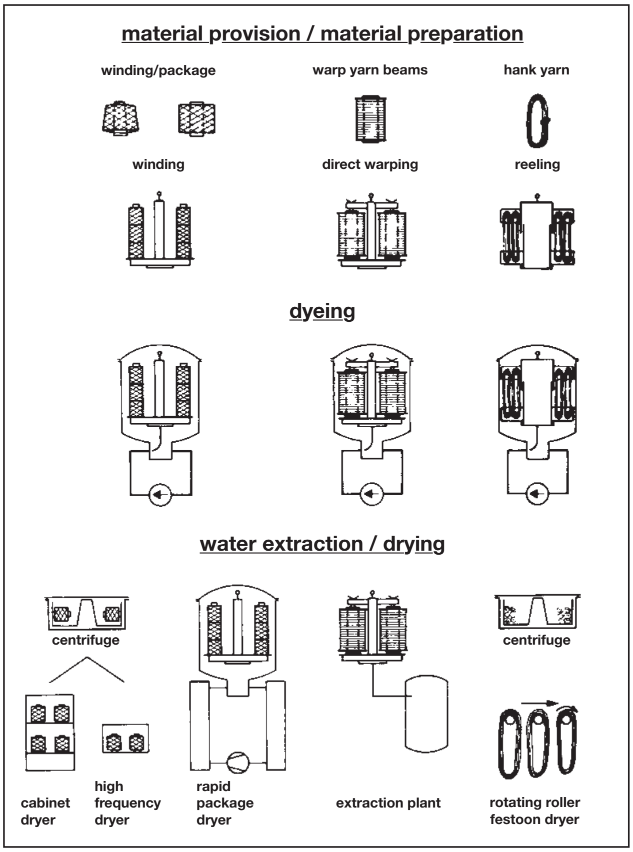

Fig. 2: Yarn dyeing (Quas).

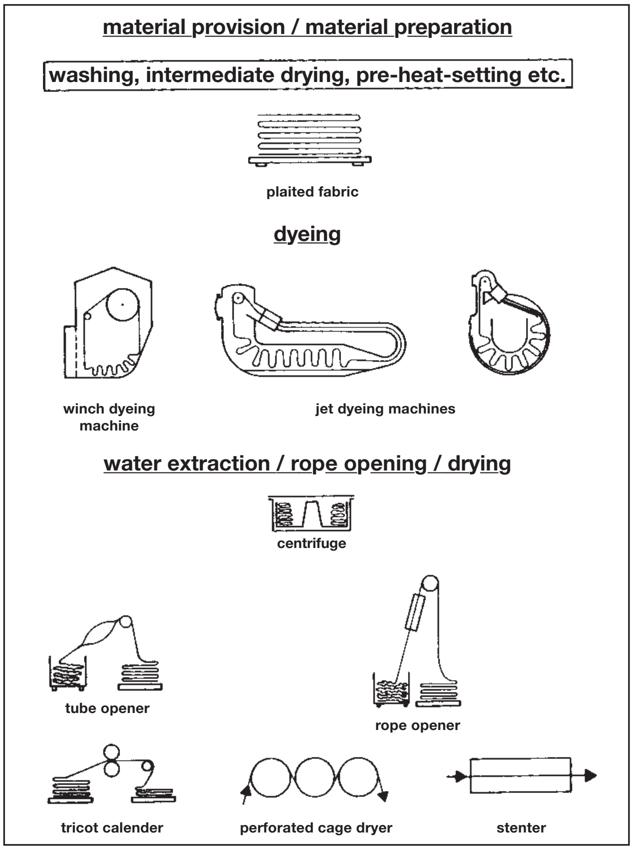

Fig. 3: Batch type rope dyeing (Quas).

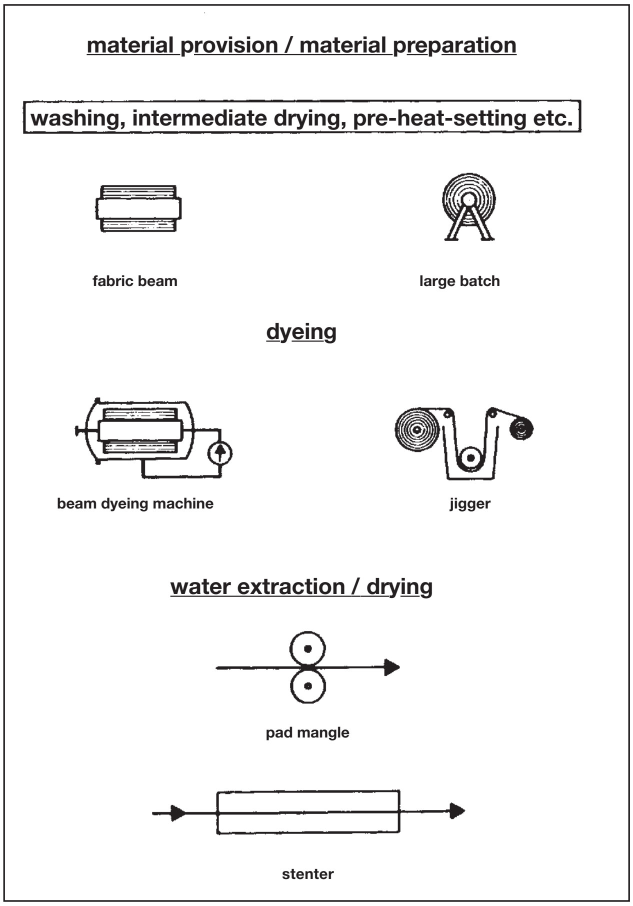

Fig. 4: Batch type open-width dyeing (Quas).

tant e.g. as → Titre of soap solution and for surfactant solutions (→: Clarification temperature; Krafft point). The cloudpoint occurs only in the case of nonionic surfactants (see Fig.). It is the point at which the solution of a nonionic surfactant becomes cloudy when it gets above a certain temperature. The phenomenon is reversible, i.e. when it cools down the solution becomes clear again at the same temperature. The reason for the occurrence of this phenomenon is linked to the hydration of the hydrophilic nonionic groups. This hydration is exothermic; when the temperature increases partial dehydration takes place and thus a new phase forms. This explanation is backed up by the fact that the cloudpoint is almost independent of the total concentration of the surfactants. The cloudpoint of nonionic surfactants can be determined in accordance with DIN 53 917.

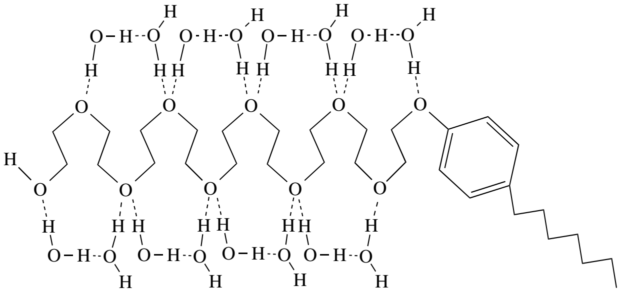

Fig.: Mechanism of the orientation of water molecules on the ethylene oxide oxygen atoms of a nonionic surfactant. Above the cloudpoint the hydrogen bonds are broken and the surfactant becomes insoluble in water.

Experiments on the effect of electrolytes on the cloudpoint of dilute solutions of nonionic surfactants show that the alteration to the effective → HLB value depends not only on the type and amount of the electrolytes added but also on the length of the polyoxyethane chain in the surfactant molecule.

Cloud point index Index for characterising nonionic surfactant raw materials with a low number (< 5) of orientated ethylene oxide molecules. The cloud point index corresponds to the amount of water in ml that will turn cloudy a solution of 1 g of surfactant in 10 ml of n propyl alcohol at 30°C. The method has good reproducibility and is very sensitive.

Cloud temperature In certain nonionic → Surfactants, the temperature above which their aqueous solutions become heterogeneous as two liquid phases form.

Cloudy dyeing Unlevel, mottled appearance dyeing. → Unlevel dyeings.

Cluett process → Compressive shrinkage processes.

Cm, symbol for curium.

CMC, abbrev. for:

I. → Carboxymethylcellulose.

II. → Critical micelle concentration.

CM cotton Cotton treated with monochloroacetic acid and then sodium hydroxide is converted into CM cotton. Two distinct types can be made in this way. One type of CM cotton has a “starched” appearance and handle. It absorbs water more readily than cotton and can accept crease-resisting treatments with greater effect. The second form of CM cotton disintegrates readily in water. It can be used as a temporary yarn for making fabrics from which the unwanted yarn can be easily removed. The insoluble CM cotton can be produced easily in mercerizing equipment at very low cost. The product can be made crease-resistant with particularly good effect.

CMD → Modal fibres, → Textile fibre symbols according to DIN 60 001 T4/08.91.

CMR, abbrev. for: Continuous Maximum Rating.

CNB, abbrev. for: Central Normalisatic Bureau, Holland; → Technical and professional organizations.

CNS Spanish Standards Association; → Technical and professional organizations.

CO → Cotton, → Textile fibre symbols according to DIN 60 001 T4/08.91.

Co, chemical symbol for cobalt.

co-, prefix meaning “together with”, e.g. coenzyme, cocarcinogen, copolymer, coagulation, coalescence, cohesion.

Coacervate (coacervated phase). Concentrated phase of a system subjected to → Coacervation.

Coacervated system Totality of the phases of a system subjected to → Coacervation.

Coacervation Mixing of a solution into two phases in equilibrium with each other, which contain the same components, but in different quantity ratios.

Coacervation system Two-phase system comprising two aqueous, immiscible phases (coacervate and equilibrium liquid). The coacervation system principle was the basis of the Cibaphasol process for the continuous dyeing and vigoureux printing of wool.

Coagulating thickeners Thickeners which coagulate with sodium tetraborate and alkalis. Special maize starches, carob seed grain ether derivatives or high-viscosity alginates are suitable for this purpose.

Coagulation (Latin: coagulatio = coagulate). Coagulation or flocculation of colloidally dissolved particles by accumulation, flocculation, small lump formation and settling to the bottom as insoluble gel. Occurs by heating or the addition of electrolytes or oppositely charged colloids. Examples: production principle of viscose filament by hardening in an acid precipitation bath; chemical purification of effluent etc. (Fig.).

Coagulation plant In the coated textiles sector, polyurethane transfer coating has made progress as opposed to rubber or polyvinyl chloride coating: the resultant composite material is water vapour permeable (incorrectly described as “breatheable”), without transporting liquid water. These types of microporous coatings can be produced on coagulation plant.

The textile substrate is sprayed or coated with a

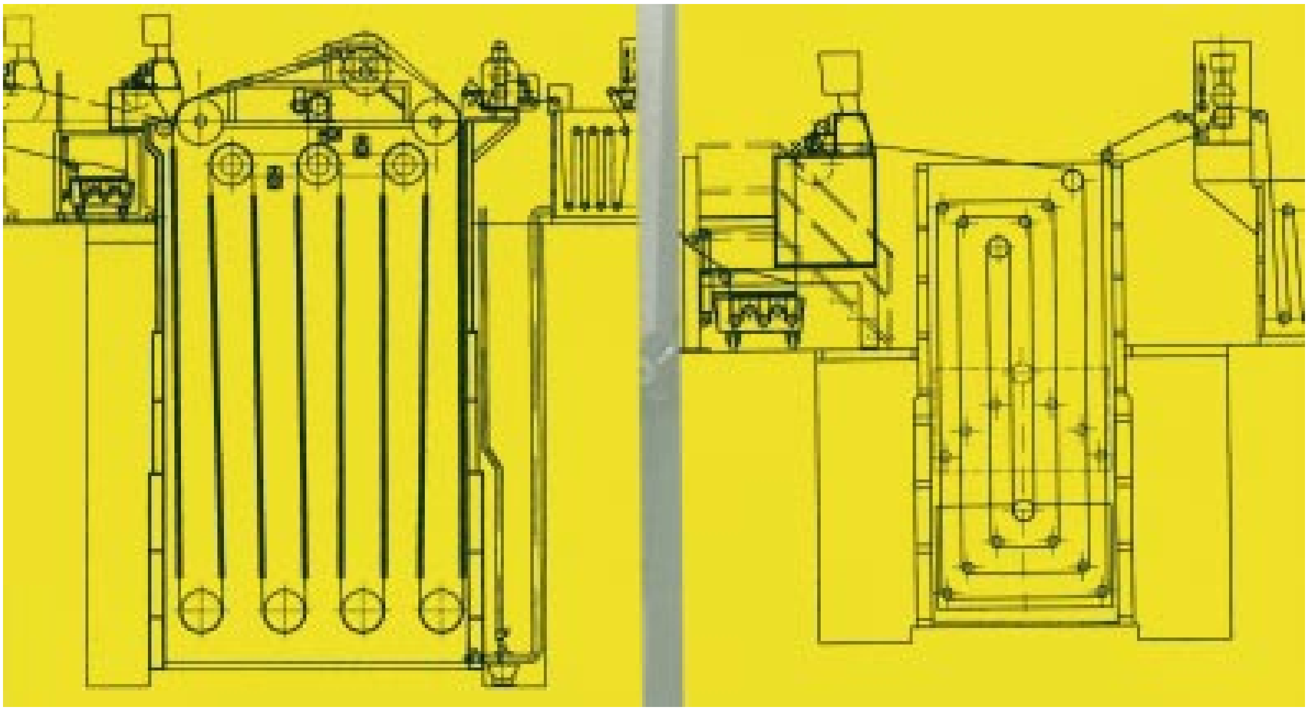

Fig.: Left side: Chain coagulation tank for very soft products (garments, hand bags); right side: Vertical coagulation tank with cylinders for a wide range of products (garments, hand bags and shoes).

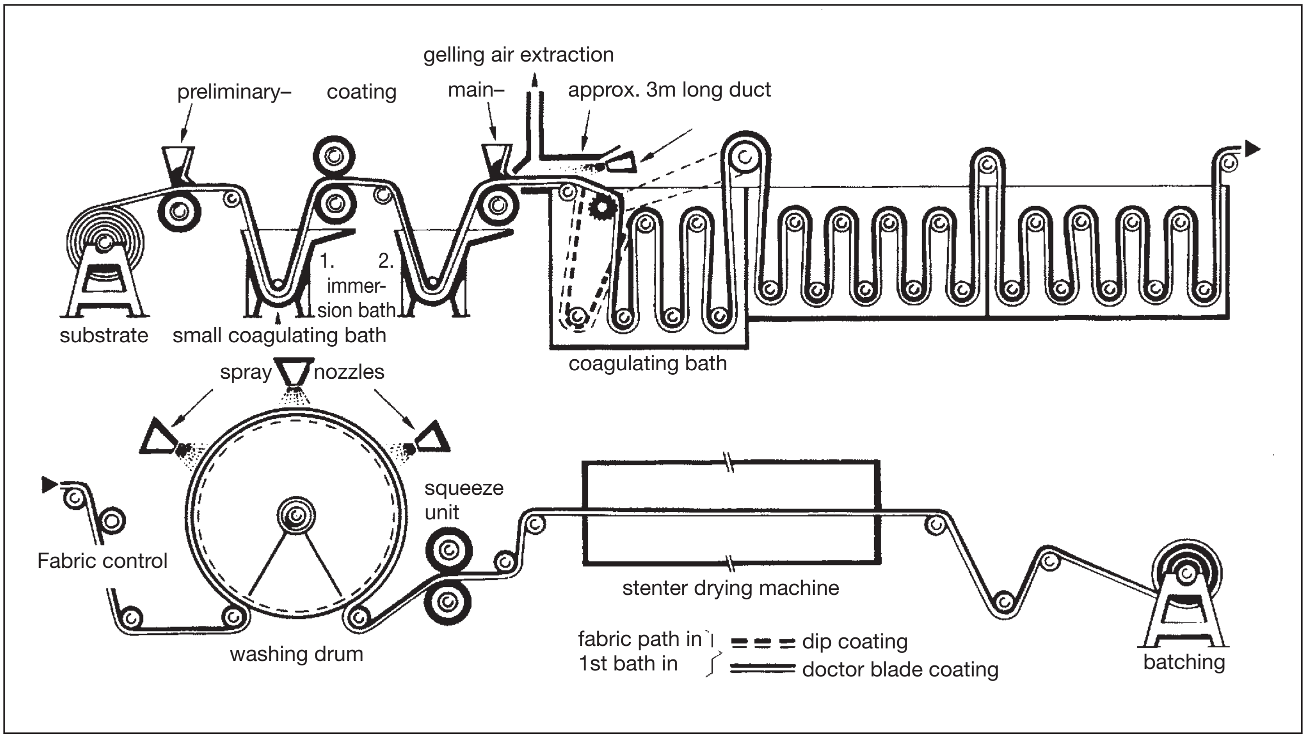

Fig. 1: Coagulation plant with coating or spray application (Bayer).

polyurethane solution (Figs. 1 and 2), the polyurethane then being coagulated into a microporous mass in a precipitating bath.

The dimethyl formamide used as solvent is unrestrictedly miscible with water. In the aqueous coagulating bath, the solvent is gradually extracted from the polyurethane so that a definite pore structure is obtained relative to the coagulating conditions (precipitating bath temperature and solvent content). These so-called poromerics have won a secure place, particularly in the shoe industry. The combination of water vapour permeability and water impermeability required in many cases cannot of course be automatically obtained with this technology. This requirement profile can be better achieved by later techniques, e.g. a) a polyurethane solution is mixed with a defined quantity of water in evaporation coagulation. The solvent is selected so that it is the first to be evaporated when the substrate is dried. The concentration of the solutiser therefore constantly decreases, while that of the non-solutiser - water - constantly increases. Finally, as with classic precipitation coagulation too, the polyurethane precipitates in microporous structure form. The pores are precisely formed so that they are large enough to allow the passage of water vapour, but not so big as to allow water droplets to pass through. b). With the aid of classic coagulation, a polyurethane which contains hydrophobic, silicone or perfluorocarbon based components is applied. c) Specific hydrophilic polymers have the power to transport water vapour by means of compli-

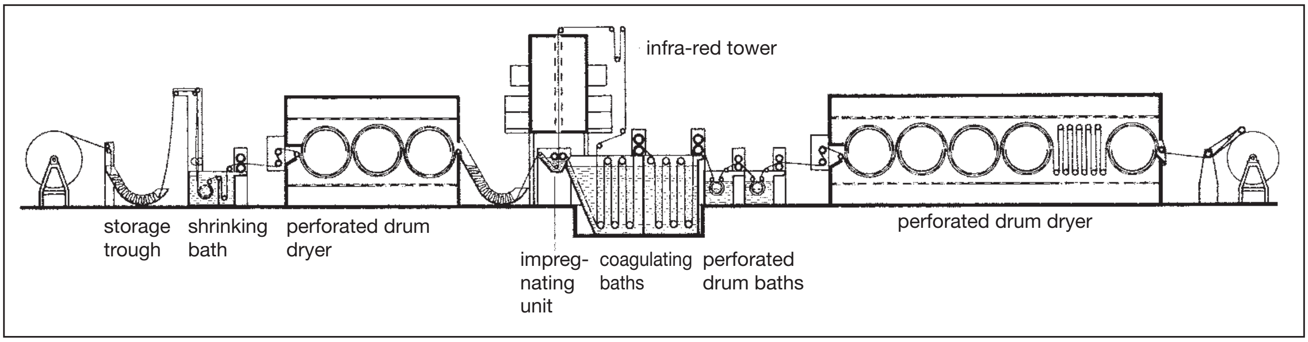

Fig. 2: Fleissner continuous line for bonding synthetic leather nonwoven substrates for latex (with infra-red tower) or for polyurethane impregnation (with no infra-red tower) with coagulation stage.

cated molecular mechanisms. This characteristic is used in reverse osmosis for example. Unfortunately, many polymers with these properties are either water-soluble (polyvinyl alcohol, polyethylene oxide) or are too stiff for textile coating. Success has been achieved in synthesising polyurethanes, which, even when applied as a compact layer, are water vapour permeable, are otherwise useful only for microporous coatings.

Coalescence Confluence of the droplets of an → Emulsion. In most cases, aggregation precedes coalescence. Coalescence leads to emulsion breaking. Macroscopic emulsions should be regarded as stable only relative to time, for there is no such thing as a thermodynamically stable macroemulsion, because they represent multi-phase systems with very large interfaces and interfacial tension which does not disappear; they are accordingly thermodynamically unstable, i.e. sedimentation or creaming of the discontinuous phase, and, finally coalescence, can occur (Fig. 1).

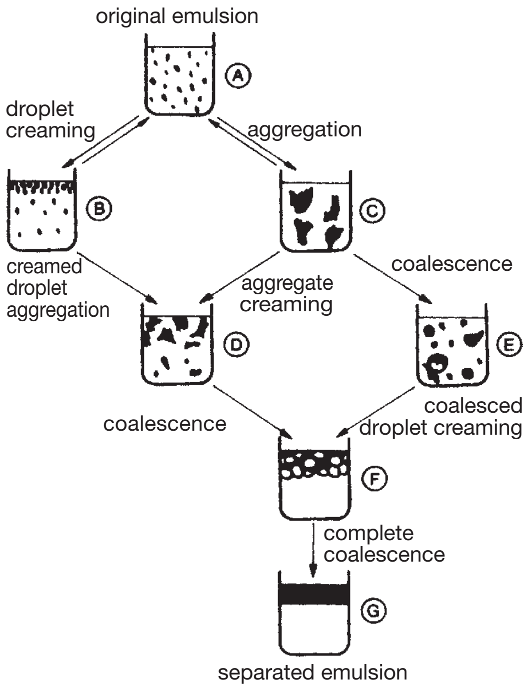

Fig. 1: Development of coalescence.

The rate of sedimentation of aggregated droplets is higher than that of individual droplets, but this applies only to diluted emulsions. Highly viscous emulsions do not settle, as these emulsions are found in any case in sediment or cream (oil and water emulsion) condition. The individual character of the droplets is maintained in the aggregates, disappearing only by oil droplet confluence (coalescence) (Fig. 2). Coalescence also takes place in the sediment or in the cream.

Coalite A product of lignite distillation. Burns, once ignited, without flame or smoke formation by incandescence (→ Thermal value).

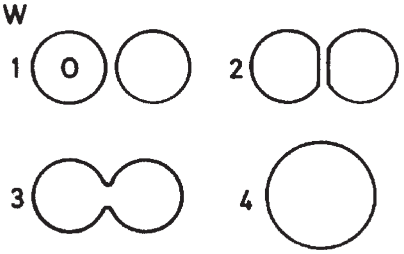

Fig. 2: Individual phases (1–4) of the coalescence of two oil droplets in water.

Coated textiles According to DIN 60 000 and DIN 16 922: fabrics produced with a surface coating on one or both sides (not always a surface coating in the visual sense) with coatings that are homogeneous or cellular in structure (synthetic polymers, natural rubber etc.) e.g. → Artificial leather, Foam laminated textiles.

Coating One- or two-sided application (Fig. 1) of coating compounds or foam films to woven fabric, knit goods, non-woven fabrics or yarns by means of coating machines, rotary screen printing or by means of the spray, hot-melt and transfer coating methods. The coating compounds are formulated on the basis of rubber or film-forming synthetic polymers, with hydrocarbons and water being used as the liquid phase. However, tighter environmental protection conditions demand a move away from products containing solvents. Coating compounds with high solids content can be replaced by powder coating systems. Adhesive lamination of foam foils can be replaced by → Flame Laminating. Coating lends textiles completely new qualities, and thus opens up further application options for them, e.g. artificial leather, rain wear, tent fabrics, tarpaulins, wax cloths, bookbinding fabrics, bag-making goods and technical woven fabrics (see Table). A distinction is made between airtight/watertight coating and water vapour permeable coating. Coating is also used to produce composite materials: →: Bond process; Laminating.

In technological terms, coating can be explained as follows: application of a layer of defined chemicals onto a carrier, so that the carrier's physical qualities or surface are altered as desired. Accordingly, coated textiles are textile carriers that are finished on one or both sides with coating formulations, as long as the textile

nature is not lost. As a rule, coatings are constructed of several coats (Fig. 2) of different formulations, each of which have to fulfil characteristic tasks.

The first coat serves to create adhesion between the coating and the carrier material. It partially penetrates into the woven fabric, and is thus decisively responsible for the handle and the resistance to further tearing, as well as the initial tearing resistance and stitch tear strength of the future product. The penetration depends on the paste viscosity, the method used, and the substrate. Complete penetration should be avoided in coating, but the coating weight of the base coat should be sufficient to prepare a smooth surface for the subsequent coats, which has as few faults – such as light spots – as possible. For the base coat, as a rule soft, highly viscous pastes are used, which penetrate only up to about one third into the cross section of the textile carrier, in order to avoid stiffening. The cover coat or topcoat is the core of the coating, since it essentially determines the characteristics of the coated material. It absorbs mechanical forces and, like the base coat, is matched to the substrate in terms of strength and elongation strength. The elongation strength of coating films makes a particular contribution to their adhesion, but is also jointly responsible for rubbing resistance and flexural fatigue behaviour. The final coat or finish coat of a coating on the one hand lends the product its surface character, for example through embossing, coloration or the like. On the other hand, it also contributes significantly to the fulfilment of the given requirement profiles, since it is the first to come into contact with other influences such as water, acid or UV light etc., and thus represents the first barrier for hydrolysis, fading etc. The durability of the top coat is often superior to that of the previous coats.

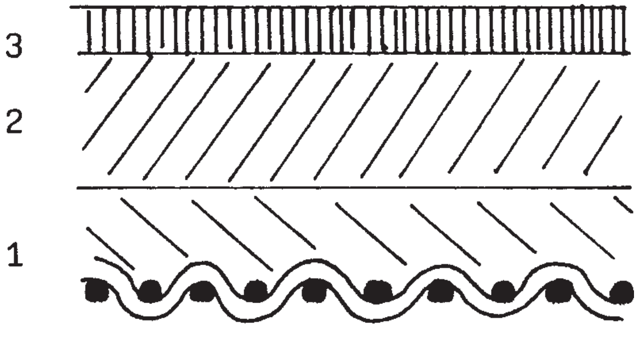

Fig. 2: Construction of a woven fabric coating.
1 = base coat; 2 = cover coat (top coat); 3 = final coat (finish coat).

In some cases, selected topcoats of sufficient hardness and dryness, or after-treatments such as e.g. waterproofing, make it possible to dispense with a finish, thus allowing a simplified procedure. Depending on the paste composition, the process technology and the requirement profile, the coating structure can be varied considerably, although it must always be taken into account that this is a system whose components are matched to one another, and whose tasks are interconnected. Due to the numerous possibilities for variation via the substrate, polymer and technology (Fig. 3), there is a broad range of applications for coated articles, ranging from fashion materials to “high-tech” ones. The technological requirements and the desired durability of the coated products vary widely, depending on the application area. Currently, mainly polyvinyl chloride, polyurethane and polyacrylate which are used, each of which has its own advantages and disadvantages.

The construction of a coating starts with the selection of the appropriate carrier material, which must be suitable for the stresses during processing and for the requirement profile of the end product. Depending on what is required, woven fabric, knit goods and nonwoven fabrics are used. For purely technical applications such as tarpaulins, conveyor belts, containers, tents etc., woven fabrics of polyamide or polyester fibres have proved successful: these are characterised by good strength and durability properties. The Construction and the weight of the woven fabrics are based on the requirements made of the finished product in terms of strength, elongation and wear, as well as on the chemical and mechanical stresses on the grey cloth during pre-treatment and processing. Thus for tent fabrics, for example, linen weave, hopsack weave and satin weave fabrics with a surface weight of 120–200 g/m^2 are the main fabrics under consideration.

The selection of a particular quality is made accord-

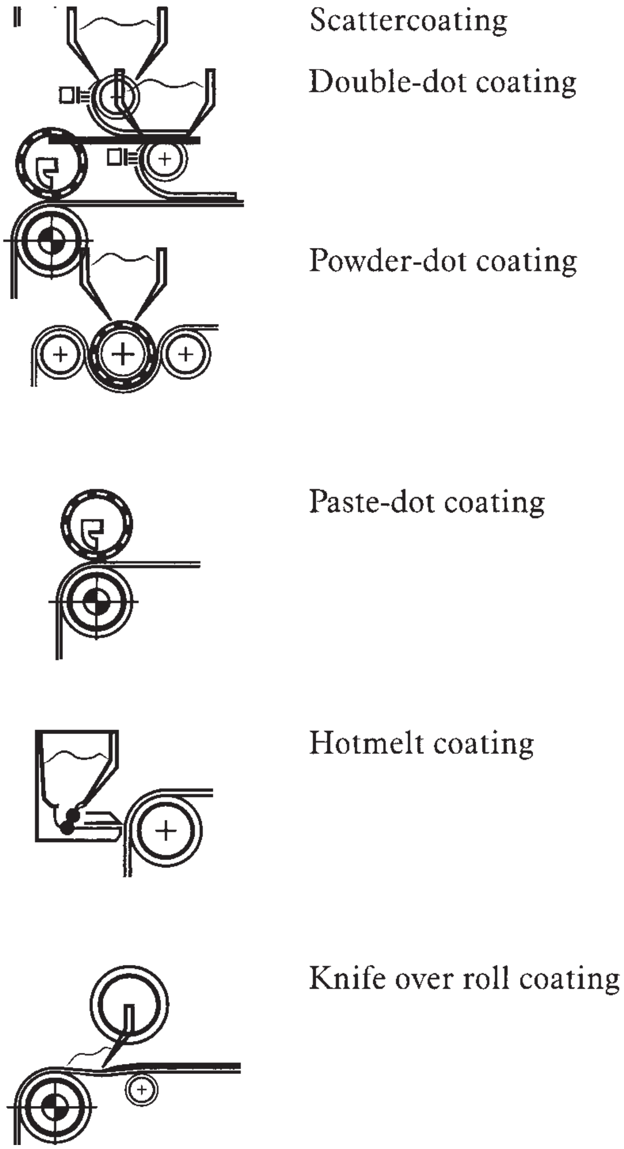

Fig. 3: Coating technologies.

ing to the specifications of the requirement profile, with the coating substrate being the main carrier of the mechanical properties of the finished article. The loom-state woven fabrics are generally subjected to different pre-treatment. These textile finishing processes accordingly serve to

- eliminate weaving faults, knots, impurities, thick yarns, surface fibres and chemicals;
- achieve fashionable effects, such as e.g. ground dyeing;
- ensure the required properties for down-stream processes, e.g. shrink resistance;
- various product parameters such as handle, coating weight, depth of penetration of the coating compound etc.

For all works processes, account must be taken of possible damage to the carrier material, e.g. reduction of mechanical strength, so that the substrate should be subjected not only to an incoming goods check, but also to intermediate checks.

Pre-treatment of the woven fabric can take place in various work cycles:

- singeing,
- treatment with alkali,
- hydrophilic finish,
- hydrophobic finish.

Singeing before coating serves to avoid knife streaks and drop formation through individual fibres that may remain hanging on the knife. A more even, pill-free surface prevents the film density from being reduced by small projecting fibres. The advantages of more even coating results can be lost with irregular fabric surface or uneven singeing that can lead to end colour variations. The 20–30% reduction in weight and the surface structuring of the alkali treatment changes the regain characteristics of polyester woven fabric in such a way that the moisture absorption rises by about 50%. The losses in stability and slip resistance of alkali-treated woven fabrics are disturbing. Hydrophilic treatments also increase the moisture regain capacity, i.e. the wettability of the woven fabric. It is produced by the use of hydrophilic films or surface active compounds, e.g. wetting agents, detergents. Some hydrophilic treatments also take on further functions such as handle, sewability, soiling behaviour or electrostatic charging. The surface characteristics are changed in the opposite way by hydrophobic finishes, i.e. moisture regain, migration and capillary transport drop. The application of silicones or fluorocarbon compounds is frequently used to create the “pearling effect”, and specific combination products achieve additional effects, such as e.g. better dry soiling repellency or oil repellency. The synthetics used in coating are present in solution, dispersed, or as a powder or a melt. In mixing the coating paste, as a rule additives are used which complete or support its characteristics with regard to the requirement profile. Besides the chemical composition, the physical properties of a coating agent, as well as those relating to safety engineering, are decisive in the choice of the system to be used. An important factor is viscosity, which as a technical parameter has a significant effect on the coating and on the flow behaviour of coating agents.

Coating compounds Used for → Coating with:

- starch paste,
- cellulose derivatives (-ethers and -esters),

- natural and synthetic rubber,
- plastics, especially polymethacrylate, polyamide, polybutadiene, polyisobutylene, polyurethane, polyvinylacetate, polyvinylchloride, foamable plastics,
- elastomers for special coatings.

A coating compound based on a polyurethane solution may be prepared as follows: The previously determined colour pigment recipe is stirred directly into the polyurethane solution with a high-speed mixer, dissolver or disperser. Under these conditions a good predispersion can be prepared. Finally the whole paste is ground on a roller mill (Fig. 1). A good, fine distribution of the pigments is obtained on a 3-roller mill. This process has the disadvantage of a substantial solvent loss through evaporation due to the large surface area. 3-roller milling machines are difficult to clean. For these reasons a single-roller pigment mill is often used for the milling of polyurethane coating pastes; the resultant solvent evaporation is reduced and it is easy to clean. The design of the single-roller mill enables it to sieve the paste. The fineness achieved depends on the setting of the roller bar. As heat is generated during the milling process, the roller and hopper must be cooled. If used carefully the single-roller machine yields a satisfactory dispersion. It is particularly suited when certain pigments must be milled several times. This should be taken into account when formulating the recipe. The method is used predominantly for two-component coating compounds. Its main disadvantage is that the whole paste must be milled. For the production of a colour concentrate (Fig. 2), the pigments are dispersed in a 10% binder solution. The predispersion is carried out in the dissolver or disperser and then the final dispersion takes place on a 3-roller machine or suitable alternative dispersion equipment. The dye concentrates must be sufficiently stable in storage and should have no tendency to flocculate. Particular attention must be paid to the precise final appearance and intensity of the shade, otherwise subsequent shading of the polyurethane coating compound is inevitable.

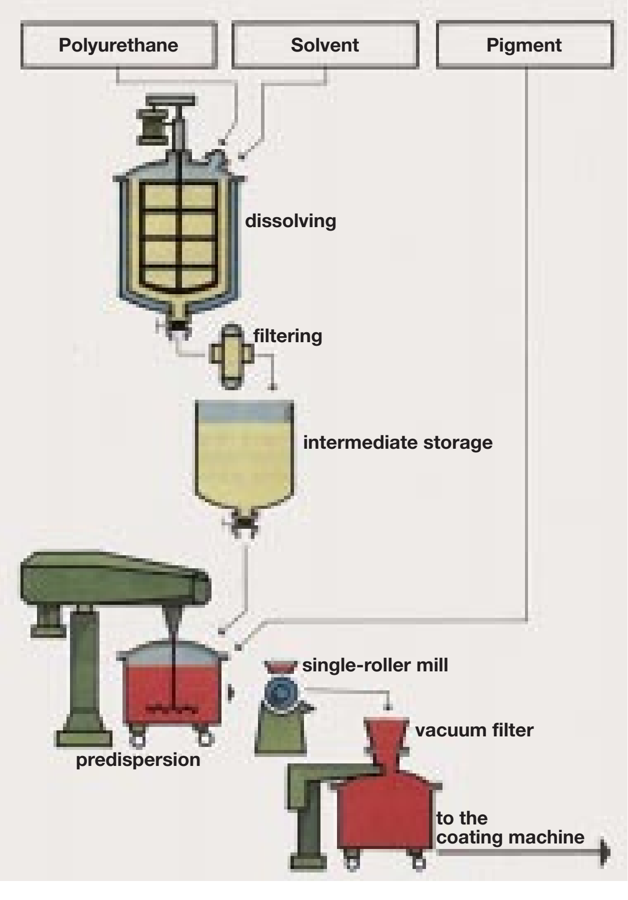

Fig. 1: Dye pigment addition to polyurethane dispersions (source: Bayer).

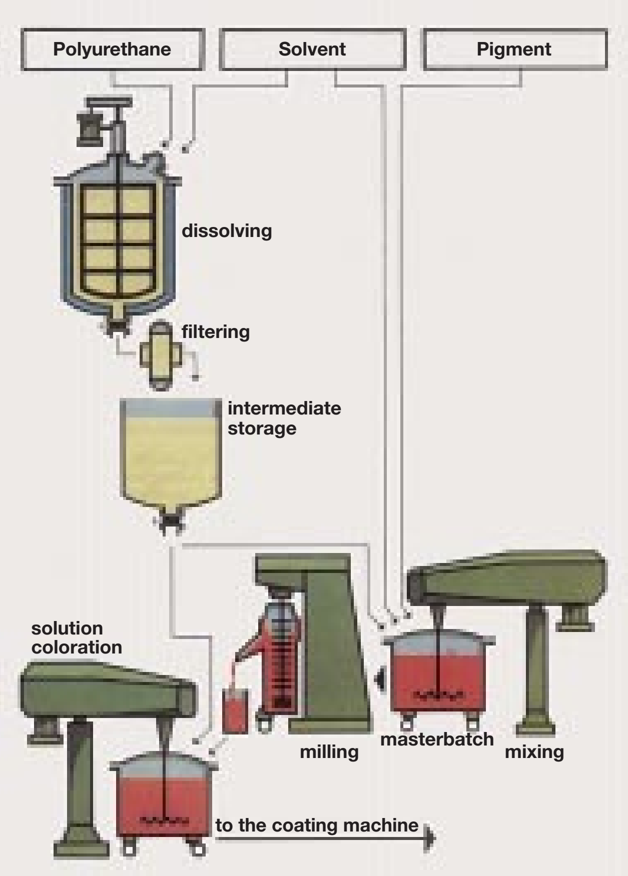

Fig. 2: Addition of colour pigments to polyurethane dispersions by masterbatch (source: Bayer).

Further additives to coating compounds include: plasticizers, fillers (inorganic and organic pigments), colour pigments. Formulations and coating methods vary according to the type of goods and the desired effect, e.g. a single, one-sided coat for down-proof, firm pile, anti-skid, non-slip finishes. For waterproofing effects one or more coats may be necessary, often using coating compounds of varying composition, e.g. a) base coat (soft film formers) for good textile adhesion; b) filling coat (soft film formers and fillers, pigments); c) final coat (harder, tack-free film formers) for surface stability of the coating. In addition to this coating based on solution or dispersion methods, there is also the possibility of film coating using various processes on the calender. → Laminating of similar or different fabrics or combinations is usually carried out using man-made materials. The adhesion properties increase as laminates are added. Fillers have an adverse effect on the adhesion. Coating compounds vary according to the goods and the application: one or more coats on the backing cloth, then (dry laminating) drying or doubling, pressing or (wet laminating) doubling, pressing, drying.

Coating finish Coating with → Coating compounds.

Coating knife Also known as a → Doctor blade; in the form of a steel blade sharpened at the application end, or a rubber blade, which is less precise in its application. Given a constant angle of application, the more pressure applied to the coating knife, the wider is the mass of coating compound before the coating knife, where it changes viscosity before flowing beneath the blade.

Fig. 1: Coating knife type: knife-over-roll.

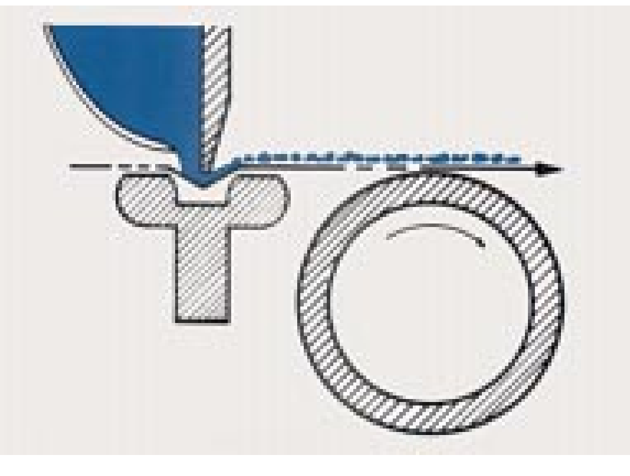

Fig. 2: Coating knife type: knife-over-hollow bed.

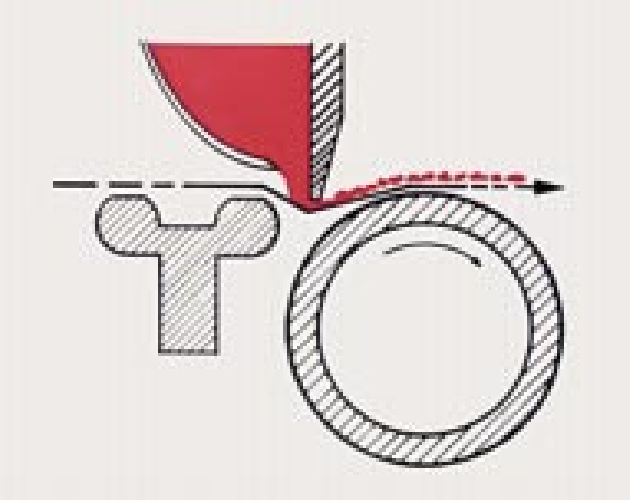

Fig. 3: Coating knife type: knife-over-air.

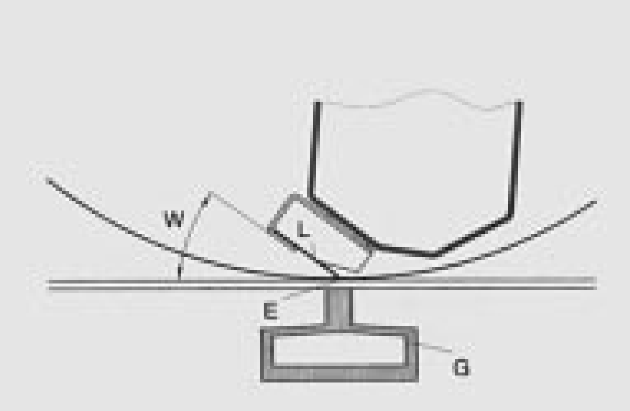

Fig. 4: Structure of the "Isoprint" coating knife system. L = blade; E = point of application; G = counterpressure system; W = blade angle.

A device is often used to supply the bank of compound before the coating head and thus provide control over the wedge of compound formed by the movement of the fabric. (Fig. 1). Different coating effects are given if there is a table underneath the fabric to be coated (Fig. 2), or an air space (Fig. 3). The nature of penetration of compound into the fabric is changed. The use of a rotating screen with control of the knife pressure by means of a magnet system (Fig. 4) ensures extremely precise metering of the paste.

Coating machine (Knife-coat machine). For coating with → Coating compounds. Consists of compound trough, coating head with adjustable height (incl. offset blades the stripping off the excess finish), fabric and guide roll systems (see Fig.). There are various types of doctor blade (→ Knife-coating principle*)*.

Fig.: Coating machine (Mascoe) with the following elements: 1 = individual side adjustment of the coating blade; 2 = vertical height adjustment of the blade; 3 = horizontal adjustment of the blade; 4 = coating table adjustment; 5 = oscillating compound supply system; 6 = display showing horizontal blade settings; 7 = blade holder; 8 = flexible cable.

Coating machine for rotary printing screens For the mechanised application of photoemulsion to rotary screen sleeves. After centring the screen, the emulsion is poured into the squeegee, and squeegeeing is started from top or bottom.

Coating machines Knife coating machines which apply coating compounds as base-, filler- and surface-coatings, at a controlled thickness, on smooth woven and knitted fabrics, usually combined with cylinder or float dryers for curing the synthetic polymers or for evaporating organic solvents (hardening the coatings), possibly for eventual embossing or smoothing (chintz) calendering (Fig. 1).

There are three different versions of squeegee available for the screen process. Two of them can be used for paste coating, the third is also suitable for coating with stable foam. The most simple execution has holes, through which paste is distributed. This type of squeegee is meant for pastes with a straightforward flow behaviour. For pastes that distribute less easily, Stork can offer a patented squeegee system with paste supply through a double slot. This squeegee sees to an optimum distribution of the paste across the entire width of the screen and thus increases the accuracy of delivery and uniformity in width direction. The application volume and penetration can be controlled via the squeegee pressure and squeegee position. The paste or the stable foam, once applied through the screen, can be levelled by an optionally available whisperblade (Fig. 2). When coating with stable foam, the foam will have to be crushed after it has dried. For this Stork offers a crusher as an optional extra.

By using an engraved screen and choosing a coloured printing paste, the CFT can be used for one-colour rotary printing.

A paste or stable foam can be applied to the substrate so as to obtain a layer of glue on interlinings for instance, the glue being distributed in a dot pattern (Fig. 4). For this one uses a screen with a relatively low mesh count. One can choose between a screen with a regular hole pattern or a screen with a random pattern. The latter makes for a more supple grip in case of laminates.

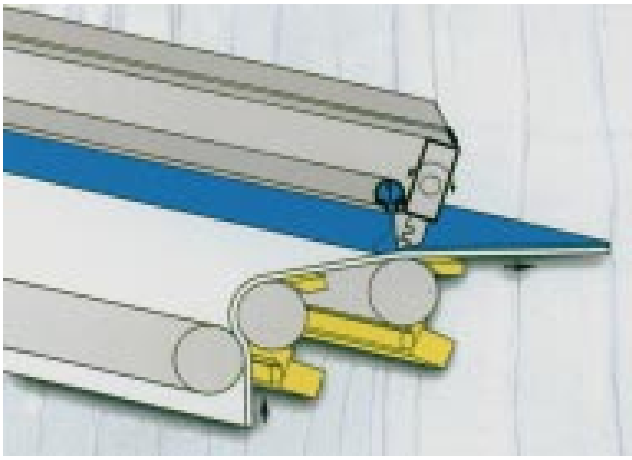

Fig. 5: Paste or stable foam coating with knife (knife over roll).

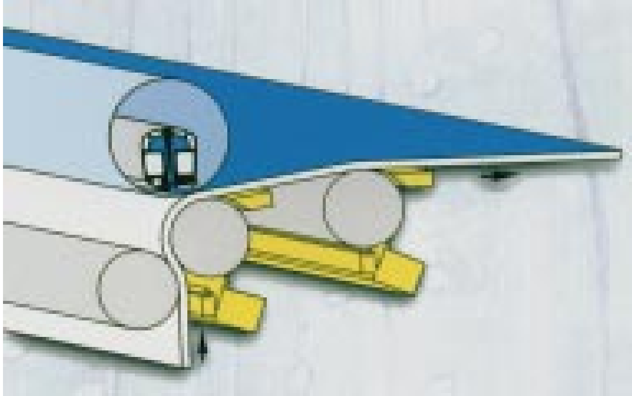

Fig. 6: Foam finishing.

For finishing with unstable foam one uses a special closed sqeegee, in which the foam is contained under pressure until it is applied to the cloth through the screen (Fig. 6). As foam enables an even distribution of the chemicals, very small amounts can be applied. Because of this it is, for instance, possible to impregnate a substrate on one side or to realise complete penetration. With one-sided applications this may yield large savings on chemicals. Furthermore, the use of foam enables the application of only a limited amount of moisture, allowing a much higher production speed with an existing drying capacity. These techniques are also referred to as low add-on or MA techniques.

Knife over roll coating (Fig. 5) is mainly done when higher add-ons are desired. An air knife (Fig. 3) is used for fabrics that need to combine a closed surface with a minimum coating weight. Also for the knife coater Stork developed a special distribution system for paste or stable foam, this system being based on the concept of the time-tested and patented extrusion squeegee that guarantees a balanced supply across the full width of the knife. The standard knife coater version has a digital height adjusting facility and is suitable for knife on air and knife on roll coating techniques. In addition to the standard version there is a heavy duty version for large widths; this latter version has been specifically designed for the coater that sets very high requirements and mainly uses knife applications. With this heavy duty version all settings can be motorised and read from a digital display. Separate arrangement of the screen unit and the heavy duty version of the knife coater is possible as well.

Coating of carpet backs → Carpet back coating.

Coating of yarns Woven fabrics made of coated yarns have characteristics different from those of coated woven fabrics, i.e. a more open structure. Thermoplastic and thermosetting polymers in solid or liquid form are used. For example, the yarn is encased by a film strip of such products and fused with it or stuck to it.

Coating polymers The synthetic polymer dispersions and solutions used in the textile industry are manufactured on the basis of urethanes, acrylic esters, vinyl chlorides, vinyl ethers, vinyl esters, isobutyls, isoprenes, styrols and butadienes. Natural latex is the only natural product in this range. The chemical and physical properties of the dispersions are varied and a suitable choice must be made according to the application area. The following are relevant to processing: chemical reaction mechanisms, particle size, stability, coating properties, viscosity and the pigment binding properties of the dispersions. The minimum film formation temperatures, hardness and elasticity of the films, as well as their resistance to water and to organic solvents, must not be ignored. Inadequate ageing stability and possible unwanted smells from the dispersions when applied to textiles are important and are often the source of customer complaints.

In the base coating of tufted carpets, the following requirements are made of dispersions:

- A high pigment binding capacity is absolutely necessary for price reasons.
- The applied film must demonstrate sufficient elasticity with corresponding hardness, and must have good adhesion to the fabric. It is responsible for the handle, the erect positioning of the pile and the quality of the pile anchoring.

- Unwanted smells and poor ageing stability can make the product unsaleable.
- The water resistance must be good, whilst resistance to organic solvents is not necessarily required.
- The coating properties and stability of the dispersions must be ensured in processing.

The viscosity of the synthetic polymer is important but even with high solids products it is normal to additionally use thickeners. Taking these factors into account, natural latex, butadiene-styrol and butadiene-acrylic copolymers, as well as their derivatives, have been successfully introduced as synthetic latexes in the back coating of tufted carpets. As regards the question of whether one should use dispersions or solutions, the decision has been clearly for dispersions. → Dispersions in coating have a low viscosity with a high solids content of approx. 50–60%, whereas solutions have high viscosity with a relatively low solids content. The problem of solvent costs, recovery with an average loss of 5%, and special working arrangements to avoid explosions when handling solvents, have led to more widespread use of dispersions. Dispersion films have the disadvantage, however, of a certain water solubility, due to the emulsifiers that remain in the film on drying.

Coating polymers on technical textiles Technical textiles are coated on a large scale with the goal of obtaining waterproof and strengthened textiles. Applications among other things are technical tarpaulins for buildings and vehicles as well as tents, conveyor belts and home textiles. Despite the outstanding price-performance ratios of PVC-coatings on technical textiles there is increasing interest in alternatives which do not contain chlorine, because of their ecological acceptance. PVC is being discussed, because it is suspected, that the monomeric vinylchloride is carcinogenic and there are problems with the recycling process due to the chlorine. Hydrogen chloride is released and the building of dioxine is possible under unfavourable conditions. Chlorine-free coatings, for instance polyacrylates and polyurethanes, have already been successfully applied in some special fields. However, the new replacement coatings with equivalent properties to those of PVC, have not been able to achieve the economic efficiency of PVC-plastisoles. The properties of PVC-plastisoles have only been reached, after the addition of additives, such as coupling agents, softening agents and anti-agers. These products are able to diffuse out of the coatings and they are partly toxic. The advantages and disadvantages of PVC-, PUR- and acrylate-binders are outlined in the Table.

Coating preparations → Coating compounds.

Coating substrates Textiles in piece or sheet form, nonwovens, film, felts, paper, etc. that are coated.

Coating technology The coating of textile substrates is divided into the following processes:

1. Application: Transfer of a liquid, highly viscous,

binders	*Advantages*	*Disadvantages*
PVC-plastisole	• good price-performance ratios • simple processing • broad application • non-ageing • weldable	• problems by the recycling process (it is not possible to completely seperate the coatings from the support) • danger of dioxine formation by uncontrolled burning • formation of hydrogen chloride during thermal disposal • good properties obtained only after the addition of additives (coupling agents, softening agents, anti-agers)
polyurethane-dispersions	• high extension at break and elasticity • good wear properties of clothes • good abrasion resistance • high flexibility at low temperatures (without softening agents) • low specific weight • wash and try cleaning resistance	• high price • possibility of recycling is restricted • disposal through burning • defects in the waterproofness
polyacrylate-dispersions	• good weatherability • good light fastness • resistent to bacteria and moulds	• high price • tendency towards stickiness • disposal through burning • defects in the waterproofness

Tab.: Advantages and disadvantages of already used binders.

molten or powder compound made of synthetic polymers onto a substrate.
2. Film formation: Solidifying of the synthetic polymer coating to form a closed film, with a certain durability to form a composite with the substrate.

Accordingly, coating plants subdivide into the following components:

- unrolling device, with suitable width control,
- application device,
- drying or gel formation oven,
- fabric take-up device, possibly with fabric cooling.

As a rule, coating plants are run continuously. However, depending on the application process, batch processes may be used e.g. in the coating of leather. The most diverse systems are to be found among the application devices and drying tunnels and gelling ovens; these differ in their suitability for certain products. The choice of system is guided by

- the application form of the synthetic polymer and its property, e.g. viscosity,
- the amount applied,
- the type of substrate,
- the required tolerances and uniformity of the product.

The most frequently used method is coating by means of knife blade coating. The coating compound can be applied directly onto the substrate (direct coating) or by means of an intermediate transfer sheet (transfer coating or transfer process). As transfer sheets, release papers are used almost exclusively, although occasionally steel bands or metal drums are still found. The decision to work using the direct coating method or the transfer method depends on the requirements of the article to be produced. Thus for example most knit goods and other elastic materials can only be coated using the transfer process, since the tensile stress acting on the substrate in direct coating is too high for these textiles. Preferably, transfer coating is used for open weaves, in order to apply a continuous film. Coating weights of 40–250 g/m^2 can be realised, whereas direct coating ranges from 10 g (finest coating) to 500 g (technical articles).

Besides the classic knife application methods, there are also numerous other methods:

1. Flow coating process: dosed pouring on of the coating paste, with no contact between the carrier and the applicator taking place; for this reason, very thin, even layers are possible, independent of the irregularities of the substrate.
2. Impregnation or dipping method: The carrier material is led through an immersion trough which holds the liquid coating compound.
3. Slop-padding process, roll coating: The carrier material takes on the coating compound from a roller that turns through a bath (direct roll coating). This can also take place via roller systems. Dosing is by wiping off the slop-pad roller or the coated goods. If the paste reservoir is located in the angle between two rollers, this is termed the roll coating method (reverse roll coater).
4. Calender application or hot melt method: With this method, granules and powders are melted between two rollers or prepared viscous plastic compounds are used, which are plasticised by the heat of the rollers. Between the calender rollers, which can be arranged in various ways, films form which can be transferred to the goods via the rollers.
5. Powder application method: Here, powder thermoplastic synthetic polymers are scattered and formed into adhesive melts. This coating technique can be subdivided into two groups: the dry method and the wet method, which are used particularly for interlining fabrics for clothes.

In addition, there are other coating techniques, which derive from combinations of known principles. These include for example the Accugravure method, which combines the working method of rotogravure printing with the technique of the reverse roll coater; or the Stork plant (Fig. 1), which has been developed from screen printing technology and is also known as rotary screen coating.

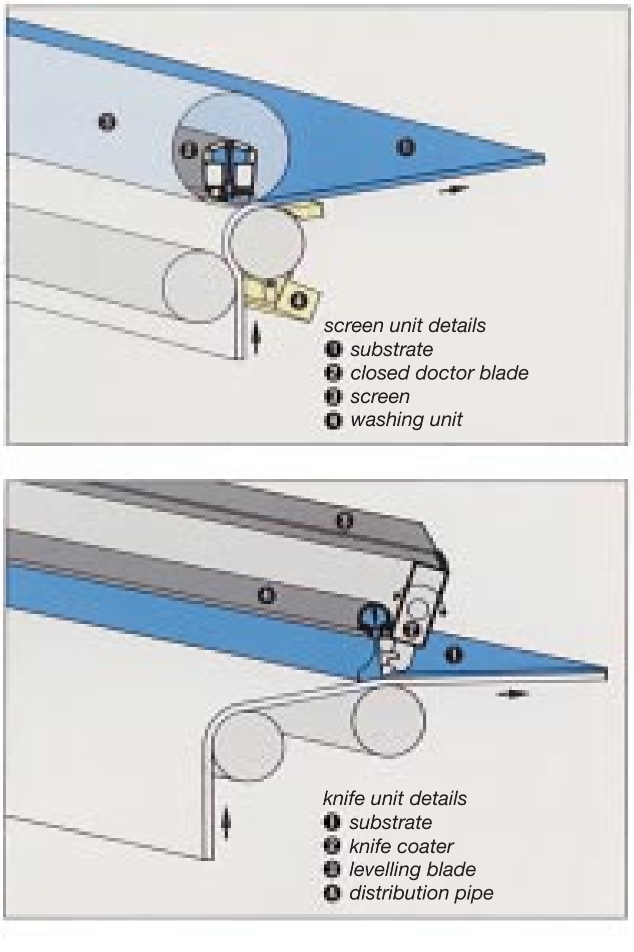

Fig. 1: Stork MCC-V combined coater unit with doctor knife or screen coating.

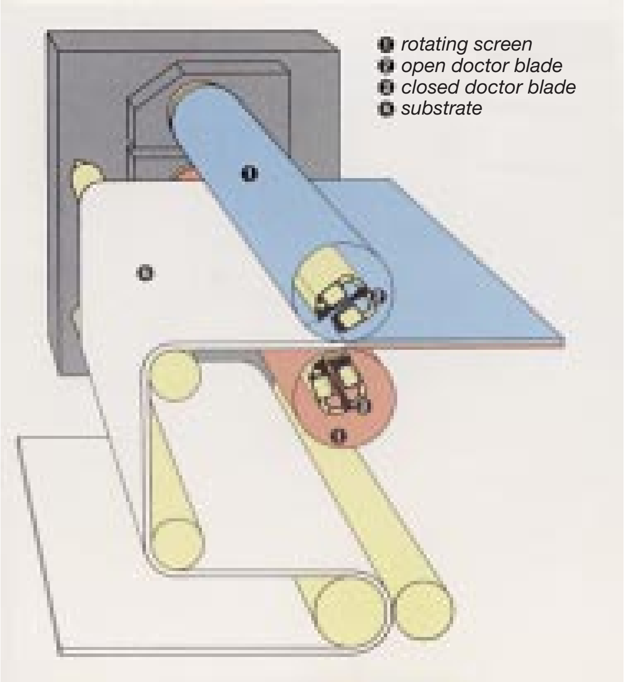

Fig. 2: Duplex coating (Stork).

The simultaneous coating of both sides of the fabric using the duplex method may also be of interest (Fig. 2).

It is a simple transition from these processes to related processes such as painting, where it is a case of straightforward surface treatment or laminating. In the case of laminating, in one working cycle the film can be formed and the lamination of the film – which is usually still viscous – on the substrate can be carried out, so that it can be counted among the coating methods. If however complete synthetic films are to be subsequently combined with the carrier, then in the stricter sense this is to be distinguished from coating, since a planar connection of two runs of material takes place. Tandem plants permit the application of two coatings one after another. These coatings can also be dried in-between stages or pass through a short gelling stage. In order to guarantee a diversity of articles, those carrying out the coating must have access to various coating technologies

Cobalt (Co). Reddish white, lustrous metal, very hard, resistant to atmospheric influences, can be polished and magnetised, atomic weight 59; density 8.5; melt point 1478°C. Slowly soluble by diluted mineral acids, more quickly by nitric acid to cobalt (II) salts. Cobalt (III) in particular tends to form numerous complex compounds. Use: cobalt salts = dye mordants, colour production, analytical chemistry, hygrometers.

Cobalt salts Qualify as carcinogenic working materials in difficult-to-dissolve form as breatheable dusts.

COBOL, abbrev. for: common business-oriented language. Term used in electronic data processing.

Cobweb finish A synthetic pilling effect achieved on → Stitch-bonded fabrics for coat linings through raising, steaming and subsequent tumble drying.

Co-carcinogen Possible cancer-inducing substance that activates potential → Carcinogens in such a way as to form a cancer that would not occur without co-carcinogens, or if just co-carcinogens were present. Co-carcinogens are therefore hazardous to humans if they affect human tissue that has been exposed to carcinogens (even years beforehand) even below the threshold dose levels.

Cochineal A fiery red → Natural dyes (mordant dye) consisting of the dried bodies of the female insects of Coccus cacti, another species of the shield-louse family, largely cultivated in Mexico. 1 kg of dye = approx. 140 000 insects. The colouring principle is carminic acid, $C_{22}H_{20}O_{13}$ (an anthraquinone derivative). It is tinctorially 11 times stronger than → Kermes which it quickly replaced. It was formerly much used on a tin mordant for the scarlet or "grain" dyeing of wool and silk and was also used to dye Morocco leather and, later, cotton. Its use as a textile dye declined due to the fact that it could no longer compete with acid scarlets such as synthetic ponceau. It is still used as a food colorant.

Cochineal reaction For demonstrating the presence of oxycellulose. Place the specimen in lead acetate solution, subsequently stain with → Cochineal. Oxycellulose takes up lead oxide, traces of which turn cochineal from red to magenta. The depth of colour corresponds to the degree of damage.

Cocoon A sort of yarn ball silkworm housing, which is spun from the protein thread of → Silk.

COD, abbrev. for: → Chemical oxygen demand.

COD in g/kg fabric → Pollution index.

Coefficient of variation (Factor of variation, v). In → Statistical analysis, the characteristic value of variation (property or measured value) as the ratio of a standard deviation s to the mean $\bar{x}$:

$$v = \frac{s}{\bar{x}} \cdot 100\,\%$$

Co-enzymes/ferments Particularly occur among → Desmolases as a so-called prosthetic group and are enzymes that are catalytically almost ineffective. These are relatively low-molecular, non-protein-like, heat-resistant, dyalizable substances such as organic phosphoric acid esters. However, co-enzymes are activated if they occur together with enzymes or ferments that often contain heavy metals (complex catalysts) as colloid carriers of proteins that are always highly complex. This kind of total ferment is called a holo-enzyme or holo-ferment.

COFREET, abbrev. for: Comité Française de l'Etiquetage pour l'Entretien des Textiles (French

Committee for Textile Care-Labelling), Paris; → Technical and professional organizations.

Cohesion (Lat.: cohaere = cohere). Based on the reciprocal attraction of chemically related molecules, which is brought about by the complex combination of the secondary valence forces (intermolecular interactions) like hydrogen bridge bonds, van der Waal forces and dipole interactions. Cohesion energy (in J) from the combined values of each chain atom (increments), which produce the following typical values (melting or decomposition point in brackets), is regarded as a measure of the secondary valence forces:

polyethylene (130°C)	1300
polyvinyl chloride (180°C)	2500
polyvinylidene chloride (180–220°C)	3500
polyvinyl alcohol (140°C)	5100
polyamide 6 (264°C)	3400
polyester (250°C)	1900
polytetrafluoroethylene (400°C)	1600

Polyester and polytetrafluoroethylene do not fit into this series. Other factors besides cohesion energy have a part to play here. In the case of polyester, the stiffening of the molecule chains associated with the incorporation of benzol rings (π-π-interactions) appears to offer an explanation, which also manifests itself with other similarly natured polymers. We see however that high cohesion energy and stiffness actually mean a high melt point. → Adhesion.

Coir fibres Coconut palm fruit fibres classed in the → Hard fibre group. Obtained from the husk of the coconut by retting, squeezing, hackling and cleaning (possibly bleaching too). Strength 12–15 cN/tex, elongation 25–30%. The fibre is lighter than water (density 0.945 g/cm^3), and has a high degree of abrasion resistance and rot-fastness, and picks up little dirt. Use: for runners, mats (possibly together with wool), carpets, drive belts, ropes, upholstery purposes, brushes etc.

Coir matting Matting woven from coconut fibre.

Cold batch process Another name for → Cold pad batch process, especially for reactive dyestuffs.

Cold dwell process This name is frequently used for the plaiting down and storing of impregnated fabric when not batched. → Cold pad batch process.

Cold dwell unit (Cold pad batch unit). For storing impregnated fabric, mainly for short-period continuous hypochlorite bleaching between scouring and peroxide bleaching processes. Short-time and combined steamers and also pad roll batching trucks are used as upstream and downstream units. The quantity of caustic soda or peroxide can be reduced by up to 50% (reduced catalytic damage) with a cold dwell unit. Despite this, better husk decomposition, better bleaching out of knops, smoother fabric appearance and a degree of whiteness up to full white can be achieved.

Cold dyeing dyes According to the → IK dyeing method, cold dyeing vat dyestuffs. There are also highly reactive cold dyeing dyes under reactive dyestuffs.

Cold dyestuffs or dyeings → Infrared-reflecting dyeings.

Cold latex (Cold rubber, cold caoutchouc), American name (now international) for Buna-S types in the cold polymerisation manufacturing process (starts at 5ºC with redox activation) for butadiene/styrene (e.g. 70 : 30). This kind of cold latex is considerably better than Buna-S (with regard to oxidation resistance, tensile strength, friction wear) and is particularly suitable for coating (excluding car tyres). Opposite: hot latex.

Cold pad batch bleach Peroxide bleaching process characterised by a high concentration of hydrogen peroxide (> 40 ml/l) and a long reaction time (24 h). Under these conditions, bath stabilisation is particularly important, and silicates, phosphates or organic stabilisers can be used for this purpose. Hot washing off with the addition of alkaline surfactants must be implemented in order to obtain absorbent fabric. Dwell time can be reduced (to 4–6 h) if a 1 minute steaming process follows storage. → Peroxide-padder-dwell process.

Cold pad batch dyeing,

I. For polyamide tufted carpet dyeing: dyeing with monofunctional acid dyes with similar combination code. Adequate liquor quantity, 180–250% necessary. Complete immersion is to be avoided, therefore pour on dye liquor. Batch must be rotated at 3–10 rpm. Dwell time is 16–24 hours.

II. → Cold pad batch process on rotating batches for reactive dyes.

Cold pad batch dyeing with reactive dyes (Hoechst). Principle: dye and alkali solution are prepared separately, and reach the padder trough only after passing through a mixer. Impregnated fabric dwells a few hours batched in open width, during which the dye is fixated. The so-called CPB pump is used as a metering, conveyance and mixing unit.

Cold pad batch printing process for wool → IWS cold-dwell print process for wool.

Cold pad batch process Process in which textile material is impregnated (padded) and usually rolled up (batched), whereupon the finishing agent that has been applied to the material is given time at room temperature (approx. 15–25°C) to be absorbed or react. Textile material is generally left to dwell for 3–48 hours. Cold pad batch processes have proved their worth in finishing textiles of various compositions and various presentations, and are gaining in importance due to the savings on energy. They run semi-continuously. Principally two types are distinguished:

1. Short processes with setting times of 2–6 hours.
2. Long processes with setting times of greater than 20 hours.

In reactive dyeing, there is a relationship between hydrolysis stability of the pad liquor on the one hand and the minimum fixation time on the other hand:

Liquor stability	Minimum fixation time
5–20 min.	2–4 h
20–40 min.	4–8 h
40–90 min.	8–20 h
90–180 min.	> 20 h

In short processes, in order to achieve sufficient reactivity the alkali addition must be so strong that within minutes more than 10% of the dye hydrolyses, and is thus lost for the purposes of dyeing. The use of a dosing pump is unavoidable in this case. Fixation times greater than 20 hours enable recycling of the alkali and thus a stabilisation of the padding liquor at 2 hours and above. In other words, if no dosing pump is available, only cold pad batch processes with longer setting times (> 16 hours) can be carried out. However, these remarks apply mainly for moderate climate zones (e.g. central Europe). In hot countries, e.g. in Asia where water and air temperatures are clearly higher, other relationships apply. Here, cold pad batch processes are considerably more difficult to carry out with a good level of shade duplication.

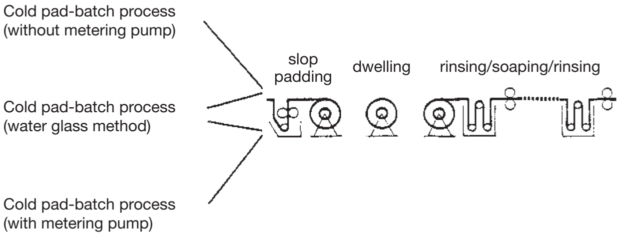

Fig. 1: Reactive dye cold pad batch setting (machine unit) on cotton fabric.

The general view is that only reactive dyes with high reactivity should be used for cold pad batch processes, e.g. in the short cold pad batch process (Fig. 1). A considerable advantage of this method is that only sodium carbonate is used as alkali, and the unwanted white or light edges, which frequently occur with the usual sodium hydroxide activation, are usually avoided. There are however problem cases where the long process represents the better solution:

- dyeing mercerised material,
- dyeing regenerated cellulose,
- seam impressions (e.g. towelling),
- heavy, closely-woven fabric,
- dyeing of raw goods.

In all these cases, reactive dyes, which require large amounts of alkali and long reaction times (24 hours), are preferred. An example of the long cold pad batch process is the combination of cold pad batch process plus exhaust method on piece-dyeing beam or jet for knit goods of cotton/polyester or cotton/polyamide (Fig. 2).

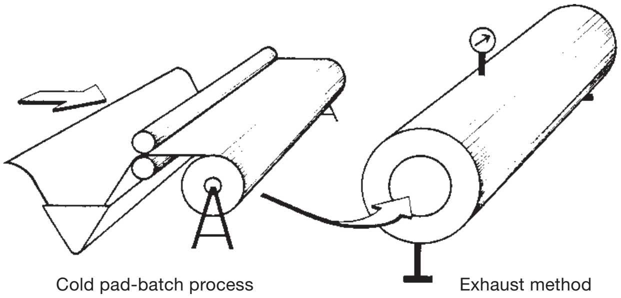

Fig. 2: Dyeing of cotton/polyester blended goods. Cold pad batch process: reactive dyeing of the cotton; exhaust method: beam dyeing of the polyester portion.

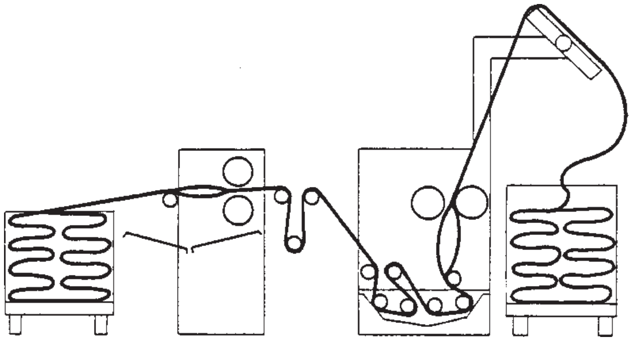

Fig. 3: Cold pad batch process for knit goods.

First of all the grey cloth is dyed with the reactive dyes in a roll batch system, and subsequently the synthetic fibre portion is dyed by exhaust method on a beam-dyeing machine (Fig. 2) or a jet dyeing machine (Fig. 4) (reverse process). Here it is apparent that reactive dyes, which require large amounts of caustic for fixation, are at a clear advantage in the dyeing of grey cloth. The impurities found on the fibre, which are to some extent dyed, are more easily and more completely removed during intermediate rinsing. This results in a considerably higher level of fastness.

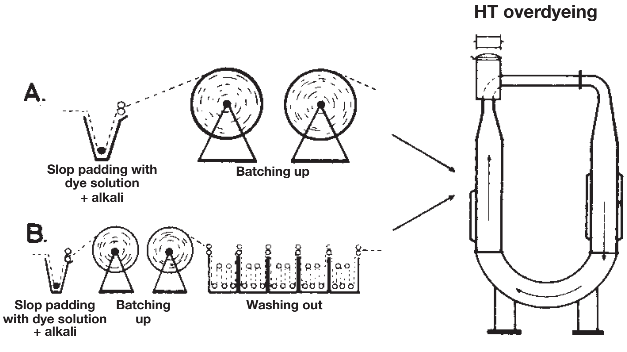

Fig. 4: Machine diagram of the cold pad batch dyeing/jet method.

When the cold pad batch process is used for circular knit goods with the roll or plaiting-down system (Fig. 3), the main problem lies in setting bowing-creases, which must no longer be visible after dyeing. Although this problem has not been satisfactorily solved for all qualities, level dyeing can be achieved by delaying the fixation or through the use of slow-reacting reactive dyes. Since the dye does not fix within a few minutes, but can migrate over the course of several hours, the chance of tone-in-tone dyeing on the "bow" is considerably greater. Advantages of the method:

- low cost for machinery,
- simple process,
- rapid colour changes,
- good dye penetration,
- high degree of levelness,
- low energy requirement.

Disadvantages:

- Relatively large metreages are dyed, and it is only after some hours, and frequently only the next day, that one can establish whether the shade is correct and that no dyeing faults have occurred. No shading corrections are possible, and correcting off-shade results or unlevel dyeings is difficult.
- Poor shade reproducibility between laboratory and dyehouse. Laboratory fixation takes a great deal of time.
- Shade reproducibility is poor with fluctuating temperatures, both of the pad bath as well as in the batch storage.
- In the case of large fabric batches, the inner layers of a batch have far greater temperature stability than the outer layers and this also leads to unlevel results.
- Other faults such as white edges, tailing, centre to edge variations are common and lead to considerable process loses.
- Where larger amounts of material are put through the works, handling the cloth batches is awkward, time-consuming and labour-intensive: cutting off, transporting, developing, transporting, sewing on, washing etc.

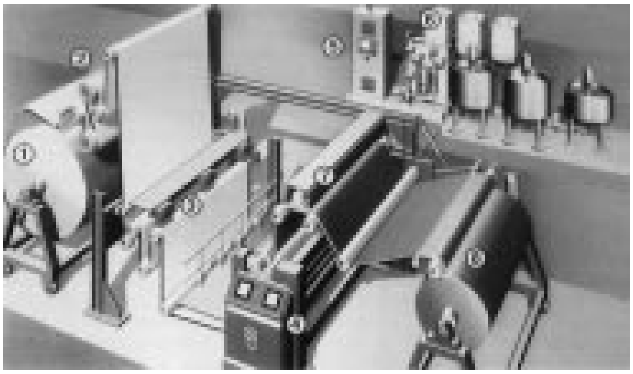

Fig. 6: With the cold pad-batch dyeing centre small lots can be economically dyed, too.
1 = low-tension batch unwinder; 2 = cooling zone;
3 = moisture measurement; 4 = "flexhaft" padder;
5 = central PC control; 6 = "Contidos SF" with colour preparation station; 7 = colour depth measurement;
8 = low-tension batcher.

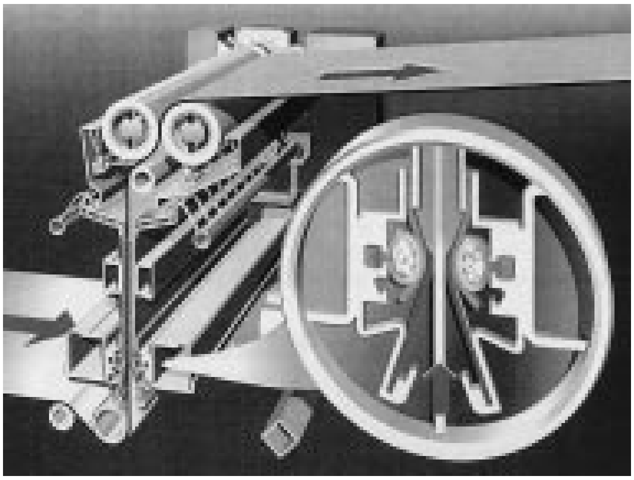

Fig. 5: Dye padder with "flexshaft" liquor application.

More modern versions of cold pad-batch dyeing are developed by Küsters (Figs. 5 and 6).

Cold peroxide bleaching The process is subdivided into application of the bleaching liquor, reaction phase, and extraction phase. Besides the term cold peroxide bleaching, in practice the expression extraction bleaching is also frequently used. This designation is used in the case of recipes free of sodium silicate, and with a high alkali content. The term is misleading, since during the bleaching process, in which 1000–5000 metres of impregnated fabric is wound up on a roller, extraction definitely does not take place, but only in the subsequent washing process.

Constituents of a cold peroxide bleach recipe, e.g.:

a) Essential ingredients:
  - magnesium ions ($MgSO_4 \cdot 7H_2O$),
  - activator (NaOH),
  - pH buffer system (sodium silicate),
  - stabiliser,
  - oxidant (H_2O_2);

b) useful supplements:
  - surfactants,
  - auxiliaries with an affinity for dyes (only for colour-woven goods),
  - persulphates (to improve de-sizing),
  - optical brightening agents (for full white effects).

Advantages: due to the low temperature of 20–40°C, the natural waxes of the cotton are not removed, or only to a small extent. For many articles, especially in the case of towelling qualities and knit goods, this yields an excellent soft handle, which allows a reduction in applied softeners. Emulsification of fats within the framework of cold bleaching is in principle only possible if the fats are present in liquid form on the goods. If they are paraffin waxes that are solid at the stated temperatures, de-greasing does not take place until the washing process, with the effect achieved being dependent to a high degree on the duration and the concentration of the chemicals. The large amounts of electrolyte which are necessary in the cold bleach recipes (caustic soda, sodium silicate and persulphate) prevent emulsion formation so strongly that large amounts of surfactant are necessary in order to achieve satisfactory de-greasing results. The risk of catalytic damage, which is ever present with peroxide bleaching processes, can be reduced to a minimum by adjusting the recipe accordingly. Compared with all other processes, significantly lower investment is required for cold peroxide bleaching processes.

Disadvantages: insufficient degrees of whiteness, even when large amounts of peroxide are used; poor absorbency; insufficient removal of sizes; poor shade r, especially in the case of commission finishers with varying raw material; high space requirement; silicate deposits on the machines when silicate is used.

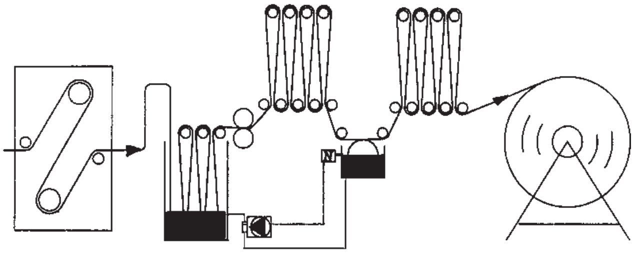

Fig.: Schematic illustration of an impregnation unit for grey cloth, consisting of a singeing machine, a small roller vat with 4–6 metres draft and low liquor content, 2 passages air run for wetting the goods and – located in between – a slop-pad mechanism to increase the liquor uptake (N = level regulator).

It is understandable that a very gentle bleaching process (see Fig.) with a maximum of operational safety in respect of the avoidance of catalytic damage cannot achieve a maximum degree of whiteness, since all the reserves which a bleaching process with hydrogen peroxide can offer are deliberately not exhausted. The majority of cold peroxide bleaching liquors are applied immediately after the singeing machine, wet-on-dry, on a multi-dip range holding 20–30 metres of fabric. Such impregnation systems often hold 1500–2000 litres, which results in an uncontrolled accumulation of sizing agent, alkaline earth- and heavy metal ions taking place in the impregnation liquors. The time taken to come to an equilibrium is determined by the production rate in kg per hour and the volume of the impregnation bath, and can be as much as several hours. The accumulation of size has various effects on the bleaching process. First of all, the viscosity of the bleaching liquor is raised so that the liquor cannot fully penetrate the fibre. The consequence of that is a low liquor pick-up of only 50–65%. Since in the case of wet-on-dry processes, a great deal of air is imported into the treatment baths, the liquors begin to foam (even when low-foaming surfactants are used), which leads to loss of liquor through overflow, and thus to a further reduction in the chemical application.

In the impregnating compartments, the accumulation of alkaline earths leads – depending on the cotton quality – to values of 25–110°d. In the reaction phase, the cold bleaching fabric beams are wrapped in plastic sheets in order to avoid surface evaporation. Single shift production at 40 metres per minute and 4000 metres per fabric beam, then one work will use at least 16 000 metres of plastic sheet per year, all of which ends up as waste. If on the other hand the fabric beams are stored in a specially prepared area with a low ceiling height and humidity control, then a direct saving can be made.

For storage the fabric beams must stand absolutely horizontal, so that the liquor is unevenly distributed and edge/middle/edge differences do not arise. Each fabric beam should be kept in rotation by its own drive. In many works 4 or more fabric rolls are placed so close together that they keep one another moving. The friction and rubbing that occurs in the transmission of the mechanical energy leads to loss of liquor in the outer layers, and thus to differences in the degree of whiteness between the beginning and end of batches.

Cold-stirred soap Soap which is produced by saponifying molten fats (mainly coconut or palm oil) by mixing with cold concentrated caustic potash lye. The heat released by the exothermic lye solution is used for completing saponification.

Cold system optical brightener Optical brightener with an optimum white effect at scouring temperatures up to 60°C. → Hot system optical brightener.

Cold unit Dry cleaning machine so called in the USA (so called WD type = washer-dryer) with a centrifuging operation but with no hot air drying (therefore “cold machine”). Fabric is merely cleaned and centrifuged. Drying is effected separately, mostly in a recovery tumbler which can also be directly incorporated. This processing method is widespread in the USA because cleaning capacity can be utilised most economically with it.

Collagen The union of a number of amino acids leads via peptide bonding to polypeptides like collagen for example.

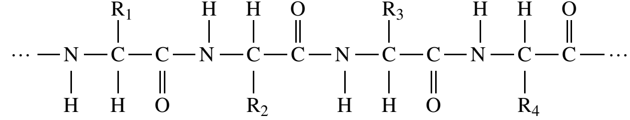
Collagen is mainly a supportive and protective element in the skin of a living animal. Chemically, it is classed as a protein, i.e. it should be regarded as a conglomerated polymer of amino acids with a colloidal

Collagen

Peptide bond:

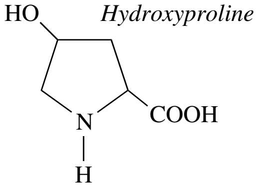
—NH—CO—

Polypeptide:



$$\cdots-NH-CHR_1-CO-NH-CHR_2-CO-NH-CHR_3-CO-NH-CHR_4-CO-\cdots$$

nature. Of the 19 different amino acids of collagen, 3-hydroxyproline is typical of this.



Amino acid composition of an untreated collagen (mol per 100 mol of amino acids) according to K. Kühn:

aspartic acid	4.65
isoleucine	1.41
glutamic acid	7.68
leucine	2.66
glycine	33.10
phenylalanine	1.26
alanine	10.56
proline	13.18
serine	3.18
hydroxyproline	8.96
threonine	1.79
histidine	0.58
tyrosine	0.39
lysine	2.84
valine	2.08
hydroxylysine	0.60
methionine	0.31
arginine	4.82

The most repeating amino acids glycine, proline and hydroxyproline represent a sequence within the polypeptide. Formation of the polypeptide chain by principal valency bonds characterises the primary structure. Some 1000 amino acids are combined in the form of an α-helix in the collagen peptide chain (Fig. 1)(sec. structure).

The α-helix structure is additionally characterised by 3.6 amino acid radicals per turn, 0.54 nm lead, 1.05 nm total diameter and stabilisation by hydrogen bonds between the O and N atoms of the peptide bonds. The tertiary structure represents the stabilisation of the spatially compact arrangement due to interactions between the side chains of the amino acid radicals (Fig. 2).

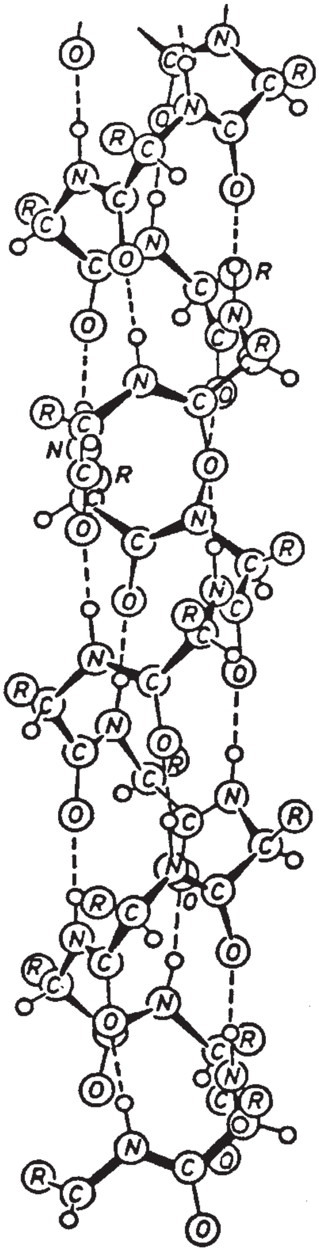


Fig. 1: Secondary structure (a-helix) according to Pauling.

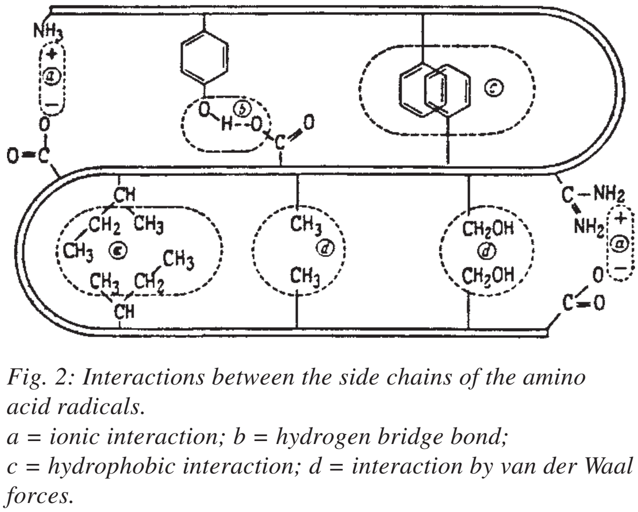

Fig. 2: Interactions between the side chains of the amino acid radicals.
a = ionic interaction; b = hydrogen bridge bond;
c = hydrophobic interaction; d = interaction by van der Waal forces.

A quaternary structure is present in collagen, consisting in fact of three polypeptide chains twisted around each other, which are called superhelix or tropocollagens (Fig. 3).

Fig. 3: Three-chain helix according to K. Kühn.

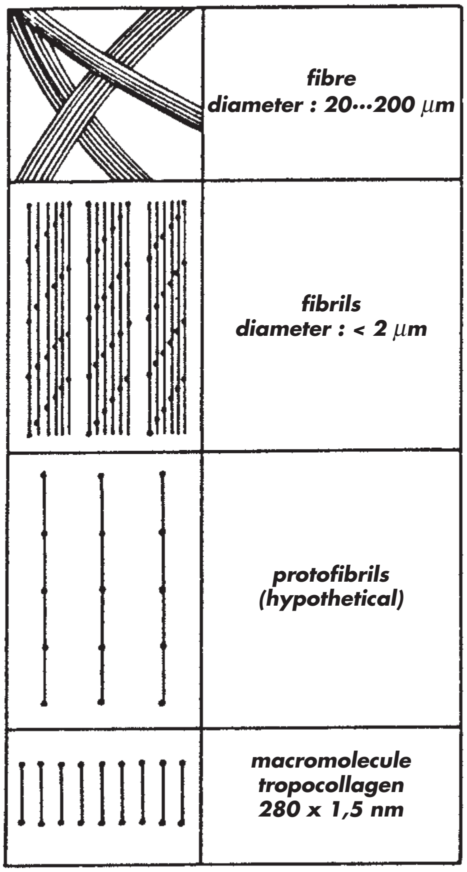

Fig. 4: Schematic diagram of collagen fibre structural elements.

With the formation of intermolecular bonds, tropocollagen molecules are arranged together as fibrils. Protofibrils are presupposed at first as an intermediate stage. The fibrils then come together as fibres and fibre bundles, out of which comes the insoluble, three-dimensional collagen fibre structure (Fig. 4).

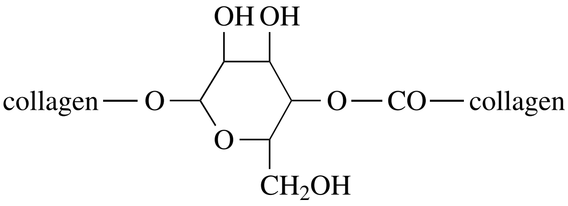

Fig. 5: Hexoses as collagen bridge links.

Classed among the intermolecular bonds is also the covalent bond, which occurs with continuous carboxyl and amino-group side chains. Hexoses also serve as bridge links, being bonded glucosidically to the hydroxyl groups of the collagen, and, like esters, to the carboxyl groups (Fig. 5).

The chemical/physical behaviour of collagen is important in leather production in its reaction with water, acids and alkalis, and against temperature and enzymes. Collagen is able to hold water (in the form of capillary water and as hydration water). The capillary water is stored in the fibre interstices, the hydration water on the collagen functional groups, particularly the carboxyl, amino and hydroxyl groups, and also on peptide groups which are not present in hydrogen bonding. As a consequence of tautomerism and mesomerism (Fig. 6), peptide groups are present as dipoles, and can hold water in this form.

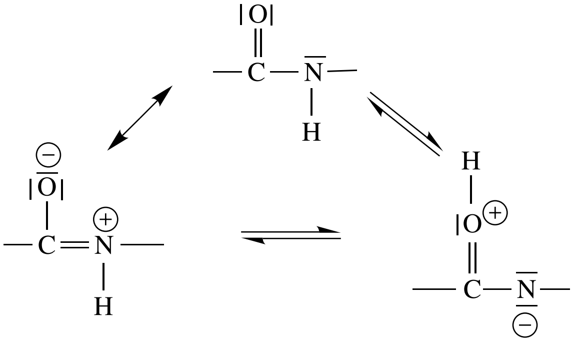

Fig. 6: State of equilibrium of the peptide group.

Collagen behaves as an ampholyte in reaction with acids and alkalis. There is equilibrium between the polar and unpolar form in the neutral zone.

$$\mathrm{H_2N{—}collagen{—}COOH} \rightleftharpoons {}^{+}\mathrm{H_3N{—}collagen{—}COO^{-}}$$

ACID REACTION:

$${}^{+}\mathrm{H_3N{—}collagen{—}COO^{-}} + \mathrm{H^{+}} \longrightarrow {}^{+}\mathrm{H_3N{—}collagen{—}COOH}$$

ALKALI REACTION:

$${}^{+}\mathrm{H_3N{—}collagen{—}COO^{-}} + \mathrm{OH^{-}} \longrightarrow {}^{+}\mathrm{H_2N{—}collagen{—}COO^{-}} + \mathrm{H_2O}$$

The same polarities in collagen mutually repel each other; the structure slackens in consequence of polar bond splitting, swelling following with the entry of water. The isoelectric point lies at pH 7.0–7.8. High temperature effects can denature collagen, intermolecular cross-linking, hydrogen bridges and hydrophobic bonds in particular being broken, and the crystalline helix structural arrangement being lost. Such processes characterise the shrinking temperature, which is 62–65°C with natural collagen. There is reverse propor-

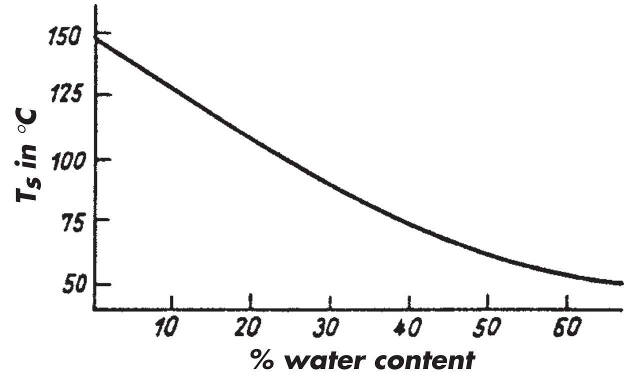

Fig. 7: Relationship between collagen shrinking temperature T_s and water content according to Witnauer.

tionality between shrinking temperature and water content (Fig. 7).

