TI-waste In order to minimize increasing quantities of waste, Technical Instructions (TI) were issued regarding the temporary disposal, treatment, combustion and permanent disposal of waste materials in need of particular monitoring, in the form of administrative regulations to underpin waste legislation (→ Environmental protection regulations). The state of the art in the context of these Technical Instructions is the development status of advanced techniques, facilities or operations, which as far as possible, guarantee the practical suitability of measures for environmentally friendly → Waste disposal. When determining what is the state of the art, preference is given to comparable, suitable techniques, facilities or operations which have been tried and tested and found to be successful in operation. All waste materials in need of particular monitoring are listed in a waste material catalogue and each item provided with a waste material code. The person responsible must keep a disposal or utilization record in the form of a declaration of responsibility (accompanying document) confirming disposal of the waste materials by a licensed waste disposal specialist. The TI-waste covers the following subject areas:

1. range of application;
2. general regulations;
3. registration of waste disposal centres;
4. allocation of waste materials to disposal procedures and facilities;
5. requirements for the organization and staffing of waste disposal centres as well as for information and documentation.

Tjanting Ladle-like container made of thin copper sheet with fine draining tubes which is used for applying wax resists particulary in the manufacture of → Batik.

Tjap print Japanese stamp batik which is carried out using so-called tjaps, stamps made of copper strips (block fastened). The process is more rapid than the free-hand method using the → Tjanting.

Tl Element symbol for thallium (81).

TLC Thin layer chromatography.

TLV Abbreviation for → Threshold Limit Value.

TLV values Maximum threshold limit values in the workplace are the highest permissible concentrations of substances such as gas, steam or other airborne substances which, on the the basis of current knowledge, do not impair the health of employees in the case of repeated long-term exposure and likewise do not place undue strain on them (→ BAT value). The dimension of the value for workplace concentration is calculated as required by means of specific testing processes for the specific contaminants in question. These testing processes are either of a purely chem., physical-chem.

or purely physical nature. Semi-quantitative measurements with gas testing tubes are adequate for monitoring TLV values which only have information character. Exact establishment of the TLV values requires a quantitative process generally on the basis of a defined quantity of air which is channelled through an adsorption or collection device. Preparation of the sample material collected in this way is mainly carried out on the basis of microanalytical processes. In the interests of simplicity and clarity, values should always be quoted in mg/m^3. The TLV values of a gas or steam can also be quoted in vol.%. If, for example, 100 ml of carbon monoxide are distributed evenly in 1 l of air, this corresponds to a final value of 100 ppm carbon monoxide (equivalent to 0.01 vol.%). The final concentration is the amount of substance or contaminant which is present after mixing, solution or distribution in the vehicle or medium. The air content of the contaminant in question can be calculated in mg/m^3 according to the following formula by conversion, in which the relative molecule mass M_r and the molvolume V have to be taken into account in relation to 25°C and 101.3 kPa:

$$\text{TLV (mg/m}^3\text{)} = \frac{V_1 \cdot M \cdot T_0}{V_0 \cdot T_1}$$

V_1 = volume of the reference in TLV (ppm),
M = molecular weight in g ($M = \text{Mol}^{-1} \cdot \text{g}$),
T_0 = temperature of 273 K,
V_0 = molvolume of a gas by 273 K,
T_1 = temperature in K.
As TLV values are basic values, the following fixed figures are used in the formula:
V_0 = 22.41 l,
T_1 = 293 K,
T_0 = 273 K.

TLV values are used to promote health protection as the basis for assessing the extent of the risk presented by existing concentrations (but not the short-term effect of higher concentrations). They are not constants from which the occurrence or non-occurrence of effects over longer or shorter periods of exposure can be calculated. TLV values are also not suitable for comparative evaluation of the risk of different substances. Simultaneous or consecutive impacts of different substances can increase or reduce the health implications considerably. The commission responsible, the so-called MAK Werte Kommission (German TLV value commission), is not yet able to establish TLV values for mixtures. This does not in any way imply that there is not a risk. Cold applications of solvent mixtures are a typical example. These are non-flammable in the state in which they are supplied, but can become flammable during use when one or more component parts evaporate. This can present uncertainties not only in terms of a risk to health but also in terms of risk of fire and explosion.

Tm Element symbol for thulium (69).

TMU Abbrev. for Time Measurement Unit, time unit of the → MTM. Conversion into other time units:

1 TMU = 0.00001 h = 0.0006 min = 0.036 s;

1 h = 100 000 TMU; 1 min = 1667 TMU; 1 s = 27.8 TMU.

TMU units are widely used for movement analyses, for workplace and goods flow studies in which the smallest amount of time corresponds to the most efficient method.

TNC Abbrev. for Swedish “Teksnika Nomenclaturcentralen Publikationer”, publication of the technical nomenclature centre.

TNO Abbrev. for Dutch “Toegepast Natuurwetenschappelijk Onderzoek” (applied scientific research) used by the Dutch research organization; → Technical and professional organizations.

TOC Abbrev. for Total Organic Carbon. The TOC value, which is quoted in mg carbon/l waste water or mg carbon/g substance, only takes into account the carbon proportion of the particular organic compound so that different organic compounds have different TOC-values. The TOC-decomposition test is a process for testing organic substances for complete biological decomposition and measures the actual mineralisation of the substance to be tested. →: Summation parameters; Waste water evaluation.

TOD Abbrev. for Total Oxygen Demand = total content of oxydisable substance (inorganic and organic substance, including nitrogen and sulphur) which is quoted in mg oxygen/l waste water or in mg oxygen/g substance.

Toile Plain weave underwear and clothing made of silk or synthetic fibres; single-colour with colour effects, printed or also embroidered.

Tolerance limits With a → Poison, the concentration in mg/m^3 which leads to incapacitation after 1 min. As max. workplace concentration → TLV values.

Toluene (methyl benzene), $C_6H_5CH_3$. Density 0.8716; Fl.p. –95 °C; b.p. 110.8°C. Clear and colourless liquid with aromatic smell; highly light-refracting and inflammable (bright-burning and sooty flame). Toluene is virtually insoluble in water; it is miscible with alcohol, ether, benzene, etc. Other properties and use are similar to those of → Benzene and → Benzine.

Toluene diisocyanates → Tolylene diisocyanates.

Tolylene diisocyanates (TDI, methylphenyl diisocyanate, toluene diisocyanate), $C_7H_6(NCO)_2$. Density 1.22 at 25 °C; mol. wt. 174.16. Tolylene diisocyanates represent technical isomer mixtures of 2.4 and 2.6 tolylene diisocyanates. Properties: clear to yellowish, flammable and relatively volatile liquid with pungent smell. The vapours are heavier than air and form an explosive mixture with air when subjected to intense heat.

Toluene diisocyanates have a highly irritant effect on skin, eyes, the respiratory system and can cause asthma and allergies. It is possible to suffer damage to health as a result of smelling the substance. It is therefore imperative to heed the many safety regulations for its use. Tolylene diisocyanates have a steam pressure of 1.33 Pa at 20°C. Their TLV value is 0.01 ppm or 0.07 mg/m^3. Tolylene diisocyanates are used as crosslinkers for polyurethane manufacture and for polyurethane coating.

Tommy dodd Term for machinery for finishing reverse side of fabrics. Consists of a trough filled with finishing liquid and a roller which is half lowered into the liquid. The fabric is processed face side up. A doctor blade wipes off the excess finish from the reverse side of the fabric. Another doctor blade cleans the roller before the incoming fabric comes into contact with it.

Tom-Tom-Dollys → Dollys.

Tone-in-tone dyeing,

I. "Same shade" dyeing in the sense of a single colour shade (→ Self shade) with mixed-fibre articles and yarn mixtures; both components of the mixture demonstrate the same colour shade.

II. "Colour shift". An example is the → Multicolour process in which only one type of fibre is used but of which a section has assumed greater capacity to absorb or to resist dye as a result of appropriate pretreatment. The dyeing process results in different colour shade intensities with the same colour shade.

III. → Dyeing of ombré or shaded effects.

Toning Previously-practised method of after-shading (→ Shading) on fast dyes, usually vat and sulphur dyes, (due to the lack of suitable products in these groups) with small quantities of brighter dyes from other categories (usually cationic dyes). This has the effect or reducing overall fastness to a greater or lesser extent. Dyes with 1 : 2-metal complex dyes are used predominantly for toning using acid dyes.

Tonne Weight measurement unit; 1 tonne (t) = 1000 kg.

Top After-dyeing of fibres in mixtures, particularly to light dyed fibres in single-bath or two-bath systems. Used predominantly for reserve and for creating two- or multi-colour effects.

Top bottom air quantity regulation Depending on the type of goods (e.g. woven or knitted; elastic textile) the dry textile material is subjected to more top or bottom air (see Fig.).

Top cloth Generic term for all materials which determine the external appearance of an item of clothing.

Top fusing Term used to describe the direct bonding of lining fabrics for collars and sleeves.

Topper,

I. Automated machine for trouser waist-band steam pressing machine after dry cleaning. It replaces the time-consuming and technically expensive process of manual steaming or pressing of trouser waist-bands.

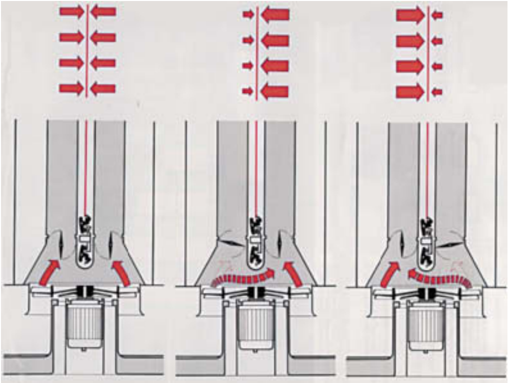

Fig.: Controlling the air quantity above and below the fabric in the stenter (Babcock) through appropriate air damper setting.

II. Garment manufacturing term: a) leisure jacket with the face edge and under seam at right angles; b) short, elegant gentleman's summer coat, fashionably wide and with lightly padded chest.

Topping dyes Dyes for topping which as far as possible do not dye the foreign fibre or only slightly. They should be simple to apply.

Top scouring Second washing process for woollen tops before spinning to remove residual grease (de-oiling), dye pigments, dust, etc. on the back-washer. To avoid subsequent fibre disruption and yellowing in drying processes, it is carried out with sodium carbonate or ammonia with calcium stable synthetic products (→ Raw wool scouring).

Tops printing → Vigoureux printing.

Top, to Production of an "after shade" in a dye solution by addition of other, usually brighter dyes (→ Toning).

Torque (Lat.: torquere = to twist), English: torque = torsional power.

Torque yarn Yarns which are fabricated discontinuously by means of high twist, fixation and un-twisting ("conventional" or "classical" process) or continuously (false twist process). Simple yarns with twisting tendency (Up-twisting of suitable high twist yarns with S- and Z-twist gives compensating possibilities).

Torr Physical pressure unit which is no longer permitted with which 1 Torr corresponds to the pressure of 1 mm mercury column on a 1 cm^2 surface. The current SI-unit for pressure is → Pascal (1 Pa = 0.0075 Torr).

Torsion (twisting, drilling, turning, → Twisting of spun yarns). Special form of shear used particularly for long shapes (rod, wire) which are fastened at one end whilst a turning moment is applied to the other end displacing the cross-sections.

Torsional elasticity Non permanent plastic deformation of a shape occurs up to a specific applied force known as the torsion modulus. Up to this limiting value it remains elastic, i.e. when the force is no longer present it returns to its original state. The torsion modulus is quoted in kg/mm^2. With fibres and yarns it is for example usually 35–200 and it facilitates assessment of the suppleness or stiffness of fibres.