Enzyme action in collagen primarily causes attendant substances to decompose, and, secondarily, splits off amino acids into telopeptides. Splitting of the polypeptide chain into peptides by proteases like trypsin, pepsin and papain is not possible. Only the enzyme collagenase has a splitting effect, splitting resulting, via peptide bridge splitting, in small-chain peptides. The optimum effect here is at pH 6–8. The action of enzymes is put to good use in leather tanning. The collagen fibrils appear in calcined leather (Fig. 8).

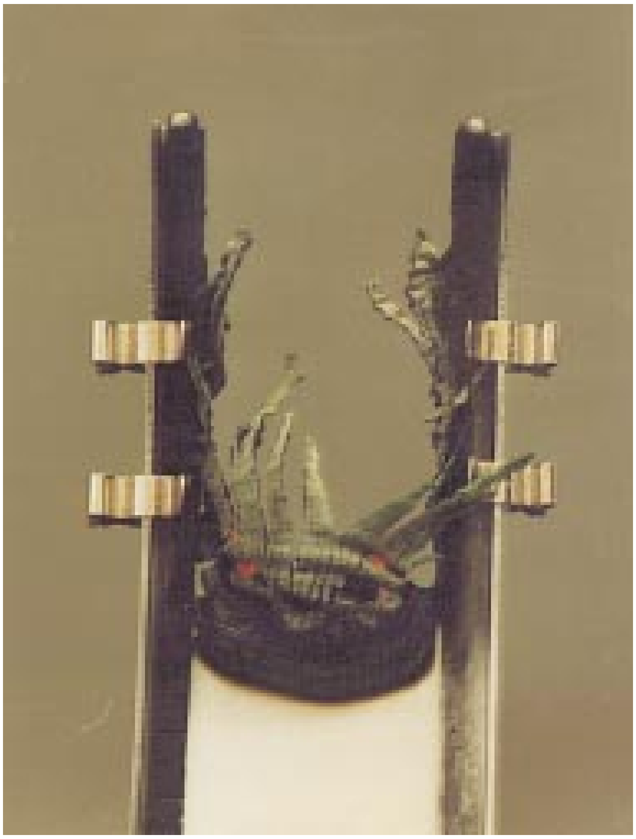

Fig. 8: Carbonised fibrils in calcined leather.

Collective sample A collection of individual samples.

Collodion Viscous solution of collodion cotton in 1 part alcohol and 2 parts ether. Use: sealing and coating agent (bottles, signs etc), adhesives, paint manufacture (cellulose lacquer), thickeners and setting agents for metal powder, pigments, lacquer printing.

Collodion cotton (cellulose dinitrate, colloxane, tyroxylin). A nitric acid ester of cellulose; cotton nitrated in a nitric acid/sulphuric acid mixture, where 2 of the 3 glucopyranose OH groups are replaced by NO_3 groups, equivalent to 10–11% nitrogen content. Therefore easily flammable (dry = explosive; moistened with alcohol/ether = steadily combustible). Similar to cotton in fibre form. Density 1.42. Otherwise largely analogous to → Nitrocellulose, but, in contrast to that, soluble in an alcohol/ether mixture (→ Collodion) and also in amyl alcohol, amyl acetate, acetone, glacial acetic acid etc. Basis of the production of the first → Man-made fibres. Use: collodion production, celluloid, adhesives, paints (cellulose lacquer); fixating thickener for pigment and lacquer printing, body colour for leather dyeing etc.

Colloid (Gk. kolla = glue), in contrast to → Crystalloid a non-crystallising substance like protein, gelatine, rubber, glue, starch and cellulose for example. Colloids are not therefore substance classes, but a concept for the dispersion conditions of the substance (→ Dispersivity).

I. Classification:

a) Dispersion colloids, produced by comminuting coarser substances into particles of a colloidal order of size, character hydrophobic (e.g. paraffin, phenolic resins); with → Protective colloids produce a colloidal “solution”, e.g. paraffin emulsions.
b) Molecular colloids, individual molecules of colloid dimensions, either “low molecular” (up to approx. 1000 atoms) or “macromolecular” (over 1000 atoms). Inorganic macromolecules: e.g. colloidal silicic acid; organic, e.g. protein (glycogen), rubber, polyvinyl products, silk, wool, cellulose (derivatives) etc. All molecular colloids are, in contrast to a), hydrophilic, and are therefore subject to swelling in water, producing, as required, concentrated → Colloidal solutions (by solvation or hydration).

II. Classification according to formation into:

a) spherocolloids: e.g. starch, protein, aminoplasts or phenoplasts in water;
b) linear colloids, like solutions of rubber, polyacrylonitrile and polyvinyl products, cellulose (derivatives) etc. Further classification according to the number of chain links into: hemicolloids (50–500 chain links, low viscosity linear molecules), mesocolloids (500–2000 chain links in the linear molecule) and eucolloids (over 2000 chain links, high viscosity, capable of swelling).

c) micelle colloids: hydrophilic individual molecules which combine in the solvent into variously large groups (micelles) of colloid particle dimensions, e.g. soaps or dyes in water, an electrical charge function (→ Colloid electrolytes).

III. All colloids appear in two different forms, the → Sol (= solution) or the → Gel (= flocculation, coagulation, concretion). Transitional form → Peptisation. Jelly (gelatine or glue swollen in water) is a lyophilic (hydrophilic) colloid gel.

Colloidal electrolyte → Colloid (more precisely: colloid-like substances between colloids and electrolytes), the particles of which contain electrical charges in aqueous solution or dispersion, i.e. form anions or cations. Numerous textile auxiliary agents for example are ionogenic, and, within the meaning of the word, so are textile fibres (cellulose fibres as anions; protein fibres: below pH 5 as cations, over pH 5 as anions).

Colloidal solution (colloid solution, sol). Suspension colloid, i.e. a finely dispersed solution. A considerably refined form of dispersion in terms of degree of dispersivity. This includes almost all dye solutions (though not disperse dyes), starch solution, glue solution, soap and detergent solution, synthetic resin solution etc. All these “solution forms” are also described by the generic term → Sol, and describe the uniformly fine distribution of a colloid in water = hydrosol, in alcohol = alkosol, in organic solvent = organosol, in air = aerosol (smoke, mist).

Colloid mill Term for a fine-milling dyestuff mill.

Colloresine process The original two-phase printing process for vat dyes. The principle is based on printing vat dyes from a thickener (originally Colloresine thickener DK) which undergoes coagulation on subsequent application of alkali and heat (steam). After printing and drying, the goods are padded with an alkaline solution (sodium carbonate or caustic soda) of a reducing agent such as Rongalite C (sodium formaldehyde sulphoxylate) after which they are steamed, with or without intermediate drying, in a conventional steamer for 3–8 minutes. Due to the high degree of coagulation of the thickener, no marking-off or smearing of the printed colours occurs in the steamer even though the fabric is in contact with the guide rollers on both sides. This process has now been almost completely replaced by the more economical → Flash ageing.

Colophonic acids → Resin acids.

Colophony (Burgundy pitch). Natural resin product. Distillation residue of pine resin or turpentine oil manufacture. 80–90% comprised of → Abietic acid. Density 1.045–1.10, saponification number 165–198. Unsaponifiable 4–14%. Pieces, brittle and with a glassy lustre, or powder, light yellow to almost black. Weakly acid. Softens at 70°C, semi-liquid (not clear) in boiling water, liquid at 120–135°C. Easily soluble in alcohol, benzine, acetone, chloroform, carbon tetrachloride etc. Saponifiable to resinates (soaps of resin) with hot alkalis. Most important use for resinates; emulsified (possibly partially saponified) as a stiffening agent; also modified (with synthetic resins etc.) for slip-proof finishing, for coarser water repellency etc.; as a resist for batik printing and in silk printing (resin resist printing); putty; for drying agents and paints. Also as a basic material for synthetic resins of the alkyd resin type for paints.

Colophony soap → Resin soaps.

Colorado Continuous overflow machine for the treatment of fabrics in rope form with up to 12 trough-shaped liquor compartments. The fabric rope is piled into the first compartment via a swimming tube from where it passes in spiral form through all compartments. The dwell time in each compartment can be controlled by selection of the rope capacity and accelerated or delayed fabric passage. Besides its use for prewashing and afterwashing treatments, combination bleaching processes are also possible with the addition of a small J-box unit. Manuf.: Brückner.

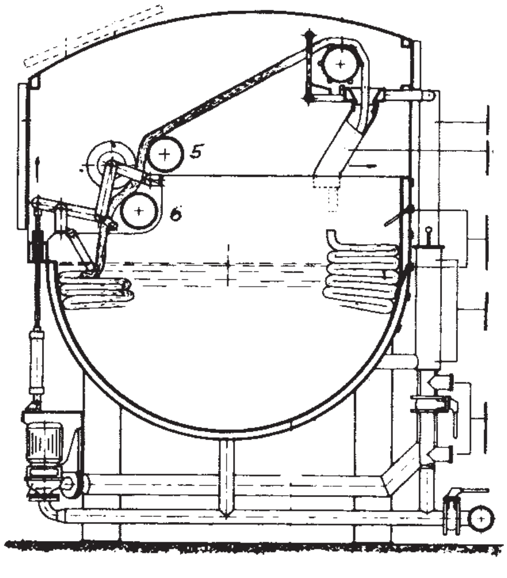

Fig.: Colorado rope washing machine (Brückner).

Colorant Standard term for chromophoric materials. This includes dyestuffs, colour lakes, pigments etc.

Colorant binders These are used in pigment printing and pigment dyeing to fix wash durable pigment dyestuffs on the textile.

Colorant channel Corresponds to the height of the space between the warp and weft yarns of a flat screen, or the depth of the perforations a rotary screen.

Coloration This is the bond between fibre and dyestuff. It comes about e.g.:

1. By heteropolar ionic bonds (salt compound) between basic fibre groups (wool, silk) and acid dye-

stuff groups (acid dyestuff, metal complex dyestuff) or vice versa between acid fibre groups (wool, silk, and acrylic and polyester containing sulpho groups) and basic dyestuff groups (cationic dyestuffs).

2. Covalently by ester or ether bonds between OH cellulose and reactive dyestuff groups or by amide bonds between NH_2 groups and wool and reactive dyestuff groups (reactive dyestuffs).
3. By developing dyestuffs which have low solubility or are insoluble, e.g. by forming dyestuffs of low solubility from soluble preliminary products (naphthol dyestuffs, phthalogen dyestuff) or by forming a low solubility colour lake from dyestuffs with groups having an affinity for mordants and metal salt mordants or by converting dyestuffs supplied from a soluble into an insoluble form (vat dyestuff, sulphur dyestuff).
4. Using van der Waals force (e.g. disperse dyestuff in polyester fibres; these forces are stronger in polyester than in polyamide fibres due to the benzene rings present in the fibre). They also play a part in dyeing cellulose with direct dyestuff or with the leuco form of vat dyestuffs.
5. Purely mechanically by “sticking” the dyestuff on the fibre using a binding agent (synthetic resins) (pigment dyestuff). → Dyeing theory.

A distinction is made between discontinuous (→ Exhaust dyeing process) or continuous processes (→ Pad process) depending on the mode of operation. Dyeings between these methods are found in the print works. Dyeings are carried out in the manufacture of man-made fibres by dope-dyeing and spin dyeing. Dyeings carried out on manufactured articles are called “fully fashioned” dyeings (Garment dyeing).

Colorex Control device for the photometric measurement of concentration changes in dye liquors. Consists of a measuring component in the form of a photometer and a component for measuring the speed at which dye is absorbed. As well as the main rate of absorption control component the Colorex system also contains a conventional, preselectable temperature program with appropriate control accuracy. In the preheating phase a preselected temperature can be reached at a maximum heating rate and controlled using an adjustable heating time. The preselectable dye absorption phase can take place using the above-described absorption control or, if this cannot be used, using a temperature program with two adjustable heating speeds (minimum heating speed 0.2°C/min. with a max. control deviation of ± 5%) and a variable temperature. The dye temperature that is selected is controlled to a fixed value during the preselected holding time and then switched to the cooling phase, which cools the dye to a fixed final temperature value at a variable cooling speed.

The preselected program runs automatically. This kind of design means that as well as performing absorption control the Colorex device can also replace an existing temperature controller or be integrated into existing general control systems. This device has not established itself in the dyeing industry - Manuf.: Sedo.

Colorimter →: Spectrophotometer; Colorimetry.

Colorimetric measures Colorimetric measures are the measures resulting from colour measurement for → Colour stimulus specification. To clearly identify these it is necessary to supply three independent figures which can be structured differently depending on the set-up of measuring instruments and which accordingly either give exact colorimetric measures or measures which deviate slightly, adjusted to the eye (→ Colour vision) in order to imitate the colour stimulus specification to be measured using additive colour mixtures.

I. Trichromatic colorimetric measures: in accordance with the international agreement (1931) three so-called standard colorimetric values (for hue, lightness, saturation) are used which are designated as X, Y and Z and also referred to as CIE tristimulus values. In line with the spectral response characteristic of the eye, the green fraction Y (luminance-brightness value) is used here to determine lightness. For surface colour, Y equals 100 for pure white with any form of lighting, and X and/or Z are correspondingly reduced. The mixtures of the CIE tristimulus values required X, Y, Z are referred to using the chromaticity coordinates x, y, z whose sum is x + y + z = 1, so that it is sufficient to determine x and y as z can be deduced from this. It follows for measured radiation = trichromatic sum X + Y + Z,

$$\textbf{for } x = (X\text{: } S \textbf{ or } x =) \frac{X}{X+Y+Z}$$

$$\textbf{for } y = (Y\text{: } S \textbf{ or } y =) \frac{Y}{X+Y+Z}$$

$$\textbf{for } z = (Z\text{: } S \textbf{ or } z =) \frac{Z}{X+Y+Z}$$

The graphical representation of the chromaticity coordinates takes place by entering the so-called colour points in the → Chromaticity diagram. The trichromatic system is exact, admittedly, but has the disadvantage of being difficult to understand for those who are not familiar with it, as the appearance of the colour does not give any real impression.

II. Helmholtz colorimetric measures are based on identification of the dominant wavelength, the luminance (lightness) and the spectral colour density (saturation) in accordance with DIN sheet 5033.

III. Luther colorimetric measures take into consideration the lightness Y and the two so-called colour moments M1 as Y–X and M2 as Y–Z. From these index numbers, which clearly represent red-green or blue-yellow, the geometric sum M

$$\sqrt{M\,{}^{1}/_{2} + M\,{}^{1}/_{2}}$$

The so-called brightness moment is formed as a measure of colour. The subsequent colorimetric measures are regarded as less exact as they are always dependent on the spectral colour stimulus condition and will tend to give more or less varied colour values for similar colours.

IV. Ostwald colorimetric measures: The shade N_{24} (chromatic circle) is expressed here together with white w and black content s, with the fraction v of the pure spectral colour resulting from $w + s + v = 1$. The measures obtained can be calculated using tristimulus values X, Y, Z and trichromatic coefficients x, y and compared with values obtained using other measuring systems. Thus e.g. yellow $N_{24} = 2.8$, $w = 0.348$, $s = 0.352$ would correspond to the following values (in brackets for comparison with spectrophotometric method): X = 57.4 (54.1), Y = 54.7 (52.2), Z = 41.1 (44.2), x = 0.373 (0.360), y = 0.357 (0.347).

V. Agahd colorimetric measures are based on measures with three colour filters which consist of second level complementary colours as described in the chromatic circle, i.e. Ostwald colour 1 = yellow 1, Ostwald colour 9 = red 3 and Ostwald colour 17 = blue 2. Accordingly, each colour consists of a max. 4 fractions a) % yellow, b) % red, c) % blue, d) % white and 100 - (a + b + c + d) energy-free % black. Reference is always made to overlaps of colour (rather than to fractions in white). Colours result from a + b or b + c or a + c = 0; mixed intermediate colours, as long as a or b or c = 0.

VI. Hunter's colorimetric measures: Conversion of CIE tristimulus values X, Y, Z into valuation constants L, a, b; form the basis of the current CIELAB formula.

VII. Colorimetric measures in colour atlases, similar to the Ostwald colour atlas (IV), → DIN colour chart, Munsell system etc.

Conversions of I–IV take place in accordance with standard DIN 5033 and can be represented either as chromaticity coordinates or graphically in chromaticity diagrams for comparison. →: Colour measurement; Colorimetry.

Colorimetric system (Colour system). This is a colorimetric ordering system to define each colour precisely, e.g. with reference to the three colour qualities of hue, saturation and lightness.

Colorimetry This is the science of dimensional relations between the colours. For this, it is necessary to describe and measure the colours clearly by means of dimension figures (→ Colorimetric measures). However, colour is not a physical property of a body, but is a sensory perception transmitted by the eye. Colour perception cannot be measured directly; it is only possible to measure the light emitted from a source that is reflected from a body and falls on the human eye. This can be physically recorded. By testing the colour vision of a fairly large number of people at the same time, the results can be related to the physical measuring results. In colorimetry, therefore, the sensory impression of colour is recorded objectively by the radiation of a body. Using the colorimetric measures obtained in this way, the world of colour can be portrayed systematically. This forms the basis for the assessment of colour differences, colorimetric formulation calculations and also has an impact on the area of art.

Colour perception takes place via radiation that, starting from a light source is reflected from a body and falls on the receptors of the human eye. This radiation is known as colour stimulus. The spectral distribution of the light source therefore has a significant influence on colour perception. For colorimetry, only the relative energy distribution is of interest, i.e. the relative radiation ratio within the entire visible spectrum. Some illuminants with their relative energy distribution have been standardised. An important example is the standard illuminant D_{65} with an energy distribution corresponding to that of average daylight.

A reflectance curve can be produced from each object. It is also possible to determine the ratio of the light reflected from the body to the light reflected from an absolute white surface depending on the wavelength. The colour stimulus is therefore determined by the spectral distribution (S_{λ}) of the source of light and the reflectance of the body (R_{λ}). The observation of the colour stimulus across the entire spectrum of visible light is described as colour stimulus function. The colour stimulus reaching the eye is transferred into nerve signals. It is thus assumed as a model that there are three reference stimuli with different spectral sensitivity on the retina, determined by three types of cone. Colour perception via the three types of cone is referred to as "trichromatic vision". If the sensitivity of the reference stimuli is viewed across the entire visible spectrum, spectral perception functions are obtained. They are expressed as CIE spectral distribution curves $\bar{x}$, $\bar{y}$, $\bar{z}$. The CIE spectral value $\bar{z}$ is particularly sensitive to blue light, $\bar{y}$ for green light and $\bar{x}$ is predominantly red-sensitive with a slight maximum in the blue range. In colour perception, they form a homogeneous effect, colour stimulus specification. The colour stimulus specification can therefore be described unambiguously using three measures. The assessment of a colour results from the portion of colour stimulus that is transmitted by the individual cones. For each type of cone, it is determined from the following, in relation to the spectrum of visible light:

$$X = \int_{400}^{700} S(\lambda) \cdot R(\lambda) \cdot \bar{x}(\lambda)$$

$$Y = \int_{400}^{700} S(\lambda) \cdot R(\lambda) \cdot \bar{y}(\lambda)$$

$$Z = \int_{400}^{700} S(\lambda) \cdot R(\lambda) \cdot \bar{z}(\lambda)$$

The quantities X, Y and Z are termed as CIE tristimulus values. They are dependent on the observer's field of vision as well as on the illuminant and reflectance of the sample. The observer's field of vision influences the CIE spectral distribution curves, as the distribution of the types of cones on the retina is altered by the presence of rods when the visual angle is above 2°. Two fields of vision have therefore been standardised by the CIE (Commission Internationale l'Éclairage):

a) 2° field of vision: the visual angle of the observer is limited to ≤ 4°. The light therefore falls only on the fovea of the retina, which only contains cones. The observer with a 2° field of vision is described as "2° Standard Observer".
b) 10° field of vision: to conform with practice, an observer with a visual angle of > 4° was introduced in 1964. Due to the different CIE spectral distribution curves, different CIE tristimulus values are obtained than those of the 2° Observer. CIE spectral distribution curves and CIE tristimulus values are identified with the "10" Index. It is not possible to convert between the CIE tristimulus values from each type of observer.

Representation of the colours in a colour space: the standard tristimulus values X, Y and Z are not very precise. To portray the colours in a more comprehensible manner, the CIE chromaticity co-ordinates x, y, z are calculated. They give the size of the fraction of each CIE tristimulus value with the total of all three values. Hue and saturation can be found using the CIE chromaticity co-ordinates x and y, which are summarised in the term "chromaticity". As 1 = x + y + z, the CIE chromaticity co-ordinate z is not required to identify a colour, as it can be calculated using the other two. As the third quantity to represent a colour stimulus specification, lightness is expressed using the CIE tristimulus value Y. This can be compared with the CIE chromaticity co-ordinate z for the 2° observer. Lightness is plotted perpendicular to the colour plane. If the CIE chromaticity co-ordinates x and y of pure spectral colours of the visible spectral range are input into a diagram, with x as the abscissa and y as the ordinate, a continuous arched, non-closed curve is obtained, the spectrum locus (→ Chromaticity diagram; Fig. 1). The straight connecting line between the two ends forms the purple boundary with the secondary colours of the spectrum.

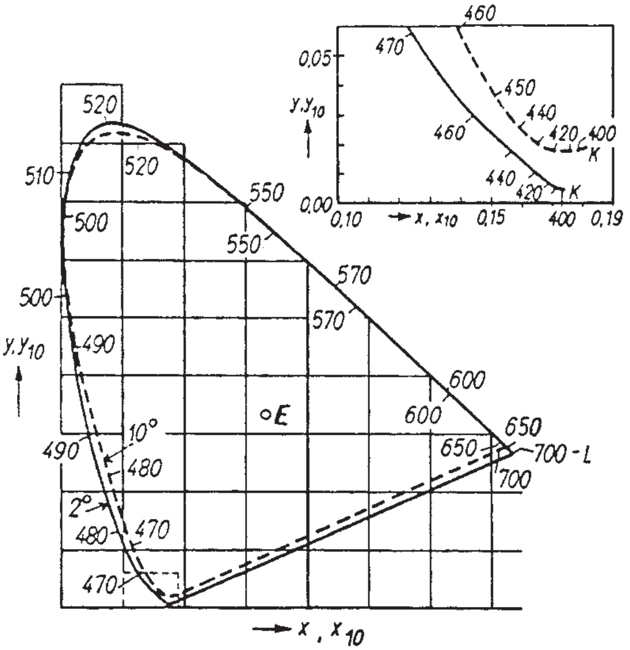

Fig. 1: CIE chromaticity diagram for the 2° system (extended line) and for the 10° system (broken line).

The achromatic point, which indicates the chromaticity of white, grey and black colours, is located in the centre. Colours of the same hue, but different saturation, which increase with the distance from the achromatic point, lie on the straight line between the achromatic point and spectrum locus. This chromaticity diagram has been standardised by the CIE and is also included in the DIN standard. It is known as the CIE tristimulus diagram or chromaticity diagram. According to DIN, hue is understood to mean "the property which distinguishes a chromatic colour from an achromatic colour. In colour stimulus specification measurements, it is generally described by the dominant wavelength λ_f. As described above, this gives the wavelength of the corresponding spectral colour that lies on the projected line between the colour location and the achromatic point. DIN states that saturation is "the degree of brightness of a colour in comparison to a grey of the same lightness". In colour stimulus specification measurements, it is given as the spectral component of colour Pe, which gives the proportion of spectral colour in the mix with neutral.

Definition of CIE tristimulus values: These can be determined using three different methods stipulated in DIN 5033 sheets 4–6. With the spectrophotometric method, it is determined using spectrophotometric measurement to give the colour stimulus function. As the spectral energy distributions S (λ) are known for standard illuminants, only the spectral reflection is measured. Next, assessment using valency measurements is carried out incorporating the CIE spectral distribution curves. This is determined using a spectrophotometer. Other methods include visual colour matching, in which colour measurement is based on comparison of a colour with unknown colour stimulus specification with colours where this is known, and the triple zone method, in which the CIE tristimulus values are measured directly. Due to lack of accuracy, they are less important in practice. In all three cases, the result of a colour measurement depends to a large extent on the measuring geometry used. Measuring geometry is understood to mean "the path of a ray from the illuminated source of light to the plane on which it falls." The direction of incidence of the light onto the sample and the direction from which the sample is being observed are important here.

In order to obtain comparable results, three measuring geometries are standardised:

a) With the 45/0 measuring geometry, directed light falls on the sample at an angle of incidence of 45°. Observation is carried out at an angle of 0°. This measuring geometry is mainly used for bright samples, as the luminosity can be eliminated.
b) With the d/8 or d/0 measuring geometry, the sample is placed in an integrating sphere. With diffuse, semi-reflected light incident on the sample, observation is carried out at an angle of 8° or 0°.
c) With the 0/d measuring geometry, the sample is illuminated vertically. The light diffusely reflected is collected in the integrating sphere and measured.

When measuring textiles, the integrating sphere is generally used, as the measuring value is independent from the direction of the textile structure to a large extent.

Colorimetric measures: according to DIN 5033 sheet 3, colorimetric measures serve "to uniquely identify a colour stimulus specification. For this, three independent figures are always required and are sufficient. If it is only necessary to identify the chromaticity, then two of the measures independent of the brightness are sufficient". The DIN standard recommends the "Trichromatic colorimetric values in accordance with the CIE standard colorimetric system". The CIE-UCS chromaticity diagram was developed in 1960 to increase conformity between the geometric distances and the visually perceived colour differences. It represents a transformation of the CIE standard colorimetric system. The co-ordinates u' and v' are determined using the co-ordinates x, y from the chromaticity diagram. This distorts the chromaticity diagram to such an extent that the green area of the diagram is shrunk and the red area is stretched. The discrepancy between the geometric difference and the perceived difference was not eliminated as a result of this, but it was possible to reduce the incongruity from 1 : 20 in the chromaticity diagram to 1 : 2. In the CIE system, colours are identified using the CIE tristimulus values X, Y and Z. When comparing two colours, the CIE system only gives information concerning the uniformity of the colours. Statements concerning the differences or distances between the colours cannot be made, as the geometric distances in the colour space do not correspond to visually perceived differences. Numerous colour difference formulae have been developed to date in order to identify differences in colours with a good correlation to the visual assessment. A distinction is made here between two starting points:

- Based on the CIE tristimulus values, a colour difference value ΔE is defined using empirical constants;
- The colour difference ΔE is determined on the basis of an equidistant colour system.

Having critically compared the formulae developed to date, M. Richter comes to the following conclusion:

- The calculated results of the various formulae are not proportional to one another. It is not possible to convert between the formulae. It is therefore necessary to quote the formula used in addition to the colour difference.
- For each formula there are areas with good correlation to the visual assessment and others with poor correlation.
- The choice of formula is secondary in in-house assessment of colour difference. The formula used should however always be the same.

Just as there is no uniform formula to calculate colour difference, the units differ for each formula. In a large number of formulae, they are adjusted to the NBS unit, however. The name of the unit comes from the NBS (National Bureau of Standard, Washington) colour difference formula. A second common unit is the MacAdam unit (MAE). On average, this is approximately half of the NBS unit. This is used to calculate colour differences using the Simon-Goodwin method and using the Friele-MacAdam-Chickering formula.

Here is a description of three of the many colour difference formulae that have been published:

1. In Hunter's colour difference formula, the valuation constants L, a, b for the colours to be compared are calculated from the CIE tristimulus values X, Y, Z using the following formulae:

$$\begin{aligned} a_L &= 17{,}5\,(1{,}02\,X - Y)/\sqrt{Y} \\ b_L &= 7{,}0\,(Y - 0{,}847\,Z)/\sqrt{Y} \\ L &= 10 \cdot \sqrt{Y} \end{aligned}$$

The colour difference ΔE_H is calculated from the differences between the two colours:

$$\Delta E_H = \sqrt{(\Delta a)^2 + (\Delta b)^2 + (\Delta L)^2}$$

2. The CIELAB formula is used to assess small colour differences and is recommended for use by DIN 6174. The colour difference is determined using a colour difference formula from the colorimetric measures L^*, a^*, b^* which result from the CIE tristimulus values X, Y, Z.

With this method, the correlation between the calculated distances and the perceived distances is very high. The determination of the colorimetric measures L^*, a^*, b^* is shown in Fig. 2. The CIE tristimulus values X_0, Y_0, Z_0 refer to the totally matt white surface with appropriate illuminant and standard observer. The L^*-value indicates the position on the light/dark axis in the L^*, a^*, b^* system, the a^*-value gives the position on the red/green axis and the b^*-value the position on the yellow/blue axis.

According to DIN 6174, the ΔE^*_{ab} colour difference is calculated as follows:

$$\Delta E^*_{ab} = \sqrt{(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2}$$

The colour difference ΔE^*_{ab} can be split up into a lightness component (ΔL^*), a saturation component (ΔC^*_{ab}) and a colour shade component (ΔH^*_{ab}). Lightness L^*, saturation C^*_{ab} colour shade H^*_{ab} can be represented more clearly in graphical form. The shade of a colour is found on the chromatic circle of spectral colours. It is determined using the colour shade angle h_{ab}, which increases in size for the shade sequence red, yellow, green, blue. The saturation or degree of brightness is identified by the distance from the origin of the coordinates, the achromatic point, to the chromatic circle. On the chromatic circle, the saturation is 100%. The lightness is plotted vertically. The saturation component ΔC^*_{ab} is therefore described by the various distances of the colour location from the achromatic point. This also applies to the lightness component ΔL^*. The colour shade component ΔH^*_{ab} is defined by the alteration in the colour shade angle h^*_{ab}. The mathematical calculation of the components is carried out as follows:

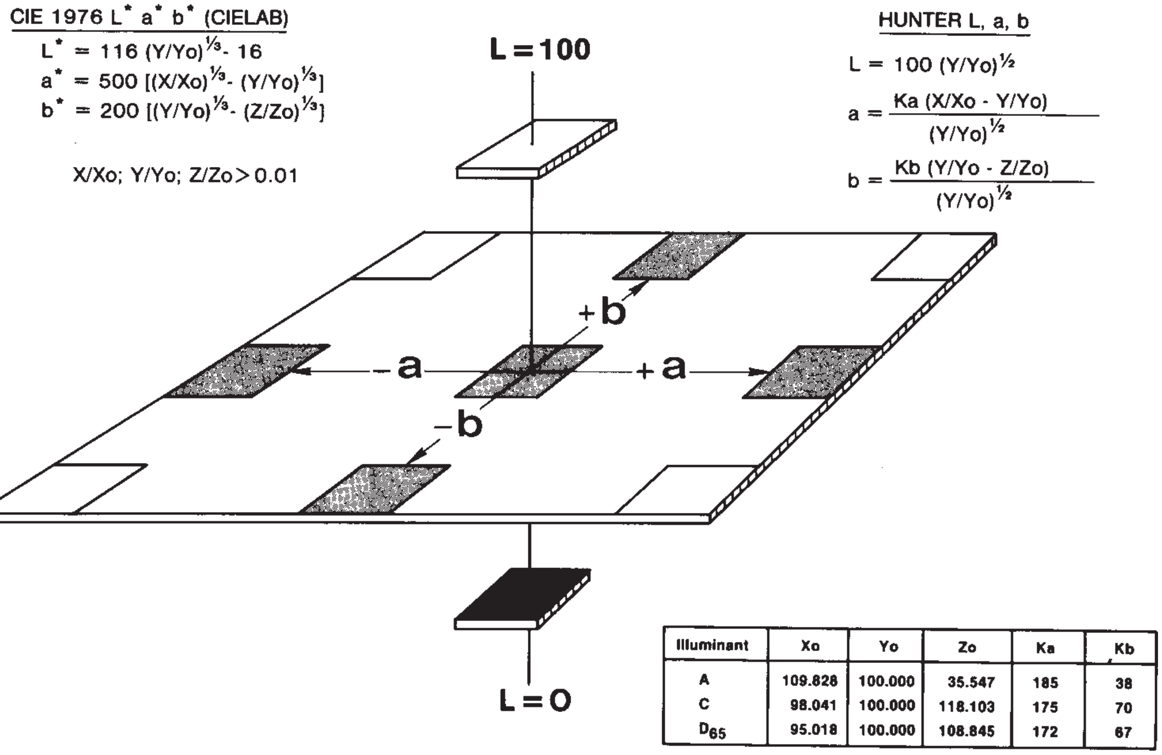
$$\Delta E^*_{ab} = \sqrt{(\Delta L^*)^2 + (\Delta C^*_{ab})^2 + (\Delta H^{*}_{ab}{}^2)}$$

$$\Delta L^* = L^*_P - L^*_B$$

$$\Delta C^*_{ab} = C^*_{ab,P} - C^*_{ab,B} \text{ mit } C^*_{ab,P} = \sqrt{a^{*2}_P + b^{*2}_P}$$

$$C^*_{ab,B} = \sqrt{a^{*2}_B + b^{*2}_B}$$

$$\Delta H^*_{ab} = \sqrt{(\Delta E^*_{ab})^2 - (\Delta L^*)^2 - (\Delta C^*_{ab})^2}$$



CIE 1976 L^* a^* b^* (CIELAB)

$$L^* = 116\,(Y/Yo)^{1/3} - 16$$
$$a^* = 500\,[(X/Xo)^{1/3} - (Y/Yo)^{1/3}]$$
$$b^* = 200\,[(Y/Yo)^{1/3} - (Z/Zo)^{1/3}]$$

$X/Xo;\ Y/Yo;\ Z/Zo > 0.01$

HUNTER L, a, b

$$L = 100\,(Y/Yo)^{1/2}$$
$$a = \frac{Ka\,(X/Xo - Y/Yo)}{(Y/Yo)^{1/2}}$$
$$b = \frac{Kb\,(Y/Yo - Z/Zo)}{(Y/Yo)^{1/2}}$$

Illuminant	Xo	Yo	Zo	Ka	Kb
A	109.828	100.000	35.547	185	38
C	98.041	100.000	118.103	175	70
D_{65}	95.018	100.000	108.845	172	67

Fig. 2: Schematic diagram of the L-a*-b* system.*
X, Y and Z are tristimulus values; X_0, Y_0 and Z_0 are tristimulus values for perfect transilluminators when they are used as illuminators. Ka and Kb are chromatic coefficients relating to the illuminator.

The indices P and B refer to sample (P) and reference (B). The algebraic sign for ΔH^*_{ab} is:

– positive, where $a^*_P \cdot b^*_B - a^*_B \cdot b^*_P \leq 0$

– negative, where $a^*_P \cdot b^*_B - a^*_B \cdot b^*_P > 0$

The CIELAB formula represents a modification to the Adams-Nickerson-Stultz colour difference formula (ΔE_{AN}). The differences are as follows: the colour differences are on average larger than those in the AN formula by a factor of 1.21. The division of the colour difference only relates to the CIELAB formula. Calculation using the AN formula is more difficult for a computer than using the CIELAB formula. The question of which formula gives the better correlation with the visual assessment continues to be discussed in practice.

3. Other colour difference formulae are the CIELUV formulae also recommended by the CIE whose initial co-ordinates are u', v' of the 1960 CIE-UCS chromaticity diagram, and the Adams-Nickerson-Stultz colour difference formula which is based on Adams' measuring system. Simon-Goodwin method for determining colour difference thresholds and the method of determining colour difference arising from this is also worth mention. Using experimental tests, D. L. MacAdam ascertained that the colour locations that can still be distinguished from a target colour are arranged as an ellipse with the target colour in the centre. The ellipses determined vary in size depending on the chromaticity (Fig. 3). If the lightness is also varied, ellipsoids are also obtained in the x, y, Y colour space.

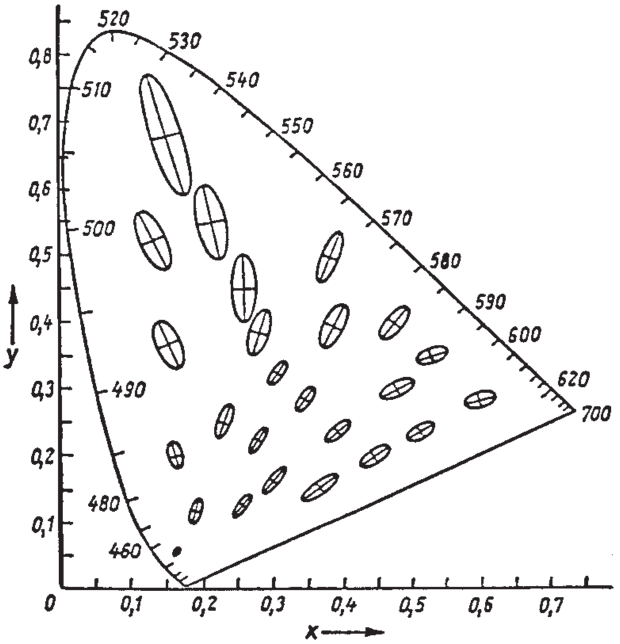


Fig. 3: Colour triangle with MacAdam threshold ellipses (the ellipses are magnified lenfold in comparison with the scale of coordinates x and y).

Simon-Goodwin determines the colour difference with the aid of charts consisting of subdomains of the chromaticity diagram as an oblique co-ordinate system. The MacAdam ellipses thus become circles. The chromaticity difference is determined using these and the total colour difference is determined using another table, including brightness. This method (where used at all) is used where only a small number of colour differences are being defined. The new CMC (I:c) formula is currently being introduced to complement the CIELAB-formula. → Colorimetric measures; Colour measurement.

Colorimetry, colorimetric analysis A process for determining the concentration of coloured solutions. Colorimetry is based on the fact that part of a light beam is absorbed on passing through a coloured solution. According to Lambert-Beer in this respect, the quantity of light absorbed is proportional to the concentration (c) of the colouring substance in the solution and the layer density (d = distance covered) which the light beam has to travel through the solution. Solutions of the same substance but of different concentrations then give rise to the same light absorption when their layer thicknesses behave conversely to their concentrations.

$$c_1 \cdot d_1 = c_2 \cdot d_2$$

The concentration of coloured solutions can now be determined by the light loss occurring due to absorption being determined visually (optically) by means of a colorimeter or photometrically with photocells.

Colorthek A colour atlas produced by BASF containing a systematic arrangement of shades from yellow to black. Dyeing recipes and colour fastness ratings are given for the combination dyeings. Volume I: 1320 shades on wool and synthetic fibres, Volume II: 2580 shades on cellulose acetate and synthetic fibre filaments.

Colour,

I. Coloristic: hue, saturation and lightness, shades. Terms used in practice for describing the perception of colour → Hue (state, difference) in sample dyeing and colour matching. Colour also relates to e.g. →: Colour sample; Colour kitchen and Colour Index (C.I.) etc.

II. Physical: An optical perception arising as a result of → Colour stimulus (state) that is transmitted via the eye to the brain where colour perception is triggered (→ Colour vision). Colour is therefore primarily an effect of the light. A distinction is made between:

a) Coloured light or spectral colours which are characteristic of a specific illuminant, e.g. as a coloured light source or illuminant. Typical for this is the composition of white daylight as an additive mix of spectral colours, i.e. the sum of all colours that make up white, and includes the fluorescent effects of optical brightening agents.

b) Surface colours arise when visible light falls on coloured, non-luminescent objects causing colour perception by selective absorption and reflection, i.e. where there is complete absorption by the exposed object, it appears black, but where there is complete reflection, it appears white. Where there is selective absorption, only part of the incident light appears as a reflected → Complementary colour. Not only insoluble mineral dyestuffs but also in a wider sense soluble dyestuffs and their dyeings are included amongst surface colours as sensory impressions. Separation into → Hue and → Achromatic colours that seem to be opposites differ only insofar as hues show a spectral colour. Ostwald defines every surface colour using a number from the chromatic circle and two letters from the → Grey scales for fastness testing. For the dyer, it is important to know that there are no truly pure colours because reflected light is not monochromatic.

Colour affinity → Dye affinity.

Colour anomaly → Anomalous colour vision.

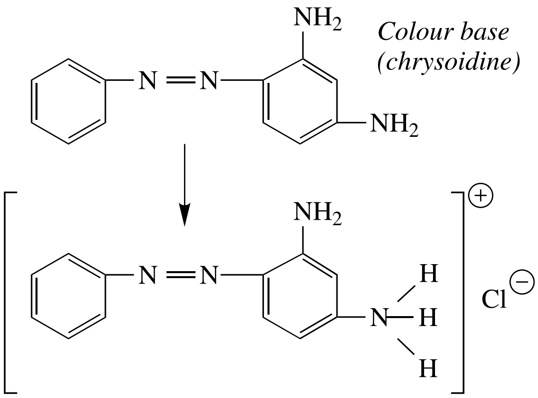
Colour aptitude →: Colour blindness; Defective colour vision; Anomalous colour vision.

Colour aptitude test (Am.). Using a 48-part colour scale consisting of individually pigmented synthetic plates; the ability to sort colours into the correct order is assessed.

Colour aptitude testing → Anomaloscope.

Colour atlas (Colour chart, colour card, shade card). Although sample cards from dye works and dyehouses generally give limited recipe collections from certain points of view or are oriented towards this, it is also possible to provide the colour sample with relevant colorimetric measures and to use them in the sense of colorimetry as subjective direct comparisons, to ascertain colour tolerances, to assess cross-dyeing, to calculate costs etc. The procedure is as follows: a colour which is to be measured at specific lighting (standard illuminant) is to be directly compared with the colour atlas. The colorimetric measure and preferred number of the corresponding sample is then made into the identifying colorimetric measure for the dyeing. Using the same principle, individual colour atlases can be formed systematically, e.g. using the DIN colour chart. This method appears very simple, however, it is always dependent on the observer and can only be used where there is no need for particular accuracy. In addition, where the colour atlas is incomplete, it is often necessary to rely on interpolations between two ordered samples which considerably increases the subjective factor of uncertainty still further. Each colour atlas also has a tendency to temporary limited light fastness and ageing which means that checks are required from time to time. The highest requirements are therefore to be made of colour atlases: they must contain all colour used in practice as far as possible, including various brilliant and gloss variations. Similar adjacent colours must be equidistant as far as possible and clearly perceivable as different by the eye. Each colorimetric measure should give reliable details of the index number (converted using DIN 5033) under specific lighting, together with details concerning light fastness etc. if possible.

Colour bases (dyestuff bases). Organic → Bases consisting of dyestuff residue with free or substituted amino groups ($-NH_2$, $-NHX$, $-NX_2$) incorporated as an auxochrome. These amino groups transfer their basic character and positive charge to the dyestuff residue that therefore receives cationic properties. These types of colour bases lack solubilising groups; however, they are frequently fat-soluble and/or alcohol-soluble. Only their salts (colour salts), usually acidified with hydrochloric acid and known as → Cationic dyes, are of any significance with respect to textiles. These salts form the prototype of cationic dyes according to the ionic properties of the salts in aqueous solution.



Colour base (chrysoidine)

Chlorine hydrate

They therefore react oppositely to dye acids and their salts (→ Dye ions). Colour bases must not be confused with → Azoic bases.

Colour blend (mixture, mix). Produced after doubling and drawing differently dyed tops, or after blending stock dyed woollen yarn wool, i.e. generally after blending differently coloured (dyed) fibres. A dyeing expression rather than a quality term.

Colour blend prediction by colorimetry The conventional recipe production of colour blends is effected in the following steps:

1. Analysing the model.
2. Recipe production in percentages.
3. Producing the test sample.
4. Comparison between model and adjustment (test specimen).
5. Optimising the recipe.
6. Producing further test samples with subsequent comparison.

7. Recipe composition for production in units of weight.

Here, depending on the complexity of the model, operational stages 2–6 can be repeated a number of times in loop form. It is by no means rare for this section to be repeated 4–6 times in practice, and even 10 times in extreme cases. In producing the test sample, this is first of all weighed on a precision balance in component terms depending on the recipe, and then blended in a laboratory blending machine (sample card). The blend is then treated with a soap solution, brought into felt form on a laboratory plate fulling machine, and finally washed. After a 10–15 minute drying period the test sample is ready for comparison. Comparisons are made in an illuminated chamber, in which metameric tests can be carried out. This expensive production process takes 20–40 min as a rule.

In worsted yarn spinning, blending is effected in the drawing passages; in woollen yarn spinning on the other hand, the blend is prepared in blending bed form and then further processed on a card. Independently of the blend production method, production of the blend recipes for both spinning areas can be implemented equally. New formulation methods have been made possible for blenders only by the colorimetry standards in the dyehouse, which have made it possible to effect the formulation process by colorimetric methods in addition to well-tried conventional blending.

The colorimetric interrelationships in a subtractive textile colour mixture and the interrelationships between colour components and the resultant colour blend can be described as follows: if two liquors of a cyanine and a magenta dye are produced, and the same quantity of stock is dyed in each solution, the remission curves in Fig. 1 are produced after the two samples have been measured colorimetrically by means of a spectrophotometer.

If the two liquors are put together, and both stock test specimens are dyed under the same dyeing conditions as in the first test, the samples are coloured violet. The associated reflectance curve can be seen in Fig. 2. This curve is produced by subtractive colour mixing.

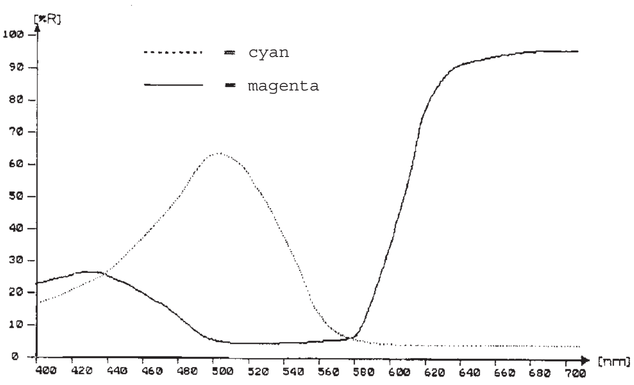


Fig. 1: Cyanine and magenta reflectance curves.

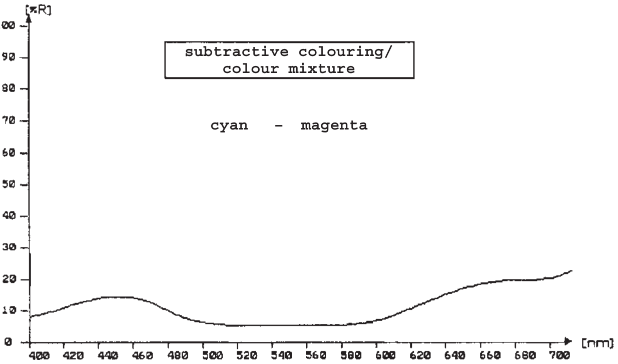

Fig. 2: Subtractive colour mixing of cyanine and magenta.

After repeating the first test, and producing the colour blend composed of the cyanine and magenta samples (50% + 50%), the same shade as in the second test with the mixture of the two liquors is obtained, but brighter and more saturated. After measuring the colour of this colour blend, the reflectance curve shown in Fig. 3 is obtained.

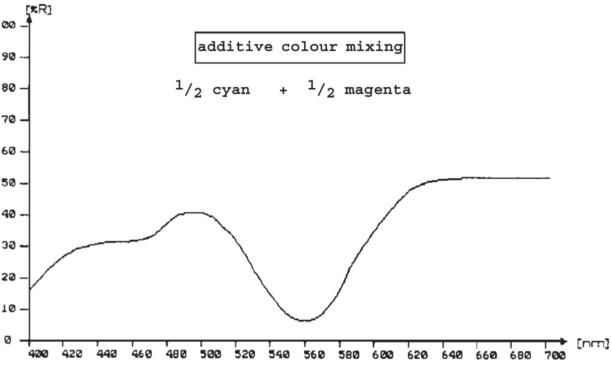

Fig. 3: Superimposition of subtractive and additive colour mixing = colour blend.

Fig. 3 involves an additive colour mixture, but with approximately half the intensity as compared with measuring the individual test samples. Colorimetrically therefore, a colour blend behaves other than a homogeneous textile dyeing, and cannot be analysed by the calculation process valid for subtractive colour mixing. Specially developed software packs are offered for colorimetric colour blending. The two solutions can be classed roughly equally in characteristic terms and as a method. The method of operation of one of these can be explained in the following steps:

1. Reference data set-up.
2. Colour blend formulation.
3. Colour blend recipe correction.

As in textile dyeing, the reference series also serves as a basis here. Only one shade series (Fig. 4) is required for each substrate. The shade series represents a continual mixture of the substrate with the darkest full shade (black) in each case. 11 gradations are produced for ex-

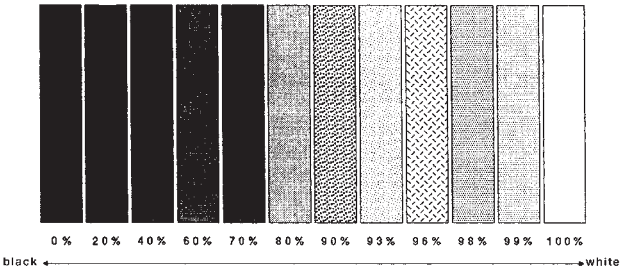

Fig. 4: Shade series.

ample from 0–100% (white), though attention must be paid to graduation in terms of perception, i.e. relative to the brightness-sensitive curve of the human eye, the concentration gradations must lie closer together in the bright range.

For full shades, only one sample is required from the respective stock on hand, which then has to be measured in. In Fig. 5, this is represented as a full shade palette, with which the model can be formulated. The size of the palette is unlimited, and makes it possible to take account of the each special batch outcome. In this way, variations in the outcome of the dyeings supplied can for example be taken into account by the programme by their acceptance into the reference data base by subsequent modification of the original recipe.

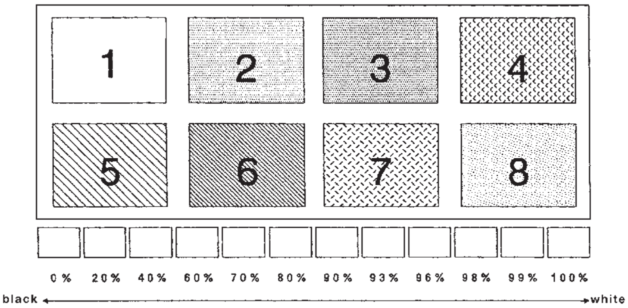

Fig. 5: Full shade palette.

Through an additionally available shade library, there is also the possibility of incorporating residual colour blends during formulation. This means that, in addition to full shades, colour blends can also become reference data, constantly supplementing the palette. This possibility increases the economic use of such a system in practice, since the residual quantities can be further processed. After producing the reference data base, the system is ready for formulation. In formulating a colour blend, not only is its colour decisive, but also its character (appearance) and its effect. Multi-colour colour blends on the one hand, and single colour blends on the other can be regarded as the two extremes. A multi-colour colour blend is understood to be a mixture, the components of which are completely or partially contrasted with each other. In the case of a single colour blend, the overall picture is rather quiet, and can almost equate with a dyeing because of the lower contrast level of the individual components. The transitions to the two forms are fluid however, i.e. in practice there are colour blends which are difficult to classify. In this case, the software offers the possibility of formulating on both effects. Formulation of the colour blends by the system takes place as follows: after measuring in or calling up the model from the memory, the colour blender selects some dyeings, vigoureux prints or colour blends from the reference data palette, and lets the computer calculate the recipe. Here, it does not matter whether the model is measured in first of all or whether the reference data components are selected. As shown in Fig. 6, obtained in the simplest case is a recipe in which the component percentage content is issued for adjusting the model, the sum of all parts being logically 100%.

In the event of brightness discrepancy, the programme automatically produces white in order to obtain the required brightness. In the reverse case, i.e. if the required depth of colour cannot be reached (recipe produced is too bright), the system gives the colour intensity achieved as a percentage of the model. The ΔE CIELAB overall colour difference and the metameric index are issued with the concentrations for the components. From a total of 13 illuminants, those which are to be formulated on can be selected, plus three additional illuminants, for which the metamerism is issued. In Fig. 6, e.g., formulation was effected on illuminant D65 (daylight), and the metamerism calculated for illuminants A, TL 84, and CWF. Illuminants D55, D65, D75, TL 84, TL 83, TL 54, CWF, WWF, ADN, C, BHS, PN25 and CR 84 can be taken into account along with the formulation. The recipes can then be analysed by the 6 colour difference formulae made available. After determining the maximum values for overall colour difference and metamerism with the selected illuminants, plus the maximum number of recipes to be printed out, the recipe variety can be kept within practicable limits. There is also the possibility of formulating colour blends on a mixed substrate basis from pure substrate components.

From the organisational standpoint, stock administration is oriented to the colour blender's method of procedure. In formulation, the first type of substrate (e.g. wool) is calculated first of all. After that, the system converts a selected recipe to the actual percentage of this type of substrate in the mixture, and takes it as a basis for formulating the second substrate (e.g. polyester). This method of procedure makes it possible to optimise recipe adjustment by taking account of the variation between model and recipe of the first type of substrate. Furthermore, each individual component can also be kept constant, or fixed at a minimum figure. The remaining stocks in the store can be incorporated

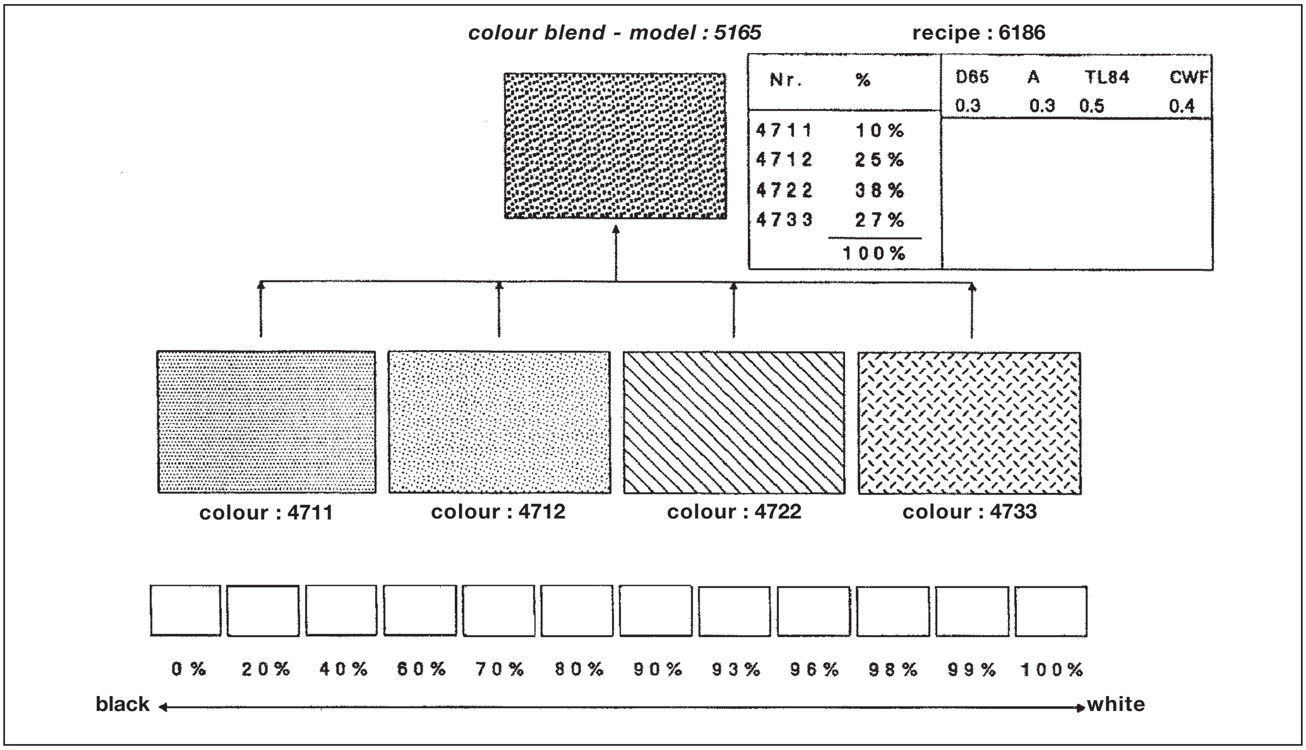

Fig. 6: Colour blend formulation.

in the colour blend in this way by fixation, which increases system efficiency, and minimises the amortisation period.

Recipe correction makes it possible to run through the widest variety of practical conditions. The diagram of a formulation with added recipe correction relates in the special case to fibre addition for shade correction. If necessary, the percentage data of a recipe calculation can be converted (in kg) in production by correction programmes to a batch size specified by the colour blender.

Colour blindness Severe form of → Defective colour vision. A distinction is made between:

I. Partial colour blindness, with little colour perception (→ Colour vision), where the world only appears in two shades of differing brightness and saturation (dichromacy), i.e. one or two bands in the spectrum are seen as achromatic (so-called neutral points). This concerns (mainly hereditary): a) protanopia, where the spectrum is reduced in the longer wavelengths; b) deuteranopia and c) tritanopia or anianthiopsy with probable reduced short wavelengths. Frequency in Germany is a) 1.1% of the male population and 0.02% of the female population; b) 1.8 and 0.02%; c) 0.003% for both males and females.

II. Total colour blindness, with no colour perception (achromasia, monochromatism), where brightness values can be distinguished. This form is rare (approx. 0.003%) and either a) hereditary, with only the rods functioning and so-called achromasia; or b) predominantly contracted – the cones are intact, but the nerves of those affected are disturbed and therefore no longer capable of colour perception (achromasia).

Colour box Rectangular trough-shaped container for print paste in roller printing machines. Print paste is transferred from the colour box via a furnisher roller to the engraved printing roller and thence to the fabric.

Colour build The intensity of colour produced by a dye in the fibre in relation to the amount of dye used.

Colour circle → Chromatic circle.

Colour clarity → Clear colour.

Colour codes → Colorimetric measures.

Colour coding for pipework Colour coding established in accordance with DIN which identifies pipework by full length painting, tags or coloured bands, coloured arrows indicating directional flow, possibly also with printed data (see Table).

Colour competence → Anomalous colour vision; Colour blindness.

Colour computer Together with a scanner, corrects hue and colour value in connection with an optoelectronic scanning process.

Colour coordinate system → Chromaticity diagram with the components of red (x), green (y) and blue (z) as coordinates.

Colour correction An electronically controlled process which takes place on a scanner after colour separation with the aid of the colour computer.

Colourcraft process (→ Space dyeing). Principle based on ombré dyeing of wool yarn hanks (5–6 shades

per hank circumference). After dyeing, the yarns are twisted to produce multicoloured effects with 40–50 shades.

Colour data processing is relevant to many areas of the coloration industry. New applications are constantly added to colour data processing every year. Instrumental colour measurement has proven particularly important for quality control. However, it now encompasses the creation of new colours with the aid of the greater ease of use of colour measurement, automation of the dyehouse laboratory with automatic metering of dyes and chemicals in conjunction with computer-controlled laboratory dyeing machines, organisation, calculation of works application, control of weighing and dosing of auxiliaries, and the computerised control of production.

Colorimetry (known for over 50 years) usually refers to the measurement of spectral reflectance values in the visible range of the spectrum. These values are processed according to known methods for determining the chromaticity-scale variables, such as colour differences, colour tolerances and colour intensity. During the past 20 years colour data processing has undergone further expansion to include the calculation of dyeing formulations, formulation corrections and dyestuff additions. The increasing importance of colour data processing in industrial applications ran parallel with the rapid development and availability of computer systems and personal computer during this period. Today colour data processing is an established and indispensable tool in the dyeing industry (see Fig.).

The purpose of each colour calculation is to reproduce a desired colour by selecting the most suitable colouring components (dyes or pigments) and by the quantitative determination of the required amounts of each component to allow the dyeing of a fibre and the eventual production of a dyed sample to reproduce the required colour. This requires that the optical data, i.e. the spectral reflectance values of the colour sample be measured with a spectrophotometer. The properties of the dyes or pigments, i.e. their optical characteristics, light absorption and light diffusion properties, must be known. It is then possible, using the Kubelka and Munk theory, to select the suitable dyestuffs and calculate the quantities required to reproduce a quantitatively measured colour of the sample using the CIE tristimulus value. The purpose of this procedure is so that subsequent dyeing can be suited to all illuminants to conform as closely as possible to the original colour sample and including control of costs.

Colour monitoring is one of the major current problems not only in the dyeing industry but also for the users of dyed materials. There is an increasing requirement between processors and users to agree on colour tolerances. However, such an agreement is not practical on the basis of visual colour evaluations. Visual colour evaluation is subjective and thus sensitive to e.g. psychological effects that will have a significant influence on a tolerance factor for colour difference. An objective, mathematical system is only possible through colour data processing. However, until very recently even the practical implementation of electronic colour monitoring was restricted. The reason is that existing colour difference formulae do not usually restore the colour differences quantitatively to the visual sensation. The tolerances in the three dimensions of brightness, hue and shade are numerically different, the degree of difference is also dependent on the location of the colour in colour space. Under these circumstances electronic colour measurement could only be implemented when a colour could be reproduced sufficiently within a very close tolerance of the original colour. Based on extensive pattern collections used in industry and which were evaluated by different colourists, it was possible to specify mathematically the dependence of colour tolerances on the colour itself. This dependence offers colorimetric colour measurement that enables colour tolerances to be determined specific to the industry,

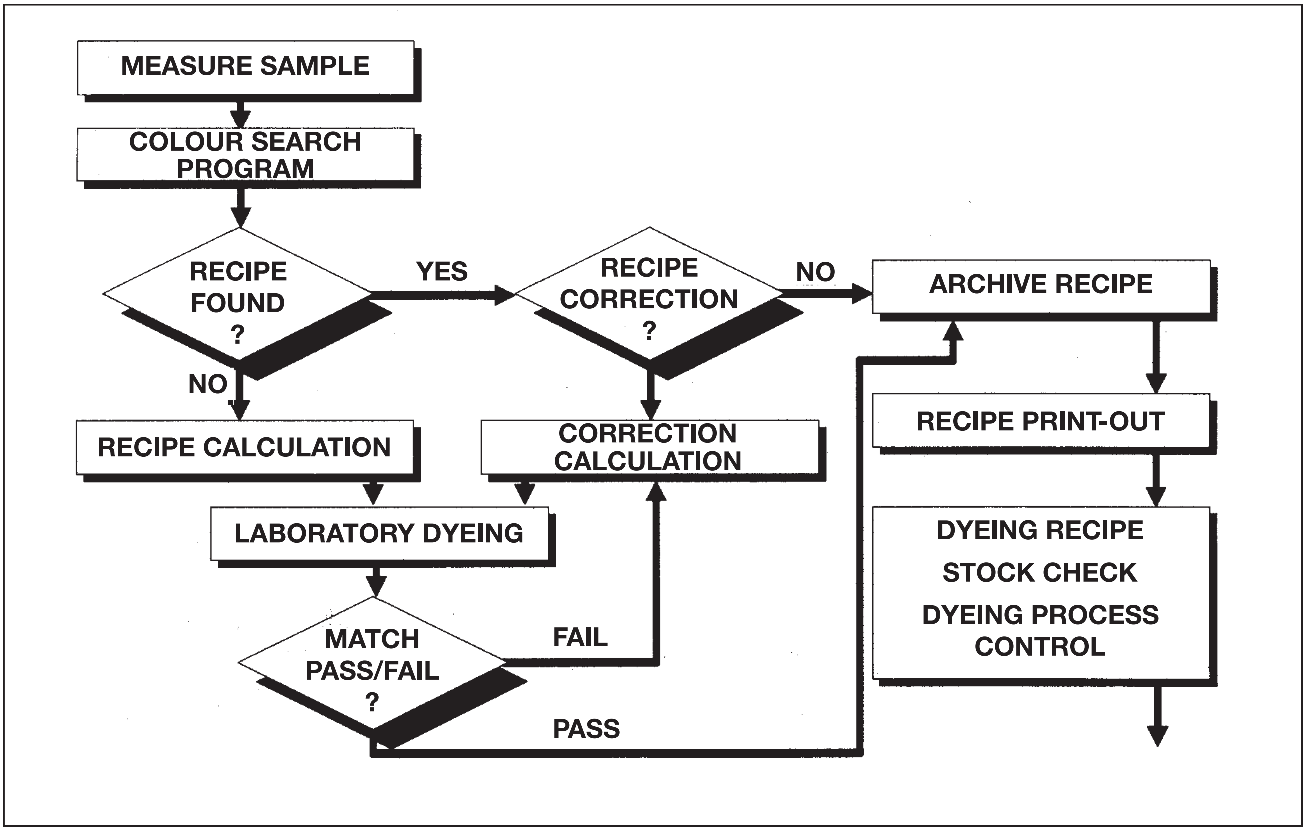

Fig.: Program flow for generating formulation using the OSIRIS program package (datacolor).

product and customer. It is known that colour tolerances are dependent also on the market situation. This circumstance can also be taken into account.

Colour data processing is possible in textile printing. In order to use a printing colour for a specific colour design, it must first be accepted in an in-house printing atlas. A CAD system can manage several printing atlases and these are separated by class of dyestuff and substrate. An atlas is selected according to the colour mode of the design. By simply choosing the required screen and the designated colour a job recipe is produced. The colour menu system is very basic. The introduction of the “English” version with its “Colour Management” brought the system nearer to a true software system. The term CAC system is also occasionally used for “Computer Aided Colouring”. The correct colour representation of printing colours is crucial for the whole of the subsequent program flow; the decision for or against a colour design depends on this correct colour representation which also affects whether the customer will accept or reject the coloration and whether or not there will be a production run.

Colour density, spectral Physical size of the → Saturation and Depth of colour. Spectral colour density is also known as → Eye sensitivity to hue, chroma and lightness.

Colour difference Two identical colours have identical CIE tristimulus values X, Y and Z in the CIE co-ordinate system (→ Colorimetric measures; Standard spectral value). Different CIE tristimulus values correspond to two different colours. However, the difference between the colour co-ordinates does not itself identify the size of the visual colour difference. Using a colour difference formula, the colour co-ordinate differences can be recalculated into one number that is a measure of the visual colour difference. This measurement is also known as the colour difference (ΔE), previously expressed in MacAdam units (→ Colour difference formulae). The calculation was frequently performed with Simon and Goodwin tables. The standardised CIELAB method is now used.

Colour difference formulae Used in the → CIE colour co-ordinates system to define the differences in colour between two dyeings showing an apparent visual difference. A mathematical value is used to correct variations in colour in → Colorimetry. The most significant are:

I. Judd formula, the oldest basis for defining the NBS colour difference unit; it is rarely used.

II. Nickerson-Stultz formula.

III. MacAdam formula, for just noticeable differences between colours (as ellipses in the CIE chromaticity diagram).

IV. Simon-Goodwin charts for practical application of the MacAdam ellipses.

V. Friele-MacAdam Chickering formula rectifies certain disadvantages of the MacAdam formula, better than IV. Computer required, extremely common. The MacAdam colour difference unit is used (1 MAE).

VI. ANS formula (Adams-Nickerson-Stultz) is recommended by the CIE (DIN 61 604). The NSB unit is used and the colour difference formula must be quoted with all details.

VII. CIELAB formula (DIN 6174) is the most commonly used formula today.

VIII. The CMC (I : c) formula of the Colour Measuring Committee (Society of Dyers and Colourists) is also gaining in importance.

Colour difference values according to CIELAB → Colorimetry.

Colour drain back plate of doctor blade Edge plate to turn colour paste back into the bank of paste before the roller.

Colour dulling → Dull colour.

Coloured articles wash All coloured or white textiles of cotton, linen or viscose which must not be washed at the boil but which will withstand washing at up to 60°C with the usual detergents. White knit goods of polyester and polyamide fibres can also be washed as a coloured wash if necessary. In laundries, coloured washes are separated according to type, colour and fibre content. Besides the 4 basic colours – yellow, red, green and blue – light and dark colours are washed separately in order to avoid cross staining.

Coloured bleach goods E.g. shirting fabrics and handkerchiefs, i.e. colour woven materials that are destined for subsequent bleaching. → Bleaching fastness.

Coloured compounds Essentially made up of three subsections: a so-called → Auxochrome group which is connected to a → Chromophore group via a system of → Conjugated double bonds. Auxochrome and chromophore groups displace the longer wavelength absorption bands of the conjugated system → Bathochrome group. Auxochromes and chromophores can be classified empirically for a specific conjugated system in order of increasing bathochromic effect. In the nomenclature, auxochromes are electron donors, chromphores electron acceptors.

Coloured discharge printing For discharge printing of white areas on a ground which contains dischargeable azo dyestuffs, a reducing agent is incorporated into the print paste so that the white ground of the fabric is developed on steaming. If a discharge-resistant anthraquinone dye is added to the discharge paste, then a coloured pattern is developed instead. If the dyes printed on are particularly luminous, then they are termed illuminating dyestuffs in coloured discharge printing.

Coloured pigments Inorganic or organic → Pigments.

Coloured resists In contrast to white resists, where the ground dyeing or the ground printing is prevented from fixing locally, and the white ground thus emerges, in the case of coloured resists another dyestuff is simultaneously fixed at this point.

Coloured woven fabric Fabric woven from predyed yarn.

Colour effect of fibres The reflective and light scattering nature of textiles is influenced by various factors that give rise to lighter or darker colour appearance with the same dye content on the same material. These factors include:

- penetration of the textile structure by the dye (e.g. when printing),
- variable dyeing behaviour of textiles,
- density of yarn and/or fabric,
- internal light scattering capability,
- special finishes, such as e.g. calendering,
- surface structure of the fabric,
- cross sectional appearance,
- fibre surface,
- fibre D'Tex (microfibres!),
- dye penetration of individual fibres.

The increase in the total surface of the fibre brings about an increase in light scattering with fibres that are becoming finer. This can be observed in the form of a lighter dyeing using the Kubelka Munk process.

$$\frac{K}{S} = F(R) = \frac{(1-R)^2}{2R}$$

R = remission,
K = measure of light absorption, predominantly determined by dyestuff,
S = measure of light scattering, determined only by the textile material.

From geometrical relationships, it follows that the specific fibre surface is inversely proportional to the root of the fibre D'Tex.

$$F = c \cdot \frac{1}{\sqrt{T}}$$

F = specific fibre surface,
T = fibre D'Tex.

If 2 different fibre finenesses are now inserted into the ratio,

$$\frac{F_1}{F_2} = \frac{\sqrt{T_2}}{\sqrt{T_1}}$$

F_1 = specific surface of the fibre of titre T_1,
F_2 = specific surface of the fibre of titre T_2,

Thus the ratio of the fibre D'Tex with different specific fibre surfaces can be calculated. Working on the assumption that light scattering is proportional to the specific surface, the ratio of colour strength with different fibre D'Tex is obtained using the Kubelka Munk equation

$$\frac{\text{colour strength}_1}{\text{colour strength}_2} = \sqrt{\frac{T_1}{T_2}}$$

As a conclusion, it can be said that as the total fibre surface increases, the dye absorption capacity also increases and therefore an increased use of dyestuff is required to achieve the same colour depths on articles with finer individual D'Tex than on articles with coarser individual D'Tex. The apparent colour of dyed fibres is dependant upon the dispersion of dyestuff through the fibre. (Fig. 1).

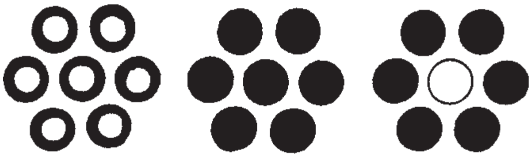

Fig. 1: Dispersion of dyestuff throughout a fibre cross section, resp. yarn cross section.

Ring dyeing and level dyeing through a fibre define the level of dispersion of dyestuff throughout a fibre cross section. Ring dyed fibres show a concentration of dyestuff in the outer areas of the cross section. A distinction should be made between this and unlevel dyeing or poor fibre penetration e.g. in the case of high-twist yarns. Certain fibre models deal with quantities of light absorbed through cylindrical fibres dependant on the form in which the dyestuff is dispersed. A round, non-delustred fibre cross section is illuminated vertically to the fibre axis by parallel beams of light. This causes refraction of the light at the air-fibre boundary (Fig. 2). The beams, which do not pass exactly through the centre of the fibre, are refracted in the direction of the beam of light that passes the centre of the fibre without breaking the boundary layer.

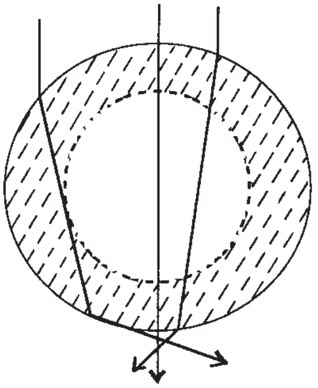

Fig. 2: Refraction of the light in the outer areas of the cross section of a ring dyed fibre.

If there are ring dyeings, those beams of light that pass though the undyed core of the fibre are not absorbed. In the area of the dyed fibre rings, however, absorption is more intense. In contrast, beams of light are absorbed right through the cross section of the fibre when the fibres are equally penetrated. Taking into consideration the diameter of the cross section of the fibre, the thickness of the layer of ring dyeing, the fibre's refractive index and other factors, it follows from this model that a ring dyeing has a lower colour yield than penetrative dyeing with the same quantity of dyestuff. A better dyestuff penetration of the fibre cross section results in a result comparable to the theoretical colour yield (visual colour sensation) where there is complete penetration. If the penetration of the dyestuff in the cross section of the fibre increases from 20% to 70% (with reference to the radius of the fibre), then the apparent (visual) dyestuff content is observed to increase by 30% where the same quantity of dyestuff is used (Fig. 3). However, an even higher percentage of penetration is barely perceivable.

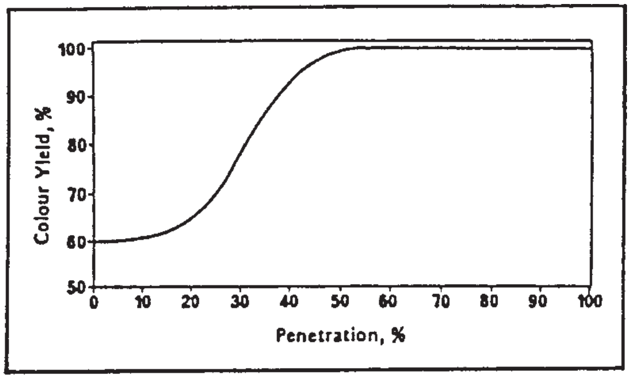

Fig. 3: Effect of the penetration of the dyestuff in the cross section of the fibre on the colour yield using Dacron by Du Pont and dispersol blue D-2R by Zeneca.

If 10% of dyestuff is dispersed through a cross section of fibre (located on the outer cross section), this corresponds to a colour yield of 60–75% of a penetration of equal concentration. The "change in colour" which occurs between ring dyeing and penetration is however larger, the smaller the dyestuff ring. Ring dyeing with approx. 70% dyed fibre radius gives exactly the same colour sensation as penetration. The → Kubelka Munk value is often used to assess the visual colour effect. This value rises as penetration increases with the same quantity of dyestuff. If approx. 80% penetration is achieved, the rise is only negligible, having very little effect on the colour appearance of the material.

Colour embossing →: Embossing; Embossing calender; Emboss printing

Colour fastness In the normal sense this is understood to refer to the resistance of a dyed or printed textile to various types of influences to which they are normally exposed in textile manufacturing and in practical use. In colour fastness tests, changes to the colour of the sample and staining of undyed adjacent fabrics tested at the same time are visually assessed using the → Grey scale and these are then given as fastness values. It is a basic concept of the tests that they are of a high level of reproducibility in result, may be carried out in a relatively short time and have a good degree of relevance to the demands of textile manufacture and use. Nevertheless they will always tend to create an artificial assessment condition and they cannot be expected to give a definitive statement of the potential behaviour of a textile in all the varied circumstances arising in manufacture, use and care of textiles. The test standards form the general basis for the testing and assessment of colour fastness properties. A specific aim of the test methods is to give clear instructions to the personnel carrying out the tests in order to achieve optimum reproducibility. In this respect, developments are to be noted which arise increasingly from the introduction of quality assurance systems and product liability. State, industrial and private testing organisations and institutions carry out colour fastness testing. Employees must be trained and qualified to carry out the testing and the whole process must lend itself to a Quality Audit system as part of a Quality Control process. The test methods can also be used to determine the colour fastness properties of dyestuffs. The dyestuffs are individually applied in specific depths of shade according to appropriate dyeing and printing processes on a suitable textile substrate and then tested for colour fastness. The fastness values obtained are shown on the dyestuff manufacturers sample cards. The changes in colour arising in the colour fastness tests and the staining of adjacent fabrics are now visually assessed in accordance with the standards ISO 105 AO2 (Change of shade) and ISO 105 A03 (Staining). It is probable that colorimetric assessment of test results will be used in the future to complement and/or replace the largely subjective assessment used at present.

1. General use fastness properties: Usually involves testing to light-, weathering- and washing-fastness and may include perspiration and crocking (rubbing) fastness.

a) The test for → Light fastness and fastness to weathering is particularly important for the permanency of the colour. The eight shades of the blue scales; standard dyeings with a geometric sequence of increasing resistance to exposure to light are the generally accepted basis for assessing light fastness. Where time is a critical factor, exposure to actual daylight has become less common due to the long testing time involved. More rapid testing is employed using a xenon lamp as energy source with an emission that is filtered to give similar values to real sunlight. A great deal of attention has been recently devoted to improving the test equipment. In addition, intensive research work has been carried out on measurement and control of the radiation, which will imitate the effects of a naturally variable source from Nature. A suitable testing method to determine the light fastness of interior materials in cars, i.e. car upholstery is → High temperature light fastness. This takes into consideration e.g. the occasionally very high temperatures arising in closed cars and the possible long periods during its use when the vehicle may be parked in the sun, resulting in the light effects being significantly intensified. This gives a requirement for extremely high light fastness. Reliable testing for this is required within a very short space of time, i.e. within a couple of days (ISO 105–B06). It is also possible to test textiles whilst they are exposed to wet conditions. This phenomenon, which is particularly significant for dyeings on cellulose fibres, of the light fastness being impaired by wetting with water should lead to new test processes. It is also possible to assess the effects of stains from cosmetics, sun protection agents or even undiluted washing liquor on textiles in conjunction with light exposure. Efforts are being made to further reduce exposure times that are decreased in exposure testing devices with uninterrupted use by a factor of approx. 1 : 9 in comparison with daylight. Often, the intensity of the emission or the proportion of short-wave radiation is too high and this questions the reliability of tests for light fastness. Such tests can at the most give a certain indication of the light fastness of the samples in individual cases.

b) A decisive innovation has been introduced in → Washfastness testing. Testing with soap as a wash active substance is complemented by washing with a compound detergent, the ECE colour fastness test detergent 77 with the addition of perborate. The use of multiple-fibre adjacent material (“multi fibre strip”) has been widely introduced. Wash fastness testing in accordance with DIN 54 017–C06 is also used as a basis for textile care labelling.

2. With fastness to processing, the → Potting fastness with wool is becoming less important, as the test conditions no longer correspond in their intensity with the relatively mild conditions with continuous crabbing. In contrast, fastness to cross dyeing has become extremely important as a result of fashion (source: Söll) → Fastness testing.

Colour fastness commission → Fastness commission.

Colour fastness improvement → Fastness improvement.

Colour fastness requirements in manufacturing → Fastness requirements in manufacturing.

Colour fastness testing → Fastness testing.

Colour fastness to acids Resistance to the effects of dilute organic or mineral acids. Three types are used with increasing severity of effect. The Standards apply to all fibre types. Treatment types: a) 100g/l crystallised tartaric acid; b) 300 g/l acetic acid 100%; c) 50 g/l sulphuric acid 60°Bé. Acetate is only tested with a) and c). Acid dilutions are prepared with distilled water. Test samples are treated with two drops of the dilutions. Assess any change in colour after 10 min reaction time at room temperature. Carry out a second assessment once the test piece has dried at the same temperature (DEK; ISO: only assessed after drying). Assessment: grey scale/change of shade.

Colour fastness to cross-dyeing → Fastness to cross-dyeing.

Colour fastness to degumming → Fastness to degumming.

Colour fastness to dry heat Synthetic fibres have become extremely important in the manufacture of yarns and fabrics. Thermal processes for setting the fibrous material itself or for thermosetting the dyes onto the material play a substantial role in the processing of synthetic fibres. The development of these thermal processes has lent increasing weight to the testing of the fastness to dry heat of the dyes. In the course of these finishing or dyeing processes the material will pass through temperature zones of 150–220ºC depending on the type of the fibre and construction of the fabric. Many dyes cannot withstand these kinds of temperatures, however, and will undergo change. Particularly with disperse dyes, which are used primarily in the dyeing of synthetic fibres, sublimation of the dye can be experienced in this temperature range, whereby the dye will either be precipitated on other parts of the fabric causing stains or else form deposits in the machines in which the processes are carried out, causing the equipment to become contaminated. It is therefore important that these phenomena are investigated in the laboratory and that the behaviour of a dye at these high treatment temperatures is predicted.

The Fixotest apparatus (Heraeus) has been developed to perform this test. In order to test the colour fastness of dyes to heat setting, ironing and contact heat, the Fixotest involves examining the effect of heated metal surfaces on the textile dyes under investigation. The test fabric is sandwiched between undyed adjacent fabric and then placed between the heated plates of the apparatus. After testing, the colour change and any transfer of the dye onto the adjacent fabric are assessed. Standards are applied in testing the contact heat stability of dyes on synthetic material by means of the Fixotest. This test is described by the International Organization for Standardization (ISO) in its ISO Draft Recommendation 173 “Colour Fastness to Dryheat” and regulated in Germany by the German Industrial Standards (DIN) in DIN 54 060 “Determining the Fastness to Pleating and Setting in Dry Heat of Dyes and Prints”. This fastness test involves the assessment of the resistance of the colour of textiles to the effects of dry heat. Both the Draft ISO Recommendation and DIN 54060 describe the testing of dyes at three different experimental temperatures (150, 180 and 210ºC) over 30 s, in which the contact pressure exerted on the test piece is 4 ±1 kPa. These standards apply to synthetic fibres and blended fabrics containing synthetic fibres, but not to determining the colour change that occurs with synthetic resin finishing processes (permanent press process or thermosol process).

Colour fastness to hot pressing → Dry heat setting and pleating fastness.

Colour fastness to milling → Fastness to milling.

Colour fastness to processing → Fastness to processing.

Colour fastness to rubbing Colour fastness of all kinds of textiles to abrasion and the staining of other textiles in use. Staining due to extensive fibre abrasion is not taken into account here. In the USA, a distinction is occasionally drawn between “crocking” and “rubbing fastness”. “Crocking” is understood to be colour transfer from the surface of a dyed fabric to an adjoining fabric of the same type or to another surface by rubbing; “rubbing fastness” describes the dyeing shade change. → Rubbing fastness testing.

Colour fastness to rubbing, organic solvents Fastness to crocking with organic solvents. This test provides an indication of the resistance of the shade to organic solvents on rubbing. Testing is carried out with the → Crockmeter (which rubs to and fro 10 times in 10 s over a distance of 10 cm with a load of 900 g). A cotton rub fabric is wetted in the organic solvent and squeezed to 100% solvent content before carrying out the test. Dry in warm air (< 60°C). Both the change in colour and the degree of staining are assessed with the grey scales.

Colour fastness to salt water → Fastness to sea water.

Colour fastness to soda boiling → Fastness to soda boiling.

Colour fastness to storage conditions (Colour fastness during storage),

I. Mainly used for → Formaldehyde fastness, as formaldehyde from packaging causes colour change under certain circumstances. Less often for sulphur dyeings, which split off sulphuric acid, and result in fibre damage.

II. → Sublimation fastness during storage.

Colour fastness to washing considerations for dyeings and prints → Fastness to washing.

Colour furnisher roller Used to transport, mostly in thickened, dyestuff or textile auxiliaries to the fabric; also in pigment printing, the roller printing machine.

Colour gate This is a term for a retractable component in roller printing machines. The colour application unit (trough, doctor, counter doctor) is stored in the colour gate, thus reducing the machine set-up times and enabling the colour way to be changed more rapidly.

Colour grinding mill This is used in printing and coating to finely grind print or coating pastes.

Colour in artificial light Visual change to the same colour under different lighting conditions (standard light types). The name for the colour shift that can occur when a material is examined under artificial light. Some dyeings exhibit different reflective properties under artificial light in comparison to daylight.

Colour Index (C.I.), well-known English reference book dealing with dyes (trade names, constitution), optical brighteners, reduction agents and developers. Publisher: Society of Dyers and Colourists. The enormous increase in the number of dyes on the market after mauve was discovered by H.W. Perkin in 1856 soon led to an "identification book" that was published by J.W. Slater in 1870 under the title of "The Manual of Colours and Dyewares". The individual products were listed in alphabetical order, which is one reason why this first classification book was unsatisfactory, as were several of the ones that followed. The new type of coal tar dye classification published by W.R. Richardson in 1885 was an improvement. It contained an alphanumeric list of all commercial names, together with the chemical nomenclature and formulae; however, the dyes were classified in spectral order. The previous most well known book was published in 1888, the "Tabular Overview of Artificial Organic Dyes" by G. Schultz and P. Julius. This was based on the chemical structure of the dyes, which were also listed in spectral order according to their hues. The publication was a great success and was the standard work for more than 50 years. The Colour Index, which was published by the SDC and was well known worldwide as a classification book, appeared for the first time in 1924. After a number of similar publications in English and German the SDC decided to publish "an English version that will provide comprehensive scientific and descriptive information on the subject of all known dyes".

The 1st issue of the Colour Index aroused so much interest among dye manufacturers and users, teachers and researchers that in the late 1940's a decision was taken to produce a second issue based on the following three objectives:

1. Including and organising the different brand names of individual dyes.
2. Providing information concerning usage, fastness properties, solubility, discharge capability etc. and the established application areas of commercial dyes.
3. Providing information on the chemical structure of technical dyes or their components and manufacturing methods, appropriate literature and patent references.

Dye characteristics that were listed under a certain "Colour Index Generic Name" had already been mentioned in the first issue. As a general guideline it may be justified to assign these characteristics to a certain chemical constitution, thus identifying them; but it must also be pointed out that the characteristics of the individual commercial products that are based on this structure are not necessarily identical. This deviating behaviour has become more and more frequent in recent years. In practice, it has shown dyers and printers time and time again that commercial dyes with the same basic chemical structure do not necessarily have to have the same properties. Solubility, dispersion, fastness and other properties may differ considerably in commercially available dyes with different history, even if they are based on the same colour index name and structure. On the whole, dyes that are exactly the same (this refers to a sole manufacturer's production, not traded dyes) are fairly rare.

Dyes always differ in the degree of purity, type and quantity of diluents and other additives, particle size, crystal structure, formulation, solubility, sensitivity to external influences etc. In recent years these kinds of differences have been even more clearly evident for two reasons; a) various manufacturers have adapted their products and manufacturing methods with regard to raw and intermediate materials, processes and industrial equipment for cost and environmental reasons; b) the products have been specifically revised as a result of increased demands for easy handling and quality in research and production and therefore tend to show differences in certain properties from those of the original product, whilst maintaining the chemical structure. The demands made of dye characteristics and the relevant testing methods have changed since the Colour Index was created; they have both become more numerous and more stringent (source: Schmid).

Colour in fashion textiles This is understood to mean the production of fashion colour effects on all types of fibrous materials using a wide variety of methods. The following processes are possible without use of engraved rollers or stencils, i.e. they are not typical print processes: tie-dyed batik, skeining process, Art-colour-Method, shock process, scattering of synthetics, burn-out styles, bubble coloration process, coloured effects, craquelé effects, degradé articles, denim, dye-weave process, crease techniques, flow-form process, grill, kasuri, warp dyeing, kiss dyeing process, knit-deknit process, Küster's colour method, multicoloured effects, multicoloured process, multi-TAK, museka, ombré dyeing, polychromatic dyeing, powdered dye scatter process, Rema colour process, reverse coloration process, shadow dyeing, space dyeing, space treating, TAK-dyeing.

Colour intensity of dyeings/printings (→ Depth of shade). The colour intensity of a shade can be determined using the simplified Gall-Riedel formula with reference to the absolute scale of the STD.

$$B = K + Sa_{(\lambda f)} \cdot \sqrt{Y} - 10\sqrt{Y}$$

B = colour intensity,
K = colour intensity dependent factor (K = 20 for $^{1}/_{1}$ STD, = 29 for $^{1}/_{3}$ STD, = 37 for $^{1}/_{6}$ STD, = 41 for $^{1}/_{9}$ STD, = 48 for $^{1}/_{12}$ STD, = 56 for $^{1}/_{25}$ STD.
Y = lightness (= CIE tristimulus value Y),
S = linear distance of the colour locations from the achromatic point (CIE triangle),
a = shade-dependent factor.

To determine S and a, the CIE tristimulus values X, Y, Z or the resulting chromaticity co-ordinates x, y are required. The S and a values can also be taken from colorimetric tables of measured values. This gives a good basis to prepare exhaustion curves. This is tested in practice.

Colour intensity, tinctorial This is the amount of a dyestuff determined by tests required to replace a reference dyestuff, in contrast to → Depth of shade that is used to evaluate the dyestuff fastness (but which is often approximately equal to the colour intensity).

Photometric determination of tinctorial colour intensity of a dyestuff.

I. Dyestuffs with unknown and known tinctorial colour intensity are applied at known concentrations C_S and C_P. The reflectance data of both dyeings R_S and R_P are determined. The ratio

$$\frac{F(R_P)}{F(R_S)} \cdot \frac{C_S}{C_P} \cdot 100$$

gives the tinctorial colour intensity in %.

$$F(R) = \frac{(1 - R)^2}{2R}$$

is taken from the Kubelka-Munk model.

II. Measuring dissolved dyestuffs. The transmission T (%) is determined. The concentration c is derived from the Beer-Lamberts law:

$$\text{Extinction } E = \log\frac{1}{\tau} = A \cdot c$$

E is taken from tables or supplied directly from the colour measuring instrument. τ is the transmission factor. The intensity ratio between the sample P and standard S can be calculated using the following formula:

$$\frac{E_P}{E_S} \cdot \frac{C_S}{C_P} \cdot 100, \text{ in } \%$$

Colourist The Latin root “colour”, still alive in many languages today, leads logically via colouration (dyeing, colouring) to the colourist, who is specifically concerned with it. The true domain of the colourist is textile printing, and the designation is largely in common use in many textile printing works today. In a more general sense (bleaching, dyeing, finishing), the professional term “textile chemist” is used.

Colour kitchen Work room for the preparation of print paste thickening and the formulations of colour pastes (Fig. 1). The way in which the colour kitchen is organised in many cases determines the productivity of the entire printing plant. Economizing in investment here is definitely false economy. A rotary printing machine running to capacity can e.g. achieve up to 5000 kg/h colour paste consumption, i.e. approx. 80 t printing paste are required in two-shift operation, for which e.g. approx. 1.5 t thickening powder must be processed. This significant amount of printing paste is under normal circumstances divided by on average 6 colours per colour design and pattern. Depending on the number of colours of the printing machine, there must be at least two printing paste containers of corresponding volume. The first container serves to feed the printing machine, and the second to prepare new printing paste. In addition a number of containers of differing volumes is required in order to formulate the appropriate quantities of printing paste economically. Care should be taken that containers with stirrers fitted must be charged with at least $^{1}/_{4}$ of their possible volume in order to ensure perfect processing of the print paste; i.e. a 3000 l tank must have a minimum of 1000 kg of printing paste, and a 1000 l tank a minimum quantity of 300 kg. It must be possible to alternately charge and combine the containers from one to the other, i.e. the containers should be inter-connected by pipes. To effectively manage the transport of the large amount of printing paste and the associated quantities of dyestuff, auxiliaries and thickeners, a system of pipes is used. The chemical storage, in the form of a tank, the dyestuff store in the form of containers, the weighing area, the solvent and paste formulation station and the metering station also form part of the colour kitchen.