Torsional strength (twisting strength). Resistance of a shape or body to a force which tries to twist it. When a force above the torsion modulus is applied, plastic changes take place in a body or shape which remain permanently after the force has been removed. The twist factor at break is used to measure plastic processes during torsion. This increases according to the fineness of a fibre or the break twist angle (as opposed to brittleness angle) which is practically independent of fibre fineness and is therefore a criterion of fibre brittleness.

Total colour management Special software for recording, monitoring and evaluating (see Fig.) for example

- dye strength,
- substrate routine,
- correlation,
- transferability from laboratory to production,
- specification and corrections calculation for continuous and exhaust dyeing,
- batch production,
- storage contents and recipe recording,
- machine programmes,
- management programmes,
- colour kitchen software.

With the aid of this software, colorimetry and a high-performance computer an exact statement is made prior to initiation of actual production on the feasibility of substrate-specific customer requirements in terms of optimum pricing and colour uniformity. Networking with operationally-relevant systems and equipment is made possible by means of the "real-time multi-user hardware" computer configuration.

Total hardness → Water hardness salts.

Total nitrogen determination (according to Kjeldahl). Determination according to DIN 38 409, Section 11. An effluent sample is mixed with concentrated sulphuric acid and a selenium reaction mixture and brought to the boil. The nitrogen contained in the sample is converted quantitatively to ammonium nitrogen and distilled using steam distillation in a strongly alkaline medium into a sulphuric acid receiver. The consumption of acid is determined by means of titration with base to which the nitrogen content of the sample is proportional.

Total production time is quoted in min/1000 m; dependent on degree of textile finishing utilisation and batch size.

Total radiation pyrometer Temperature measurement unit, e.g. for steam boiler firing. Principle: concentration of heat radiation by means of a lens on blackened platinum sheet and measurement thereof by means of a thermoelement.

Touch and close tapes Textile tapes are used in many articles including many specifically technical articles. The most widely-known fastenings are zips and touch and close tapes. The latter are products with many applications for clothing, shoes, medicinal and military textiles, hobby and sport articles, automobile and aeronautical industry. There are two different types of touch and close fastening, the adhesive fleece fastening and the mushroom tape fastening. Both products are woven with the aid of special techniques. The specific after treatment results in the touch and close tape.

The male and female fastening (Fig. 1) consists of two tapes, one with numerous hooks, the other with numerous small loops. When they are pressed together the hooks are compessed into the fluffy looped surface where they bind, resulting in a fastening which can be reopened simply by pulling it apart. When the tapes are pulled apart, the hooks stand up

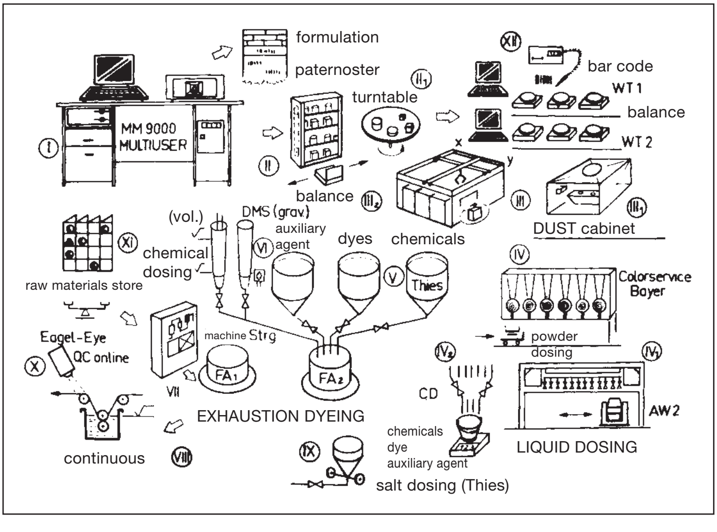

Fig.: Total colour management-automation in the textile mill.

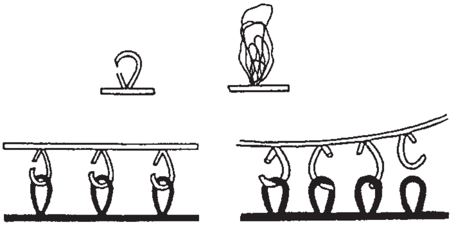

Fig. 1: Male fastening (schematic) (according to Mageba).

releasing the loops. This special opening technique allows the fastening to be used many times.

The mushroom fastening (Fig. 2) likewise consists of 2 tapes, one of which has numerous mushroom-shaped protrusions and the other numerous small loops which, when compressed, attach themselves around the mushrooms-shaped protrusions. These are torn, however, when the tapes are pulled apart. As a result this type of fastening can only be used a limited number of times.

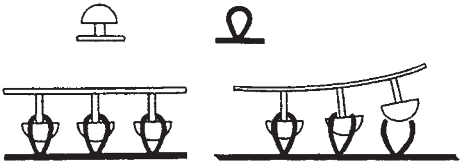

Fig. 2: Mushroom fastening (schematic) (according to Mageba).

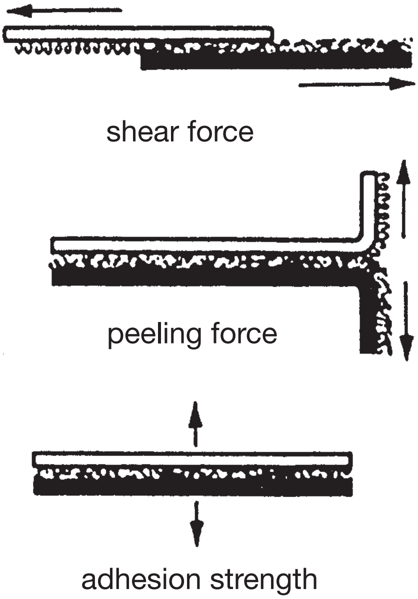

Fig. 3: Active forces on touch and close tapes.

On opening and closing, touch and close tapes are subjected to different forces (Fig. 3). Differentiation is made as follows:

a) Shear force: the force which is necessary in order to pull the 2 tapes apart in length direction. The difference in effect during closing and opening of the two types means that the force on the mushroom tape is highest (hook tape: 5-10 N/cm^2; mushroom tape : > 10 N/cm^2).
b) Peeling force: the force necessary to pull the tapes apart ("peeling off") (hook tape: 1–1.5 N/cm^2; mushroom tape 0.5–1 N/cm^2).
c) Adhesion strength: the force which is necessary when pulling the tapes apart in a vertical direction (hook tape: 5 N/cm^2; mushroom tape: 6 N/cm^2).

The forces vary from fastener to fastener and are dependent on the raw materials used. The values quoted are the mean values of various polyamide fasteners (according to Mageba).

Touch-up roller →: MA process; Applicator roller.

Tournay carpet Named after the Belgian town, a wire insertion pile velour carpet with numerous and varied coloured warp pile giving sharply defined jacquard patterning; also seen as → Face-to-face Tournay carpet in a double velvet technique.

Tow,

I. → Tow yarn fabricated of short fibres as opposed to → Line (yarn).

II. → Combed top.

III. spin, fibre tow: manufactured form of chemical fibres which are combined taken off the spinning jets as a bundle of parallel aligned, single endless fibres; virtually no twist → Multifilament with counts of > 3 ktex. Further processing is by means of cutting and breaking (converting) or by stretch-break or texturising.

IV. marine rope.

Tow dyeing process Dyeing facilities (perforated-drum or perforated conveyor system) for continuous processing for the dyeing of spinning tow (Fig.).

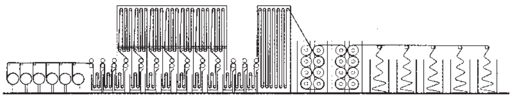

Fig.: Tow dyeing process by Sucker-Müller.

Tow yarn Yarn spun from tow.

Toxic,

I. Having a poisonous effect.

II. Caused by or resulting from → Poison. TLV values are used for reference.

Toxicology The science of poisons (toxins) and their effect on the organism. This area of pharmacology is divided into chem. medical and forensic toxicology. Toxicology investigates the harmful effects of chem. substances on living creatures with the aim of recognizing the risks and averting damage to the health of humans and animals. Toxicological research fields include both experimental as well as epidemological studies in which particularly qualitative-analytical and quantitative-biological aspects are differentiated. A large volume of data for toxicological characterization has to be investigated to establish the harmlessness of a substance. The toxicological data investigated make it possible to classify the effect of the substance according to the degree of potential damage and to make an appropriate toxicological evaluation in the sense of weighing up the benefits and risks.

Classification of the effect of substances:

- physiological effects (tendency to deviate from the mean);
- faults which can be compensated (deviation from physiological area);
- reversible damage to organs and organ systems (clinically-manifest symptoms of poisoning);
- irreversible damage to organs and organ systems;

Toxicological evaluation:

- differentiation between indicator, disruptive and damaging effects (classification of substance effect);
- setting up of recommendations for the substitution of harmful substances (substitution research);
- determining means of counteracting the damage of a substance taking into account not only the effect of the finished product but also the damage which can occur during manufacture or on destruction.
- setting up a framework outlining human ability to withstand exposure (sum of all possible effects in relation to the range of individual sensitivity).

The basis of evaluation of the risk to health, and therefore the assessment of the toxicological profile of a substance, can generally only be provided by results from tests on animals during the first phase of investigation. New substances must therefore initially be tested for acute toxicity by means of appropriate investigation in order to have a concept of the effects on important bodily functions after administering a single dose. It is not necessary to use a large number of animals for this purpose. It is sufficent to determine the toxicity ranges in the sense of an “approximate LD_{50}” (lethal dose resulting in the death of at least 50% of the tested animals). Such investigations are generally carried out after oral use of the test substance. In the case of substances which can be inhaled whilst conforming with the specified application, acute inhalation toxicity should also be tested (→ Poison).

Investigations to establish sub-acute toxicity are of particular significance as they make it possible to obtain information about the toxicity of a substance over a prolonged continuous period including that of smaller quantities. It will also be necessary to clarify whether and what type of damage occurs and which organ systems are affected. The cutane resorption rate of a substance is significant, i.e. determination of the substance quantity which penetrates the main barrier and is therefore distributed and can develop its effect. In the interest of minimizing animal tests whilst at the same time retaining the necessary guarantee of harmlessness to health the following possibilities are available:

- There is no cutane resorption of a substance. In this case it is possible under certain circumstances to do without testing for sub-acute and sub-chronic toxicity.
- The cutane resorption rate of a substance is known. In this case under certain circumstances sub-acute toxicity testing can be carried out using only one dose.
- The “no observed effect level” of a substance is known from a sub-acute toxicity test. If this value is greater than the substance quantity, which taking into account the safety factor can do no more than penetrate the skin from the point of view of calclulation (worst case calculation), it is possible to do without determination of cutane resorption.

Tests of chronic toxicity in any case encompass continuous administering of the test substance over a period of more than six months and provide information on organ behaviour after prolonged continuous administration of quantity substances which should exceed the exposure level of normal use. If in an individual case investigations to establish the carcinogenic nature (→ Carcinogens) of the test substance are necessary, these will generally be carried out over the lifetime of the corresponding species. Such investigations can at the same time provide information on possible toxicity of the test substance when used over a longer period of time and therefore also on older animals and the changing state of the metabolism which come with more advanced age, although the primary aim of such tests is to gather evidence of possible tumour-producing effects.

In the same context it is absolutely imperative to carry out investigations of mutagenity and of embryo toxicity on suitable models. In these particular areas methods are available which do not involve tests on animals. Even if toxicological charcterization and evaluation of the test substance on the basis of evaluation of the results of these investigations is mainly possible in terms of systematic toxicity in the sense of assessing a health risk, evaluation must be carried out with the aim of a decision regarding “harmlessness to health” together with a benefit/risk analysis which also encompasses evaluation of other “benefits”.

Further research into and particularly validation of in-vitro methods as alternatives to animal tests should be given priority. But not until in-vitro methods meet the current standard of excluding toxicological risks in terms of comparison and validity of conclusions reached can the extent of methods used to date be reduced or replaced (according to Lüpke).

Toxic substances (Gk.: toxicon = poison), poisonous (toxic) substances which are attributed to five different hazard groups according to the degree of toxicity and are usually regulated normatively. Employees in the workplace have to be protected from their damaging effect particularly in the case of toxic gases, vapours and particles. → TLV values.

Toxins Organic poisons (usually proteins or lipopolysaccharides), particularly from pathogenic → Bacteria.

TP Abbrev. for → Triple point.

Tracers → X-ray fluorescence.

Trachea Respiratory organs of insects at which → Respiratory poison is aimed.

Tracheids Fibre cells which form the main body of coniferous trees but are also found in deciduous trees (→ Woody fibre); generally several mm long, having alumen to a greater or lesser degree and with pointed ends. Spring tracheids have thin walls and their main function is as sap conductors. Late tracheids have narrow lumens, have thick walls and have the function of reinforcement elements.

Trademark Legally protected word and/or symbol denoting goods which have been fabricated in the same way by a certain company and can be differentiated from similar goods, such as, for example, the Indathren trademark. Trademark designation by the letter ® represents the so-called "Registered Trade Mark". (→ Quality symbols).

Tragacanth (gum tragacanth), → Vegetable gums produced from the southern Astragalus species which has various forms, is up to 20 cm long and yellow-red-brown in colour (also bleached white); normally found in powder form. Tragacanth consists of 50–70% → Bassorin. Good quality tragacanth is transparent. The following types are differentiated:

I. Smyrna tragacanth: high quality tragacanth available in tape or sheet form, 2–5 cm long, parallel striped surface.

II. Morea tragacanth (Greek): variety of external forms (some of which have similarity with the best Smyrna types, also all types of irregular forms).

III Syrian tragacanth: much lower quality than Smyrna tragacanth (various forms, sizes and colours).

Commercially available raw tragacanth is a mixture of 40–50% white or sheet and/or tape form, 15–25% brown, 10–25% worm form tragacanth and 10–15% other usual tragacanth types. Waste tragacanth is an irregular mixture of grains of all possible sorts and colours which is not necessarily of inferior quality. Tragacanth imitations exist to a greater or lesser degree. Tragacanth is not easily soluble but is usually soluble with the addition of ammonia. Tragacanth solutions are light in colour or slightly coloured and have a slimy and sticky consistency. It can be washed out of textiles easily. Tragacanth is used as a finishing agent (for example for cellulose goods, ribbons, silks and lace) and as a thickener in printing.

Train oils Fats and oils, light-yellowish brown in colour, penetrating fish odour. Produced from the fatty tissue of large acquatic animals (whales, sharks, dolphins, seals, etc.). Contained in → Olein, stearic acid and various → Glycerides. Used especially in the leather industry. Solid fats with virtually no odour can be obtained by means of catalytic hydration. These are represented in important textile auxiliaries.

Tram Slightly-twisted silk thread (fabricated from Grège threads) for weft yarns (weft silk).

Tramlines,

I. Localized faults in fabrics, in the warp direction (dent stripes).

II. Missed sections in direct printing due to uneven repeat.

Trans-cis-isomerism (→ cis-trans isomerism). Light causes transformation of the lower-energy trans-form of the brightening molecule into the higher-energy cis-form, which absorbs shorter-wave ultra-violet light than the trans form and is no longer fluorescent in the visible range (Fig. 1). The change takes place all the more easily, the more inadequately the fluorescent whitening agent is fixed on the substrate. Fluorescent

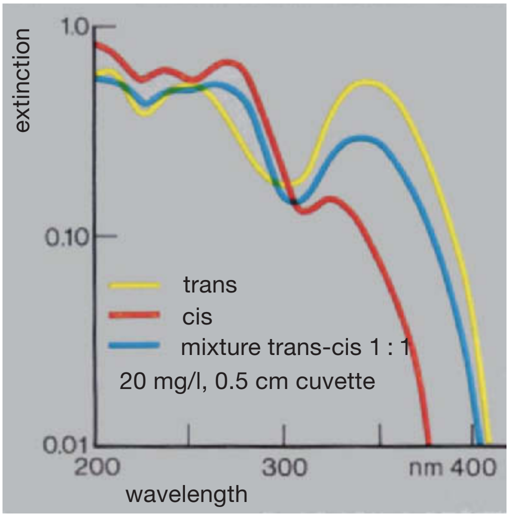

Fig. 1: Reflectance curves of aqueous fluorescent whitening agent solutions of the trans-form, cis-form and a mixture of cis-form and trans-form. The trans-form absorbs at approximately 300 nm, the cis-form at approximately 280 nm. The reflectance of the mixture diminishes, shown by the decrease in fluorescent whiteness (by Bayer).

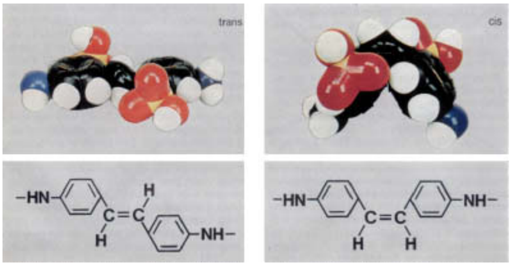

Fig. 2: Trans-form and cis-form of optical brightener molecules (by Bayer).

whitening agents are commercially available in the trans configuration. The conditions under which transformation into the cis-form can take place and the significance of trans-cis-isomerism in practice can be explained. A non-brightened filter paper is submerged in a 0.2% water-based solution of an optical brightener. Subsequent testing in ultra-violet light results in clear fluorescence. After rinsing in a basin with luke-warm water the sample is again subjected to ultra-violet light. The fluorescence is just as strong and the fluorescent whitening agent has not been rinsed out. A 3–4 mm shallow layer of the same solution is irradiated with ultra-violet light in a developing tray. A filter paper which is then dipped into the solution is already considerably less fluorescent than the one soaked in non-irradiated solution. After rinsing (as in part 1 of the test) fluorescence can scarcely be seen in ultra-violet light. The brightening molecules were transformed by the radiation from the trans-form into the cis-form which has only low substantivity to cellulose and can easily be rinsed out.

If a diluted fluorescent whitening agent is exposed to daylight, it penetrates the solution and in time converts the trans-form into the less effective cis-form. The light cannot penetrate deep into concentrated solutions; the transformation takes place more slowly. It is therefore imperative that diluted brightening solutions should be protected from light and particularly laboratory stock solutions should always be stored in brown bottles. Trans-cis-isomerism is reversible but only with ultra-violet light. For test purposes, treat a shallow layer of 0.1% water-based solution with ultra-violet light for approx. 3. min., submerge a filter paper in it and dry it without washing it out. If the paper is now subjected to ultra-violet light for a longer period, it gradually becomes fluorescent again. The effect is clearly visible if part of the paper is covered during the ultra-violet radiation treatment allowing the original state to remain for the purpose of comparison. Tests should not be carried out in strong light in order to eliminate light sources which might interfere with the process. The molecule models in Fig. 2 show why the substantivity of a brightener decreases on transition from the trans-form into the cis-form. The trans-form is almost even and can therefore be taken up easily by the fibre or binding agents such as starch, casein, polyvinyl alcohol, etc. The oblique cis-form has significantly less contact surface with the substrate and therefore poor affinity. Also the conjugated system is disrupted by steric hindrance of the ortho substituted H-atoms of the cores. They are forced into a crooked position, the resonance of the molecule is reduced and the more energetic cis-form is no longer fluorescent.

Transfer coating,

I. Process for coating or laminating fabrics (see Fig. 1) in which adhesives and coating compounds are not applied directly to the fabric width but are first applied onto a specially prepared paper (release paper) or endless metal band, onto which they are dried and subsequently combined with the fabric. This circumvents the problem of unwanted push-through of coating compounds.

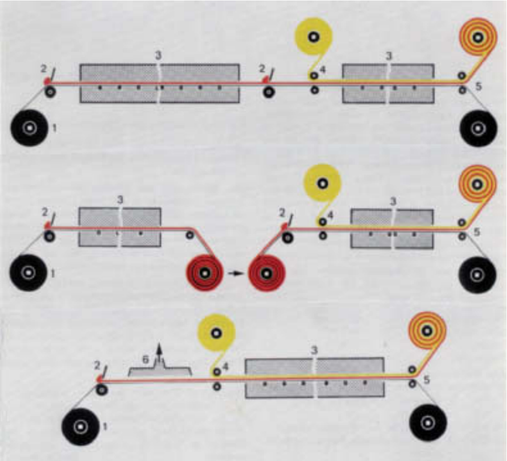

Fig. 1: Transfer coating (by Bayer).
Top: Tandem-machine (continuous); middle: discontinuous process; bottom: continuous process with a coat.
1 = carrier sheet; 2 = coating application (red); 3 = drying; 4 = substrate (yellow); 5 = separation.

II. Transfer coating works on the basis of the same application principle as direct coating. Instead of the final carrier material, an intermediate or auxiliary carrier is coated first (usually a paper siliconized on the coating side which is known as the transfer or release paper). The sequence of layers applied is reversed (see Fig. 2): what will eventually form the outside layer is applied first. A subsequent coating station can be used to apply a blowing agent or compact middle layer. The last coating station will apply an adhesive or laminating

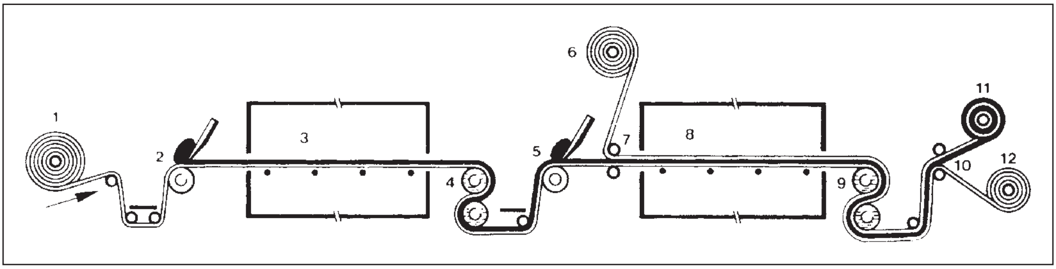

Fig. 2: Transfer coating installation (by Bayer).
1 = paper take-off; 2 = coating unit (cover coat); 3 + 8 = drying tunnel; 4 = cooling cylinder; 5 = coating unit (tie coat); 6 = textile carrier; 7 = laminating unit; 9 = cooling cylinder; 10 = separation device; 11 = batching of the coated goods; 12 = paper batching.

coating. Between the last coating station and the following heating zone the carrier fabric is introduced onto the coating that may be still liquid or paste-like form and is lightly pressed onto the coating by a roller running with the fabric direction.

The composite material then passes through the drying or gelling channel before being stripped from the paper. Paper and goods are rolled up separately. The paper can be used several times.