Chemical store: Larger containers which can be refilled from the tanker are generally used for the chemical store, containing approx. 3–5 t. The store for fluid products is generally specifically arranged below the working level. The liquid products are transported to

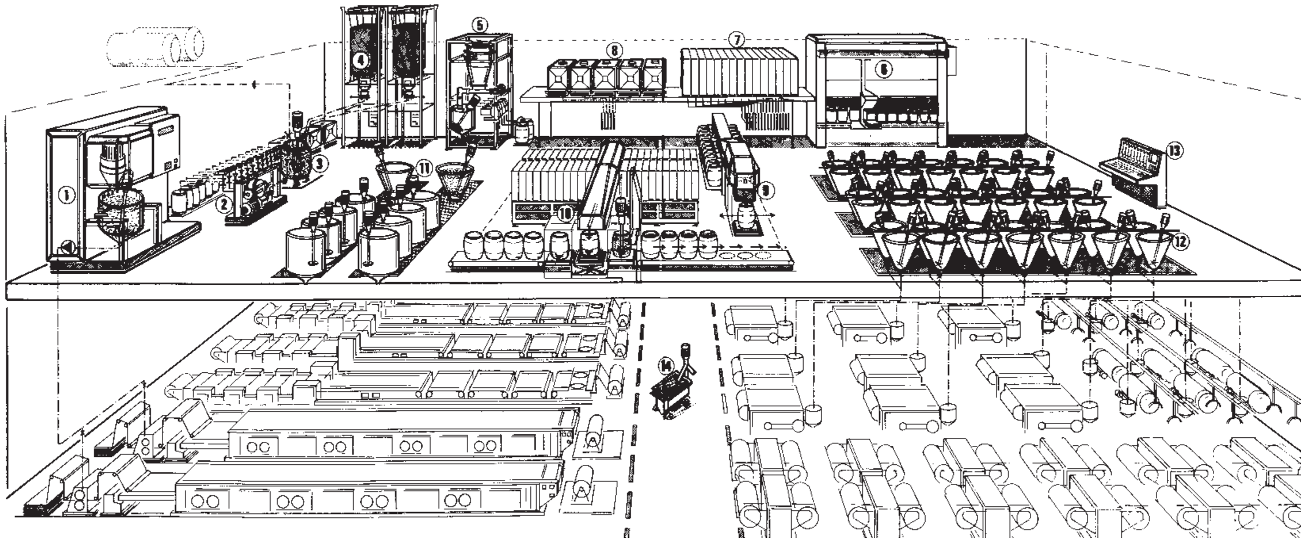

Fig. 1: Van Wyk printing and dyeing colour kitchen details.
1 = colour paste stirrer; 2 = metering unit; 3 = mixing tank; 4 = metering unit; 5 = sodium dithionite station; 6 = paternoster; 7 + 8 = chemical metering; 9 = small batch stirrer; 10 = paste metering; 11 + 12 = dissolving tanks; 13 = control cabinet; 14 = salt metering.

the working level or to the formulation station by means of feed pumps. The pipework is made of plastic. Glass fibre reinforced polyester resins, if necessary with polyvinyl chloride lining are gaining in importance as a material for this type of formulation vessel. The position of the filling station on the outer wall is particularly important so that filling can take place directly from the tanker. Chemical metering takes place in so-called measuring cylinders or plastic containers (suitable for chemicals). The quantities are accurately measured by shared metering pumps. Dyestuffs and auxiliaries are delivered in solid and liquid form in sacks, barrels, containers and tankers. The supply of salt, required for dyeing cotton with reactive dyestuffs, has developed to the point where salt is delivered using large bulk food transporters, storage takes place in large volume and space-saving storage bins. It is transported from here to the dyehouse by means of screw conveyors. In many dyehouses, brines produced in-house are used. A concentrated salt solution, the so-called brine, is manufactured in large basins and is then metered via pumps to the relevant areas where it is required.

Dyestuff store: The main store for the dyestuff required is chosen to ensure its smooth transportation. The climatic conditions (cool and dry atmosphere) of the store is adjusted such that the products cannot bond together or clump together. The dyestuff store should be set up in a manner which facilitates the handling of the fluids. A variety of packaging is available for liquid dyestuffs: barrels, canisters, cans or containers. With cans, a larger opening than with canisters is preferred so that a small mechanical agitator can be used for stirring. As moisture must be avoided, the dyestuff store is separated from the actual colour kitchen where the dyestuffs are weighed out and dissolved. When storing dyestuffs and chemicals, specific guidelines are to be observed to avoid certain risks. It is not universally known that dye powders are highly flammable. Dye powder fly is also toxic under certain circumstances.

Weighing area: The weighing area and dissolving plant should if possible be situated close together. In the intermediate storage, paternoster systems or dyestuff carrousels have proved their worth compared to stacking shelves. In the weighing area, the heart of a colour kitchen, electronics have revolutionised weighing. A significant factor in the successful reproduction of dyeing processes is the precise adherence to the quantities of dyestuff and chemicals prescribed in the recipe. Electro-mechanical scales connected to a computer are used.

Dissolving plant: This is a working area in which the dye solutions and print pastes required for dyeing and printing textiles are prepared. Efficient production operations have central mixing and dissolving plants equipped with state of the art equipment. Walls and floors have ceramic tiles. Slatted floors above the floor help to increase cleanliness and prevent accidents. The actual formulation station consists of groups of containers which correspond to the machine types and assemblies. Each production machine should generally contain at least one dissolving tank to avoid periods of overlap and waiting time in the formulation and feed stages. The force of gravity aids the transportation of formulated liquors through glass pipes.

Automatic dye metering plant (Fig. 2): The process requirements of dye metering plants have increased considerably, as substantially higher precision is re-

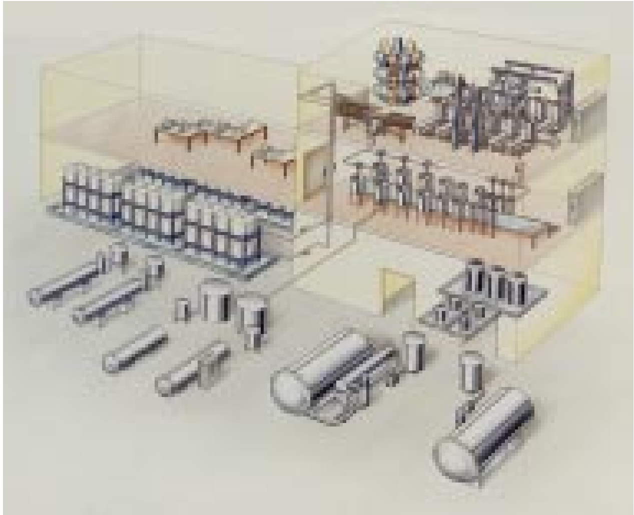

Fig. 2: Colour kitchen for open-width dyeing.

quired. To achieve this aim, a metering combination is used. The metering head can be fitted with two or three metering devices. The working volume of the metering devices used is fixed at 0.1 over 1.0 to 10.0 cm^3 per stroke. A distinction is made between a central valve arrangement with stationary scales and valves arranged in rows with movable scales. Three-stage dye metering valves can be arranged in groups or in rows and thus be adapted to the spatial requirements. A distinction is made between the following metering systems:

a) pump metering using volumetric pumps;
b) metering where the weighing receiver is installed securely,
  - with rotating metering head
  - in annular form securely mounted ("cluster");
c) linear metering with movable scales;
d) combination of the above systems for dye houses and finishing.

Purely gravimetric plants: This method is dependent on a number of parameters which can be defined as follows

a) inner precision of the scales;
b) external influences on the scales (vibrations, air blasts etc.);
c) type of metering valve.

Scales must achieve the required precision tolerances. First, it is necessary to define the over-run. Without wishing to go into the details of the laws which influence automatic metering, the significance of the following factors should be emphasised:

- the product rheology,
- the metering quantity,
- the relative height between the container and the metering valve,
- the inertia of the scales.

This operation requires the correct software. In gravimetric metering in practice, there is the problem of over-run: The flow dynamics cannot be interrupted abruptly without a slight surplus. A classic gravimetric device is composed predominantly of a liquid feed pump. When choosing such a pump, it is important to note that this must have a constant feed capacity. An elegant technical alternative is possible by choosing a pump capable of precise feed capacity by means of computer-control. Regulation of the feed capacity can be optimised by adjusting the main metering slide valve, altering the inflow to a greater or lesser extent to adjust the feed capacity of the pump.

Volumetric metering: This can be divided into two categories:

1. Volumetric metering using metering pumps: Due to the high costs involved in achieving sufficient precision, metering pumps are not used where several components are to be metered. Metering pumps can only be successfully used when precision is not an important factor and when average production rate is required.
2. Volumetric metering using impulses: With this method, the product to be metered is introduced into a calibrated chamber before being released into the processing container. An example of this is piston metering. This permits a 100% metering or a multiple of this metering by repetition. A method derived from this principle consists of using several metering chambers (modules) of varying volumes in order to achieve metering of different volumes, e.g. 110, 10.1 and 0.1 cm^3. Thanks to this system, a high degree of precision can be achieved. With a metering module of e.g. 100 cm^3 the tolerance is ±5%, which corresponds to 0.005 cm^3. The rheology of the products naturally impairs the smallest possible metering quantity.

Gravimetric-volumetric metering: A combination of both the systems discussed above. This enables high and precise performance to be achieved, taking advantage of the benefits of both basic methods. In practice, it should be noted that gravimetric-volumetric metering sometimes eliminates one or more work stations. It is possible to achieve metering of e.g. 0.1 cm^3 on one work station when a batch of 1 t is being metered.

The textile industry requires a high degree of precision from colour kitchen manufacturers on the one hand, and on the other a high performance (speed). Even in order to dilute dyestuffs, it is necessary to be able to meter very small quantities, if possible, smaller than or approximately 0.1 g. These conditions lead inevitably to a volumetric-gravimetric solution.

Colour kitchen installation (for printing). Machines and equipment for the preparation of print pastes, e.g. boiling kiers for thickening agents with or without stirrers, sieves and screens, vacuum filter machines etc.

Colour lakes Metal-dyestuff compounds which arise e.g. during cationic dyeing and mordant dyeing processes or when developing dyes using metallic salts (→ Chroming of dyes). The low solubility of this type of compound and their strong adhesion in or on the fibre determines the relative high fastness to processing and wear resistance of such dyes. Pre-prepared colour lakes are → Colour lake substances.

Colour lake substances Partially water-soluble dyestuffs, and also frequently not real dyestuffs, but → Colour lakes, and then correctly subordinated to → Pigment colorants. Use: dyeing lacquers, plastic masses, metal foils etc. Frequently in pigment printing (flock, lacquer and porcelain); dyeing coating masses; for spraying and stencilling (edging) coir matting etc.

Colour location (Colour point). The → Chromaticity diagram includes colour locations of different → Type of colour. Colour locations of the same shade are located on straight connecting lines between the achromatic point (= colour location of the physical ideal white) and the demarcations of the chromaticity diagram. As the hue moves away from the achromatic point, the colour becomes more saturated.

Colour manipulation The work of a colourist in the printing plant also includes determining the colours used in a design. Of the many colours that can be perceived by the human eye, he must select the ones which best suit the design he is preparing and harmonise these with one another. Fashion, trends and market developments must be taken into consideration. His choice determines the success of a specific design. There is also the problem of increasing time pressure due to the fact that different collections are being released in more rapid succession. If 5–6 collections are to be brought out every year, it must be possible to decide which designs and which colorations go into production quickly and sensibly. The modern colourist cannot allow designs to be printed without control. The time pressure already mentioned together with financial considerations force him to make a selection in advance. For these reasons, it is logical that there is a need for computer systems that support the colourist in his work (Fig.).

Colour manipulation is integrated into the system: Design (e.g. purchased); this design is taken into the computer system using a scanner; Colour and form are manipulated on-screen, the design is printed out on paper or fabric as a strike-off for approval, recipes are formulated for the printing plant (colour physics); weighing-off of the dye pastes in the colour kitchen and printing in the print area.

1. Reading-in: A creative draft on textiles or paper can be read-into the CMS-2000 system (Stork) in two ways: firstly with the aid of an online connection to a scanner and secondly by reading-in digital information from a videodisk which has been produced e.g. by the engraver.
2. Reducing: When a design is keyed in, the number of colours can be reduced, the number of half tones defined and the overlap determined. The Stork CMS-2000 system can carry out these processing stages.
3. Coloration: After reduction or reading-in the actual work of composition of the colours can begin. The user can call up thousands of different colours using the CMS-2000 system and assign these to the design. When selecting the colours, several colour charts stored in the memory can be used.

Colour Atlases provide various colour models such as RGB, CIELAB and HSV. The various colour atlases can be matched to dye groups, substrate, client, season etc. This enables the colourist to work quickly and selectively for various clients or target groups. The user can compile these colour atlases himself and make changes where necessary. If a spectrophotometer is connected to the system, colours can be measured with greater accuracy and these colours can be added to the colour atlases. During the colouring process, a selection can be made from the various colour atlases and these can be added to colour cards. These colour cards can be displayed on the screen with the colour atlases if required. With the aid of the printer, it is possible to print out colour atlases on paper or on fabric with Stork ink jet printing which implies that the system automat-

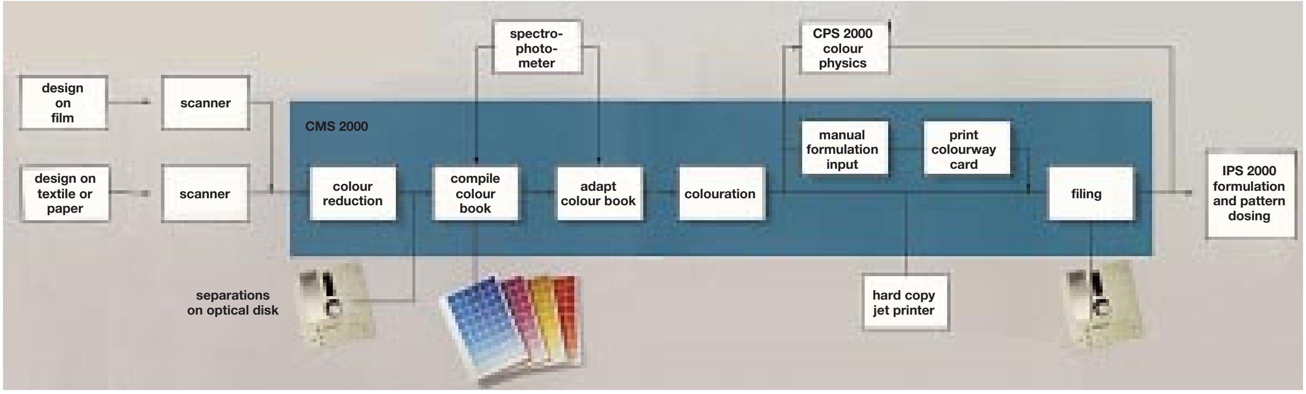

Fig.: Colouration in the printing system (Stork).

ically adjusts the colours used by the printer. The client receives a total overview of the possible colours. This provides the client with the opportunity to state which changes he would like. After compilation of the various colorations, this information can be printed out or stored on the videodisk for archiving. The information can also be transmitted to the Stork Screens Image-3000 engraving system.

Colour matching lamp This is used for colour matching with a specific illuminant. The most common example is the → Xenon arc lamp. With inert gas high-pressure discharge lamps, e.g. the spectral energy distribution corresponds almost entirely with that of the cloudy sky and the solar radiation and shows a practically constant light. This type of systematic illumination is therefore suitable for → Colour matching of dyed/printed samples.

Colour matching of dyed/printed samples Comparison of dyed materials to a standard sample. Usually takes place in colour matching cabinets under specific lighting conditions, D_{65}, TL 84, (→ Standard illuminants). In order to support subjective visual colour matching, colour measuring devices are usually used. Some colour matching still takes place in daylight (north light, walls and equipment in neutral grey). Problems are revealed using different sample surfaces (e.g. glossy, textured etc.) and the matchers' different subjective sense of colour (deviation from normal colour perception).

In order to remove the influence of the varying composition of daylight (see Fig.) on colour matching, standards and dyeing samples are viewed under technical light sources. Here the colour matching cabinet has the advantage that it narrows the colour matcher's field of view to the area that is important for colour matching, and shuts out the surroundings that affect colour perception. Daylight lamps or xenon colour matching lamps are used in colour matching cabinets.

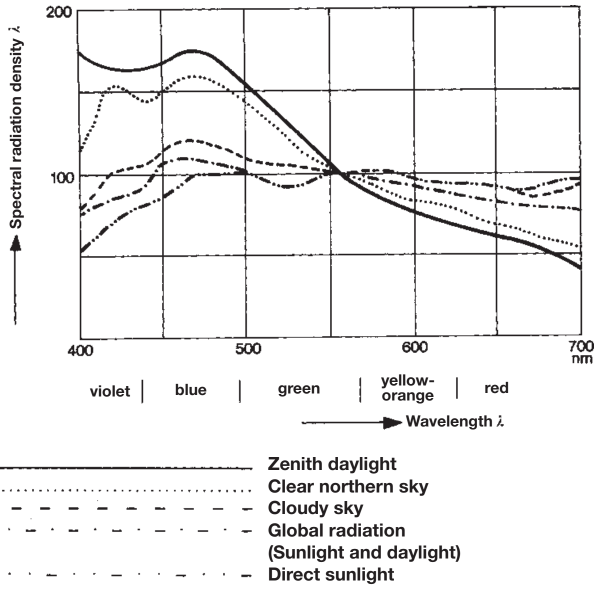

Fig.: Relative spectral radiation density distribution of natural daylight (source: Taylor and Kerr).

I. Daylight lamps: these provide extremely good colour reproduction characteristics, since the relative spectral energy distribution is adapted to the daylight phase D_{65} (colour temperature 6500 K). The Original Hanau daylight lamp is designed to be suspended from the ceiling. It is housed in a special anodised aluminium reflector. 2 special neon tubes with an output of 40 W provide the radiation source. The relative spectral energy distribution of the radiation, which remains constant over the entire lifetime of the neon tubes, is particularly beneficial. The manufacturer recommends replacing the neon tubes because of intensity fluctuations after 2500 hours of operation. Special mention must be given to the low operating costs of the radiation source with an output of just 80 W and immediate readiness for use, since no warming-up time is required. The operators do not have to put up with smells or heat since neither ozone not nitrous oxide are formed, not does heat radiation occur.

Entire rooms or material webs can be illuminated using the daylight lamps, e.g. examination tables, tensioning machines, printing and coating machines. The light intensity is 1150 lux at a distance of 80 cm from the material and with an illuminated area of 18 x 81 cm.

II. Colour matching lamp: The colour matching lamp can be used where high qualitative demands are made of the daylight phase D_{65}. The radiation source also efficiently adapts itself to the daylight phase D_{65} in the UV range. This means using colours that also absorb radiation in the UV range during colour matching, because they contain white colours (optical brighteners), for example, or when illuminating white materials. In the above-mentioned field the xenon colour matching lamp has benefits compared to the Original Hanau daylight lamp. D_{65} daylight has been standardised for colour matching in the spectral range of 300-700 nm in the German standard 6173 in the FRG. This standard assigns colour matching lamps to quality categories with regard to adaptation of the spectral distribution to standard light type D_{65}, whereby adaptation in the UV range is also evaluated. For this reason the colour matching lamp complies with quality class 1, whereas the daylight lamp is assigned to quality class 2. Other points concerning the colour matching lamp must be highlighted:

- the light intensity is 2500 lux in the centre of an illuminated area of 25 x 25 cm with the colour testing lamp at a distance of 50 cm from the observation plane.
- the colour testing lamp is supplied with direct current via the fluorescent lamp transformer so that the spectral energy distribution does not change when

mains power fluctuations occur. This guarantees colour reproduction conditions that can be repeated time and time again.

- the device consists of a housing with a 150 W Xenon radiator, an ignition device and a fluorescent lamp transformer and rectifier. Light types D_{55} (colour temperature 5500 K) and D_{75} (colour temperature 7500 K) can be realised using appropriate adjustment filters. Preference should be given to the use of a xenon colour matching lamps if only absolute balancing of artificial radiation to global radiation is expected during the colour testing of white materials and dyes with absorption in the UV range.

III. Colour sampling cabin: the colour sampling cabin contains 4 types of radiation for comparing colours under optical conditions, such as those occurring in daylight, standard light A (evening light), department store light or long-wave UV radiation. This universal arrangement allows metameric colours to be investigated by observing them under two different types of light and simulating department store light conditions. Furthermore, the UV radiation sources allow fluorescence appearances to be checked in fibres, dyes and all materials treated with optical brighteners. The Variolux colour sampling cabin is also a UV analysis lamp.

The 4 types of light in the colour sampling cabin:

- daylight with a colour temperature of 6500 K, good adaptation to standard light type D_{65} and an illumination intensity of at least 1000 lux.
- standard light type A (evening light) with a colour temperature of 2800 K and an illumination strength of approx. 3000 lux.
- department store light, a cool white fluorescent light with a colour temperature of approx. 4400 K and an illumination intensity of approx. 2000 lux.
- long–wave UV radiation with the maximum radiation intensity of approx. 0.1 mW/cm^2 at a wavelength of 360 nm.

The specified illumination intensities apply for an illuminated area of 80 x 60 cm at a distance of 80 cm from the material. In order to avoid intensity fluctuations the manufacturer recommends replacing the lamps after 2500 hours of operation. All 4 types of light have a separate time recorder. Other features of the colour sampling cabin should be mentioned:

- the light types are mutually interlocked in order to avoid mixed light if erroneous operation occurs.
- the UV radiation can be separately adjusted or added to any other kind of light.

The Variolux colour sampling cabin is used in the textile, paint, plastics and car industries and by material testing bodies.

Colour matching to pattern The dyer's principal aim is to produce, using the dyestuffs available, problem shades that are a perfect colour match to the pattern. This aim is to be achieved not after several attempts but first time, even for each new dye formulation. A change in the dyestuff batch or source should not be noticeable.

As colour is a sensory perception, all its intrinsic significance must be detectable by the human eye. On the one hand colour differences that are undetectable to the eye are meaningless; on the other hand colour differences that the eye recognises with any degree of clarity are also to be rejected. Hence the requirement that variations in dyeing strength and shade within the tolerance range must not give rise to noticeable colour differences. It is important here to specify objectively what a detectable or acceptable colour difference is.

One of the basic tasks of → Colour measurement is to help determine colour differences. Determining the colour differences from physical measuring data is a complex task, because the colour vision of the human eye must be simulated. Of the various colour difference formulae in existence the CIELAB formula in its modified form of CMC (2 : 1) can be used. Therefore it is used for making estimates. A value of 0.3 units is applied as a limit value for a colour difference that can still be tolerated. This value is only a guide value. It must in no way constitute a generally accepted tolerance, since in practice the tolerance range (limit of acceptability) depends on requirement, substrate/item and shade.

By calculating the colour recipe it is possible to investigate the effect of the colour strength tolerance on the dyed result. Starting from a reference shade the resulting deviation from the reference shade is calculated by varying the concentration of the dye.

The "acceptable" variation in dyeing strength can be read directly off the boundary line $\Delta E = 0.3$.

In the case of single dye shades, for 10% variation there is colour interval of a maximum of 0.7 CMC (2 : 1) units, that is a value for the "acceptable variation" of approx. 4%. This intrinsic significance is based on calculations using a number of dyes of different shades and different brilliancy. The effect of the colour strength is somewhat less for yellow shades and generally somewhat greater for matt colours. For mixed shades the effect is, as one would expect, greater, by approximately a factor of 2–2.5 maximum.

It depends on the colour range (colour location) how sensitive the effect of the colour strength variation is. In the range of saturated colours the effect is hardly greater than for single shades; it increases inversely, i.e. in the direction of unsaturated colours, and is most pronounced for almost neutral shades, i.e. for grey (source: Broßmann).

Colour measurement This is used to determine the chromatic impact (→ Colour stimulus) of body colours, coloured fluids etc. The purpose of colour measurement is to establish the term "Colour by means of

Next Page

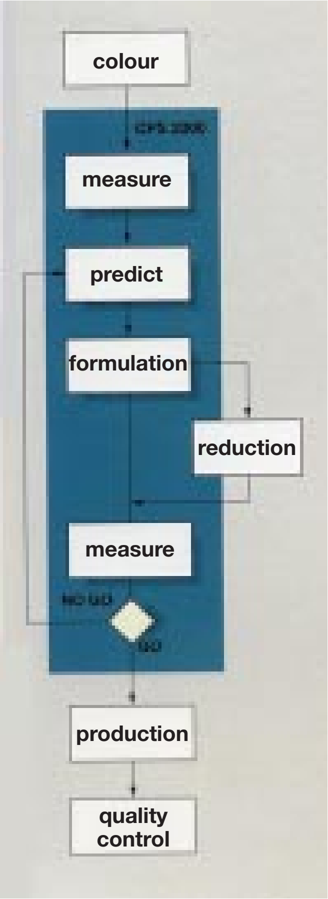

Fig.: Stork method of colorimetry in printing for checking a print colour produced with a colour model with the possibility of correcting printing paste formulations.

reproducible variables", i.e. → Colorimetric measures. Obviously any attempt at establishing exactness in colorimetry needs to be based on important working rules (DIN standards), with matters such as colour and contrast vision (→ Adaptation) also being taken into account in subjective colour measurement. The methodology of colour measurement (see Fig.) is defined by a wide variety of measuring devices and procedures. The operating principle and numerical assessment of these tend to vary from one to the other to a greater or lesser extent. Depending on the requirements, either photometric or visual comparison measurements can be selected. This results in either subjective or objective colour measurement.

Objective methods use physical measuring methods followed by valency evaluation: they eliminate interfering effects to a large extent and are therefore the most accurate and offer easily transferable internationally accepted colour measurements (CIE tristimulus values or CIE chromaticity coordinates). It is also possible to transfer these into monochromatic colour coordinates which can be understood in practice as fundamental calculations for colour matching tolerances as well as between sample and dye bath. A distinction should be made between the following:

1. Spectrophotometric methods measure the luminance factor or the transmission factor of tested dyeings, dyestuffs or dye baths using spectrophotometers (monochromatic or trichromatic). This method only requires a small quantity of the specimen, though it generally requires expensive equipment.
2. Brightness methods measure the comparative brightness against ideal white as a luminance factor that can easily be converted into CIE tristimulus values by means of successive photometry through three colour filters. Due to the difficulty of filter designs that correspond exactly to CIE spectral distribution curve, the accuracy of the spectrophotometric method is generally not achieved, and the accuracy of eye sensitivity is only achieved in special cases.

Subjective methods work empirically on the basis of comparison. They therefore require the observer to have correct colour vision and brightness response in the eye. It is also always dependent on the spectral difference in colour stimulus, although not only on colour stimulus specification as is the case with the objective methods.

1. Visual colour matching methods measure an unknown colour photometrically through coloured filters with known comparative values that are mixed additively in the measuring device. The mixing ratio read from the device gives trichromatic (standard values) or monochromatic colorimetric measures depending on the scale. A variant is the compensation method in which the measurable additive mixture is compensated to neutral (half-shadow photometers according to Ostwald); white and black content measurements can naturally also be carried out using the same principle.
2. Colour atlases are used to make subjective direct comparisons with patterns with known measured values.

The practical application of colour measurement in textiles must be decided for each individual case taking into account the required measuring accuracy that governs the choice of the method and its limitation. However, it continues to gain in importance even if it is not possible to totally replace assessment and valuation of colours by the human eye. From the wide range of applications, the following examples should be mentioned: creation of ordering systems for colours, colour formulations etc.; presetting new formulations; stipulating colour tolerances for pattern conformity; operational testing of differences in shade depending on the type, trend and degree of deviation; colour tests, determination of dye solubility, dye concentration, dye resistance, dye affinity, the effect of aftertreatments and loss of fastness, as well as degree of scouring and bleaching etc. Colour measurement also has its limits however. These concern personnel, size of samples, sample structure, multifilament yarn mixes, special dyestuff categories, variations in shade and end test. → Colorimetry.

Previous Page

Colour measuring instruments These are spectrophotometers and consist of four basic elements: light source, sample holder, monochromator (filter, prism or grating) and photocolorimetric receiver. The light from the lamp falls on the sample and the white standard (ceramic, porcelain, opal glass or barium sulphate) that are measured under the same lighting and observation conditions (measuring geometry). Classification:

I. Triple (zone) filter photometer for colour measurement using the brightness process (Fig. 1): The light reflected from the sample and white standard is measured consecutively with three filters. Sensitivity distribution of the filter/receiver system corresponds to one of the CIE spectral distribution curves $\bar{x}$, $\bar{y}$, $\bar{z}$ (sensitivity of the human eye). As the source of light always supplies standard illuminant, the CIE tristimulus values X, Y, Z for this standard illuminant are always obtained directly. The majority of devices operate with standard illuminant D 65. Photoelectric cells or photoelectron multipliers with constant sensitivity over a long period of time are used as receivers (the long-term consistency of the equipment is dependent on this). Suitable for all measurements where CIE tristimulus values X, Y, Z do not need to be very precise, e.g. to recipe correction, for dye house production control, assessment of degree of whiteness etc.

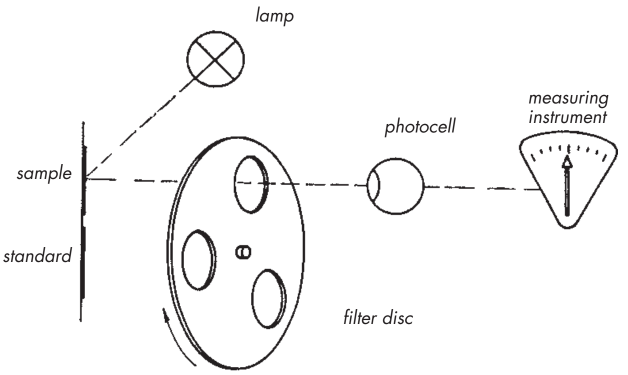

Fig. 1: Diagram of the Triple zone method.

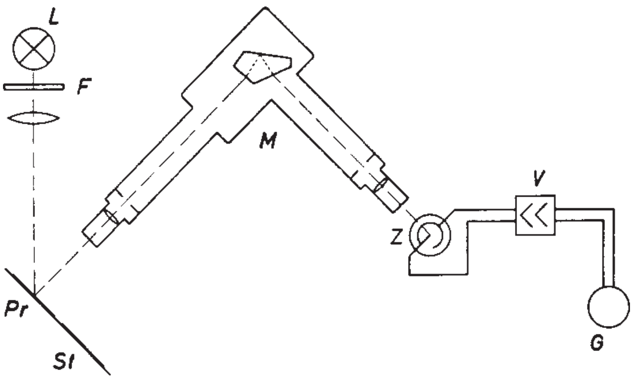

Fig. 2: Diagram of the spectrophotometric colour measurement.

5 = measured light; 6 = photometer flash; 7 = light barrier and movement sensor; 8 = metre counter; 9 = moving fabric;
10 = computer; 11 = printer.

II. → Spectrophotometer for colour measurements using the spectrophotometric method (Fig. 2). This is the most accurate method of colour measurement. It takes place in two stages:

a) Spectrophotometric measurement to determine the spectral energy distribution and b) calculation of the actual colorimetric values. The first stage is a purely physical measurement that is often carried out outside the visible spectrum (IR, UV) for analytical purposes. The second stage is an assessment using the colour vision function of the human eye. Using the spectrophotometric method it is possible to measure the colour of primary light sources and the colour of non-self luminous colours reflected from or transmitted through an object. Colour measuring instruments on moving conveyors are also available (Fig. 3).

Colour migration on drying → Dye migration in drying.

Colour mixtures A distinction is made between additive and subtractive mixing.

I. Additive or optical colour mixtures arise from the almost simultaneous overlay of colour stimuli perceived by the eye that are therefore perceived as one colour. Example: If a beam of white light is passed through a blue filter and a yellow filter side by side, then both coloured beams of light produce white once again when they are recombined. Evidence: the complementary colour, yellow, absorbed in the blue filter now supplies the yellow filter, which has absorbed the complementary colour of blue, so both beams of light when mixed contain all the colours of the white spectrum and therefore must give white light. The theory follows: two colours are complementary when white is formed from their additive mixture. This only applies to respective colour stimulus specifications, not to the spectral nature of the colour stimuli. By additive colour mixtures, a linear relationship can always be formed between four colour stimulus specifications. This is based on the adjustment of uniformity of colour mixtures made up of A, B, C, the results of which can be predicted as a sum of the colour equation. Specific colour measuring devices (→ Anomaloscope) are used for the experimental adjustment of such colour equations.

II. Subtractive or material and substantial colour mixtures arise by directing a beam through several coloured bodies. The beam is altered between each body. Examples: Production of a green colour from blue and yellow dyestuffs. The same occurs if a beam of white light passes through a blue and a yellow filter consecutively: first the complementary colours yellow and red are absorbed (blue filter) and then blue (yellow filter), with the result that only green remains. Subtractive colour mixtures (in contrast to additive colour mixtures) are therefore dependent on the spectral nature of the components, the colour stimulus specifications of which are therefore not able to give information concerning the colour stimulus specification of a subtractive colour mixture.

Colour mixture triangle Chromatic concept; when a shade is to be dyed in trichromatics, i.e. in the yellow, red and blue shades, the dyes employed are arranged schematically in triangle form (Fig.), and as many intermediate shades as required are dyed within the triangle in gradations of the three dyes.

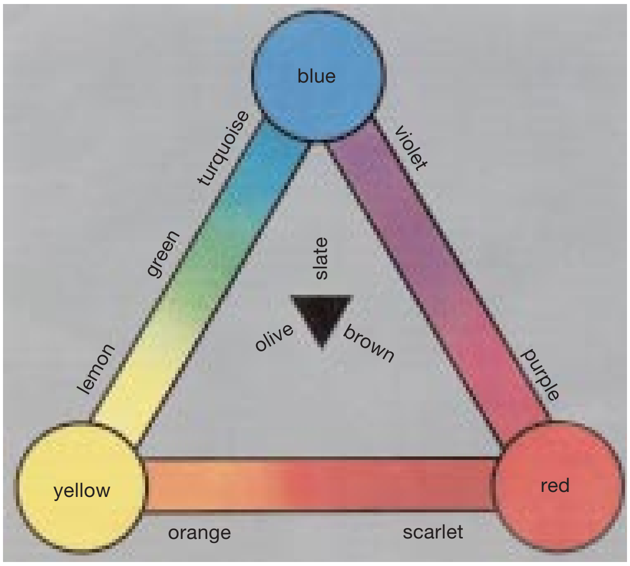

Fig.: Dyes colour mixture triangle for organising dyeings in accordance with the trichromatic process (Otto's colour mixture triangle).

Colour quality This is a term used in colorimetry for three-dimensional changes in direction of a colour relating to →: Hue; Saturation; Lightness.

Colour sample (Sample pattern). Colour sample as per order for →: Sample dyeing; Colour matching of dyed/printed samples.

Colour sampling device Used for testing dyes, textile auxiliaries, flat screens, working methods, electrically operated doctor blades for the laboratory, etc.

Colour saturation (depth of shade) → Saturation.

Colour scanner → Scanner as a piece of electronic equipment for reproduction technology. The structure of the colour scanner for paper printing is essentially adapted to trichromaticity (+ black = quadrochromaticity) and is generally used to produce coloured output on films.

Colour screen → Screen.

Colour separation,

I. This is a process in the automatic production of colour separation from a multi-coloured sample with the aid of a scanner. After passing through a sampling drum, the coloured beam of light is captured by an optical head which disperses it via screens, prisms, interference filters and colour separation filters into 3 reference beams in yellow, red and blue.

II. Transfer of individual colours from a colour submission to the printing rollers and/or screens from a pattern submission in textile printing. Manually prepared, it is a time-consuming operation. Resolution of the original pattern drawing as a pure contour film for each colour with the rest of the surface blacked out by hand painting.

Colour separation, electronic Colour separation as a fully automatic procedure with the aid of colour scanners utilising → Optoelectronics, shade and colour value corrected by colour computer and directly recorded onto a film via a printing head. Has the option of increasing or decreasing the pattern size as well as displaying motif and correcting partial images.

Colour simulator Represents hues for digital transmission that can be subsequently visualised or used as numerical values. Reproduction by numerical data on digital display.

Colour soiling,

I. Term with multi-colour printing machines for uncontrolled "migration" of dye from the printing trough into other printing paste containers, the affected dye soon reaching such a concentration that it soils other printing pastes, and changes the shade, which, at high fabric speeds, can easily reduce the value of large quantities of fabric. Colour soiling is ascertainable by adding radioactive tracers to the suspect printing paste. Located before the next printing roller is a stripping roller which tests the radioactive radiation of the stripped colour, and triggers off a warning signal at maximum deviation.

II. Colour soiling can occur in multi-colour roller printing if the rollers in the second, third and subsequent printing rotations pick up small quantities of moist printing paste on places which have not been engraved from fabric which has already been printed by preceding rollers. This paste then enters the dye paste trough via the dye paste applicator rollers. Remedial measures can be taken by a) fixing a counter doctor, b) attaching a water roller in sequence, c) adding chemicals in the dye paste trough which dissolve the dyestuff drawn in to the trough, but not that contained in it. The principle of roller printing should also apply: “The smallest dye (in terms of lightness and cover) should be in the first printing roller.”

Colour soiling test → Methylene blue method.

Colour specks → Specky print pastes.

Colour splashes Colour splashes due to the rapid lifting of a printing screen doctored with excessive printing paste. The cause is screen or fabric sticking, and the local splashing of printing paste on pulling loose.

Colour spray process This method was chiefly developed in non-textile sectors (such as facsimile copying, silent printers and typewriters). Activity in the textile sector has grown through multicolour fashion. The dye liquor is sprayed on to the fabric either in a random manner or according to a pattern.

Colour stimulus This is the luminous radiation recorded by the eye that, according to its energy distribution, stimulates the colour-sensitive cones (→ Colour vision). This colour stimulus is not sensory perception however, rather a radiation with colour stimulus function which must be converted into a sensation. The eye functions as a grid-like arrangement of three types of receptive organs each having different spectral sensitivity (→ Eye sensitivity to hue, chroma and lightness). Expressed mathematically, the eye now operates in such a way that it multiplies the colour stimulus function for each wavelength by the corresponding CIE tristimulus values $\bar{x}$, $\bar{y}$, $\bar{z}$ and obtains the three effects caused by integration as colorimetric measure coordinates X, Y, Z (→ Colorimetric measures), which then combine in the perception of a uniform colour effect, the colour stimulus.

Colour stimulus specification Determined as a consequence of “colour stimulus function” when comparing two colour stimuli (→ Colorimetric measures). The colour stimulus specification is particularly significant in regard to the nature of the shade of so-called additive colour mixtures.

Colour temperature Thermal radiation, expressed in → Kelvin. As the temperature increases, the waves emitted become shorter. The colour temperature scale covers the entire wavelength region from infrared to ultra-violet. Short wavelengths (bluish light) have a high colour temperature, long wavelengths (reddish light) a low colour temperature.

Colour tolerance This is an allowed colour deviation from a standard.

Colour transfer belt Used in Vigoureux printing to transfer the print paste from the frame to the engraved roller.

Colour triangle,

I. → Chromaticity diagram.

II. Triangular classification of colour patterns, in which the standard dyeings of selected dyes occupy the corner points of a colour triangle. In the colour triangle illustrated (trichromatic dyeing) these are e.g.: yellow, red, blue (Fig.). The numerical values relate to the percentage applied for each dye in the combinations and each colour pattern consists of the 3 values, % yellow dyestuff + % red dyestuff + % blue dyestuff. In the example all dyeings are set up for a total of 1% dyestuff. The proportion of relevant dyestuff therefore decreases as the distance from the corner point in question increases, which greatly simplifies the patterning.

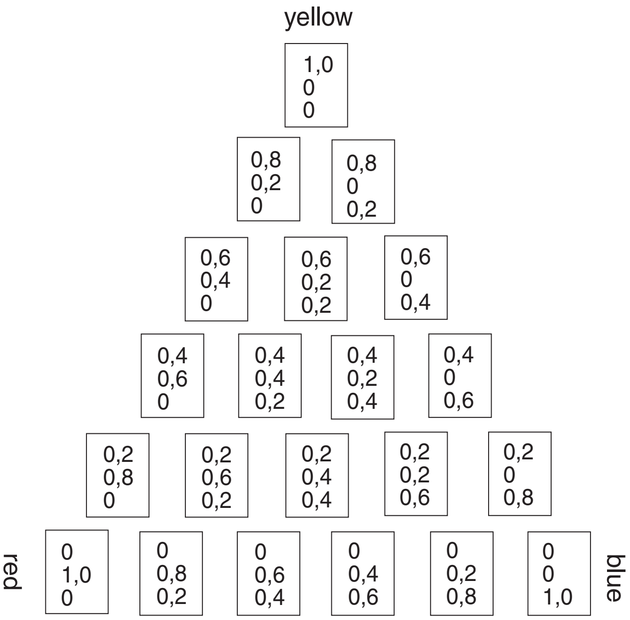

Fig.: Colour pattern classification system in the form of a triangle.

Colour trough Contains the printing paste on printing machines or dye solution on dyeing machines. Usually made of copper or stainless steel.

Colour vision Light entering the eye falls on the net-like arrangement rods and cones of the optic nerves (retina) causing → Colour stimulus. The eye functions as follows:

1. Colour sensitive cones (approx. 7 mill.) lie within a 2° radius of the vertical angle of incidence where the actual colour vision occurs. Each of these cones has a selective sensitivity to blue, green or red, so each → Colour arises from a multitude of individual points consisting of a mixture of the 3 primary colours.

2. Lightness-sensitive rods (approx. 120 mill.) cover the entire inner field of vision of the retina and only trigger light-dark perceptions, i.e. non-coloured lightness vision. In e.g. only poor light, the function of the cones and especially the blue sensitive ones are minimal. The disturbance to the ability of the cones to function causes → Defective colour vision. (→ Eye sensitivity).

Colour way,

I. Colouration, colour effect.

II. Textile printing: colour composition with the number of colours determined by the design. Any required number of colourways can be produced per design.

Colour wedge In flat-screen or rotary screen printing, a wedge of print paste is built by the action of the squeegee (→ Squeegee contact angle). The squeegee pressure is important in controlling the push-through of the colour wedge.

Colour yield Quantity of dye fixed on the textile substrate in % by weight of the quantity of dye used.

Column type metering stations → Metering system with proportioning cylinders.

Comb doctor Version of a → Doctor roller, in which a flat doctor blade has comb-like indentations.

Combed top Semi-finished product of → Worsted spinning. Sliver-like web of parallel wool fibres obtained after passage through the so-called comber. Combed top is frequently dyed (in package dyeing machines or on perforated tubes in creel-type dyeing machines) and printed (vigoureux printing, top printing). Further processing in the spinning mill for fine worsted yarns (woven and tricot fabrics).

Combinability of wool dyes → K-value is determined by DIP tests on woven wool test fabrics at a constant pH of 4.5. To this end, the test fabric is pretreated with citric acid and disodium hydrogen phosphate (Na_2HPO_4) for 20 min at 98°C. The quantity of acid or buffer required in each case is determined in a preliminary test:

a) pretreatment: 1 l of Levatit water + 30 ml/l of 0.1 mol citric acid + 4 ml/l of Na_2HPO_4 50 g/l of solution. 6–7 test specimens of 5 g, 20 min at 98°C.

b) DIP test: 6–7 x 5 g material specimens in each case are dyed successively in 250 ml of a dye liquor containing different shades of dye. The shade change is visually assessed.

Standard conditions: pretreated woven wool test fabrics; two combinations, each of 1/1 RT and 5% sodium sulphate calc. pH 4.5 set with 2.15 ml of 0.1 mol citric acid and 2.3 ml of Na_2HPO_4 50 g/l solution. If complete bath exhaustion is required, the last test specimen is acidified during dyeing. 80°C with the first test specimens, 98°C with the others.

Combination bleach → Combination bleach process.

Combination bleach process The alternate action of hypochlorite or chlorite and oxidative bleaches with the aim of an improved and not subsequently yellowing maximum white with maximum fibre protection, as is possible with the aid of a single process. Sometimes a reduction bleaching process is also included.

Combination desize/dyeing A combination process which involves desizing in the dyebath. In individual cases, it is possible on the jig for cotton and blends of cotton with regenerated cellulose.

Combination desize/scour process A single-bath combination of desizing/scouring, particularly for wool and wool blends. Method: e.g. gently heat the liquor to 40°C, set the bath with the normal detergent concentration, add a diastase desizing agent; if necessary, add a fat emulsifying agent, then treat as before, rinse, etc.

Combination dyes Dyes, which are used together in the dyebath, and which exhaust in such a way that their concentration ratio changes little or not at all during dyeing, are easily combinable. Combination dyes should behave like “1” dye in the ideal case. Here therefore, the final shade is built up from the start of dyeing.

Combination milling Alkaline and then acid milling. Provides good felting and excellent handle. Alkali and acid resistant milling agents are necessary.

Combination pretreatment The classic continuous pretreatment of cotton and cotton blend fabrics takes place in 3 stages: de-sizing, boiling off, and bleaching. For some time now, for reasons of economy and ecology, intensive efforts have been made to shorten the conventional 3-stage process by combining it with other processes. Here, particular importance is accorded to the liquor application technique. At ITMA (the international exhibition of textile machines) in 1991, new technologies for combination pretreatment were presented. The Flexnip pretreatment concept (Küsters) provides for a combined boiling-off and bleaching process after a separate de-sizing with recovery of the sizing agent. The addition of the heavily alkaline bleaching liquor without liquor exchange, which takes place by means of Flexnip wet-in-wet, ensures even pretreatment results. A spraying technique using Raco-Yet (Ramisch-Kleinewerfers) makes it possible to achieve dye-ready goods from unbleached cotton fabric within 2–3 min in a single process step, regardless of the sizing agent applied. For this, large amounts of sodium hydroxide, hydrogen peroxide and stabiliser are used, as well as a specially developed multi-functional auxiliary.

Combination process Process in which two operating stages are combined (cost-saving). Examples: sizing + dyeing; desizing + bleaching; bleaching + optical whitening; bleaching + dyeing; shrinking + dyeing; non-crease finishing + dyeing.

Combination steamer In the process of alkaline steaming of cotton fabrics (boiling off, bleaching), in the swelling phase there is a risk of fixing creases; for this reason, the fabric must be guided through the steamer as free of creases as possible (see Fig.). This takes place with fixed cloth guidance via guide rollers. Since this method is very cost-intensive, due to the numerous rollers which in each case are held in expensive external bearings, fixed cloth guidance is abandoned as early as possible, i.e. towards the end of the swelling process, in favour of the cheaper free cloth guidance (laying on conveyor belt, roller bed or other systems). The combination steamer offers both types of cloth guidance: first the fabric passes through the rollers of the fixed cloth guidance system in the upper part of the steamer, and then it is flat-folded through a funnel slit and deposited onto the plaiting-down table. Here, it is necessary to turn the fabric package during plaiting-down at the half-way mark, to ensure even exposure to steam.

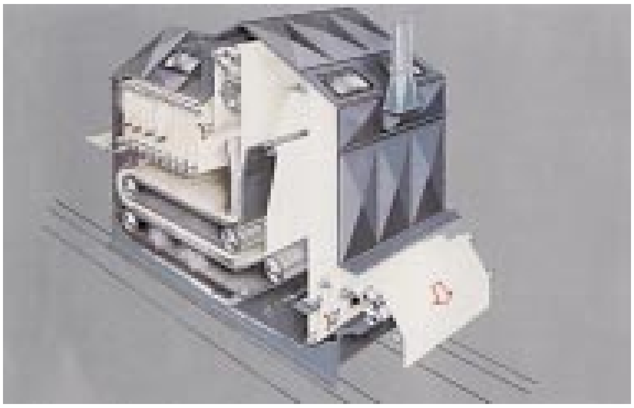

Fig.: Combination steamer (Küsters).

Combined dyeing and finishing Single bath fixation of dyestuffs e.g. pigment dyestuffs, selected vat and reactive dyestuffs (Procion Resin Process) and finishing auxiliaries, particularly for cotton and polyester/cotton.

Combing noils Short fibres separated out by combing in the production of → Worsted yarn.

Combining of print fabric Preparation of lightweight woven fabrics or highly elastic warp knitted fabrics for printing in order to avoid distortion or creasing. In roller printing, a picot or finely hatched roller is installed in the first place, applying adhesive to the endless blanket. In the second place, the first printing roller presses the fabric on to the endless blanket. In screen printing, it is combined on machines suitable for that purpose. Endless blanket and fabric are pressed together after the adhesive has been applied, dried, rolled up, and fed to the printing machine.

Combi-squeegee Combination of a magnetic pressure-application doctor roller and a print paste blade similar to a doctor knife in contact with it, the blade being attached to a print paste feed pipe. The combi-squeegee combines the advantages of both doctor types: effective nip and deep penetration. – Manufacturer: Joh. Zimmer.

Combi-Woolmark, → Woolmark for blend materials containing a minimum of 60% virgin wool.

Combustion Combustion is the reaction of a substance with oxygen (generally in the presence of an oxygen concentration equal to that of air), whereby heat is generated with a consequent burning or → Smoulder.

Combustion characteristics of fibres → Burning behaviour of textiles.

Combustion drying → Remaflam process.

Combustion factor (Substance/time), the amount of material burnt, based on the burn length, during the elapsed time (g/cm per min) (ISO).

Combustion gases Combustion is an oxidation process in which oxygen is used up. When the oxygen content of air falls below a certain value, there is a risk to life. If, for example, the O_2 content drops from 21% to 15%, humans are no longer in a position to escape unassisted. Such values are reached relatively quickly. If for example a large candle is lit in a space of 10 m^3, the O_2 content will drop to 15%. When organic material is burned, CO_2 and CO are evolved. CO_2 is not toxic, but if the CO_2 content in the air rises to 6–7%, even this is fatal. A CO concentration of 0.5% by volume has the same effect. Other toxic gases which can arise during the combustion and decomposition of organic material are HCN, HCl, H_2S, SO_2, NO_2 and numerous organic compounds such as acroleine, acetaldehyde, isocyanates etc. Particularly dangerous is hydrogen cyanide, which leads to death within a few minutes when it is present in the air at a concentration of 0.04% by volume. Testing of combustion gases for toxic compounds can be carried out in accordance with two methods, which are based on different principles:

1. Determination of the chemical composition of the combustion gases: This is generally based on the quantitative determination of the most important and most hazardous toxic compounds such as CO, HCN, HCl, SO_2, H_2S, NO_2 and CO_2. It has the disadvantage of not indicating exactly the connection between the chemical composition and the toxicity of the gas analysed. Whilst the toxic effect of individual compounds such as CO, HCN, $COCl_2$ etc. are well known , little is known as yet about the toxic effects of gas mixtures. The individual compounds may influence the effects of the other compounds, which may result in an intensification or attenuation of the toxic effect. Thus for example in the case of combinations of CO and HCN, synergistic effects were established, i.e. the result was more than an addition of the individual effects. In the case of mixtures of CO and HCl for example, on the oth-

fibre	Products of pyrolisis and combustion.
cellulose	CO, CO_2, H_2O, methanol, ethanol, furane derivatives, formic acid, acetic acid, formaldehyde, acetaldehyde, acrolein, hydrocarbons.
wool	CO, CO_2, H_2O, H_2S, SO_2, ammonia, amines, HCN, H_2, lower hydrocarbons (CH_4).
polyester	CO, CO_2, H_2O, acetaldehyde, benzoic acid, terephthalic acid, acetic acid, hydrocarbons, CH_4, benzene, vinyl benzoate, divinyl terephthalate.
polyamides	CO, CO_2, H_2O, mono and dicarboxylic acids, adipic acid, cyclopentanone, hydrocarbons, ammonia, amines, HCN, acetaldehyde, formaldehyde, caprolactam, benzene.
polyacrylonitrile	CO, CO_2, H_2O, CH_4, ammonia, nitriles, HCN, acrylonitrile, lower hydrocarbons.
polypropylene	CO, CO_2, H_2O, saturated and unsaturated hydrocarbons, propylene, pentene, ketones, acetone, ahdehydes, formaldehyde, acrolein, methanol, formic acid, acetic acid.
polyvinylchloride	CO, CO_2, H_2O, HCl, saturated and unsaturated lower hydrocarbons, CH_4, chlorinated hydrocarbons, vinyl chloride, benzene, toluene.
aramids	CO, CO_2, H_2O, saturated and unsaturated lowerhydrocarbons, acetaldehyde, acetone, HCN, NH_3, benzene, benzonitrile, acetonitrile, NO_2, toluene, acetic acid.
cellulose acetate	CO, CO_2, H_2O, acetic acid, methane, ethylene etc, hydrocarbons up to C_6, furane, vinyl ether, methanol, acetone, acetaldehyde, acrolein, ethyl acetate, benzene.

Tab.: The most important products of pyrolisis and combustion (combustion gases) of various textile fibres.

er hand, an antagonistic effect was found, i.e. the gases counteract one another, and to some extent have an ameliorating effect on their individual potential.

2. Performance of animal trials: Here, in general rats and mice are exposed to the combustion gases in a room of defined dimensions, and the behaviour of the subjects is recorded. This method has the advantage that (without knowing the composition of the gas mixture), the overall toxicity is determined directly on the living organism. The difficulties with this method and its defect lie in extrapolating the results from animals to humans. The effect which specific gases or gas mixtures has on experimental animals sometimes differs considerably from that on humans.

Even where there are clear differences in the toxicity of the combustion gases of different materials, this can hardly lead to a process of selection of textiles, since the fire hazard and the fire risk are co-determined by many other factors, including ignition temperature, combustion speed, smoke density etc. The toxicity of the combustion gases cannot be regarded as the main factor for the fire risk of a material. In the case of modacrylic fibres, for example, considerable amounts of toxic gases occur during decomposition. However, since the material is self-extinguishing, it prevents fires occurring or spreading, and thus also the formation of toxic gases. Wool creates considerable amounts of toxic combustion gases, and is among the less combustible fibres. The prime importance of low flammability with its protective action must not be ignored in the assessment. The table shows the most important compounds which occur in the combustion of the various fibres, and the strongest toxins are underlined or double-underlined, depending on their significance. This table can be used as an initial orientation guide to the combustion gas composition of different fibres (source: Einsele).

Combustion gases of textiles → Combustion gases.

Combustion heat per unit of time The amount of heat generated by a burning body during a unit of time.

Combustion index → Thermal value of fuels.

Comeback wool Wool from sheep back-crossed between crossbred and merino sheep.

Comfort factor (CF value). An index applied to pile carpets incorporating, along with pile mass and number of tufts, a factor quantifying the sensation experienced by walking on the carpet. This produces an objective index of the subjective concept of carpet comfort.

$$CF = 5 \cdot K_H + \frac{m_P}{100} \cdot \sqrt{\frac{NZ + 20\,000}{10\,000}}$$

K_H = tread value (according to Herzog)
m_P = pile mass (g/m^2)
NZ = number of tufts

In 1982 the formula was amended to distinguish between the comfort factor of a) “cut-pile” and b) “uncut pile” carpets:

$$\text{a) } CF = \frac{a_{20,P}}{5} \cdot \frac{m_P}{100} \cdot \sqrt{\frac{NZ + 20\,000}{10\,000}} + 5 \cdot B_i$$

$$\text{b) } CF = \frac{a_{20,P}}{6} \cdot \frac{m_P}{100} \cdot \sqrt{\frac{NZ + 20\,000}{10\,000}} + 5 \cdot B_i$$

$a_{20,P}$ = pile thickness over the carpet primary backing (mm)
B_i = → Tread comfort value (according to DIN 54327)

Comfort finishes Finishes applied to textiles composed of synthetic fibres to reduce the build-up of electrostatic charges and soiling, as well as to improve hydrophilic properties and soil release.

Comingled yarn In aerospace textiles, two or more continuous multifilament yarns, the filaments of which have been intermixed with each other without adding twist or otherwise disturbing the parallel relationship of the combined filaments. Usually consists of a reinforcing yarn, such as graphite or glass, and a thermoplastic matrix yarn. → Intermingling.

Comité International de la Rayonne et des Fibres Synthétics (CIRFS). International head organization of man-made fibre producers with headquarters in Paris, to which the German IVC (Industrievereinigung Chemiefaser) also belongs; → Technical and professional organizations.

COMITEXTIL, abbrev. for: Comité de Coordination des Industries Textiles de la CEE (Coordination Committee for the Textile Industries of the European Community), Brussels, Belgium. The national head associations of the various European Community countries as well as specialized textile associations operating at this level belong to this organization; → Technical and professional organizations.

COMMENTEX International Committee for Fabric Care Meetings, with headquarters in Paris; → Technical and professional organizations.

Commercial forms of dyestuffs The commercial form of chemical products, defined as physical form and composition, is responsible for essential application characteristics from the user's point of view. It is also used for dyes and chemicals in the market place as an essential tool for differentiation. Quality is guaranteed by testing the long term stability of powder, granule and liquid forms using testing and production methods e.g. diaphragm separation and granulation methods. The term commercial forms is also used to describe the overall physical and chemical properties insofar as they are recognised from the chemical plant to the finishing works. The commercial form affects all stages of the packaging, storage, transportation, recipe formulation and liquor preparation, as well as the use and application itself (→ Dyestuff formulations). The optimum commercial form for a particular range and specific area of application is determined by objective market research of selected customers. The priorities thus determined are, for solid forms, freedom from dust, good solubility and lump-free mixing, for liquid forms stability in storage and favourable viscosity and concentration values. The introduction of new forms and qualities is only possible taking account of the production stages from dye synthesis to despatch (Fig. 1).

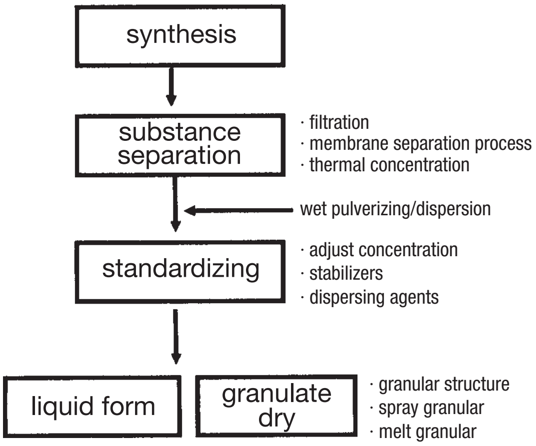

Fig. 1: Commercial dyestuff form production.

Promising requirement profiles of commercial forms generally require several stages of production processes. The additional operations necessary for the fulfilment of higher quality standards increase the cost of the finishing of the products, which accounts for 10 to 20% of the total production costs. Substantial developments have been made by various manufacturers in the production stage for solid forms. Areas for optimization include grain compactness and granule size to give fast distribution and good solubility. In the case of reactive dyes for cellulose fibres, regular improvements in improved constitution came on to the market, with improved ease of application stemming from criteria such as fixing properties, reproducibility, dye yield, ecology. Concurrently with these developments increased demands were placed on the commercial forms. Initially powders which gave off a lot of dust were used commercially; for reasons of working hygiene these were cleaned up with liquid antidust compounds (Fig. 2). The optimization of these require-

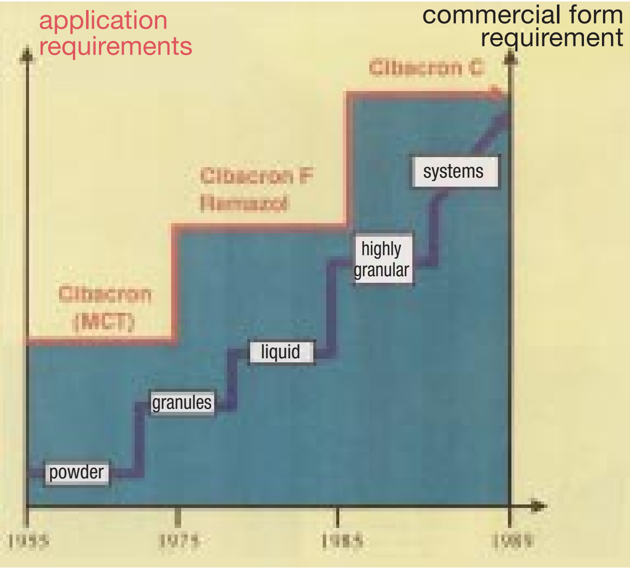

Fig. 2: Increasingly stringent requirements on application properties and on the commercial form, taking reactive dyes for cellulose fibres as an example.

ments lead to a granular form and (depending on the range), sooner or later to liquid form. At present, the so-called high granulate and the particularly promising solid forms are on the increase. The aim is the optimum fulfilment of customer requirements within the scope of ease of application, constitution, commercial form, from supply methods to container disposal.

Manufacturers and users of chemical products agree that workplace hygiene should be given the highest priority; this means reducing the volume of airborne dust to a minimum. The degree of fine dust critical to health is determined by various standards, e.g. in the definition of the TLV (Threshold Limit Value for Chemical Substances and Physical Agents in the Workroom Environment; EC Standards). The practical or operational value for airborne dust is far higher then the TLV; for chemical production it is stipulated that all fine particles < approx. 0.08 mm (TLV 0.008 mm) should either be bound or removed. Taking into account the facts on the one hand of the hygienic and operational nuisance caused by dust at the lower end of the particle size scale, and on the other hand the difficulty of dissolving or distributing larger particle sizes at the higher end of the scale, a practically acceptable range of approx. 0.1–1 mm is used in the area of fine granulates (Fig. 3).

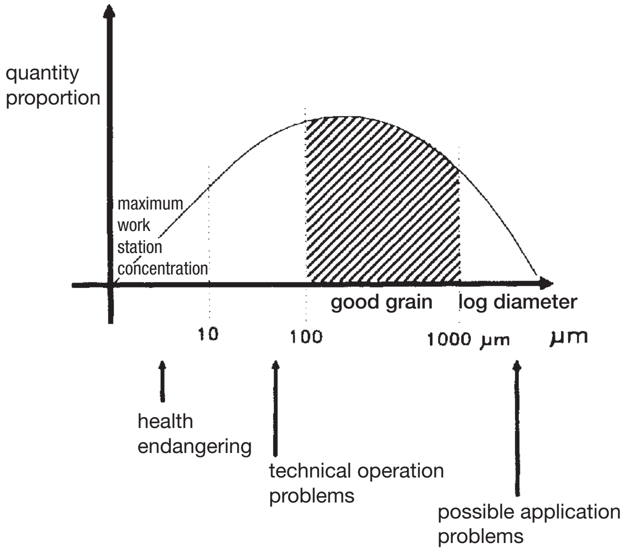

Fig. 3: Grain distribution in solid commercial dyestuff forms.

Liquid forms with good storage stability are characterised in recent years by diaphragm separation processes such as ultrafiltration and reversible osmosis. Accompanying substances from the dye synthesis such as electrolytes, organic by-products and a large percentage of the water are separated by a semipermeable diaphragm and treated by the effluent treatment plant of the chemical works. The purified raw material is refined by the addition of formulation auxiliary materials such as buffer substances, stabilisers, and other functional additives to the desired rheology and stability levels, and the necessary concentration. The cleaning operations (Fig. 4) have a substantial influence on the storage stability of the liquid dye make-up (source: Bruttel).

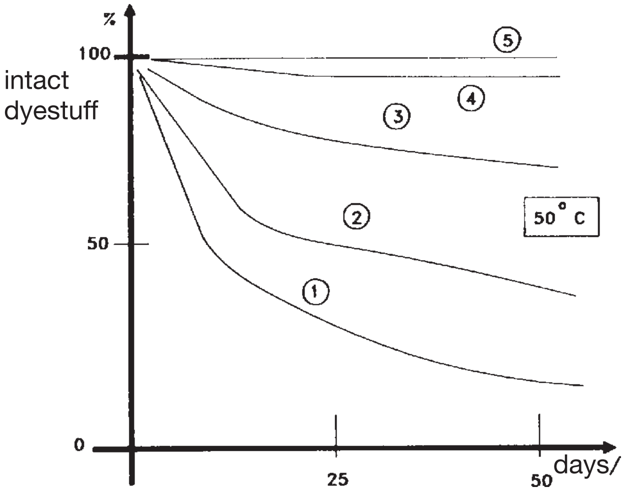

Fig. 4: Cleaning and storage stability (triazine fluoride type). Cleaning time: 1 = crude solution tel quel; 2 = 2 hours; 3 = 6 hours; 4 = 12 hours (extensive electrolyte removal); 5 = stabilized.

Commission dyeing Textile dyehouse which dyes textile fabric to the order of another firm without owning the fabric itself. Also called → Commission finishing.

Commission finishing If a textile finisher takes in for processing textiles that belong to a customer, finishes them as per the customer order and receives “payment” for his work after correct delivery and invoicing (previously known as payment finishing), his work is called commission finishing. The relationship to previous and subsequent stages is shown in the models in Figs. 1–4.

The main difference between a commission finisher and a vertical company is that a commission finisher usually knows little about history of materials for processing, particularly with regard to the composition of sizes and waxes. The finishing process must be adapted according to the goods in process and the require-

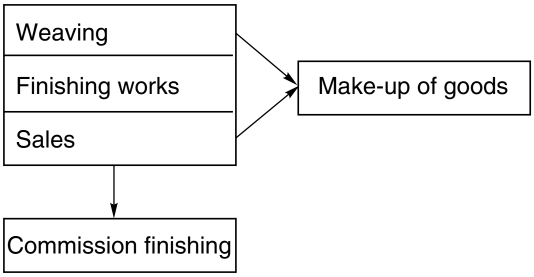

Fig. 1: Structural model 1.

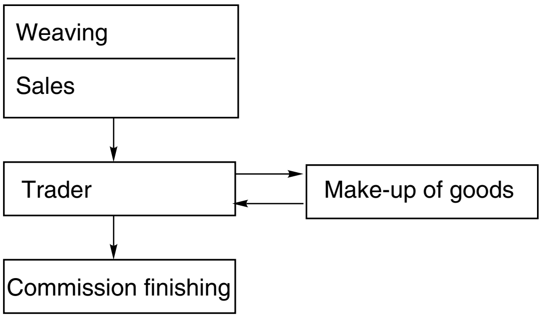

Fig. 2: Structural model 2.

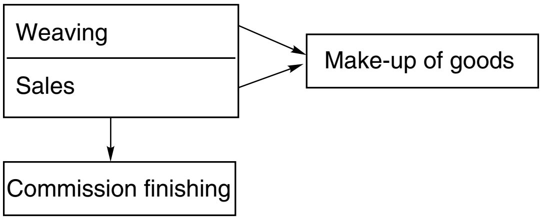

Fig. 3: Structural model 3.

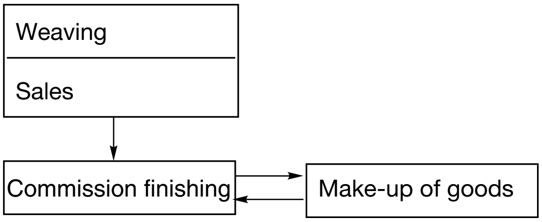

Fig. 4: Structural model 4.

ments of the finished product. This results in the problem of having a wide range of processes due to the many and varied raw materials and finished product requirements → Organizational structures in textile finishing

Commission wash Washed goods belonging to the customer.

Common salt → Sodium chloride.

Comonomers Monomers of different chemical types used, e.g. as chemical modification components to open up the intercrystalline structure of linear polymers, or modification of dye affinity in man-made fibres, etc. Comonomers are currently of interest for "molecular engineering" possibilities in e.g. the production of polyamide fibre modifications (additional acidification to confer affinity for cationic dyes) and polyester fibre modifications (for types with differential-dyeing and stepwise shrinkage characteristics).

Compact foam Smooth, unstructured, foamed back coating for carpets, compact, with smaller pores; term however not precisely delimited as against standard smooth foam (flat foam). Chiefly based on latex or polyvinyl chloride.

Compact package dyeing machine For cones, warp beams, slivers and tow. Pack cylinder for loose stock, muffs and hank yarn. Expansion tank in the dye vessel. Square preparation tank around the dye vessel, or a separate tank (near the compact package dyeing machine). Square structure requires only short connecting pipes, thus saving space. Centrifugal pump under the dye vat. Partial and full flooding. Equipment details effected in the vat (instead of above the lid as usual) (Fig.).

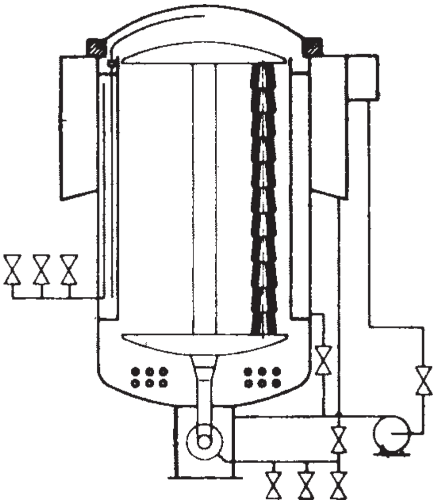

Fig.: Compact yarn dyeing machine (Jasper).

Compartmented (X-compartmenting). Division of drum into four internal compartments, giving four chambers in the drum cross-section.

Compatibility value (CV). A compatibility value, K, proposed by the Basic Dyes on Acrylic Fibres Committee of the Society of Dyers and Colourists to characterize cationic dyes according to their compatibility. It is therefore useful for the classification of cationic dyes with regard to their suitability in combination. The scale of K values ranges from 1 to 5. Dyes with CV = 1 exhaust more rapidly in combinations than those with higher CV values.

Compatibility value K (Bayer). Value for classifying cationic dyes in terms of combinability, the scale ranging from K 1 to K 5, Value K 1 dyes being quickly exhausted, and K 5 dyes slowly.

Compensator in flat screen printing Flat screen printing is effected intermittently, i.e. the printing screens are set down on the stationary fabric, rising up again after the printing paste has been spread (by the doctor stroke) before the fabric is moved on by one repeat by the rubber blanket. This repetitive, phased motion must not be transmitted to the fabric running into the printing zone because otherwise adhesion to the rubber blanket is interrupted each time it stops. A compensator (Fig. 1) is therefore installed so that the fabric is gummed on to the rubber blanket continuously.

The rubber blanket either moves forward from a

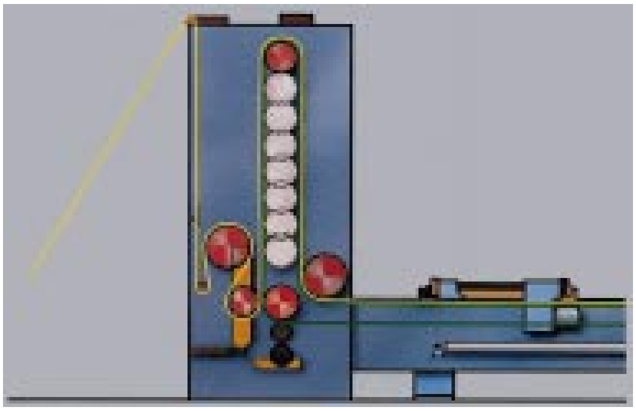

Fig. 1: Fabric entry (Buser Hydromag 6) with compensator for intermittent motion in the vertical direction.

fabric store at the printing machine exit under the table with the screens set down, i.e. stationary rubber belt on the table, in order to be gummed to the incoming fabric in the front fabric store, followed by further movement of the sandwich with the screens lifted; or the fabric only is moved with the screens lowered, before the sandwich is moved jointly with the screens raised (Fig. 2).

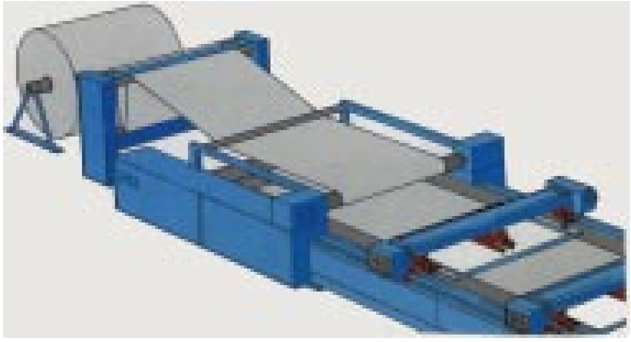

Fig. 2: Fabric entry (Reggiani Avant) with compensator in the horizontal direction.

Compensator roll control The functional principle of tension control by means of a → Compensator roller. (→ Compensator roll device).

Compensator roll device Device for regulating uniform fabric run and fabric speed or machine elements by raising and lowering motions. If two machines arranged in series (e.g. in continuous woven fabric pretreatment) need to be synchronised (Fig.), a compensator roller (or an identically functioning dancer roller as an alternative) is located between the machines.

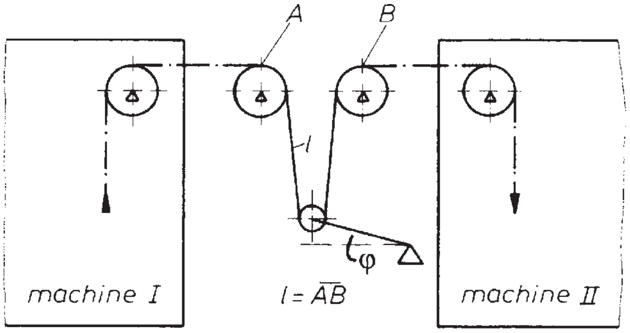

Fig.: Compensator roll device for the synchronisation of two machines arranged in series.

The compensator roller motion is transmitted to the actual value sensor via a chain drive with a transmission ratio of i_K. The angle of deflection φ on the actual value sensor is therefore defined as the controlled variable. A potentiometer, the terminal voltage of which illustrates the compensator roller angle in analogue terms, serves as a measured value transducer. One possibility of affecting the speed of the fixed traction roller, and therefore the fabric speed, is to change the transmission ratio of the steplessly adjustable PIV gear by servomotor. Changing the transmission ratio is possible via the axial displacement of the two bevel wheel pairs. Another possibility is to transmit the potentiometer setting via appropriate pulses to the DC motor (with variable speed via the voltage) or to an alternative AC motor with frequency control in order to let a machine run faster or slower. In this closed control circuit therefore

- the fabric is the controlled member,
- the compensator roller is the sensor,
- the drive to the rear machine is the actuator,
- the speed of the first machine is the reference value, to which the actual value of the second machine "lines up" via the compensator roll.

Compensator roller (dancing roller). Roller which moves up and down on movable bearings for equalising the tension on open-width piece goods between continuous operation finishing machines.

Complementary colour If rays of light visible to the eye meet coloured compounds, the absorption of specific ray zones occurs out of the numerous light pulsations, and the coloured compound appears in its so-called complementary colour (Table).

Wavelength (in mM)	Absorption colour	Complementary colour
approx. 725	magenta	green
645	red	bluish green
590	orange	blue
550	yellow	indigo blue
530	greenish yellow	violet
510	green	magenta
490	bluish green	red
455	blue	orange
425	indigo blue	yellow
400	violet	greenish yellow

Tab.: Absorption colour and complementary colour in the visible wavelength band (in nm).

The eye experiences white when incoming light contains unweakened the wavelength 750–400 nm. Coloured when any one or more wavelengths of this visual band is absorbed or changed (fluorescence) (i.e. are missing) by the body in question. Black, when all the radiated light is absorbed, increasing wavelengths being equivalent to a falling pulsation count, and vice-versa. → Chromatic circle.

Complementary dyeing of partially saponified acetate fibres Saponification of acetate fibres until partial saponification occurs. Then simultaneous dyeing of the unsaponified fibre core with acetate dyes, and the saponified fibre surface with direct dyes, e.g. a brown: red acetate dye and grey direct dye (grey overlaid red shade = brown).

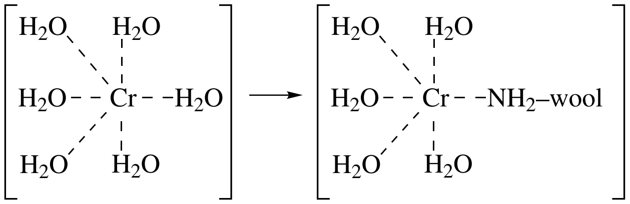
Completition time → Execution time.

Complex (Latin: complexus = enclosure). Composite unit.

Complex catalysts Act as permanent finish catalysts in so-called shock condensation; mixtures of the metal salts of strong acids with complex-forming α-hydrocarboxylic acids.

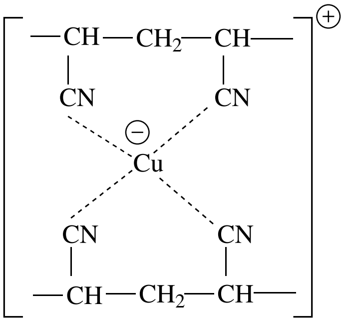
Complex compounds Higher molecular arrangements, in the construction of which not only atoms and radicals (e.g. SO_4 group, NO_2 group) are involved, but also molecules capable of independent existence (e.g. H_2O, NH_3, HCl, and also the wool, polyamide, polyacrylonitrile molecule etc) so that so-called ligands group around a central atom in each case (in the event of a number of central atoms, the term “multi-nuclear” is employed). These types of complex compounds reveal substantial stability, in that the total complex stays together in dissolution, i.e. does not (or only to a small extent) break down into ions. A distinction is drawn according to the type of chemical bonding:

I. Orientation complexes, as occur due to coordinative bonding in the form of partial valencies between ions or between ions and dipoles, e.g. in mordanting wool with chromium salt, the latter first of all forming, with chromium as the central atom, a complex hydrate with 6 H_2O molecules which gradually dissociate on boiling, and coordinatively combine in the first phase with an undissociated wool NH_2 group in the following way for example:

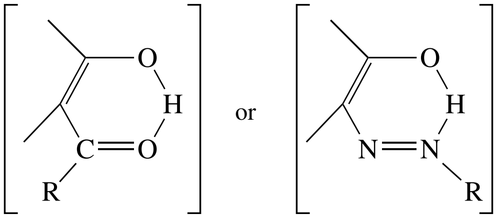


Such complex compounds are not very resistant to heat. The following are much more resistant:

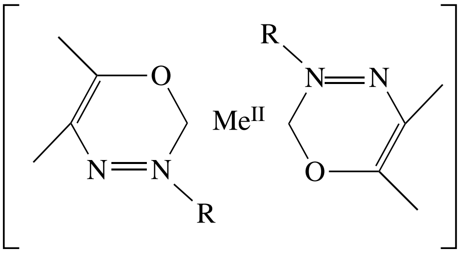
II. Penetration complexes, in which electrons of the partner mutually combine penetratively into an individually positively charged complex compound. Here, a partial valency type of coordination bonding can also exclusively be present, as for example in dyeing polyacrylonitrile with acid dyes by the cupro-ion process:



or atom bonds also occur additionally in principal valency terms in the form of chelate bonding, hydrogen for example occurring first of all so to speak as a monovalent but two digit complexing agent (hydrogen bridges) with approximately the following grouping as with mordant-uptake dyes:



from which (now as a penetration complex) the metal complex compound then results as dyeing:

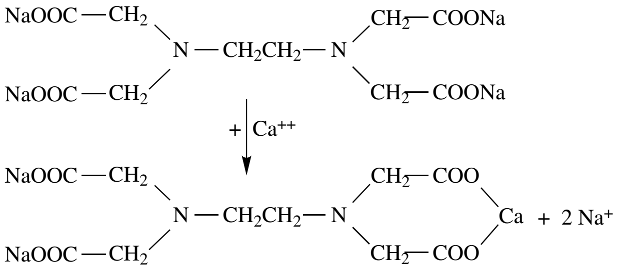


Complex formation The formation of a new ion from a metal ion by the action of molecules which have at least one electron donator group. In practice, the ability of the → Complexing agent to bond cations so that they can change their chemical properties. Example: 2 : 1, 1 : 2 complexes, with metal complex dyes, the usual characterisation of the metal atom to dye molecule relationship, which plays an important role in regard to the associated dyeing properties etc.:

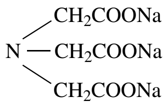
1 : 1 complex = 1 metal atom : 1 dye residue,
1 : 2 complex = 1 metal atom : 2 dye residues.

The production of metal complex wool dyeings by the pre-mordanting single bath and after-chroming process leads to 1 : 1 or 1 : 2 complexes. In essence, premetallised dyes, i.e. commercial metal complex dyes, are either 1 : 1 complexes, which contain soluble-making sulpho-groups, and are dyed highly acid, or it involves a) sulpho-group-free 1 : 2 complexes; b) 1 : 2 complexes with one or two sulpho-groups. There are other mixed complexes, e.g. sulpho-group-free chromium complex dyes with a colourless complexing agent residue (e.g. salicylic acid), i.e. also 1 : 1 complexes. In a similar way, 1 : 1 chromium complexes are also converted with non-metallised dyestuff to asymmetrical or symmetrical 1 : 2 complexes or 2 : 3 complexes.

Complex-forming ability Substances which form undissociated complexes with bivalent and trivalent cations frequently belong to the so-called chelating agent group. The name is derived from the Greek chele = crab's claw, and therefore describes the ability of these compounds to bond a multivalent metal ion by two or more atoms, the ligands encompassing the ion like crabs' claws. The compound on which this phenomenon has been studied most exhaustively is ethylene diamine tetra-acetic acid (EDTA). Two of its acetic acid residues react with the calcium ion in forming the unassociated complex; the other two residues are bonded ionically by sodium.

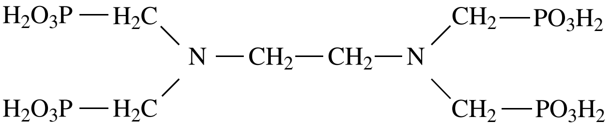


The prerequisite for developing chelates is a specific arrangement of the acid groups of the molecule, as is the case with EDTA and many other organic acids. The type of bonding of the metal ion in the chelates and related compounds is described as "charge transfer" complex bonding; it is characterised by the fact that the metal ion is bonded non-ionogenically, and no longer has any hydrophilic character. The sodium salt of nitrilotriacetic acid (NTA) has similar complexing-forming properties to EDTA, with the added advantage of lower molecular weight and a therefore 50% greater metal bonding capacity.

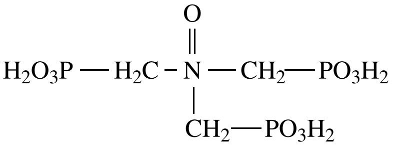


(NTA) molecular weight = 191

The salts of phosphoric acid also have a complex bonding capacity for metal ions:

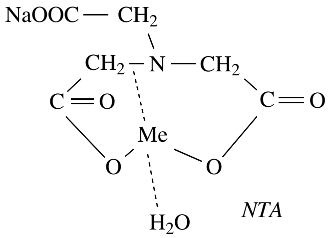


Ethylene diamine tetramethylene-phosphoric acid (EDTMP) molecular weight = 436

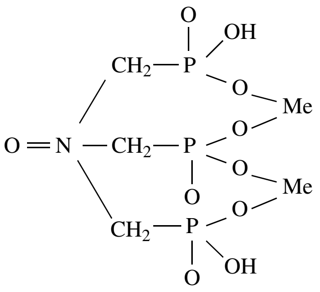


Oxyaminotrimethylene-phosphonic acid (N-OX-ATMP), molecular weight = 315

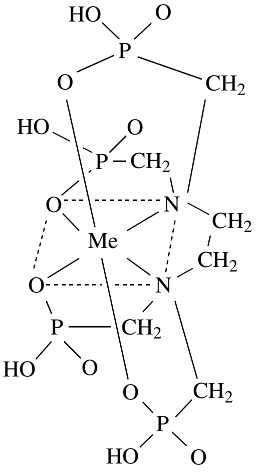
The stability constant of a complex, for Fe^{3+} for example, has the value 15.87 (NTA). The stability constant of the polyphosphonic compounds is higher than that of NTA, and these should therefore be effective complexing agents. Polyphosphonic compounds can be present in sodium salt form with partial or complete neutralisation of the phosphonic acid, and consequently the pH of their solution varies between 7 and 12 in the case of commercial products. These compounds complex one or two metal atoms per mol of polyacid:



NTA



N-ox-ATMP

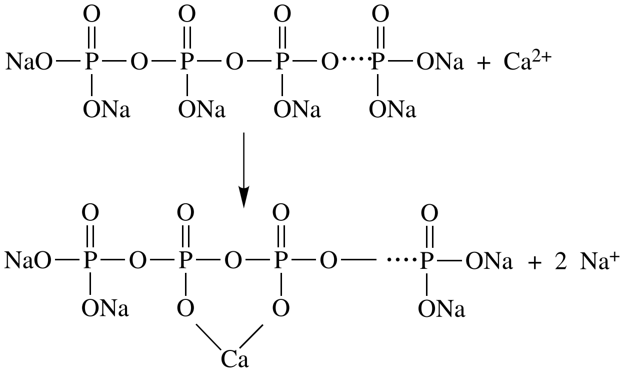


EDTMP

The respective calcium complex of these chelates is more resistant than the sodium complex of the starting substance added to the water, because energy is produced in consequence of an increase in the number of freely movable electrons, if ligands (Na^+) which can take up only one coordinate position are replaced by those (Ca^{2+}) which can have several coordination positions. Since derivatives of phosphoric acid in water courses require eutrophication, phosphate substitutes are of interest in regard to their complex bonding capacity. The tertiary amines especially (as are the quats [quarternary ammonium compounds] too) are not however clarified in terms of their biological degradability, their behaviour in purification plants and their effect on biocoenosis. Whether they remove metal ions from systems, or give off complex-bonded metal to the system, depends on the effect of the system on the complex formation constants. In any case, sequestering agents give rise to environmental problems for that reason. This statement applies also to metal complex dyes, in the case of which little is known about their behaviour in biological systems.

Complexing agent (metal complexing agent, inactivating additive, sequestering agent, chelating agent). Products which are qualified by characteristic functional groups to change metal ions by → Complex formation, and to improve their solubility in a specific medium. This occurs by the coordinative bonding of unwanted metal ions in the soluble complex in order to avoid metal precipitation in the liquor and on the textile product, and to dissolve metal compounds already deposited on the textile product. Classification:

I. Inorganic complexing agents, in which the large group of → Complex phosphates is included, such as sodium triphosphate or higher molecular polyphosphates which form soluble metal complexes in accordance with the following principle (ion exchangers):



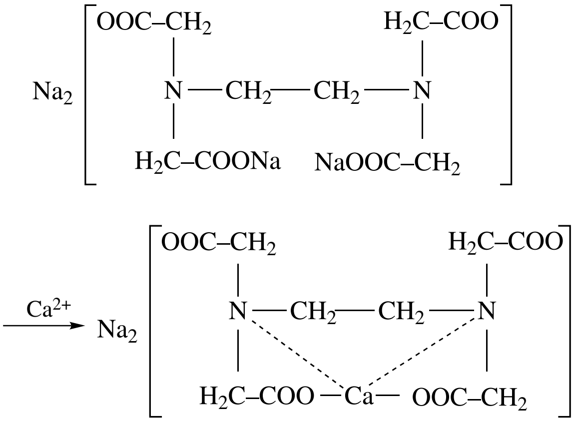
This reaction always presupposes an excess of complexing agents, so that soluble sodium metal polyphosphates form. With an excess of metal ions, all sodium ions are replaced by metal, producing insoluble salts.

II. Organic complexing agents, including oxalic, tartaric and citric acid (aminopolycarbonic/carboxylic acids), nitrilotriacetic acid and ethylene diamine tetra-acetic acid and their sodium salts, soluble metal complexes also being formed in the following way:

with nitrilotriacetic acid:

$$2\ Na_2\left[N(CH_2COO)_3Na\right] \xrightarrow{Ca^{2+}} Na_4\left[N(CH_2COO)_3Ca(CH_2COO)_3N\right]$$

or with ethylene diamine tetra-acetic acid:



Although inorganic and organic complexing agents appear to be very much alike as regards alkaline earth and heavy metal ion bonding, their behaviour under specific conditions (pH, temperature, time) is so characteristic that clear delimitation of fields of application have appeared. In dyeing with metal-containing dyes, demetallisation (shade change, impaired fastness) occurs due to organic complexing agents. On the other hand, inorganic polyphosphates can be used in all dyebaths in common with metallised dyes with the exception of the 1 : 1 metal complex dyes. In general, complexing agents should be added before the addition of dyes and other auxiliary agents. Furthermore, complexing agents act as oxygen stabilisers in peroxide combinations, and as fibre protectors against cellulose. Polyphosphates greatly increase the washing power of soaps or surfactants, for which reason they have achieved great importance in detergent synthesis. → Complexometry.

Complexometry (chelatometry). Simple volumetric process (→ Titration) of universal application, which is used for the quantitative determination of cations (Ba, Ca, Co, Cu, Fe, Mg, Mn, Ni, Pb, Zn etc.) and anions (halogens, phosphates, sulphates etc.) by means of → Complexing agents and special indicators. Quick and easy implementation with a high degree of accuracy has been found of great importance for determining water hardness. Reaction principle: exchange of sodium for calcium and magnesium ions in the water into masked, soluble complexes which are detected by colour reaction.

Complex phosphates Term for polyphosphates as condensed phosphates with a chain structure. The term is used because they display the typical behaviour of complex compounds during dissolution in water and in their type of reaction. In water softening (i.e. Ca ion bonding), the undissociated Na atoms or H atoms in the polyphosphoric acids are always exchanged first of all. The solubility of the complex salts decreases as the calcium content increases. From this, it follows that polyphosphates always have to be metered in a specifically stoichiometric excess in order to obtain soluble calcium (or other metal) complexes.

Complex phosphates are typical complex salt formers which dissolve alkaline earth carbonates and metal oxides etc., thus resulting in metal corrosion. The extent of corrosion of bright metal surfaces depends not only on the polyphosphate type (chain length) but also decisively on the prevailing conditions (pH, concentration, temperature, attendant substances etc.). Corrosion can be controlled by careful polyphosphate selection, and, if necessary, the co-application of suitable inhibitors.

Component fibres Consist of two or more different high-polymer types, e.g. → Bicomponent fibres (Fig.).

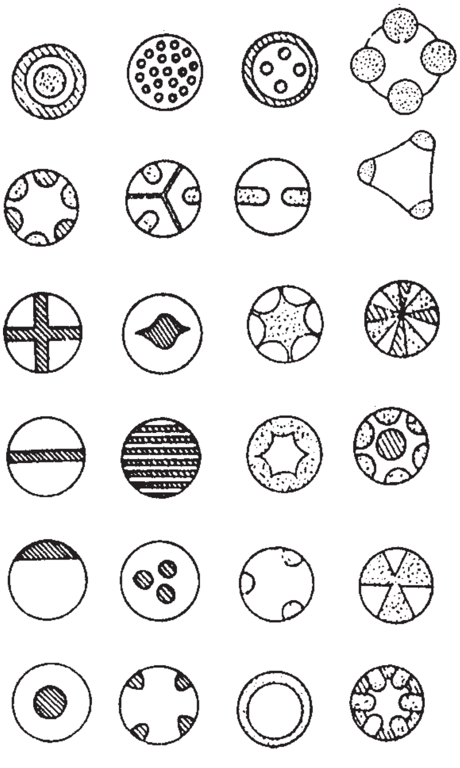


Fig.: Different component fibre types.

Composite,

I. An article or substance of two or more constituents, generally, with reinforcing elements dispersed in a matrix or continuous phase.