This type of coating is usually used when the coating compound would penetrate too far or go straight through due to its low viscosity when using the direct process or where the carrier is too elastic or not sufficiently resistant to tear to carry the weight of the coating. The process is also used increasingly where direct process coating would actually be possible.

Transfer dyeing unit Based on the Palmer system of dyeing disruptive foreign fibres in woollen articles and woollen articles as well as articles made of cellulose/synthetic fibre mixtures. This consists of predyeing the main portion of the fibre in the usual way and colouring synthetic fibres by means of the transfer dyeing unit. A re-colourable polyester “reservoir” fabric is used instead of the usual paper to transfer the dye.

Transfer paper control This is used for monitoring printed transfer paper, for cutting the edges and rerolling onto smaller roller diameters. It accommodates up to 200 cm wide transfer paper rollers. Monitoring field 200 x 80 cm. Max. roller diameter 30 cm. Operating console with foot-operated switch for switching on and off, pre-selectable speed and electrical meter counter.

Transfer paper printing/gravure screen size For printing paper for → Transfer printing with water-based printing pastes on a vertical roller printing machine a 60 mesh screen is used. Eight colours can be printed onto the paper using the Portalrouleaux printing machine (Fig.) prior to drying in an overhead drier. Disperse dyes are normally used.

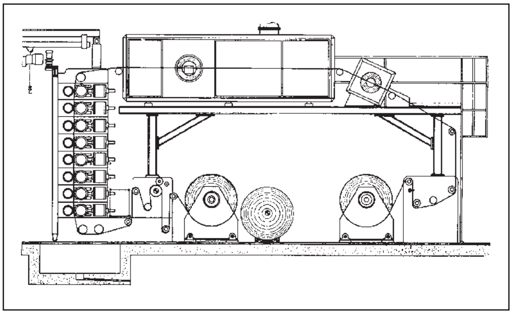

Fig.: Diagram showing the paper run with direct printing of transfer paper printing on the Saueressig roller printing machine.

Transfer printing Indirect → Transfer printing processes. Printing does not take place directly onto the fabric but onto paper (Fig.). In a second process the design is then transferred from the paper to the fabric. During the transfer printing process a paper printed with special disperse dyes is brought into contact with fabrics, knitted fabrics or nonwovens made of synthetic fibres (particularly polyester, triacetate, possibly polyacrylnitrile and polyamide) at a temperature of 190–215°C for 18–30 s. This causes the greater part of the printed dyes to sublime from the paper and be adsorbed onto the fibre material causing it to take on the pattern.

The printing processes applied are gravure printing, offset printing and rotary film printing. As mainly paper is printed, typical paper printing machines were used at first, initially almost exclusively rotary gravure printing machines such as are used for paper; later flexoprint machines were also used as well as offset machines.

The printing pastes generally only contain thickeners and disperse dyes. Alginates, locust bean flour derivatives, guar gum derivatives, cellulose derivatives and high-viscosity synthetic thickeners can be used as

Transfer printing – advantages/disadvantages

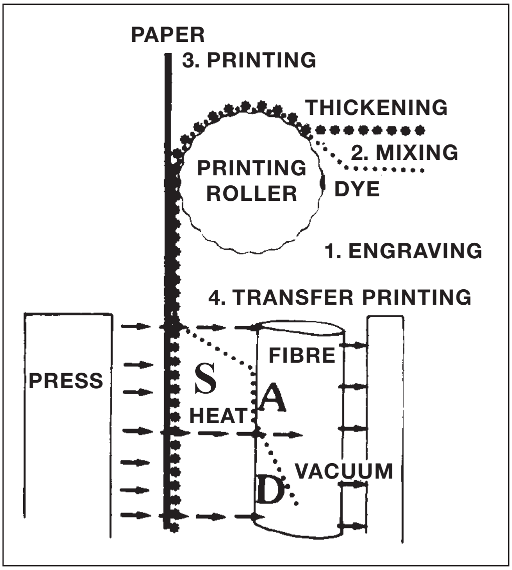

Fig.: Vacuum transfer printing (schematic). Process stages 1–3 take place in paper printing; the transfer stage 4 on the fabric printer.
S = sublimation in air; A = adsorption on the fibre; D = diffusion in the fibre.

thickening agents. In transfer printing the thickener stays on the paper which is burned to dispose of it.

Transfer printing – advantages/disadvantages,

I. Advantages:

- particular simplicity of process sequence compared with classical textile printing (Fig.),
- low investment capital and personnel costs,
- no waste water,
- low space requirement,
- steaming, washing and drying (heat setting after-treatment) not necessary,
- important advantages in the case of short metre lengths in terms of setting-up and idle machine times; dye losses no longer occur,
- risk of producing seconds quality is low; no high-quality materials are involved,
- quicker reaction to changes in fashion, little storage of raw fabric, shorter delivery times,
- fewer reproduction problems,
- problem free printing of bonded fabrics, geometrical and horizontal designs are easier to print,
- full use of gravure printing technique (effective shading of full to zero shade),
- highly-qualified personnel not necessary in laboratory, printworks, steaming facility, washing-off, etc.,
- flexibility during machine changes,
- simple order planning.

II. Disadvantages:

- difficulties in procurement of sample material (price) in the case of exclusive designs,
- not all fibre materials can be printed,
- limited fastnesses in the case of certain fibres, above all with dark shades,
- lack of colour brilliance in the case of polyacrylnitrile and mixtures of synthetic fibres with cellulose and wool,
- storage of large quantities of paper over prolonged period of time is a risk in terms of undiscovered faults,
- articles which require sublimation-fast dyes cannot be used,
- less print-through and associated danger of “grinning”,
- structured articles become flat, deterioration of handle in the case of certain qualities,
- lower production speeds due to existing transfer calenders,
- increased demands on colour technicians; necessity to re-think.

III. Parameters for strong position of transfer printing:

- trend towards increased use of synthetic fibres,
- responsibility for creativity is devolved to the paper supplier,
- non-skilled personnel can be used for transfer printing,
- risks of producing seconds quality in the case of difficult articles such as georgette, voile, satin, polyester/wool mixtures are drastically reduced.

This development has not yet been completed. Further development impulses can be expected due to:

- scarcer and more expensive resources,
- conventional printing in commission finishing plants becoming more expensive,
- increasing ecological sensitivity in society,
- expanding exportation of fashionable transfer paper from Europe into so-called development countries.

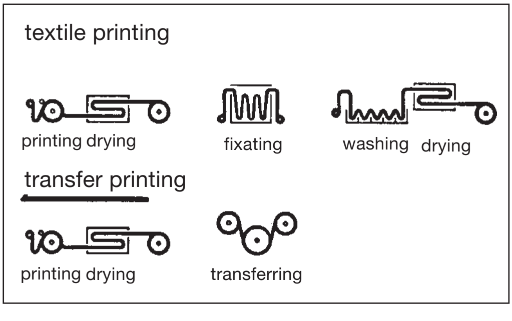

Fig.: Transfer printing/textile printing comparisons; schematic comparison of operating cycles.

Transfer printing calenders For standard fabric widths with a roller diameter on the electrically heated cylinder of approx. 800 mm, for production speeds of approx. 10 m/min (Fig.).

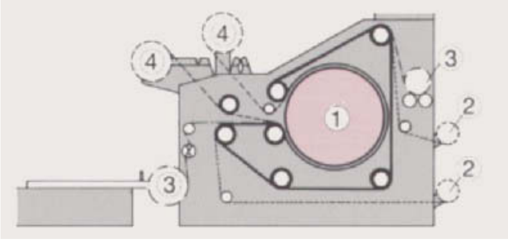

Fig.: Transfer printing calenders (Stork).
1 = heating; 2 = backing paper; 3 = substrate; 4 = transfer printing paper.

Transfer printing dyes Non-sublimation-fast → Disperse dyes which (when printed on an intermediate carrier) are transferred to the textile substrate during transfer printing at high temperatures (Fig.).

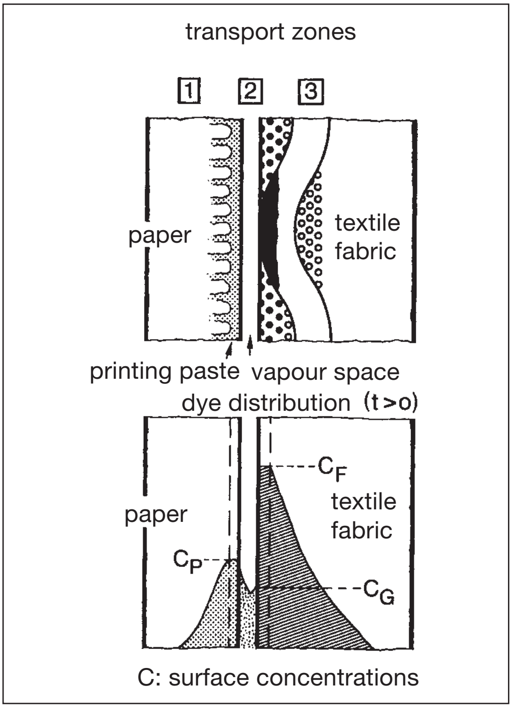

Fig. Schematic illustration of transport zones and dye concentration profiles in transfer printing (according to Hoffmann).

Transfer printing of floorcoverings Advantages compared with conventional → Carpet printing:

- simple process requiring temperature, contact time and vacuum only;
- dry process can be used even on rubber-coated material; no steaming, drying, no harm to the environment, economical in terms of energy;
- low investment costs compared with high costs for screens in conventional carpet printing;
- no aftertreatment except brushing;
- flexible process in terms of size of print commissions.

Transfer printing of polyamide Polyamides are not always suitable for transfer printing due to the varied manufacturing processes used. Careful selection of dyes does, however, allow good transfer printing results to be achieved, particularly on polyamide 6.6.

Transfer printing of wool In order to apply transfer printing techniques to wool the fabric has to be pre-impregnated and post-steamed for approx. 30 min after printing. Certain dyes have to be used which are not commercially available. Further advice for the process: a) Transfer printing with sublimable disperse dyes is possible after pretreatment of the goods with textile auxiliaries. This also applies to polyester/wool. b) Wool is pre-treated with a mixture of chromium salts, urea, lactic acid and surfactant. Then thermal transfer printing techniques are used to apply sublimable polyazo dyes which are capable of forming a metal complex due to hydroxyl groups in the ortho position. This is followed by steaming. Washing out is not necessary. For printing on polyester/wool specific dyes are added to standard transfer dyes.

Transfer printing on cotton and polyester/cotton In order to achieve good results with selected disperse dyes using transfer printing techniques on cotton and polyester/cotton it is necessary to modify the dye. The affinity of the disperse dye to cellulose must be increased. The following are used:

1. Glycols, e.g. polyethene and polypropylene glycols with a particular molecular weight, together with special agents, in particular DHDMEU.
2. Selected melamine/formaldehyde compounds.
3. Certain polymer dispersions, e.g. acrylate.
4. Formation of polymers on the fibre, e.g. polyester (from an acid chloride and a bisphenol) or polyamide (from an acid chloride and a diamine).
5. Partial acetylation which results in the best washing fastnesses.

Cotton and polyester/cotton textiles which are pretreated in this way are then transferred under standard conditions (e.g. 20–30 s at 200–225°C) and using standard transfer techniques. Transfer and crosslinking of the N-Methylol compound can be carried out in a single stage.