II. Hard or soft constructions in which the fibres themselves are consolidated to form structures rather than being formed into yarns. Rigidity of these constructions is controlled by the density, the modulus of the load-bearing fibres, and the fraction of fusible fibres. Strength is cont adhesion and shear-yield strength of the matrix unless fibres are bonded in a load-transferring matrix.

III. A structure made by laminating a nonwoven fabric with another nonwoven, with other materials, or by impregnating a nonwoven fabric with resins.

Composite fibres Fibres composed of two or more polymer types in a sheath-core or side-by-side (bilateral) relation. → Bicomponent fibres.

Composite plastic and textile fabrics Composite fabrics of which at least one layer consists of flexible, textile fabric like woven and warp knitted fabrics, nonwovens for example, and the other layer is a plastic coating with a leather-type (or leather-like) surface; also called → Artificial leather. Depending on the type of textile fabric: woven artificial leather cloth, warp knitted artificial leather cloth, nonwovens artificial leather cloth (DIN 60000, 16922).

Composite plastic material Plastic sheets of two or more layers, at least one of which is of → Plastics, e.g. → Composite plastic and textile fabrics.

Composites Combinations of two or more materials, bonded at the macroscopic level to form a new material which seeks to balance the disadvantages of the first component with the advantages of the second. A microscopic bonding of materials, as with alloys, also creates “compound materials”; these, however, are homogeneous at the macroscopic level. The actual composites, on the other hand, are non-homogeneous and generally demonstrate anisotropic properties i.e. the physical properties are directional dependent. With the isotropic body, in contrast, the sizes of the vectorial properties do not depend on the direction, but rather all directions in relation to their physical properties are of the same value.

I. So-called particle materials: The particle materials (Fig. 1) involve materials in which fillers consisting of one or more materials are embedded in a matrix of another material. The properties of such composites change in a variety of ways compared with the original unfilled state, e.g. by an increase in elasticity and impact resistance, change in viscosity, flame retardancy, etc.

II. Fibre-reinforced materials: In the bonded fibre fabrics or fibre-reinforced fabrics (Fig. 2) fibres are embedded in the matrix. These fibres frequently have much better mechanical properties than the surrounding matrix and even the same material of which the fibre consists in its original form. These fibres improve the performance properties of the composite considerably due to their great strength.

III. Layered materials: The layered materials (Figs. 3–4) consist of at least two different materials that are combined to achieve greater strength, rigidity, resist-

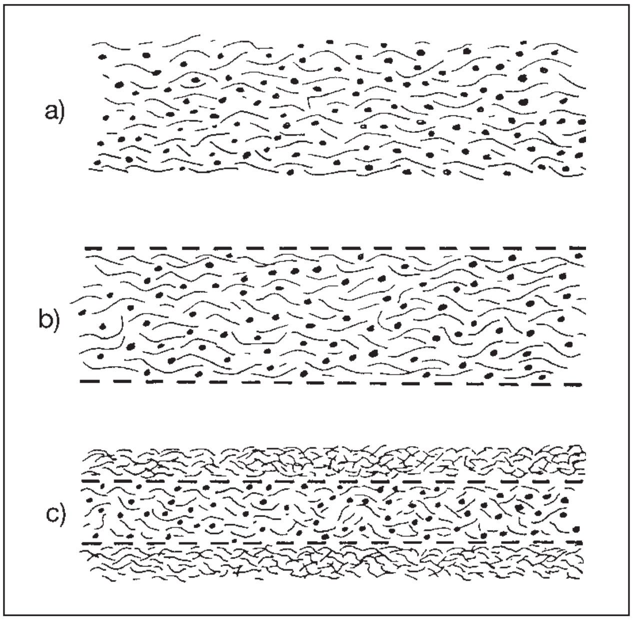

Fig. 1: Particle materials as a form of composite: a) fleece core with inlaid silicic acid particles, where the composite is fixed by needle-punching; b) as a) but with flame retardant fabric on the upper and lower side as a laminate; c) as b) but with fleece covering layers.

ance to corrosion, etc. Often a component will serve to protect the other by sheathing it. The coated fibre-reinforced materials are a special case in point (so-called → Laminates) since these are classified as both layered materials and fibrous materials. On the one hand, the fibre is protected by embedding in a matrix, on the other, the desired properties can be deliberately developed in any direction from the properties of the heavily anisotropic layers by superimposing them to form a multilayered composite.

To clarify the concept of reinforcement, i.e. the improvement of the mechanical properties of an unreinforced matrix material can be demonstrated by reference to the materials‘ stress/strain diagrams. In Fig. 5, left-hand section, two different types of materials, polymer and high-modulus fibre (HM fibre), are depicted in terms of a stress/strain diagram. Polymers are characterized by their high degree of elastic deformability, and high elongation at break. The high-modulus fibres behave in exactly the opposite way, with a high modulus of elasticity, great strength, but low elongation at break. The reinforcement is based on the insertion of high-modulus fibres into a matrix with a high elongation at rupture (see right-hand section of Fig. 5). Ac-

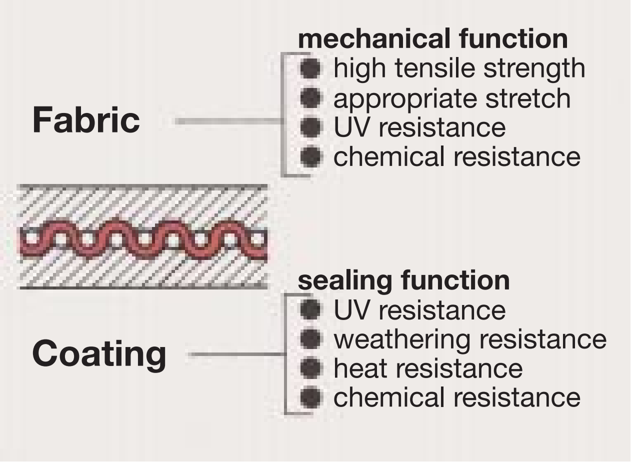

Fig. 2: Schematic representation of a coated fabric.

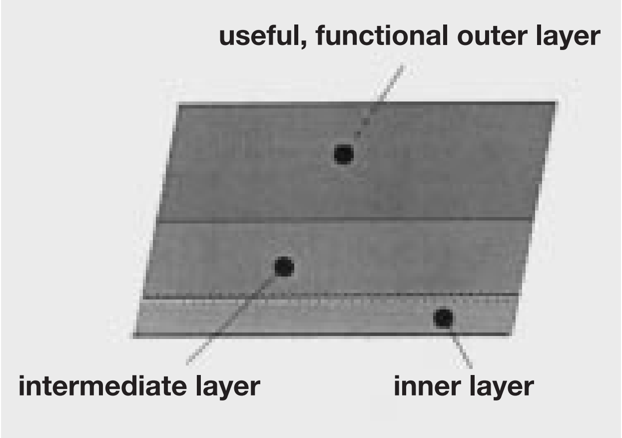

Fig. 3: Structure of the rubber shrinkage cloth with its three layers.

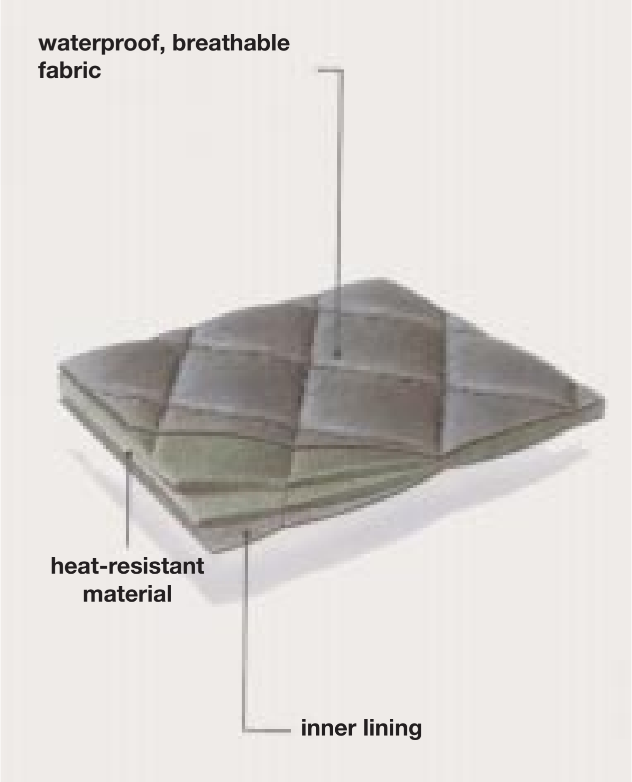

Fig. 4: Layered material as a protective fabric for firefighting uniforms.

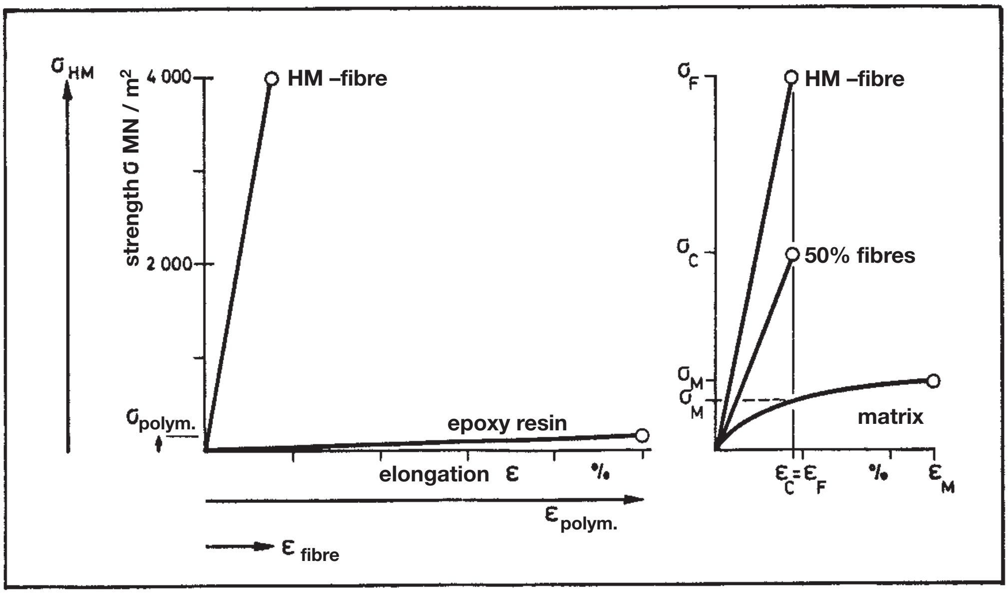

Fig. 5: Tension/elongation diagram of an HM fibre, of an epoxy resin and composite with 50% by vol. fibrous content

cording to the Mixing Rule, the components contribute to the overall properties of the composite body proportional to their share of the volume. The break point is found only when the more brittle components exceed their normal elongation at rupture. The high elongation at break of the polymer matrix means that the brittle fibre's contribution to the material strength of the composite can be exploited to the full. In Fig. 5, on the right, the stress/strain diagram has been drawn for a composite body with 50% by vol. of fibres. From this figure it is possible to derive a crudely simplified requirement profile of the composite or its components, the matrix and reinforcing fibre.

The fibres used should have the following property profile:

a) Requirements of processibility:
  - good wettability,
  - adaptable to the method of processing,
  - no shrinkage or change in length during processing,
  - not sensitive to moisture and temperature conditions.

b) Requirements of ultimate properties: The matrix is the carrier of tension from fibre to fibre in the composite. It should therefore not only be plastic, but also "bondable" with the fibre. In addition it must also absorb any possible breaks appearing in the fibre component of the composite and be able to dissipate the forces responsible.

The matrices should satisfy specific requirements during the manufacture of the composite, or rather in the finished article:

a) Requirements of processibility:
  - good wetting (affinity) of the reinforcing material,
  - low-viscosity system,
  - processibility with lowest possible pressure and low temperatures,
  - sufficiently long life,
  - with polymers: controllability of the polymer structure.

b) Requirements of ultimate properties:
  - good long-term performance with static and dynamic stress,
  - good bonding between matrix and reinforcing materials (requisite polymer compatibility) to avoid delamination,
  - good chemical, heat and corrosion resistance.

Since the matrices always need to be softer than the reinforcing fibres (with the exception of shock-resistant polystyrene), only plastic metals and macromolecular materials can be reinforced in principle. Of the metals it

Polymer structure Behaviour	linear  branched 	cross-linked 
Description	Thermoplast	Duroplast
Solubility	usually good	insoluble, swellable
temperature increase > T_G	become soft, viscous flowing	become soft rubbery, dimensionally stable
Processing	of the finished polymer	low-molecular raw materials
Processing temp.	mostly above 180°C	up to 150°C
Matrix penetration in bundle of fibres	slow	rapid
Process adjustment	difficult	good

Fig. 6: Polymer structures and their most important properties, which need to be taken into account in the manufacture of composites.

is the easily deformable and workable ones especially that are involved: aluminium and magnesium alloys, lead or tin. When selecting the polymers, a choice must first be made between thermoplastics and duroplastics. A comparison of the most significant characteristic features of these types of structure highlights the advantages of cross-linking structures as shown in Fig. 6.

Nevertheless it is the state of the art to reinforce thermoplasts, especially the high-quality technical thermoplasts, with suitable additives, e.g. various fibre combinations. The metallic deformability of such composite systems ought to remain the driving force behind their continued development in future. Cross-linking systems currently enjoy a dominant significance. They are generally composed of low-molecular raw materials, which are transferable to macromolecules through polycondensation, polymerization or polyaddition. Since duroplasts are not deformable thermally, each forming process must take place in a non-cross-linked state during the application process.

In principle there are two possibilities available for the cross-linked structure:

a) cross-linking of tri- or polyfunctional raw materials
b) use of mixtures of bifunctional monomers with tri- or polyfunctional monomers.

While tri- and polyfunctional components are carriers of the cross-linking process, bifunctional monomers affect the degree of cross-linking. At the same time, it is possible to use components which possess two completely independently reacting functional groups, with the result that the network is built up in stages via two independent reaction mechanisms. Since with the manufacture of composites the displacement of low-molecular components is undesirable, cross-linking syntheses proceed by polycondensation reactions. More significant still are cross-linkings via polymerizations and all polyaddition systems.

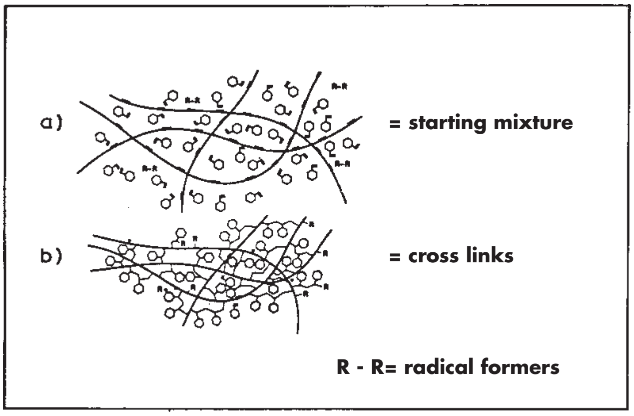

Fig. 7: Cross-linking process of unsaturated polyester with styrene.

Of the family of cross-linked systems brought about by polymerization, the unsaturated polyesters assume an important position. They have the advantage that, as a result of numerous, easy-to-obtain structural variations, their end properties can be easily adapted to a variety of requirement profiles. Their structure is comparatively simple and is illustrated in Fig. 7. The properties of the network can be varied through the composition of the unsaturated polyester and the use of variously structured unsaturated co-monomers. The volume shrinkage of 6–9% by vol. characteristic of these systems with the transfer of the liquid mix into the network can be greatly reduced by the addition of thermoplasts; however, this inevitably leads to a change in the physical properties.

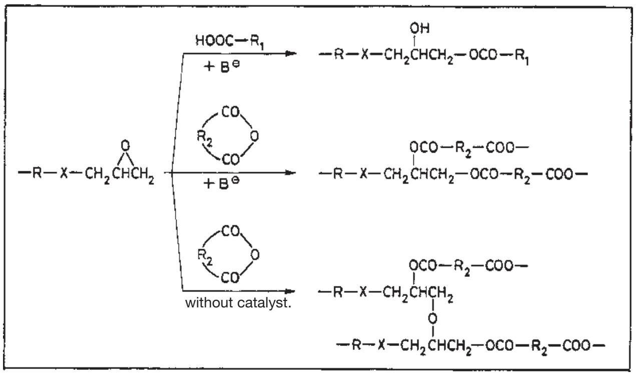

Fig. 8: Additions of carboxylic acids and carboxylic acid anhydrides to epoxy compounds.

Of the matrices gained from the polyaddition principle, the epoxy resin systems dominate. They offer broad opportunities for adapting to required product profiles and processing conditions. These systems are illustrated in the structural fragments of Fig. 8 and Fig. 9. Fig. 10 depicts the polyaddition of bis-maleic-imide taking a diamine as an example of a cross-linking system. Compared with the epoxy resin systems, these systems are characteristically different. The starting components represent crystalline or vitreous substances with high melting and/or glass transition temperatures, which means that they usually need to be applied

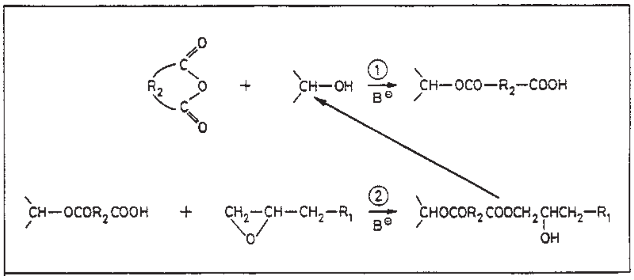

Fig. 9: Development of anhydride cross-linking.

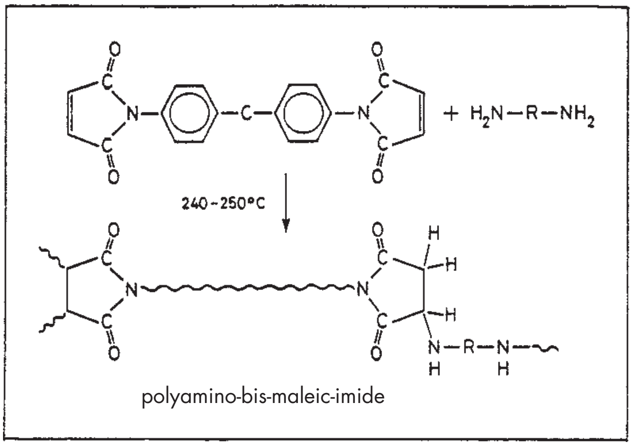

Fig. 10: The polyaddition of bis-maleic-imides taking a diamine as an example.

to the reinforcing fibres from solvents. Finally, the solvent needs to be re-volatalized, a definite resin flow obtained in a preliminary reaction and ultimately the actual hardening achieved with increased temperatures (> 200°C). This requires the use of expensive, explosion-protected plant facilities.

Polypropylene or polyethylene fibres are difficult to wet-out and are plasma or corona treated to give a more hydrophilic surface. A pretreatment of polypropylene sheets by means of corona discharging is associated with an increase in surface energies (e.g. 10^{-3} J/m^2). The station for the corona discharging should be located just before the coating unit because the surface effects are not permanent. The pretreatment via corona discharge is not sufficient for many coating systems. If, for example, coating is to involve non-blocking PVDC dispersions or contact adhesives, then an adhesion promoter needs to be applied first. The adhesion promoter (also → Primer) may be an aqueous dispersion or be in a dissolved form. Thermally cross-linking, 100% solid primers on a PU basis with layers less than 1µm thick are also in use.

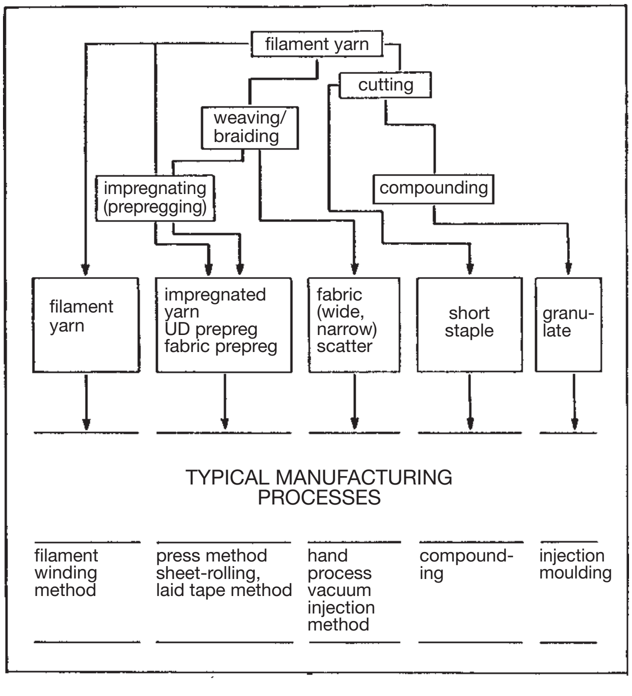

Fig. 11: Semi-finished products and manufacturing processes for composites.

After the pretreatment of the reinforcing materials, the reinforcing materials and matrix polymers are produced as a semi-finished product (Fig. 11).

The hand lamination process (Fig. 12) is the oldest method. Chopped strand mats and/or roving fabric are used as reinforcing material. Depending upon the type of parts being manufactured, mats with powder or emulsion binders are used. Fabric and/or mats are laid in the mould, then manually impregnated with resin and deaerated using a fluted roller. This process is used to manufacture small series of technical parts such as are found in boat building.

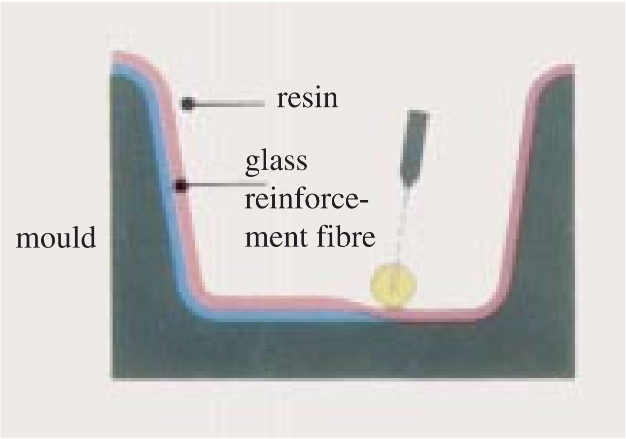

Fig. 12: Hand lamination process (after Vetrotex).

With fibre-resin injection moulding (Fig. 13), a further development of the hand lamination process, the materials are applied with the aid of a spray gun, which will cut the glass fibre and simultaneously inject it into the mould with the resin. Here, too, the mould is finally treated with a fluted roller. The injected layers of fibre may be alternately processed using roving fabric. Careful impregnation and deaeration are crucial for the quality of the moulded part.

With medium-sized batch productions on the scale of 1000 to 10 000 units per year, reproducibility becomes an important aspect. For this reason alone, craft processes and their related disadvantages (large proportion of manual work and a non-smooth surface) are out of the question. To increase the working speed and achieve a smooth appearance for both surfaces, while at the same time retaining a certain freedom in the forming and dimensioning, the manufacturer will decide in favour of the injection or low-pressure moulding proc-

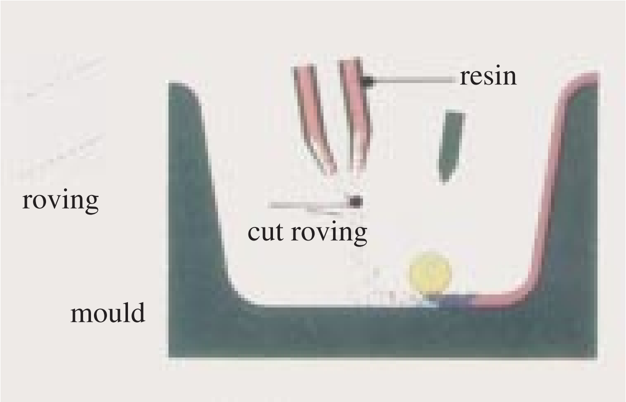

Fig. 13: Fibre-resin injection moulding (after Vetrotex).

esses, which are especially suited to limited-run batch productions. The investment costs required are relatively small since the mould halves are mostly made from composites.

Injection moulding (Fig. 14) involves a process for medium-sized batches. The end product involves components with a good surface appearance that are covered in a fine coating. Continuous filament mat cuttings are used for textile glass reinforcements since they guarantee good mouldability. The mat may also be premoulded. In many cases fabric can be used as well. The reinforcement is integrated between the mould halves. Once the mould is closed, the resin is injected under low pressure. The reinforcing material is impregnated gradually. It is possible to inject the resin into the cold, hand-hot or even hot mould. This process is also possible with a low vacuum, which makes impregnating the textile glass reinforcement easier. The vacuum injection process does require the whole mould to be absolutely leakproof, however.

To acquire the equipment necessary for the low-pressure moulding process (press with low mould clamping force compared with large batch systems and composite moulds) moderate investment is required. Continuous mats are generally used for the reinforcing materials since these can be pre-moulded if need be. Fabric is also suitable. The pressure is between 2 and 4 bar. As with injection moulding, any heating temperature for the moulds is possible, from room temperature up to 80°C. Preforms made of continuous mats involve reinforcement in the form of the manufactured part. The preform is used in injection moulding and wet pressing to manufacture parts with complex shapes or a high proportion of glass. The preform offers the following advantages:

- less time spent on incorporating the reinforcement;
- avoidance of resin-rich zones;
- reduction or avoidance of waste.

For small and medium-format parts of various shapes such as those found in large-scale manufacture, the use of presses or injection moulding equipment is recommended. On account of the high pressures (15–150 bar) and mould temperatures (100–160°C) that occur, the use of metal moulds that are clearly more costly than composite moulds cannot be avoided. The industrial manufacturing processes are characterized by their short production sequences: 1–4 min each according to the thickness and complexity of the moulded part. Hot pressing involves the use of presses between 10 and 20 bar and temperatures around 110°C. Normally continuous mats, but in some special cases chopped strand mats, serve as reinforcement. Preforms and fabric are just as suitable, however.

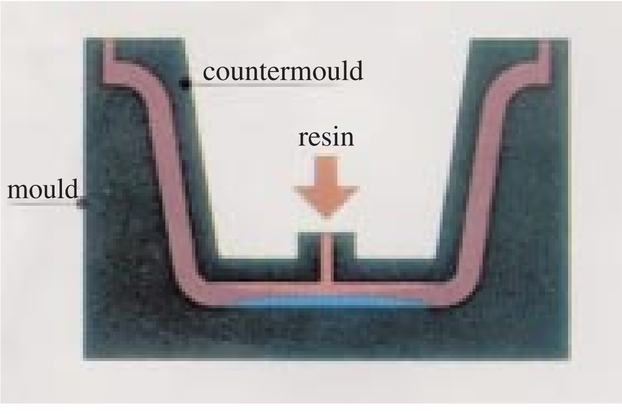

Fig. 14: Injection moulding (after Vetrotex).

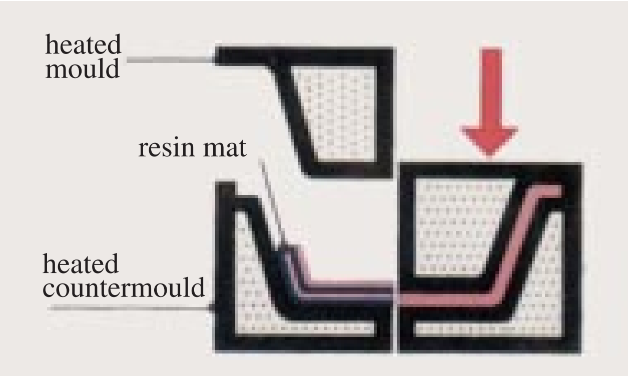

Fig. 15: SMC process (after Vetrotex).

Unlike the other processes described above, the hot pressing of resin mats utilizes an immediately usable material in the form of a pre-impregnated mat, which is generally described as SMC (sheet moulding compound – see Fig. 15). The resin mat consists of cut fibres, 25 or 50 mm in length, which are embedded between two thin foils. First of all, cuttings are made which are smaller in area than the part being manufactured. These cuttings are stacked on top of one another and inserted into the mould. The effects of pressure and

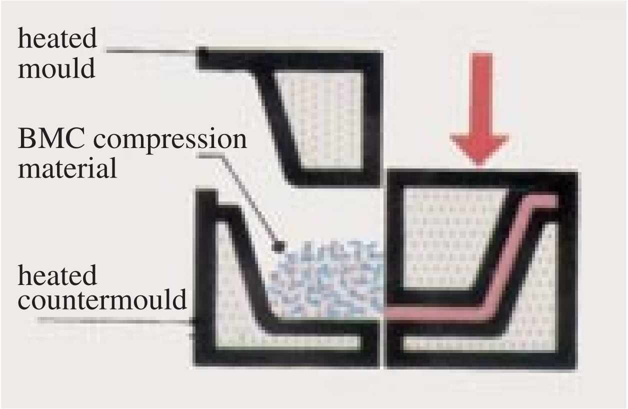

Fig. 16: BMC process (after Vetrotex).

temperature will cause the material to flow and fill up the cavity of the mould. Polymerization is triggered by the heat of the mould. This process allows parts with walls of varying thickness, bridges, undercuts, etc. to be manufactured. The pressures are between 30 and 100 bar, the temperatures between 140 and 160°C.

BMC (bulk moulding compound), a.k.a. as duroplast or premix compression moulding material, is a mixture of cut textile glass, resin and fillers. The processing of BMC and SMC differs in that the materials vary in form. Unlike the sheet resin mats, BMC is a fibrous moulding material with a dough-like, flowing character. The textile glass reinforcement consists of cut fibres of usually 6 or 12 mm in length. The filler content is often higher than with SMC, whereas the textile glass component is smaller. That is why a greater mechanical strength is obtained from SMC than from BMC.

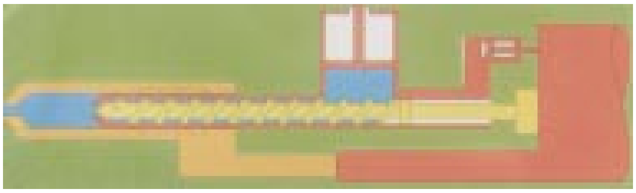

Fig. 17: Injection moulding ZMC (after Vetrotex).

For large-scale manufacture using duroplasts, injection moulding (Fig. 17) is suitable on account of the automation possibilities and the high ejection rate. ZMC does not only describe a material or a process, but also the combination of product and technology (fibre – moulding material – press – mould – finishing stages). With this system, which is characterised by a high degree of automation, the moulded parts produced have an improved mechanical strength compared with the parts manufactured according to the classic injection moulding method using BMC. ZMC allows a high surface quality to be achieved. Processing temperatures around 160°C and injection pressures between 150 and 200 bar are employed. As with hot presses, the heated moulds are made of pressure-resistant steel. Hollow bodies can be manufactured by means of two different processes.

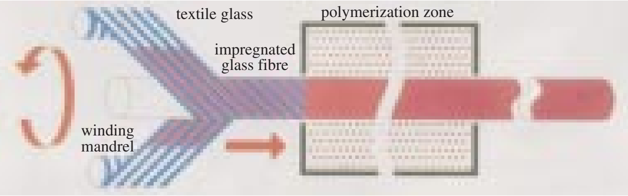

Fig. 18: Winding method (after Vetrotex).

The winding method (Fig. 18) is used to manufacture pipes, flanges, collars, etc. Manufacture occurs by winding resin-impregnated roving strands (in situ or pre-impregnated) around a core turning about an axle (mandrel). The roving strands can be attached either vertically to the winding mandrel (surface-driven winding) or at an angle to the axle (helical-type winding). This method allows high textile glass content levels to be achieved (60–75%), which ensure good mechanical properties. Additional textile glass mats or cut rovings, which are cut and sometimes combined with roving fabric directly before the feed to the winding mandrel, can also be used as reinforcing materials. These kinds of combined reinforcing structures are recommended if the product rigidity is a prime feature. The use of pre-impregnated rovings facilitates the manufacture of parts with a high textile glass component (80% by weight) due to their good processibility. The moulded parts manufactured by the winding method always have a smooth surface regardless of the type of machinery (whether continuous or batch production).

The centrifugal method (Fig. 19) is suitable for manufacturing hollow bodies with smooth inner and outer surfaces. The textile glass reinforcement (usually

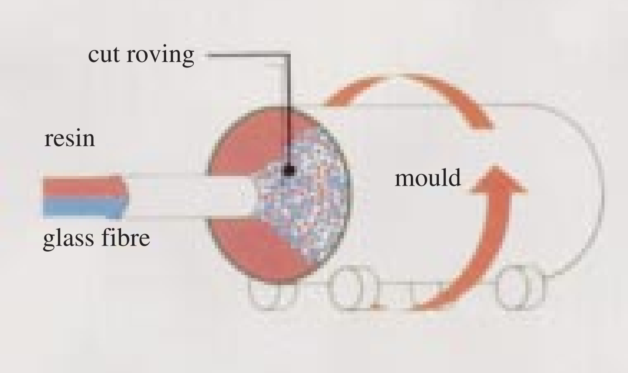

Fig. 19: Centrifugal method (after Vetrotex).

cut roving in situ) and the resin are injected inside a cylindrical mould, which is revolving at great speed. Textile glass mats or textile glass fabric may also be inserted in the mould beforehand. Under the effect of the centrifugal force, the reinforcement is saturated with resin. The centrifugal method is best suited to the manufacture of composite components made of polymer concrete, foam, anti-corrosion film, etc. The centrifugal method is chiefly used to manufacture cylindrical parts (tanks, silos, etc.), although it is equally suited to the production of slightly conical parts such as masts or pillars. With low circumferential speeds (e.g. for parts with large diameters) one talks in terms of “rotational casting”. This technique requires the provision of a vent in the mould.

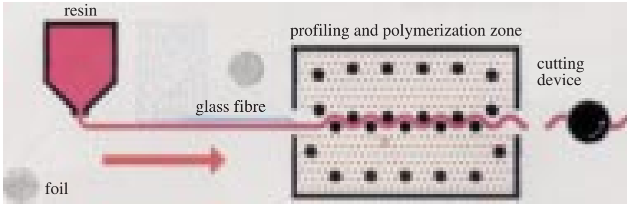

Fig. 20: Continuous plate production (after Vetrotex).

Plates are manufactured in large batches on continuously operating systems (Fig. 20). The textile glass (chopped strand mat, continuous mat or cut roving) and the resin are applied to a sheet which is spread out on a horizontal work-table. The impregnation that follows is supported by compression elements. Following impregnation a second sheet is applied to the surface of the glass/resin mixture. Thus prepared, the material passes through calibrating rollers and subsequently the polymerization tunnel, which contains the moulding elements in the front section. Upon exiting the continuous oven, the plates are trimmed and cut to the desired length. The two sheets do not only serve as carriers, but also allow the plates to obtain smooth surfaces on both sides. This technique, used mainly in the manufacture of flat and corrugated plates, can also be used to produce open profiles with simple forms and sufficient radii.

The pultrusion process (Fig. 21) serves the continuous manufacture of every type of profile. Here the resin-impregnated reinforcing material is drawn through a heated mould in which the profiling and polymerization take place. Roving, mat and/or fabric can all be processed as reinforcement. Impregnation occurs either through submersion in an impregnation tank or by injecting the resin at the nozzle head. Polymerization of the product occurs upon passing through the heated polymerization zone at 120–150ºC. The drawing mould is usually made of smooth-polished and chrome-plated steel. The profile is drawn at constant speed by a device arranged for this purpose behind the drawing mould, which makes for continuous operation. This process allows complicated parts, hollow or solid, to be manufactured with great mechanical strength.

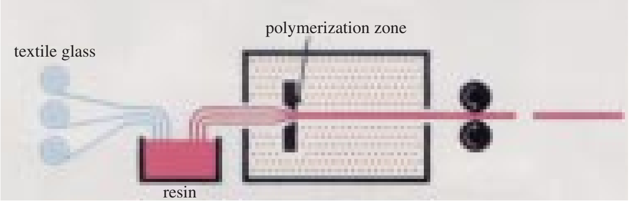

Fig. 21: Pultrusion process (after Vetrotex).

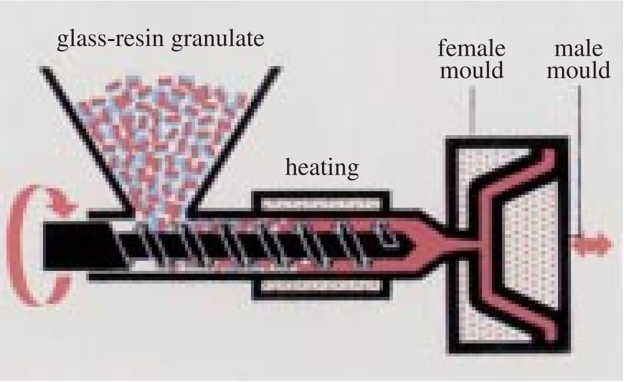

Fig. 22: Injection moulding of granulates (after Vetrotex).

With injection moulding (Fig. 22) of reinforced thermoplasts, in 90–95% of the cases a semi-finished product in the form of textile glass reinforced granulates is used. The textile glass, usually 4.5 mm long cut fibres, can be mixed initially with the pure resin granulate (premix) or can be fed separately to the extruder (separate dosage). In some cases, e.g. with twin-screw extruders, it is also possible to feed the textile glass directly to the resin melt in the form of roving strands. The reinforced granulate is processed in the injection moulding, whereby the same plant facilities can be used as for the processing of unreinforced thermoplasts. Owing to the high injection pressures (> 350 bar) it is only possible in terms of equipment to manufacture parts up to a particular size. The processing temperatures are usually 10–20°C higher than those for unreinforced thermoplasts. Injection moulding also allows complex forms with bridges, overhangs, bore holes, undercuts, etc. with high ejection rates to be manufactured from thermoplasts.

Moulded parts made of thermoplast plates, reinforced with long glass fibres, are manufactured according to the processes of moulding compression and extrusion of reinforced thermoplasts. Different processes are available for the manufacture of these reinforced thermoplast sheets (GMT). The sheets are heated up to the softening temperature of the resin matrix and formed in a cooled mould. In the same way, only by

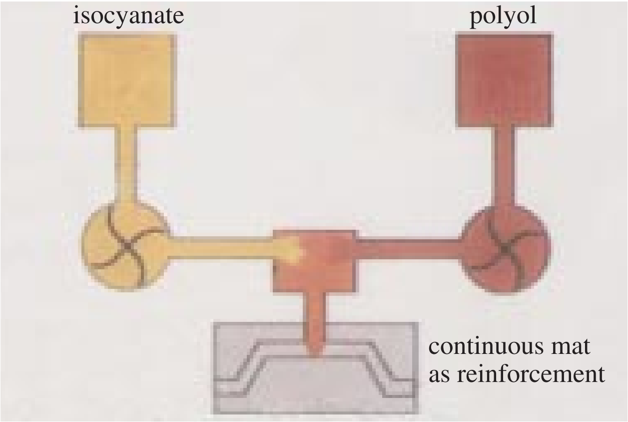

Fig. 23: PUR-M process (mat reinforcement) (after Vetrotex).

altering the cuttings and the moulding pressures, they can also be processed by the extrusion method. The actual pressures used depend on the shape and thickness of the part being manufactured. The pressures with moulding compression are between 20 and 50 bar, with extrusion between 120 and 150 bar.

Textile glass also serves as reinforcement of polyurethane foams. These reinforced foams obtainable in semi-rigid or rigid form are gaining increasing acceptance due to their low weight and easy processibility. Of the wide range of applications, if one takes the case of the automobile industry, here parts made of reinforced foam are chosen for fitting out the interior of cars and commercial vehicles. Through reinforcement with textile glass mats (Fig. 23) polyurethane foams acquire better mechanical properties and greater dimensional stability. The most common reinforcing materials used for this purpose are continuous mats, which can be preformed if need be. A mat is inserted in the mould: the polyurethane resin can now be spread over the mat prior to closing the mould or be injected into the closed mould at a low pressure. The expansion and reaction of the PUR mix occur during its time in the mould. Should the exterior of the part need to be decorated, this can occur directly during the moulding, by inserting the material or plastic film in the mould prior to reinforcing.

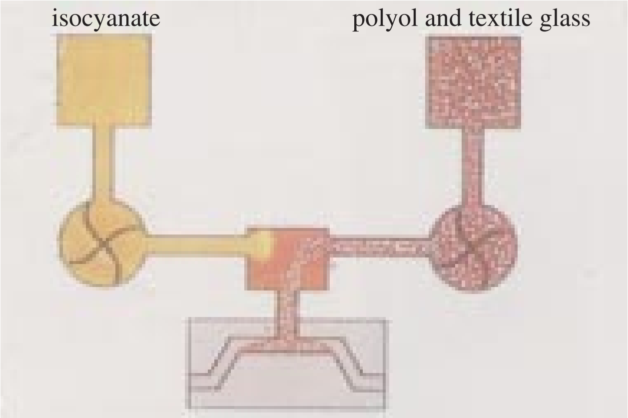

Fig. 24: R-RIM process (after Vetrotex).

The term R-RIM (reinforced reaction injection moulding) describes both process (RIM) and material used (Fig. 24). This normally involves a polyurethane resin that is reinforced with very short glass fibres (short fibres). The textile glass is mixed into one of the polyurethane components (into the polyol) prior to mixing it with the second component (isocyanate). The moulds are heated up to approx. 50°C. This process makes for high ejection rates. Thanks to the textile glass reinforcement, parts are obtained with improved mechanical properties and greater dimensional stability (according to Loy, Gehring, Brüning, Planck, von Falkay, Lehner, Pagendarm and Vetrotex).

Composite yarns →: Flock yarn; Core-spun yarns.

Compound Finished thermoplastic. Many uses, e.g. in the manufacture of tufted carpets for finished recipes for base/pre-coat coating as backing, precoating and foam compounds. Typically includes latex, polyurethane compounds etc. Modified compounds contain, in addition to water, filler (chalk), thickener etc., additional application variants (flame-retardant, antistatic and biocidal).

Compound oils (Compounded mineral oils), greased mineral oils, i.e. mixtures of mineral oil and vegetable or animal fats or oils or fatty acids (olein, castor oil, bone oil, etc.). Uses: as lubricant, greasing agent, preparation agent).

Compounds → Chemical compounds.

Compound threads/yarns Combinations of yarns of different fibre materials, bicomponent fibres, mixed count man-made fibres, core spun yarns, textured combination yarns, metal effect threads etc.

Compressed air Air at higher than atmospheric pressure. Compressed air utilises an important property of gases: i.e. compressibility. It is the energy carrier for pneumatic systems.

Compressed air jet → Jet nozzles.

Compressibility →: Thickness of textile fabrics; Stating loading resistante.

Compressing (Lat.). Compressing, compacting air and gases by means of → Compressors to form compressed air and compressed gas (liquid gas).

Compression (Lat.). Pressing together, compacting (gases, vapours).

Compression channel → Stuffer channel.

Compression, resistance to Resistance to compression (compare → Flexural resistance) of textiles under loading, e.g. of a strip of fabric folded one or more times. In contrast to the ability to recover from compression, the ability in this case to unfold again on release from loading due to the flexural elasticity of the textile. If the compressive force is plotted against the percentage compression (Fig.) curves are produced following a similar pattern to force-elongation curves.

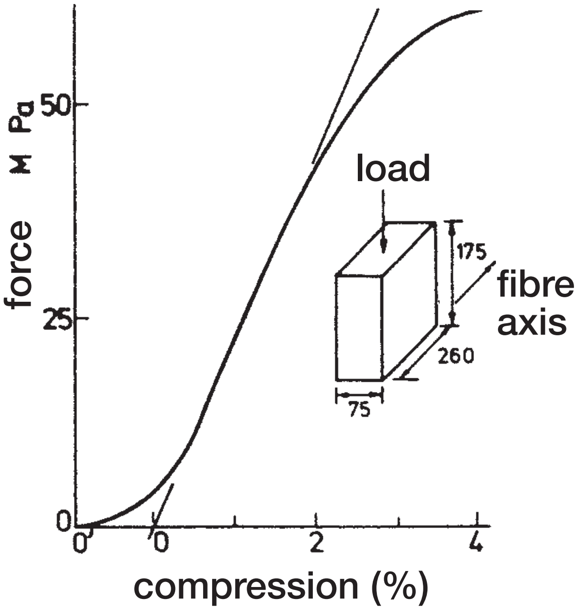

Fig.: Compression curve of a keratin block produced from horse hair at 20°C, 60% relative air humidity and a 3 %/min increase in force effect (Bendit).

Compression-type coolers (cooling units). Housed ready for connection in a compact housing with fan-cooled refrigerating plant together with pump and control unit; connected to one or more water supply tanks (= cold reservoir). Have the following advantages over → Cooling towers: fewer setting-up problems, easier installation, smaller water storage tank required, closed circulation, no water consumption due to evaporation (water cost approx. zero), waste heat usable for space heating, intake air removable from workroom (room ventilation), electronic temperature control optimises current consumption, maintenance-free. Disadvantages in comparison with cooling towers: more energy consumed, greater air throughput (a great deal of fresh air required), running noise (official regulations).

Compressive shrinkage Mechanical process for applying a → Pre-shrunk finish and reducing residual shrinkage in textiles. One of the factors affecting the suitability for purpose of a textile is its ability not to shrink when it gets wet or is washed. → Dimensional stability is required. Increasing consumer demands have compelled the finisher to pay particular attention to this aspect in all textile products. The shrinkage of woven and knitted fabrics is partly attributable to tensions imposed during the manufacturing cycle (Figs. 1 and 2). These tensions are released in finishing.

New tensions should be avoided where possible by operating free from tension in this final stage. The textile engineering industry has catered for these needs by designing tensionless drive mechanisms (Ward-Leonard control), tension-free jigs and driers (e.g. short-loop drier). But tension-free finishing alone is not sufficient for achieving a fully-shrunk finish.

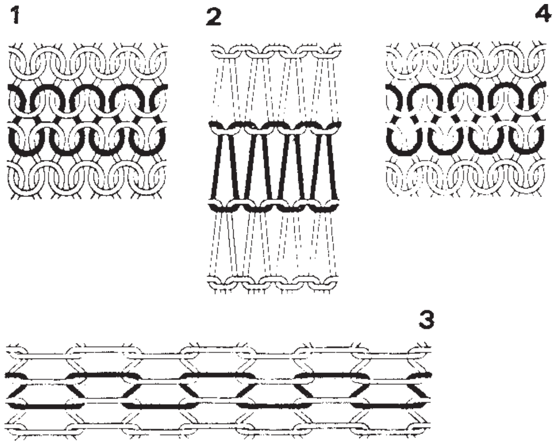

Fig. 1: Knitted fabric elongation conditions.
1 = grey fabric; 2 = stitch shape after length direction loading; 3 = after transverse loading; 4 = relaxed form.

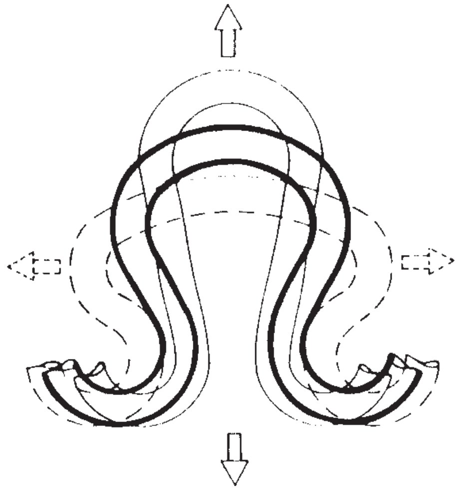

Fig. 2: Configuration of an individual stitch under various elongation conditions.

Methods of compressive shrinking are intended especially for fabrics in 100% cotton and its blends with synthetic fibres. The oldest and most important is the CCS (controlled compressive shrinkage) process of Cluett-Peabody, the Sanforizing process, the principle of which (Fig. 3) consists of stuffing together the fabric along its length (warp-way) on a machine resembling a felt calender and setting it in this state, so that when it is subsequently washed no further shrinkage will occur. Sanforized materials of this kind should if possible be set to a residual shrinkage of max. 1%. During manufacture and especially in finishing, fabrics are subjected to varying degrees of tension in the warp direction. Across the width (weft-way) tension is much lower. It is logical that after Sanforizing (Fig. 4) there must be no further finishing treatment of the fabric. The Sanfor-Plus process represents a combination of mechanical and chemical systems. For repeated laundering at the boil, dimensional stability can be achieved only with a

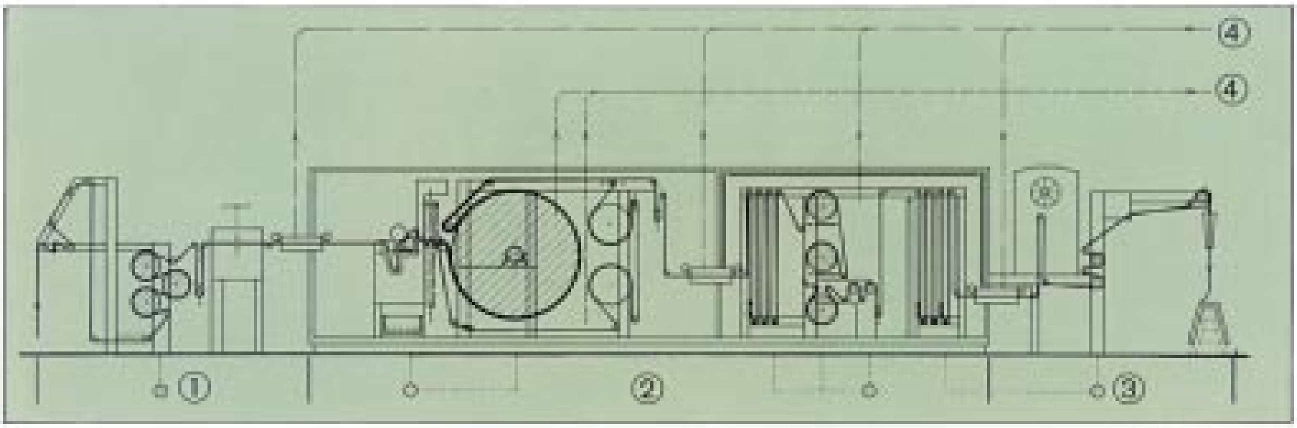

Fig. 5: Sanfor-Set line based on "liquid ammonia" (Monforts).

supplementary resin finish. The Sanfor-Set process is a further development in which the preliminary mercerising treatment takes place in liquid ammonia (Fig. 5).

In principle the fabric is only able to shrink if the hydrogen bonds in cotton are first substantially broken by humidification and steaming. This is brought about by mechanically stuffing the fabric together before the new state is set by drying (locking the hydrogen bonds in place).

The fabric entry to the rubber belt shrinking unit is formed by the sandwich created by a large heated cylinder and a continuous rubber belt (67 mm thick, 40° Shore hardness). The fabric is placed on the extended surface of the rubber belt and is thus forcibly contracted by the shortening of the surface of the rubber belt, with the smooth surface of the cylinder presenting virtually no impediment to this process. The greater the contact pressure of the rubber belt the greater the shrinkage. At the entry point the rubber belt can be compressed at most down to 30% of its normal thickness. The corresponding Sanfor-Knit process is used for tubular knitted fabrics and also for open-width flat knits.

The "Bestan" machine (Fig. 6), used to shrink tubular knits, operates in a similar way to a rotary press. In the Tube-Tex-Compactor (Fig. 7) the fabric is passed over a roller running at higher speed and into the gap it forms with the hot shoe. Because the take-off roller, which has deeply engraved lateral surface grooves,

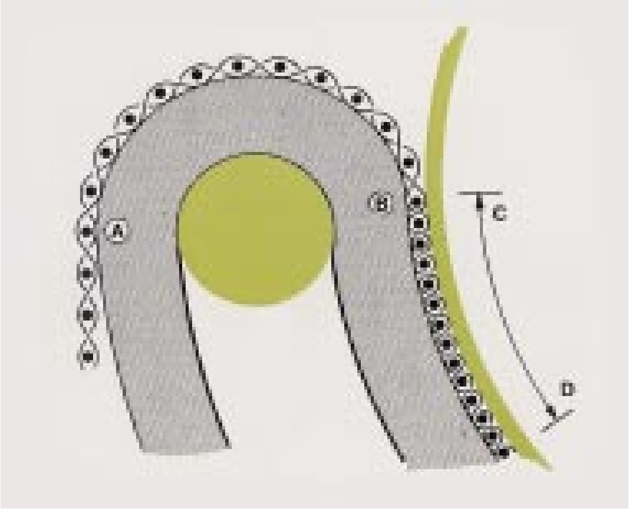

Fig. 3: Functional diagram of fabric path during compressive shrinking.

runs more slowly the fabric is shrunk in the highly condensed core zone as a result of having been steamed in a twin-jet chamber before entering. Further versions of the belt-shrink type are the Toptex-W system and the shoe-shrink type for tubular fabrics by Monforts, and the Pak-nit-II system and the C 2000 Compactor for open-width knitted fabrics both by Tube-Tex.

Denim fabrics need to be shrunk at the most economic rate possible. To impart the necessary humidity to the fabric for shrinking in the rubber belt shrinking unit it is possible at considerable expense to rehumidify on the padder followed by post-drying to a specific humidity level on cylinder dryers (Fig. 8). It is appreciably cheaper to humidify by low-level foam application without the need for drying and then apply the shrink process.

Tension-free shrinking of wool fabrics is peformed on special machines (Fig. 9).

Compressive shrinkage processes (sanforizing), compressive, controlled shrinkage process, also known as the Cluett process. In 1928 the American, Sanford Cluett, developed the compressive felt shrinkage machine. This was used for the mechanical compression of woven fabrics, mainly cottons, in their length. Machines of this kind are generally known as Sanforizing machines (Fig. 1). The term Sanforizing is now no

longer protected by patent. In the classic felt shrinkage plant (made by Cluett-Peabody, USA), as the fabric enters it is sprayed with a fine mist of water, steamed in a steam box and surface-dried on a cylinder drier.

The goods are extended to full width on a short frame at a higher speed before reaching the shrinking device. The shrinkage takes place immediately after passing the hot shoe at a temperature of approx. 180 °C (Fig. 2). The flexural strength of the fibre is decreased, the physical crosslinking is broken, and the textile material is more easily compressed. Drying takes place immediately after the subsequent felt calender. The shrinking capacity of this machine is max. 10%. The degree of shrinkage is determined by the thickness of the felt. The thicker the felt, the higher the shrinkage capacity. The degree of shrinkage is regulated by altering the shrinking shoe.

The conveyance of the goods by the rubber belt shrinking plant is similar to that of a felt shrinkage plant (Fig. 3). Here, however, the shrinkage effect is achieved by the large surface extension and subsequent pressing together of a continuous rubber belt in conjunction with a drum heated to approx. 100–140°C. The rubber belt shrinking plant is more widely used in preference to the felt shrinking plant because of

- the higher shrinking capacity of the textile goods, approx. 17%,
- the attainment of higher production speeds,
- the simpler operation of the machine for setting shrinkage values.

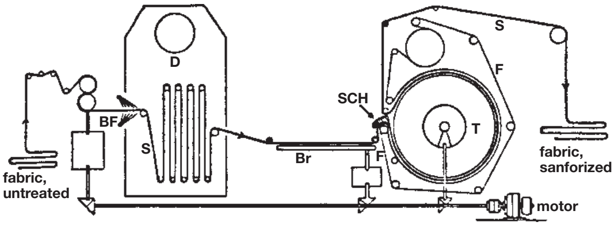

Fig. 1: Diagrammatic section of the compressive shrinkage process.

The system has been developed further by replacing the steam box with a steaming cylinder heated with saturated steam, along with additional improvements such as low-tension fabric feed.

The Sanfor-Set finish (by Cluett-Peabody, USA) is a combination of two finishing stages, treatment with liquid ammonia and shrinking on the Sanforizing or shrinking plant (Fig. 4). The finished cotton fabric is introduced to the treatment chamber thoroughly dry and cool, and soaked in liquid ammonia (NH_3) at approx. –34°C. It is then squeezed and left to dwell in an enclosed space. The liquid NH_3 penetrates the fibre and causes an intracrystalline swelling and release of tension. The ammonia enables a high number of hydrogen bonds to be broken, thus splitting the crystalline structure of the fibre. During recrystallization the crystalline structures are smaller but more numerous. In the subsequent felt calender the swelling agent is removed from the fabric by drying and steaming. Finally, the goods

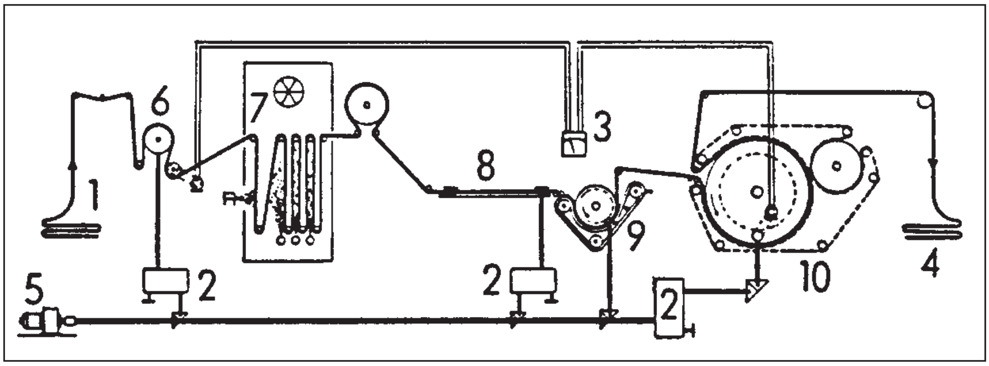

Fig. 3: Diagram of a Cluett rubber belt plant. 1 + 4 = goods; 2, 3 + 5 = synchronization of the different drive mechanisms; 6 + 8 = higher speed sections; 7 = steaming; 9 = rubber belt; 10 = felt calender.

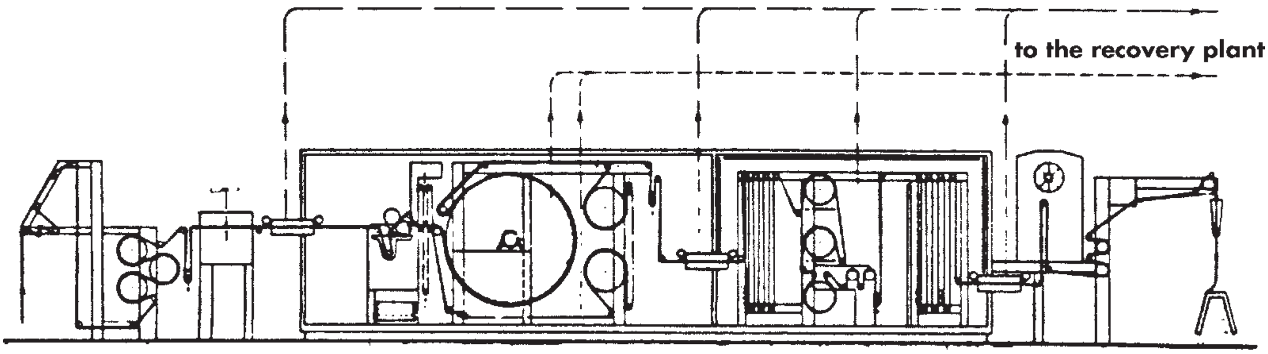

Fig. 4: Sanfor-Set plant without shrinking machine (liquid ammonia basis).

are treated with steam and fed to the compressive shrinkage plant. According to the details provided by the licensor, the Sanfor-Set process gives cotton fabrics the following qualities:

- better technological values,
- improved dry crease recovery,
- improved residual shrinkage resistance after boil wash and tumble drying,
- low, permanent lustre effect,
- smooth fabric surface,
- soft, pleasant handle.

A further combined finishing and shrinking plant is used for denim fabrics. This combines processes such as cleaning, singeing, soaking, drying and shrinking.

The Supatex shrinking machine by the English company of Mather & Platt (Fig. 5) is a variant of the rubber belt shrinking machine; it combines features of the Bestan Compactor and the Evaset MK 3 shrinking machines. The rubber belt encircles two rollers of equal size according to the principle of the open flat belt drive system. Above the feed roller, on the open rubber belt surface, is a heated, smooth shrinking cylinder. The shrinking cylinder and the roller, which provide the guide system for the rubber belt, are driven separately. Once the cloth is introduced to the shrinking plant, it runs through the passage between feed roller, rubber belt and shrinking cylinder. The shrinkage is caused by the pressure of the cylinder and the relative movement of the rubber belt. The distance between the rollers and the pressure exerted by the steel cylinder are infinitely adjustable.

The American Tubular Textile Machinery Corporation makes two compactor plant:

- the C 2000 compactor for open width knit-goods (Fig. 6),
- the Paknit II compactor for tubular goods (Fig. 7),

which are well known worldwide under the trade name Tube-Tex Compactors.

1. C 2000 Compactor: the cloth is steamed without tension in twin chambers and introduced to the compacting zone. The compacting zone consists of the following components:

- an electrically heated, chromed compacting shoe with smooth surface,

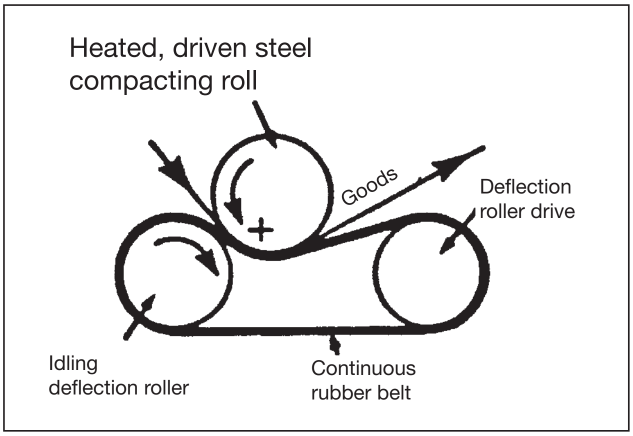

Fig. 5: Diagrammatic section of the shrinking section of the Supatex shrinking machine (Mather & Platt).

- a fast-running, steam-heated feed roll with rough, sandpaper-like surface,
- a steam-heated retarding roll with cross-grooves.

The distance between the roll pair and the compacting shoe is infinitely adjustable. The compacting shoe presses the cloth as it enters the compacting zone at higher speed against the feed roll. The retarding roll lowers the speed of the cloth and controls the degree of shrinkage.

2. The Paknit II has two compacting zones, so that both surfaces of a tubular knit fabric receive the same treatment. There is a second compacting shoe in the compacting zone, designed to back up the retarding roll as the tubular fabric is taken up, so that the layers are not displaced. There is a choice of a plaiting or rolling device at the exit from the machine.

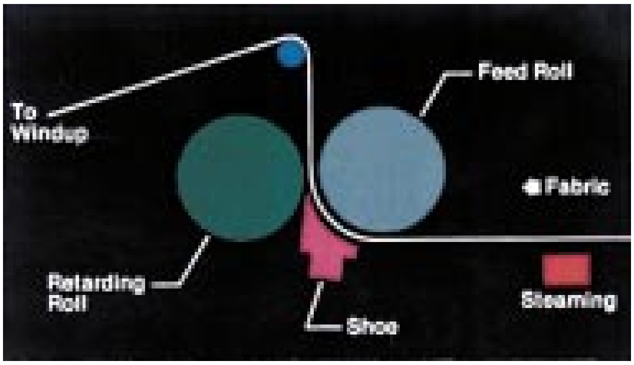

Fig. 6: Diagrammatic section of the compacting principle of the C 2000 Compactor (Tubular Textile Machinery Corporation).

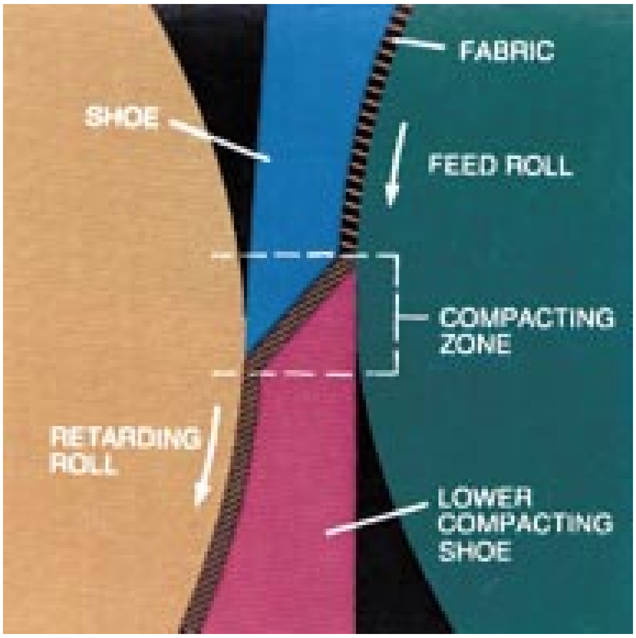

Fig. 7: Diagrammatic representation of the two compacting zones of the Paknit II (Tubular Textile Machinery Corporation).

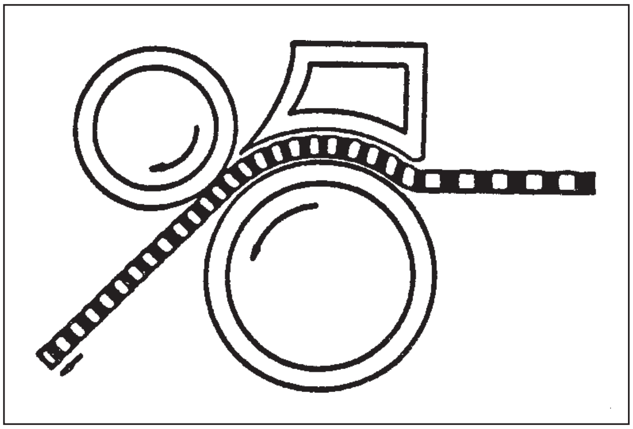

Fig. 8: Operating method of the Bestan machine (Hunt & Moscop).

The Bestan machine (Hunt & Moscop) consists of two rollers and a smooth stainless steel heater (Fig. 8). One roller (pressure feed roller) is coated with ebonite; the heater is positioned above this. As the knitted fabric passes through these two components it is taken up by a slower retarding roller coated with soft rubber. The effectiveness of the compression depends on the differing speeds and the friction coefficients of the rollers. The retarding roller has a comparatively high friction coefficient and a lower circumferential speed than the pressure feed roller.

The Gullwing Stabilizer (Fab-Con Machinery) is similar to the Tube-Tex Compactor; the tubular cloth is stretched to the desired width by two independently adjustable rollers, steamed and then introduced into the compacting zone. The heated compacting triangle consists of two rollers engraved with deep cross-grooves, and a compacting shoe. Feed and retarding rollers rotate in the same direction; the degree of compaction is adjusted by means of the pressure of the compacting shoe and the speed of the feed and retarding rollers (Fig. 9).

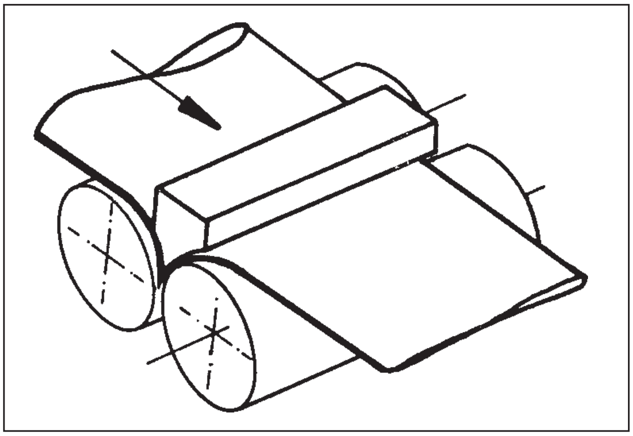

Fig. 9: Diagrammatic section of the compacting principle of the Gullwing machine (Fab-Con Machinery).

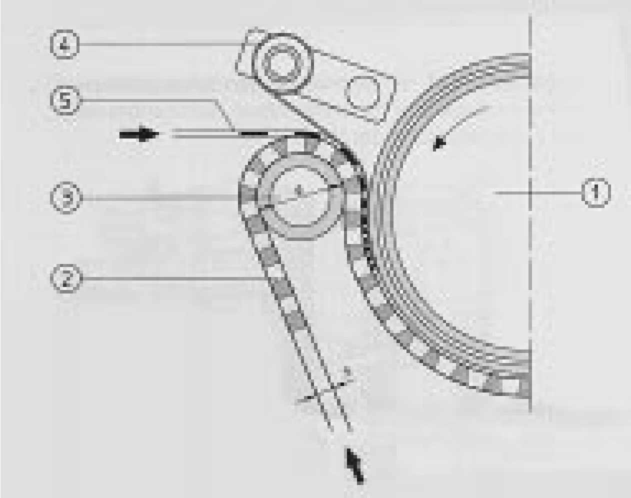

Fig. 10: Compression unit according to the Sanfor-Knit process, constructed by Sperotto-Rimar.
1 = steam-heated steel roller; 2 = continuous belt; 3 = roller for guiding the belt and feeding the fabric (5); 4 = fabric feed unit.

The Sanfor Knit Process (by Cluett-Peabody, USA) for tubular knitted fabrics was developed by specialists in the Sanforizing technique working together with knitted goods manufacturers. The most important components of this plant are:

- a felt calender with 2000 mm diameter,
- a guide shoe, providing acceleration and ensuring even pressure on the felt as the fabric is fed in,
- an expander roller.

After the continuous felt belt has been around the heated calender along with the previously steamed fabric, it travels around a drying cylinder and is then ready to repeat the process with new fabric to be compressed. The dampness is removed from the knitted fabric as it passes around the felt drum; its dimensions are stabilised. Fig. 10 shows the Sanforizing principle as it is applied by Sperotto-Rimar.

The construction of the Top-Tex/W rubber belt shrinking machine (Montforts) comprises the following principal components:

- fabric feed with expander roller,
- steam device,
- rubber belt shrinkage unit, consisting of a heated metal cylinder or shrinkage cylinder and a circulating rubber belt,
- drying cylinder,
- cloth take-off or winding device.

The shrinking process can be explained using this machine as an example: compressive shrinkage takes place when a textile fabric is hydrothermically treated and compressed lengthwise. The degree of shrinkage can be regulated by adjusting the pressure of the rubber belt on the compacting cylinder. The compression of a textile fabric by means of the rubber belt shrinking unit is achieved as a result of the surface extension and immediate surface compression by the rubber belt whilst simultaneously altering the direction of curvature. The pressure of the rubber belt on the compacting roller alters the form of the soft, elastic material. The rubber belt is proportionally thinner in the compacting zone. Because of the constancy of volume of the rubber, the belt must therefore be extended lengthwise, i.e. its surface area is increased. The knitted fabric to be shrunk first reaches the extended rubber belt surface shortly before the compression gap. On leaving the compression zone the forced extension is elastically retracted, i.e. the rubber belt once again becomes thicker and thus shorter. The knitted fabric carried along with it must follow the movement of the rubber belt, as it clings to the surface of the rubber; the smooth, heated compression cylinder is on the other hand able to slide past the fabric. Thus the knitted fabric is forced together, which is evident in a thickening of the fabric.

In order to maintain the achieved compression of the stretchable knitted fabric, the most important prerequisite is the low tension of the fabric feed. As a consequence the fabric guide systems within the plant and on introduction and take-off must be kept as short as possible. The low-tension core winding is controlled by a computer according to the increase or decrease of the batch diameter (up to 20 000 mm), so that at any point in the take-off or winding process the knitted fabric is maintained at the lowest possible tension. In addition, the fabric feed rollers of the double-loop compensators forming part of the unwinding and winding mechanism are controlled by an auxiliary drive, so that the bearing friction is surmounted by the drive and not by the take-off of the fabric. Pneumatically raised and lowered swivel arms ensure winding and unwinding without creasing. These can be adjusted with optically controlled gap regulation, so that the support roller always maintains the same distance from the fabric roll. Variations on this are the side-controlled twin-roller winding device or the twin ascending batch roller, if the edge diameter is not to exceed 500 mm. So that the shrinking or finishing procedure need not be interrupted during cutting or bale change, a conveyor belt is installed before the winder, on which the fabric is stored when the Top-Tex/W is still running but the winding mechanism is stopped. The speed of the conveyor belt is controlled by a photocell, so that the volume of fabric lying on it is kept between a minimum and a maximum. Before the twin ascending batch roller is a fabric centring device which works on the principle of a slatted expander. The whole DC drive system is controlled by a digital network system, so that at every change of speed the preset fabric feed remains constant.

Compressors (condensers, air pumps). Used for compressing and conveying air and gases above atmospheric pressure. Power consumption varies according to size, design, number of compression stages and type of cooling.

Distinction is made between:

I. Reciprocating (piston) compressors (today generally with valve control, vacuum filter and incorporating water and oil trap). Up to maximum pressures (300–400 bar in 4 and more stages). Predominantly with automatic pressure regulator (mechanical or electrical, both pressure controlled by compressed air pressure). Special dry running compressor versions for production of oil-free compressed air. Also in vacuum pump form, one and two stage with slide-valve control = air pump.

II. Centrifugal or turbo compressors (axial-flow condensers): Generally several impellers arranged consecutively radially or axially on the same shaft, rotating at high speed. Suitable for high throughputs (exceeding 5000 m^3/h) and moderate pressures.

III. Rotary compressors (cellular condensers): rotating machines operating on the same principle as reciprocating compressors.

End-uses: Predominantly for producing compressed air (for blowers, compressed-air tools, compressed air motors and pumps for pneumatic conveyor and control systems) and pressurised gas (for pressing and singeing machines, heating and lighting purposes, industrial chemistry processing).

Compressor systems Compressed air is an essential form of energy. Increasing numbers of finishing machines are equipped with pneumatic control. One suggested way of minimising the load on a compressor that has to cater for an increasing volume of air consumption, sometimes experiencing considerable peak loads, is as follows: The existing reciprocating compressor operates for approx. 75% of the time, for which purpose a pressure vessel is required from which the required working pressure can be obtained in the after-cooling phase. A rotary compressor, however, is designed to operate 100% of the time and the greater the load the more economical it is. A rotary compressor should therefore be used to provide continuous compressed air production. The rotary compressor is designed only for the normal air requirement of the mill as a base load provider. Over-specification to cater for peak loads in compressed air consumption is unnecessary since the existing reciprocating compressor can be used as peak load provider. A pressure regulator is fitted between the rotary compressor and the old reciprocating compressor, with the latter cutting in briefly only when sufficient demand occurs (Fig.).

Computer applications in textile dyeing and printing Computers are used in four traditional areas of textile dyeing and finishing:

1. Development of design and print ranges (CAD)
2. Planning of production and control of the preparation of goods
3. Operational economy uses in book keeping, payroll and cost calculations
4. Computer assisted production, principally in colour measurement, control of dyeing and printing machines and automation of dyeing and printing processes.

Some abbreviations used in computer technology:

CAD	Computer Aided Design
CAM	Computer Aided Manufacturing
CAP	Computer Aided Promotion
CASP	Computer Aided Synthesis Planning
CC	Computer Chemistry
CIM	Computer Integrated Manufacturing
MIS	Management Information System
MRP	Material Requirement Planning
PC	Personal Computer
µ-P	Microprocessor
AI	Artificial Intelligence
ES	Expert System

Computers are typically used in dyeing and printing for: research, marketing, administration, production and providing information.

Research: Databases of all types are used in all parts of the world. Among other things CC, e.g. CASP, can be used for finding relationships between structure and

Computer applications in textile dyeing and printing

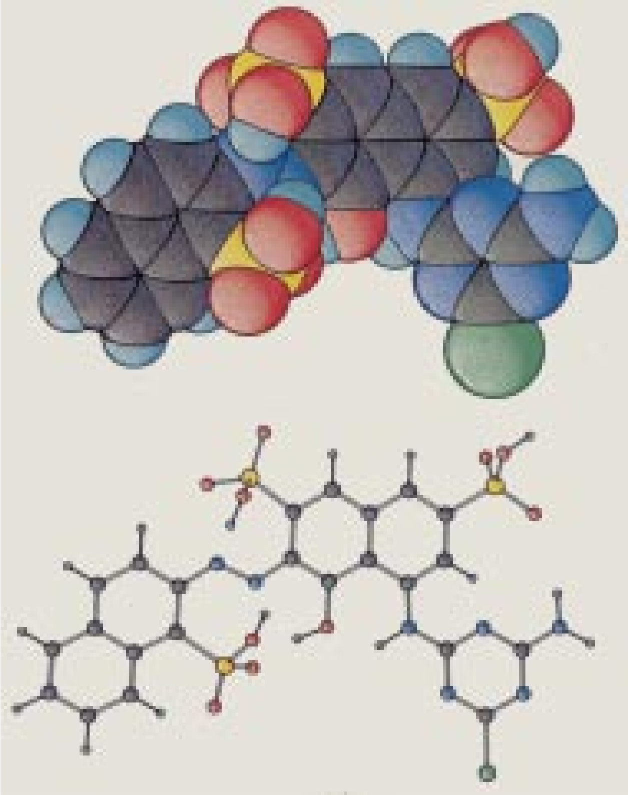

Fig. 1: A computer generated space-filling model of an azo reactive dye (above) compared with the ball-and-stick model (below) (after Dörr).
black = C; cyan = H; red = O; blue = N; green = Cl; yellow = S.

properties. They can save expensive laboratory and analytical work and not least duplication of effort. The chemical industry co-operates in the comprehensive planning of total syntheses through linked expert systems. The information that is collected about all the components is fed into a computer library; by recovering the information, the synthesis can be carried out in reverse on the screen, starting from the required structure (the new product that is wanted), back through the intermediate stages of decreasing complexity down to the necessary raw materials.

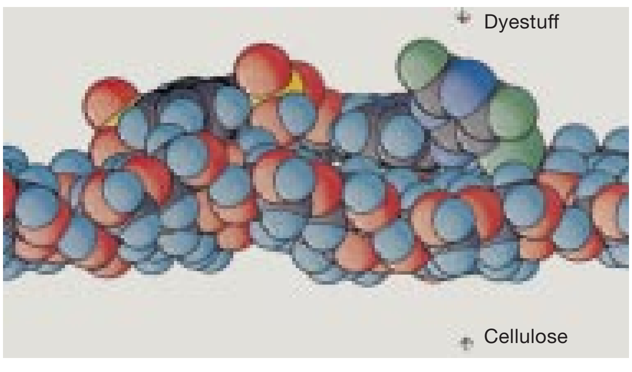

Fig. 2: A space filling model of a reactive dyestuff adsorbed onto cellulose.

Molecular simulations (Figs. 1 and 3) or chemical reactions, for example a reactive dyeing (Fig. 2), lead to a better understanding of chemical processes. The molecule from the terminal is displayed on the screen. With Sybyl, the package most often used in the industry, the user can readily construct the molecule on the screen by putting molecular fragments and individual atoms together. In addition the geometry of the molecule can be altered by making appropriate changes in bond lengths and angles. Then calculations are carried out and the geometry is optimized.

Fig. 3: Computer model of a phthalocyanine dyestuff (green = copper).

Marketing: MIS includes logistical, commercial and technical data about products and has been so widely introduced that it is impossible to imagine being without it. Direct links with computers at suppliers' and at customers' premises to rationalize the running of the business are being introduced. If there are a lot of application packages for different jobs, it is better to use a PC-network so that individual applications can be run without interfering with one another. There is also a series of applications which have to be run continuously. In these cases, the user in a multi-user application has to accept the loss of performance, e.g. graphical presentation of the selling figures with simultaneous and multiple display of customers' orders. A disadvantage is that the typical batch run offs, e.g. bookkeeping evaluations, payroll calculations, final monthly results, have still to be developed for multi-user applications. In general, such diverse applications are better carried out with a network.

Administration/customer service: Apart from colour measurement, which has been the traditional field of application for the computer, new areas are opening up: most importantly, expert systems have been introduced. They allow a pool of knowledge to be held, added to, broadened and used systematically. Laboratory automation is also being introduced into the dyeing laboratory (pilot plant). By connecting commercial and technical data it is possible to get the necessary transparency to make the best decisions for optimizing operating costs. The computer as a storage medium with data banks is the traditional alternative to expert systems. It also provides the opportunity of simulating processes. The computer can also be useful in statistical experimental planning and analysing the results.

The idea of data bank systems is to manage information in a systematic way and prepare it for the user. A data bank system is organised as follows:

a) the data base which is a systematically stored collection of data;
b) the data bank management system that manages and regulates the data and allows access to it;
c) the application programs that can question the data management system through programmable search paths.

In contrast to a data bank system, which essentially manages and organises data according to well known structures, information retrieval systems offer greater possibilities for retrieving information. If a retrieval system is considered as an information system, an → Expert system can be thought of as a prototype intelligent system. The prerequisite for a dialogue with an information system is that the user has to translate his problem, which is naturally expressed initially in normal, everyday language, into a query in a formal questioning language that has been programmed into the computer. To be able to search efficiently, the user must have knowledge of the data arrangement of the system (search fields) and of the formal syntax of the questioning language. The conversion of the query from normal language into the formal questioning language and further support of the dialogue between the user and the information system, so that knowledge of the system would no longer be necessary, would be a sensible application of an expert system. The setting of the query in normal language is a problem that should not be underestimated.

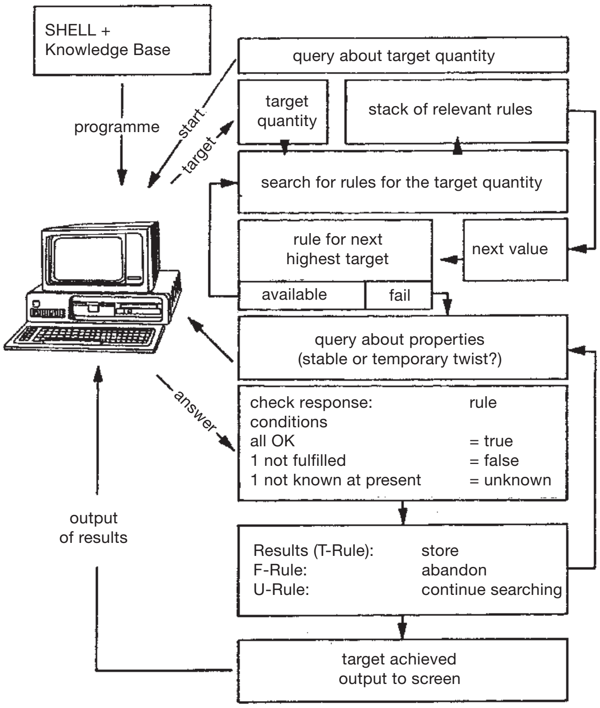

Fig. 4: Working mode of an expert system (after Rüttiger).

Generally an expert system (Fig. 4) supports the solution of complex, trade specific problems by having clarifying and advisory functions: clarifying in that the system can check every step or every question set by the user as well as every result, advisory in that it can come to a definite conclusion based on its viable knowledge base. The problem solving capability of expert systems comes from suitable trade specific systems of rules. The combination of the system of rules with appropriate factual data leads to an intelligent information system, which can be constructed, for example with the help of "expert system shells" which have been developed meanwhile. Hence, the knowledge base of this shell depends on the application background of the user and so is limited to that subject area. 4 functions are interconnected with one another: the problem solving component works on the user's query and amplifies the query interpretation function for the process of reaching a conclusion. The explanatory component records the problem solving process so that solutions that have already been worked out can be recalled. The knowledge acquisition component is used for extending and modifying the information base. Apart from carrying on the dialogue with the user, the dialogue component analyses and translates queries that are set in normal language. Thus, documentary, communication, and professional knowledge and information are brought to work together.

Daisy-Tex-System: with the Daisy-Tex-System, Babcock has shown that significant progress has been made in process simulation. The system covers the introduction of the working media (water, steam, air, chemicals), improves the transparency of all the functions (as far as possible) and gives supervising personnel on-the-spot help in tracing faults.

Routines can be run either at timed intervals or at any moment by pressing programmed function keys and can be used, e.g. for displaying goods, to find the cause of faults. In addition, an end-of-job routine (at the ends of shifts or at batch changes), which is useful for subsequent calculations, is available. In a continu-

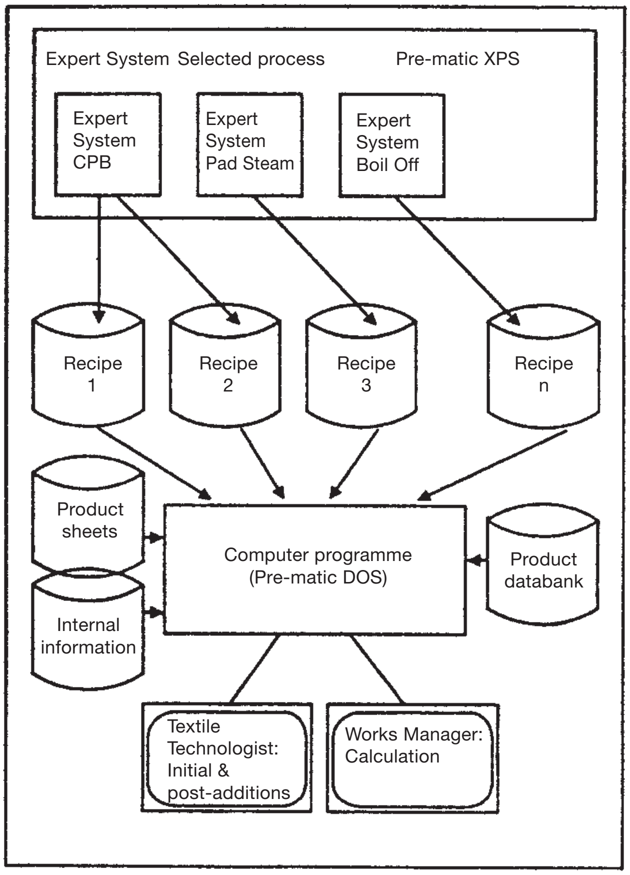

Fig. 5: Linking of a computer programme (Pre-matic DOS) for a textile technologist at the plant with the central expert system of a dyesuff supplier (Pre-matic XPS from Ciba-Geigy).

ous pretreatment plant, for example, the individual parts of the process are synchronised by compensating rollers. After the individual equilibria of such a plant have been set up by step motion of the individual units, an indicator can show when and how often a particular compensating roller deviates from its normal position by ± 15%. The cause of the errors can then be corrected (a particular compensating roller will be shown on the screen) before a stationary compensating roller brings the whole plant to a halt.

Pre-matic (Fig. 5): a software package which was developed by Ciba-Geigy in an interdisciplinary team as a marketing tool for textile processing. The system was conceived specifically as a user-friendly programme for use on portable PC's and to provide a technical information service, readily available advice and on-the-spot solution of problems at customers' premises. The system consists of an expert system (XPS) and a computing programme (DOS). The expert system selects the current bleaching process and optimizes the recipes to the customer's requirements. The computer system, which is built to international specifications, is used for translation of the recipes into practical terms at the customer's premises and, apart from cost calculations, provides data about bath concentrations, amounts of additions, pump settings and allocation of chemicals to the dosing pumps that are specific for the machinery and the goods. However a disadvantage for the technical user is that the advice from the various expert systems is not compatible, as each product supplier has worked on his own assumptions. Griese has shown in a case study that, for the process of wet-on-wet impregnation, four product suppliers have used four different formulae for calculating the liquor exchange for their own expert systems. Unification of the fundamental principles into a generally accessible expert system would be desirable for textile dyeing and printing. The "CASP" system could serve as a standard as it is available to all the large suppliers of dyestuffs for simulation of chemical reactions on a PC.

It should be emphasized that in discontinuous processing the automation will also provide improved control and regulation and data on production machinery. Depending on the software, a CAM system in textile dyeing and finishing can determine the processing conditions using data about the substrate and kinetic values. Data about the goods being dyed, e.g. in an exhaust process, can be used for automatic correction of the process. Obviously, a terminal in the dye kitchen is essential in the concept of automation of the dye works. The value of automation increases with the number of components in the recipe. Consequently e.g. the "WOOLY" expert system has been developed for wool dyers to optimize the range of dyestuffs being used (Fig. 6).

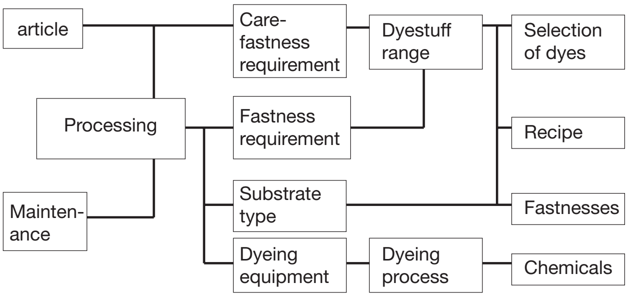

Fig. 6: Structure of the WOOLY expert system (Sandoz/ Clariant.

WOOLY: with this expert system the user enters which woollen articles are to be processed. The program asks for the required care level to be entered (D = only dry cleaning, H = hand washable, M = machine washable); from this the care-fastness profile with all the required fastnesses is obtained. WOOLY contains standard care-fastness profiles which comply with the recommendations of the IWS for a large number of woollen articles. Specific profiles which are not included can be entered at any time. The articles and care and fastness levels required determine the processing route.

Fig. 7: Simple control of machine speed by microprocessors that get information from suitable sensors (after Rüttiger).

other tools can be used to reduce costs, shorten delivery times and achieve constant quality of production. The state of the technology, i.e. that has been installed by about 50 % of the larger companies, is

- colour measurement with utility programmes,
- μ-processor control on single machines/groups of machines (Fig. 7),
- commercial computers.

The following developments are well advanced:

- CAD systems in design, recipe and screen production in printing,
- computerized systems for automatic making up of laboratory dyebaths or dye standards in production,
- departmental CAM for controlling/loading etc. the machines in a whole department,
- integration of technical and commercial data for optimizing operations.

Dyeing and printing carried out by computer is not far away in the future. However, as dyeing and printing is changing from being wage intensive into a capital intensive industry, the computer is becoming more important as a production tool.

CIM stands for Computer Integrated Manufacturing and can be used as an umbrella concept for all the "three letter words" such as CAD, CAM, CAE, PPC etc. A diagram can be drawn with sales and production at the centre and with the other areas represented as sub-systems of the central CIM system. The many links between the central CIM and the production area are not affected by the CIM. This sub-system is not a deterministic data circle inside which the production is optimized by the computer; it is much more that the CIM and MIS systems form independent systems (Fig. 8). The production planning and control system can be viewed as the heart of a CIM system. An order to supply will come from a given sales plan and go into the system. From the order, firm instructions will be sent out which will allow optimum use to be made of the production facilities.

The use of computers in the colouring side of print works is well advanced (Fig. 9): designing – engraving – sampling – print paste production (→ CAD in textile printing). Additionally, textile printing can only react in instant mode (quick response) when the output from production is fast. In coloration CAD encompasses:

- scanning,
- composition on the monitor,
- colouring,
- printing samples on paper.

A technically sound coloration process on textile mate-

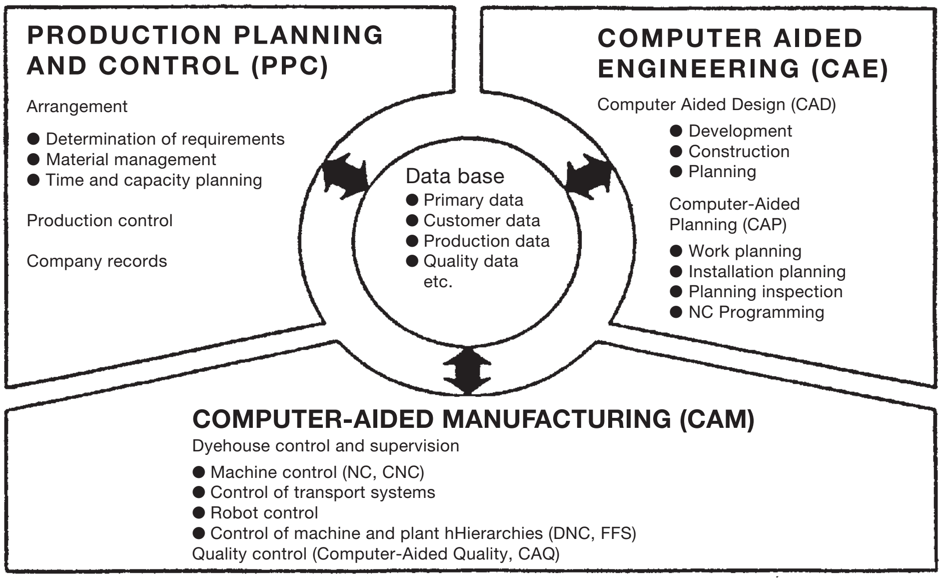

Fig. 8: Arrangement of Computer Integrated Manufacturing.

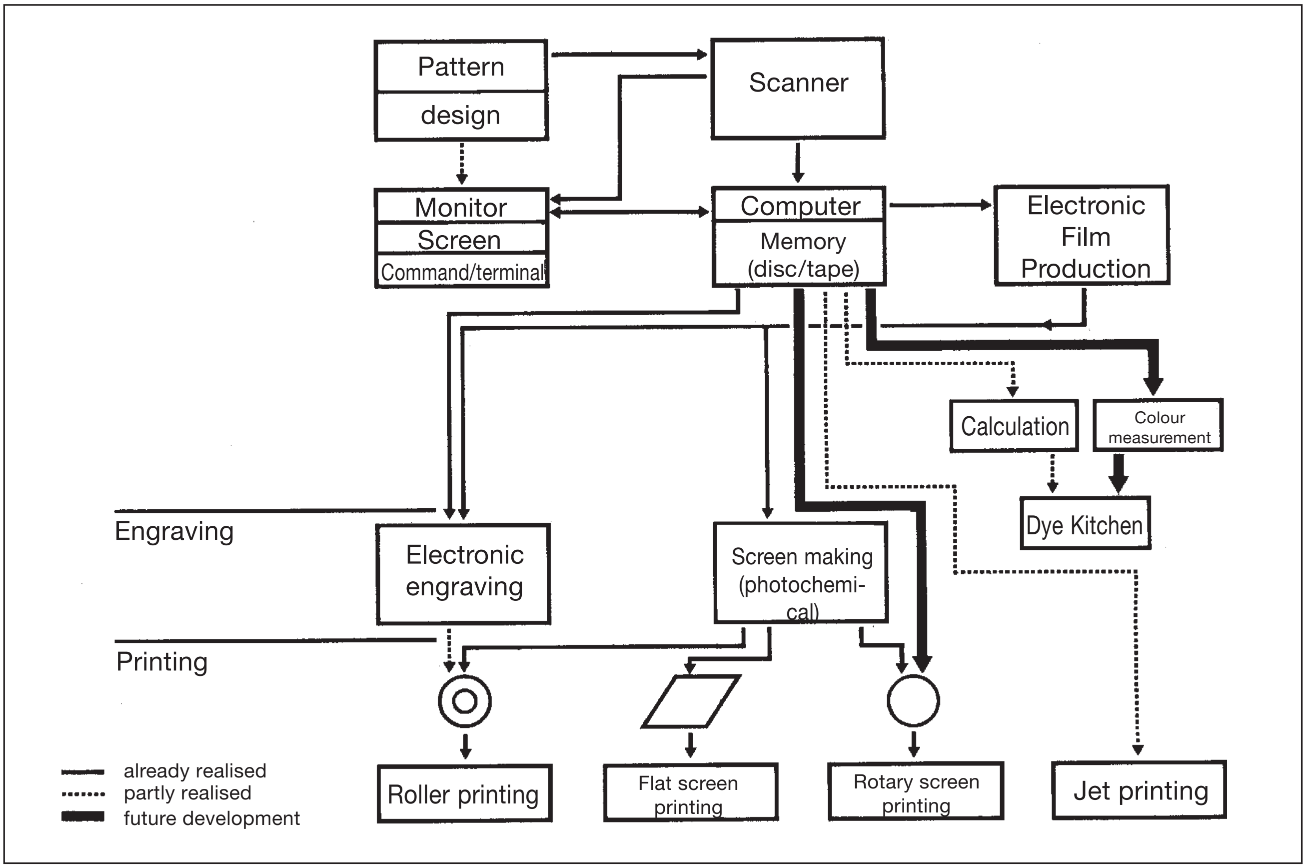

Fig. 9: Scheme of present and future developments in pattern design/screen production/recipe formulation.

rials begins with colour matching. It is very important that the first prints are made with the optimum recipes. The colour atlas can be optimized with the help of computer assisted colour measurement. The CIELAB system is suitable as it demonstrates clearly the distribution of shades on the colour circle and also shows colour build up. A suitable introduction of colour measurement into the printworks enables:

- faultless estimation of the colour values (curves, build up behaviour), establishment of the concentrations of the standard paste,
- the optimum colouristic choice of dyestuffs for producing the core range of colours,
- lowest cost recipes,
- building up the most economical and colouristically and technically flawless colour atlases.

The computer will control the printworks of the future to a large extent. In the first place, it will implement the artistic design and carry out the technical printing, but the economical and rapid production of the printing equipment (rotary screens) by laser engraving will also be controlled by the computer to produce quality. In this connection, two types of quality have to be differentiated: primary qualities can be measured physically and analysed by the computer; they are determined by molecular properties. However, the human being is necessary for the secondary qualities, to perceive them with his senses. So for example, the reflection spectrum of a mixture of dyestuffs can be characterized by its spectrum which can be displayed on a screen (a primary quality), but this spectrum has also a secondary quality: the colour that the human eye sees. Computer and human being must complement one another to create meaningful quality.

Computer colour matching Instrumental colour formulation as colouring process based on recipe calculations using the spectrophotometric properties of dyestuffs and fibres (see Fig. 1). Necessary details concerning reflectance curves are obtained by measuring so-called calibration dyeings.

A computer is required. This gives the following advantages: a) extremely accurate recipe calculations in a very short time; b) most rapid determination of the cost price of dyes for the calculation; c) optimal selection of the cheapest dyestuffs for the intended purpose; d) reduction of the laboratory dyeings previously required; e) reduced addition rate; f) shorter processing time, increased usage of the dyeing machines and more gentle treatment of the fabric as recipe additions are greatly reduced or avoided altogether.

When a fabric has to be dyed to match a new sample, the dyer has to prepare a recipe. With the aid of → Colorimetry this can be done quickly and reliably; classical methods for preparing the recipe could also be considered.

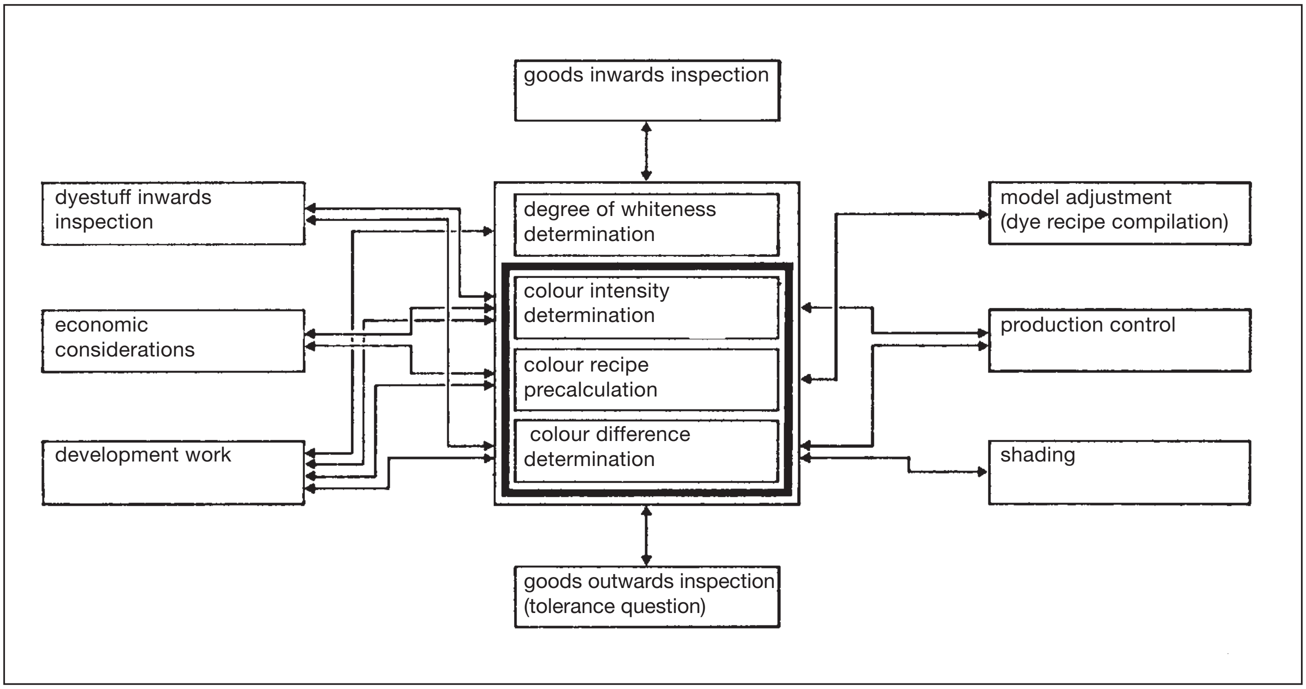

Fig. 1: General colorimetric formulation diagram.

The importance of colour measurement with its many and varied possibilities is no longer in doubt. The advantages of using colour measurement to help in colour matching are obvious and colour measurement systems have been installed in almost every dyehouse. Colour measurement is generally recognized as being useful for preparing recipes and selecting from alternative recipes using price, metamerism and fastness criteria; it can lead to significant savings in dyestuff costs. Evaluating alternative recipes from the technical point of view is a function that is hardly used yet. Automatic colour matching combined with colorimetric control of the dyeing kinetics and choosing the optimum recipe and the optimum dyeing programme will be the basis of rationalized batch dyeing in the future. So the main tasks for dyehouse staff are to coordinate recipes and dyeing programmes or to develop programmes that are specific for a given recipe, so that the reliability of the process and also the time it takes can be optimized. In this process, particular attention must be paid to the compatibility of the dyestuffs.

A flow scheme for a colour matching calculation (also see Fig. 2):

1. Measurement of the sample with a colour measuring instrument.
2. Choice of dyestuff:
   a) by colouristic and economic principles: class of dye (according to substrate), fastness, dyeing properties, suitability of certain dyeing processes, compatibility, concentration limits, price;
   b) by optical characteristics.
3. Entering the data into a computer.
4. Calculation process in the computer.
5. Choice of results from colouristic and economic angles.

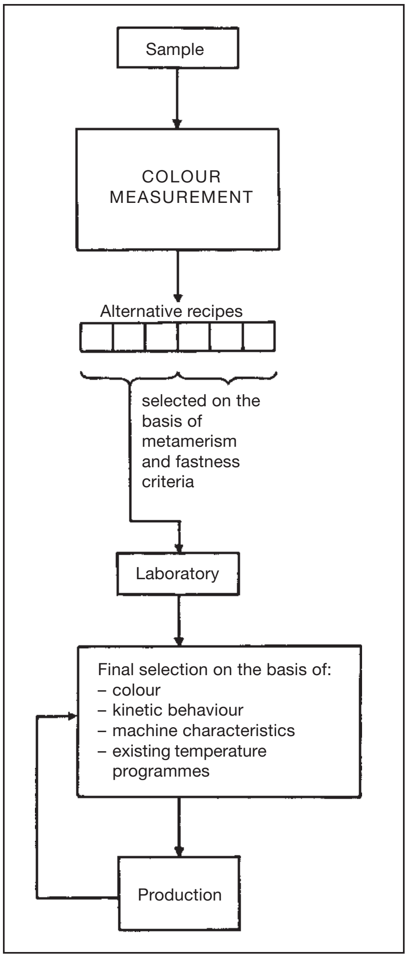

Fig. 2: Production of dyeing recipes using colour measurement and laboratory testing.

6. Dyeing the first recipe.
7. Correction of the first recipe:
   a) measurement,
   b) calculation of correction.
8. Dyeing the second recipe (corrected recipe).

Automatic colour matching together with colorimetric control of the kinetics of dyeing are used by the dyeing technician to help in reaching a decision on the final choice of recipe and dyeing process. The optimum recipe should be used in combination with the optimum dyeing programme. Several of the alternative dyeing recipes generated by the computer can be ruled out by the dyer in a first stage, because of high metamerism or unsuitable fastness properties. If e.g. three alternatives are left for a given shade, the most economical does not necessarily correspond to the most technically reliable or the most rational.

An important aspect known to every dyer is the degree of compatibility. The different kinetic behaviour of dyestuffs in combination, the effect of auxiliary chemicals and the different dyeing conditions obviously make selection difficult. In this context, it should be noted that real tertiary combinations (compatible dyestuffs that exhaust at absolutely the same rate, irrespective of the proportions in the mixture or of auxiliary chemicals that might be added) strictly speaking do not exist at all. This obviously does not apply to dyestuffs with good migration, but only for those with good fastness properties (which have poor migration by definition), where the poor levelling ability means that in practice the result is determined in the adsorption stage. Moreover, given shades can often not be achieved at all with so-called compatible dyestuffs. Compatibility is always an important criterion for the final selection of a recipe.

An obvious precondition is that standard curves and other basic information about the particular dyestuff are available. The more accurately the standard data have been prepared and the better the dyeing conditions in the production of the standard correspond to those in the bulk dyeing, the better the results that can be expected from a colour matching calculation. However it must be appreciated that in practice in many cases the second condition in particular, i.e. the conformity of the dyeing conditions and hence identical results from dyeings on small and large machines, cannot be completely satisfied. This often depends on the technical conditions.

Transfer of results from the laboratory into practice is important. In the laboratory recipes can be dyed by a temperature programme used in production. It can then be established whether the process reliability of the existing programme is suitable for the new recipes. At the same time the laboratory can contribute to optimization of the programme by eliminating unproductive time etc. If a new recipe cannot be carried out directly with an existing programme, it is the job of the laboratory to set up a new temperature/circulation programme or temperature/time programme. This may be a very simple programme that will ensure the necessary reliability and will in general also be suitable for a larger group of recipes. Programmes suitable for specific recipes may be established to optimize the time as well as the reliability of the process. This contribution to process rationalization is one of the most important functions of a dyehouse laboratory. Automatic dye recipe prediction takes certain routine tasks away from the colourists, so that more time is available for the more important aspects of making the final decision about the recipe and process (contributed by Carbonell, Hasler and Walliser and also by Thurner).

Computer graphics (CG), is highly regarded in the field of information technology. This is based upon its special features that distinguish it from the other information technology disciplines. It offers methods and techniques for producing and manipulating images, these images representing a special type of computer data. This different type of output and input gives computer graphics a special role in the field of man – machine communications, as images are used to impart more information that can in turn be more quickly assimilated by man, more quickly than tables of figures or bodies of text (conventional electronic data handling). The high cost of graphics equipment and high computer processing demands has delayed the spread of graphic application systems. Improved computer processor power capability will allow computer graphics to be used economically. Computer graphics is incorporated into the IT systems used. It offers a broad base for the practical application of knowledge and methods of other areas. Its tasks include techniques for the description, output, and modification of graphic representations and their applications. The ISO definition describes computer graphics as "Methods and techniques for converting data to and from graphics displays via computer". Computer graphics was divided into the separate aspects of data, visual displays and computers contained in this description some 10 years previously (Figs. 1 + 2), and into the sub-areas of generative computer graphics, image processing and picture analysis.

INPUT OUTPUT	IMAGE	DESCRIPTION

Fig. 2: Graphic data processing zones.

Generative computer graphics involves the processing of artificially produced pictures which are available in the form of picture descriptions (data formats) and are produced by the computer (i.e. the program).

The actual data may
- be input by the user,
- be produced or compiled by the computer,
- result from user commands in a graphics-working environment.

The generative computer graphics are divided into two areas:
- passive systems,
- interactive systems.

Passive systems are to be regarded as a subset of the interactive systems. Passive generative graphics concentrates on the problems created by the output of graphic data. Once the picture has been represented, no further modification is possible. Prior manual redefinition of the data and subsequent complete regeneration of the picture can only achieve this. The term interactive graphic system is applied to systems consisting of appliance configurations and program systems suited to generating and reproducing graphic output and which in addition have hardware and software components which support an interactive working method. The interactive system describes the processes used to carry out a dialogue between man and machine which overall represents passage through a decision network of representations and commands, or actions and reactions. In contrast to the passive systems, interactive graphic systems allow the user to have a dynamic influence on the image or image object.

The imaging methods provide processes and techniques for altering the generation of an image in such a way that, for example, the human perception of the information content of an image is easier. Pictures used are obtained by digitalisation of photographs or TV pictures. The process of altering the image is based on unstructured images. This is also the essential distinguishing feature between graphics systems and image processing systems (Fig. 3). The processed data in generative graphics are a structured volume of output elements. In image processing an image is regarded as a volume of n by m picture elements (pixels), whereby each picture element has a grey value or colour. Otherwise an image does not have a structure. For this reason, image processing is often regarded as the application of algorithms to numerical fields.

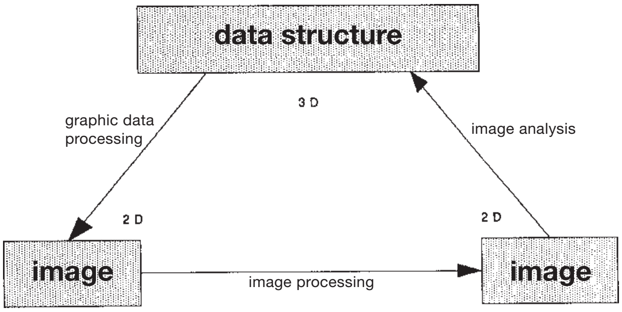

Fig. 3: Relationship between image processing and graphic data processing.

The principal tasks of image processing are represented by the following disciplines:
1. image enhancement, e.g. by increased contrast or suppression of background disturbances,
2. image evaluation, i.e. size determination, contour recognition, recognition of particular image qualities,
3. character recognition, i.e. the extraction and classification of image qualities.

In image analysis, unstructured images (pixel groups) are investigated in order to discover structures and objects and place these in relation to one another. The image analysis is concerned with the breakdown of images into proto-images, i.e. into known graphic objects (such as triangles, circles etc.), so that known data structures can be built up. Images can be recognised by subsequent comparison with known breakdowns. The image analysis thus uses image processing methods for the breakdowns, and generative computer graphics techniques for the composition of the proto-images.

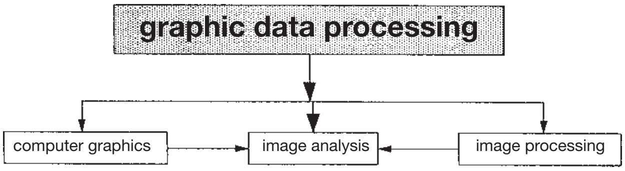

Fig. 4: Dialogue between graphic data processing zones.

This exchange between the sub-areas of Computer graphics is clarified by the diagram in Fig. 4.

The techniques of Computer graphics are used in numerous branches of industry, management, public areas such as administration, training and for entertainment purposes. The number of applications is constantly on the increase, not least because graphics output equipment is being developed into affordable mass products. The following shows examples of some typical areas of application of computer graphics (Fig. 5).

a) Plotting systems for producing drawings: in the commercial sector, science and technology, 2D and 3D graphics systems are used to represent mathematical, physical and even economic functions. The results are presented in the form of histograms, bar charts, functional diagrams, pie charts, flow charts etc. and thus presented in a clear, structured way. Computer graphics are used in this area to give an overview of complex systems and their contexts and to support decision-making.

b) Cartography: graphics systems are used to compile precise representation of geological and geographical data. The output is given on paper or film. This makes it possible to generate several drawings from one data structure and to use the graphic substructure for the production of different images and different sizes (e.g. in different colours). Examples include maps, layout plans, relief maps, weather maps etc.

c) Computer Aided Design (CAD): interactive graphic systems are used here for design purposes. One such application is for design systems in the area of textiles (see Fig. 5). In CAD systems which are regarded as the application of a graphic system, structures are built up and manipulated, such as houses, cars, production plant, machine components or textile designs. CAD systems support both the draft phase and the compilation of parts list descriptions or production specifications arising therefrom.

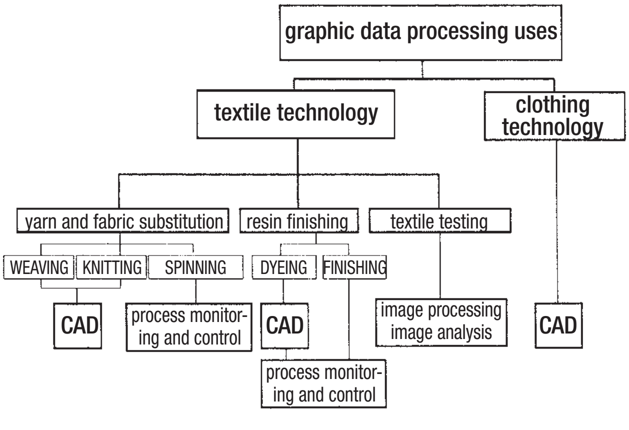

Fig. 5: Uses of graphic data processing in the textile and clothing sectors.

d) Simulations: processes which happen quickly, e.g. deformations, chemical reactions (molecule design) etc. can be simulated and shown in a series of images as calculated time studies. The chronological progression of a chemical process can thus be represented using the sequence of the time studies. Flight simulators enable image generation to be realised in real time by means of interactive graphic systems.

e) Process monitoring: in the process control system, sensors detect a large number of measurement values that are transferred to a control centre. They are combined here to form a representation of the actual process, and shown on control screens. Critical values or situations are shown to the operatives by means of special optical signals (colours, flashing etc.), so that the operative can take any necessary action. These methods are used to control technical processes in nuclear power stations and chemical works, but also in dyeing plant.

Graphic systems are therefore subject to certain prerequisites, depending on their field of application:
- passive systems (with/without real time requirements, on-line/off-line),
- interactive systems (with/without real time requirements),
- resolution and colour characteristics,
- image data types, image types,
- 2D, 3D, surfaces, vectors etc.,
- image structures, relationships between partial images,
- image manipulation logarithms.

The wide range of criteria, which may be applied to a graphics system because of the extent of possible application systems, cannot generally be fulfilled by a "universal system". For this reason, graphics systems are configured according to requirements, i.e. selections are made accordingly from a range of hardware and software components.

Computer language Electronic data processing is based on the use of the binary number system. The "internal" language of the computer (1st generation language) is called computer language. From the technical standpoint, the numbers 0 and 1 can mean "yes" or "no", or "open" or "closed" for example.

Concave (Lat.: concavus = annular hollow). Hollow, recessed, inwardly arched. Antonym → Convex.

Concave frames Are screen frames (in screen printing) with a specific outward curvature, by which flexure caused by gauze tension can be compensated.

Concentrate High percentage → solution.

Concentration of desizing When woven fabrics are desized, the washing liquor, which contains water-soluble size (polyacrylates, polyvinyl alcohols, soluble polyesters), is concentrated (Fig. 1) in order to enable it to be re-used for sizing subsequent to a post-starching process. One possible method of size concentration is to evaporate washing liquors.

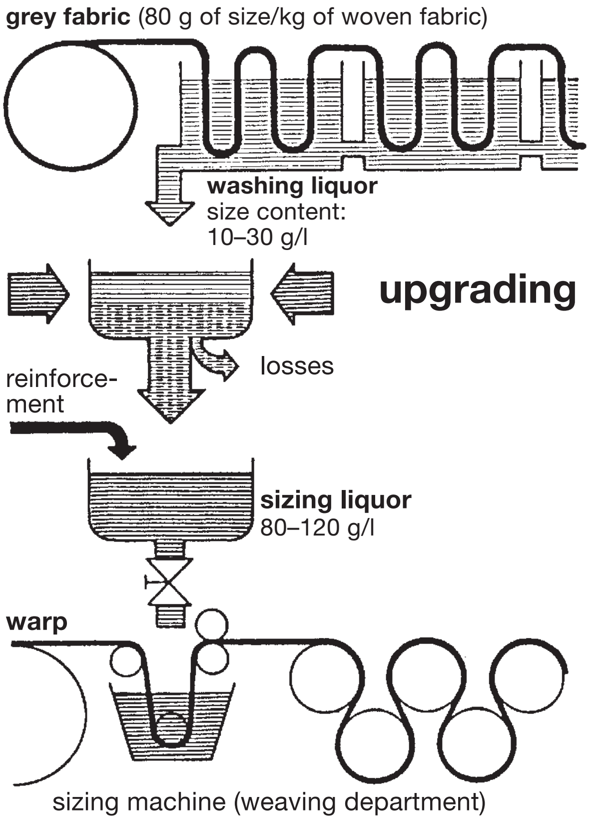

Fig. 1: Size washing liquor upgrading.

The hygroscopic concentration technique (Fig. 2) is used in accordance with the Recupra process by bringing averagely concentrated washing liquors into contact with the fabric to be sized by means of an impregnating roller, the dry fabric exhausting water from the liquor on account of its capillary forces without absorbing the polymer molecules from the fibres.

Concentric Having a common centre point; e.g. in fibre cross-sections (e.g. flax, wool), means concentric layering and the layer-like structure from the centre point (cell lumen) to the periphery.

Condensate (condensation water). Atmospheric water or exhaust steam water from steam pipes and vessels. Valuable as soft water, and used particularly for dissolving dyes, chemicals and auxiliary agents. Available only to a limited extent in the works. As a rule, condensate is returned to the steam boiler and recycled.

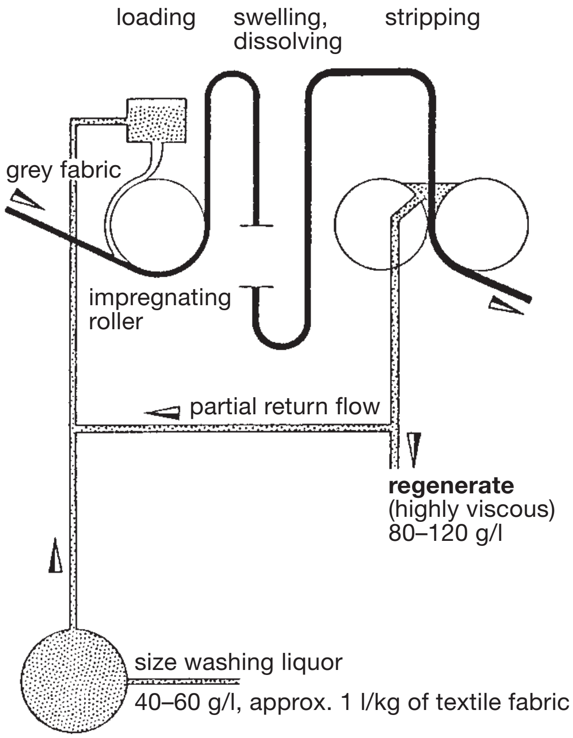

Fig. 2: Technique of the hygroscopic upgrading of desizing wash liquors in the case of acrylate sizes (BASF and Benninger).

Condensate return Important savings can be made by returning (Fig. 1) as much as possible of the condensate (→ Steam trap) occurring in the works.

Simple condensate return methods cannot generally be employed in practice (gravity condensate return) or are not economic in consequence of their associated shortcomings (steam pressure condensate return). Thus, for example, steam pressure condensate return - regarded as economic - is in fact possible, and even necessary, in selected cases, but has slightly more disadvantages than advantages: lifting or returning condensate gives rise to counter-pressure in the steam trap (approx. 0.15 bar per 1 m of lift), reducing the differential pressure in the steam trap, and therefore its power. If this is not taken into account, both too small and too

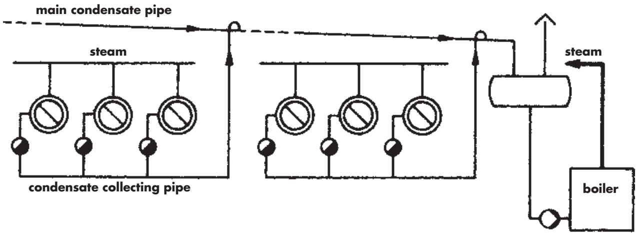

Fig. 1: Condensate return to boiler.

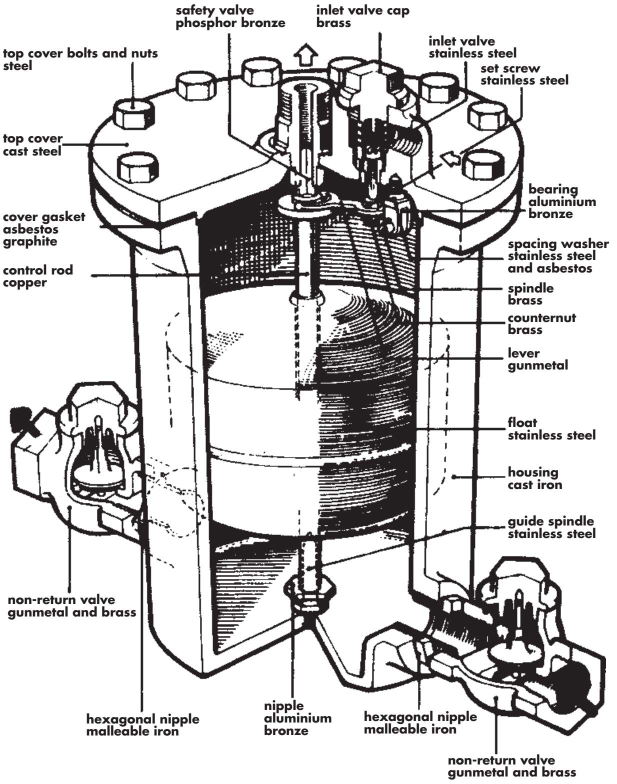

Fig. 2: Condensate lifter (Spirax Sarco).

large steam trap dimensions can be uneconomic; too high a counter-pressure in long condensate piping renders this method of operation no longer applicable. In addition, in the case of steam pressure condensate return, the pipelines cannot be emptied when out of operation (risk of corrosion and destruction), and noise nuisance is to be reckoned with on starting (hot steam = cold condensate), while slower starting impairs efficiency. Feeder stations (pumps or pumping stations) are an economic and operationally reliable alternative: they enable the plant to be emptied, and prevent corrosion, steam or water hammer, noise nuisance etc, and can often be financed by smaller nominal condensate return dimensions in the case of large plants.

Since steam or compressed air is available in most works in any case, steam or compressed air-operated condensate pipe systems can be preferentially employed (condensate lifters or condensate lifting stations for example), the simple and robust construction of which is very suitable (Fig. 2).

In the event of greater heights, larger quantities and greater distances due to multi-branched plant, or the necessary operating pressure for steam or compressed air operated condensate lifting stations being unavailable in the works for steam traps, electric condensate return feed equipment is recommended.

Condensate return piping Piping for returning condensate from steam pipes and steam consumers, mainly to the ventilated boiler feed water tank. At the end of the condensate piping, there is usually a receiver which is either under atmospheric pressure or subject to a slight overpressure of 1.1–1.2 bar due to the thermal degassing unit. The pressure in the condensate piping must be somewhat higher than in the receiver so that the condensate definitely flows to the receiver.

Condensate water softening unit Used for preventing residual hardness in boiler feed water as a pressurised “safety filter” in condensate piping. Incorporated in the piping for degassing or as a feed water tank. Must be designed to be resistant to hot water, and should be checked regularly at 4-week intervals; regeneration unnecessary.

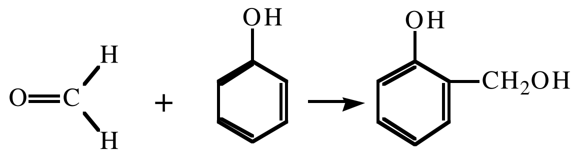
Condensation (Latin: condenso = condense),

I. Physical: change of state from vapour or gaseous form into liquid form (moist air = dew, mist formation), in contrast to → Votalization

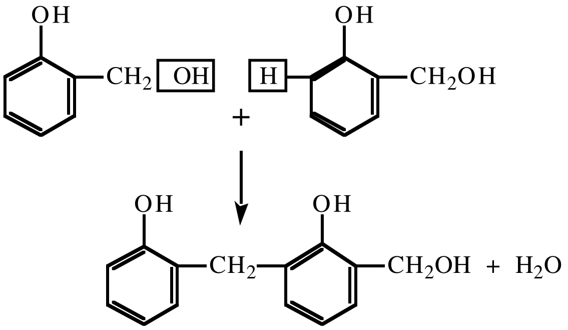
II. Chemical: combination of two molecules into a bigger one with the occurrence of water. If this process takes place into large molecules, it is called → Condensation polymerisation.

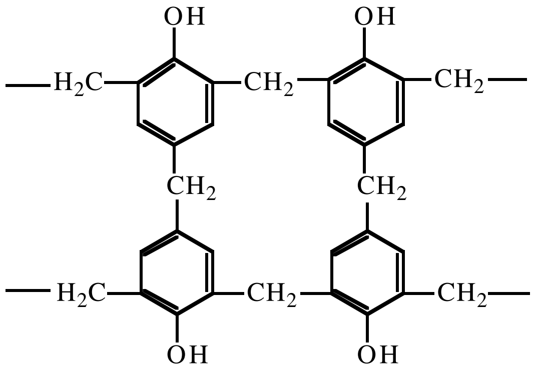
Condensation heating Heat exchange system by means of which condensation heat released in steam condensation is utilised. In contrast to heat exchange via circulating fluid heat transfer media (e.g. circulating oil system), in which turbulence frequently cannot be prevented, uniform temperature distribution is achieved even on large contact surfaces (like transfer calender cylinders for example).

Condensation polymerisation Combination of molecules with the splitting of – mostly - water. Phenolic resins (→ Phenolic plastics) are a classic example of condensation polymerisation, new phenol molecules constantly combining with the emergence of water as follows:

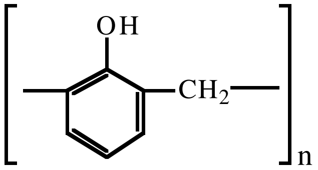


1 mol formaldehyde + 1 mol phenol = phenol alcohol (o-methylol)





In the final state, practically all phenol alcohol molecules are bonded to each other into three-dimensional macromolecules with the emergence of water. This type of condensation polymerisation is represented in simplified form by the following constitutional formula:



Similarly, with the involvement of other phenol and urea functional groups, urea resins (aminoplastic resins), and, of 1,6-diaminohexane and adipic acid, → Polyamide fibres (→ Polycondensation fibres) etc. are produced.

One example in nature is the condensation polymerisation of cellulose or starch under the action of sunlight from carbon dioxide and water (photosynthesis) from the three elements carbon (C), hydrogen (H) and oxygen (O) into an annular self-closing glucose molecule:

$$6\,CO_2 + 6\,H_2O \rightarrow C_6H_{12}O_6 + 12\,O$$

→ Polymerization reactions for fibre-forming macromolecules.

Condensation process for exhaust air cleaning Gases in the exhaust air from stenters can be condensed out by cooling the exhaust air. A relevant Behr unit (Fig.) cools the air to approx. 100°C at first in air to air heat exchangers. Further content substances are condensed out in the second stage by air to water heat exchangers. In stage 3, other contaminants are removed by electrofiltration. Odoriferous substances are particularly difficult to remove by condensation.

Condensation resins → Polycondensation products with a synthetic resin nature.

Condensed ring systems → Cyclic hydrocarbons.

Condenser Equipment for condensing the moisture contained in a medium, e.g. in a hot airflow, either by indirect condensation (i.e. water-cooled heat exchange) or by direct condensation (by spraying in water).

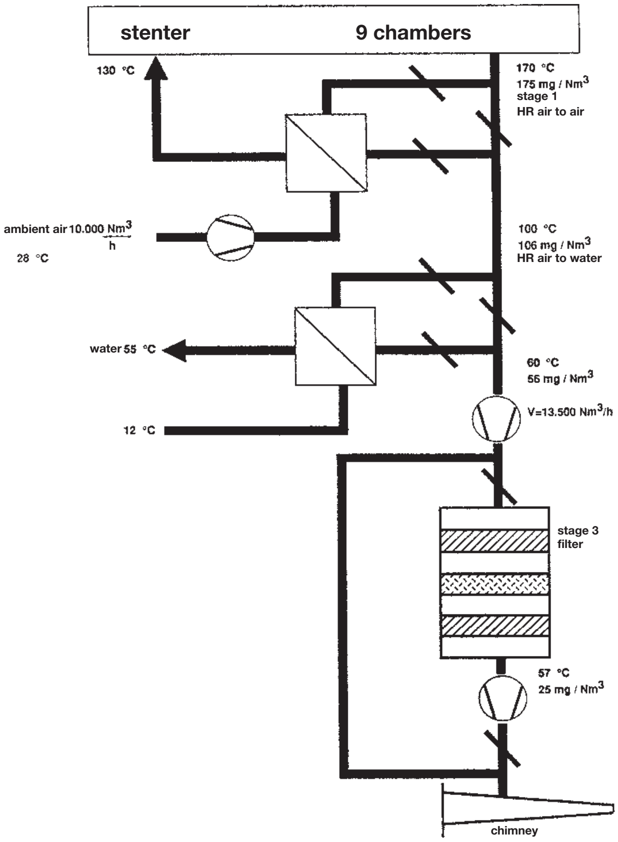


Fig.: Functional diagram of a plant for cleaning exhaust air by condensation and heat recovery (HR) (Behr system).

Condenser yarn,

I. Low grade cotton yarn (waste yarn) in high linear densities usually made from East Indian (Bengal) cotton (→ Imitation yarn).

II. Generally, woollen yarn produced by the so-called double condenser spinning process, spun from roving collected from strips of card web by rubbing in a tape condenser.

Condensor → Compressors.

Conditioning,

I. Allowing materials to come to hygroscopic equilibrium with a standard atmosphere, e.g. for textiles 20 ± 2°C and 65 ± 2% relative humidity.

II. Term for establishing the moisture content of textile raw materials and yarns in conditioning apparatus. Since textile raw materials due to their hygroscopic properties absorb varying amounts of moisture, the trade has agreed on regains and allowances to be applied for commercial transactions. To test the moisture regain, samples are taken and dried at 105–110°C. The commercial mass is obtained by adding the standard regain to the oven-dry mass (BS 1051, DIN 53 822 and ITMA, IWTO and BISFA standards).

Conditioning of calender bowls Preparations for commissioning paper or cotton calender bowls in order to even out the wrappings especially in the case of freshly covered bowls on which the subsequent durability and (for paper bowls) accurate, perfectly embossed effects, as well as the elimination of embossing damage due to engravings being too sharp are dependent. When recommissioning, the surface of the covered bowls which is still rough after turning off must first be smoothened and strengthened. For this purpose, a smooth steel bowl heated to approx. 120°C is used: the bowl is moistened during running (exit side to avoid accidents) with softened water or condensate at approx. 50°C, plus a little neutral soap or detergent containing a fatty alcohol sulphate using a natural sponge, but only to the extent that it becomes dry again after a few rotations. This moistening treatment is repeated. In order to condition all the bowls (apart from engraved embossing bowls), the pressure is increased over 10–20 h to the normal subsequent operating pressure, as a result of which the bowl surface becomes noticeably smoother. By contrast, engraved embossing bowls are conditioned initially without pressure (so that the roller surface can take up water) and only then run in at full working pressure and operating temperature, since the steel bowl expands under the influence of temperature and a bowl which would have shrunk when cold would cut the fabric when running warm later on. For engraved embossing bowls, it is therefore incorrect to condition them with slowly increasing pressure, which can also cause the design to become "fixed". During the course of subsequent bowl maintenance, they should be conditioned again at least once a week for a few hours (after first cleaning off any residual finishes). Slight indentations (e.g. due to the passage of seams in the fabric) can be effectively removed by daily afterwashing at the normal working pressure and operating temperature, which does not usually take much time. The conditioning process has been carried out correctly if, during continuous observation from a certain distance, the steel bowl (and also the paper bowl) appears equally bright (with no matt areas) across the entire width, i.e. with no shading or darker areas.

Conductance, electrical → Electrical conductance.

Conductivity The sodium chloride and sodium sulphate salts used in dyeing dissociate into anions and cations in aqueous solution.

$$\mathrm{NaCl} \underset{-\,H_2O}{\overset{+\,H_2O}{\rightleftharpoons}} \mathrm{Na^+ + Cl^-}$$

$$\mathrm{Na_2SO_4} \underset{-\,H_2O}{\overset{+\,H_2O}{\rightleftharpoons}} \mathrm{2Na^+ + SO_4^{2-}}$$

When an electrical voltage U is applied, a current I flows over the electrically charged ions through the salt solution (Fig. 1), the ions discharging on to the electrodes (electrolysis).

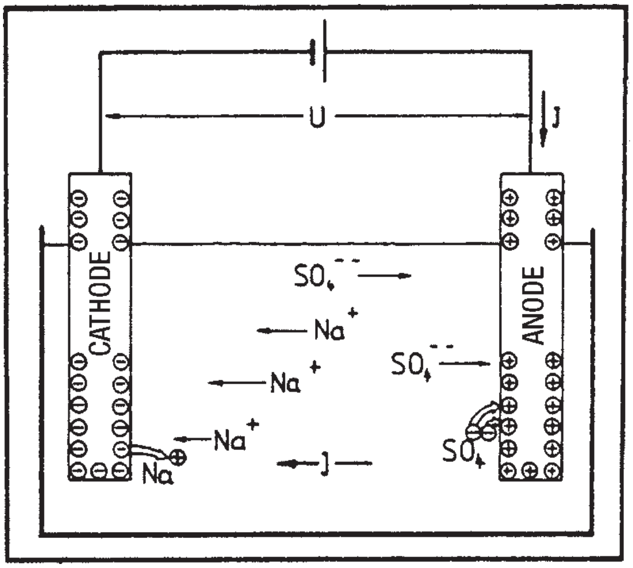

Fig. 1: Electric conduction in an electrolyte.

The parameter which is suitable for determining an electrolyte concentration, and is obtained by electrical measurement, is conductivity. It is the reciprocal of specific resistance, with Siemens per metre (S/m) as its unit. With a homogeneous conductor in a homogeneous electric field, the electric current intensity I depends on the externally applied voltage in the following way:

$$I = \chi \cdot \frac{f}{l} \cdot U$$

f is the cross-section, l the length and χ the conductivity of the conductor. With mixed phases, the dimension χ depends on the composition, the temperature and (insignificantly) on the pressure. With the resistance value

$$R \equiv \frac{1}{\chi} \cdot \frac{l}{f}$$

ensues Ohm's law for the given special case:

$$I = \frac{1}{R} \cdot U$$

Electrical resistance $R = \frac{U}{I}$

Specific resistance $\rho = \frac{R \cdot A}{l}$

Electrical resistance $\chi = \frac{1}{\rho}$

In the case of measurements on solutions (e.g. with dipped electrodes), the geometric dimensions of the arrangement are summed up by introducing a cell constant

$$C \equiv \frac{l}{f}$$

and

$$R \cdot \chi = C$$

is obtained.

This relationship is used for measuring resistance R with known conductivity χ for determining cell constants C, and for determining conductivity χ at a known cell constant C.

The equivalent conductivity $\wedge$ of an electrolyte is defined by

$$\Lambda \equiv \frac{\chi}{c^*}$$

c* is the equivalent concentration of the electrolyte, which, in the case of electrolytes each with one sort of cation and anion, results from a concentration (substance quantity concentration) c as follows:

$$c^* = z_+ \nu_+ c = -z_- \nu_- c$$

z_+, or z_- is the sum of the charge number of the cations or anions, and v_+ or v_- the decomposition number of the cations or anions, by which is understood the figure for the complete dissociation of cations or anions originating from the neutral electrolyte molecule. With 1 : 1 valent electrolytes, which are considered below,

$$z_+ \nu_+ = |z_-| \nu_- = 1$$

$$c^* = c$$

for the limit of equivalent conductivity $\wedge^o$ with infinite dilution

$$\lim_{c \to 0} \Lambda = \Lambda^o$$

is valid:

$$\Lambda^o = \lambda_+^o + \lambda_-^o$$

λ_+^o and λ_-^o are the limits of ion conductivity λ_+ and λ_- with infinite dilution:

$$\lim_{c \to 0} \lambda_+ = \lambda_+^o \, , \quad \lim_{c \to 0} \lambda_- = \lambda_-^o$$

For a given solvent and fixed temperature, the limits of ion conductivity λ_+^o and λ_-^o are a characteristic parameter of the relevant type of ion. From experience, it is independent of the nature of the counterion in each case. This statement is described as „Kohlrausch's law of independent ionic migration". From the physical standpoint, this means that the ions of the electrolyte in the solution are so far removed from each other in the infinitely diluted solution that their interaction can be ignored.

For electrolytes, electrical conductivity runs linearly to concentration in concentration ranges of a few hundred milligrammes per litre. If the concentration increases in ranges which are taken into account for textile chemical finishing processes (up to several hundred grammes per litre), linearity comes to an end; it can even result in reduced conductivity.

Non-linearity in true electrolytes is caused by a) reduced dissociation as the concentration increases, and b) interionic interactions. a) means that the number of electrically charged particles does not increase linearly with the quantity of dissolved salt. In the case of b), the interactions impede ionic mobility. Apart from the concentration, this is determined by the ion dimension and the hydrate envelope covering the ion. Dye molecules for example are particularly large ions.

The temperature of an electrolytic solution has a great deal of influence on conductivity. Both dissocia-

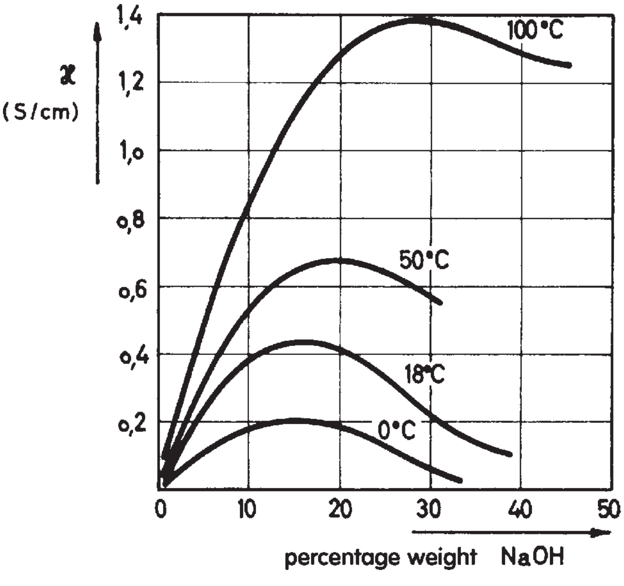

Fig. 2: Specific conductivity of caustic soda.

tion and ionic mobility are affected by temperature (Fig. 2).

A temperature correcting link b serves to integrate the temperature in the conductivity values. b can assume values of 1–6% per degree. Calculation of the temperature coefficients with

$$\chi_R = \frac{\chi}{1 + b\,(\vartheta - \vartheta_R)}$$

ϑ_R = reference temperature

Like equivalent conductivity $\wedge$ (and conductivity χ), ion conductivity values λ_i depend on electrolyte concentration, and, to a lesser extent, on pressure. Concentration dependency is different with weak and strong electrolytes. The ion conductivity values of strong electrolytes change as the concentration changes, whilst, with weak electrolytes, which are also incompletely dissociated with increased dilution (α <1), they are approximately independent of concentration. Under this premise, the Arrhenius formula

$$\alpha = \frac{\Lambda}{\Lambda^0}$$

is valid in diluted solutions for the degree of dissociation α. With diluted solutions of weak electrolytes, the degree of dissociation α can therefore be determined by conductivity measurements. The ion separation and concentration change at the electrode surfaces caused by electrolysis poses a technical measuring problem. Conductivity is reduced by an apparent increase in electrolyte resistance. This effect, which falsifies measured values, is called polarisation. Polarisation diminishes

- on measurement with an alternating voltage of increasing frequency,
- with an increasing electrode surface.

Non-contact conductivity measurements (inductive, capacitive) reveal no polarisation. Four electrode or multi-electrode measurements produce very little polarising effect. Virtually currentless voltage measurement ensures control of the electrode current, which is then dependent only on the actual electrolyte concentration.

Water (if only a little dissociated) is also a weak electrolyte. Moisture content differences in textiles change conductivity by powers of ten. The water content and electrical conductivity of fabrics containing cellulose are linked with each other via an exponential function, and can be measured on the fabric under certain circumstances (Fig. 3).

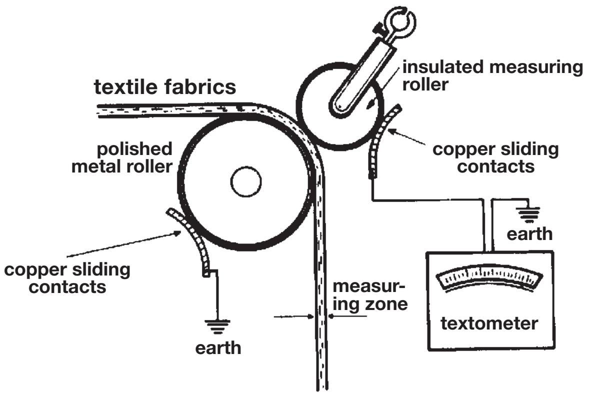

Fig. 3: Mahlo conductivity moisture measuring unit.

In the residual moisture content range, neither the fabric weight nor the properties of the water, and neither the thickness of the fabric to be measured nor the liquor composition have only approximately as great an effect on electrical conductivity as the quantity of water in the fibre. For this reason, determining the residual moisture content in textiles by measuring electrical conductivity (or its reciprocal - electrical resistance) is relatively insensitive to disruption. The exponential link between moisture and conductivity exists exclu-

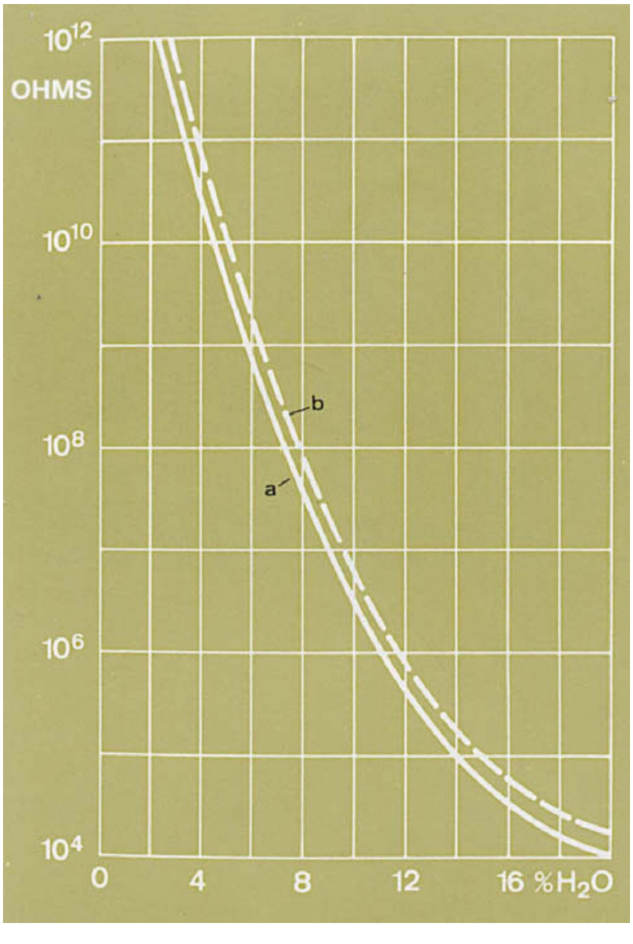

Fig. 4: Relationship between the moisture content and conductivity of a textile fabric (fabric weight a = 120 g/m^2; b = 240 g/m^2).

sively in the residual moisture range (Fig. 4). If surface water appears, and the fabric feels perceptibly wet, the exponential function becomes linear, and cannot therefore be used for moisture measurement.

Conductivity, measurement of Conductivity is measured by the electrical resistance of a solution. The measurement has to be carried out with an alternating current as the electrolyte decomposes when direct current is used. To determine the electrical conductivity of a fabric, a sample has to be extracted with distilled water at an exact liquor ratio of 20 : 1. The conductivity of the distilled water used for this purpose should not be greater than 2µS/cm. The conductivity measured in the extract is used for characterizing the fabric (Fig. 1). When the washing efficiency of preparation equipment is compared, the values determined from the extraction must be compensated to allow for the absolute amount of the fabric.

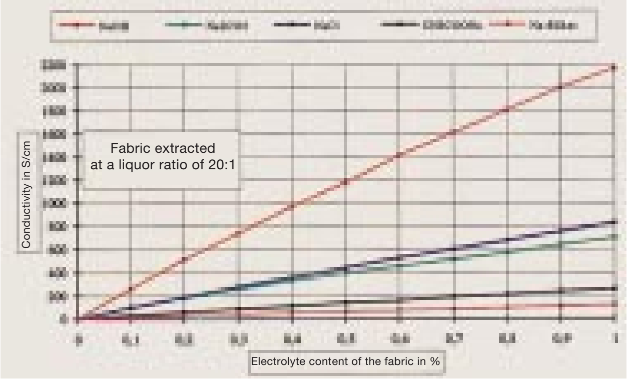

Fig. 1: Relationship between the electrolyte content of the fabric and the conductivity.

In Fig. 2 and 3, the conductivities of various samples of process water as well as a sample of river water are shown. It is interesting that water that has been passed through an ion exchanger has a significantly higher electrolyte content than untreated town water. If this ion exchanged water is exchanged again through an H-ion exchanger the conductivity is about a three times higher, because the solution has a very acid reaction as the Na have been exchanged for H ions. After neutralization with caustic soda, the conductivity shown is reached (contributed by Hipp).

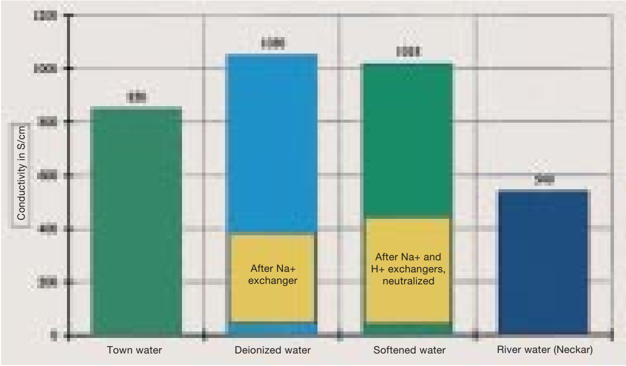

Fig. 2: Conductivities of various process water (work diagram).

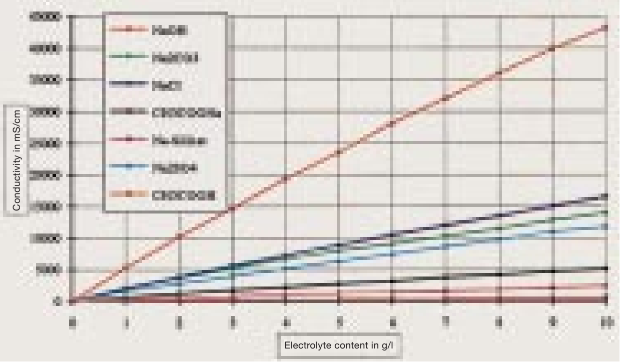

Fig. 3: Dependence of conductivity of various electrolytes on concentration.

Conductivity measuring instruments are used a) for moisture measurement; b) for measuring static charges; c) for measuring pH; d) for measuring the r_H value.

Conductometric measurement For determining the ion concentration c by measuring specific conductivity

$$\chi = \frac{c\, n_e}{1\,000} \cdot (l^- + l^+)$$

n_e = electronic valency,
l^-, l^+ = anion and cation mobility (constant for given electrolyte).

Limitations: only for dual component systems, possible complications at higher concentrations due to the effect of the activity coefficient. Particularly suitable for washing bath control.

Cone →: Package; Conical.

Cone changers Are used for changing the cones of conical cross-wound bobbins, e.g. to replace stainless steel cones with cardboard cones for further processing.

Cone dyeing machines Dyeing machines used for dyeing (hat) stumps. They prevent the formation of heat creases otherwise easily occurring in loose dyeing; the hat shape is completely retained, and even the most difficult stumps are perfectly dyed in a short time with no consequential disaggregation. For dyeing, the stumps, carefully made to measure, are drawn on to a perforated cone, through which the dye liquor is then pressed. In the case of open machines, the dyeing temperature is approx. 95°C, and with enclosed machines,

Next Page

up to 110°C (temperatures above 100°C should as a rule be avoided on quality grounds). 1 : 1 and 2 : 1 metal complex dyes and acid levelling dyes for example are used.

Cone loading and unloading unit For the automatic loading and unloading of cone centrifuges and yarn package dryers. Continuous package feed and removal, star-shaped bar grid and package presser operating at intervals. Replaces high cost manual loading; suitable for creel-type and porcupine systems.

Cone mill Dye kitchen device for mixing and milling printing thickener and prepared printing pastes.

Cone thrust lock Sealing unit for the continuous inlet and outlet of textile material in endless rope form. Has the form of a double truncated cone, and is generally produced from elastic material. In a special version, the ends can twist against each other, the cross-section of the two superimposed truncated cones then being altered.

Confidence factor (statistical probability; Px). Probability that a statistical statement is correct, e.g. that a parameter is within the → Confidence interval.

Confidence interval Interval of values used in statistical evaluation to calculate on the basis of random sample findings the unknown value of a parameter of an assumed distribution. The interval includes all parameter values where the random sample finding appears in the range of random scatter with a specified probability γ. Thus, for example, the limits of the confidence value $\propto_{un}$ and $\propto_{ob}$ are calculated for the unknown mean value μ of a parent population with normal distribution, on the basis of a sample of scale n with an arithmetical mean value $\bar{x}$ and standard deviation s, as follows:

$$\mu_{un} = \bar{x} - t \cdot \frac{s}{\sqrt{n}}$$

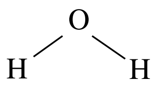
$$\mu_{ob} = \bar{x} + t \cdot \frac{s}{\sqrt{n}}$$

Here t is the limit value of the "t-distribution" (also referred to as the "student number"), dependent on the sample number n and the predictive probability P_A (following which $P_A = 95\%$):

sample number	n	5	10	15	20	25	30
	t	2,8	2,25	2,15	2,1	2,07	2,05

The confidence interval becomes smaller with increasing scale n of the sample, i.e. the mean value $\bar{x}$ calculated for the sample increasingly approximates the actual mean value $\propto$ of the parent population.

Configurational formula (geometric formula). Characteristic formula of three-dimensional configuration. Example: in contrast to the → Structural formula of water (H–O–H) for example, the configurational formula takes account of the fact that both H atoms form an obtuse angle of approx. 105° to the O atom:



(→ Spatial formula).

Conforming to type,

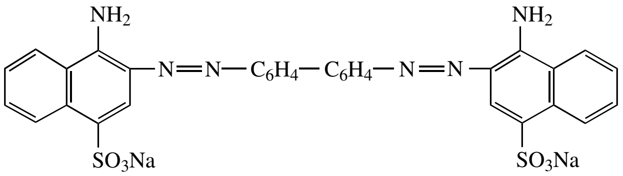
I. Expression of grade in the dyeing and auxiliary industry and the textile finishing industry for products that correspond to a standard type as regards concentration, physical, chemical and application behaviour and shade. Producers make use of quality control in order to attain standardisation tolerances.

II. Expression used in textile finishing for dyeing, printing and finishing effects that correspond to a specified standard type.

Synthetic organic dyestuffs, show by their synthesis process that a typical by-product presence is found and that their reproducibility from batch to batch changes very little. When the → Formulations of dyes can also show good reproducibility, it can be assumed that the composition of the dyestuff is constant from one delivery to another, i.e. the dye conforms to type. It must be borne in mind that dyestuff diluents may be hygroscopic, which means that the moisture content of dye powders may vary according to storage conditions.

Conglomerate (Lat.). Mixture of numerous individual particles, mainly of different or similar types.

Congo red Red direct dye (Böttger 1884). Benzidine-bis-1-naphthylamine-4-sulphonate:



Dissolves reddish brown in water, colloidal; a blue precipitate occurs with hydrochloric acid, and a reddish brown one with caustic soda; it dissolves blue in concentrated sulphuric acid. Use: as congo red paper and as a concentrated solution in dye microscopy for differentiating between viscose filament (dyed light) and copper filament (dyed dark). – Manuf.: Bayer.

Congo red paper Colour indicator on acid traces, colour change interval pH 3 (bluish violet) to 5.2 (reddish orange, brownish).

Conical (Lat.: conus = cone) tapered.

Conical packages → Crosswound yarn package.

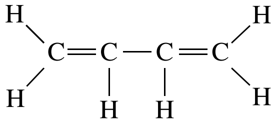
Previous Page

Conidia (Gk.). Fungus spores, → Moulds

Coning oils → Spin finish to improve the winding performance of yarns and thus increase the flexibility and low friction properties of yarns for winding and knitting processes. In spinning mills coning oils may cause corrosion of needles. The products are based on oils or water emulsifiable oils, which can be formulated with surfactants. They are commercially available with various suffixes from different manufacturers.

Conjugated (Lat.: coniugare), alternately bonded.

Conjugated double bonds Molecule construction system of alternating double and single bonds, e.g.



Such bonding systems endow relevant substances with increased reactivity, and play an extremely important role in the synthesis of numerous textile auxiliary agents, solvents, plastics (rubber, buna), dyes etc.

Consolidated shrinkage Compaction shrinkage. Delayed → Relaxation shrinkage. The (additional) shrinkage following the latter under dynamic (active) conditions, e.g. in the scouring process, unless this shrinkage is already identical to → Felting shrinkage.

Consolidations strengthening, compaction.

Constituents Chemical term for the number of substances differing from one another, from which a (phase) system is constructed. The number of constituents can be lower than the number of phases, as in the 3-phase system of the closed vessel with air, water and ice, where 2 constituents can be selected, namely air and water or air and ice, since the two phases water and ice are produced from one substance (ice or water). The number of constituents can also be greater, however, as in the 1-phase system of a salt solution, as this consists of just one phase – the solution – which has 2 constituents, namely salt and water.

Constitution (Lat.: constituere = compose). Sequence of atoms in the molecules of a chemical compound. →: Structural formula; Spatial formula (→ Formula).

Consumption prediction Because of the typical machine designs, residual liquor after padding is unavoidable. Environmental concerns are demanding the elimination of residual liquors (residual bath minimization). Effluent water that accumulates during the overall dyeing and finishing process, largely from residual liquors, involves extra costs because of the value of the products lost in the effluent (chemicals and dyes) as well as the continuously rising costs of disposal. It is therefore scarcely surprising that more and more often the question of how to deal with the effluent is asked. There are two basic solutions: the volumes of effluent that accumulate can be reduced by various subsequent processing. Large volumes of effluent can also be avoided from the beginning e.g. by minimizing the amounts of residual liquors in finishing, preparation, dyeing and sizing. There are many opportunities to minimize the amounts of residual liquor: the choice of products and recipes, knowledge of the goods, the arrangement of fabric and liquor, the methodology of preparation of the bath, re-use of residual baths. Measurement and control equipment is required for determining all the relevant parameters associated with applying the liquor, and information systems are required to manage other data that affect the amounts of residual liquor and to enable the optimum use to be made of these data.

In the course of a pad application, consumption is predicted with the help of three signal generators (liquor level in the bath, length of fabric and liquor input) that send the continuous liquor requirement of a machine to a central control unit. The system analyses the data produced and after a short time predicts the amount of liquor that will be used. A running rapid calculation means that even after a few metres an exact prediction of the liquor requirement per 100 m can be made. The additional liquor can then be made up exactly, to keep the residual to an absolute minimum. Full baths and half filled addition tanks left after the application process has finished are eliminated. The system can only react to the total liquor requirement prediction if the production run lasts long enough and the liquor can be made up quickly.

A system for predicting the requirement (Fig.) consists of three components or part systems which control mixing of the solution. The first part is combined with the coating unit. It determines and minimizes the liquor requirement of the unit. Large volumes of liquor to provide adequate safety margins then become superfluous. A second component that is purely software serves as a management and information system for all data relating to the application, such as chemicals, recipes, arti-

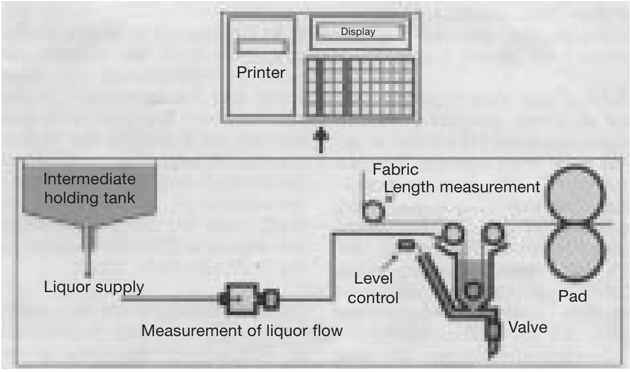


Fig.: Diagram of the "Alux 9000" and "Alux 9090 Cart" equipment for consumption prediction.

cles and application units. The third component unites the first two parts into an integrated system that takes account of all aspects of liquor management. The aim: to be able to supply the right liquor at the right time in the right amount in the right place (contributed by Frey and Wyss).

Contact angle In a plane which is vertical to a boundary line formed by three phases, the tangents laid on the two curves limiting a phase are examined. The angle formed by these is the contact angle of this phase relative to the other two (→ Wetting angle).

Contact corrosion Special case of → Corrosion, where, with direct contact between two different metals, a corrosive fluid is present acting as an electrolyte, under the influence of which the electronegative or baser metal is generally quickly destroyed (→ Electrolytic corrosion). In this respect, one can assume that there is no danger of corrosion in putting stainless steel with copper, bronze, brass and light alloy, if these metals are completely resistant in relevant solutions, as is stainless steel. In accordance with this principle, rustproof steel sheets can, without misgivings, be put together with brass coverings or brass rivets or nickel silver in washing machine construction. Where these factors do not exist, insulating layers should instead be interposed between different types of metal materials.

Contact drying Drying is implemented here by contact with heated cylinders or plates. →: High temperature contact process; Drying systems.

Contact-free measurement Under certain circumstances it can be of interest to scan textiles for a measurement value without contact taking place. An example would be the contact-free measurement of the speed of the goods (see Fig.): This is a correlation-optical process with grid sensors. The measurement information is obtained from the relative movement between the image and the grid. Through the choice of the representational scale and the grid constants, the work distance, the speed measurement range and the resolution can be freely selected, within certain limits. The only requirement which must be fulfilled in order to ensure the functioning of the measurement process is that the measurement object must have an optical structure. This could be random colour structures or weak light-dark differences, such as occur in almost every object to be measured; sometimes the contrast points are not discernible to the naked eye and appear only when suitable lighting is applied.

During measurement, the beam of light from the optical system transmits the object image onto a prism grid. With the relative movement of the sensor, the contrast points of the measurement object are modulated in such a way that a speed-proportional frequency arises via the photo-receiver system.

Contact heat resistance → Thermo stability of dyes.

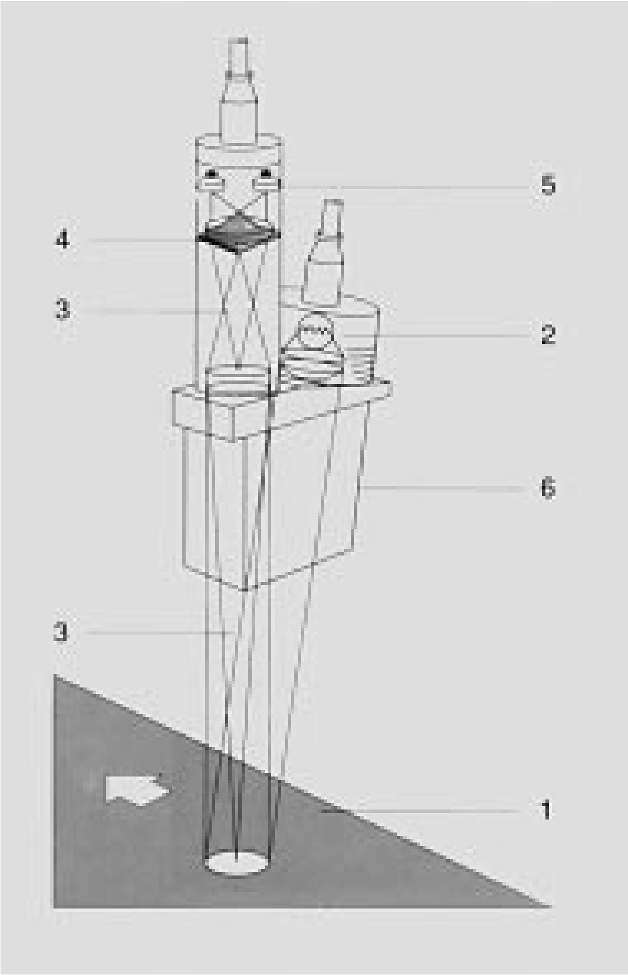

Fig.: Principle of operation and structure of the Correvit-L4/75 optical length and speed sensor for non-contact measurement.
1 = test object; 2 = illuminating system; 3 = optical beam path; 4 = measuring grid; 5 = photodetector system; 6 = spray protection.

Contact poison Contact poison in contacting textile pests as an immobilising/destroying neurotoxin. → Mothproofing.

Contact pressure Pressure applied to the pressure table by the pressure plate in thermal printing presses, using electro-hydraulic power transmission.

Contact printer In the half-tone process, the screen, which is necessary for better adhesion of the printing paste in the engraving, and for preventing the doctor blade from “dipping into” the engraving, is produced either in photography by inserting a glass/engraving contact screen, or by direct use of contact screen films, or also by screen films on a contact printer. → Half-tone screens.

Contact printing process A colour extract is transferred to flat or rotary screens in the contact printing process, the two-dimensional image of the transparency master being projected on to the copying layer, in which a three-dimensional pattern appears with the image produced whereby print shoulder and print flank are evaluated for copying definition.

Contact time in transfer printing Time span of the effect of the contact heat issuing from the transfer unit on to the printed transfer printing paper in close contact with the textile product.

Contaminants The textile process produces waste such as end fents and off-cuts that have no commercial value and indeed may be contaminated with process chemicals or oil. They may be contaminated with chemicals or waste products or may contain waste products from thermal processes such as oils, fats and waxes condensed from exhaust gas control processes. Similarly there are wastes such as the condensates from flame laminating processes. Many types of packing material will also result in contaminated wastes.

The disposal of such waste is linked to high administrative cost. It is important to define and separate waste or accept the high cost of "worst case" control of the hazard. For this reason there is a precise commercial advantage in sorting and separating waste into defined categories for disposal. It is normally the case that the polluter pays, so the responsibility for overseeing the process of disposal through to the final stages is a requirement.

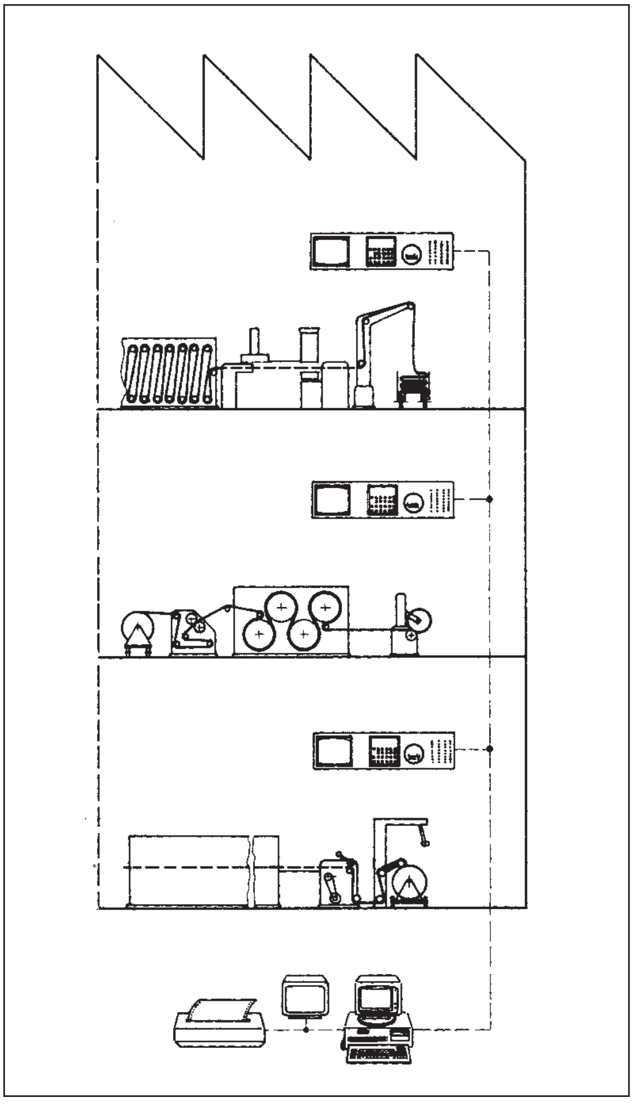

Fig.: Diagram of an operational monitoring system in a textile finishing plant.

Monitoring production helps in recognising waste at an early stage. The figure shows centralized monitoring of the individual stages of processing in a textile finishing plant. The operator observes e.g. mainly the automatic setting processes. Set values and actual values can thus be compared on the computer screen. After the batch is processed the computer produces a batch report or these data are copied onto other computers by file transfer.

It is a normal requirement that all processors carry a responsibility to control the waste they produce from processing. The control of recording the isolation and eventual disposal of waste is an important aspect of this responsibility, extending even to monitoring the efficiency of a sub-contracted waste disposal agent. (partly according to Marzinkowski).

Contaminant-tested textiles The letter T in a circle representing the globe (the inner section may be interpreted as a tree, protected by the surrounding bracket) with the legend "contaminant-tested textiles" (Schadstoffgeprüfte Textilien) (plus control number = "Kontrollnummer") (Fig.), used as a manufacturer's mark of the German textile industry; → MST (Markenzeichen schadstoffgeprüfte Textilien = "Contaminant-tested textiles mark").

Fig.: German "Contaminant-tested textiles" mark.

Conticrabbing Continuous wet finishing machine without conveyor belts (see Fig.). Cloth speed 8–24 m/min; length without wash section 5.50 m; width 3.20 m; height 4.75 m; water capacity in treatment compartment 3500 l, in cooling bath 1000 l; installed power 15 kW; incorporating pressure reduction and level control. For permanent-set finishes on wool fabrics. Setting prevents creases forming in rope dyeing, permitting even difficult fabrics to be rope dyed without problem. Irregularities in quality in the loomstate fabric can be compensated by water treatment at 110°C. – Manuf.: MAT di A. Bertoldi S.p.A.

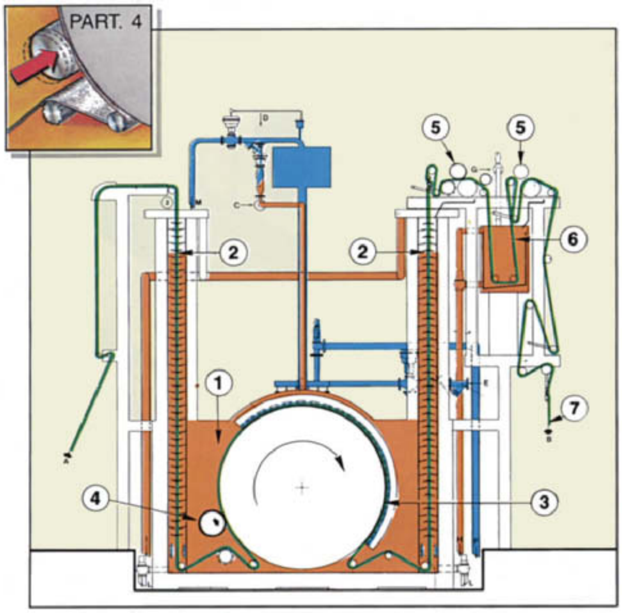

Fig.: Principle of MAT Conticrabbing machine.
1 = treatment compartment; 2 = water heads; 3 = main cylinder; 4 = counter-pressure roller; 5 = squeeze rollers; 6 = cooling bath; 7 = cuttling.

Continuous ager A continuous steamer or ager, rapid steamer and screen-print steamer.

Continuous bleaching plants Consist of a J box (rope form), impregnating machines (open width form) steaming systems and rewashing lines (see Fig.). The uniformity of the bleaching effect depends largely on the consistency of the chemical concentration and treatment time and temperature. Relevant measuring and control units are essential.

Continuous boiler → Steam boiler.

Continuous decatizing (Am. decating). Dry decatizing: Continuous decatzing processes improve wool and mixed-fibre fabrics, especially in respect of handle and appearance. The fabric is exposed to steam in either expanded or cooled form (suction principle) or controlled humidity is applied to the cloth in the treatment zone and this is converted into steam by applying pressure and heat (vaporizer principle Fig. 1).

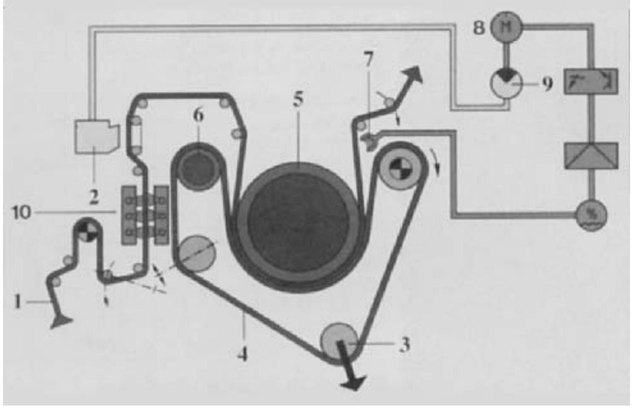

Fig. 1: “Superfinish” by Menschner.
1 = cloth path; 2 = controlled humidification unit (rotor-spray device); 3 = tensioner device; 4 = compression belt (wrapper); 5 = heated counter-roller; 6 = heated roller (compression belt); 7 = sensor for measuring released steam cloud; 8 = drive motor; 9 = supply pump; 10 = auxiliary special steam-lock.

The “Superfinish” (Menschner, Fig. 1) and the Multiset (Sperotto Rimar, Fig. 3) produce their own steam, constantly adjusting the rate of application to the moisture content of the entering cloth. This creates relatively high temperature through to the core of the cloth (125–140°C) depending on the pressure exerted on the cloth in the vaporization process (Figs. 5 and 6). This is 20–35°C higher than in conventional decatizing machines operating on the suction principle. Higher temperature means better set in the cloth. As shown in Fig. 1 controlled humidity is applied to the cloth immediately before pressing and decatizing treatment. Pressing and decatizing then follow with contact pressure on the counter-roller being applied via the compression belt (wrapper) pre-tensioned by the tensioner device. Controlled heat is applied to both faces of the cloth by heating the compression belt and the counter-roller. The heated compression belt is impermeable and sealed from the environmental atmosphere, so under these circumstances, i.e. under high-temperature conditions, the moisture applied to the cloth is converted into steam.

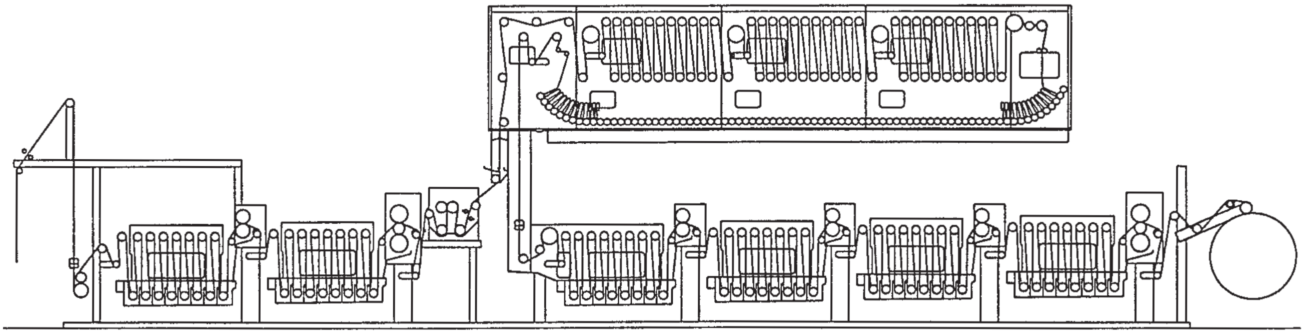

Fig.: One-stage-pretreatment range for cotton fabrics from Goller.

The “Hygromat” sensor system of the “Superfinish” measures the steam released using a special sensor which establishes its degree of saturation. The results obtained are amplified to produce proportional output signals for controlling the amount of steam applied. Water supply is metered by controlling the speed of the supply pump drive motor. This method of steam measurement enables influences of factors such as cloth density, amount of air trapped in the cloth, sorption characteristics, initial moisture content, treatment temperature and cloth throughput speed to be taken into consideration. The moisture content is established during treatment by pre-entering the target degree of steam saturation. The moisture necessary for producing the finish is applied to the cloth in the vaporization system. The sensor analyses the moisture content following vaporization and compares it with a pre-entered reference value. As shown in Fig. 1 a special rotor-spray device enables useful steamed finishes to be obtained. With materials having lower absorption characteristics or with sensitive materials such as piece-dyed goods, it is advisable to incorporate a special steam-lock before the actual spray device. This combination enables the efficiency of humidification to be improved.

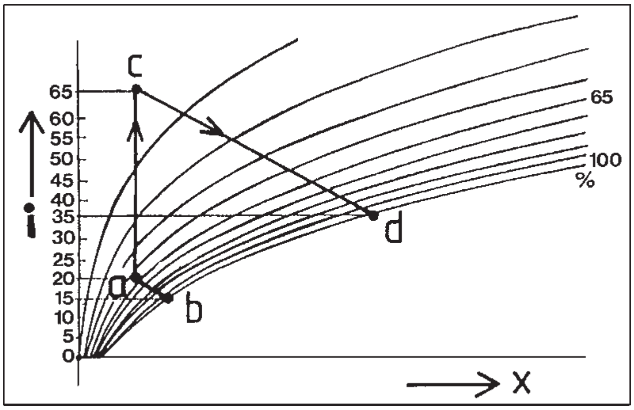

Fig. 2: Mollier diagrams for moist air (source: Menschner).

The Mollier diagram (Fig. 2) illustrates the benefits of steaming followed immediately by spray application of water. Applying steam to the cloth heats it up (points a–c), and at the same time the relative humidity of the air trapped in the textile material is reduced. With the fibre assembly in this state it is possible to apply a great deal of water (points a–d) before the 100% saturation point is reached. It also needs to be recognised why spraying the cold textile material (points a–b) produces a relatively low absorption of water. A relatively low amount of water already causes dew to form. Since the air trapped in a woven fabric can account for as much as 80% of the volume, the result of humidification of the air evenly distributed throughout the cloth means that humidification is efficiently performed.

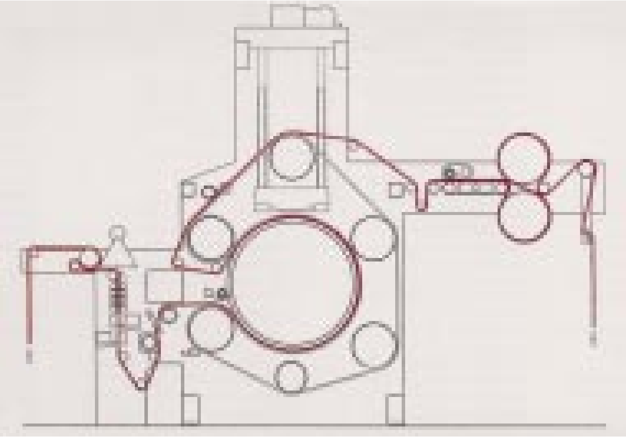

Fig. 3: Multiset continuous decatizing machine by Sperotto Rimar.

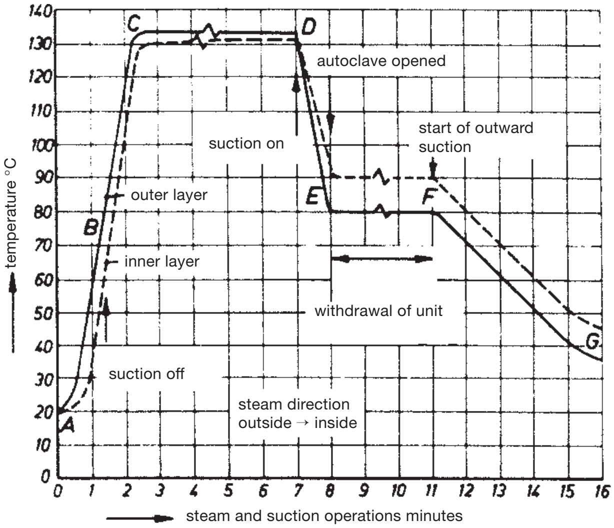

Fig. 4: Temperatures during steam and suction operations in the outer and inner parts of the roll for steam pressure ρ = 2.0 bar in batch kier decatizing (source: Sustmann).

Results with and without steam-lock demonstrate that, depending on water pressure and cloth weight, a moisture content increase of 6.2–18.7% can be achieved with rotor humidification and 7.5–19.7% with auxiliary steam-lock. Incorporation of the steam-lock thus produces a further increase in moisture content of 2.2% (otherwise 1.0–2.2%). But it is significant that with the steam-lock uniformity is far better along the length and across the width of the cloth, thereby preventing undesirable streakiness. Another favourable point noted is that steaming and humidification causes the cloth temperature to rise to 58°C. Temperature and humidity levels created by this procedure are maintained through to the “Superfinish” virtually without dropping at all and under the prescribed conditions of pressure and temperature in the press treatment zone are converted into steam.

In the vaporizer principle far higher temperatures

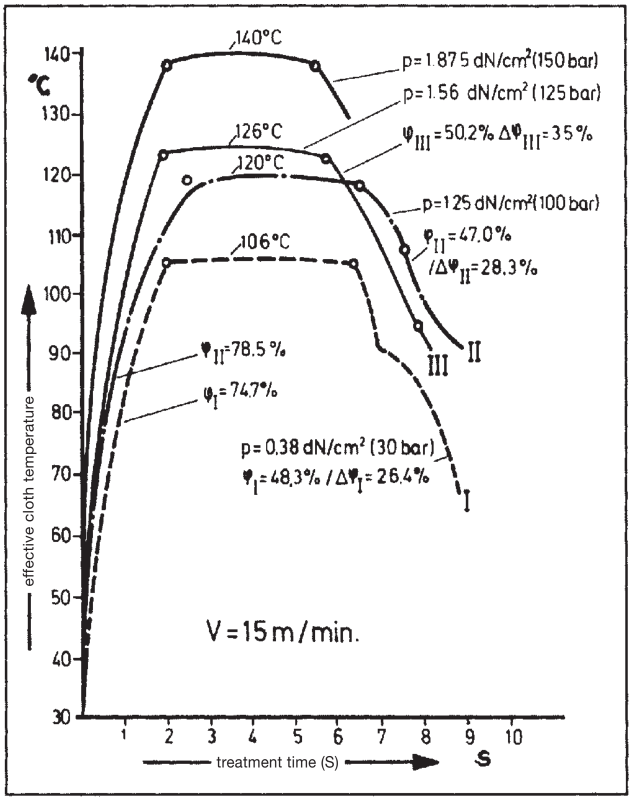

Fig. 5: Effective cloth temperatures in relation to treatment time with v = 15 m/min (counter-roller/compression belt heated to 185°C). (Source Michels – measurements made on a Menschner "Superfinish").

are achieved in the core of the cloth than in current methods of continuous decatizing operating on the through-flow principle and achieving a maximum of 105°C. The effective cloth temperature during "Superfinish" treatment has been measured using a cupronickel thermocouple. Diameter and length of the sensor wire permit smooth passage of cloth and thermocouple, with the cloth folded double and the thermocouple being passed all the way through the treatment zone sandwiched in the folded cloth. During treatment measurements can be taken every 5 seconds, fed into a minicomputer and reported. Figs. 5 and 6 show the relation between the effective temperatures measured inside the fabric sandwich and treatment time. It is evident from these experiments that the contact pressure from the compression belt (wrapper) has a major influence on the effective temperature. For instance at a stress of 30 bar and a surface pressure of approx. 0.38 dN/cm^2 the water applied (moisture in the cloth) is heated to steam temperature between the heated counter-roller and the heated compression belt, creating a temperature of 106°C in the cloth. With every increase in stress there is a rise in effective temperature. The corresponding treatment time is approx 4 seconds before the cloth running at a speed of 15 m/min emerges from the sandwich. The spontaneous temperature rise in the relatively damp cloth is surprising, reaching its maximum after just 1.0–1.5 seconds. This may be compared with the temperatures achieved in a kier decatizing machine (Fig. 4).

In a continuously operating decatizing process (Contidec – Superfinish 2 – Menschner) the machine need not be stopped for replenishing the treatment unit or changing the cloth roll. This is performed by the cloth accumulator located above the machine. The positively driven feed roller can either replenish the accumulator in fast mode or synchronously to maintain a uniform amount of cloth in reserve. The "Correfix" weft straightener then comes into operation and passes on the cloth for treatment by the "Superfinish 2" . Stage 1 is humidification, with water in the cloth under contact pressure being converted into steam and the cloth thus set. In stage 2 the cloth, still under contact pressure, is subjected to suction extraction and cooling. For stage 1 an impermeable compression belt is provided which is capable of exerting high pressure, whilst for suction extraction a permeable compression belt is used, likewise with controllable contact pressure. The peforated cooling cylinder is subjected to vacuum so that the cloth being treated is pressed against the cylinder by the compression belt and suction extraction applied. The purpose of this stage is to improve cloth handle following the actual decatizing process. This is especially important in cases where a solid or relatively

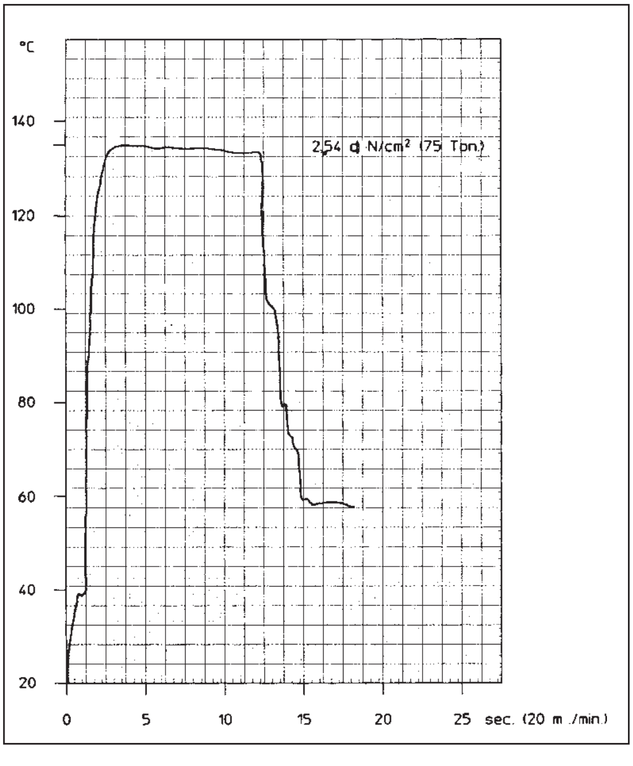

Fig. 6: Effective cloth temperature in a "Multiset" decatizing machine by Sperotto Rimar in relation to dwell time in the sandwich (see Fig. 3) at 2.54 dN/cm^2 contact pressure.