A reactive transfer printing technique for cotton makes use of vinyl sulphonate dyes which are printed onto paper. During transfer the entire print paste is transferred onto the cotton fabric without the reactive dye having previously reacted to the paper. After the dye reaction with the cotton it is necessary to rinse in order remove the surplus of print paste. The transfer printing machine of Küsters uses three "swimming roller" pairs (Fig.).

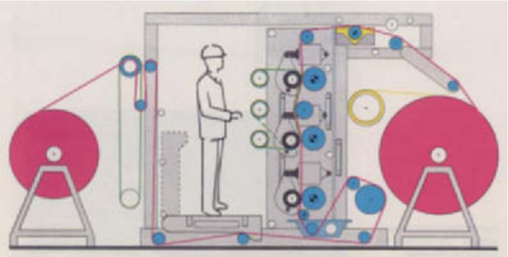

Fig.: Transfer printing machine for the Dansk "Cotton-Art" transfer printing process (Küsters).

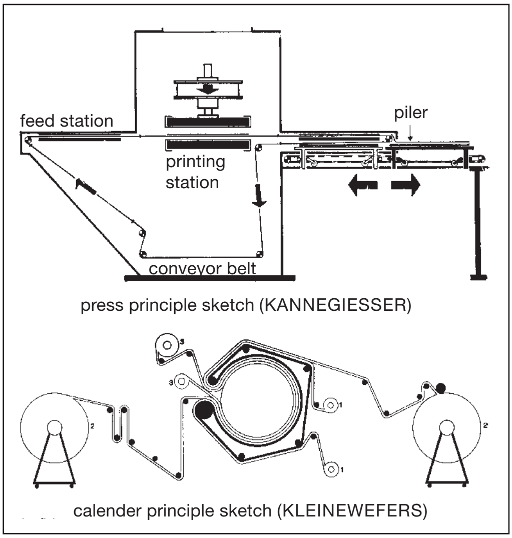

Fig.: Comparison of batch type (top) and continuous transfer printing (bottom) in the transfer printing process.
1 = protective paper; 2 = fabric; 3 = printing paper.

Transfer printing papers are available in two categories: omnibus and exclusive quality. The former quality is supplied at a reduced price to all interested parties without any type of limitation, usually with a minimum quantity of 500 m. The second quality can be reserved for certain companies for the duration of a year or longer at a corresponding surcharge with no minimum quantity being specified. Manufacture is by means of gravure printing, offset printing, screen printing .

Requirements:

1. Printability depends on surface smoothness of transfer printing paper (achievable by means of calenders or coating and/or choice of raw material and paper manufacture).
2. Handling during transfer process requires a certain suppleness which is promoted by low humidity content (4-6%). Even thickness and absence of folds are important.
3. The process of transferring the printing dyes onto the textile substrate must take place uniformly and effectively. The structure of the transfer printing paper has a great impact on this.

Transfer printing processes Indirect transfer of colour designs onto textile material, i.e. via previously executed printing onto rubber cloth (offset printing) or paper rolls (Fig.), in the latter case transfer by means of hot calender rollers. → Transfer printing.

Paper transfer printing is the basis of the Italian Colombo- and Star printing processes and the American Dynascope process works in a similar fashion (Sark process). In the Star process slightly smoothed paper is pre-coated with gelatine to prevent the printing paste from being absorbed. The paper is then printed with the addition of a easily melting resin (direct, reactive, acid, vat or disperse dye) continuously (4-dye copper roller rotary press) or discontinuously (with copper plates, 4-dye pattern, i.e. 4 prints). Transfer takes place onto the suitably prepared fabric on a heavy calender between steel and cotton roller, steel roller approx. 160°C, print at 1600 mm width 70 t, speed 6–10 m/min. The unprinted paper side runs counter to the steel roller and the paper sheets are manually placed directly in front of the calender gap onto the fabric roll. The melting print paste and the already well-mixed screen print on the paper cause the dyes to flow together on a screen-free surface where they are adsorbed by the fabric. This process makes it possible to transfer finely-structured designs onto relatively coarse fabrics and even onto velvet (85% dye transfer = good result). The process is completed by standard steaming and washing, etc.

Transfer printing resist effects Printing over or under a board with a print paste in which a blocking agent ensures that the dyes on the board are not transferred. There are two possibilities: a) blocking agent in the form of reactant resins, e.g. hexamethoxy methyl melamin and acid catalysts; b) blocking by means of metal salts with complex-forming capability. All salts of multi-valent ions such as iron, chrome, cadmium, aluminium can adopt this function. Copper is the most suitable in the form of acetate in a copper/amine complex.

Transfer system in dry-cleaning Dry-cleaning system on the principle of the → Cold unit. The transfer system in dry-cleaning may only be used in the Federal Republic of Germany if the operating company has been granted an individual exemption approval upon application in accordance with § 3, Para. 3 of the German Accident Prevention Regulations that control the assessment and definition of hazard (VBG 110). This also requires the approval of the supervisory trade authority.

Transfer zones In → Transfer printing dyes have to be selected which transfer as evenly as possible. These can be referred to as optimum transfer zones (Fig.); at temperatures which are too low, dyes which sublime too rapidly are frequently the origin of blurred printing edges (so-called bleed-out).

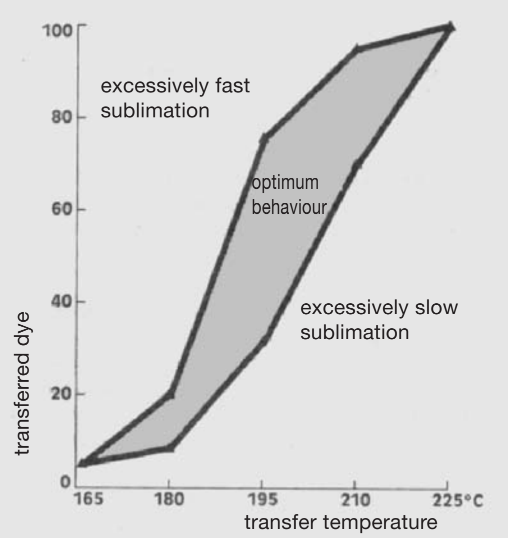

Fig.: Effect of temperature on dye transition in transfer printing.

The sublimation properties do not depend entirely on the dye molecule but also on the physical form of the dye (commercial form) and the dye concentration used. It should be noted that paper only absorbs approx. $^1/_5$ of the print paste quantity as compared with direct printing onto textiles and the dye quantities used in paper print pastes are much higher than in textile printing. The special commercial dye form with high dye content and low electrolyte content has to be adapted to these circumstances. Use of large dye quantities in liquid form (also simple colour kitchen work) is preferable.

trans form (opposite form) → cis form.

Transformation temperature (→ Accomodation point), temperature at which the fluctuations of the molecule cease in the non-crystalline ranges of a polymer i.e. are frozen. Example: Heating of thermoplastic fibres above the glass point brings about a partial splitting of the hydrogen bonds which solidify again into new bonds when they cool down stabilizing the new state. This temperature varies with different fibres: e.g. polyamide 6: 65°C, polyamide 6.6: 82°C, polyacrylnitrile: 75°C, polyester: 87–90°C. The freezing temperature is not identical with the → Softening range.

Transformers are used for converting electrical voltage of alternating or three-phase current, e.g. with air or oil cooling, as protection transformers for low voltage mains networks (of 110–300 volt to 24 volt), as regulator transformers for step changing on machines, apparatus, etc.

Transmission (transmitting). Term denoting the proportion of radiation which is neither (completely) absorbed nor reflected by the irradiated goods but is allowed to pass through to a greater or lesser extent. Transmission represents an important function in the case of infrared or ultra-violet absorption as not only the atoms at the irradiated surface participate in the energy exchange but also the adjacent atoms located in the lower layers. The less energy each atom layer converts into collision energy and passes this on as irradiation energy, the greater the penetration depth. On transmision, each atom functions as a secondary radiator passing on the primarily absorbed energy collision free directly to adjacent atoms as potential energy.

Transmission belts, drive belts are used as → Transmission for driving machines of all types and for connecting movable machine parts the speed of which is adjustable at will by selecting appropriate drive belt discs. Depending on the type of use, belts are made of leather (split and chrome leather), rubber or textile material. The latter are made of impregnated camel hair, cotton, silk (for rapid shift), viscose, synthetic fibres, possibly as an insert in rubber with sprung steel insert, etc. In addition to standard drive belts also tensioning roller leather belts (perforated), semi-, cross- and cone discs (→ V-Belts), angle belts, etc. →: Belt drives; Motive power engineering.

Transmission measurements on dye liquors According to the Lambert-Beer's Law, extinction and concentration of a dye in diluted solutions are directly proportional. White light of varying wave lengths passes through the measurement sample; as this happens a substance-specific light weakening of certain wave lengths occurs (Fig. 1). In this wave length range the light intensity of the incident light Φ_0 sinks to the light intensity of the transmitted light Φ_{trans} the ratio of which is the degree of transmission (Fig. 2).

$$\tau = \frac{\Phi_{trans}}{\Phi_0}$$

The light absorption corresponds to extinction (E) which is related to transmission in the following manner:

Transmission measurements on dye liquors

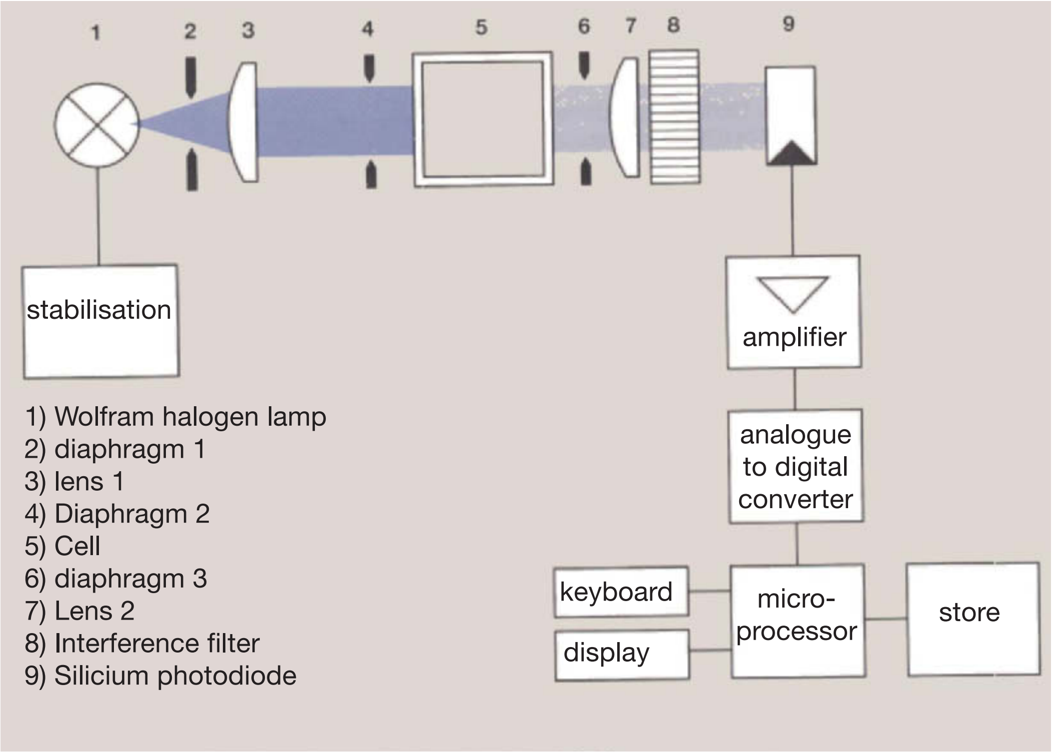

Fig. 1: Construction and measuring principle of a transmission measurement photometer (Merck).