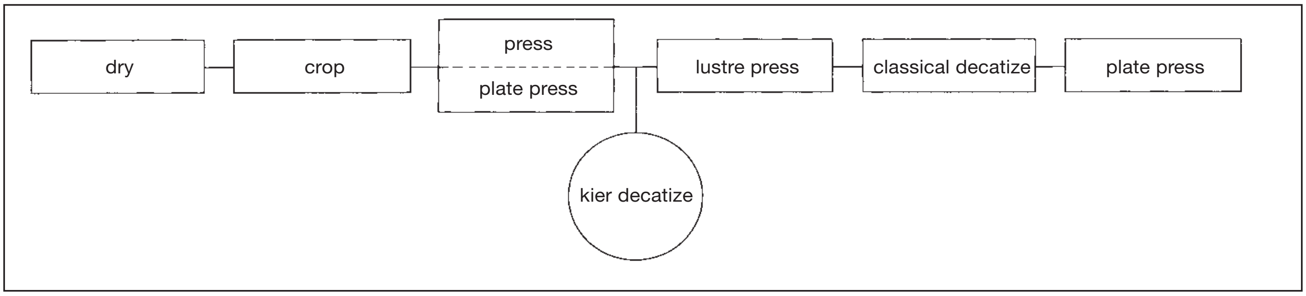

Fig. 7: Sequence of processes in traditional dry finishing of fabric of all-wool and wool mixtures.

crisp handle is required. From practical experience with this machine it may be suggested that stage 1 substantially produces the classical decatized finish and stage 2 the classical pressed lustre finish. Reducing the contact pressure in suction extraction enables finishes of an intermediate nature to be produced. However, without changing the passage of the cloth through the machine it is possible to obtain the classical decatized finish, for example by switching off the vacuum in the cooling cylinder and by reducing the contact pressure of the compression belt in stage 2 to almost zero. In these respects it is possible to employ the “Superfinish 2” as an all-purpose continuous decatizing machine for both conventional decatized and pressed lustre finishes.

Fig. 7 illustrates the sequence of different treatment stages in dry finishing. It should be remembered that on the one hand the best pressed finishes are created by treating dry cloth and on the other hand the best decatized finishes are obtained by treating thoroughly humidified cloth. In the “Superfinish 2” the two processes can be run consecutively non-stop simply by switching the humidification device on or off, with no need for resetting the machine or changing the way in which the cloth passes through. Such machines can be used for the following processes:

– as a pressing machine to precede conventional decatizing, e.g. before kier decatizing;
– to obtain a pressed lustre finish (comparable with the finish on on the classical batch decatizing machine);
– to obtain a classical decatized finish (comparable with the finish on on the classical batch decatizing machine);
– to follow kier decatizing;
– as a setting machine to perform the durable-press process;
– to produce a finish comparable to flat-plate pressing.

The wide versatility, especially the facility for switching from pressing to decatizing without having to rearrange the sequence of pieces or readjusting the machine, makes these machines attractive even for relatively small finishing plants. The travelling cuttler unit, i.e. laterally mobile cuttling device, makes a major contribution to the non-stop operation of the machine. The benefits of the vaporization system need not necessarily be combined with stage 2. If the conventional decatized finish is required then the suction extraction and cooling sections are omitted. These variants are provided by the “Contidec-Superfinish-1” (Fig. 8) where the actual setting unit is preceded by just one cooling zone for the effective cooling of the cloth.

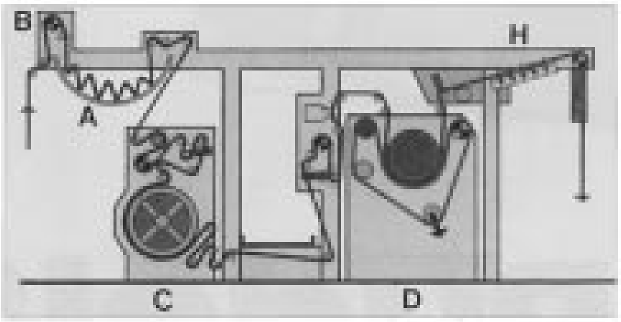

Fig. 8: “Superfinish-1” continuous decatizing machine by Menschner.
A = cloth accumulator; B = driven transporter roller;
C = “Correfix” weft straightener; D = “Superfinish” ;
H = cooling zone.

Apart from finishing wool cloth, continuous decatizing may also be employed to advantage for finishing polyester/wool, polyester/viscose, cotton/viscose, linen and mixed-fibre fabrics in a very wide variety for the outerwear sector and for improving the handle and crush-resistance of speciality upholstery materials. In the treatment of cotton a high-temperature stage is required (possibly oil-filled heating for compression belt heater roller and counter-roller). The variety of decatized finishes obtainable may be compared to classical batch decatizing, in many cases it is even superior. Cloth handle is decidedly improved, e.g. it is possible to modify the handle of wool cloths to resemble cashmere and wool/polyester mixtures to resemble all-wool. Lustre and bulk in the cloth can be positively varied within a wide range by control of cloth moisture content. For solid and relatively crisp handle the essential feature is a suction extraction system with a variable degree of contact pressure. The pressed finish of the cloth can also be accentuated by increasing the temperature.

Continuous → Wet decatizing: In continuously operating systems it is impossible to maintain the strict conditions of temperature, humidity and time by which means sulphide bonds are broken and permanent set finishes produced. The setting propensity of wool must be supported by treatment with chemical reagents. In chemical decatizing, agents releasing SO_2 for example are used which reversibly break the disulphide linkages in wool in a sulphitolysis reaction. Cysteine and cysteine-S-sulphonate residues are formed:

$$\textcircled{W}-CH_2-S-S-CH_2-\textcircled{W} + HSO_3^-$$
$$\rightleftharpoons \textcircled{W}-CH_2-SH + \textcircled{W}-CH_2-SSO_3^-$$

As in kier (batch) decatizing, it is possible here to utilize the properties of steam at 140°C for the disulphide exchange process if the compression belts (wrappers) used are impermeable to the steam pressure occurring in the sandwich (Fig. 9).

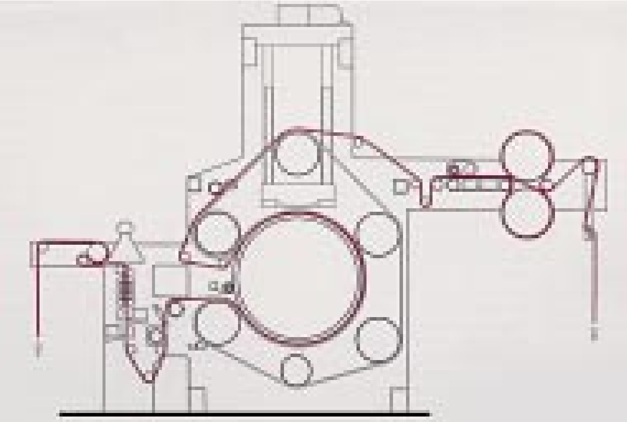

Fig. 9: Multiset continuous decatizing machine by Sperotto Rimar.

The necesary humidity can be applied by a spray device such as that supplied by Weko. In two-phase decatizing wool cloth is remoistened using a purpose-designed device on the capillary active principle, and then decatized in two phases (wet and dry) (Fig. 10).

The optimum decatized finish is obtained when the cloth reaches its normal moisture content shortly before the conclusion of the drying stage. As soon as the moisture content is too low following the end of the wet phase, it must be remoistened. The necessary mechanical pressure is produced by a compression belt (in silicone polymer and polyester fabric) which also makes the sandwich airtight so as to create high-temperature conditions. The necessary dwell of the cloth in treatment is obtained by it passing over a number of cylinders.

Continuous desizing Suitable for woven cotton and blended cotton/synthetic fabrics. Although enzymatic starch decomposition is time-consuming, continuous desizing can be effected with bacteria-diastases (other amylases are unsuitable): fabric is impregnated with hot enzyme solution and deposited in a heated J box for 3–5 min. Liquid absorption must be high (100% and over).

Continuous dyeing Dyeing process in which the dye liquor is applied to a moving fabric.

Continuous dyeing of woven PES-containing fabrics A distinction is particularly drawn between the continuous dyeing of woven fabrics of 100% polyester and blended polyester/cellulose fabrics.

I. Thermosol process for 100% polyester: thermosolling is used for tow, sliver, belts, above all woven fabrics and some knitted fabrics. The padding liquor contains the dye, a thickener or migration inhibitor, and possibly a hydrotropic agent (urea, thiourea) and possibly a substance giving off acid. Liquor uptake is 30–40%. Various units are employed for drying: jet dryers, stenters, cylinder dryers. Pre-drying by infra-red heating elements is recommended in any case in order to forestall dye migration. The dye deposited on the fibre

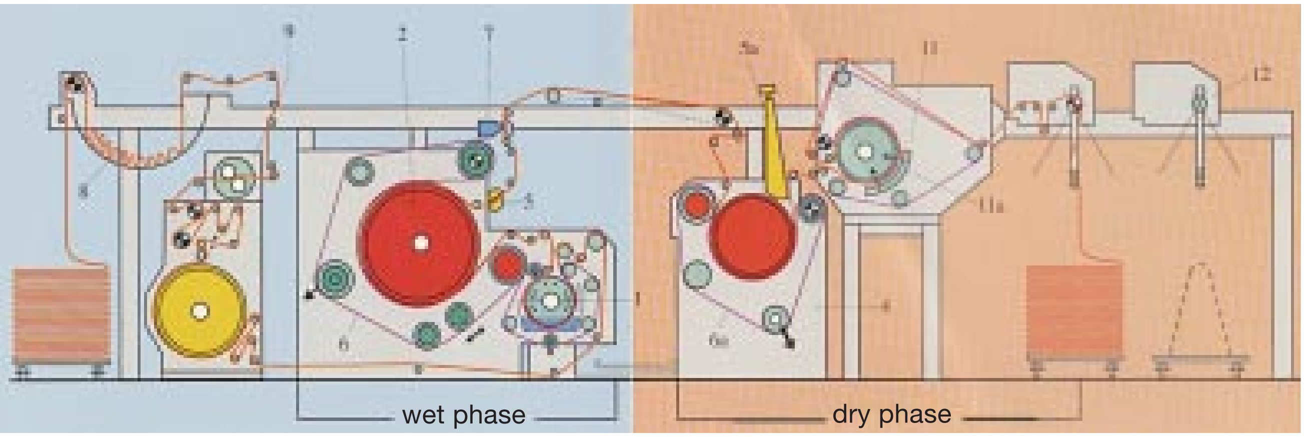

Fig. 10: Two-phase decatizing (Menschner).

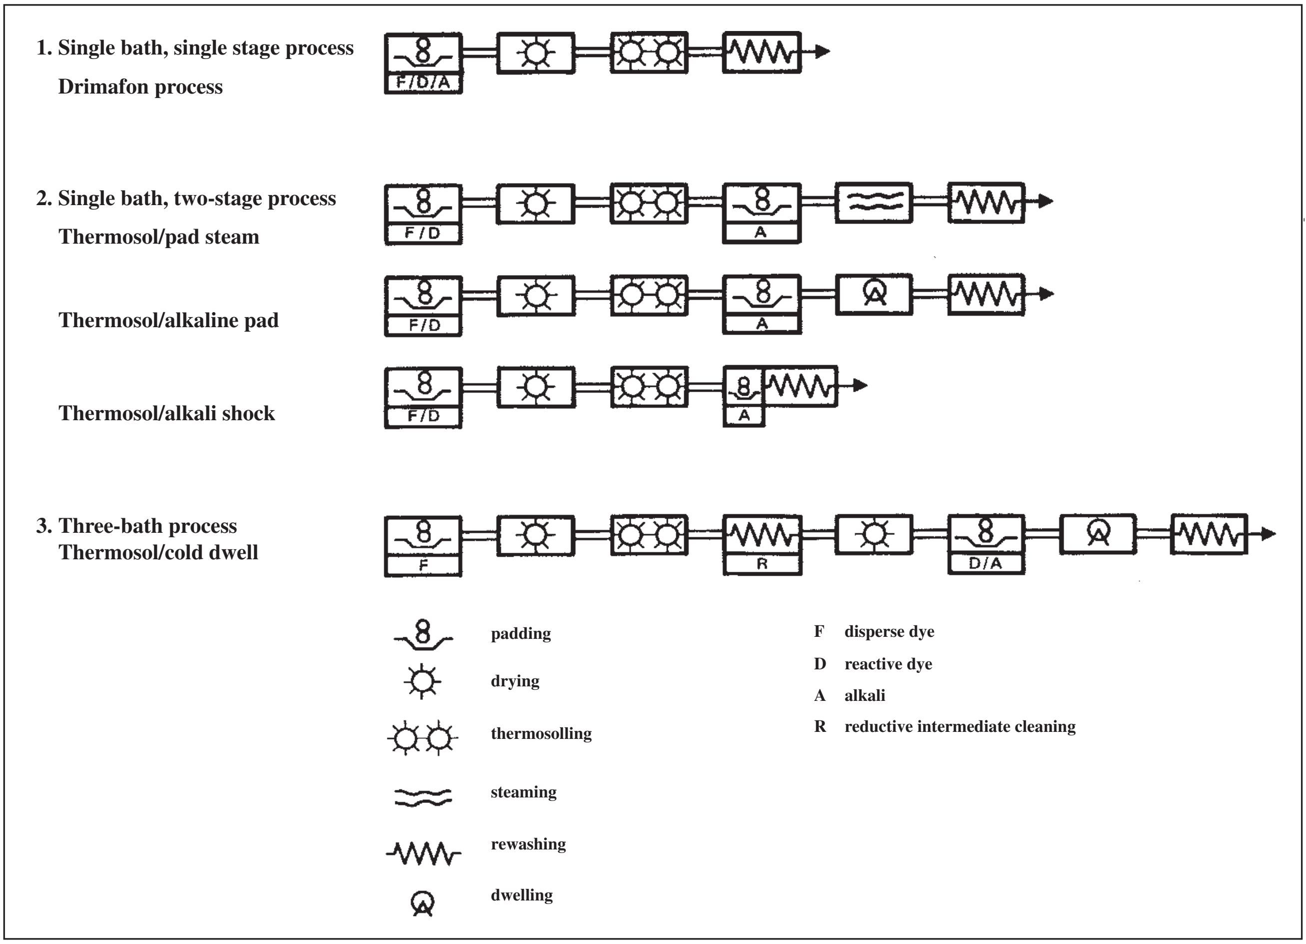

Fig. 1: Survey of processes suitable for disperse/reactive dye systems.

surface and also located to some extent in the skin now diffuses into the fibres. Diffusion takes place to some extent via the gas phase. Thermosolling conditions should be selected in such a way that each dye is provided with optimum temperature and time (attention should be paid to this in combination dyeing). It has been shown that the optimum values of the individual disperse dyes in combinations can be changed by reciprocal effects. The dye manufacturers' sample card data is therefore to be strictly observed. With too high temperatures, part of the dye already in the fibre can sublime off again. Thermosolling can be carried out in hot air or superheated steam, by contact heat or irradiation. Hot air fixation is the most important. Here, it is important that the fabric is subjected to the same conditions over its full width, for temperature differences are marked by colour differences in the dyed fabric. Where this is not guaranteed, dyes which are least susceptible to temperature differences should in any case be selected. The fabric should not be dried to the absolutely water-free state before themosolling. Some moisture is necessary for achieving max. dye yield, but there should not be too much, as otherwise dye agglomerates (specks) can form.

II. Padding process for woven polyester/cotton fabrics: in padding, cotton takes up almost twice as much disperse dye per unit of weight as polyester. Dye migration from the cotton to the polyester already starts during dyeing. Most of the dye migrates however only by contact transference and sublimation during heat setting; smaller quantities also migrate of course into the cotton fibre interior, so that complete removal becomes difficult. Cotton staining by disperse dyestuff is therefore greater in the thermosol process than in the exhaust process. With the exhaust process, however, it is particularly a question of the molecular weight of the dye. The fastness of this staining is limited. Intermediate cleaning must be carried out in the case of exacting requirements. A distinction is drawn between single and two-bath processes. In the two-bath process, the disperse dye is padded first of all, and fixated by thermosolling before reactive dye, for example, is applied separately (continuously or in batches). The reverse sequence is also conceivable of course. In the single bath process, there is a distinction between single stage and a two-stage processing, reactive dyes being extremely important for the cotton content. The true continuous processes are of special interest from the economic standpoint, but the fact that two different fibres are blended must be taken into account: the hydrophobic

Continuous dyeing of woven PES-containing fabrics

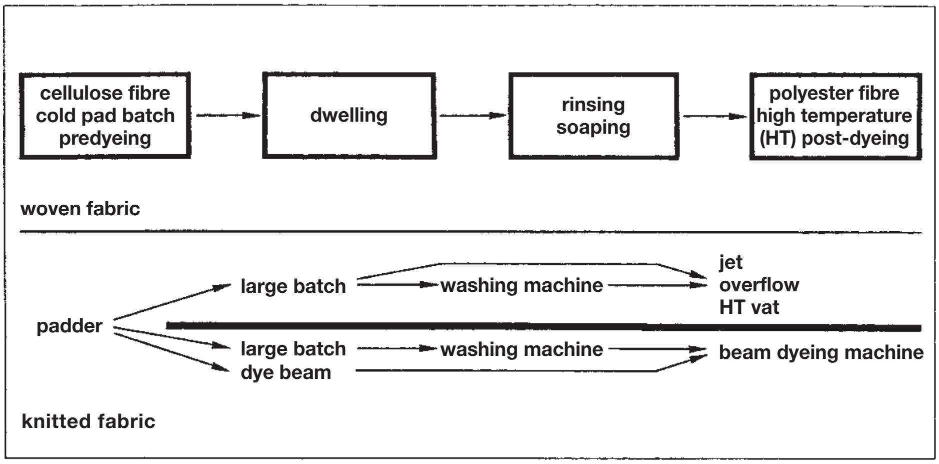

Fig. 2: Cold pad batch dyeing.

polyester fibre, the dye fixation of which requires dry heat, and the hydrophilic cotton, which requires steam, or in dry heat fixation, at least a hydrotropic agent for dye fixation (Fig. 1). For cotton, cold pad bad processes and semi-continuous cold dwell processes (Fig. 2) are useful if polyester is post-dyed.

The different fibres (cotton and synthetic fibres) require different conditions for fixating their dyes in each case in the → Pad-Steam Process (Fig. 3); cellulose fibres need steaming times from 16 to 60 s, while polyester fibres are not actually fully fixated in saturated steam. The short loop steamer was developed for the superheated steam fixation of polyester. In the heat fixating/setting/thermosol process, the reactive dyes are bonded to the cellulose only when highly polar substances (Fig. 4) promote diffusion of the dye into the fibre interior. Urea is not so suitable here, since it can decompose under the effect of heat. Here, dicyandiamide is of interest with the use of reactive dyes, because it enables reactive dyes to be fixated to cellulose

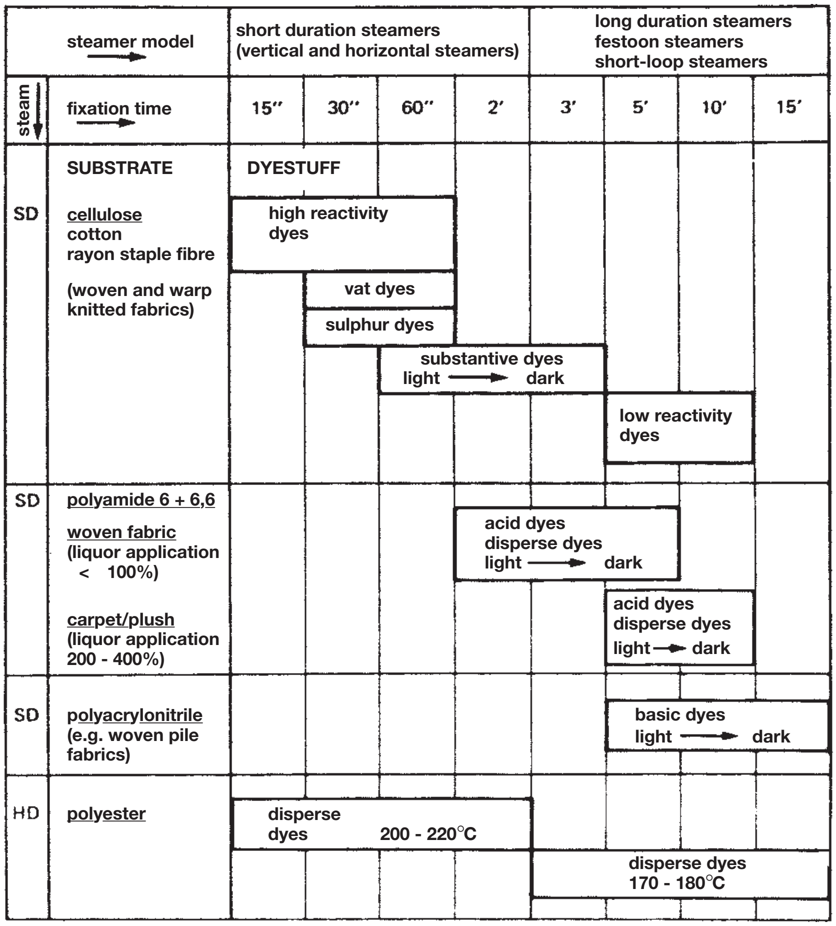

Fig. 3: Steaming times relative to substrate, type of steam, steamer model and dyestuff. SD = saturated steam; HD = superheated steam.

even without alkali when used as a slightly basic compound in the acid thermofixation process (Fig. 5).

$$H_2N-CO-\boxed{NH_2+H}-NH-CO-NH_2 \rightarrow$$

$$NH_2-CO-NH-CONH2 \;+\uparrow NH_3$$

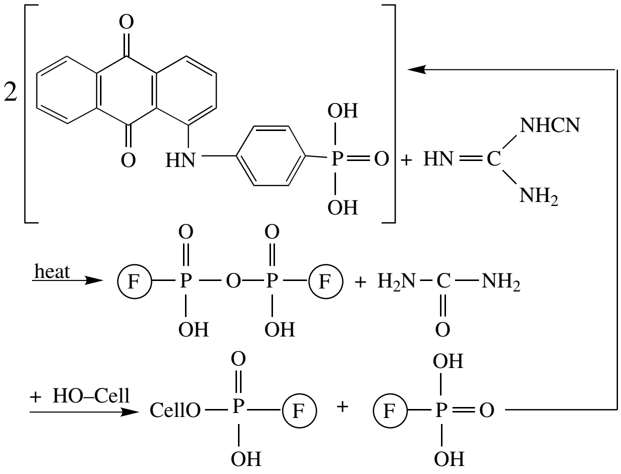
$$OC(NH_2)_2 \rightarrow \uparrow NH_3 \quad + NCOH$$

$$3\ NCOH \rightarrow (NCOH)_3$$

compound		melt point
urea	 $O=C(NH_2)_2$	133
thiourea	 $S=C(NH_2)_2$	180
dicyandiamide	 $H_2N-C(=NH)-NH-C\equiv N$	209
biuret	 $H_2N-C(=O)-NH-C(=O)-NH_2$	193

Fig. 4: Decomposition of urea under the effect of heat and alternative products for use in the TT process (Bayer).

Dicyandiamide also has the special function of activating reactive dyestuff:



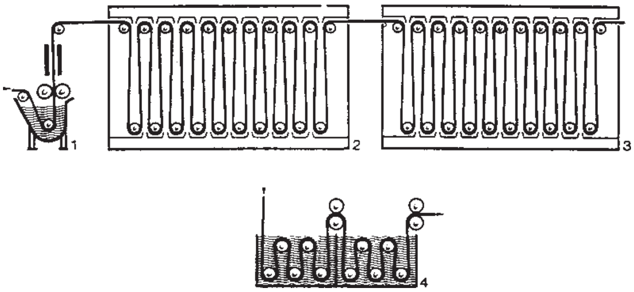


Fig. 5: AT process sequence.
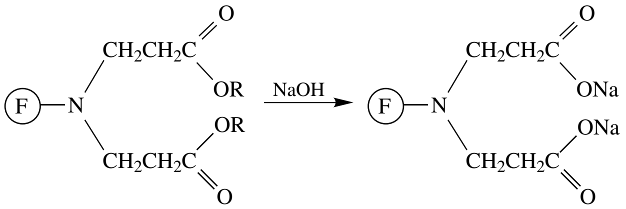
1 = padding and pre-drying; 2 = drying; 3 = thermosolling; 4 = rinsing, soaping.

Depending on the reaction method, the reactive dyestuff is padded together with the disperse dye (for polyester) in order then to be fixated to the cellulose by thermosolling. In the subsequent re-washing process, 4 g/l of caustic soda are added to the first bath in order to hydrolyse the unfixated disperse dye, and enable it to be washed off better:



Combinations of continuous and batch dyeing processes are shown in Fig. 6. There are also special processes which have advantages depending on local circumstances:

- Process 1: Mixed dyes dye both fibres to the same depth in the thermosol process.
- Process 2: Limited to lighter to medium shades. Not all disperse dyes are resistant to the large quantities of urea and alkali necessary for reactive dye fixation. Rapid intermediate drying at approx. 140°C is advisable. Reactive and disperse dyes are matched to one another, and are fixated under identical conditions. Reductive after-treatment should be unnecessary. Some processes also operate without alkali: in its "2-DA" process, Sandoz uses dicyandiamide and sodium acetate, and Hoechst/USA sodium formiate, in the padder bath instead of urea and alkali.
- Process 3: In the case of disperse and leuco vat ester dye mixtures, the disperse dyes employed are oxidation-resistant. The Hoechst A.T.E. process is a similar process. The simultaneous use of disperse dyes can be dispensed with in the case of pastel shades.

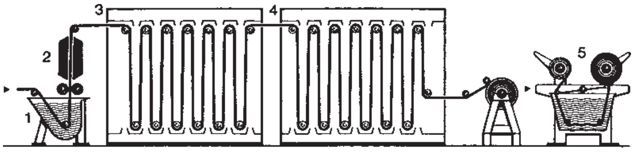


Fig. 6: Thermosol-jigger development process.
1 = padding; 2 = pre-drying; 3 = drying; 4 = thermosolling; 5 = jigger development.

Continuous dyeing plants

- Process 4: Instead of single bath processes, the cotton can also be dyed as usual by ground dyeing with the naphtholate, intermediate drying and coupling with the fast base, and then padding with the disperse dye, drying and thermosolling. In this way, the naphthol dye residue on the polyester fibre migrates to the cotton so that better rubbing fastness is obtained.
- Process 5: The dye mixtures mentioned in process 2 come into the picture for this. If combinations of the two dyestuff types are made up, allowance should be made for the alkali sensitivity of many disperse dyes. Yellowing of the cellulose fibre, caused by the alkali, can be prevented by adding 5 g/l of sodium tetraborate.
- Process 6: With the thermosol/pad/steam process, good cooling of the blank vat should be ensured. The bath temperature rises due to the passage of the disperse dyes into the bath. With the thermosol/alkali shock process (Fig. 8), the cellulose fibre material used must have a high degree of substantivity.

The diversity of the plant offered by all the large machinery manufacturers for dyeing blended polyester/cellulose woven fabrics is well known. One large dyeing line (Fig. 7) comprises fabric entry, padder, infrared dryer, hot flue, fixating/setting machine, steamer, washing machine and dryer (cylinder dryer or stenter); many different manufacturers come into consideration for this (Fig. 9).

Continuous dyeing plants Depending on class of dyestuff, they comprise padder, dryer (cylinder, hot flue dryers), continuous steamer and open-width washing machines.

Continuous dyeing range Machinery range for padding, setting/steaming/drying, wash-off of suitable dyestuffs (e.g. disperse, vat and reactive dyestuffs) in correspondingly large dye batches for increased productivity and economy in dyestuffs, chemicals and energy usage. Process generally uses a liquor ratio of 1 : 1, i.e. the pad-liquor pick-up = 100% = 100 kg dye liquor/100 kg fabric.

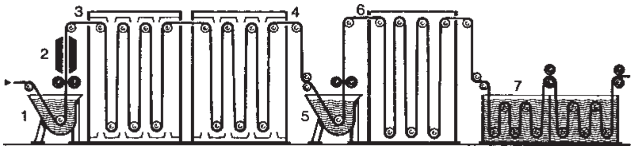

Fig. 7: Thermosol-pad-steam process.
1 = padding; 2 = pre-drying; 3 = drying; 4 = thermosolling; 5 = chemical padding; 6 = steaming; 7 = after-treatment.

Examples for plants with open-width piece goods are shown in the Figure.

I. Semi-continuous:

a) → Pad-Jig Process: pad the dyestuff/chemical liquor on the pad mangle, fix, wash off (jigger).

b) → Pad-Roll Process: pad the dyestuff/chemical liquor on the pad mangle, take-up on special beams, develop on the beams in steam fixation chambers, wash off (open-width washer).

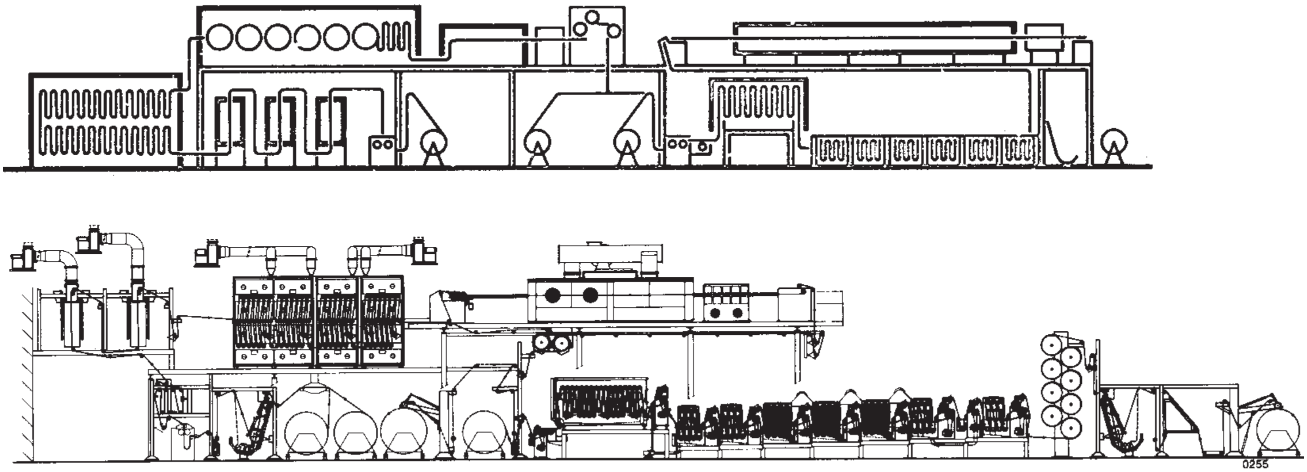

Fig. 9: Fleissner continuous dyeing plant (top) and a line comprising variously composed machines (bottom) for dyeing woven blended polyester/cellulose fabrics.

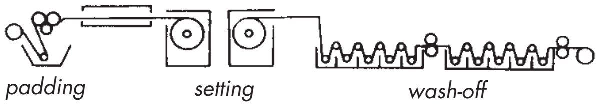
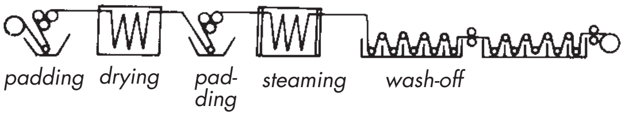
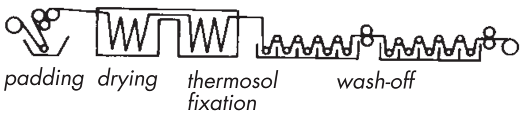


1 Pad-roll process

2 Cold-dwell process



3 Pad-steam-process, double dip



4 Heat-setting process

Fig.: Examples for plants with open-width piece goods.

c) → Cold-dwell process: pad the dyestuff/chemical liquor on the mangle, batch on special beams and hold at room temperature to develop, wash-off (open-width washer), especially suited to reactive dyestuffs.

II. Continuous:

a) → Pad-Steam Process: single-dip:
Pad the dyestuff/chemical liquor, dry. Double-dip: Pad dyestuff, intermediate dry, pad chemical liquor on a second mangle, set on the steamer, wash-off (open-width washer).

b) → Heat setting processes: pad the dyestuff/chemical liquor on the mangle, dry and thermosol in one process wash off (open-width washer).

Continuous filament → Elementary filament.

Continuous filament yarn A continuous → Filament yarn which, according to DIN 60 000, is composed of one or more → Elementary filaments with/without the insertion of twist. The antonym is → Spun yarn. With pure silk, only the reeled silk from the cocoon can be described as a continuous filament yarn whilst schappe silk, on the other hand, is a spun yarn.

Continuous finishing processes For treating woven and knitted piece-goods of unlimited length, the fabric passing only once through the machinery necessary for finishing. A defined quantity of finishing agent is applied to a generally open-width moving fabric in separate stages (mainly successive). In contrast to → Exhaust dyeing processes, all continuous finishing processes have a high finishing agent concentration and little liquor. The fabric/liquor ratio averages 1: 0.5–1 (except in washing processes).

Continuous ink jet printing A coloured ink jet process with dye solution (non-contact dye application system) in which the stream of coloured ink is squirted continuously from a tiny nozzle. Printing is controlled by withdrawing or interposing a baffle plate (Electrocolor process) or by deflecting the ink jet with compressed air (Millitron process).

Continuous laundering line (Washing pipes) → Continuous washing plant, consisting of a 4–7 m long, slightly inclined, tubular inner and outer drum, with 12 washing and rinsing zones based on the contraflow system, with subsequent squeeze water extraction and contraflow/shaking step drier. The laundry is transported by means of rotation, drum inclination and a ribbed carrier, along with reversing of perforated inner drum. Dewatering to approx. 60% residual moisture. Output of various sizes of continuous laundering lines approx. 400–1000 kg/h dry product. Total laundering time 30–45 min.

Continuous liquor flow laundry wash process → Flow washing process.

Continuous rope treatment plant For the continuous pretreatment, bleaching, dyeing (Fig. 1) and after-treatment preferably of cotton knitted fabrics.

Counter liquor flow in up to 12 fabric stores; operat-

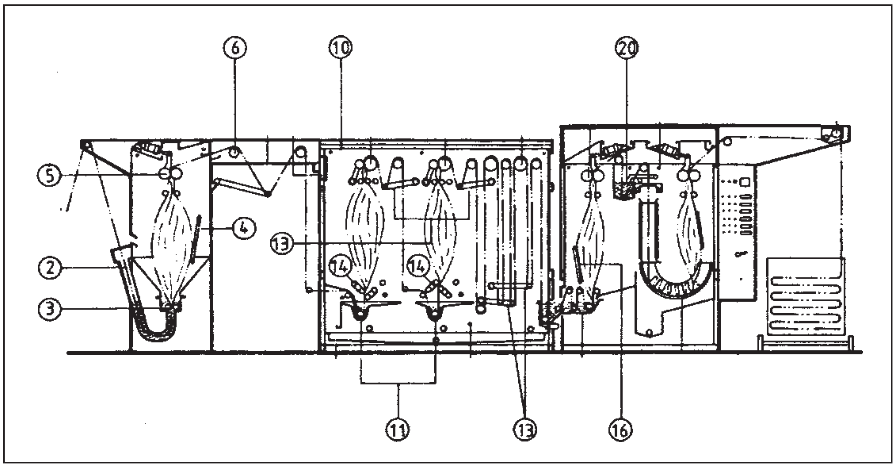


Fig. 1: Tubocolor plant for dyeing knitted fabrics (Brückner).

ing speeds from 10 to 100 m/min. With depository for optimum fabric shrinkage/relaxation. Rope washing on a continuous jet (Fig. 2) is especially suitable for improving efficiency in the continuous after-treatment of static bleaching and dyeing processes.

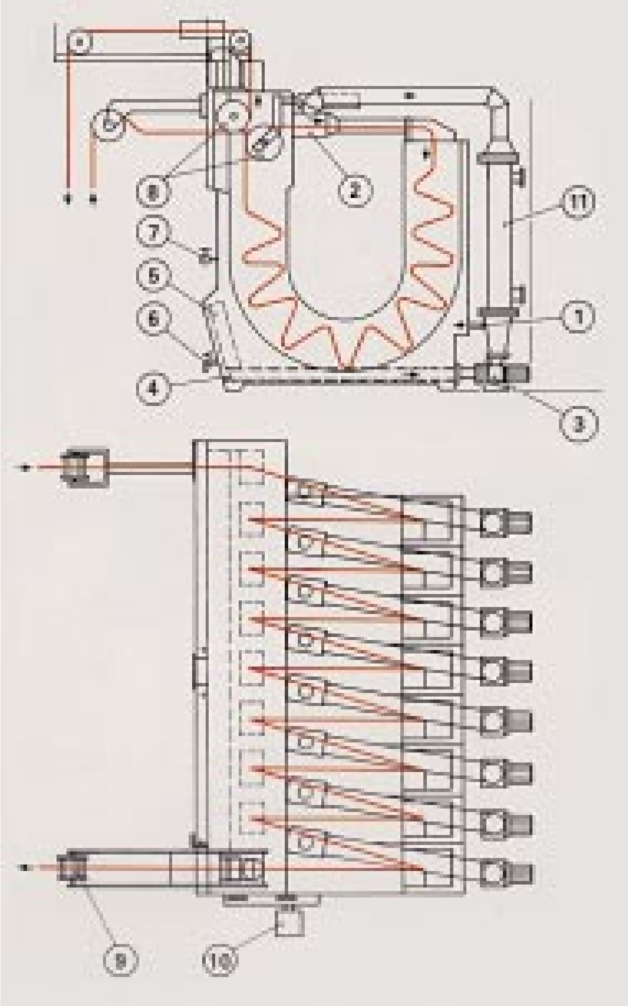

Fig. 2: Rope scouring jet (ITM).
1 = counter current; 2 = jet; 3 = circulation pump; 4 = filter; 5 = overflow; 6 = drain valve; 7 = water inlet valve; 8 = squeeze roller; 9 = unloading winch; 10 = motor; 11 = heat exchanger.

Continuous steamer So-called continuous ager for printed fabrics and large-scale production, mainly for short or long steaming times. There are various steamer chamber designs, e.g.:

I. Fabric transport by means of running rails or a few larger diameter idling rollers in the case of festooned fabrics (festoon steamer), especially for screen printing.

II. With guide rollers top and bottom as a rapid steamer (flash ager).

III. Similar to I, festoon design but with a continuous pin chain, as a screen print festoon steamer.

IV. Tower steamer: fabric path 10–20 m once up and down (entry, reversing and exit rollers), also particularly suitable for screen printing.

Continuous tumbler In contrast to classic → Tumbler drier, the continuous tumbler (Fig.) provides for uninterrupted fabric throughput. Technical processing alternative to the shrink tunnel. Whereas the fabric runs in open width in that process, the fabric runs in rope form in the continuous tumbler. The line consists of a perforated stainless steel drum with reversible drum drive for continuous rope detwisting; water/chemicals spraying, wetting zone and infra-red radiator. Main areas of use: relaxing high pile fabric, crashing warp knitted and woven velours, crushing coating products with embossed effects. Especially interesting for achieving low-shrink effects.

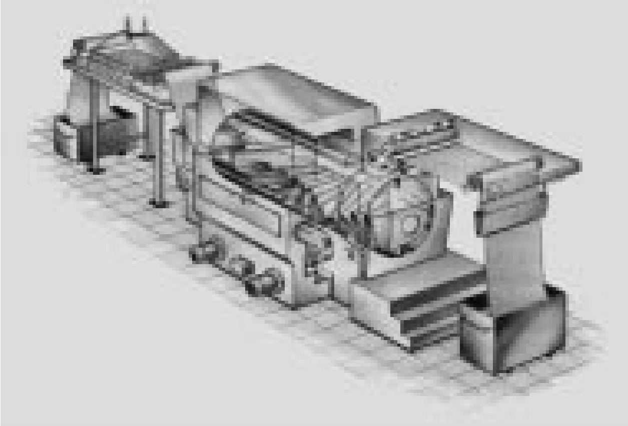

Fig.: Continuous tumbler (Obermaier).

Continuous washing plant Automatic flow throughput of the wash between separated loading and unloading bays, generally using the counter current washing process (water intake at the laundry exit) using a mechanically or electrically controlled washing programme, intermittently or continuously through the individual technologically linked working stages, with pre-wash, main wash, hot and cold rinses always occurring at the same place. Classification:

1. Continuous washing plants without batch separation as so-called washing tubes, with wash throughput through a tube-like washing drum which is either open or divided into sections. Examples: washing conveyor, steam-line washer.
2. Continuous washing plants with batch separation, wash throughput through processing sections which are separated from one another, connected in sequence and linked together securely.

Contipress process Combines the finishes imparted to woven and knitted fabrics by setting machines and rotary or flat presses. The finish is obtained by a high-strength continuously circulating compression

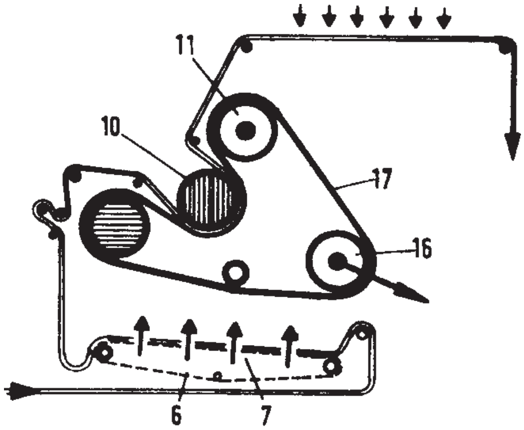

Fig.: Path taken by cloth in Contipress (Menschner).

belt. Contact pressure variable between 0 and approx. 120 bar. Temperature 100–150°C (Fig.).

Contract carpet (Fitted carpet, wall-to-wall carpet, textile floor covering). Textile floor covering in the form of fitted carpet (usually wall-to-wall carpet) in widths or carpet tiles (glued or self-adhesive) or as fitted carpet. Made in large lengths/widths or in the form of lengths sewn together: woven, needle-punched (→ Needle-punched carpets), tufted (→ Tufted carpets), pressed/glued (bonded loop carpets), knitted, flocked. Carpet fibre materials include: wool, sisal, viscose, polyamide, polyacrylonitrile, polypropylene, etc.

Contract cloths, name for “uniform cloths”.

Contraction (Lat.: contrahere = come together). To be understood particularly as shrinking processes in the textile context.

Contraction, take-up and twist,

I. Take-up: a contraction of the yarns used in weaving caused by the interweaving of warp and weft. Calculation: L_1 = length of the stretched yarn taken from the fabric, L_2 = the same length of yarn in the piece.

$$\text{contraction (\%)} = \frac{L_1 \cdot L_2}{L_1} \cdot 100\ (\%)$$

II. Twist contraction: the shortening of a thread caused by a twisting process (yarn twist). Calculation as above (length of the individual thread L_1, length of the twisted yarn L_2).

Contract textiles Sometimes also termed uniform textiles, or named according to their intended end-use. Collective term for all trouser, blouse, jacket and coat cloths for authorities such as postal, railway and customs services, armed forces, police etc. Namely materials intended for uniform purposes. These must be manufactured to precisely defined specifications. The specifications issued by the different authorities are so extensive and varied that they are outside the scope of this publication. The materials are normally not available to the trade in general.

Contrast colour → Complementary colour.

Contrast reduction Poor reproduction of fine contours in the production of screen printing screens; effect of → Underexposing photosensitive screen.

Control charts Management tool for ongoing operational statistical → Quality control. Examples of their use include immediate quality reports per unit time, quality assessment of personnel, of trends at respective control points and suchlike. Control charts must be clear and capable of quick evaluation. Graphic presentations are especially appropriate, e.g. test results over the course of time (marker zones for permitted tolerances) or statistical reports (defects, yes/no). Also include important printed forms with such as date, time, fabric, batch, personnel, machine, defect classification and suchlike. Numerous control chart systems exist, designed for customised report data. Standard control charts for every testing position would include for example: number of samples, target value, actual value, variation, mean, plus assessment information such as random sample, sampling procedure, range width, standard deviation and coefficient of variation.

Control equipment (control and regulating technology). Automatic control equipment makes possible convenient use with simultaneous protection for the operational plant. Control equipment is used for maintaining specific conditions (pressure, quantity, mixing ratio, temperature, speed etc.) independently of contingencies, i.e. control in accordance with a predetermined plan. Pulses mainly weak, but diversely amplified, reach the servomotor via an actuator which carries out the necessary adjustments. Power conversion: a) hydraulic, by jet pipe nozzle (acts on a piston valve by a membrane-directed oil jet). b) pneumatic, with 2 bar compressed air as auxiliary power, especially for maintaining pressure, temperature, flow and fluid level. The controller’s power switch sends digit pulses by way of pressure changes to the control valve, which is provided with a diaphragm drive. c) electric, with servomotor and electrical energy as auxiliary power. The advantage is a simple means of control for various combinations (e.g. boiler and feed water control). Often only optimum performance through combination with a) or b); numerous types for different purposes. d) electronic, with photocells, electronic valves and amplifying valves. Important for time switches and speed control in the 20 : 1 range (machine drive with DC motor), up to 60 : 1 (with additional voltage change at the generator), where the voltage is to be increased from 0 to maximum instantaneously. Braking can be effected by current reversal. Adjustment of the unit to a specific speed also automatic by physical or chemical effect, electron stream transmission being controlled accordingly. Principle of operation of electron exchange in valves (thyratrons filled with inert gas or mercury vapour, with several electrodes); electron emitter is a cathode, the receiver an anode, and, in between, a grid for controlling the electron stream. → Automatic control systems.

Controlled coloration Market dynamics have had a considerable impact on the textile supply chain as a means of service differentiation from commodity imports which focus principally on cost. Market segmentation, late stage coloration with minimum inventory, and monitoring of sales to meet customer demand, have resulted in shorter production runs, vastly reduced lead times, and improved speed of response to the customer. In order to meet the demand for shorter lead times, a radical change in philosophy has developed in which an expectation of Right-First-Time production through the control of the coloration process is now the norm for progressive dyeing operations. Efficiency of production, elimination of the cost of non-conformance (whilst minimising the impact on the effluent loading) has led to the development of "Controlled Coloration." Controlled Coloration is the fusion of three technologies which must complement each other (Fig.1).

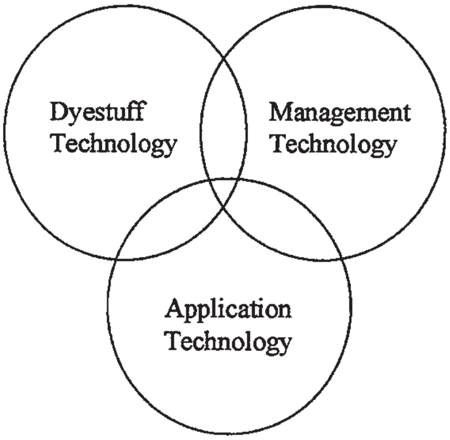

Fig. 1: Controlled Coloration.

To reach this target future developments are the following:

1. The ultimate goal for the coloration of cellulosic fibres must be to achieve 100% colour yield from an environmentally friendly application which produces a high fastness result to the new generation of detergents based on TAED activated peroxy compounds.
2. Research work continues to study means of overcoming the negative-negative reaction between ionised cellulose and reactive dye by cationising the cellulose fibre. However the problems associated with control of reaction, migration (in exhaust application), effect on light fastness and shade and soiling have not been resolved.
3. Other studies have focused on the esterification of cellulose using benzoyl chloride via a Schotten-Baumann reaction to enable the application of disperse dyes. Limitations on this technology are again fastness to the modern detergent formulations and also a restricted shade gamut.
4. Developments on more conventional reactive dye chemistry have focused on increasing the number of reactive groups to enhance the probability of reaction and thereby increase the colour yield, increasing the substantivity by incorporating aliphatic linking diamines with the bis-chromophore structure to reduce electrolyte concentration (but counter effective in the wash-off process), and by increasing the chromophoric strength to achieve depths of shade at a lower applied concentration of dye (thus achieving higher fixation levels from a lower position on the build-up-saturation curve).
5. The future progress in the coloration industry rests with those companies committed to research and innovation which should be supported by the whole textile chain - for if the funding in research is curtailed, so will the progress in developing the highest performance dyes to meet the ultimate goal.

New measuring and control methods allow for safe and reproducible dyeing and are field-proven today. Data of the humidity to be controlled are loaded as signals into Programmable Logic Controller (PLC) and will acti-

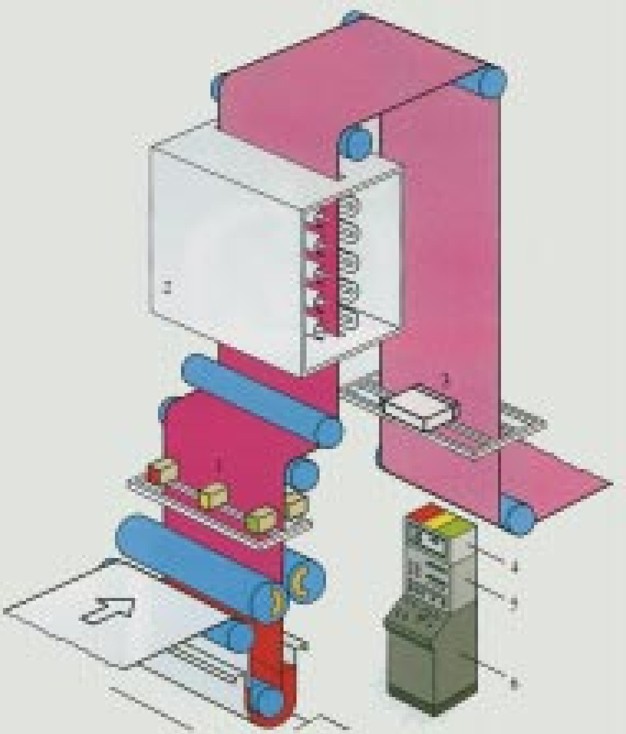

Fig. 2: Controlled Coloration.

vate the control by way of pressure control impulses (Fig. 2).

Controller A term originating in the USA for a member of the board of directors, or at least senior management, whose responsibility involves control of the entire business operation. His remit is to achieve optimum collaboration between all departments of the business by making use of all the information available to him. The controller's task must involve the comparison of planned and actual production levels. In order to achieve an optimum utilization of information, an integrated monitoring system capable of evaluating and interpreting all relevant captured and recorded data is necessary. The controller's entire responsibilities are subdivided into the following specific categories: accounting and statistics, planning and planning control, and reports. It appears to be necessary for the "controlling" function to be placed directly under the authority of senior management or have it structured as a staff department. In any case, however, it must be absolutely independent of normal official channels.

Controller, control unit → Automatic control systems.

Control limits are the limits of variation which must not be exceeded that are entered in the → Control charts.

Controlling The term is not identical with the control of business activities and those responsible for it. Controlling is to be understood rather as a dynamic organizational leadership involving sophisticated planning of all activities and comparison with actually achieved results, precise and rapid analysis of deviations from target to actual data and a rapid introduction of appropriate control measures. Essential preconditions for the introduction of controlling are a clear organizational structure and the precise acquisition of performance and cost data. The individual duties, responsibilities, and fields of competence of the various leadership roles, as well as the hierarchical structure and lines of communication, must be clearly laid down by the organization.

Control sample In textile investigations, the comparative value for an untreated initial product.

Control systems for dyeing plants Development of control systems has led from fully automatic control of individual functions to electronic, microprocessor-based multi-process control, i.e. a central control system. This is not limited to the control of dyeing plant, but also includes integrated data capture. → Automatic control systems.

Control technology in dyeing Essential for control of the dyeing process. An instrumentation and control system (see Fig.) provides a comprehensive control

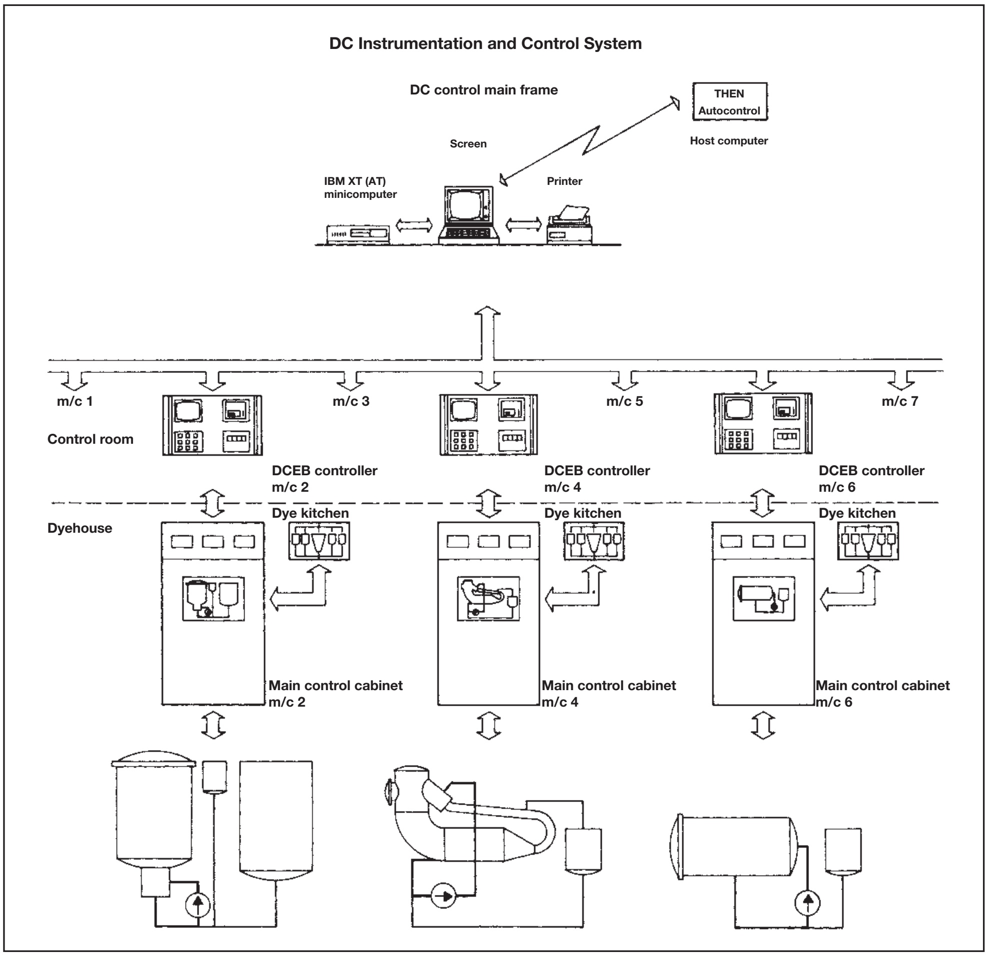

Fig.: Then-Datacomp control system.

system built up on a modular basis, i.e. all levels of automation are included, from simple temperature / time control through fully automated systems to the control main frame with data capture and data processing. The control elements are all capable of expansion, from the basic levels to the central control level. With individual machine process controls and automatic valves it is possible to avoid manual control of the machine i.e. semi-automatic control. With fully automatic dyeing processes, the individual machine control system is replaced by a fully autonomous microprocessor-controlled system with the possibility of program defining and saving options.

Several machines can be controlled from the central control system. The program compilation and saving is then carried out at the terminal of the control main frame. Data is also collated here for the various commercial, technical and production requirements. In addition, it is possible to communicate with a mainframe computer or with additional PCs in the dye kitchen and colour measurement and recipe calculation department. The individual controllers can be installed initially as a simple temperature / time control system and later upgraded to give fully automatic control.

Hardware is built up using a system of standardised plug-in cards. The programs are keyed by a menu-technique with an alphanumeric keyboard and displayed on a screen. The programs are saved on the usual computer data storage systems. When establishing a dye-program the operator is led through a dialogue by an interactive menu, he/she requires neither computer programming experience nor knowledge of coding lists. All controllable functions appear on the screen in clear text. The automatic system will not accept any illogical steps; errors can be corrected.

Before beginning a dyeing operation, the desired program is loaded into the program memory, where it is automatically controlled and displayed on the screen. After loading the program, the time-elapsed machine status appears on the screen with program and equipment reference number, time, date, and actual and desired values for temperature, gradient, dwell time, status etc. together with a superimposed display of the running programme.

Control variation → Variance comparison.

Convection (Lat. convectio = carry along with). Heat transfer (temperature equalization) by flow movements according to the buoyancy principle resulting from different temperature and different density. Since warm air rises in cold air and cold air falls in warm air, masses of different heats intermix and their temperatures are equalized by convection.

I. Convection drying → Convective drying.

II. Convection as a means of accelerating mass-transfer in fabrics.

1. As a batch process forcing liquid through fabric as it passes overs rollers in open-width washing machines (Fig. 1). In the wedge-shaped slot formed by the roller and the textile passing over it a slight pressure rise can be detected which causes transverse convective flow through the fabric. When the fabric emerges from this zone a vacuum is created which causes convective flow in the opposite direction. This convection phenomenon influences the efficiency of an open-width washing machine.

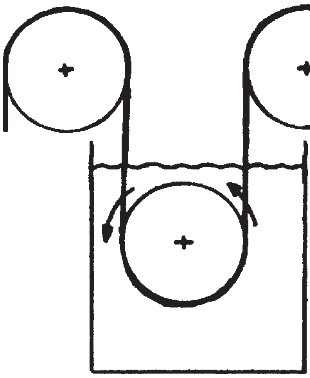

Fig. 1: Flow penetration (convection) of textile fabrics in open-width washing machine roller nips.

2. As a continuous forcing of liquid flow around the thread structure of fabrics in centrifugal washing machines (Fig. 2). Diffusion due to fibres and threads is simultaneously combined with convection around the thread structure.

3. As a forcing of liquor around and into thread structure in Mach slots (Fig. 3). The fabric is passed

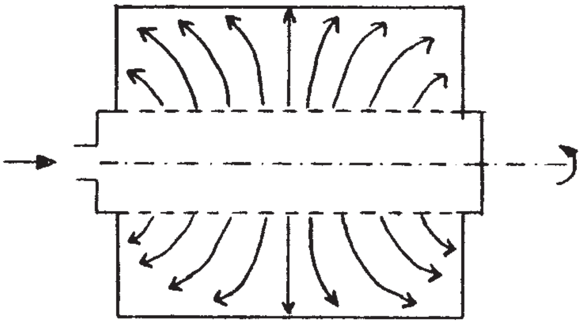

Fig. 2: Flow penetration (convection) of a woven fabric batched on a perforated roller as a consequence of centrifugal force when the batch is rotated.

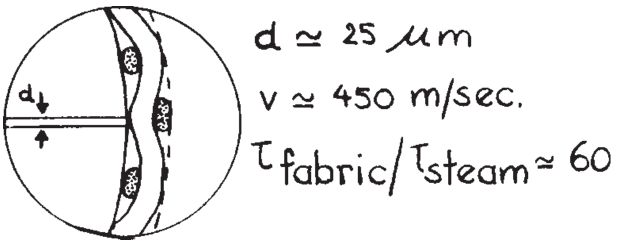

Fig. 3: Mach nozzle principle.

through the slot of approx. 25 µm. Air or preferably steam is introduced into the slot and under certain pressure ratios steam then emerges from the slot at subsonic velocity. With the dwell time before the slot being much greater than the dwell time in steam, the thread structure is also penetrated.

Convective drying The most common method of drying using air as the drying medium (→ Drying systems). The advantage of convective drying is that the conditions under which drying is performed can be varied at will. Two variants have gained wide acceptance over the course of time:

- air impingement drying and
- air circulation drying.

The air impingement technique, when applied to both faces, has the advantage of managing to avoid any contact during the drying process. The diagram clearly demonstrates the relationship between the measured drying curve (above, drying time plotted against cloth moisture content) and the drying rate curve (below). The drying rate calculated from the slope of the drying curve is plotted against the percentage moisture content of the cloth. The division of the convective drying process into three phases is clearly evident.

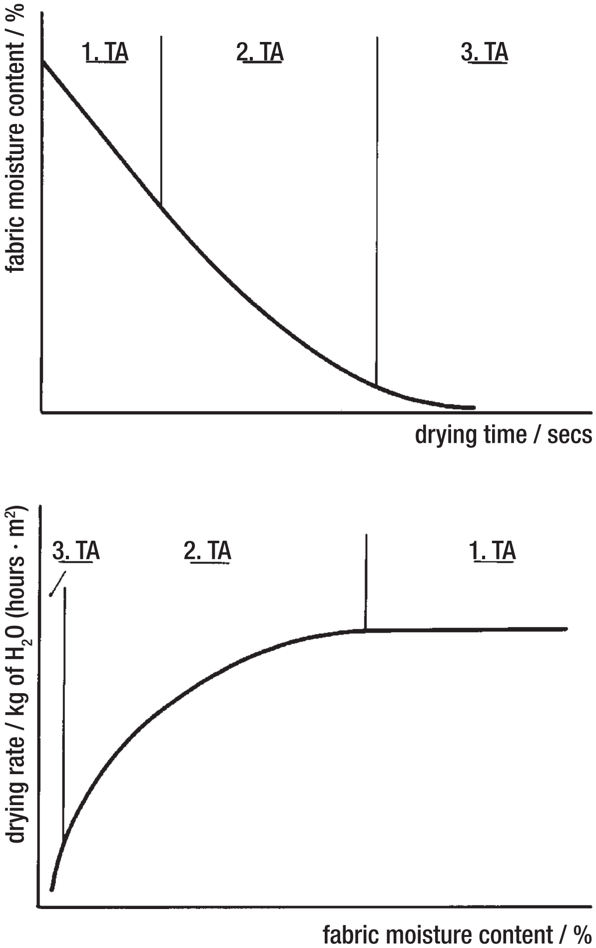

Fig.: Textile fabric drying curve.

Since at high moisture contents a liquid level occurs at the surface of the cloth, in phase 1 of the drying process the conditions prevailing resemble those of evaporation at a water surface. Due to constant partial pressure and temperature differences there is constant evaporation of water per unit time. The drying rate which has its maximum in phase 1 is thus constant. Once capillary transport is no longer capable of transferring sufficient water to the surface, the drying rate declines. The salient point marking the transition to phase 2 is not so distinct with textile fabrics (especially thin fabrics) as it is with other materials that are dried. Instead the transition is smoother. The reason for this undoubtedly lies with lack of homogeneity. With hygroscopic materials phase 3 starts at low cloth humidities with the drying rate declining further and approaching zero. However, this zone is of minor importance in the drying process for textile materials since it is not or at least not fully completed (after Meyer).

Conversion (Lat.: conversio = conversion), reversion, transformation.

Conversion print Multi-colour overprint, e.g. produced by means of overprinting rollers, where colour change is achieved by the overprint print paste taking over the development and fixation of the pre-print print paste, places not overprinted therefore remaining colourless, and, without pre-printing, patterns of the second print paste developing in the intrinsic shade of the second colour print. These kinds of patterning effect presuppose dyes which can be mutually resisted and discharged, and also possess different development and fixation characteristics.

Conversion styles Textile fabrics printed by the → Conversion print.

Convex (Lat.: convexus = convex). Bellied, arched outwards. Anonym → Concave.

Conveyor belt Endless belt for transporting goods without stress.

Conveyor belt shrinking machine To relax woven or knitted fabric, the fabric is placed on a perforated conveyor belt, which runs through a tunnel. Vi-

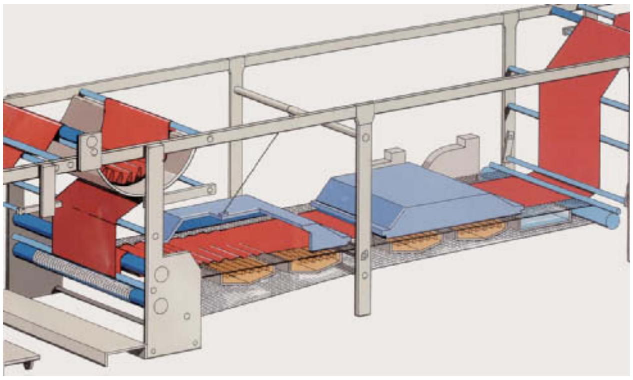

Fig. 1: Conveyor belt shrinking machine (Menschner).

Fig. 2: Montex-Dyn-Air conveyor belt dryer by Monforts.

brating elements or bursts of steam keep the fabric appropriately moving (Figs. 1 and 2).

Conveyor drier Circulating air drier as a) drier for loose material which is carried through the drying room on brattice conveyor; b) piece goods drier, in which the goods are carried through the drier on a conveyor belt. Particularly for knits and other cloths in piece form that are susceptible to tension. → Drying systems.

Conveyor dwell section → Dwell units.

Conveyor installations → Transport equipment.

Cooking salt → Sodium chlorite.

Cooling cylinder A perforated roller through which cold air is drawn. Serves to cool down decatized goods during unloading after a full steam process.

Cooling towers (evaporation towers). Used for recooling water. By evaporating a small proportion of the circulating water, heat is extracted so that water cooling is possible depending on dewpoint. Only the quantity of water lost in the evaporation process is added. Up to 98% water saving can be achieved in this way. Cooling tower efficiency depends on relative humidity and external air temperature. The absorptive capacity of the air for water vapour falls as the moisture content rises. Less heat of evaporation can thus be extracted from the water to be cooled. The maximum cooling limit in high summer is 20–22°C. Provision should always be made for installation possibilities for feeding in colder mains water or well water as a safety factor in the event of unsatisfactory cooling. Use in textile cleaning and solvent textile technology.

Cooling unit Unit for cooling fabric (DIN/ISO 5250).

Cooling zone On stentering and drying machines, the section between the heat treatment zone and the machine exit zone. The fabric can be rapidly cooled in the cooling zone (DIN/ISO 5250).

Cool Wool Quality brand assigned to extra-light wool fabrics (no precise weight range), created specifically in Woolmark qualities in tropicals, gabardines, wool poplins, crêpes and estamenes. Reducing the weight per unit area is achieved by a) using extra-fine wool fibres (< 20 µm) (Fig. 1); and b) weaving singles yarns in warp and weft (warp sizing necessary) (Fig. 2).

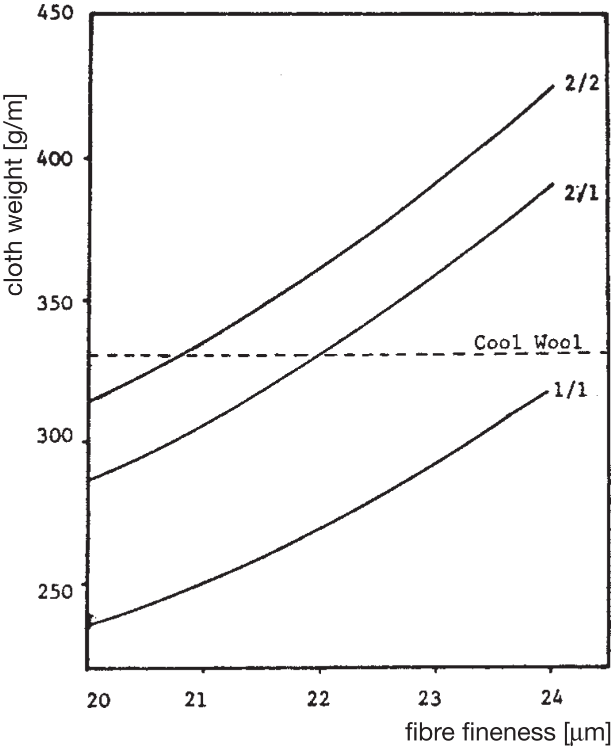

Fig. 1: Cloth weight (in g per running metre) for fibres of different fineness and different weaves in Cool Wool products.

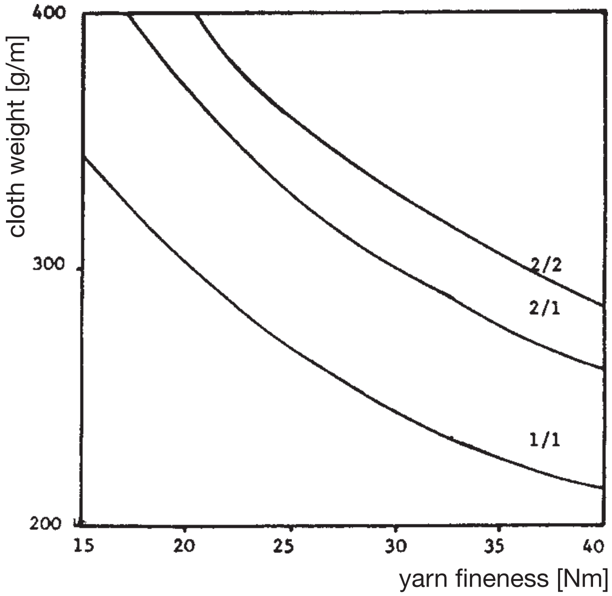

Fig. 2: Cloth weight (in g per running metre) in relation to yarn fineness in Cool Wool products with different weave structures.

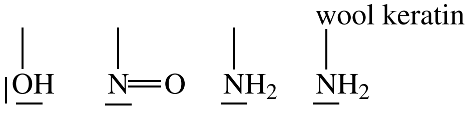
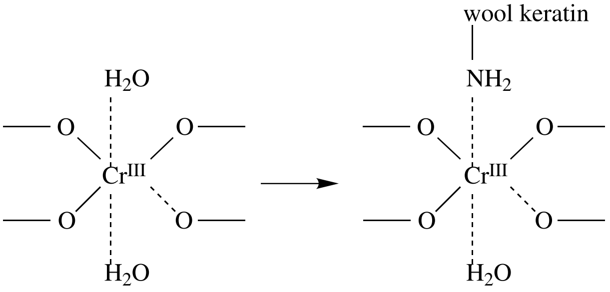
Coordinate atomic bond (coordination compound). A bond based on → Secondary valency forces as a special → Atomic bond. Occurs in molecules mostly of a higher order (complexes), in the structure of which atoms, radicals and even molecules capable of independent existence (e.g. H_2O), NH_3, wool keratin molecules etc) participate in the same way as mostly monovalent partners. Whilst however in the case of normal atomic bonding each atom partner contributes a valency electron in each case to the common pair of electrons in principal valency style, here, only one partner provides the bonding electron pair, which consists of two free valency electrons or "solitary" electrons. These are symbolised at the relevant atom by horizontal lines e.g.



In the last example therefore, an undissociated wool NH_2 group is readily available for coordination. A suitable partner would for example be a chromium-containing mordant dyestuff. The chromium atom is available as a so-called → Chelate bond, i.e. in this case also three-fold coordinatively bonded on its part (in addition to a 3-atom bond).



Coordinate system Latin coordinare = coordinate) System of vertical axes (ordinates) and horizontal axes (abscissa). In a right-angle coordinate system, the numerical position of each point in a graph can be determined from the spacing of successive intersections.

Coordinative (Lat.), involved in the same way or in equal value.

Cop Term used for a yarn package spun on a spinning frame. The package generally has tapered ends (→ Biconical package) and is cop-wound (→ Cop winding).

Copals Mostly semi-fossil → Resins, e.g. Australian Kauri copals, which also include amber. Wine yellow to reddish brown, very hard, granules or flat pieces up to 20 cm in length, lustrous to matt, fracture concoidal and lustrous, more or less with a balsam odour (heating). As copals are not homogeneous crystallised compounds, simple melt point data is insufficient. Solubility: Zanzibar copals (after lengthy steeping) completely in an excess of alcohol, but only partially soluble in other solvents; soft (mock) copal dissolves directly in hot alcohol and turpentine oil. Use: (only in combination) for viscose filament oil sizes; in many countries also for finishes, coatings; for oil or resin paints.

COPANT, abbrev. for: Comisión Panamericana de Normas Técnicas (PASC = Pan American Standards Committee) with headquarters in Buenos Aires, Argentina; → Technical and professional organizations.

Copolymer fibres (multipolymer fibres). Synthetic fibres manufactured according to the principle of → Copolymerization. They are produced for the purpose of achieving or enhancing specific properties, e.g. dye affinity, hydrophilic/hydrophobic characteristics, thermostability, etc.

Important examples include modacrylic fibres, modified polyvinyl chloride fibres as polyvinyl chloride copolymers and polyvinylidene-dinitrile fibres.

Copolymerization Many monomers can form polymers not only with monomers of their own type but also with other monomers. This opens up the range of possibilities enormously. For example, radical polymerization converts styrene to polystyrene, methyl methacrylate to polymethyl methacrylate and vinyl acetate to polyvinyl acetate. A mixture of styrene and methyl methacrylate gives polystyrene-co-methyl methacrylate even at a very low extent of conversion. However a mixture of styrene and vinyl acetate will give practically pure polystyrene at first and then when all the styrene has been used up, almost pure polyvinyl acetate. That is to say, a mixture is produced and no copolymer. On the other hand stilbene does not give any homopolymer on radical initiation and maleic anhydride only gives a polymer of low molecular weight. However a mixture of the two monomers leads to a copolymer of the two monomers in a 1 : 1 ratio.

Copolymerization is technically extremely important. By introducing a small amount of a second monomer certain properties can be improved (e.g. dyeability, adhesion etc.). Copolymers generally do not have the same composition as the original monomer mixture. The composition depends on the reactivity (measured by the rate constants) and the concentrations of initiator (e.g. radicals) and monomers. During copolymerization, the reactive monomer will polymerize preferentially. The copolymer formed at low conversions will therefore depend on the composition of the monomer mixture and the reactivities of the reacting monomers. As the more reactive monomer is used up, its concentration in the remaining monomer mixture is reduced. Hence the copolymer made on further conversion must have a different composition to that of the initial copolymer. The composition of the copolymer will be the same as that of the starting mixture only with a definite combination of reactivity and concentration.

To get a relationship between the composition of the monomer mixture, the reactivity and the composition of the copolymer it is assumed that both monomers 1 and 2 react by the same bimolecular mechanism. Four rate constants for the growth of the polymers can be defined:

$$\ldots M_1^* + M_1 \rightarrow \ldots M_1M_1^*\,;\ v_{11} = k_{11}\,[M_1^*]\,[M_1]$$
$$\ldots M_1^* + M_2 \rightarrow \ldots M_1M_2^*\,;\ v_{12} = k_{12}\,[M_1^*]\,[M_2]$$
$$\ldots M_2^* + M_1 \rightarrow \ldots M_2M_1^*\,;\ v_{21} = k_{21}\,[M_2^*]\,[M_1]$$
$$\ldots M_2^* + M_2 \rightarrow \ldots M_2M_2^*\,;\ v_{22} = k_{22}\,[M_2^*]\,[M_2]$$

These equations assume that the penultimate unit in a growing polymer chain does not affect the polymerization. The so-called copolymerization parameters (reactivity ratios) are defined (according to Elias):

$$r_1 = k_{11}/k_{12}\ ;\ r_2 = k_{22}/k_{21}$$

Copolymers → Polymers consisting of two or more → Monomers (→ Copolymerization) for creating new product characteristics. A distinction is made between

- → Block polymers in which larger “Polymer pieces” constructed from a monomer alternate with “pieces” from another monomer.
- → Graft polymers in which other monomers or polymers are linearly added as side chains (grafted on).
- Statistical copolymers with various monomers in a “random” arrangement.
- Alternating copolymers, whereby two monomers are installed in the chain alternately.
- Crosslinked copolymers, with polymer bridges belonging to another monomer installed between the individual chains of a polymer.

Copolymers made from two monomer components are called bipolymers, those made from three are called terpolymers and those made from four are called quaterpolymers.

Since the largest group consists of bipolymers, this is the group to which the expression copolymer usually refers. The previously used name of “mixed polymer” should no longer be used because of the risk of being confused with polymer mixtures.

Copper (Cu). Atomic weight 63.6; melting point 1065°C. Red, semi-precious metal, quite soft; extensible, malleable, can be rolled; a malachite green-like surface layer (patina) forms in moist air containing carbon dioxide. Quickly dissolves in nitric acid and hot concentrated sulphuric acid, and slowly in diluted hydrochloric, sulphuric and acetic acid, and also ammonia. Excellent conductor of heat and electricity.

Use as a metal for armatures, plant and machinery components, sheathing, containers, wire (electrical technology). Non-metallic compounds: oxygen carriers, fastness after-treatment, antiseptics, analytical chemistry (oxycellulose identification), impregnation, dye and colour production, electroplating etc.

Copperas vat (iron vitriol vat), obsolete type of reduction vat for → Indigo.

Copper complexes → Complex compounds with copper as the central atom.

Copper detection in fabric dyeing Incinerate a woven fabric test specimen, dissolve in hydrochloric acid, and implement the following reactions:

I. Add excess ammonia: deep blue colouring = copper. Concentration limit 40 000 : 1.

II. Add some sodium acetate and potassium hexacyanoferrate (II): reddish brown colouring = copper. Concentration limit 90 000 : 1.

III. Mix some pyridine and a few drops of potassium or ammonium rhodanide solution with some sodium acetate: greenish yellow precipitate (pyridine copper rhodanide) = copper. Soluble in chloroform with a greenish yellow colour. Concentration limit 800 000 : 1.

Copper dyes Expression for → Aftercoppering dyes.

Coppered block In contrast to the → Blocks for printing with carved wood relief in hand printing, the coppered block has brass strips and pins as pattern elements. Coppered blocks, much better as regards fineness and accuracy, are used, on the basis of their artistic fineness and the inimitable character of their patterning, in printing wool fabrics and also in silk discharge printing.

Copper electroplating Galvanic process for refurnishing repeatedly machined printing rollers with an adequately thick copper layer. Copper is electrolytically precipitated on to the printing roller from a sulphuric copper sulphate bath.

Coppering → Copper sulphate after-treatment of direct dye dyeings.

Coppering dyes Direct dyes which have to be after-treated with copper salts in order to achieve the correct shade. → Aftercoppering dyes.

Copper man Jointed doll in human form (→: Charly; Termoman) of copper sheeting used for trial purposes in → Clothing physiology with a more or less sophisticated heating system with temperature control for head, trunk and individual limbs etc for testing the heat insulating properties of clothing.

Copper mannequin Highly developed electrical → Copper man of the US Army Natick Laboratories.

Copper naphthenate Copper salts and → Naphthenic acids. Formerly the usual solvent for oil-soluble products for the rot-inhibiting, mildew-proofing and weather-resistant finishing of heavyweight fabrics and cordage.

Copper number Expression of the degree of damage especially of overbleached fabrics (→ Oxycellulose), which have not been boiled during or after bleaching. Principle: determination of reductive capacity by treating the test specimen with Fehling’s solution, dissolution of the deposited cuprous oxide, and titrimetric determination as to how much copper has been precipitated on 100 g of test material: unchanged cellulose (copper number) 0.2–0.3, pure oxycellulose 14.2.

Copper-8-oxyquinoline $Cu(C_9H_6ON)_2$. Olive green powder with 18% copper content. Effective preservation agent for good weather and wash resistant mouldering effects. Insoluble in water and many organic solvents. Used mainly in aqueous dispersion form; not common nowadays.

Copper salt aftertreatment → Copper sulphate aftertreatment.

Copper salt dyeing method → Cuprous ion dyeing method.

Copper-sensitive dyes → Aftercoppering dyes.

Copper sulphate after-treatment Of direct dyeings, for the purpose of significantly improving light fastness, and mainly at the same time too the washing fastness of appropriately suitable dyeings (→ Aftercoppering dyes).

Implementation:

1. Rinse after dyeing.
2. Treat fresh bath for 30 min. at up to 50–60°C with 1–3% of copper sulphate and 2–3% of 30% acetic acid or 0.46% of 85% formic acid.
3. Final rinse (or saponify at 50–60°C with 5 g/l of soap).

Cop tube Tube onto which a Cop of yarn is spun, of cylindrical or slightly tapered form or as a former for a "hollow cop" with or without base. Cops used to be made in cardboard, alloy and steel, both varnished or unvarnished. Nowadays plastics-coated steel, some with textured surface (smooth, matt, grooved, "orange-peel").

Cop winding Created (e.g. on the ring spinning frame) by the rapid upward travel and slow downward travel of the ring rail with a gradually shifting deposition of the wound coils, i.e. the winding density and angle of the coils formed by the traversing motion are varied. The traverse of the outer coils is smaller than that of the inner coils, thus forming tapered ends to the cop.

Copying definition Depends on the perfect formation of the print shoulder in conformity with the object and the vertical run of the print flank. Is affected by the path of the rays (possibility of under-radiation), but not by radiant intensity in a given direction and the spectral distribution of the radiated light.

Copying ink pencils (Crayons). These contain clay, graphite, water-soluble coal tar dyes (methyl violet, methylene blue) and carrier media (tallow, traganth).

Copying lamp Exposure unit for producing printing screens. Various light sources can be used as copying lamps: xenon, mercury vapour, halogen and fluorescent lamps.

Copying process In producing a printing roller or screen, only one transparency is required for the copying process. After exposure, this is moved in terms of height and width around the relevant repeat dimension, thus adding repeat to repeat.

CPB, abbrev. for: → Cold pad batch process.

Cord,

I. Term applied to woven rib fabric with weft yarn floats creating pronounced cord-like raised lengthway ridges; a plain fabric without pile warp or pile weft (contrast with → Corduroy).

II. String-like round braid (→ Braid), in contrast to tape braid. Cord tape braid: tape braid edged with cord.

Corded velvet → Corduroy.

Cord yarns Mostly plied yarns of relatively high resultant linear density, in viscose (high-tenacity) or synthetic fibres (generally filaments). Employed in textile casing (→ Case cord) for car and aircraft tyres, conveyor belting, drive belting etc. Have progressively replaced cotton cord yarns in general use since the 1930's.

Corduroy Today often wrongly referred to as → Cord. Corduroy has a ribbed velvet face with cut weft pile. Warp-way rib structure produced by weaves with weft floats (e.g. Genoa cord, Manchester velvet), can also be modified to piqué form (with weft-way ribbing).

Cotton corduroy: Robust tough cotton fabric with characteristic (dense) warp-way ribbing. Along with piece-dyed and yarn-dyed qualities a marl effect warp is now often used. The marl effect is also often imitated by discharging a piece-dyed fabric. End-uses: for workwear trousers which are invariably heavily napped on the back; for leisure wear, generally with yarn structure well-defined on face and back; jackets, coats, suits, sports jackets and trousers (bengaline) in men's and ladies' outerwear.

Wool corduroy: All-wool qualities with worsted in warp and weft or with worsted warp and woollen weft, low-quality fabric with viscose warp and woollen (shoddy) weft. close-napped finish. Mostly stock-dyed or yarn-dyed; often marl yarn warp. Used for sportswear, riding breeches, workwear, upholstery covers.

Corduroy and velvet finishing This is undertaken by relatively few finishers since it calls for a pur-

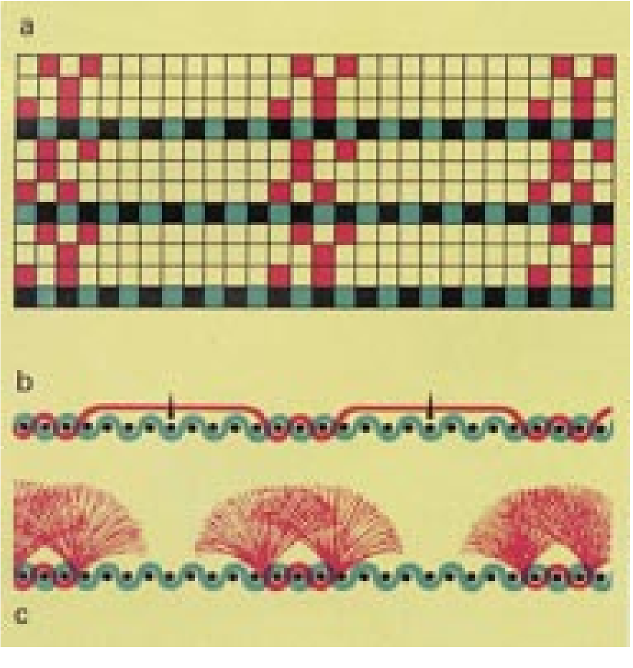


Fig. 1: Principle of corduroy manufacture.
a = weave design; b + c = weave cross-sections; c = cut ribs.

posely-designed range of machinery that cannot be used for other textiles, plus well-trained technical staff.

In weaving terms, corduroy is a heavyweight form of ribbed velvet. The weft-float weave is a characteristic feature, representing the transition from a two-thread system (warp and weft) to a multi-thread system. The warp is generally a plied yarn and the weft a singles yarn. With “binding ends” (shown in green in Fig. 1) incorporated as the third thread component, the ribs are caused to emerge from the woven fabric structure in the form of undulations and the characteristic structured finish is thus shown to best advantage. Genoa cord has relatively broad ribs; breeches corduroy incorporates additional filler warp ends.

The Table illustrates the basic sequence of the exceptionally diverse finishing processes. In practice there are a large number of variants.

“Normal” cord 100% cotton medium wide rib	Fine cord 100% cotton	Stretch cord with PUE content

Tab.: Standard variants for current qualities to produce appropriate finishes.

The loomstate fabric is inspected, burled, mended where required and allocated a piece number. For downstream finishing it is absolutely essential to identify the beginning and end of each piece.

Napping, emerizing (mechanical cleaning and softening): Napping the back of the fabric imparts a fuller handle, better uniformity and greater suppleness, which is important for the cutting process which follows. Corduroys with up to 40 ribs/10 cm are generally napped on the back. Finer qualities are emerized in order to make subsequent cutting of the ribs easier. If the weft in the loomstate fabric contains impurities, a light pass on the emerising machine can greatly assist the cutting process. To obtain a clean stable cut in fine corduroy it is advisable to pre-treat the pile face with a soap and caustic soda solution. But care must be taken that there is no strike-through of solution, and the fabric must be dried on the cylinder dryer immediately after pre-treatment.

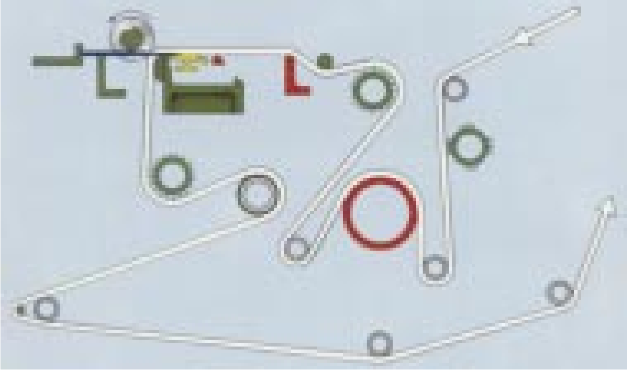

Fig. 2: CR-2 corduroy cutting machine by Sucker-Müller.

Cutting: This is performed on the corduroy cutting machine (Fig. 2). The correctly prepared fabric is cut on the corduroy cutting machine, i.e all ribs up to a density of 48/10 cm can be cut in one pass. Densities greater than 48/10 cm and up to a maximum of 55/10 cm are cut in two passes, i.e. ribs 1/3/5 and so forth in the first pass and 2/4/6 and so forth in the second pass.

The circular knives used for cutting are arranged on a cutter shaft which rotates at high speed. The number of knives is equal to the number of ribs to be cut. The knives are set to cut only the pile thread floats. Each knife is guided by a forked needle. The needles (Fig. 3) are guided through the channel formed by the pile weft yarns and the warp yarns. The size of the cutter needle depends on the width of the rib. For standard corduroy qualities in which all ribs are of the same width, the needle is forked in the centre. If the needle is forked asymmetrically then the rib is not cut in the centre but

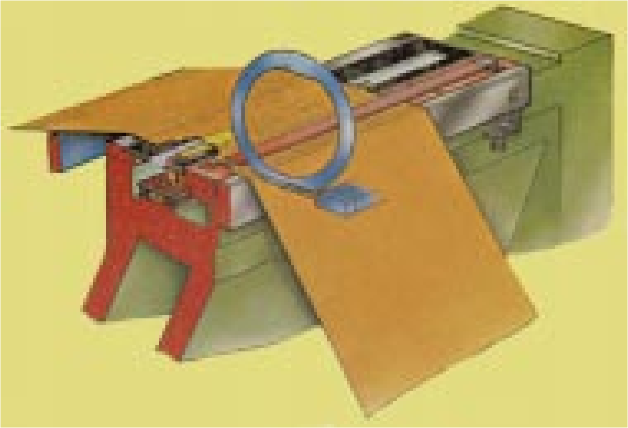

Fig. 3: Fine corduroy/velvet cutting machine by Sucker-Müller.

offset to one side, thereby creating pile ribs of different widths (fancy corduroy). As it is impossible to guide the fabric in an absolutely straight line the knives on the knife shaft are able to move freely axially and are thus controlled by needles and fabric. Weaving defects or impurities in the fabric cause needles to be pushed out, resulting in automatic stopping of the machine. In about 90% of all cases of needles being pushed out it is possible to reposition the needle at the point where it was pushed out, obviating any subsequent need for cutting by hand. In cases where repositioning is not possible the site must be marked and cutting at this site must then be performed manually on the inspection table.

For fabrics with rib densities of 55/10 cm and greater the velvet cutting machine must be used. This operates on a totally different principle. Whereas on the corduroy cutting machine there is a knife with guide needle for every rib to be cut, the velvet cutting machine uses only one cutter element consisting of guide needle with knife, i.e. every rib is cut separately. However, the cloth speed is appreciably higher. It can be varied from 250–500 m/min. A special piece-sewing technique enables pieces to be assembled for a piece to be cut continuously in a spiral in rope form.

Desizing and washing: This process must be as thorough as possible in order to effectively swell the pile and substantially remove the twist from the yarn tips. Inadequately desized fabric creates problems in downstream processes since the size residue penetrates the pile and sticks it together, which can cause streakiness in cross-brushing for example. Open-width washing is generally employed, often incorporating intermediate brushing units. The wet-brushing machines optimise the cleansing action with the result that higher speeds are possible in subsequent brushing passes or brushing passes can even be omitted.

Dewatering of the desized washed fabric: As a rule high-performance squeezers are used. The aim is to reduce residual moisture to 65%.

Brushing processes:

a) Wet-brushing machine (Fig. 4): The aim is to pre-orientate the ribs in an aqueous medium.

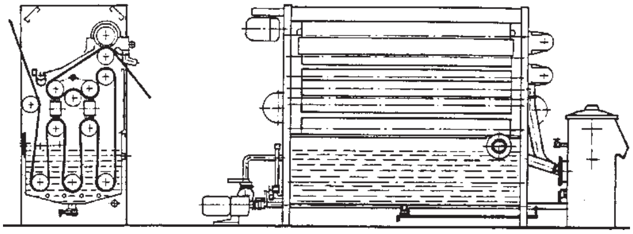

Fig. 4: Wet-brushing machine for corduroy .

b) Diagonal-brushing machine (Fig. 5): The ribs are orientated in the wet state. Mainly used for corduroys of medium to coarse qualities.

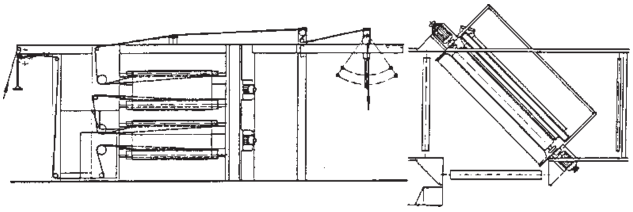

Fig. 5: Diagonal brushing machine for corduroy.

c) Cross-brushing machine (Fig. 6): Brushing open the orientated dried ribs, any residual twist in the pile weft is further released.

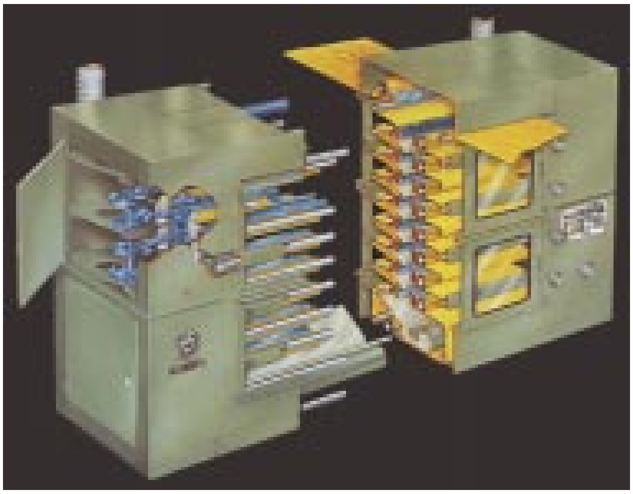

Fig. 6: Cross-brushing machine for corduroy (Sucker-Müller).

d) Belt cross-brushing machine (Fig. 7): The brushed-open ribs or pile are levelled and brushed out.

e) Rotary brushing machine (Fig. 8): For levelling and orientating the pile in a warp direction and to impart a smooth even surface appearance to the fabric.

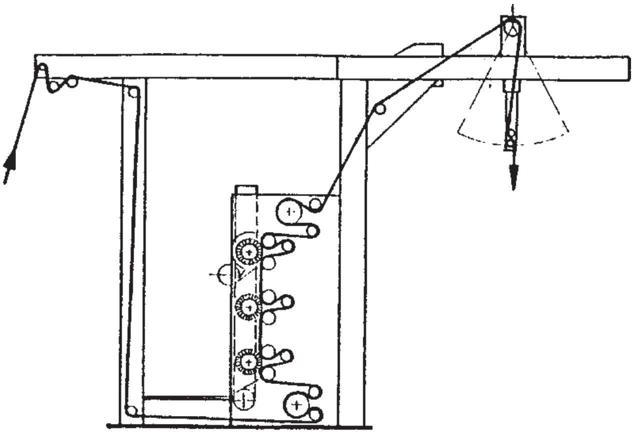

Fig. 8: Rotary brushing machine for corduroy .

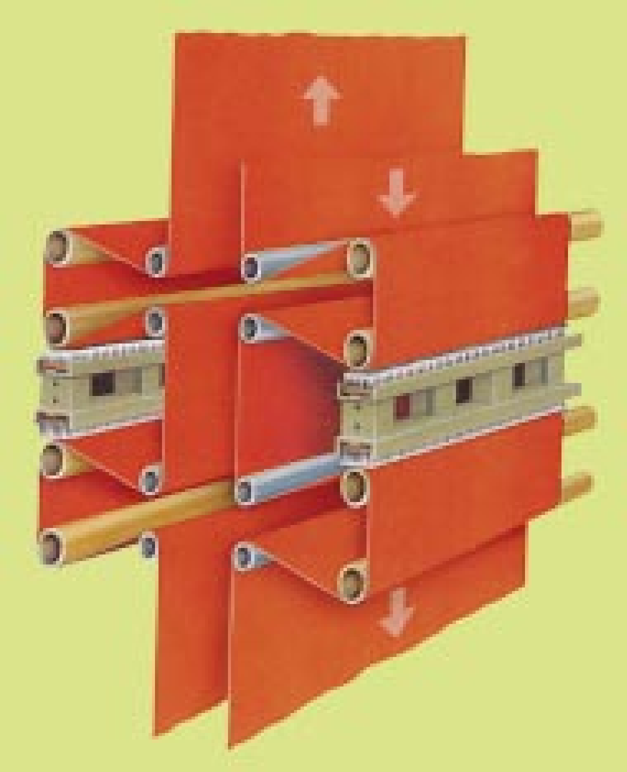

Fig. 7: Belt cross-brushing machine for corduroy (Sucker-Müller).

f) Combination brushing (Fig. 9): For relatively small batches it is advisable to use a combination brushing process comprising steamer, cross-brushing machine with eight cross-brushes, belt cross-brushing machine with four belts with two-fold brushing action and rotary brushing machine.

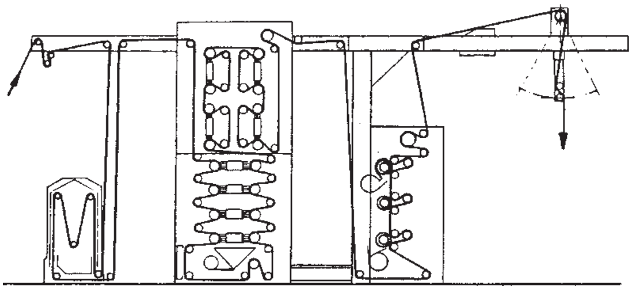

Fig. 9: Combination brushing process for corduroy.

Washing and final finishing (Fig. 10): To impart its highly desirable soft handle and lustrous finish to corduroy, a thin film of wax is applied to the pile face (except for proofed fabrics). The wax film is pulverised in subsequent final finishing. Lustre can also be imparted by incorporating silicones in the dyebath but the handle is gritty. The final finishing machine operates with two high-speed finisher rollers covered with a tubular felt. The pressure of each of these two rollers can be adjusted individually to produce higher or lower lustre. This stage concludes the finishing process for corduroy.

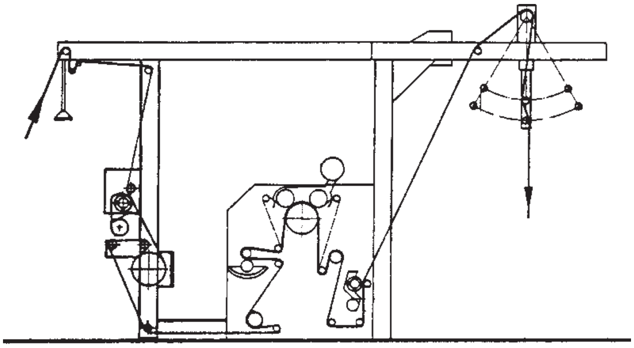

Fig. 10: Wax finishing machine for corduroy.

Corduroy cutting machine Machine used for cutting open the pile weft in cord fabrics (Fig.). Uses revolving blades running between twin needles.

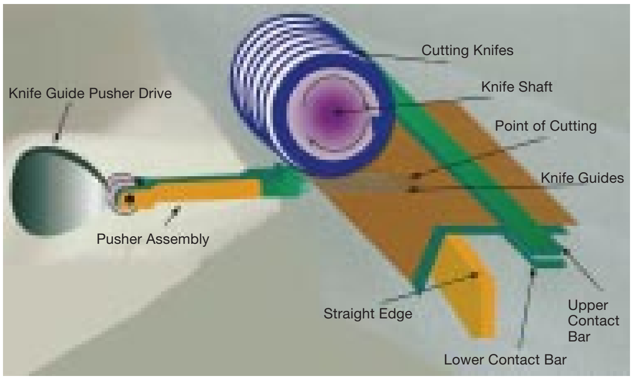

Fig.: Corduroy cutter (West Point).

Corduroy wet brushing machine Corduroy finishing machine for a smooth transition from wet to dry finishing. Used for wet shaping the rib, takes place immediately behind the washing areas: integrated wet band brushes, brush coating. A rotary brush is installed at the end of the machine in order to give the fabric the required nap before it runs into the rolling machine.

Core The term applied to a central core, e.g. spinning core for → Core-spun yarns.

Core-sheath bicomponent fibres → Bicomponent fibres.

Core-sheath fibres → Bicomponent fibres.

Core-spun yarns (“Hetero” yarns, core threads), since the early 1960’s “core-sheath” textile yarns have had special “stretch yarn” significance. In principle, a core thread (core), usually highly elastic, is used as the source of mechanical properties, and has a sleeve fibre wound round it that determines its appearance and feel. The core material should preferably consist of elastomer threads, rubber threads or non-shrunk chemical fibre filaments. Almost any kind of natural

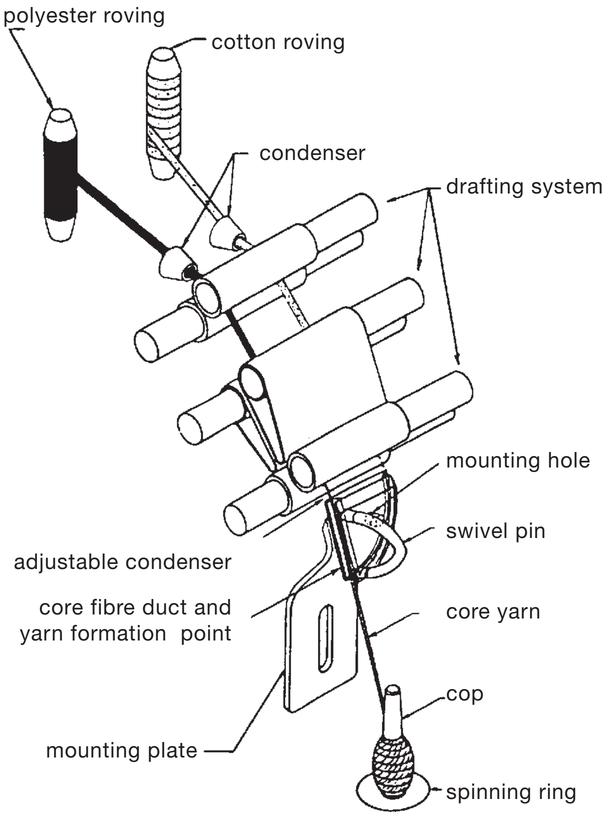

Fig.: Ring spinning machine principle with special core yarn unit.

or chemical fibre is used as sheathing material, including textured filaments and mixed fibres; elastomer threads sometimes occur in the sheath rather than the core (see Fig.).

Further processing into elastic woven fabrics, hosiery, and knitwear. Used in ladies, men's and children's clothing, sports clothing, pullovers, blouses, shirts, swimwear, etc. Core-spun yarns should be thermofixed (177–195°C for 10–20 s depending on sheathing material) before wet finishing takes place, since without thermofixing there would be too much contraction and the textile material would be too dense.

Core yarns → Core-spun yarns.

Corona discharge Weak current discharge under atmospheric conditions that occurs when a high voltage is applied to electrodes, but an isolator between them prevents a spark from discharging. In order to trigger a corona discharge a high field strength must be produced at one of the electrodes. The electrons that are produced by this electrode are accelerated towards the isolator by a high voltage that is directly beneath the substrate that is being treated, e.g. a woollen fabric. On its way to the substrate the electrons collide with air particles, forming ozone and nitrous oxide. The electrons that reach the substrate can split covalent bindings because of their high energy level (approx. 5 eV). This produces radicals on the surface of the fibre that react with ozone and nitrous oxide, i.e. the surface of the fibre is oxidised and therefore becomes more polar.

Corona discharge polymerization Enables certain finishing effects to be achieved, e.g. the antifelt finish of wool. → Corona treatment, in the presence of monomers on the fibre surface, initiates polymerization leading to film formation.

Corona treatment Method of influencing fibre properties using corona discharges. The use of gas discharging in technologies that modify the surface properties of high polymer materials is being discussed for the textile area, among other things. Technological improvements to the process of corona discharging, i.e. brush-like electrical discharges at atmospheric pressure and low temperature plasma, i.e. glimmer discharge in a vacuum, are becoming more important. These technologies are used to treat fibres such as wool, mohair and cotton and textiles made from synthetic fibre materials in order to achieve certain effects such as improving the adhesion of coatings. Previous investigations on wool and mohair showed that corona treatment made considerable improvements to yarn strength and shrinkage behaviour. The yarn strength of cotton was also improved, which is particularly important in OE yarns. Positive results were also achieved in the areas of cross-linking, creasing behaviour and dirt retention. Similar property changes can be achieved by treating with low temperature plasma. The fine fibre structure of the surface layer was also able to be modified by giving polyester fibres → Plasma treatment, which led to a clear increase in dye absorption. Plasma processes are not just used to modifying but also coating if the treatment chamber contains a gaseous polymer (plasma polymerization) or if the long-life radicals produced during the treatment are used to initiate graft polymerization (plasma grafting, SAC process). These techniques open up the following application areas:

- Making wool lint-free.
- Making chemical fibres hydrophilic,
- Increasing cross-linkage and adhesion capability of fibres for dyeing and printing
- Improving the adhesion of textile laminates, e.g. web bonding, laminates made from sheet materials and films etc.

Coronizing process Glass fibre fabric finishing:

1. Heat passage for approx. 5–15 s at 650°C (impurities are burned off, fabric weave is fixed, simultaneous fibre relaxation).
2. Pad with resin solution (acrylonitrile) possibly with dye pigment, thermal polymerisation at 160°C.
3. Pad with stearic acid chromium chloride, thermal treatment at 170°C.

The finishing effect should provide the best possible shearing resistance and excellent washing stability and water-repellent properties.

Corporate wash Bulk wash in the corporate sector, e.g. armed forces, hospitals, hotels, for industrial concerns, department stores etc.

Correction of faulty dyeings Correction of shades in the same dyebath in order to obtain the specified final shade. Correction treatment: term for correcting unlevelness and, if necessary, poor fastness (inadequate fixation, inadequate wash-off), and also creases. Since this type of fault is discernible only after the fabric has been dried, another treatment operation is virtually necessary. Redyeing: in the event of failure of shade correction and correction treatment, it is necessary either to cross dye the entire batch darker, or redye it after stripping. All three concepts are measures for eliminating faulty batches, which have a significant effect on production costs.

Correction of shade → Levelling in finishing.

Corrosion (Lat. corrodere = to gnaw). Destruction of materials (generally metals but sometimes plastics) resulting from chemical or electrochemical reactions with their environment. One of the most important corrosion processes from the practical aspect is the rusting of iron. The surface nature of a material is the factor having the greatest influence on its suceptibility to corrosion since it is on the surface that the protective inactive film is formed, a non-porous oxidic coating. Cracks and roughness inhibit the formation of a continuous inactive film.

Chrome-nickel steels for instance corrode at the sites where this protective film 0.10–0.12 µm thick is interrupted by pores of diameter greater than the thickness of the protective coating or by roughness. Therefore the lower the three-dimensional surface area of a material, the better its corrosion characteristics. Under certain circumstances these surface areas also become aniodic in relation to the inactive areas of the surface. Interruption of the natural oxidic film thus results in electrolytic corrosion and consequently pitting due to chlorine ions (Fig. 1). Acid having an oxidizing action depolarizes large cathiodic areas and accelerates pitting. Also in cases of stress crack corrosion (often triggered by casting strain) the protective coating becomes cracked and in the course of crack propagation there is a shift in the elctrochemical potential to the more base side (Fig. 2). →: Contact corrosion; Pitting corrosion.

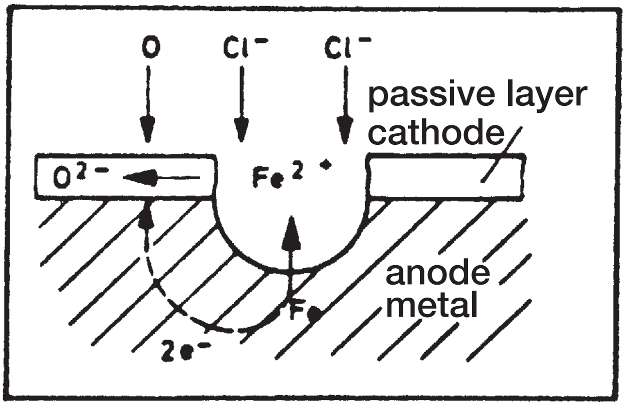

Fig. 1: Corrosion due to pitting by chlorine ions.

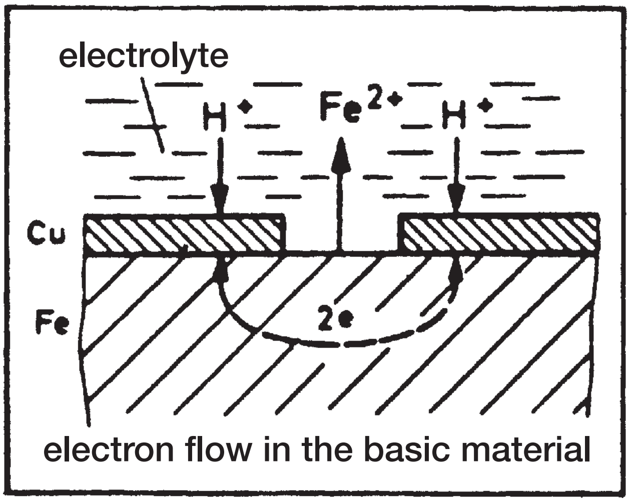

Fig. 2: Corrosion due to local element formation with different metals.

Corrosion inhibitors (anti-corrosion agents). Apart from specific → Rust prevention, corrosion inhibitors (Fig. 1) are paid considerable attention, especially in regard to universally applicable raw synthetic washing materials and such combination products in washing machines. Here, soluble silicates are the most used corrosion inhibitors for preventing corrosion in light metal alloy and copper/zinc, copper/nickel alloys etc. by carbonates, orthophosphates and polyphosphates in synthetic detergents. Condensed phosphates have the greatest corroding action. It is certain that most synthetic detergent liquors promote the corrosion of base metals, and also, oddly enough, the non-ionogenic ethylene oxide addition compounds, in many cas-

Oxide formation:	$Zn + 2\,OH^{\ominus} \rightleftharpoons ZnO + H_2O + 2e^{\ominus}$	–0,893
Cathodic hydrogen development:	$2\,H_2O + 2e^{\ominus} \rightleftharpoons H_2 + 2\,OH^{\ominus}$	–0,828
Cathodic oxygen reduction:	$O_2 + 2\,H_2O + 4e^{\ominus} \rightleftharpoons 4\,OH^{\ominus}$	–4,401

Tab.: Possible reactions on zinc electrodes in aqueous solutions.

es more so than the anionic ones. Alkyl phosphates for example are an exception. Despite this, surface-active substances like fatty alcohol sulphates, secondary alkyl sulphates and alkyl aryl sulphonates are added to rust prevention baths because they increase corrosion-inhibiting activity without reacting directly with the metal, i.e. iron rust is "equalised", thereby repressing holing.

Particularly effective and easy to handle are inhibitors which are added to liquids or gas phases too. Benzotriazol (BT) and 3-amino-5-heptyl-1,2,4-triazol (AHT) have proved themselves as copper corrosion inhibitors. The Table provides a survey of the most important corrosion reactions of zinc in ventilated solution. This involves anodic decomposition to Zn^{2+}, oxide formation, and oxygen reduction and hydrogen development as the cathodic reaction. The associated equilibria potentials depend of course on the concentration and the pH in any one case.

The structure of the phase boundary between the electrolytes and the zinc (Fig. 2) depends on the pH at any one time. The metal surface is either blank or covered with oxide. In the presence of inhibitors, the phase boundary is considerably more diverse. The inhibitors can cover the electrode in adsorption layers on the blank metal surface or in three-dimensional protective coatings (Wippermann et al.).

Corrosive poison Substances which cause localised corrosive injuries to the body, e.g. caustic potash (potassium hydroxide), caustic soda (sodium hydroxide), soda lye, hydrochloric acid, sulphuric acid and the like.

Cortex (Lat. = cover, bark, shell),

I. In wool structure, the cortical or spindle cell layer.

II. In silk structure, the cortical layer in the fibroin filament and the fibroid interior of the sericin layer.

II. Cortical (cell) layer, in → Wool structure, the largest internal layer of spindle cells.

Corundum More or less impurified → Aluminium oxide, water-free, extremely hard, insoluble in acids and alkalis. Pieces, grained, powdered. Melt point approx. 2000°C. As natural corundum (melted in electrical ovens), fused corundum and (with bonding agent) sinter corundum. This also includes the so-called special fused alumina, natural and synthetic precious stones like rubies and sapphires. Use: abrasive material, matting/delustring brushes, fireproof building materials, chemical apparatus etc.

Co-spun yarn Produced by the simultaneous spinning of two different types of polymer to give an enclosed mixed fibre.

Cost accounting The so-called → Break even point (BEP) is applied in order to obtain a productivity comparison based on pure cost comparison. If the production quantity per unit of time is traced in the abscissa of a graph, with the relevant costs plus the relevant proceeds in the ordinate, a point of intersection occurs which can be described as the profit or loss threshold (BEP). The cost product unit is necessary in order to make cost comparisons between plants or between alternative products in a plant. This is understood to include the assignment of costs to the product unit. A distinction is drawn between cost product time unit and cost product piece unit.

I. Cost product time unit: here the costs of the total output over a specific period are determined in order to compare them with total output. This is a period-related plant profit and loss account, and can be carried out in two ways: in accounting form on the class 9 plant trading result account (bookkeeping treatment) or in tabular form on a cost product time sheet (statistical treatment). The cost product time unit compares the costs of an accounting period with its output. There are two different processes:

a) Turnover cost process: only the cost of the products actually turned over are compared with the proceeds. The arithmetic determination of the plant trading result is effected as follows (according to Olfert):

$$G_B = U - x_{ai} \cdot k_{si}$$

$$G_B = x_{ai}\,(p_i - k_{si})$$

G_B = plant trading result,
U = turnover,
x_{ai} = quantity of product type i sold,
p_i = product price i,
k_{si} = prime cost per piece.

Since the proceeds and the cost of identical products are compared with each other in the turnover cost process, there is an advantage in that one obtains the trading result contribution per product unit or group. In addition, the exclusion of stock on hand from the plant result enables short-term profit and loss accounts to be produced at short intervals as required. The disadvantage is that this process can hardly be incorporated in the double entry bookkeeping system, since the individual cost types are charged to the cost centres or product units with the aid of the plant statement sheet.

b) Total cost procedure: here, all cost types occurring during an accounting period are compared with the turnover proceeds of the outputs attained. One must of course take account of the fact that a correct trading result can be achieved only if all products produced have actually been sold, that is to say that there have been no changes in stocks of finished and unfinished products. These (possibly) occurring stock changes have to be taken into account in determining the trading results. Mathematical calculation (according to Olfert):

$$G_B = U - (+\,(x_{pi} - x_{ai})\,k_{hi}) - k_j$$

x_{pi} = production quantity per product type i,
k_{hi} = production cost per piece of product type i,
k_j = cost types used.

The advantages of the total cost process lie both in the ease of incorporation in the double entry bookkeeping cost system, the possibility of tabular representation, and in producing the annual profit and loss account in the financial accounts department by amalgamating the 12 (monthly) produced trading results. The disadvantage of this process is that the physical stock has an effect, particularly in plants with a number of production stages and an extended production range. Divergence errors, which are more noticeable over short periods than in the annual accounts, occur, particularly in recording semi-finished goods stocks.

II. Cost product piece accounting: here, the costs for the individual piece (product units product unit groups) are determined, i.e. the prime costs of the individual product or the individual order unit; for this reason, this form is also called cost accounting. Companies which produce piecegoods use the number of pieces produced as accounting units, a distinction possibly being drawn between multicomponent and single-component piecegoods. Single-component piecegoods are screws, bolts, brackets etc. Here, the piece costs of the individual end-product can be directly calculated. For multi-component goods such as in the vehicle and electrical industries for example, individual component accounts have first of all to be produced for the in-house produced individual components, from which the piece costs of the end-product can only be directly compiled. In mass or production line companies such as those in the chemical industry, spinning mills, cloth-producing mills etc. weight, length, area or capacity units are

Account	*DM/m²*

= Material costs	
Direct costs + production overheads + special individual costs of production	
= Manufacturing costs	
= Production costs	
Administrative overheads + sales overheads + special individual sales costs	
= Prime costs	

Fig.: Basic accounting diagram (Kilger).

mainly used in accounting. In multi-stage companies which manufacture marketable intermediate products, the products of the stages following each other in the production process must be separately accounted for, the piece costs of the preliminary products going in each case as accounting prices into the accounting process of the following stage. A generally applicable accounting process cannot be produced for all areas, since it is greatly influenced by the technological product structure and the manufacturing process employed. The same cost type groups go however into each account in a specific sequence, so that a generally applicable basic diagram is produced (Fig.).

Cost calculation in textile finishing The textile industry is obliged to split up at any one time the largely automated and clearly arranged production of yarns, woven and knitted fabrics and nonwovens over very widely differentiated market demands as regards colours, design, surface effects and wear and care properties, with corresponding smaller order slots. In order to meet all these requirements and yet still be able to produce competitively, chemical finishing plants must have available a comprehensive machine park and qualified staff. Chemical finishing to order is therefore a pure on-call industry, which is both personnel and capital intensive.

1. Cost classes: approximate share of individual cost classes in total finishing costs:

personnel	42–45%
process materials	16–20%
energy, water/effluent	15–21%
repairs, maintenance etc.	4%
capital	8%
other costs	8%

In order to achieve the most accurate calculation of production costs it is essential to apportion the variable proportions of cost classes to the individual production stages, all costs which are involved in work in progress being basically regarded as variable.

a) Personnel costs: despite increasing capital intensity, personnel costs in the textile finishing industry are the largest production cost components. In order to calculate the precise cost of an operation therefore, it is necessary to relate the personnel costs to the „output“ of the relevant cost centres, i.e. to their associated machine running times. Essential here for the most accurate determination possible is the retiming of all the plant's work stations in order correctly to work out the activities associated with production in progress, and to define relevant work station parameters and/or personnel loadings in the case of cost centres with multiple machine work.

b) Process materials: this covers all materials necessary for chemical finishing, including all additives such as chemicals, dyes, sewing materials etc. In this way, process materials are directly involved in production in progress, have to be allocated to the production cost centres of the individual operations, and charged to the hourly machine rate.

c) Energy, water/effluent: precise allocation of these costs to the individual production stages is also a prerequisite for accurate cost accounting This means that the variable energy, water and effluent costs have to be determined per net machine hour or per unity of quantity. This is possible at a relatively low and justifiable cost by in-house or external personnel by means of meters incorporated in the consumption cycle (e.g. intermediate electricity meters and intermediate water meters).

d) Repairs/maintenance and spare parts: these costs are easily ascribed to the production cost centres, i.e. the operations or machines in which they occur. In this way, the allocation of these costs to the hourly machine rate presents no problems.

e) Capital: the important elements of capital and calculatory costs are calculatory depreciation and calculatory interest. Means of production such as machinery and tools have a specific working life, period of use or service life, during which their value diminishes. Reasons for this reduced value are: a) technical wear; b) technical supersession; c) economic supersession. This loss of value of means of

Next Page

production is taken into account in depreciation. Interest is also included in cost calculation along with depreciation. In so far as the calculatory and capital costs of a specific machine – and therefore a production stage – can be allocated, they are included in calculation of the hourly machine rate.

2. Short interval performance and cost calculation are necessary in textile finishing because strong seasonal swings plus other lasting but unforeseeable variations are typical of order books. Other characteristics are greatly varying order sizes per colour classification, constantly changing colour palettes, comprehensive performance patterns in pretreatment, dyeing (e.g. fastness), printing (number of colours and degree of severity), after-treatment and service together with different raw materials. In commission finishing, there is no possibility of producing for stock, thereby incorporating a buffer between market requirements and plant production potential. Owing to the above-mentioned peculiarities, cost and performance planning are subject to difficulties for textile finishing firms, but are indispensable. In order to be rapidly informed and to be able to act quickly if necessary, cost and performance calculation is necessary at short intervals, e.g. monthly, rapidity being more important than absolute accuracy. For this reason, it is still usual to calculate specific overhead costs relative to other cost figures, i.e. in the form of percentage surcharges. This calculation method produces extreme inaccuracy. Calculating percentage surcharges always requires two attuned amounts, i.e. the basic amount and the surcharge amount. Significant differences may occur if the value of either amount is changed. Additionally, this method does not conform with the cause-justified calculation otherwise aimed for. The purpose of cost calculation aided by electronic data processing is to eliminate the above-mentioned inaccuracies.

3. Graduated costing: the complex performance requirements on textile finishing, which can comprise up to 20 operations, require sophisticated, graduated costing, which should be built up of as many costing components as there are finishing operations. The main influencing factors are the order quantity per colour, the depth of shade, the fastness required, the design, the fabric weight in the case of fabrics, incidental finishing operations and service. Thus, with fixed order costs of 100–400 DM/order, there is already a difference if a customer's order is 100 or 1000 kg. A precalculation matched precisely to the performance requirements, i.e. a graduated precalculation, is the basis for market-oriented, cost-covering pricing.

4. Costing in accordance with individual orders, product ranges and customer groups is becoming increasingly important in textile finishing despite the sometimes not inconsiderable cost of calculation. The function of costing is a test bed for current revenue levels and a control element for the firm's future marketing activities. In addition, it serves as an instrument for checking preliminary costings.

5. Quality: since the domestic textile finishing industry is in competition with cheap labour countries, quality enjoys high status. Basically however, the following rule applies here too: the cost of control must be adapted to the product, its purpose of use, and the price paid. The more stringent the customer's quality requirement, the greater the expense necessary on personnel and processing technology. Costs due to quality requirements are relative to the product and the economic situation. Low value products are subject to less stringent quality requirements than high value products, and it is a fact in economic terms that there are more complaints in bad times. Quality requirement costs include:

a) length compensation, short measure and weight: these cost classes are quite typical in textile finishing. Natural raw material differences, e.g. weight per square metre and shrinkage behaviour, always result in variations. Agreement between finisher and customer on a margin of tolerance is therefore to be recommended.
b) compensation for fabric damaged in finishing.
c) credits/price reductions for faulty finished fabric.
d) return costs: internal works and customer returns, including associated freight costs.
e) compensation: this includes price reductions for non-compliance with delivery dates in accommodation cases.

Costs due to quality requirements amount in total to about 6–10% of turnover. They vary relative to product type; in the case of simple products, they are about 3%, whilst they can be as much as 15% with high quality products. Here, return costs make up the biggest items at approx. 50% . Quality assurance is an instrument for reducing costs due to quality requirements. We can differentiate basically between two types of quality assurance: operational checks (semi-finished and finished inspection) and the work carried out in the laboratory for quality assurance. Operational check costs are difficult to particularise, since operating personnel and supervision, which also check at the same time, are essential in any case. Precise costs are not recorded, but amount to at least 5% of turnover. Quality assurance itself, including the work carried out in the laboratory to that end, represents a cost factor of approx. 1.5% of turnover. As far as the laboratory is concerned, an investigation should be carried out as to whether installing and using an in-house laboratory is more cost effective than engaging the services of an independent institute. In any case, it is sensible for small and medium-sized firms to have special checks made by testing institutes, since it is uneconomic to buy expensive special testing equipment which is seldom needed.

Cost comparisons Not only colour, design and quality, but also price, are decisive in textile finishing for the success or failure of a collection. Particularly important for pricing in the case of a fashion-dependent product are product appraisal by the customer, and the limit of his or her readiness to pay. In pricing, fashion article producers must be oriented to target group purchasing power, and may not exceed the selling price of an upper limit laid down by consumers. The lowest price limit for a product is set by the production piece costs incurred. Piece costs for calculating selling price are determined via cost calculation, which is preceded by cost class calculation and cost centre calculation (in the following weaving/printing comparison).

1. Cost class calculation embraces the itemisation of all costs the company has to bear, and is dependent on company size and structure. These costs comprise:

a) the annual fixed costs (interest, amortisation, maintenance costs, premises etc);
b) material costs;
c) personnel and personnel incidental costs;
d) energy costs (these are considerably higher in printing than in weaving, owing to water and steam costs);
e) other costs occur in printing by way of dyestuffs and chemicals, which occur only indirectly in weaving as warp and weft yarn dyeing costs.

2. Cost centre calculation involves the allocation of total cost to individual production areas. The main cost centres "printing" and "weaving" should be clarified in comparing the cost of printing and jacquard weaving for example. Recording these costs poses a particular problem, since they are affected by different variables within the recording period. For the "printing" cost centre, these are:

- the printing process used,
- the number of designs printed,
- the number of colourways printed,
- the number of colours per design,
- the number of metres printed per design and colourway.

From these, various production times, change-over and machine stopped times, fabric production lengths and fixed cost contents occur for the cost centre, from which the cost per metre of individual products is calculated. For the "weaving" cost centre, the following variable parameters have to be taken into account:

- woven fabric construction (number of warp ends and picks/cm, number of warp and weft systems),
- number of designs woven,
- number of colourways woven,
- number of colours per design,
- running qualities of warp and weft yarns,
- the number of metres woven per design and colourway.

As in printing, and for the same reasons, there are different costs per metre for a product. The cost of producing pattern carriers, jacquard cards and printing screens can be apportioned in different ways:

a) the average screen or card costs are recorded per season, and apportioned as a patterning surcharge on the total patterning cost.
b) screen or card costs are apportioned to the lifetime of the design, it being taken into account that not every design has the same lifetime, while some are not even put into production under certain circumstances.
c) screen or card costs are apportioned over the lifetime of the screen or the card.

As far as the latter are concerned, the cost of printing after-treatment (fixation, washing and drying) and fabric finishing (desizing, washing and drying) have to be calculated for the "printing" and "weaving" cost centres, since they differ in terms of printing process, fabric weave and raw material. In addition to the purely technical costs, the development and patterning costs play an important role. They are to be calculated as special individual costs as a rule, since, independently of the number of metres produced, they represent one-off costs, which may have a different volume depending on type of order (in-house production or production to order).

3. The individual product cost can be calculated from the total cost determined (cost class calculation) and the costs arising in individual production areas (cost centre calculation) with the aid of cost product unit calculation. Short-term cost product unit calculation is indispensable, particularly for the fashion-oriented business with a wide product range, in order to be able to calculate products newly admitted to each collection. In the preliminary calculation, the variable costs and the fixed costs calculated on an assumed production quantity form the calculated unit price (price per metre). The actual unit cost can be determined in costing only if the number of units sold is known. The higher the sales figures for a design, the lower the fixed cost proportions, and the more easily the product can be calculated. Unit cost comparison between a print design and a jacquard design is extremely difficult due to the different production cycles and operational stages in weaving and printing. Nevertheless, identical basic assumptions must be laid down for the calculation example in order to obtain, via the product unit calculation, comparable results for the print design and weaving design product units (Tab. 1).

a) Only the cost of the materials supplied and the technique employed are compared. Design patterning and development costs are not taken into account in the calculation.
b) The cost of the printing forms and jacquard cards are apportioned over the number of metres produced (150 m, 3000 m, 10 000 m).

Cost comparisons

Material/operational stage		150 m	3000 m	10000 m
1. Printed fabric	3 DM/m	450.00	9000.00	30000.00
2. Printing form	600 DM/colour	1200.00	1200.00	1200.00
3. Ground dyeing	0.10 DM/m	15.00	300.00	1000.00
Colourways	7 DM/colour	63.00	63.00	63.00
Printing paste	3.20 DM/kg 0.08 kg/m	38.40	810.00	2700.00
4. Printing	(*1)	631.00	10800.00	17800.00
Fixation	0.23 DM/m	34.50	690.00	2300.00
Washing	0.52 DM/m	78.00	1560.00	5200.00
Drying	0.09 DM/m	13.50	270.00	900.00
Total price of batch		2523.40	24693.00	61163.00
Unit price per metre		16.82	8.23	6.12

Tab. 1: Figures in product unit calculation for producing a printed product on a rotary screen printing machine. (circa 1990) with production lengths of 150 m, 3000 m and 10 000 m per design with 3 colourways.
*(*1) printing cost for 150 m = 4.21 DM/m; for 3000 m = 3.26 DM/m; for 10 000 m = 1.78 DM/m.*

c) The personnel and machine costs per hour for single shift operation form the basis of the cost per metre used for operational stages 3 and 4 of the product unit cost calculation.
d) The products to be produced should be of equal value as regards raw material, colourability, finished width and quality.

The costs used for operational stages 1–4 are average values, which can be changed upwards and downwards in the individual case. The prices for the grey fabric supplied are dependent on fabric quality and country of origin, and also on the expenses necessary for print preparation. The screen costs to be used (Tab. 2) are calculated from screen size, gauze mesh fineness, the transfer process and the time required for producing colour separations and complete films. The price difference for flat printing screens and rotary printing screens is of a ratio of 2 : 1.

Screen type	Printing width (in mm)	Screen fineness (points per inch)	Price (DM)
Rotary screens	641 / 1620	40 - 80 mesh	728.00
	819 / 1620	40 - 80 mesh	785.00
	914 / 1620	40 - 80 mesh	940.00
Flat screens	1250 / 1500	40 - 80 mesh	372.00
	1500 / 1500	40 - 80 mesh	400.00
	1750 / 1500	40 - 80 mesh	438.00

Tab. 2: Cost example (circa 1990) for rotary printing screens and flat printing screens with identical mesh fineness and the indicated printing widths.

The cost of ground dyeing, colourways and printing pastes is dependent on the dyestuff classes employed and the required quantity/kg. In printing paste calculations, account should be taken of the fact that 13 % of the paste does not reach the fabric. The loss is due to residues in containers, pipes, pumps, screens etc. The cost per metre of the printing, fixation, washing and drying operations is calculated from the personnel and machine cost/hour and metres produced/hour ratios, different hourly rates being used for the printing process relative to fabric length.

The unit costs listed in Tab. 3 are incurred for producing the jacquard product in batch sizes of 150 m, 3000 m and 10 000 m:

Material/operational stage	150 m	3000 m	10000 m
1. Material			
Warp 2.18 DM/warp metre	399.00	7980.00	26600.00
Weft 0.48 DM/m weaving length			
2. Jacquard card 1175 DM	1175.00	1175.00	1601.00
3. Weaving 1000 picks à 1, - = 3.60 DM/m	540.00	10800.00	36000.00
4. Washing 0.52 DM/m	78.00	1560.00	5200.00
Drying 0.09 DM/m	13.50	270.00	900.00
Total price of batch	2205.50	21785.00	70301.00
Unit price per metre	14.70	7.26	7.03

Tab. 3: Unit costs (circa 1990) for the production of a jacquard article in various batch sizes.

Here too, the costs used for operational stages 1–4 are average values, which can be changed by different affecting parameters. The warp and weft yarn costs are dependent on raw material prices and dyeing costs, and can reveal big differences. The costs to be used for the jacquard card are oriented to the number of picks in the repeat and the number of controllable warp ends. Depending on repeat dimensions, there are big price differences, which can be illustrated for a 1344 jacquard machine.

The cost of reading in the model, copying in the card via the computer, and card copying for the required card length is calculated. Depending on the mill, the weaving costs lie between 0.08 DM and 2 DM per 1000 picks. The cost of after-treatment (point d of the product unit cost calculation) is calculated from the personnel and machine cost/hour and metres produced/hour. The cost calculation result for both articles points to a different cost degression as product quantity increases. Cost degression comes about because a specific proportion of fixed costs (printing forms and colourways, jacquard cards) are offset by the quantity-proportional costs (material and personnel costs). Comparison of the degression curves shows that, with a production quantity between 4000 m and 5000 m, the unit costs for a comparable jacquard woven article are lower; above this quantity, the prices per metre of the printed article are lower.

The difference in cost degression curves is, among other things, attributable to the fact that jacquard cards have a shorter working life (4000 m to 5000 m) than printing screens (10 000 m to 15 000 m). After 4000 m to 5000 m production length, the cost of a new set of cards (card copying and punching) increases the proportion of fixed costs for the jacquard product, while the fixed costs of the printed article remain the same up to a production length of 10 000 m to 15 000 m. After that, the cost of a new set of screens arises here too. The calculated unit prices of the jacquard article at 14.70 DM, 7.26 DM and 7.03 DM and the printed product at 16.82 DM, 8.23 DM and 6.12 DM are very high, since single-shift production was taken as the basis of calculation. With optimum utilisation of the production capacity in three shift operation, the unit costs of the printed article can be reduced by about 30% because, among other things, the high proportion of setting-up time at the beginning and end of the shift in single shift operation can be used as production time in three-shift operation. In jacquard weaving, a unit cost reduction of approx. 15% is possible in three-shift operation, since here there is no significant setting-up time at the beginning and end of the shift as compared with printing. This means that the degression curve for a printing works producing in three shifts reveals a considerably steeper rise as that in the weaving mill, and the intersecting point of the curves moves in favour of the course of unit costs in the printing works. Nevertheless, unit prices for the jacquard product are lower here too with short fabric lengths.

The unit prices to be calculated by the manufacturer for the individual articles of a collection are not exclusively determined by patterning technique. Depending on plant size, production capacity and production quantity, an article can be produced more cost effectively or at the same cost with one or the other patterning technique. A further decision criterion for using one or the other patterning process is represented by the economic requirements on fashion-dependent production.

Cost structure Reveals a hierarchy in textile finishing. If one looks at the cost of a textile product from the consumer standpoint, the textile pipeline cost structure breaks down into the following areas: commerce, making-up and textile industry. Thus, the cost of a man's cotton/polyester suit for example is illustrated in Fig. 1.

If the selling price is 100%, approx. 15% falls to value added tax, 39% to sales, 29% to making-up, 15% to yarn and woven fabric production and 2% to fibre material (raw material purchase). If we examine the cost structure of a finished woven fabric, we see that the yarn production cost makes up only 20–30% of the cost incurred in spinning, weaving and finishing. Here, the yarn must meet the following requirements:

a) the yarn structure must be suitable for the end-product.
b) running behaviour must be free of problems in weaving and weft and warp knitting, inclusive of all preparation stages. Yarn breakage behaviour in spinning is a determining factor for behaviour in further processing. This also applies to fly, the adhesion of fibre to fibre and work capacity.
c) the raw product must be capable of being used again without difficulty after finishing.

The costs incurred in producing a woven fabric are as follows (Fig. 2):

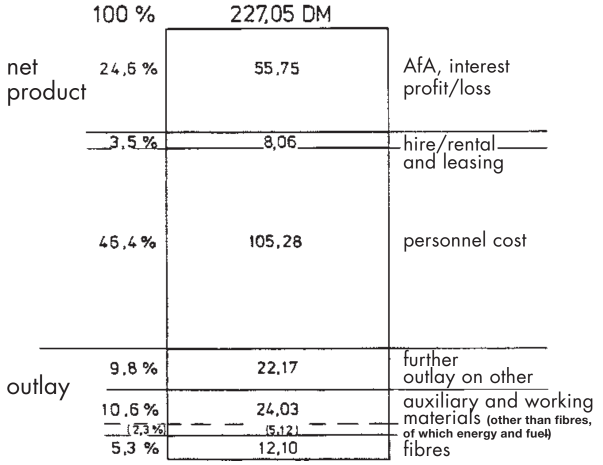

Fig. 1: Possible cost structure in the textile pipeline of a man's suit (wool/polyester).

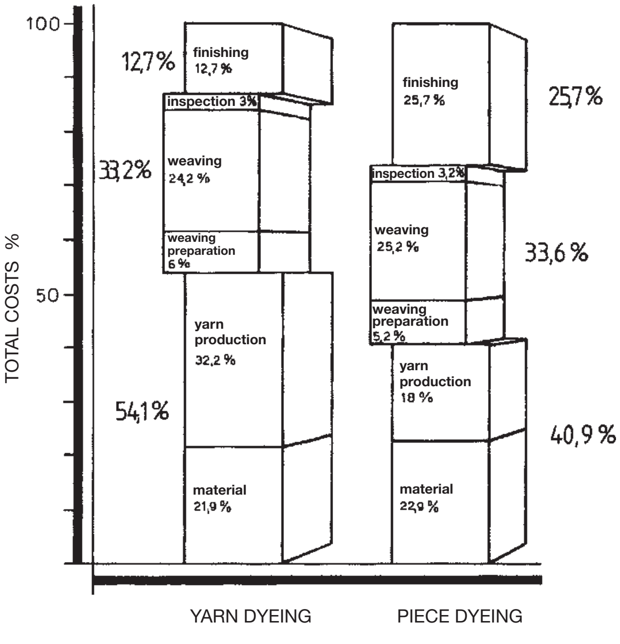

Fig. 2: Cost structure of a woven fabric up to finishing.

Cost structure

	% cost with articles of Cotton	% cost with articles of Wool/polyester
Material	23	34
Spinning	14	38
Weaving preparation	8	
Weaving	35	} 19
Darning	6	
Dyeing and finishing	14	9

Tab.: Cost distribution in woven fabrics of different raw materials.

Production method of course has an effect on this cost structure, depending on the fibre material employed (Tab.).

In a commission finishing mill which turns over DM 50 mill. per year, and brings into circulation a fabric value of approx. 300 mill. DM, the cost structure is composed as follows (with no material cost incurred):

– wages	42%
– energy	18%
– dyestuffs	16%
– effluent	3%
– administration	3%
– repairs	4%
– craftsmen	2%
– returns	6%
– depreciation	6%

Relative to an individual dyeing process, we differentiate between net dyeing cost and added dyeing cost. Net dyeing cost proportions (Fig. 3) can be determined by computer or by programmable examination. Brought together under the added dyeing cost concept are all machine dyeing cost percentages, which also change during net dyeing time specifically to operations and batches, particularly those relative to quality and delivery, and for which calculatory processing and production time reserves are prescribed on the basis of operational experience values. In addition, it is advisable to view the drying and additional cost of part batches, overhead costs and quality assurance and testing costs under the aspect of added dyeing costs, as this contributes considerably to cost transparency between technology-oriented and experience-oriented cost percentages.

In Fig. 3, we have taken the representative net dyeing cost of a machine dyeing example. The percentage net dyeing cost was entered for batch weight $G_T = 200$ kg and $G_T = 500$ kg. In addition, the net dyeing cost of a 200 kg batch was illustrated in column terms, relative to dyeing times of 4, 6 and 8 hours. Under the pump drive aspect, it should be recognised that approx. 10% of net dyeing cost is taken up by the pump drive power cost. The effect of pump drive speed regulation on energy cost can be estimated by examining the fact that the hydraulic output of a centrifugal pump changes approximately as the cube of the pump speed. If pump output is reduced to 80% of nominal speed, the hydraulic output of the pump falls to $(80\%/100\%)^3 = 0.51 \cdot 100\% = 51\%$ of output at 100% nominal speed. Even

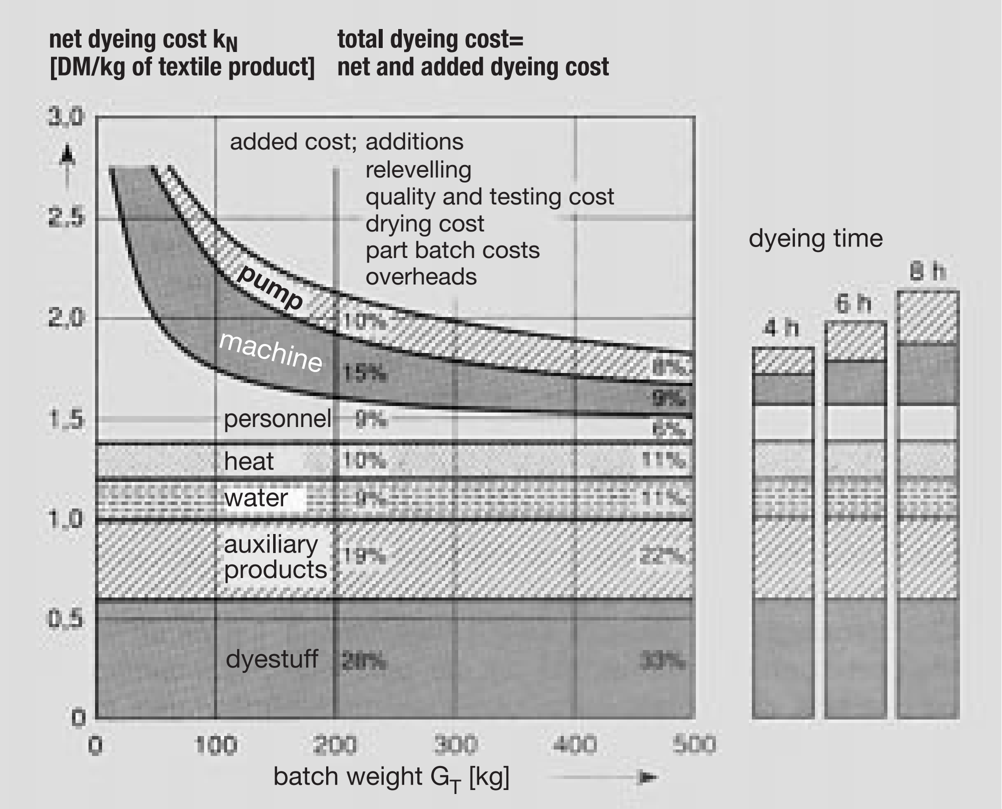

Fig. 3: Spread of representative net dyeing costs over the batch weight of an exemplary machine dyeing (Kretschmer).

taking account of the speed-dependent pump and motor efficiency level, it is permissible to assume that the power cost of the electric motor drive falls approx. quadratically as the speed is reduced. If pump speed for example is reduced to 80% of nominal speed, the energy cost falls approximately to $(80\%/100\%)^2 = 0.64 \cdot 100\% = 64\%$ of the energy cost at 100% nominal speed. In line with trends and practical experience, it is also of advantage in cost terms to operate piece beam and yarn package dyeing machines with speed controlled pump drives, particularly as this is amortised in less than 1 year (partially in accordance with Kretschmer).

Côtelé (Fr.: côte = rib). Worsted and cotton fabric with fine compact warp ribbed or striped textured appearance, sometimes in patterns or checks etc., commonly called bengaline (England and U.S.). French term for corduroy, although in German trade terminology generally used for finely constructed fabrics having cord-like warp-way ribs. End-uses: ladies wear, suits and coats.

Cottage steamer → Steam mansard.

Cotton The seed hair of plants in the Gossypium botanical genus of the mallow family. After flowering the ovary located in the calyx develops into an elongated capsule which bursts open to allow its seed hairs to billow out. A cotton capsule contains about thirty seeds and each seed is host to 2000 to 7000 seed hairs. Depending on cultural strain, climate and cultivation, plants attain a height from 25 cm to over 2 metres. They are cultivated predominantly as shrubby annuals. There are only a few areas (Peru and North Brasil) where cotton is grown as a perennial and here plants may be up to thirty years old. The period from sowing the seed to harvesting the cotton amounts to between 175 and 225 days. At the time of sowing the plant needs moisture and when it is ripe in needs considerable heat. Therefore the zones of cultivation are located in tropical and sub-tropical zones. After harvesting the cotton bolls are allowed to mature and dry for around thirty days and are then ginned in cotton gins which separate the fibres from the seeds. 100 kg cotton bolls will yield about 35 kg fibres, 62 kg seeds and 3 kg trash. The cultivation of one tonne of harvested cotton requires 400 kg fertiliser, 40 kg insecticide and 1.2 kg defoliant (systemic in action). Examples of yields per hectare in 1990 were: Israel up to 1300 kg, USA and China each approx. 650 kg, Uganda approx. 30 kg. For the purpose of transport the cotton fibres are press-packed into heavy bales wrapped in jute and held by steel bands. They are shipped in this form and arrive at European warehouses and spinning mill destinations via transshipment ports such as Bremen, Venice/Trieste, Rotterdam/Antwerp.

Raw cotton in the trade is classified by fibre length (staple), uniformity, fineness, colour, cleanliness, handle, strength and elasticity. Principal defects are impurities, short staple and high content of immature and badly developed or "dead" fibres. Some grades are of harsh rough handle whilst others are silky soft. In terms of colour, raw cotton is graded as "white", "creamy", "light spotted", "spotted" and "light grey". The most important quality attribute is the staple length. This is generally between 18 and 42 mm. The separate grades are divided into the following four classes according to their maximum staple length:

short staple	< 26 mm
medium staple	26–29 mm
long staple	30–38 mm
extra-long staple	> 39 mm

Quality criteria are:

- length and length distribution, including uniformity of length and percentage short fibre (excessively long fibres can also be troublesome)
- strength
- trash content, subdivided as follows:
  - a) Trash: percentage content, particle size and nature of the trash (taking into consideration the propensity for removal, seed hull fragments, particulate matter etc.).
  - b) Dust: percentage content and particle size (distinction is made between micro-dust and inhalable dust).
  - c) Foreign matter and contaminants (e.g. plastics).
- Fineness (micronaire).
- Maturity index and distribution, including "dead" fibres.
- Colour (including dyeing characteristics and colour defects; generally associated with certain fibre dimensions and structures); other colours such as beige, brown or green are genetically possible.
- Neps (size and distribution).
- Fibre convolutions (twists).
- Stickiness (mainly but not solely caused by honeydew).
- Fibre friction (probably mainly associated with surface wax).
- Elasticity, modulus and breaking strength (associated with some of the attributes already listed).
- Bulk and crimp (associated with convolutions and other properties).

A great deal of progress has now been achieved in efforts to characterise objectively, comprehensively and precisely the textile quality and value of cotton. Systems such as the AFIS method of integrated comprehensive lint analysis and the NIR system (e.g. for stickiness, maturity, dyeing propensity, moisture content and nature of the trash content) could be features of the new generation of HVI (= High Volume Instrumentation, comprising at present micronaire index, strength, length, length uniformity index, colour reflectance index, yellowing, colour gradation index and trash content, plus classified grade). It is important for existing HVI tests to be standardized, improved and fully utilised and for the present HVI system to be extended to include other significant fibre properties. It is a challenge for all spinners throughout the world to make effective use of present and future HVI data.

Some possible applications of the HVI system include:

1. Classification, marketing and the use of data telecommunication systems in cotton classing and data processing.
2. Optimum selection of cottons for specific end-products, processing conditions and for intended blend assembly (e.g. the EFS programme).
3. Establishing the price of cotton in relation to its true textile value and its quality.
4. Cotton breeding and cultivation with improved interchange of information between breeders, producers, gin operators and processors, although for example fibre strength should not necessarily be the main criterion in the breeding programme.
5. Ginning trials, estimation of cleaning propensity and fibre damage, although still better SFC and neppiness test methods are needed.
6. Accurate forecasting of processing performance and product quality using empirical regression equations specific to the spinning plant.
7. Computer controlled and computer assisted fibre processing and yarn production.

The fibre presented for processing is often heterogeneous containing a certain proportion of immature and dead fibres. Immature and dead fibres, because of their different nature, do not conform in their dyeing behaviour and require additional processing stages (Tables 1 and 2). “Hard” and “red” cottons are the exception with a high content of calcium and iron compounds respectively. With the former, problems can occur for example with constantly increasing liquor contamination, especially in continuous preliminary processes such as short liquor treatments. In the case of “red” cotton problems in the form of “dirty whites” arise in bleaching and optical brightening.

Cotton, acetylated → Acetylated cotton.

Cotton, aminoethylated → Aminoethylated cotton.

Cotton damask Jacquard-patterned cotton fabric with satin ground, for bed linen and table linen. The clarity of the figurative designs is achieved by the technique of warp and weft satin weave. The silky lustre is intensified by a special finish.

Content of:	Content in:	
	ripe cotton	unripe cotton
Cellulose	90 - 95 %	reduction
Pectins	0.7 - 1.2 %	–
Proteins	1.1 - 1.9 %	increase
Wax, fats	0.4 - 1.0 %	increase
Organic acids	0.5 - 1.0 %	increase
Total sugar	approx. 0.3 %	–
Ash	0.7 - 1.6 %	increase

Tab. 1: Characteristic composition of ripe and unripe cotton (CO).

Impurities	Colouristic effects
With raw fibres	
Seed husks, leaf and stem residues Neps	Impairment of fabric appearance depending on article and dye selection
Residues of: - insecticides - growth regulating agents - defoliants	Staining, possibly resisting
Metal traces	Rust stains, bleach damage
Foreign fibres	Resisting
After spinning, weaving	
Size and spin finish residues	Unlevelness, resisting
Oil and graphite residues	Light/dark stains
Abraded metal	Light stains, possibly holes
Dirt Dust from storage	Unlevelness Resisting

Tab. 2: Impurities in cotton articles from which difficulties frequently arise in textile finishing.

Cotton dust → Byssinosis.

Cotton fibre fine structure The molecular chain of cellulose (Fig. 1), as the basic substance of cotton, is stretched. Stretched conformation of the polymer chains is also present in analogous form in polyamide fibres and polyester fibres, as well as in the crystalline areas in silk. By contrast, the chain molecules in unstretched wool (α-keratin) and in polypropylene fibres are shortened by helix formation (screw formation).

The cellulose molecules stabilise themselves, lying parallel, through inter-molecular and intramolecular hydroxyl bonds (Fig. 2) which, in spatial construction, leads to a unit cell in X-ray terms. In the cellulose grid according to Fengel, the chain pairs run counter to each other.

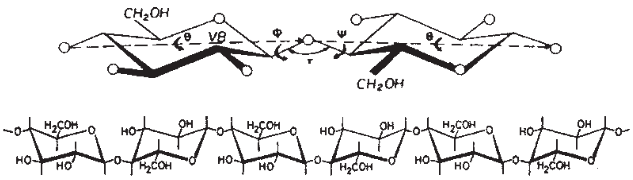

Fig. 1: Steric cellulose formula of the cotton fibre (bottom) with possibilities of free turning capacity in a cellobiose unit (top).
VB = molecule longitudinal axis; Q = rotation of the entire monomer; t = bonding angle with the glycosidic oxygen;
F and y = rotation about the C–O bond with the glycosidic oxygen.

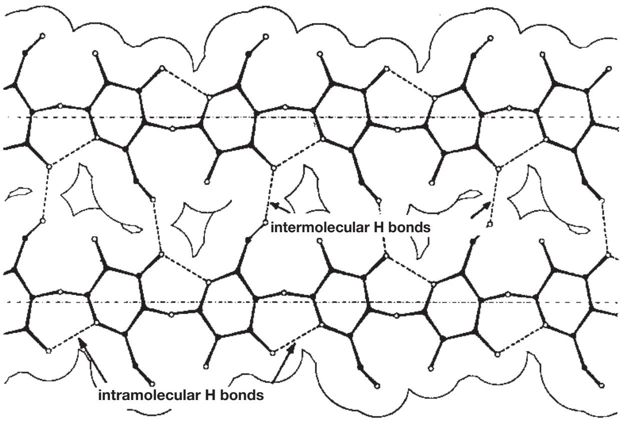

Fig. 2: Intramolecular and intermolecular hydrogen bridge bonding in two adjacent cellulose chains of the cotton fibre.

The internal structure of the fibrils has not yet been fully described, and various models will be discussed. The models are, however, based on 3 basic types:

1. Micelle model, in which the less ordered areas are formed from molecule chains that change over from one fibril to another. With this model, a certain variation in the fibril diameter can be explained (Dolmetsch, 1968).
2. Strand model, which consists of individual fibrils of the same diameter with non-ordered areas or defect points (Mühlethaler, 1969). Particularly in the second case, additional non-ordered cellulose molecules are necessary for the corresponding degree of crystallinity to be achieved.
3. Fold model, in which the non-ordered areas are explained by the reversing points of the molecule chains. An anti-parallel chain course results from the change in direction of the molecules (Marx-Figini, Schulz, 1966; Menley, 1964). However, the physical behaviour of the cellulose contradicts a model of this kind to a certain extent.

In the supra-molecular construction, the elementary fibrils organise themselves into microfibrils. The amorphous area of the cellulose fibre cotton is characterised by its ability to swell in water; during drying, this water is removed with the release of energy (Fig. 3). In contrast to this reversible swelling, the whole fibre structure reacts irreversibly in the case of swelling with soda lye (e.g. in the case of mercerisation), with cellulose I transforming into cellulose II (Fig. 4).

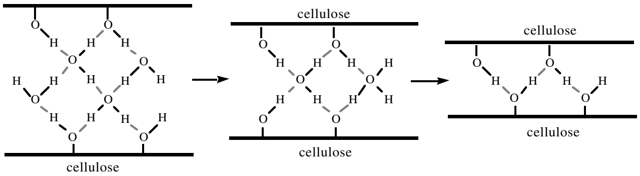

Fig. 3: Drying process between cellulose surfaces of the cotton fibre.

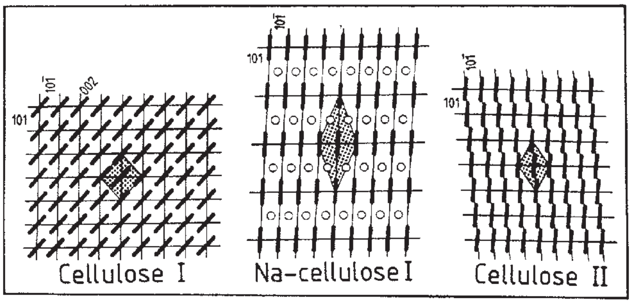

Fig. 4: Grid of cellulose I, sodium cellulose I and Cellulose II. The horizontal mathematical lines connect a "sheet" in each case (a series of imbricated cellulose molecules in the cellulose I) of the cotton fibre.

Whilst the models of Frey-Wyssling and Mühlethaler are still 2-phase models, the alternative concept of the cotton fibre represents a 1-phase model, which assumes homogenous, crystalline cellulose, with certain faults in the crystal structure. This direction has been most emphatically pursued by Statton. However, a super lattice of the cellulose results not only – as for example with synthetic fibres – from the sum of the faults caused by the ends of the molecule chains in a fibre crystal ("kinks", "jogs"). Rather, a certain number of parallel cellulose chains combine to form sub-units, which then cause the typical morphological structure of the cotton.

If one follows the efforts of the structure researchers in the field of cotton to discover the smallest sub-unit of fibre morphology, then one could state that since the use of the electron microscope (around 1953), the diameter of the smallest sub-unit which can still be demonstrated has shrunk to around 30% with the increasing perfection of the techniques applied. The most extreme view represents the claim that the smallest sub-unit, which it will not be possible to demonstrate optically only because of deficiencies of resolution, is the cellulose macro-molecule. On the other side, studies from quite different directions (X-ray, infra-red spectroscopic, electron-microscopic, chemical, physico-chemical) have now condensed the picture of the morphological structure of cotton to such an extent that it is more appropriate to postulate a bio-synthetically-based basic unit, the elementary fibril, than to assume a distribution of all possible fibril diameters which is subject to the laws of probability. This view is also supported by a study by Mühlethaler, which showed that certain amoebae produce polysaccharides in biosynthesis in an extra-cellular manner, in the form of proto-fibrils with a diameter of 3.5 nm.

When the biosynthesis of the cotton fibre in the seed

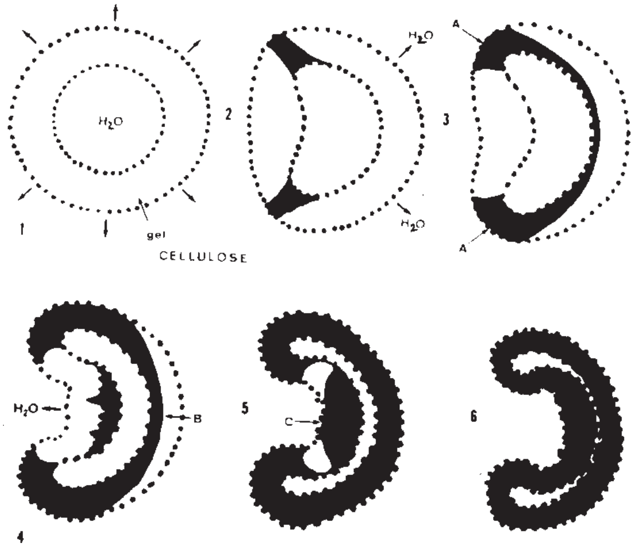

Fig. 5: Kinetics of cotton fibre collapse in original drying (Kassenbeck).

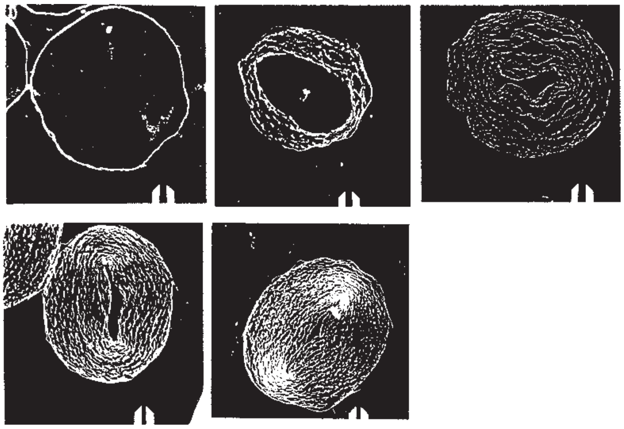

Fig. 6: Cotton fibre growth in the cross-section of a series of electron microscope photographs. After initial formation of the primary wall, which illustrates the "transport line" for conveying the cellulosic building block material, the secondary wall layers appear in concentric rings, growing from outside to inside.

capsule is complete, the product is present as a more or less cylindrical fibre. The capsule bursts open, and the young fibres are subjected to a drying process. Kassenbeck was able to show that the fibre collapses (Fig. 5) depending on origin (degree of maturity, provenance, fineness), resulting in the familiar kidney-shaped fibre cross section. Lately it has been conjectured that the collapsed state grows as such (Fig. 6).

During this collapse (primary drying), asymmetrical, mechanical tensions arise, which cause zones of varying density. Compression forces that act radially lead to an increase in the packing density of the fibrils, and to a parallelisation of the fibril layers in the convex part of the collapsed fibre. The concave fibre wall, lying on the inside, suffers a reduction in the degree of order, due to compression forces that act tangentially. This bilateral structure (Fig. 7) leads, when viewed macroscopically, to differing accessibility of the various areas, so that e.g. in the case of enzymatic hydrolysis of the fibres (a process which – like any finishing operation – is associated with a swelling of the fibre wall), it is predominantly the non-ordered, concave area which is destroyed; the remaining convex part becomes soluble only at an advanced stage of hydrolysis.

Fig. 7: Bilateral structure of cotton according to Kassenbeck.

Kassenbeck showed that this concept also has consequences for the cross-linking of the fibre (with formaldehyde). According to that, due to greater accessibility far more bonds are constructed, but due to the high degree of swelling during cross-linking, the bonds formed are mainly intra-fibril. In contrast to this, the degree of swelling and the accessibility of the convex fibre part is so low that only a few bonds are formed, but these are inter-fibril, and therefore are effective in terms of the desired mechanical stabilisation of the fibre. A disadvantage of this sequence of the cross-linking process is the reduction in the originally good stability of the convex fibre part, which was due to the high degree of order; however, since the stability of the unordered concave fibre part is not changed by the cross-linking, and thus is not improved either, the overall stability of the fibre drops.

Kassenbeck showed that the swelling of the fibre depends, in terms of macroscopic visibility, on the swelling agent used. Thus it has been demonstrated, for example, that caesium hydroxide, in contrast to sodium hydroxide or morpholine, specifically swells the concave part of the fibre. Rolins demonstrated that morpholine separates the crystallites visible by electron microscope from one another, whilst zinc chloride solution swells in an inter-crystalline manner. The crystallites observed here are probably the crystallographically aggregated elementary fibrils demonstrated by Ingram. With the aid of the so-called "dark field image technique", it has been possible to quote the dimension of an elementary fibril as 5.0 nm. These elementary fibrils aggregate to crystallites of varying size, in that their surfaces lie so close to one another that in X-ray terms they form one unit, i.e. they fuse, and therefore together they present a smaller surface when attacked by a medium which swells in an inter-crystalline manner, such as morpholine. Zinc chloride on the other hand cam burst such aggregates of elementary fibrils or crystallite (Fig. 8).

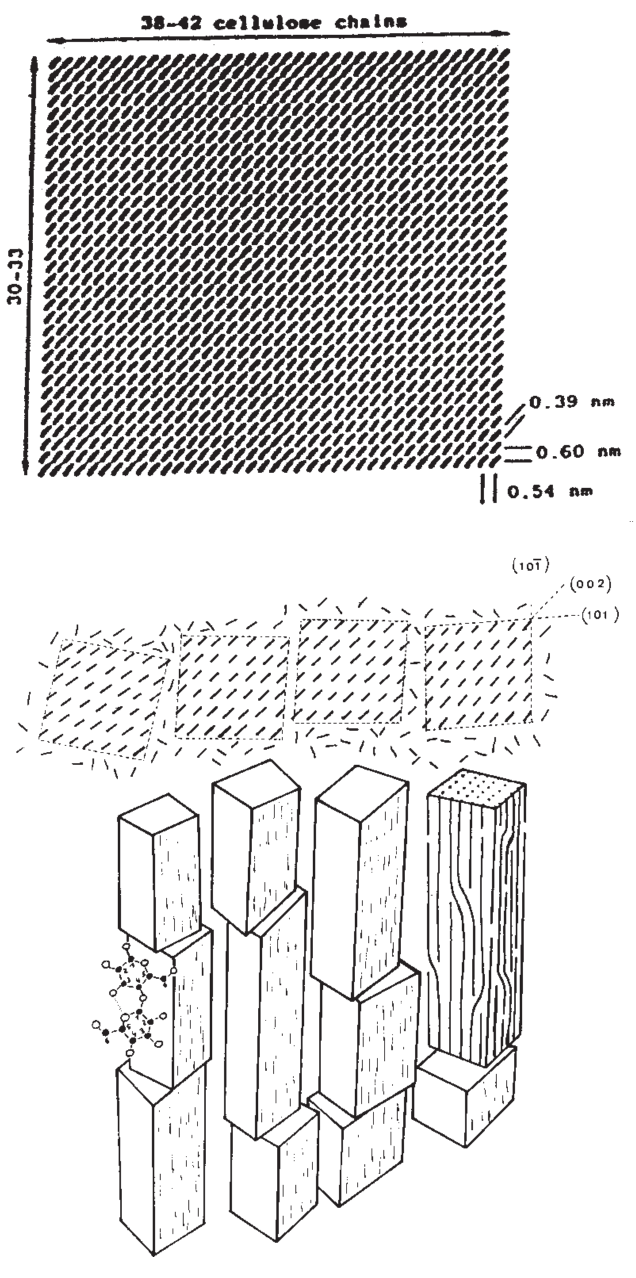

Fig. 8: Difference between models of cotton fibre elementary fibrils which are crystallographically aggregated (Ingram, bottom) and of monocrystals as microfibrils with perfectly arranged cellulose molecules (Sugiyama, top).

Using older terminology, one would probably have described these crystallites as microfibrils of differing diameter. With the aid of repeated methylation operations with diazomethane, Roberts concluded from the accessibility of the cellulose which he had measured, that on average 4 elementary fibrils bundle together, and layer to form higher units. This magnitude accords with electron microscope data from Frey-Wyssling and Mühlethaler concerning the dimension of the microfibrils. Also striking is the agreement between the measurements of an elementary fibril which have been achieved by chemical and optical methods. Mühlethaler established the diameter of an elementary fibril of cellulose as 3.5 nm, which corresponds approximately to an arrangement of 7 x 6 cellulose macromolecules in a rectangular cross section. Roberts determined the dimension of this rectangle as 8 x 12 molecules, of which on the surface of the elementary fibril, during inter-fibril swelling, 36 molecule chains are accessible for chemical reactions.

According to Sugiyama (Fig. 8), however, there are no crystalline sub-structures (elementary fibrils) in the cell wall of Valonia macrophysa, a green algae. Rather, each lamella in the cell wall consists of a flock of microfibrils, the directions of which change by 90° between neighbouring lamellae. The microfibril is a monocrystal with lateral dimensions of 20 x 30 mm, consisting of 1200–1400 perfectly arranged cellulose chain molecules. Sugiyama was also able to isolate amorphous and crystalline substances from cell walls of the green algae, and to distinguish them from one another by means of special staining techniques: here, the crystalline microfibrils of cellulose appear light, and are surrounded by the particles stained by metal salts. The encrusting matrix substances are thus brought into association with the microfibrils, so that on the one hand homogenous, stratified arrangements of micelles are formed, whilst on the other hand the micellar systems of the 2 different substances penetrate in such a way that all surfaces of the one substance are covered by the other. For this reason, the more strongly dispersed phase can develop cohesive bonding features like a type of putty substance.

If one extracts using alkali (e.g. in boiling off), then the encrusting matrix substances are dissolved and what remains is the insoluble crystalline cellulose. After Preston had already questioned the existence of the elementary fibrils as long ago as 1958, he later demonstrated that the microfibril which he favoured is surrounded – as the smallest sub-unit of crystalline cellulose – by a matrix. The matrix contains not only other polysaccharides, but also isolated cellulose chains which, although they are oriented, are not crystallised. These substances which accompany cellulose cannot crystallise at all. Nevertheless, one should not speak of amorphous areas, since this interlaying material is tightly interwoven with the cellulose crystals, whose crystallinity is not necessarily 100% either. Since, on the other hand, surface zones of the microfibrils are para-crystalline or non-crystalline, these days we no longer speak of a 2-phase model of crystalline and amorphous phases, as in the earlier Fransen micelle model. According to Sugiyama, whilst the amorphous material, which can be stained with metal salts, forms a shell around the crystalline microfibrils, so that a network similar to a honeycomb is formed (honeycomb model), this amorphous material is encrusted in such a way that the honeycomb structure of crystallised cellulose microfibrils is probably closer to a 1-phase model, even if gaps are to be observed between the cellulose crystallites and the amorphous polysaccharides. These gaps are enlarged by boiling off with alkali to form pores, so that the dye uptake correlates with the increase in pore diameter. Safaan and Habid define micropores as < 1 nm diameter, transitional pores from 2–6 nm, and macropores > 6 nm. A diameter of 1–3 nm for dye molecules is particularly effective for dye adsorption in equilibrium. This porosity in the water-swollen state has a considerable influence on the speed of chemical reactions and dyeing processes for cotton.

Taking as a basis the unit cell of Marchessault, in particular the anti-parallel arrangement of the macromolecule chains, and taking into account the arrangement – postulated by Hermans – where the anhydroglucose units which follow one after another (with intramolecular hydrogen bonds between the OH group on the C_3 atom and the pyranoside-oxygen of the neighbouring anhydroglucose unit) are slightly rotated against one another, the following sequence results for the chemical reactivity of the OH groups on the surface of the elementary fibrils: $C_6 > C_2 > C_3$.

To sum up, we can state the following:

1 cotton fibre = 15 000 microfibrils
1 microfibril = 400 elementary fibrils (aggregated crystallographically)
1 elementary fibril = 100 cellulose chains arranged in 6–8 packages
Diameter of macrofibril = 400 nm
Diameter of microfibril = 200–300 nm
Diameter of elementary fibrils = 3.5 nm

In the inter-fibrillary spaces of 5–10 width, lignin – amongst other things – fills in as a "cement". The intermicellar spaces of 1 nm located between the elementary fibrils are accessible to H_20, $ZnCl_2$ or I_2, but not for dyes (unless the pores are expanded through boiling off with alkali). Macroscopically, this structure peaks in the texture of the secondary wall, which is surrounded by the thin primary wall (Fig. 9).

The mechanical properties of the cotton fibre depend on this supra-molecular structure; the mechanical stability of the fibre is reduced by chemical cross-linking. The initial stability of the fibre can be increased by more than 10%, so that certain unavoidable losses of stability are of barely any consequence. A corresponding method works as follows:

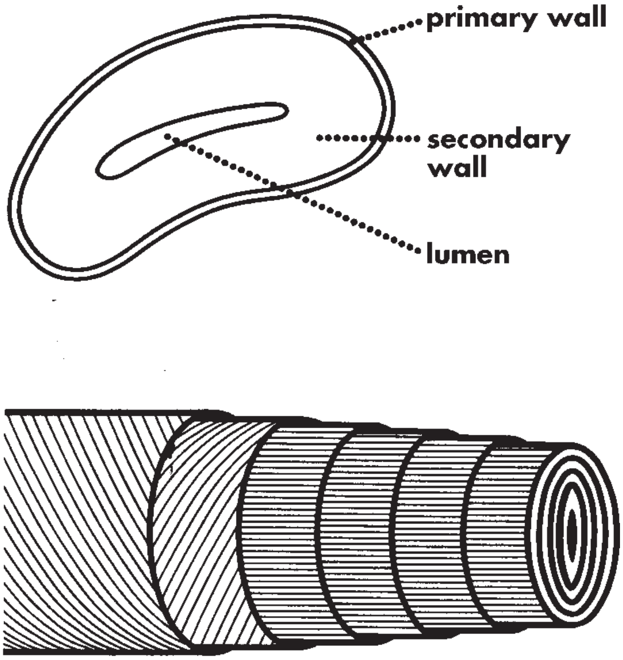

Fig. 9: Model of a convolution-free cotton with its primary wall removed (bottom). The daily secondary wall rings follow on the transition lamella consisting of two opposed layers. Growth in thickness occurs from outside to inside starting from the primary wall (top).

The fibres are treated in mercerisation lye, in the course of which they shrink as usual. Before the fibres are washed out, they are stretched to the original length. The stretched fibre is rinsed, dried and fixed at 120°C. In this way, the typical kidney-shaped cross-sectional shape changes into a round shape, and in stereo-scan electron microscope images, the new fibre is shown to be an even cylinder with a smooth surface. The unwanted bilateral structure is eliminated, and the cross-linking can proceed more smoothly from a macroscopic point of view.

But the fine structure of the fibre has also changed during the treatment, benefiting the stability of the untreated and/or cross-linked fibre. If one takes the 1-phase model of cotton as a basis, the following picture results: The elementary fibrils running parallel in the fibre show differing contact points. Either they are crystallographically aggregated, or they are held together via non-covalent physical interaction (hydrogen bonds, van der Waals forces). The greater the number of these lateral contacts, the lower the possibility of one elementary fibril slipping off from another when subjected to tensile stress or compression load; furthermore, an acting force can be distributed more evenly over the fibre from fibril to fibril. A concentration of

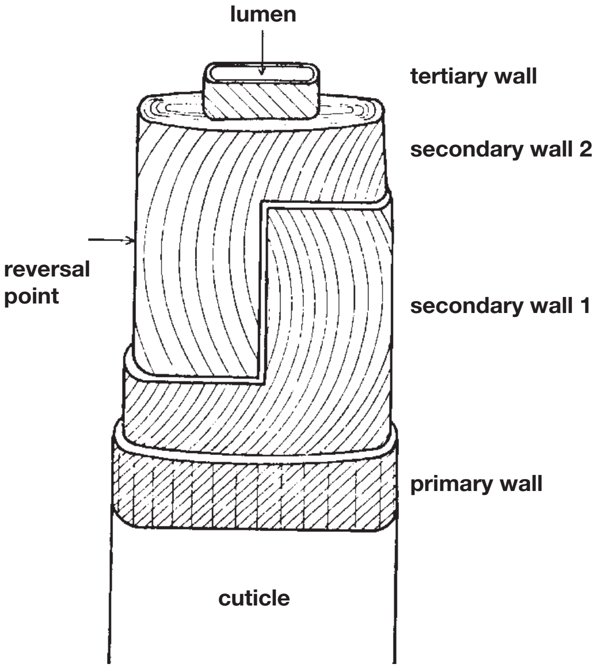

Fig. 10: Sematic model of the cotton fibre with structural reversal points.

the forces will however take place at the point at which a slipping-off of the elementary fibrils is possible due to an insufficient number of contact points between the elementary fibrils. This point (“structural reversal”, in Fig. 10) is the weak point in the system. Here is where the starting point of any tear in the fibre lies, which from this point then progresses fairly regularly along a neighbouring fibril longitudinal axis (Fig. 11).

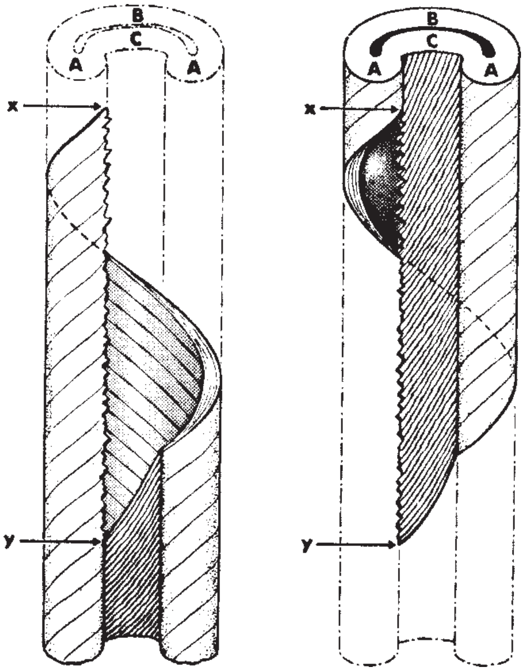

Fig. 11: Fracture along the fiblar longitudinal axis of a cotton fibre (Hearle).

The strength of a fibre thus essentially depends on the regularity (and also of course on the number) of the contacts between the elementary fibrils. The random irregularities that occur during the growth of the fibre would probably be tolerable in this respect if they were not emphasised through the first collapse of the fibre when the seed capsule bursts open, and the associated drying. This can be counteracted either by the production of cotton varieties which have a less pronounced bilateral structure, or by compensating the differences in the packing density of the fibrils which exist in the fibre by means of processes such as mercerisation. Such a homogenisation of the fibre structure prevents the situation where – despite optimum cross-linking in relation to the evenness of the finish -one accentuates those differences which exist in natural untreated cotton, thus causing great losses in stability. For whilst if, in the areas of the firm, untreated cotton, a slippage of the elementary fibrils (even if limited by the unevenness of the fibre) when a force can help to distribute the load a little, by cross-linking the fibres one forces very tightly defined areas to take the entire strain.

The most direct way of achieving a re-packing of the elementary fibrils consists in swelling the fibre up to a cylindrical shape, which was originally set for it during biosynthesis. Through suitable re-crystallisation of the fibre cylinder, this form must then be fixed in order to prevent renewed collapse. There is a pre-treatment process which was developed for yarn by the English firm Coats (Prograde method) and for woven fabric by Norwegian researchers, and which is technically applicable. It involves pre-treating the fibres with liquid ammonia, in which an improvement in the stability of the cotton fibre is likewise achieved (even if not to the extent of mercerisation), so that the subsequently cross-linked woven fabric still demonstrates better stability than the untreated woven fabric. If one treats cotton in this way, a strong swelling occurs, in which H-bonds of the cellulose are split (→ Hierarchical fibre structure).

Cotton fibre tufts Short cotton tufts, coarse, very stiff, more or less coloured. They are found at the pointed narrow end of the cotton seed, and frequently occur in clusters in neps. Cotton fibre tufts can only be separated from the cotton seeds with difficulty and normally require ginning that results in seed shell fragments, in which they are firmly anchored, being found with them. Even after boiling that dissolves the seed shells, the cotton fibre tufts remain spun into the yarns as burls.

Cottonized flax By → Cottonizing of → Bast fibres with a cotton-like short staple is produced with high strength and linen- to silk-like handle. Due to their smoothness, they are usually used in combination with other fibres (cotton, spun viscose, wool etc.), in the cotton spinning system. They are especially suited to fabrics that are very hardwearing and wash-resistant. → Mulberry cottonized bast fibre.

Cottonized mulberry bast fibre → Mullberry cottonized bast fibre.

Cottonizing "To make similar to cotton", i.e. cottoniszing → Bast fibres. Term for chemical retting by alkali scouring for example or acidic chlorine bleaching, the result being the exposure of individual fibre cells cemented and bundled by vegetable glue, which are spun by the 2 or 3-cylinder spinning process into yarns like cotton (→ Cottonized flax).

Cotton maturity index Important factor in evaluating the average stage of development of a cotton quality (→ Green unripe cotton). Due to the use of mechanical pickers, the proportion of immature, abnormal fibres has increased. Determining this proportion is important, since the immature fibres result in a reduction in the quality of the textile goods. The maturity index in accordance with DIN 53 943 indicates the proportion of the number of mature fibres to the total number of fibres in the sample.

Test method:

1. Microscopic procedure, swelling with soda lye: action of 18% NaOH: The assessment is made by assignment to one of the two groups "mature" (cylindrically swollen fibre), or "unripe" (tightly twisted fibre) and/or "dead" (thin-walled, remaining flat) under the microscope.
2. Causticaire method: Determination with the aid of an air flow test device with a causticaire scale. The air flow through it is determined before and after the sample has been treated with NaOH; the so-called causticaire value is calculated in % from the two values.
3. Microscopic method under the polarizing microscope: The interference colours observed on the fibres under the polarizing microscope depend on the specific double refraction of the fibre substance and on the optical thickness of the fibres. With the same fibre substance, the height of the interference colour is a measure of the differing wall thickening. A direct value for the maturity index is obtained.

Cotton Press International Cotton Council International's information office for the processing of cotton; → Technical and professional organizations.

Cotton resist agent →: Retarding agent; Immunization.

Cottonseed oil Density at 15°C = 0.92–0.93. Half-drying oil of shelled and pressed cotton seeds. External features: light yellow, typical odour; raw: reddish brown, odour/taste bitter/rank, saponification number 191–198 (unsaponifiable 1.7%). Without an emulsifier, blown cottonseed oil produces a highly resistant and consistent, slightly soap-like emulsion; reoxidation and rancidification should be excluded. Desize with water at 50°C. Used for oil sizing.

Cotton waste → Linters.

Cotton wax Constituent of raw cotton (→ Raw cotton composition) at 0.4–0.8%. Melting point 70–75°C, saponification number 65. In particular free → Fatty acids of higher molecular weight ([carnuba wax alcohol-] fatty acid ester), 50–55% free, unsaponifiable high molecular alcohol and hydrocarbons. Accordingly around half can be removed by hot alkaline liquors (kier boilings) via saponification. The rest is insoluble and only emulsifiable.

Cotton with natural green colour → Green unripe cotton.

Cotton wool In compliance with DIN 60 000: loose mass of fibres, usually built up in layers (of nonwoven fleece) and condensed, made of fibrous material open to a single fibre, whereby the fibres are held together only by their natural adhesion. Application: upholstery padding; industrial padding (RAL 319 A); glued wadding (glued on one side) for wardrobe inserts; medical padding (DIN 61 640) for bandage and surgical dressings.

Coulomb Physical unit for the quantity of electricity flowing through a conductor in 1 s with a current of 1 ampere. It follows that:

Coulomb = ampere x second

This unit is therefore independent of the electrical potential (volts). The electrochemical equivalent is the amount of electricity required to deposit one (gram) equivalent in electrolysis. According to Faraday, this is 96 500 Coulombs:

1 Faraday (F) = 96 500 Coulombs = 26.81 ampere-hours.

Coulometry allows organic substances to be determined by measurement of the amount of electricity required for their reaction, and so allows Faraday's Law (96 500 coulomb of electricity is needed for the electrolytic deposition of one equivalent) to be applied to analysis. Coulometry used for the determination of organically bound carbon, of adsorbable halogens and of adsorbable, organically bound sulphur depends on the same measuring principles in each case: the gases produced from burning a sample in a stream of oxygen in an infra-red oven are led into an electrolyte. There they react with a part of the electrolyte and so reduce its concentration in the solution. The electrolyte that has been used up is regenerated electrochemically to get back to the original concentration. The amount of current needed for this is proportional to the amount of gas produced and therefore also to the element to be determined in the sample. In coulometry the amount of electricity takes the place of the "titrating agent" . The big advantage of this type of detection is that no calibration is needed.

Counter coat process → transfer coating.

Counter current In drying: the drying medium (hot air, steam, hot gases etc.) flows against the direc-

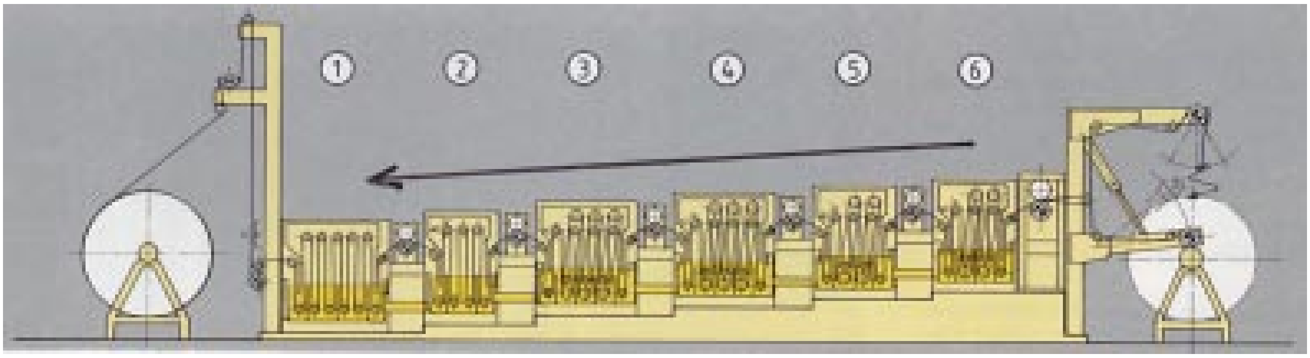

Fig.: Arrangement of 6 roller vats in the counter current principle (fabric flow = left to right; water flow according to the arrow).

tion of the fabric movement (→: Uniflow principle in drying; Circulating air drier). In scouring: the scouring liquor flows against the direction of the fabric movement (→ Counter current washing process).

Counter current principle Diffusion-controlled processes such as scouring are affected both by temperature and an existing concentration gradient. In an open width wash range, it is preferable to bring the clean, fresh detergent solution into contact with the goods being processed at end of their dwell in the range so that the cleanest process liquor meets the cleanest goods in process (see Fig.). By using a counterflow system, the goods first entering the range with the highest level of soiling meet the process liquor with the highest rate of soiling and this soiling is then carried out of the system by the liquor flow. It is necessary to ensure sufficient detergent is used to maintain the efficiency of the scouring process in the first tank. The counter current principle is also used in single-vessel systems (e.g. goods moving from below upwards, solution from the top down) and in the movement of fabric and energy in air currents (when drying).

Counter current washing process Continuous → Flow washing plant with counter-current water supply (bath current) and fabric transport: water supply in the last spray zone and drain-off in the prewash section. Counter current washing processes allow savings in water usage and optimisation of detergent and heating energy. In principle, a series of separate but interlinked machines with phased washing output, either with up to 12 washing units in a double row (individual machines back to back) or in circular layout in series as a carousel (washing machines in the form of frontal washers or Pullman type), on a turntable with localised charging. In the latter case at each phased change all washing units move one stage forward, each washing unit passing through all stations and returning to the start, which is both loading and unloading station. The phase duration depends on the number of machines; in the case of household washing of average soiling 4–8 min. Further developments have led to → Continuous washing plant.

Counterpile rollers The actual raising rollers in the → Raising elements of raising machines.

Counting glass → Piece glass.

Counting tube → Radiation meters.

Couple, to Operation in dyeing: the bottomed naphthol colour is coupled to the dyestuff with diazotised azoic base or the dyeing salt.

Coupling components → Developer.

Coupling of dyeing machines Dyeing machines are coupled in order to extend the capacity of existing dyeing machines, e.g. for large batches. This can be done by parallel coupling or cross-coupling. Existing valves can of course be regulated in such a way that each machine can also operate individually (i.e. uncoupled).