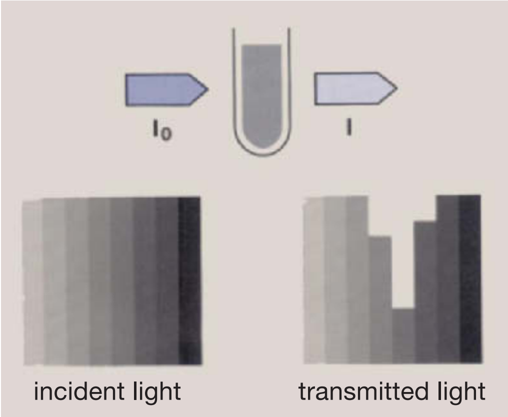

Fig. 2: Transmission measurement principle.

$$E = \log \frac{1}{\tau} = \log \frac{\Phi_0}{\Phi_{trans}} = \varepsilon \cdot c \cdot d$$

(Lambert-Beer's Law)

→ Extinction E increases with the concentration c of the disolved substance in the measurement solution and the depth of the cuvette. The extinction coefficient e is a substance-specific constant and depends on the wave length used, i.e. on the chosen interference filter. The following simple ratio results with constant layer depth of the cuvette:

$$C = \varepsilon \cdot F$$

F = factor

A blind sample is always measured first. This is followed by conversion of the mg/l-indication of the photometer into mg/kg of goods.

The existence of associates, agglomerates and coloured dye components which are inactive in terms of dyeing does not limit the validity of the proportional relationship between extinction and concentration within the degree of accuracy necessary for the dye liquor measurement. The decisive factor is that the relative number and size of associates and agglomerates, i.e. the particle size distribution of dispersions, must not be dependent on concentration. As long as this prerequisite is fulfilled, transmission measurements have proved to be an exact method of determining concentration including dye dispersions.

In order to facilitate comparative statements over a period of time, the consistency of supplies in terms of particle size distribution and relative content of coloured but colour-inactive dye elements should be indicated. If this important prerequisite is fulfilled, the ratio of measured extinction ranges and colour-active liquor components can be reproduced. As long as the dyeing properties of the substrate and the process sequence can be reproduced, liquors with corresponding extinction ranges can be expected to result in comparable colours.

The solvent for transmission measurement should be chosen so as to ensure that the dyes in the relevant concentration range are either totally soluble or are so difficult to dissolve that the dyes are available virtually completely as a dispersion and the dissolved molecule element is negligible.

As textile dyes are usually standardized for colour effectiveness which can be reproduced, coloured elements which are inactive in terms of dyeing, such as for example sythesis by-products or hydrolized reactive dyes, give the impression of having too high an effective dye concentration during transmission measurement. Errors of this nature are likely to occur when dyed by-products fluctuate markedly from batch to batch and a dye preparation is based on calibration measurements resulting from batches with deviating colour-active dye content.

Systematic optimization of dye synthesis, which is of economic interest, has resulted in the content of synthesis by-products in commercially available dyes becoming relatively small and reproducible. Within these parameters transmission measurement is also used by dye manufacturers for quality control and standardization of dyes in terms of intensity and shade. The Inter-Society Color Council and well-known dye manufacturers have publicised guidelines for the use of transmission measurement in quality control. The system for dye liquor measurement consists of a spectral photometer, a dilutor and a personal computer with a printer (according to Locker and Firmann).

Transmission profiles Longer wave absorption max. of sulphonated ultra-violet absorbers at 330–340 nm can be used for investigating their distribution in fibre cross-sections. With the aid of a rapid computer-controlled scanning table and the APA-MOS-programme (Zeiss) fibre cross-sections can be analysed with comb-like action and the transmission intensities in the absorption max. analyzed. The width of step in each direction is specified in advance. It depends on the degree of fineness of the fibre material investigated. A width of step of 1–2 µm in each direction has for example proved suitable for fine merino wool.

In this way transmission profiles can be achieved for woollen samples which have been pre-treated with ultra-violet absorbers. The profiles allow a statement to be made regarding the migration of the ultra-violet absorber into the wool fibre under the existing conditions. There are a variety of techniques for evaluating the resulting transmission profiles of a wool fibre cross-section. For transmission profiles of fibre cross-sections the minimum (T_{min}), max. (T_{max}) and fibre interior (T_M) as well as the differential ($T_M - T_{min}$) transmission values can be used to recognize the extent of ring dyeing. Low t-values are characteristic for wool with high ultra-violet absorbers concentrations.

In addition to this evaluation process, the area containing the ultra-violet absorber or dye can be placed in relation to the entire area. From this the degree of dye penetration can be calculated (Fig. 1).

$$A = \pi (R^2 - r^2)$$

$$\text{degree of dye penetration} = \frac{\pi (R^2 - r^2)}{\pi (R^2)} \cdot 100$$

r = total fibre radius (µm)
R = "ring-dyed" fibre radius (µm) which contains dye

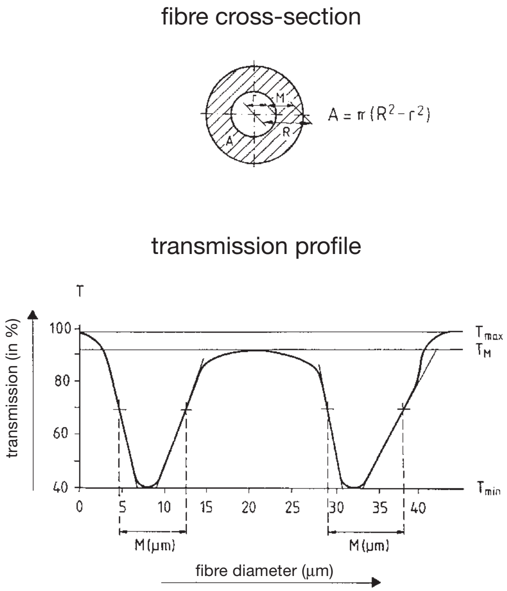

Fig. 1: Diagram of a ring-dyed wool fibre cross-section and an average transmission profile of a wool fibre cross-section (DWi).
A = the area containing dye; M = migration of the dye into the fibre.

Emission ranges (Fig. 2) and intensities can be measured on white-tinted woollen fibres making comparison of fluorescence intensities during various treat-

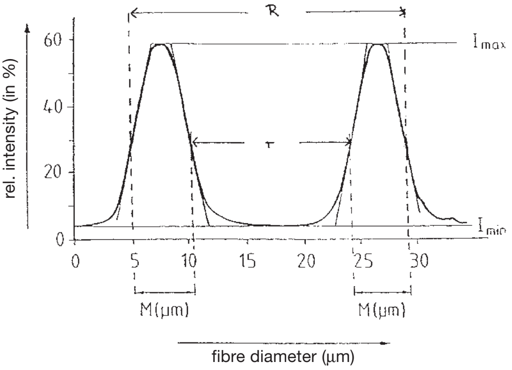

Fig. 2: Diagammatic average emission profile of optically brightened wool. The relative fluorescence intensity interrelates to a fluorescence standard (DWi). R = fibre radius (µm); r = radius of the fibre zone showing no fluoresence intensity; I_{max} = max. fluorescence intensity; I_{min} = min. fluorescence intensity; M (µm) = migration into the fibre (µm).

ments possible. The fluorescence intensities attained with the aid of photometric microscopy represent relative measurement values (according to Schäfer and Höcker).

Transmissions Devices for transmitting energy, e.g. between electrically-driven gears and apparatus, machinery, etc., such as for example → Transmission belts, drive belts.

Transparency The measure of light transmitted by a transparent medium. It is a function of the wavelength of light and decreases exponentially as the wavelength of the incident light increases. The transmission ratio is the ratio of the transmitted luminous flux to that incident upon a transparent medium. It is the reciprocal of opacity.

Transparent and opal finishes,

I. (→: Glass batiste; Organdy finish), used to create more or less transparent and stiff elastic effects on fine cotton fabrics (batiste). Principle: treatment in concentrated sulphuric acid, mercerization must also be carried out before and/or after acid treatment; possibly without tension. Organdy (glass batiste): glass-like transparency and boil-resistant stiffness effect. Opal: milky-white somewhat lower transparency. Imago: embroidery-like pattern created prior to acid bath treatment by printing a resist. Resisted areas appear matt white on a base which shows through.

II. Fabrics made of polyester fibres are subjected to a “de-weighting process” in which the fibres are peeled off from the surface by means of saponification. The process aims to achieve weight reductions of 10–20%. Reduction of the fibre titre achieves a casual appearance. The fibre itself takes on a slightly irregular surface structure and has a very similar appearance to silk fibre. As manufacture of light, transparent fabrics requires sophisticated spinning and weaving techniques, burn out processes are also occasionally used by means of which the cellulose component is removed from polyester/cellulose fibre mixtures. The treatment stages mentioned, which depend on the type of article, only represent a basis for fashion-conscious finishing which should be flowingly soft, lively and, whenever possible, hydrophilic.

Amino-modified polysiloxanes, transparent micro emulsions, represent an important group for achieving the specific handle characteristics of these materials. They differ from conventional polysiloxanes and softeners due to the low particle size of their active substance.

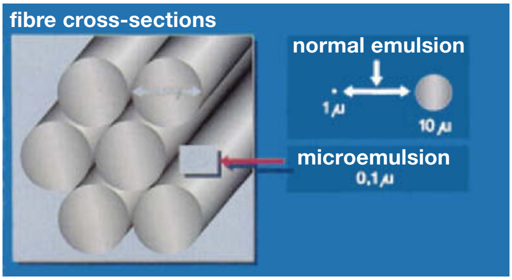

Fig.: Particle size in emulsions (Sandoz).

The Fig. is a schematic representation of the size ratios of particles of an emulsion and microemulsion as compared with a fibre bundle. They show that products based on microemulsions penetrate the fibre bundle far more easily and are distributed more homogeneously over the fibre surface than conventional emulsion softeners whose particles are mainly deposited on the fibre exterior. This explains why it is possible to achieve previously unknown soft handle effects with these products working on the basis of an action principle which could be described as “inner softness”.

Unfortunately the most effective of softeners create a decidedly hydrophobic surface and reduce the absorbency of the fibre material. This can on the one hand impair wearing comfort due to lack of perspiration absorption and on the other hand increase soiling properties in terms of greasy soiling agents such as skin grease and oily soot as well as increasing soil redeposition from washing liquors which again impairs the care characteristics. These disadvantages can be eliminated by using hydrophilic softeners without any major sacrifices in terms of soft handle characteristics.

Transparent films Thin materials made of cellulose-based fabric (cellophane) or synthetic high polymers (polyamides, polyester, polystyrol, polyolefins, polyvinyl alcohol, etc.). Ranging from very thin to cardboard thickness, transparent, non-transparent, glossy, matt, colourless, coloured, printed. Used particularly for film packaging.

Transparent prints Cotton fabrics can be made transparent (parchmented) by printing with suitable chemicals. → Transparent and opal finishes.

Transportation time Proportion of → Handling time factor or goods transportation time outside/within a company or organization which is necessary to process goods. This is totally unproductive time from a microeconomical point of view.

Transport equipment This includes for example conveyor belts, spiral conveyors, cable systems, garment lifts, chain drives, pneumatic systems, lifts, cranes, etc. → Transport systems.

Transport systems Transport automation takes up, sorts and transports individual parts produced by machines to the next production location. An example is the Pally (Innovatex) which is used as a transport system in spinning. The Pally drives up to a machine, which has indicated that a certain number of packages is ready to be picked up, and positions itself. The Pally takes on two packages simultaneously without touching the yarn systems and deposits them on a pallet with perforated or embossed intermediate shelving. After filling a shelf, the Pally removes an intermediate storage shelf from the pile and places this on the paletted package level. The completed pallet can be deposited by the mobile unit using the lifting and moving forks either directly behind the machine (e.g. on roller tracks) or alternatively the pallet is positioned at the end of the group of machinery at a transfer point for further transportation within the company or organization (Fig.).

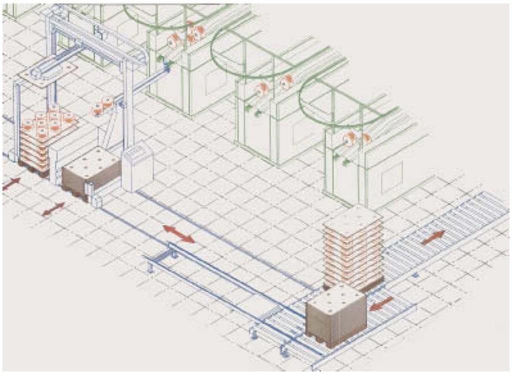

Fig.: Automatic paletting of cross-wound bobbins and transport system for the palettes (by Innovatex).

Transport tarpaulins Fabrics for covering lorries and containers, coated with polyvinyl chloride (PVC) on semi-calenders or blade coating with stenter processing. The base fabrics of polyester fibre are generally plain or panama weave in weight category 600–800 g/m^2. The coated surface is lacquered with solvent based polymers. The PVC paste is prepared with pigments, softeners and possibly filler materials and give the transport tarpaulin typical coloration (also signal effect). → Tarpaulin coating.

Transverse brittleness angle → Torsional strength.

Transverse cutting machines automatically separate the fabric web at a pre-specified meterage, deposit the finished fabric roll and provide a new wooden or cardboard roller for the next fabric roll without interrupting the process.

Transverse tricot (traverse tricot). → Tricot with wide transverse weave ribs, particularly elastic and stretchable. Opposite:→ Warp rib tricot.

Trash Contamination of cotton including dust. Mechanical operating systems, such as, for example, the Shirley analyser, Shirley trash separator and the Uster-MDTA dust and trash tester are used to measure contamination of cotton from bales, card lap or tow. Cotton contamination particles are separated from the fibres by means of dissolving and cutting devices before being weighed. The percentage value of contaminated content can be calculated from the weighed contamination quantity expressed as a proportion of the overall sample quantity. The contamination particles are divided into three size categories which generally include particles of 0.05 mm^2 to 3.00 mm^2 surface content:

category A (small)	from >0.05 mm^2 to 0.30 mm^2
category B (medium)	from >0.30 mm^2 to 0.70 mm^2
category C (large)	from >0.70 mm^2 to 3.00 mm^2.

Traverse mechanism Fabrics with thick edges form bulges in wound form which can cause the fabric to stretch; the edges mark the elastic rollers in the calender. The traverse mechanism displaces the fabric web laterally by a variable dimension; the edges are no longer aligned on top of one another.

Traverse winding Winding of threads with slight traverse movement resulting in the individual thread layers not being located exactly above one another. The thread conductor traverses in addition to its stroke when forming the spool; this strengthens the spool edges and a better spool form results. This thread conductor stroke displacement serves to build the spool structure and is created by the traversing gear. Traverse winding improves the thread location on the beam during building of warp beams; the individual layers do not cut in. (Additional) cardboard layers can also be inserted to prevent individual layers from cutting in. → Traverse mechanism.

Tread comfort value This is intended to give an indication of the degree of tread comfort when walking on textile floor coverings. It is determined by the deformation energy on compression in accordance with DIN

54 327. Increasing pressure in 6 specified pressure stages (p_1 to p_6) is used to determine different deformation energies. The ratio of these deformation energies to correspondingly specified reduced deformation energies provides indicators (B_i) which are used to determine the tread comfort value. Tread comfort values B_W, B_A and B_{SP} are differentiated for different use areas (living (w), working (a) and sports (sp) areas).

Tread sound insulation (carpets) This concerns the actual tread body sound; the denser the carpet the better the tread sound insulation. The underlay plays an important role (felt, foam backing, etc.). The degree of tread sound transmission is expressed by normal sound level and is measured in a room under a ceiling construction when a standard hammer device impacts on this. A simple dimension for the quality of tread sound insulation is the ISO-recommended tread sound insulation index I_i in decibels (dB). For the purpose of comparison with the German norm, additional indication is made on the sound prevention scale (TSM) in dB. The higher the degree of tread sound insulation, the smaller the decibel number of the insulation index I_i or the greater the TSM-value. A further dimension is the tread sound insulation improvement $V1_i$ of the uncovered floor through the tested carpeting = difference of the index values without and with carpeting.

Tread surface Walking surface or uppermost layer of carpeting.

Tree beard Colloquial term for → Tillandsia fibre.

Tretrad (walk wheel) This device consists of a rotating 4-part wheel with “feet” and is used to determine wear on textile floor coverings. It is also known as a Lisson unit on the basis of the Lisson tretrad system. It is used for measuring weight loss in g/m^2 due to abrasion. The device enables abrasion-sensitive fibre materials to be determined and assesses their suitability for use on stairs. It is suitable for use on pile carpets as well as needle felts and needle punched floor coverings.

TREX English textile machinery association; → Technical and professional organizations.

TRI Textile Research Institute; → Technical and professional organizations.

Tri (from the Greek: tris = three),

I. Prefix meaning “three times, triple”, e.g. trioxide (containing 3 oxygen atoms).

II. Short form for → Trichloroethane.

Triacetate According to DIN 60 001 this is a generic term for → Triacetate fibres with at least 92 wt.% acetylated –OH groups in accordance with American proposal.

Triacetate fibres (cellulose triacetate, primary cellulose acetate), belonging to the group of regenerated cellulose fibres on the basis of → Cellulose acetate; at least 92% of cellulose hydroxyl groups are acetylated. Although related to so-called normal → Acetate fibres, there are significant differences in terms of various important details. Manufacture: known for a long time; but initally difficult to spin due to predominant insolubility in technically easily accessible solvents (e.g. production costs too high using chloroform); the use of the cheaper dichloromethane made manufacture economically viable; dry and wet spinning processes possible. Thermosetting process is used to improve properties which results in modification of the crystalline structure. Large-scale production since the middle fifties. Properties for textile use (quoting acetate for comparison in brackets): density 1.30 (1.33); humidity absorption: normal 4.9–4.5 % (6.0–6.5%), thermoset 2.5–3.0%; water retention capacity: normal 16–17% (25–28%), thermoset approx. 10%; tear strength: 10–13 cN/tex; elongation at break: 18–30%; crease resistant, low electrical conductivity. Resistant to micro-organisms. Light, ultra-violet and weather resistance similar to acetate fibres. Good temperature stability: melting point 300°C (225°C); easily pleatable: pleating temperature 165–175ºC (mixed fabrics to 185°C); boil-resistant (HT-process possible), easy-care. Thermosetting necessary (surface shrink unset 16%, set approx. 3–4% after 2 h machine wash at 60°C), always measured after dyeing at the following setting temperature:

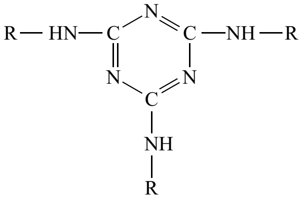
\>180°C = improved washing, gas and abrasion fastness.
\>200°C = increased ironing point, improved dimensional stability and crease-resistance.
\>210/220°C = modification of crystalline structure, improved thermal stability.

Usually dry heat setting. Ironing temperature: normally max. 180°C, thermoset 240°C. Chemical stability as compared with acetate fibres: acids such as acetate (strong acids are corrosive), more resistant to alkalis (mercerisation in cotton mixture is safe; to pH 9.5 and 95°C “no noticeable saponification”; concentrated alkalis saponify, particularly at higher temperature), more resistant to oxidation bleaching agents, i.e. difficult to bleach (suitability of chlorite, per acetic acid, hypochlorite). Soluble in various organic solvents (→ Acetate/triacetate – solubility in organic solvents). Used in pure form and in mixtures for ladies’ clothing (dresses, blouses), children’s clothing, fleece fabrics, technical fibres (mixtures with polyamide, polyacryl nitrile, polyester, wool).

Triacetate fibres/damage Testing by determining the → Viscosity index of a diluted solution of triacetate in m-cresol.

Triacetate fibres in dyeing → Dyeing of triacetate fibres.

Trialkylmelamines Category of → Defoamers effective against all types of anionic and cationic surfactants at concentrations of 0.1–1% in terms of washing agents; completely independent of water and type of complexing agent.



Triangular spindles Spindles used during dyeing of yarn packages to accommodate the spools and attached to the base plate of the dye package carrier.

Triarylmethane dyes → Triphenylmethane dyes.

Triaxial fabric These consist of 2 warp and 1 weft thread systems crossed at an angle of 60°. This arrangement results in excellent strength values at reduced weight. Compared with conventional fabrics (biaxial fabrics) of the same weight, triaxial fabrics have a tear strength which is four times higher. Elasticity and strength should be approx. the same in all directions. Used particularly in technical fabrics, they offer great potential for the clothing sector and curtains in conjunction with appropriate material and fabric construction.

Triazones → Dimethylol-triazone.

Tribasic Term for acids with 3 effective acid hydrogen atoms which are ionisable and metal-replaceable; e.g. phosphoric acid H_3PO_4, trisodium phosphate Na_3PO_4.

Tribology Term used to denote the theory of surfaces which impact on each other in terms of relative movement and of associated problems. Term for the theory of friction which also includes the surface properties of fibres and their behaviour towards solids, liquids and gases.

Tributyl phosphate (TBP), phosphoric acid tributylester), $(C_4H_9O)_3PO$; density 0.977; boiling point 289°C (decomposition). Light-coloured solution, virtually odour-free, easily soluble in alcohol, soluble in water. Used also for → Antifoams; not easily biologically degradable.

Tributyltin oxide $(H_9C_4)_3$-Sn-O-Sn-$(C_4H_9)_3$; organo-metallic compound with bactericide and fungicidal effect. Water-soluble liquid. Boiling point 180°C. Wood protection agent; used for odour control with textiles and the like.

Tricarballylic acid $(CH_2–COOH)_2–CH–COOH$. Produced by the reduction of → Citric acid which contains one additional oxygen atom. Sulphonated tricarballylic acid esters make highly effective wetting agents (→ Sulphonated polycarboxylic acid esters).

Trichloroacetic acid (TCA), $CC1_3–COOH$; molecular weight 163.4; density 1.62. White dissolving crystals with a slightly acid smell, soluble in water, carcinogenic. Results from oxidative decomposition of tetrachloroethane (under ultra-violet rays and ozone).

Trichloroethane (1.1.1-trichloroethane, methyl chloroform), $CH_3–CC1_3$; molecular weight 133.42; density 1.31-1.35; boiling point 74°C) (azeotropic mixture with water at boiling point 65°C with 95.7 wt.% trichloroethane). Colourless liquid; volatile; evaporation index 2.6. Not easily flammable. Good solvent for lubricating greases, mineral oils, resins, waxes, tar, vinylidene chloride. Corrosive in pure form (therefore for chemical cleaning with up to 6% stabiliser); hydrolysing in the presence of water. Used as cold cleaning agent for metal surfaces, solvent for chemical cleaning, raw material for adhesives, putty, dyes, aerosols, spotting agents. → Chlorinated hydrocarbons. Prohibited for use as a chemical cleaning agent in the Federal Republic of Germany.