Only machines with identical capacity, identical pump characteristics and identical heating systems should be coupled. Classic cross-coupling (Fig.) is worth while as long as the operation is carried out with a low bath circulation and at low heating-up rates. As we know, bath circulation, heating-up rate and dye exhaustion behaviour have an orderly relationship. When

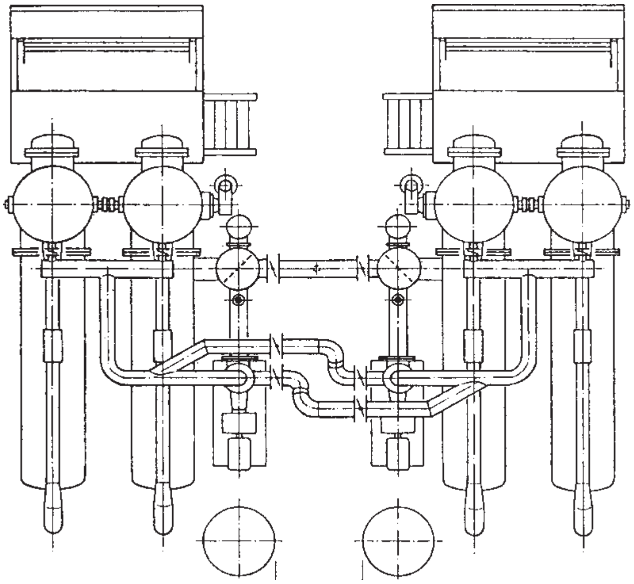

Fig.: Cross-coupling of overflow dyeing machines.

coupling by means of cross-piping, the pumps are located one behind the other, thus halving bath circulation. The consequence of halving batch circulation is that level dyeing can be achieved if the heating-up rate is also halved. If we assume that the heating-up rate is largely utilised up to the maximum possible in individual dyeing operations, the problem of cross-coupling becomes apparent.

If individual and coupled batches are to be treated by the same programme and under identical conditions, the parallel coupling system is offered as an alternative. With this coupling system, the pumps remain in parallel, and the bath circulations are adapted to the size of the batch. Two equal sized machines with identical pumps and heating systems, located close by each other if possible, are linked via a mixing chamber. The liquor of the two machines flows through this mixing chamber relative to bath circulation frequency, and pressure is equalised. Four cut-off units per machine prevent liquor from passing from one machine system to the other in individual dyeing operations. Since the mixing chamber is located between the four cut-off units, this chamber is provided with a drain, which is open for individual dyeing operations, and closed for coupled batches.

Couplings A connection between two coaxial shafts to form one length of shafting and to transmit torque, e.g. from one shaft to another, to gear wheels, pulleys etc. Often also used to transmit power to a machine tool from a motor. They basically consist of two halves connected together by frictional contact or positively (by bolts, claws, springs, teeth). The form of connection depends on what purpose it serves. A bolted coupling is solid and rigid, a claw coupling is positive without being rigid, and flexible couplings are formed by rubber, plastics or sprung steel. Couplings intended for engagement and reengagement during use are termed clutches or release couplings forming a positive connection. These are for use in suituations where a shaft needs to be temporarily stopped or there has to be a change in speed or in direction of rotation.

Course counter For counting the number of courses in → Knitted fabrics.

Because the loops of the courses are aligned three-dimensionally by the hooks in the production of knitted fabrics, the stitch structure can be observed in finishing quality control by optically photocopying these "highlights" by radiating them with light (Fig. 1).

With the Tube Tex "Stitchcounter", an instrument for the quality control of knitted fabrics on running on a shrinkage line, the fabric is illuminated by point light and photographed by a video camera with the aid of a stroboscope (Fig. 2). With the aid of software, the entire background can be filtered out in order to photocopy only the "highlights" – the uppermost tips of the wales and courses of the fabric - on the screen. From this image, the stitch density is calculated in order to obtain a quality standard. "Highlights" are therefore projecting occurrences which it is effective to filter out from the noisy background.

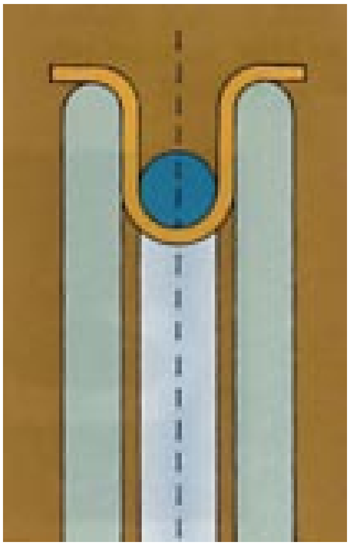

Fig. 1: Interaction between a knitted fabric loop and luminous radiation.

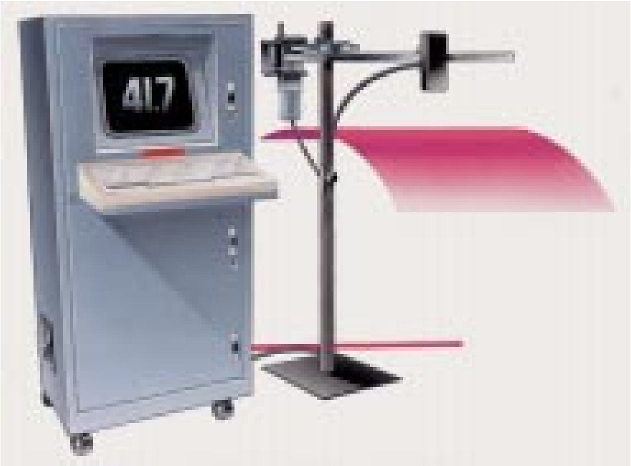

Fig. 2: Tube Tex Stitchcounter (knitted fabric course counter).

Covalent bond → Atomic bond.

Covercoat (Overcoat). Warp generally mouliné twist (which gives a finely mottled appearance) from worsted yarn or carded yarn, weft also made of worsted or carded yarn. In the past, fine covercoats were manufactured from super-fine spun carded yarns with a fine napped finish. By comparison, today's worsted covercoats are generally napless or have a melton finish with a carded yarn weft. Weave: 5-harness reinforced satin. Similar to a gabardine in appearance. Uses: men's coats and rainproof jackets (frequently given a waterproof finish).

Covered yarns Elastomeric yarns covered with continuous filament synthetic yarns or with spun natural fibre yarns of mixtures with synthetic yarns. Not to be confused with (→ Core-spun yarns), in which the elastomeric yarn is spun together with natural or synthetic yarns.

Covered yarns have the following uses:
- hosiery: tights, stockings, socks, men's knee socks;
- clothing: waistbands, gymnastic clothing, ski clothing, underwear, foundation garments, general sportswear;
- technical uses: automobile industry (upholstery); medicine (bandages, surgical stockings); paper industry (reinforcement material for paper felt); protective wear (military uses: nuclear- or gas-protection; special carbon fibre core with sheath made from synthetic or natural fibre), fire brigade, steel industry: as protection from heat; glass with aramide fibre sheath; abattoirs, woodworking: steel core with sheath made of kevlar filaments; space technology, high-temperature protection: quartz or ceramic core with sheath made of synthetic filament yarns.

Yarns for clothing and technical applications (e.g. automobile industry and medicine) usually contain an elastic core. Covered yarns for hosiery and clothing necessitate the production of a dual-component yarn for core and sheath. The core is normally an elastomeric, either a synthetic elasthane or a natural rubber product. The sheath consists of a textile yarn, normally synthetic filament yarns; but there are also products with synthetic and natural fibre spun yarns. The synthetic filament yarn may be either flat or textured and may, depending on its final use, be made with either a single or a double cover.

The most active branch of the covered yarn industry is the market for ladies' hosiery, especially in the USA where it is twice as big as in Europe. Whilst demand in the US was originally for products with fine titres and double sheaths, in the last few years it has developed into a market for practically 100% single-sheath products.

Growth is now in air jet sheathing because of the cost per kg. It is estimated that 50% of the 1500 mill. pairs of ladies' stockings manufactured annually in the USA have an elasthane core:
- 3% with double covering,
- 36% with single covering,
- 10% with air jet covering and
- 1% without covering.

Around two thirds of them have a sheath of textured polyamide 6.6 and the other third of flat filament yarn. The trend is towards flat yarn and away from textured yarns for covering, except for air jet covering, in which textured yarn is currently used. Developments in the field of polyamide 6.6 support this trend. Thus for example DuPont's product with greater strength and lower flexural modulus and other microfilaments are the reason for the trend away from textured yarn for covering in ladies' hosiery; another reason is less twisting (according to I.C. Dupenble).

Cover factor (CF),

I. Knitting. A term used for the comparative assessment of knitted fabric density. The cover factor CF is calculated from the number of knitted courses c, the number of knitted wales w, and the yarn count Nm.

$$CF = \frac{c + w}{\sqrt{Nm}}$$

Alternatively, the density coefficient, D_{coeff}, which is given by the stitch length l (in cm) and the yarn count, can also be used:

$$D_{coeff} = l \cdot \sqrt{Nm}$$

There is a linear correlation between the two. The cover factor is important for the shrinkage behaviour of knitted fabrics during washing. An inverse relationship exists between the CF and the shrinkage in surface area, i.e. the higher the cover factor (knit density) the lower the shrinkage in surface area.

II. Weaving. The cover factor (CF) is a figure indicating the extent to which the area of a woven fabric is covered by either the warp or weft (filling) threads. It is the ratio of fabric surface occupied by yarns to the total fabric surface. Thus for any woven fabric two cover factors are involved, i.e. the warp cover factor and the weft (filling) cover factor.

Covering layer (covering zone, covering effect, skin effect, fibre sheath). A microstructural outer peripheral zone with a physical behaviour differing from that of the fibre core is familiar in various man-made fibres. Differently distributed packing densities in the fibre cross-section entrain far-reaching consequences, particularly in swelling behaviour terms, in dyeing processes (e.g. the retarded dye uptake rate of viscose as against copper fibres) and other intercalation reactions. A denser covering layer, where molecules have preferably to be oriented parallel to the fibre surface, is further demonstrated by polyamide 6.6. for example. In → Silk structure, we also talk of a covering layer in terms of the outer layer zone of degummed fibroin filaments. In the case of viscose fibres, covering layer formation starts as early as in the spinneret (reduced flow rate in consequence of friction at the spinneret rim). In the precipitating bath, during compaction and shrinkage in the fibre core, there follows much quicker coagulation of the outer zone, surface crystallisation being further encouraged, its extent, in the extreme case of stretch spinning, resulting even in a hollow fibre interior. Crystallite orientation in the covering layer begins with the stretching itself.

Cover roller → Blotch roller.

CPB → Cold pad batch dyeing.

CPB (cold pad-batch) liquor stability calculation programme Calculation, developed by Hoechst, of the stability of alkali-reactive dye padding liquors. Following input of the processing parameters and the hydrolysis and temperature constants, the concentration of active vinyl sulphone in the padder trough is calculated by means of a computer programme, preventing any shading occurring due to hydrolysis.

CPB jet dyeing processes Dyeing processes for woven polyester/viscose fabrics, in which a soft, wool-like handle is to be achieved. Cellulose fibres are predyed with vinyl sulphone dyes (reactive dyes) by the PCD process, and the polyester fibres then cross-dyed with disperse dyes in an HT short liquor jet.

Cr, chemical symbol for chromium.

Crabbing Preparatory process for undyed woven fabrics (e.g. ladies and menswear fabrics in worsted, Cheviot and mohair) a) for setting the cloth to restrict excessive creasing and felting in subsequent dyeing, and b) for removing oils and additives. In the case of dyed fabrics, for smoothing and evening out running (rope) marks after dyeing. Undyed fabric after washing is wound under tension onto a roller or in the → Crabbing machine in water at approx. 60–80°C (with the possible incorporation of wetting or cleansing additives). After 10–30 min. dwell in the hot water the cloth is allowed to cool in the roll, or is cooled down rapidly in open-width by cold water, or whilst still warm is immediately rewound onto another roller and allowed to cool. → Wet decatizing.

Crabbing fastness → Fastness to hot water.

Crabbing jack Serves for → Crabbing wool fabrics and mixed fabrics for the purpose of stabilising the dimensions (length and width) as well as immunisation against felting in the subsequent dyeing process. For this, the run of fabric is wound onto a fixed batch roller, which dips into the liquor. Depending on the desired effect, the wound roller rotates for a shorter or longer time in the boiling liquor, and after the process has ended, it is stripped hot or cold (flat-folded or wound up).

Crabbing machine → Crabbing.

Cracking of thickener films If the thickener film placed on the material is not flexible enough it may have a tendency to crack when the dry material is being transported, particularly if hydrophobic fibres are being used. The cracks deposit themselves on the material and lead to dye specks on the material that cannot be removed.

Crackle effects Specific colour effects on woven fabrics, which consist of polygons combined in rows and thin, and from time to time also intersecting, lines, like "splintered" glass or a "broken" glaze in the case of pottery. Produced for example by the → Bubble coloration process.

Craquelé (→ Cloqué). Fabric with relief texture woven with synthetic fibres. Generally produced by mixing high-shrinkage and low-shrinkage synthetic yarns woven in fancy design, the effect being obtained by appropriate finishing. At high temperature (in hot aqueous solution or steam atmosphere) the high-shrinkage yarn contracts and acting in association with the low-shrinkage yarn produces the relief effect. Similar effects can also be obtained by topical application of fibre-swelling or fibre-contracting agents (alkalis, phenols, cresols etc.).

Crayons → Copying ink pencils.

CRB, abbrev. for: Centre de Recherches de la Bonneterie (French Research Centre for Knitwear and Hosiery), Troyes, France; → Technical and professional organizations.

Creaming Term used to describe the upward sedimentation of an oil-in-water emulsion. → Coalescence.

Cream of tartar → Potassium bitartrate.

Crease formation This subject falls within the category of deformations where a distinction has to be made as to whether these are present in a superficial or a substantial form. Whether a permanent distortion forms or not is dependent on the geometry and the friction (superficial form) as well as on the stability of the structural state (substantial form). The entire problem of crease formation is exclusively a question of → Relaxation. Consequently, materials in unstable states are quite easily deformed. Since the relaxation is dependent on time and temperature, process selection and control as well as the correct stabilization of the material are of decisive importance. As soon as a fabric is produced the possibility exists for creases to form: in laying-up, plaiting down and during storage in general, during transportation, and in dyeing and finishing through careless treatment. The fabric is particularly at risk when subjected to wet finishing processes in rope or tubular form. Shrinking can also form creases, which calls for particular attention when developing crimp during the relaxation of textured knitgoods. It should also be mentioned that if dye liquors are cooled down too quickly after dyeing this can also encourage the formation of creases.

A permanent crease in a two-dimensional material is formed by the irreversible shifting of structural elements. The likelihood of the components of a fabric to undergo displacement is encouraged amongst other things by a loosely woven construction, a floating weave and the slight extension of continuous warp and weft threads. Knitgoods exhibit less tendency to form creases than wovens, and is likewise dependent on the structure. Knitgoods are produced from single yarn structures, whereas wovens are built up from two independent yarns. A knitted structure reacts to a deforming influence as a coherent system which can adapt itself and then recover again. This is not generally possible with wovens. On the one hand, there is a lack of extensibility and, on the other hand, the weft and warp behave like two more or less independent systems. Moreover, the thicker the fabric, the greater the deformation into a crease and vice versa, thus creases are more likely to be prevented in a fine fabric than in coarse cloth. Lastly, fibre also plays a role during creasing which is not insignificant. The fibres are subordinate to the weave structure, knit structure and yarn structure and follow the deformation of the fabric, but nevertheless behave in accordance with their physical properties towards mechanical influences. Their behaviour can either be of an elastic or plastic nature and, in borderline cases, destructive phenomena may be involved.

Crease-free dyeing of tubular knitgoods Semi-continuous dyeing process for cotton and cotton/viscose tubular knit goods for crease-free dyeing with reactive dyestuffs according to the pad-roll dyeing process. After the dye liquor application in the pad trough, there follows compressed air injection and inflation of the fabric tube before squeezing and winding onto the perforated cylinder where the fabric will dwell (2–6 hours). Washing then follows on the same perforated beam.

Crease permanence → Pleat resistance.

Crease recovery angle (uncreasing angle). Dimension for determining the effect of non-crease finishing (→ Crease resistance). It is a measure of the recovery power of a fabric. It is the angle which results after a specific time when a straight yarn test specimen, folded through 180°, is released after prior loading. In contrast, the angle achieved in immediate back spring is described as the immediate crease recovery angle. A distinction is drawn between the wet and dry crease recovery angle and the measuring process, depending on test set-up with upright or hanging free end (DIN 53 890 and 53 891).

Crease resistance (fastness to creasing). Resistance of textiles to → Creasing in terms of wet and dry crease resistance. Not only measurement of the wet and dry crease recovery angle, but also the actual wash and wear behaviour of a woven fabric is used for qualitative assessment. Temperature, air humidity, period of loading and recovery time have a great effect.

Crease-resist finishing → Anti-crease finish.

Creasing Sensitivity of individual fibres to continuous flexure, creasing, pressing, squeezing across the fibre direction, in woven fabrics transversely to warp and weft ends. Assessment by the so-called → Crease recovery angle or creasing angle. It is dependent on fibre structure, mechanical fibre properties, fibre water content and swelling, fibre air content, type of yarn and fabric structure (count, twist, torque, yarn density and construction) plus the type of finish.

Creasing angle →: Creasing; Crease recovery angle.

Creasing behaviour of cellulose fibres As with the mechanical characteristics, the tendency to crease also depends on the macromolecular structural features of the fibre. The dimensional stability of a fibre depends on the arrangement of its structural elements and the forces bonding them. In the case of the cellulose chain, the individual glucose components are bonded covalently with each other via a glycosidic oxygen bridge. The bonding of cellulose chains with one another is made possible by van der Waal forces and by the development of hydrogen bridges. The forces acting from outside in system deformation tend to break existing bonds. If the latter resist this influence, full recovery to the initial position occurs when the load is removed. Residual deformation (creases) stems from irreversible bond changes, as may occur in the slipping of fibrils and molecules by hydrogen bridge fracture. Of importance in the crease behaviour of cellulose fibres is the degree of orientation, which describes the proportions of amorphous and crystalline zones. The creasing tendency rises as the polymer degree of orientation increases. The degree of orientation also has an effect on the creasing tendency and strength of polynosics.

Bending a cellulose fibre leads to a change in bonding angle. The material is stretched on the outside, and compressed on the inside. Recovery is a function of the condition of reversible and irreversible deformation, and is dependent on the dimension and duration of the acting force. Deformed fibres return to their initial position with the aid of stored energy; rupture of hydrogen bridges allows the polymer chains to slide. In the deformed state however, newly formed hydrogen bridges oppose recovery when the load is removed. Similar importance is to be attached to the van der Waal forces, which do not withstand a specific tensile load, and which are reoriented following chain slippage. As soon as some irreversible deformation occurs after fibre bending, a new force equilibrium sets in when the load is removed, preventing complete return to the initial position. Crease recovery is therefore incomplete.

Creasing inhibitors Textile auxiliaries for the prevention of → Running creaser, especially when dyeing in rope form.

CRECIT, abbrev. for: Centre de Recherches d’Essai et de Contrôles Scientifiques et Techniques pour l’Industrie Textile (Scientific Technical Research Centre of the Belgian Textile Industry), Tournai, Belgium; → Technical and professional organizations.

Creel system for dyeing machines Device for permitting liquor circulation with reloadable magazines containing the material carriers.

I. For festooned yarn hanks with box magazine, into which rods are placed on which the yarns are suspended. Once the doors are closed, the conveyor unit transports the yarns into the dyeing tank.

II. For cones and cheeses with feed apron or box magazine, which contains vertically fitted, perforated bobbin holders (hollow or channelled spindle) for stacking the material.

III. For cones and cheeses with beam-type magazine, which is a warp beam, into the axially drilled holes of which perforated bobbin holders are screwed.

IV. For cheeses with porcupine-type arrangement of the dye packages on the outer shell of the dyeing cylinder, similarly to III. Alternatively, for cheeses or warp beams combining systems III. + IV.

Crêpe (Lat: crispus = puckered). Textile fabrics with a typically wavy, grained or puckered surface (patterned). A distinction is made between:

I. So-called true crêpe produced by weaving with → Crêpe yarns, where the weave, type of material and finishing effects combine to create the crêpe effect. In this case, the crêpe is formed by crêping, where contraction of the extremely overtwisted crêpe yarn systems takes place as a result of swelling in a hot, moist state. Fabrics produced in this way include numerous types of so-called fashion crêpes (type: bark crêpe and hammerblow) and the woven crêpe constructions (e.g. crêpe jersey or sand crêpe). Typical types of crêpe generally contain, in at least one direction, a crêpe yarn system produced from highly overtwisted yarns in alternate S and Z twist (type: crêpe de chine), preferably in the weft and less frequently in the warp. Fabrics of this type include crêpe chiffon, crêpe chinette, crêpe cloqué, crêpe craquelé, crêpe flamenga, embossed crêpe, crêpe iris, crêpe orientale.

II. So-called false crêpes, including → Woven crêpes and certain smooth fabrics with embossed designs such as embossed crêpe and crepon printed effects produced by localized caustic soda treatment, etc.

Crêpe Charmeuse A fine, soft (as well as stiffer) crêpe in twill or plain weave (one warp and two weft systems, i.e. a crêpe backing weft and a crêpe face weft). The face exhibits a satin crêpe effect, and the reverse a shaded crêpe effect. Use: for elegant womenswear.

Crêpe chiffon A printed, true crêpe with a chiffon character.

Crêpe cloqué → Cloqué.

Crêpe de chine,

I. (Yarn). A silk yarn made from raw silk filaments with a more or less left-handed twist which have been very sharply twisted together to the right.

II. (Material). A soft, supple dress fabric in plain weave with e.g. a raw silk warp and a crêpe weft (produced from two S and Z highly twisted alternating yarns). It is usually either piece-dyed or printed.

Crêpe façonné A crêpe fabric with small woven patterns, → Façonné.

Crêpe Flamisol A so-called matt crêpe fabric made from e.g. a warp delustred in spinning and a crêpe weft.

Crêpe Georgette A fine, matt crêpe fabric, similar to voile (gauze-like). It has a fine irregular surface with a grainy, dry, firm handle. The warp and weft consist of highly overtwisted crêpe yarns (ply yarns), with alternating pairs of S and Z twist yarns in a plain weave construction. The fabric is tightly woven but nevertheless transparent. It is dyed in the piece or printed. Uses: blouses, dresses, skirts, gowns and millinery.

Crêpe Gloria A crêpe fabric having pleat-like lengthwise folds in a plain weave construction.

Crêpe Jersey A crêpe fabric resembling jersey-knit produced in a plain weave construction (with a crêpe weft consisting of 2 Z-twist and 2 S-twist yarns) used for womenswear fabrics.

Crêpe lavable A more tightly woven example of an easily washable crepon or crêpe de Chine with only a slight crêpe effect.

Crêpe Marocain A light, finely ribbed, puckered crêpe (similar to crepon or crêpe de Chine) with a crimped, grainy surface, (slightly wavy weft), in plain weave, also patterned (jacquard fabrics).

Crêpe Marocaise A lustrous crepe comprising a viscose warp and viscose filament or spun yarn or crepe wool crepe yarn weft, lightly crimped appearance in taffeta or rib weave.

Crêpe Mousseline A transparent, light crêpe fabric with a wool-like character produced in a so-called sand crêpe weave.

Crêpe ondé A crêpe with yarns consisting of folded crêpe yarns with chemically spun viscose slub filaments.

Crêpe piqué A matt crêpe fabric with a piqué-like character.

Crêpe prepared by steeping in caustic soda Treatment by local causticisation of mainly woven cotton fabrics with concentrated caustic soda, in which locally shrunk and therefore – on untreated sections – crimped areas produce different types of crêpe effects, which are also described as crimp crêpe. These types of process are technically extraordinarily good value, and make interesting dyeing effects etc. possible.

I. Lye printing process: on cotton muslin (27 warp ends/24 picks), which is well desized and bleached so as to be easily wettable, thickened caustic soda is printed in accordance with the pattern by a roller printing machine. Hot treatment with 0.5–1 g/l of sodium metaphosphate prior to printing has a beneficial effect. The viscosity of the print paste has a marked effect on the crêpe appearance, for excessively thin print paste is squeezed out into unprinted places, while excessively thick print paste produces too narrow stripes. Plaiting down is followed by a maximum dwell time of 30 min. for exothermal swelling and shrinking; here, any temperature increases must be watched for (they can lead to charring of the piece) in order to be able, if possible, to intervene if necessary by ventilating the pieces. Lengthwise contraction should be approx. 15%, and width contraction about 18%. Further treatment must follow with care and without tension or pressure, i.e.

neutralising with diluted hydrochloric or sulphuric acid in rope form in large washing vats, rinsing in running cold water up to neutral reaction, rinsing off with formic acid for a good handle, gently centrifuging, plaiting down and drying in festoon dryers, and then pulling out to the correct finished width on a single level stenter with intensive steaming. The woven fabric to be printed can also be predyed or printed with lye-resistant dyes, or these dyes can be added to the lye print paste.

II. Resist process: a thickener which resists caustic soda is applied by roller printing in accordance with the pattern, a causticising passage following on the padder. The process permits storage of the piece for as long as necessary before the causticising passage, i.e. no synchronisation is necessary between printing and washing off. In addition, operation is more reliable, eliminating rapid and expensive printing machine back grey wear, but against which costs are higher due to the high thickening agent consumption. Predyeing can be effected with lye resistant dyes prior to resist paste application. Indirect heating of the printing trough to 80–90°C by means of a steam coil is recommended for good penetration and bilateral reservation on account of the large quantity of resisting agent dry substance. If dye has been added to the resist paste, the print must be fixated after the printing process, otherwise an open-width passage through 24–35% caustic soda ensues at 18–20°C on a two-roll padder, or slop padding with a picotised roller on the printing machine. Another possibility is to dry rigorously after resist printing, carrying out the lye treatment if necessary. Further treatment is similar to the lye printing process. Used as resisting agents in addition to rubber thickeners are synthetic resin condensates, to which dyestuffs and white and dye pigments etc. can be added. In this case, causticizing is preceded by drying, calendering and curing. One variant is provided by a combination of the above-mentioned mechanical resist with a chemically acting one which prevents the shrinking action of the caustic soda in the sense of a neutralising process; to this end, acid salts or solid organic acids, which require careful selection, can be used in order to prevent granular precipitation in the preparation of an absorbent printing paste.

Crêpe reversible A fine, double-sided, patterned crêpe fabric (produced mainly with jacquard effects); the face is e.g. matt with a crêpe character and the reverse is smooth and lustrous (similar to satin), other variations also exist.

Crêpe Romain The finest crêpe fabric, similar to crêpe Georgette, with a check-like surface, in a panama weave construction (therefore also referred to as panama crêpe), with two alternating warp and weft threads.

Crêpe Satin A generally small-figured crêpe with an ultra-bright face and a low lustre reverse, the latter having a ribbed effect; the ground fabric is in plain weave and the pattern effects in satin weave (2 S-twist and 2 Z-twist threads).

Crêpe yarns These are highly twisted, tightly folded yarns, produced in S or Z twist, used to produce crêpe fabrics in various patterns thereby giving the fabric its characteristic puckered crêpe effect after the so-called → Crêping.

Crêping Development of a special surface effect for → Crêpe products in the chemical finishing stage with completely tension-free treatment. Up to 40% fabric contraction in the crêpe yarn system direction.

I. Woven cellulose fabric: requires great experience. Relevant preliminary trials should be carried out beforehand on each quality in order to achieve the best results. Thus, the embossing roller pattern, the caustic soda concentration, the crêping bath temperature etc. all have an effect. Most qualities must be pre-calendered on the embossing calender to produce uniform contraction. Woven fabrics with no acetate content shrink best in a 1.5–4.5% (2–8°Baumé) cold caustic soda bath. They then go, with or without rinsing, into the scouring or crêping bath, where the fabric can shrink. Fabrics with an acetate content come directly to the hot scouring bath. Only after full shrinkage is further treatment possible in rope form.

II. With wool crêpe too, hot water treatment with soap or detergent takes the place of lye.

III. Polyamide crêpe is embossed under 5 tonnes pressure at a maximum of 70°C, and is crêped, with added detergent, for 1–1.5 hours with 1 g/l of 33% caustic soda (38°Baumé). By processing shrunk and unshrunk polyamide yarns with weaving techniques, the crêpe effect can be produced by heat treatment in water or steam.

Crepon,

I. Yarn: → Crêpe yarns.

II. Material: a crêped material which only has crêpe yarns of one twist direction in the weft or both the warp and weft, or even 3 Z-twist threads alternating with 2 S-twist threads, which gives rise to the typically wavy folds. It is generally produced in plain weave.

Crepon printed effects,

I. On cotton piece goods: crêpe prepared by steeping in caustic soda.

II. On wool piece goods: on the same principle as described under crêpe prepared by steeping in caustic soda, but preferably with calcium rhodanide, which has a very energetic action without affecting wool strength. Up to 15% fibre shortening occurs in the warp and weft on suitable woven wool fabric (e.g. muslin). The required crimp effect is produced with regularity here only under condition that the wool is not chlorinated, since chlorinated wool largely or completely loses its ability to shrink. In contrast to crêpe prepared by steeping in caustic soda, the crêpe effect on wool is completely fast to washing and ironing.

III. Polyamide piece goods: cloqué effects by printing on swelling agents like phenol type substances, organic acids, calcium rhodanide and aliphatic alcohols according to pattern. The shrink effect is 10–15% and more. Considered for machine printing are preferably 20–25% resorcin or phenol solutions (less in screen printing), mainly in Senegal or gum arabic, British gum or modified carob seed grain thickening. Swelling agent combinations with added glycerine are also usual to some extent. Afterwards, tension-free steaming, either on a star ager for 5–10 min. or in a setting unit at a higher temperature for a shorter time, i.e. 2–3 min. at 130°C. The cloqué effect formed in this way withstands subsequent dyeing well, and is also adequately fast to ironing with careful processing. The print pastes can also contain dyestuff. Printing on thickened lactic acid (possibly with urea) or with calcium rhodanide is less established. Tensioning or stretching the fabric is to be avoided as far as possible during any treatment. A short loop dryer for example is suitable for tension-free drying.

IV. Polyester piece goods: by printing on according to pattern print pastes which contain 20–50% carrier-active substances in dispersed form, and subsequent treatment in hot steam (20 min. at 1.5–2 bar).

CREST, abbrev. for: Centre de Recherche et d'Enseignement Supérieur Textile (French Research and Textile Secondary Education Centre), Villeneuve d'Asq, France; → Technical and professional organizations.

Cretonne A rather strong, more or less tightly woven, cellulose fabric or plain weave construction; fine qualities used for washable dress goods, coarser qualities for printed articles. First produced in Créton, a village in Normandy. Cretonne is encountered in the trade in the form of bleached, piece-dyed or printed fabric. Uses: shirts, bed linen, aprons, everyday dress, traditional costumes, upholstery and curtain fabrics.

Crimp Waves and curves exist in virtually all staple fibres and are especially evident under the microscope. The nature of the crimps and their frequency vary widely (→ Crimp, types of). Crimps hold fibres apart thus producing numerous air cavities in the yarn which influence to varying degrees its bulk, softness of handle and insulation properties.

Crimp contraction (or crimp retraction). Defined by the Textile Institute (see also BISFA) as the contraction in length of a previously textured yarn caused by the formation of crimp in individual filaments under specified conditions of crimp development. It is expressed as a percentage of the extended length. It thus represents an index of the elastic recovery of yarns and is generally expressed wet/dry (wet under high loading, dry under low loading) or where required also dry/dry. A high crimp contraction implies high elastic recovery:

non-stretch bulked yarns	< 15 %
low-stretch yarns	20–30%
high-stretch yarns	50%

Crimp crêpe The term is not quite correct. What is meant is fabrics with a crêpe-like effect a) like the crepon printed effect on cotton or wool, or b) with the use of crimp yarn.

Crimp effects → Crepon printed effects.

Crimp elongation Max. stretch or elongation of a crimped yarn/thread (or fibre) under tensile loading up to the neutralisation of crimp or up to the start of effective material elongation. Is expressed as a ratio to original length, and serves as a measure of volume increase due to texturing, i.e. high crimp elongation is equivalent to large volume increase.

Crimped fibres Wool-like crimped man-made fibres after texturing.

Crimp frequency (crimping arc count). Number of crimping arcs/10 cm, independent of count. Controlled by texturing in the case of textured yarns.

Crimp index Synonym for → Crimp contraction.

Crimping of wool hair Lower quality wool can be crimped on special machines by the → Overfeed system (IWS process), "programmed pile".

Crimp modulus Force required to stretch crimped (textured) yarn by 100%: e.g. at its lowest with polyamide 6 (2.1), polyamide 6.6 (2.4), at its highest with polyester (3.5).

Crimp process Designation for the IWS (International Wool Secretariat) process for inducing crimp in smooth wools, especially those of New Zealand origin.

Crimp stability in textured yarns The ability of a textured yarn to retain its crimp, measured before and after mechanical or thermal stress imposed under specified conditions.

Crimp, types of The → Crimp of natural fibres is a natural attribute whilst in man-made fibres it is created in fibre production in apparent or latent form. In man-made fibres distinction is made between the following types:

I. Stuffer-box crimping: Crimp-free filaments in tow form are by mechanical means or fluid-jet forcibly injected into a stuffer-box where they buckle and fold to form crimps (optionally followed by crimp stabilisation by steam/hot air).

II. Bicomponent fibre crimp: Contrived crimp imitating the crimp structure of wool (paracortex/orthocortex) produced with → Bicomponent fibres comprising components of differering shrinkage characteristics. Shrinking treatment then creates a highly stable three-dimensional form of crimp (e.g. Superbulk-PP).

III. Hot-water crimp is created by immersing filaments in a relaxed state in hot water (caused by unequal shrinkage of fibre matrix and sheath) in the form of irregular three-dimensional arcuate crimp.

Crin d'Afrique (crin végétal, African fibre). A coarse variety of → Palm fibres (*Chamaerops humilis*) with a similar texture to horsehair native to North Africa and Southern Spain. Used for upholstery and braids. It is nearly always black, dyed with cationic dyes.

Crinkle Crimp, e.g. the production of crimp yarn by the texturing of yarn hanks made from bicomponent yarns (hot air treatment in a textile tumbler).

Crinkle process Texturing process (knit-set-deknit process) for polyamide and polyester textured yarns. The yarns are used in knitgoods, jerseys and hosiery garter tops.

Crinkle yarns → Crinkle process.

Crinkling In the sense of uneven waves, for example through excessive stretching of seams, edges, folds, pleats during ironing.

Crispy handle → Silk scroop.

Critical add-on value This refers to the amount of finishing liquor which must still be applied with low pick-up systems in order to avoid uneven distribution of the resin finishing agent after drying and curing.

Critical concentration In detergent chemistry, any detergent concentration above or below which washing power declines.

Critical micelle concentration (CMC, c_k). Characteristic concentration of surfactants in solutions, above which the number of micelles increases to the extent where the concentration dependency of specific physical properties is rapidly changed. The critical micelle concentration is determined by the intersection of two extrapolated curves, which describe the property of the solution as a function of concentration (see Fig.).

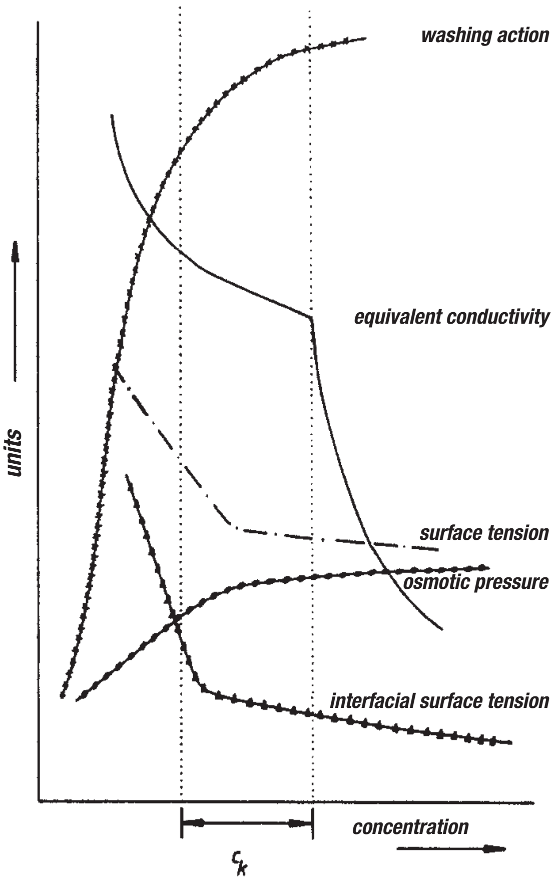

Fig.: Critical micelle concentration c_k relative to various properties (ordinate) and concentrations (abscissa) of a surfactant solution.

Critical path analysis Developed from a planning and control system used primarily for military purposes (Polaris weapons systems), now mainly employed in the fields of development and production. Critical path analysis forms part of operations research and graph theory. Especially suited to complex production processes of which an overview is difficult, the introduction of new operational sequences, maintenance tasks, the introduction of new products, systems and procedures. Critical path analysis ensures that operational sequences are fully thought through and encourages Cupertino. A critical path network plan may, for example, be based on events (for leading departments). The relevant overall project is broken down by specialist employees (start/end of the task) and denoted by numbered circles (intersections) and connecting lines (edges) with directional arrows and time entries. Procedures, the delay of which would endanger the project as a whole, are designated “critical” (see Fig.).

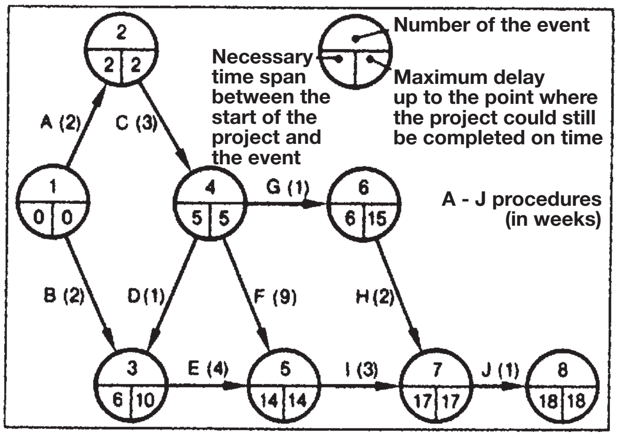

Fig.: Example of a critical path network plan.

Network plans enable improved coordination and constant controls. Any problems arising from new calculations of data can be recognised by their effect on the whole project, thus offering the potential for time or cost savings to be made.

Crocking Detrimental manifestation of indigo, naphthol, vat and pigment dyeing or prints.

Crockmeter Standard test equipment for testing the → Colour fastness to rubbing of dyed or printed textiles. Traditionally hand-operated, electronically-controlled crockmeters have also become available recently.

Croisé (French croisé = twill). A twill weave cotton fabric (generally 2/2), smooth on the face side, and heavily brushed on the reverse to a varying degree. It is generally extremely difficult to differentiate between finette and croisé. The former is generally more finely ribbed, the latter more heavily ribbed. There is, however, an intermediate designation as well (croisé-finette). It is available in the market bleached white, piece-dyed in delicate colours, or printed. Uses: nightwear, skirts and winter wear.

Cropping → Shearing.

Crossbred wool A fairly frequently processed wool variety: it falls between merino and cheviot wool in terms of count, strength, lustre and crimp. The sheep are a cross between the fine-fleeced merino sheep and the coarse-fleeced Lincoln breeding ewes. Crossbred sheep provide strong wools with a high fleece weight, between B and C in count.

Cross-brushing machine for cord finishing Special form of → Brushing machines for cord finishing. Makes possible double fabric contact with each brush. Positive brush control on a bar provides for a reproducible brushing effect.

Cross-dyeing polyamide fibres → Differential-dyeing polyamide fibres.

Cross-laid nonwovens Nonwovens preferably with fibres oriented by web crossing.

Cross linkages,

I. → Hydrogen bonds.

II. Cross linkages in proteins: important features of the fibre protein wool are its insolubility and indigestibility, which has been explained by Zenko Stary by the presence of cross linkages. The sulphur-containing amino acid cystine - incorporated in wool keratin to an approximate level of 12% – the functional groups of which can be components of two adjacent polypeptide chains (inter-chain) and/or of one chain (intra-chain), stabilises the fibre structure in covalent bonding with its disulphide grouping. Disulphide bonding is the most important natural, covalent wool cross linkage, and, as such, is important for the numerous characteristics of the fibre. The frequently expressed formulation of ester bonding from the hydroxyl groups of combined serine/threonine with ω-carboxyl groups is pure speculation. Nor is there any evidence of the presence of ω-amino-peptide bonds in or between the polypeptide chains, as have been found in collagen for example. In 1941, Horn, Johnes and Ringel discovered the thioether amino acid lanthionine in wool treated in alkali, which is not found in natural wool. Its formation is linked with a reduction in disulphide content and decreased solubility of the wool in a urea-bisulphite solution. In this reagent, the thioether bonding of the lanthionine is stable against the sensitive disulphide bonding. Observed in addition to disulphide bond decomposition was a reduction in free lysine-amino groups with weak alkaline fixation. One possible explanation of this discovery by the assumption formulated by Speakman that sulphenamide bonds could have formed, has not been analytically provable. With the discovery of a new amino acid - lysinoalanine – in the hydrolysate of alkaline-treated ribonuclease, the study of the alkali effect on wool has experienced a new impetus.

The first trial was conducted in accordance with the fixation conditions employed by Speakman in his time, in which a bundle of wool fibres, extended by about 40% of its clamped length, was heated up to 100°C for 60 min. in an 0.05 molar borax solution (pH 9.2). Found in the hydrolysate of this test specimen with the aid of the automatic amino acid analyser - in addition to reduced lysine, cystine and serine values - was a compound unknown in wool, which was identical with lysinoalanine. Over and above that, considerable quantities of lanthionine had been formed. On the assumption that the alkali attacks combined cystine first of all, the formula pattern illustrated in Fig. 1 ensues for the formation of lysinoalanine and lanthionine:

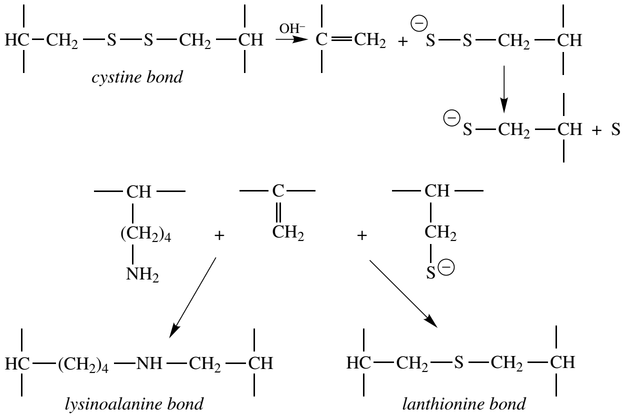

Fig. 1: Cross-linking of wool by lanthionine and lysinoalanine in alkaline treatment.

The bimolecular, nucleophilic, β-eliminating reaction forming the basis of the formation of both amino acids, which results in intermediarily occurring reactive dehydroalanyl residues, appears in fact to be most plausible. Yet other mechanisms were also discussed however as regards lanthionine formation. Since the initial publication of the discovery of lysinoalanine in alkaline treated wool in the autumn of 1964, trials have been conducted on the effect of different alkaline reagents for example on lysinoalanine formation, varying the duration of effect, the temperature, the pH, the ion concentration etc, and the effects in terms of changing physical characteristics studied in connection with the cystine and lanthionine cross-linkages. Some studies have attempted to clarify whether the dehydroalanyl residue necessary as an intermediary product in the formation of lysinoalanine is due to the alkaline decomposition of cystine and/or serine. In addition, a simplified method of simultaneously determining lysinoalanine and lanthionine was worked out. Despite the wealth of knowledge, the question as to whether one of the two new covalent bonds of incorporated lysinoalanine and lanthionine formed in the alkaline medium results in bond formation within or between chains has not been answered with any degree of certainty. The reduced solubility of alkaline treated wool in urea-bisulphite solution can in fact be seen as the resultant cross-linking of the polypeptide chains. However, a disulphide exchange reaction can also take place simultaneously. Both this reaction and the formation of lanthionine and lysinoalanine result in some degree of chemical stabilisation, although wool like this has technologically inconvenient behaviour. In addition to increased solubility, there are yet other observations where weak alkaline treatment of wool results in cross-linking. Thus, the extent of supercontraction decreases after replacing disulphide bonds by thioether bonds, and, especially, by NH bonding. Some of the last mentioned bonds already have a significant effect. If all processes are looked at in terms of their chemical and physical change, to which the wool is exposed in the various stages, raw wool washing already deserves notice. In the washing of greasy wool with synthetic detergents with added sodium carbonate, there are already conditions as regards pH and temperature, which can lead among other things to lysinoalanine and lanthionine formation. This applies moreover to the steaming of worsted yarns, the decatizing of woven fabrics and improper dyeing in the weakly alkaline range. Cross-links can also be incorporated in wool or other proteins by conversion with bifunctional cross-linking agents. Thus, the yellow reactive dye o,o'-difluorodinitrobenzol can cross-link wool in such a way (Fig. 2) that cross-links can be insulated by two formic acids coupled on to it (Ziegler).

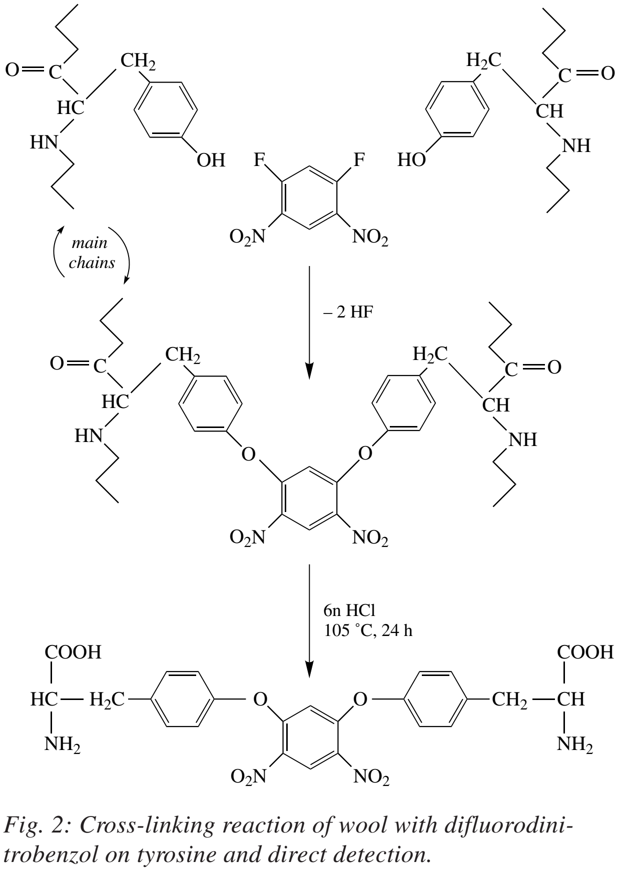

Fig. 2: Cross-linking reaction of wool with difluorodinitrobenzol on tyrosine and direct detection.

Cross-linkers Chemicals which build linear molecules of macromolecular chemicals with reactive sites into networks of three-dimensional structure by forming intermolecular bridges. → Cross-linking.

Cross-linking Connecting of linear molecular chains to form three-dimensional networks, e.g. of synthetic resins in → Resin finishing. A polymer-like reaction of two macromolecules with bifunctional bridge-type cross-links causes covalent bonding of polymers via their side chains. In the process the properties of the polymer materials will change, as seen in the tanning of collagen to leather or the vulcanisation of natural rubber to rubber. In wool there are natural cross-links in the form of cystine bonds, which are formed at the keratinization stage through stretching in the hair follicle during the growth of the fibre. Low-molecular cross-linking agents are applied in the crease-proof finishing of cellulosic fibres; at the same time, as with all cross-linking of fibres, their swelling capacity will decrease or the state at the time of the cross-linking will become fixed. Cross-linking reactions also occur with the use of bifunctional reactive dyestuffs to increase the fixing rate with the reactive dyeing of cellulose fibres; these may react according to the addition or substitution mechanism. The condensation of polymers which function as binding agents for nonwoven fabrics or as binders in pigment printing leads to cross-linking due to the displacement of water after drying when there is no more water present in the system (Fig. 1).

The chemical properties of polymers will change during cross-linking. Hence cotton, which as untreated cellulose has a very definite, so-called critical solution strength in concentrated sulphuric acid, will only dissolve after cross-linking with greater concentrations of sulphuric acid. The principle behind this method should be understood as follows: sulphuric acid works on cotton as a swelling agent for as long as the concentration lies below the critical strength. In the event of swelling the van der Waals bridge-type bonds are pushed apart between the OH groups of cellulose. In the event of cross-linking, i.e. the insertion of a bridge-type link between the OH groups (e.g. N-methylol bonding, ether formation), any dissolving and swelling is only possible for the cross-linked area if the ether formation is split up by the intermediate stage of an oxonium salt formation. This presupposes, however, a greater acidic strength than is given for the critical solution strength of non-cross-linked cellulose (Fig. 2).

Cross-linking

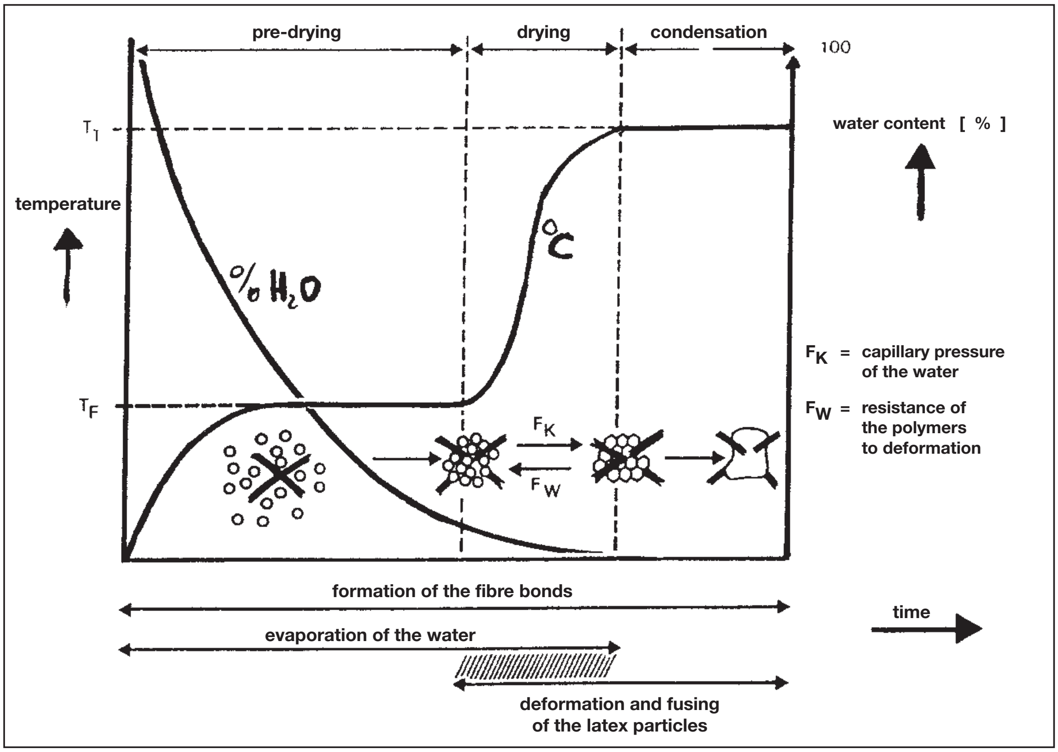

Fig. 1: Temperature development. Reduction in water content and formation of the fibre linkage during the drying process.

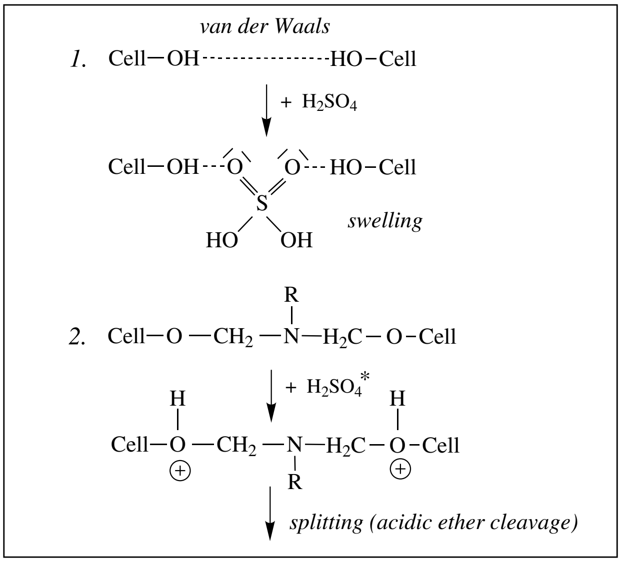

Fig. 2: Swelling of cross-linked cellulose in sulphuric acid (compared with non-cross-linked cellulose).
** more concentrated than with 1.*

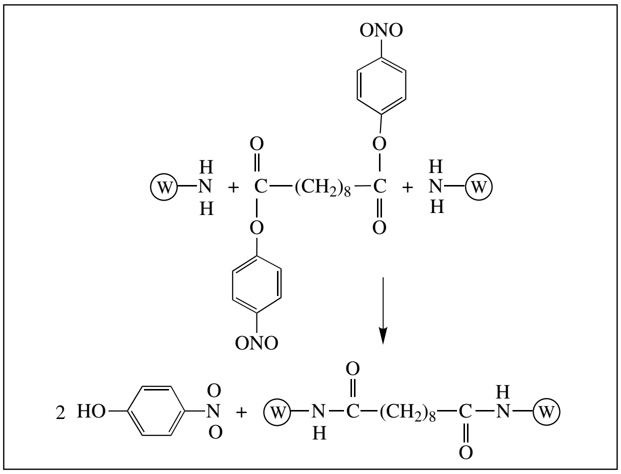

Fig. 3: Cross-linking of wool-linked lysine with p-nitrophenyl ester of sebacic acid.

If wool is cross-linked with bifunctional p-nitrophenyl esters, e.g. sebacic acid, then a severe change in solubility behaviour will occur in ammonium performate (Fig. 3 and Table).

With the self cross-linking of wool with alkali, cystine will be converted into lanthionine so that the urea-bisulphite solubility of wool will fall from approx. 60% to 0% (Fig. 4).

To protect the wool from damage during HT dyeing (separation of keratin material from the non-keratin

	Wool [%]	
fraction	untreated	cross-linked
insoluble	13 β-keratose	69
precipitated at pH 4	53 α-keratose	0,3
soluble	22 γ-keratose	17

Table: Fractionation of untreated wool, cross-linked with di-p-nitrophenyl sebacic acid ester, with ammonium performate.

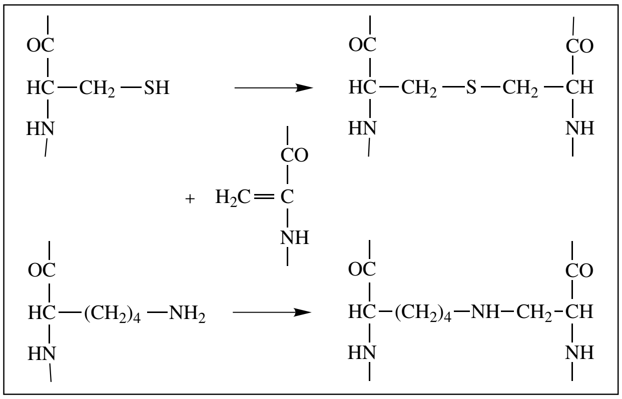

Fig. 4: Formation of lanthionin and lysinoalanine in wool through the addition of an SH group (top) or NH_2 group (bottom) to aminoacrylic acid residue.

proteins) cross-linkers such as formaldehyde are added to the dye bath in order to stabilise the composite structure of the wool.

Cellulosic textiles are resin-finished to improve their properties, such as dimensional stability and crease resistance. This is achieved by cross-linking some hydroxyl groups of cellulose through derivatives of urea or melamine and through cyclic cross-linkers based on ethylene and propylene urea.

Fig. 5 depicts a typical dye curve (Rhodamine B) of cross-linked cotton fabric, as found via extraction of marked patterns. What is noticeable from the curve obtained with the aid of remission readings is that the positive function changes to a negative with a certain cross-linker content. This is an availability phenomenon: in the rising section of the curve the cross-linking agent binds the dye before the availability of cellulose for the dye is reduced due to the high degree of cross-linking. Such availability of the cross-linked cotton very much depends on the cross-linking conditions.

Cross-linking mechanism, chemical In macromolecular chemistry the spatial connecting of polymer chains to form a polymer network. This reaction occurs with the hardening of synthetics, the vulcanisation of rubber, the tanning of leather, the crease resist finishing of cellulosic textiles, etc. With increasing branching of the polymer chains the degree of cross-linking, and hence the hardness of the end product, also increases. The cross-linker is typically a bifunctional, low-molecular weight compound in a suitable medium for the polymer to be cross-linked and must be provided with suitable conditions to allow cross-linking to take place. Much more important for the process are those cross-linkers that are added in the synthesis of polymers from monomers to the parent monomer mix as co-monomers in order to create copolymers, which combine the cross-linkers as side chains.

Textiles are impregnated with such cross-linking copolymers before bringing the cross-linkable groups in this heterogeneous system to a reaction. Where the cross-linking of copolymers with N-methylol groups or N-methylol ethers is concerned, there are two mechanisms to differentiate between:

- a purely thermal mechanism,
- condensation in the presence of acidic hardeners.

Fig. 1 shows the purely thermal condensation (100–200°C). The end result is a methylene bridge. It is supposedly formed in two ways:

- via the cleaving of an intermediate ether bridge (left-hand side of Fig. 1),
- via the cleaving of formaldehyde by the formation

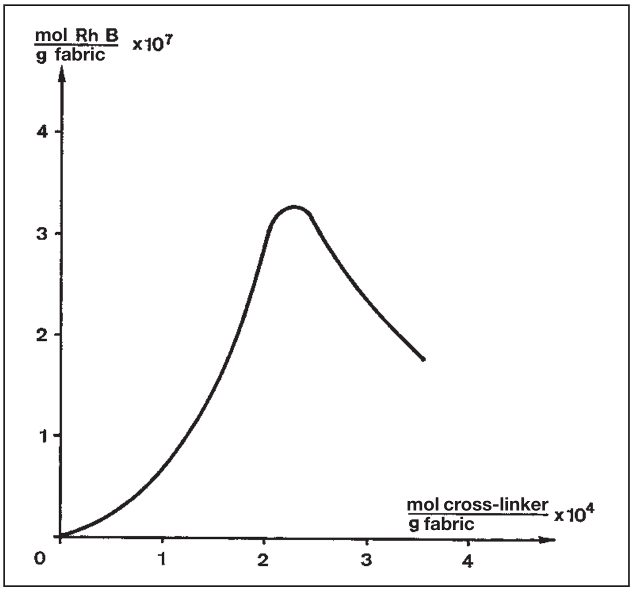

Fig. 5: Rhodamine B uptake as a function of the amount of cross-linking in the fabric.

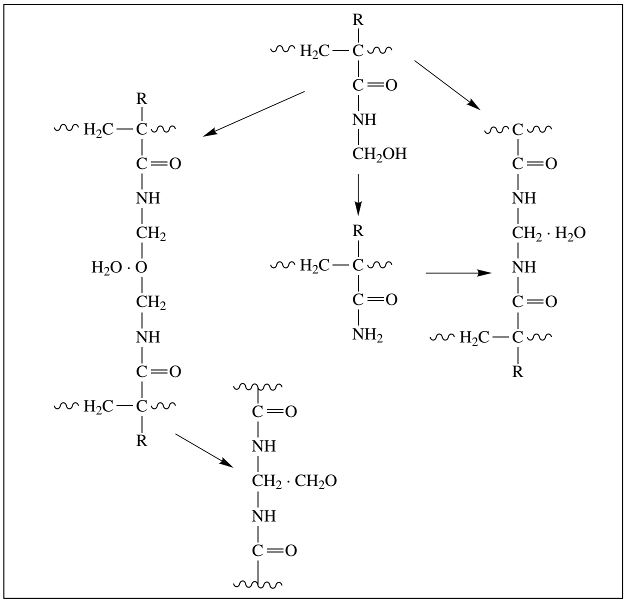

Fig. 1: Thermal condensation of polymers containing N-methylol groups (after Hübner and Kollinsky).

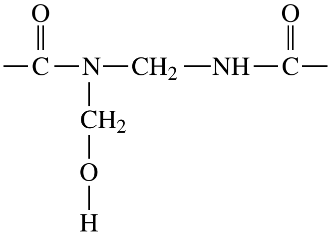
of an amide group and the reaction of this amide group with an N-methylol group (right-hand side of Fig. 1).

According to the findings of Petersen when investigating the reactivity of low-molecular N-methylol and alkoxyl methylol compounds, a mechanism might be probable where the N-methylol groups do not only react to form ether but also via the grouping



$$-C(=O)-N(CH_2-O-H)-CH_2-NH-C(=O)-$$

which because of the weak bonding of a molecule of formaldehyde immediately splits off this formaldehyde. Subsequently thermal condensation of polymers containing N-methylol groups ought to develop in line with Fig. 2.

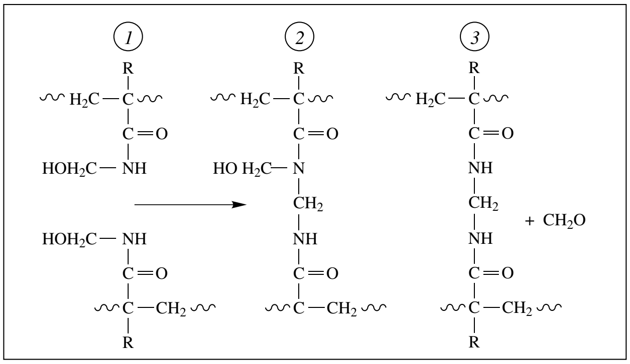


Fig. 2: Thermal condensation of polymers containing N-methylol groups on low-molecular N-methylol compounds (after Petersen).

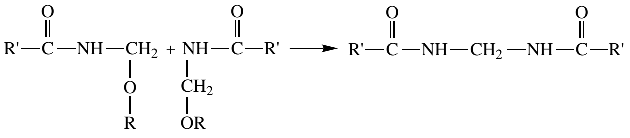
The purely thermal condensation could also develop, especially with N-alkoxyl methylol compounds, according to a "four-centre mechanism". In a synchronous reaction two molecules of an N-alkoxyl methylol compound can condense under by a rearrangement of bonds to N,N'-methylene bis compound:



$$R'-C(=O)-NH-CH_2(-O-R) + NH(-CH_2-OR)-C(=O)-R' \longrightarrow R'-C(=O)-NH-CH_2-NH-C(=O)-R'$$

As shown in Fig. 3, with hardening in the presence of acidic hardeners, a proton attaches to the amide nitrogen or ether oxygen. A carbamide group and formaldehyde are formed from the N-addition product. The O-addition product forms an immonium ion mesomeric with the carbonium ion. If this carbonium ion combines with an amide group, a methylene group (left) will result; if it joins an N-methylol group, an ether bridge will be the result. The condensation of N-methylol compounds catalysed by acid is not a specific acid catalysis only dependent on the concentration of the protons, but rather a general acid catalysis. The cleaving velocity of the C-O compound is responsible for the reactivity of the N-methylol and N-alkoxyl methylol groups.

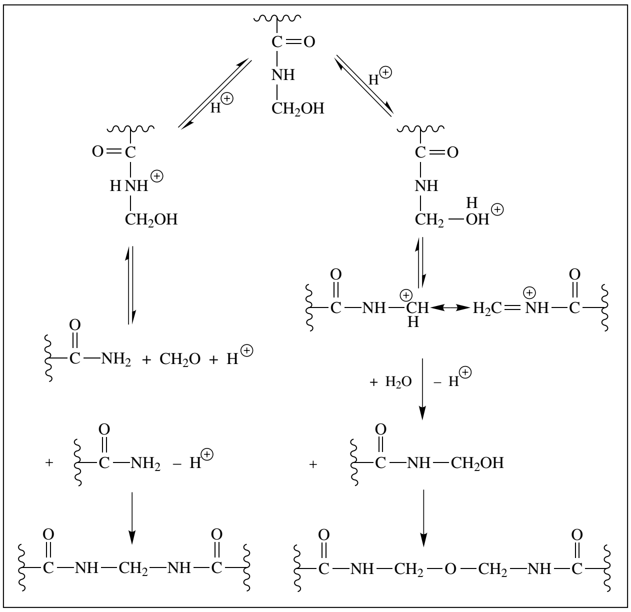


Fig. 3: Condensation of polymers containing N-methylol groups in the presence of acidic hardeners (proton catalysis).

Fig. 4, shows the transfer of these mechanisms to the N-methylol compounds of copolymers. Under the influence of an acid HS mesomerically stabilised carbon amidomethyl (carbonium immonium) ions (3), which can react with NH groups or other nucleophile partners (4). The carbonium ions can react with water to the N-methylol group (5), which in turn can split up into a carbon amide group (6) and formaldehyde (7).

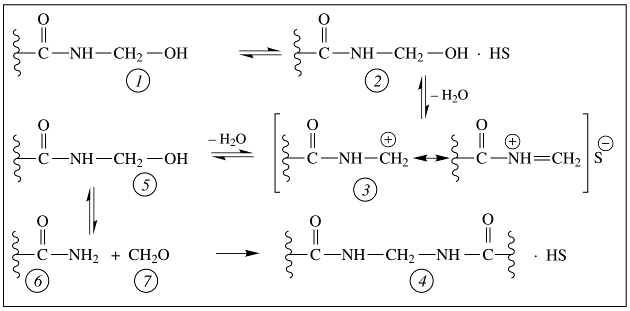

Fig. 4: Condensation of polymers containing N-methylol groups in the presence of acidic hardeners (after Petersen).

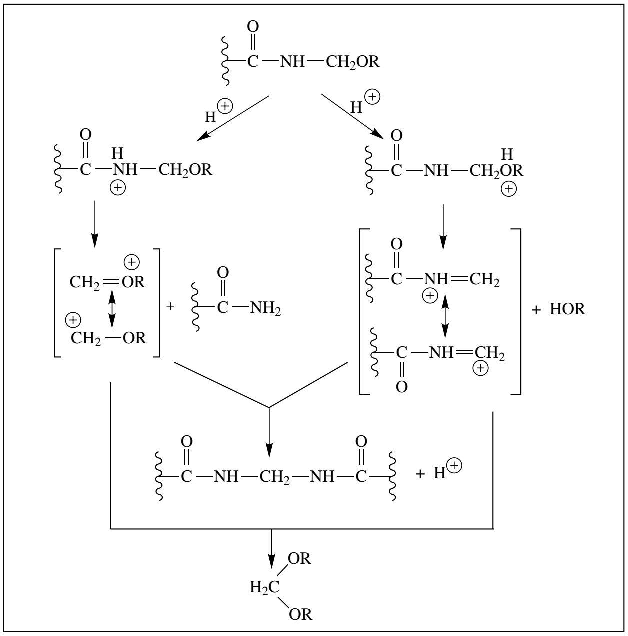

Fig. 5: Thermal cross-linking of copolymers containing N-methylol ether groups in the presence of acidic hardeners.

As a result of the acidic hardening of copolymers with N-methylol ether groups, dialkyl formals are obtained, i.e. cross-linking via methylene bridges. In Fig. 5, a proton attaches to the amide nitrogen (left) or to the ether oxygen (right). A carbamide group and the carbonium ion are formed from the N-addition product. The carbonium ion mesomeric with an immonium ion results from the O-addition product. This can react with the resulting amide group in methylene bridge formation. The carbonium ion takes up the alcohol released in the formation of the carbonium ion by forming dialkyl formal.

If one draws on the work of Petersen on low-molecular alkoxymethylol compounds for the cross-linking mechanism, then a schema can be constructed as in Fig. 6 for the cross-linking of the polymers by cleaving off dialkyl formal. According to this schema, mesomerically stabilised carbon amidomethyl (carbonium immonium) ions (3) are formed under the influence of the acid HS (2) from the N-alkoxyl methylol groups (1) of the polymer by splitting off alcohol. They react with water to the N-methylol group (5), which can split up into the free carbon amide group and formaldehyde. The free carbon amide group (6) reacts as a nucleophile partner with the carbonium immonium ion (3) to the methylene group. The free formaldehyde can react with the displaced alcohol (8) to dialkyl formal (9). The water (10) that is released in the process can attach in turn to the carbonium immonium ion by forming an N-methylol group.

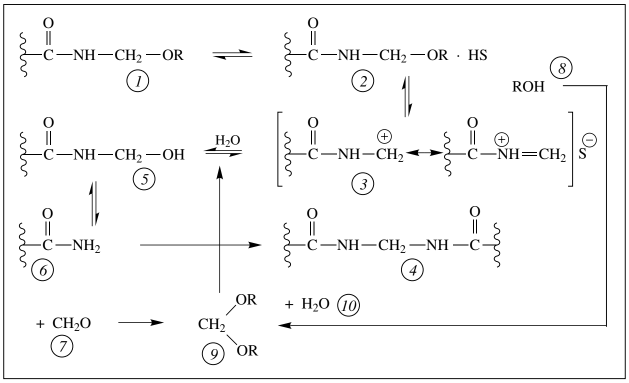

Fig. 6: Thermal cross-linking of copolymers containing N-methylol ether groups in the presence of acidic hardeners (following Petersen).

The overall catalytic effect is composed of several components. When using any acid HS and water as a reaction medium, the following velocity equation would have to be used:

$$v = \left[\wr\!-\overset{\overset{\displaystyle O}{\|}}{C}-NH-CH_2-OR \right] \cdot \left(K_{H_2O}[H_2O] + K_{H_3O^\oplus}[H_3O^\oplus] + K_{HS}[HS] + K_S[S]\right)$$

The greatest catalytic effect indicates the H-ion concentration.

$$K_{H_3O^\oplus}[H_3O^\oplus]$$

Cross-linking resins Amongst the reactive long chain polymers used for textile applications are found acrylamides and methacrylamides with N-methylol or N-methylol ether groups. Acrylamide and its N-methylol compound are easily soluble in water. The somewhat lower solubility of methacrylamide and its methylol compound is of benefit for emulsion polymerisation. Reactive long chain polymers used for textile applications containing carboxyl groups as found in acrylic acid or methacrylic acid. They are used to stabilise dispersion systems, provide adhesion to substrates, change mechanical properties and alter the reaction towards solvents after application. Carboxyl groups are also involved in the cross-linking process. The reaction of mixed polymers having only carboxyl groups with hexamethoxymethylmelamine suggests that the cross-linking here occurs via a methyl ester bridge (Fig. 1).

In practice mixed polymers as aqueous solutions or dispersions with amide groups are found. The aqueous solutions mostly contain polyacrylamide or mixtures of acrylamides with methacrylamide. Methylol groups are unstable in aqueous solution with the result that cross-linking will take place even with short-term storage.

Cross-linking resins

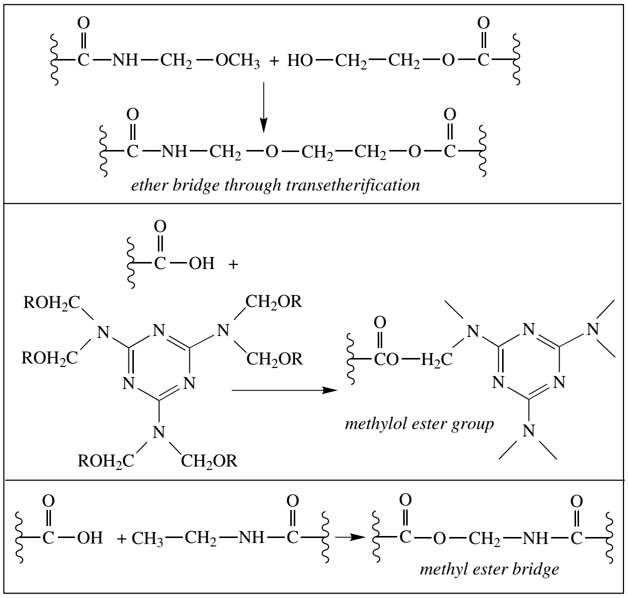

Fig. 1: Cross-linking possibilities between macromolecules.

Carboxyl groups are undesirable because the copolymers can flocculate prematurely in mixture with acidic components in a formulation. The finishes become less durable to washing with increasing carboxyl content.

These products have formed part of the palette of textile finishing agents since 1955 as finishing agents resistant to washing at the boil and wash durable sizing agents for cotton and viscose. As additives for finishing baths, they provide body, handle and stiffness, without affecting the creasing properties. With wool they confer a stretch/recovery effect and a full handle. For cellulosic textiles it is necessary to use formaldehyde condensates as co-reactants for easy-care effects. Co-reactants are the resin hardeners and reactants generally used. For crease resist finishing the resin cross-linkers used are dimethylolurea, partially etherified mixtures of dimethylolurea and monomethylolurea, trimethylol melamine, etc. They become deposited in the capillaries and micelles of the cellulose fibres, forming resins and accumulating as an amorphous filling. If a mixed polymer containing an amide group is used then part of the resin will react with it (Figs. 2–5).

The emulsion polymers, commonly used as print binders, also contain amide groups, these are replaced by the self-crosslinking N-methylol and N-methylol ether groups. With the cross-linking of polymers containing N-methylol groups and with low-molecular N-methylol compounds, formaldehyde and water are displaced and methylene groups will remain. If polymers containing N-methylol ether groups react with low-molecular compounds containing N-methylol ether groups, then methylene groups will form with the separation of dialkylformamide. In this case reactions between polymer-precondensate adduct and precondensate may take place. Quasi-crosslinking is similarly possible through polyvalent metallic ions such as calcium, aluminium or zirconium.

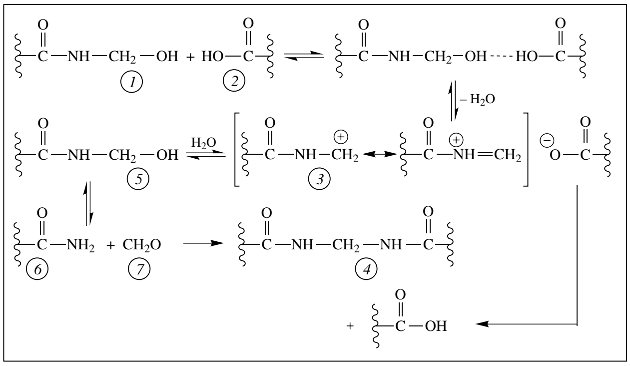

Fig. 2: Carboxyl groups as “ internal” catalysts in the cross-linking of copolymers containing N-methylol groups.

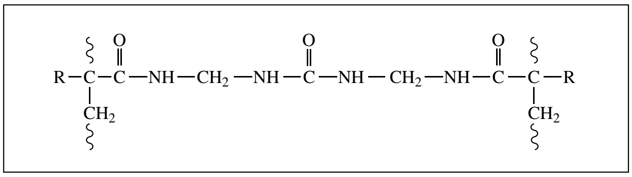

Fig. 3: Dimethylolurea as a linking agent between copolymers and polymers containing amide groups.

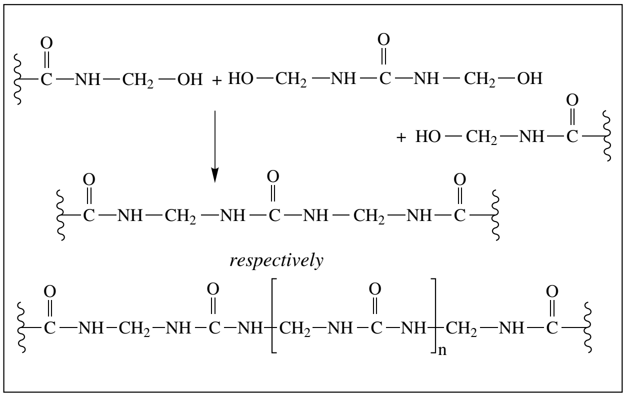

Fig. 4: Reaction between dimethylolurea and copolymer in the presence of acidic substances.

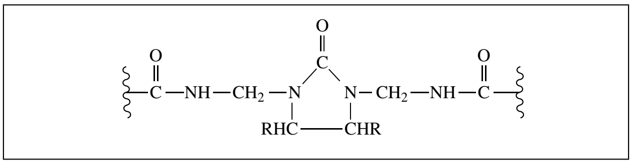

Fig. 5: Cross-linking of copolymers containing N-methylol ether groups with etherified precondensate.

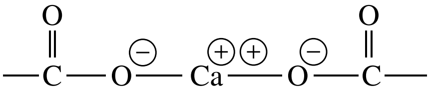

$$-\overset{O}{\overset{\|}{C}}-O^{\ominus}-Ca^{\oplus\oplus}-{}^{\ominus}O-\overset{O}{\overset{\|}{C}}-$$

The cross-linked polymers, however, will swell in the water, while the polyvalent ions may be exchanged, e.g. in the washing process. This reaction was used in the past for the manufacture of non-woven fabric. Nowadays it is mostly used solely in combination with other types of cross-linkage, e.g. with coatings. These additional cross-linkages increase the resilience of textiles. A reaction that also occurs at room temperatures is the cross-linking of the carboxyl groups with di- or polyepoxides (Fig. 6).

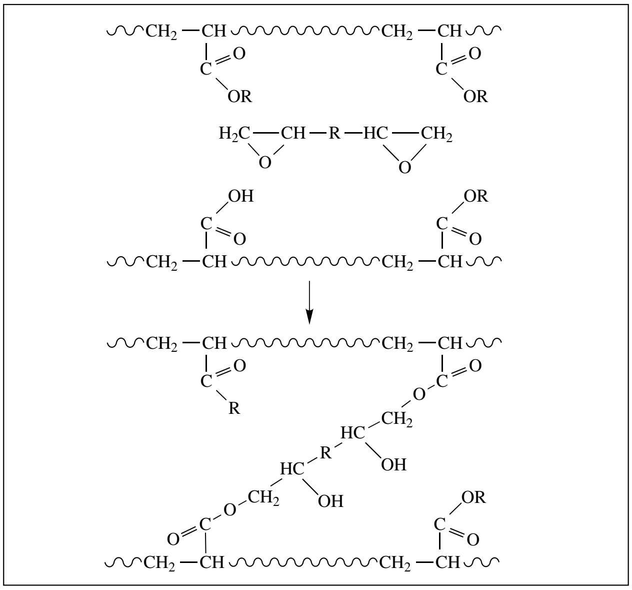

Fig. 6: Cross-linking of copolymer containing a carboxyl group with a diepoxide.

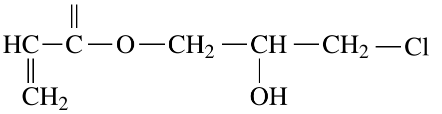
For textile applications, e.g. pigment printing, pigment dyeing, permanent sizing, diglycidethers are especially recommended as epoxy compounds. The chlorohydrin group is so insensitive to water that it can be used in emulsion polymerisation. The allyl ether of 1,2-dioxy-3-chloropropane, for example, is suitable as a monomer. However, the acrylates or methacrylates are also preferable here, e.g. the 2-oxy-3-chloropropylacrylate or the 2-oxy-3-chloropropylmethacrylate,

2-oxy-3-chloropropylacrylate or methacrylate



$$\underset{\underset{CH_2}{\|}}{HC}-\overset{\overset{O}{\|}}{C}-O-CH_2-\underset{\underset{OH}{|}}{CH}-CH_2-Cl$$

which is easily available from acrylic acid or methacrylic acid and epichlorohydrin. In this case it is possible to manufacture a reactive polymer from a copolymer (Fig. 7) since epichlorohydrin reacts fairly quickly with carboxyl groups. The reaction occurs in an aqueous medium at normal temperature and can be used as an aqueous dispersion in emulsion polymerisation.

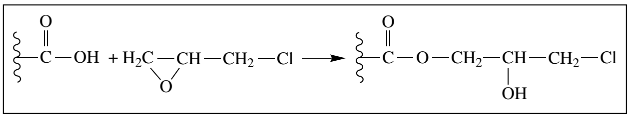


Fig. 7: Reaction of epichlorohydrin with carboxyl group of a polymer.

The condensation conditions of these types of copolymers are suitable for the fibre sector: 0.5–1% sodium hydroxide solution, approx. 5 min. with 100–140°C. For this reason it is recommended wherever acidic hardeners are not useable. For cross-linking the assumption is that chlorine is separated off with the addition of alkaline substances, whereby an intermediate epoxy group is formed. This reacts immediately with carboxyl groups of the copolymer (Fig. 8).

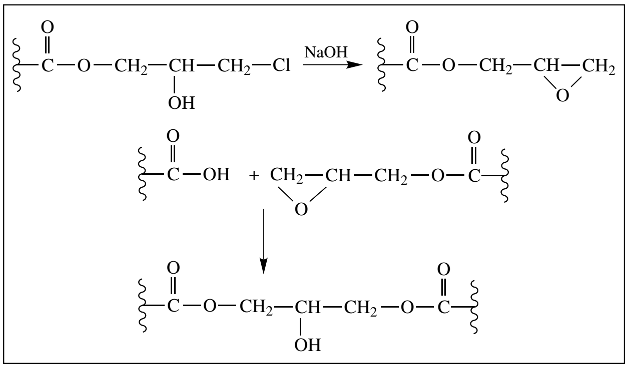

Fig. 8: Cross-linking of copolymers containing chlorohydrin groups.

It is not possible to carry out in an aqueous medium some of the reactions indicated because the reactive groups of the polymer or those of the cross-linker prefer to react with water (hydrolysis). Included here are systems such as

- copolymers containing hydroxyl groups with isocyanate groups,
- self-crosslinking copolymers with glycidyl groups.

Solutions of copolymers with these reactive groups are used for coatings and impregnation. Their films are more water-resistant than dispersion films because they are free from emulsifying agents. Through incorporating the reactive groups they become solvent-resistant after cross-linking. Both the hydroxy isocyanate system and the epoxy system are used as reaction polymers for this. However, the isocyanate groups of the cross-linker prefer to react with water, and epoxide groups do not survive the usual emulsion polymerisation with the result that a copolymer containing a hydroxyl group is formed (Fig. 9). The isocyanate group

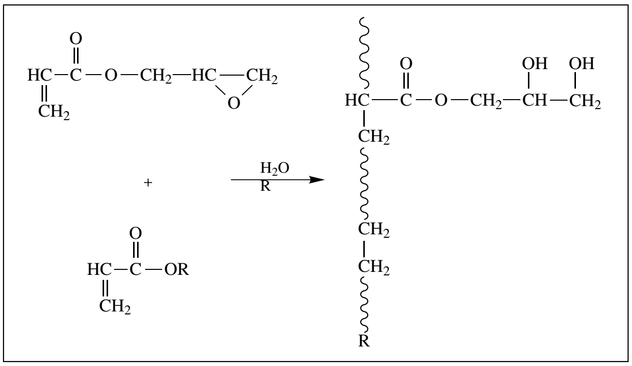

Fig. 9: Formation of copolymers containing hydroxyl groups by the emulsion polymerisation of epoxy group containing monomers.

may be masked, however, e.g. with alcohols, phenols, ketimines, lactams, etc., that it becomes insensitive to water and only reacts at high temperatures under separation of the masking agent. Polyisocyanates containing both free and masked isocyanate groups are able to react with compounds that contain both hydroxyl and epoxide groups. If, on the other hand, the epoxide groups are allowed to react with an amide, products are obtained which contain amino groups, masked epoxy groups and free hydroxyl groups. They will emulsify in water (Fig. 10) following acidification (source: Wilhelm).

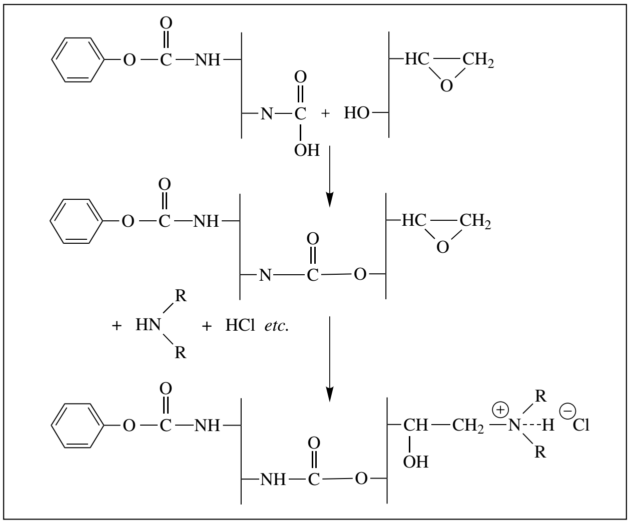

Fig. 10: Reaction of a partly masked polyisocyanate with a secondary amine containing hydroxyl groups.

Cross migration When dyeing blend fabrics containing polyester fibres, the second fibre is often heavily stained by the disperse dyestuffs used for the polyester. It will be necessary to use a two-bath dyeing process or a subsequent clearing bath for a single bath technique (see Fig.).

Even with pre-dyed polyester there remains a danger of dyestuff bleeding off the polyester and cross-staining the second fibre during cross-dyeing e.g. with acid dyestuffs in the dyeing of wool-polyester blends based upon pre-dyed polyester fibre.

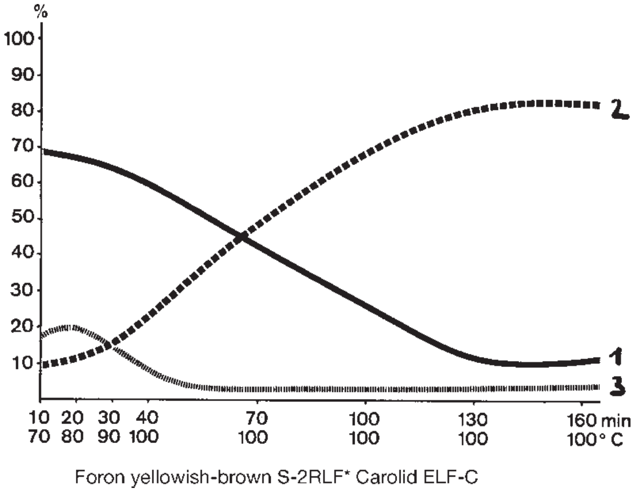

Fig.: Distribution of disperse dye (as a % of the amount of dye used) when dyeing at the boil or during boiling depending on the dyeing time (according to Sandoz).
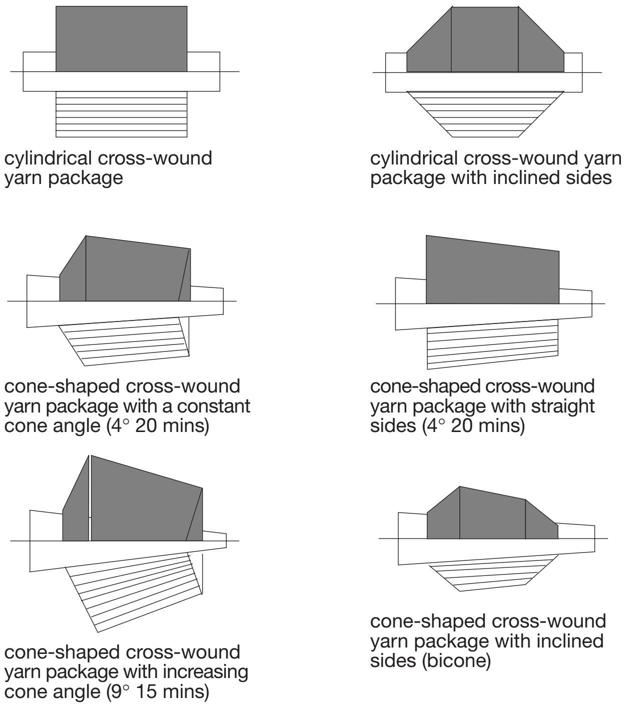
1 = dye bath; 2 = polyester; 3 = wool.

Crossover point Crossing point between warp and weft yarns in woven fabrics.

Cross-sections of fibres A preponderant number of microscopic studies of the textile fibre cross-section are concluded with a predominantly qualitative report. Longitudinal textile fibre sections on the other hand are largely necessary for quantitative tests in as much as light-optical microscopic orders of size are involved. The production of fibre sections, particularly with the aid of the microtome, is a preparation process for light-optical microscopy. In the electron microscopic testing of textile materials, the ultra-thin section production method is employed in addition to the classic replica technique. Compared with the light-optical microscopic section preparing methods and the operational technology of scanning electron microscopy, which also employs the usual microtome section, ultrasection technology is making slow progress in textile research. Technical sectioning problems are probably largely responsible. The nature of the textile fabric represents the real problem in the production of textile cross-sections. For cutting, all textile materials have to be "stabilised" by embedding, and this represents the biggest difficulty for developing an easily employable method, in that textile fibres cannot be penetrated by the embedding agent. Thus in section testing, other processing questions and effects appear basically as biological histology preparations in sectioning for example.

Crosswound yarn package Package of yarn wound onto cylindrical or conical former characterised by the crossing of the successive helices of yarn. A



cylindrical cross-wound yarn package

cylindrical cross-wound yarn package with inclined sides

cone-shaped cross-wound yarn package with a constant cone angle (4° 20 mins)

cone-shaped cross-wound yarn package with straight sides (4° 20 mins)

cone-shaped cross-wound yarn package with increasing cone angle (9° 15 mins)

cone-shaped cross-wound yarn package with inclined sides (bicone)

Fig.: Types of cross-wound yarn package.

cross-wound package from which the cylindrical former has been removed is termed a muff. The successive coils wound onto the package lie parallel to the surface of the former (both cylindrical and conical). Formers comprise paper or varnished paper tubes or for dye packages perforated tubes (usually in rustproof metal or plastics), whilst muffs are crosswound onto spindles from which they are removed. The principal advantage of crosswound packages and muffs is their stability, with each successive coil retaining its predecessors and overcoming the need for costly flanged formers. Yarn can be unwound from the centre of muffs as from a ball of knitting yarn. Cylindrical and conical packages with parallel or tapering sides are distinguished by their particular forms (see illustration) whilst the most common form for man-made filaments is the tapered pineapple (or biconical) cheese with taper at each end.

Crow's feet Technical term for folds and creases in densely woven piece goods (poplin, gabardine) treated in rope form.

CRTM, abbrev. for: Centre de Recherches Textiles de Mulhouse (French Textile Research Centre of Mulhouse), Mulhouse, France; → Technical and professional organizations.

Crushed Foam Rohm and Haas Company produce a variety of Primax acrylic emulsion polymers designed specifically for crushed foam coatings (Fig.). The acrylic copolymers withstand the high shear encountered in mechanical foaming devices and adhere well to both natural and synthetic fabrics whether woven, non-woven or knit. They provide softly clear or pigmented coatings durable to repeated laundering and dry cleaning and contribute to good low temperature flexibility without the incorporation of external plasticisers (Tab. 1 + 2). Crushed foam systems based on Primax emulsions which can be used for clear or pigmented coatings are also excellent adhesives for producing laminated fabric composites. Properly compounded and applied, acrylic foams exhibit minimal penetration into the base fabric and therefore, desirable aesthetic properties can be achieved with a wide variety of substrates.

The crushed foam coating process is simple and consists of the following sequence of operations:

1. Foaming of the Primax emulsions.
2. Coating of the foam onto the substrate.
3. Drying of the foam.
4. Calendering of the dried foam with or without lamination.
5. Curing of the crushed foam.

Depending on the end-use applications, the curing process can be deleted or the crushed foam coated fabric can be treated (e.g. for soil release or water repellency) prior to the curing operation.

The foamer pump should be adjusted to deliver the amount of compound required for the proposed coating speed and the wet density of the foam for most applications should be set at approx. 0.15 to 0.25 g/cm^3 by regulating the air flow and turbo speed. The consistency of foam is very similar to that of aerosol shaving cream. The gap setting of the metering device should be adjusted over the substrate to give a dry add-on of the desired weight.