Trichloroethylene (tri, ethylene trichloride), $HC1C=CC1_2$. Colourless liquid, clear as water, nonflammable, evaporates easily, smell similar to chloroform, strong anaesthetizing effect, prolonged presence on the skin causes “burn blisters”. Does not corrode standard construction metals (except light metals) at temperatures under boiling point. Not easily soluble in water; hygroscopic; miscible with almost all organic solvents. Dissolves light and heavy greases, oils, resins, rubber, waxes, tar, oil-based dyes (if not too resinated, otherwise + alcohol + benzene soap), bitumens. Dissolving tendency for certain acetate, naphthol and vat dyes; also for polyvinyl chloride fibres (becoming hard and brittle), certain plastic parts (buttons, zips, buckles and the like) as well as plasticised finishes. Particularly dangerous, carcinogenic substance the use of which is prohibited in Germany. → Chlorinated hydrocarbons.

Trichlorofluoromethane → Chlorofluorocarbons.

Trichloroisocyanuric acid → Chloroisocyanuric acids.

Trichloropyrimidine The basis of certain commercially available reactive dyes. → Reactive dyeing.

Trichlorotrifluoroethane (R113), $CF_2C1–CFC1_2$, boiling point 47.6°C; density 1.58. Refrigerant used in chemical cleaning for cleaning leather, furs and delicate items of clothing in special cleaning machinery. Its use is prohibited in Germany. → Chlorofluorocarbons.

Trichromat Perception of colour by the normal-sighted. → Colour vision.

Trichromatic Three-coloured (→ Chromatic), the normal perception of colour (→ Trichromat). Deviations: → Defective colour vision.

Trichromatic colorimeters → Colour measurement.

Trichromatic colour coordinates → Colorimetric measures. In this context the following concepts are identical: trichromatic system X,Y,Z = trichromatic components = norm colour values X, Y, Z. Trichromatic coordinates or coefficients = norm colour value proportions x, y, z.

Trichromatic colour values Identical with the so-called trichromatic → Colorimetric measures, also known as tristimulus values or tristimuli.

Trichromatic dyeing Dyeing with triple combination of yellow (or orange), red and blue (basic colours). Widely used in the dyeing of wool and synthetic fibres, not generally used for dyeing cellulose fibre. → Colour triangle.

Trichromatic printing (three colour printing). Use of printing rollers with appropriately graded engraving depth or templates with corresponding grid with which multi-colour pattern is achieved by means of multiple fall-ons. A 4th roller or template is often used for black or grey.

Trichromatic RGB system → RGB colour measurement system.

Tricot,

I. Elastic fabric with fine, narrow ribs in warp direction, transverse or diagonal direction (warp rib, transverse, diagonal tricot). For suit and coat materials (e.g. uniforms) and sports clothing (e.g. riding trousers).

II. Single-surface weft-knitted fabrics with right and wrong sides. Used mainly for underclothes and T-shirts.

Tricotine Diagonal-weave, worsted fabrics with tricot-like appearance used for ladies' dresses and suits (with smooth finish).

Tricot weave,

I. Created in fabrics by tying reverse warp threads (warp rib tricot) or reverse weft threads (transverse tricot) as well a special weave (diagonal tricot).

II. A form of ground structure used in warp knitting in which the threads are transferred from one needle to its neighbour and returned.

Tricresyl phosphate (TCP, → Alkyl phosphates), $(C_6H_4–CH_3)_3PO_4$. A tricresyl phosphoric acid ester. Oily liquid, colourless, neutral, odourless; density 1.172; molecular weight 368. Almost insoluble in water; soluble in alcohol, ether, chloroform, benzene, glacial acetic acid, lipoids. Ortho-tricresyl phosphate is an extremely powerful nerve poison whereas meta- and para-tricresyl phosphates are harmless. Used predominantly as plasticiser for artificial leathers, synthetic resins, waxed cloth, etc. Also used as a preservation agent for sizes and finishes.

Triethanolamine $N(CH_2–CH_2–OH)_3$; density 1.119–1.124; boiling point 270–279°C. Reaction product of ethane oxide on ammonia. Thick oil similar in consistency to glycerine, slightly fishy odour, sticky, hygroscopic, absorbs carbonic acid from the air, very alkaline. Miscible with water, alcohol, glycerine. Slightly soluble in acetone, chloroform, virtually insoluble in ether, benzene. Triethanol compounds with oleic acid (triethanol-soaps) are soluble in water and are neutral, fibre-friendly, highly effective emulsion agents (for dirt, oils, waxes, chlorinated hydrocarbons, etc.) Used as emulsifiers, pasting agents for vat dyes, solvents for acid dyes. Also used as additives in lubricating oils. Component part of wetting, cleaning, softening, sizing and finishing products.

Triethanolamine ester salts Cationic surfactants in which 1, 2 or 3 hydroxyl groups of → Triethanolamine can be esterified.

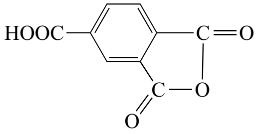
Triethylamine $(C_2H_5)_3N$, colourless liquid with odour similar to ammonia. Density 0.73; boiling point 89.4°C. By-product of manufacture of quarternary compounds. Used amongst other things as a stabiliser for chlorinated hydrocarbons.

Triethylsulphateamine, disodium salt Used as a resin finishing agent for alkaline wet crosslinking and for two-step processes.

Trifluorochloroethylene $F_2C=CFCl$, colourless gas which is polymerized to form → Polytrifluorochloroethylene.

Trifluorotrichloroethane → Chlorofluorocarbons.

Trimellitic anhydride (TMA). $C_9H_4O_5$, a hemimellitic acid. Colourless crystals. Use: for synthetic resins, adhesives, textile auxiliaries, surfactants, polyvinylchloride softeners.



Trimer Oligomers of three monomers.

Trimers as a problem source of polyester oligomers Most polyester fibres contain approx. 1.5% → Oligomers, of which 1.1–1.2% are cyclic trimers. The surface content of the polyester is from 0.1-0.3%, of which 97% are trimers. According to experience, difficulties start to arise when the surface concentration of oligomers reaches 0.3%. Trimers such as those of low water solubility, with a tendency to crystallise rapidly and which are resistant to alkalis, are mobile in the non-crystalline areas of the polyester fibre and migrate (depending on the fibre structure and temperature and duration of dyeing) to the surface of the fibre and into the dyebath where they form saturated solutions and rapidly crystallise on crystal nucleii which have been on the fibre from the outset. As well as this, crystal nucleii form on rough, sharp-edged components of the dyeing machine, in preference where the temperature periodically fluctuates or is lower than at other sites in the machine. Oligomeric deposits inside the dyeing machine increase from one dye batch to the next when only polyester fibres are dyed, and if the machines are seldom cleaned, using reductive-alkaline media. Using the shortest possible dyeing times can somewhat reduce the release of trimers and growth of large crystals (= well adjusted dye formulation without shading times and optimum temperature/time programs). Carrier additives tend to produce thicker deposits. Even carriers, the active components of which dissolve trimers, are not a reliable solution to the problem as they are extensively absorbed by polyester fibres at dyeing temperatures and the small amounts which remain in the aqueous emulsion in the dyebath are normally not sufficient to dissolve the trimer deposits completely. Neither can other auxiliaries (dispersants or emulsifiers) reliably keep the trimer crystals in a dispersion which is fine enough to be drained later with the liquor. More trimer crystals are removed by draining the liquor at high temperatures (125–135°C) than by draining the liquor after it has cooled down (particularly in the case of wound (yarn) package and flocks). The removal of deposits from dyeing machines after dyeing using saponification catalysts seems promising. One trimer-specific development clearly promotes the saponification of trimers in alkaline cleaning liquors, keeps the surfaces of dyeing machines free from trimer deposits and leads to improved polyester-flock and combed-top spinning behaviour.

Trimethoxymethylmelamine → Methoxymethylmelamines.

Trimethylglycocoll Same as trimethylglycine → Betain.

Trimmings,

I. Smooth, (so-called double-braided) → Braids made from cotton, viscose or mixed yarns (8–10 braids/cm). Examples of use: bordering furnishings, covers and curtains.

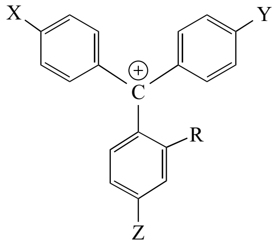
II. Used for hems, borders or decoration of textile products. Restricted use, for example, as fringes, tassels →: Braids; Gimp and → Tuft and the like.

Trioxane $(CH_2O)_3$, particularly stable cyclic oligomer of → Formaldehyde. Freely soluble in water, alcohol and ether. Among other things, used as a stabilizing agent for trichloroethylene. Heating trioxane and acids in the absence of water produces pure, dry formaldehyde in its gaseous state. (→ Polyoxymethylenes).

Triphenylmethane $(C_6H_5)_3$–CH, → Cyclic hydrocarbons made up of three benzene nuclei linked to a single carbon atom. Parent substance of → Triphenylmethane dyes.

Triphenylmethane dyes (triarylmethane dyes). Dyes derived from → Triphenylmethane, the water-solubility and dyeing properties of which are determined by the amino-, sulfo-, and carboxylic groups attached to the molecule.

Among these are cationic dyes, acid dyes, a few chrome or mordant dyes, substantive dyes and fat-soluble dyes. Some xanthene dyes are triphenylmethane dyes. (→ Carbenium ions).



e.g.

malachite green type: $X = Y = NR_1R_2$, $Z = H$

crystal violet type: $X = Y = Z = NR_1R_2$

phenolphthalein type: $X = Y = OH$

Triphenyltin chloride $(C_6H_5)_3SnCl$; molecular weight 385.45; colourless substance, relatively non-poisonous, almost water insoluble; soluble in alcohol, ether and acetone; unstable in hot solution. Used in the form of an emulsion as, for example, moth repellents during dyeing and bleaching (with sodium dithionite and sodium peroxide). Triphenyltin chloride is absorbed rapidly by wool with good fastness properties.

Triple point → Reference temperature of the three phases (solid, liquid and vapour) in a one-component system, such as water, in which case it is the ice point (±0°C) and the steam point (+100°C).

Triple point of water This is the fixed point on the international temperature scale, where ice, water and water vapour are in equilibrium, i.e. exist simultaneously and reversibly. This temperature is 273.16 K (Kelvin) = ±0°C (Celsius).

Triple pressure zone calander When building the calander, an effort is made to align the rollers in different positions in relation to each other in order to achieve a uniform distribution of pressure over the width of the goods and to apply particularly high pressures (Fig. 1). A Nipco roller with three pressure zones

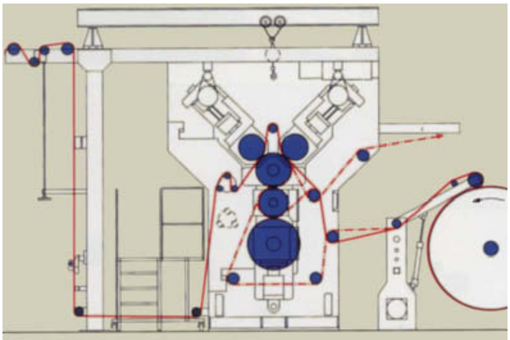


Fig. 1: Typical triple pressure zone calander with Nipco roller in the centre of the pressure zone (Kleinewefers KTM).

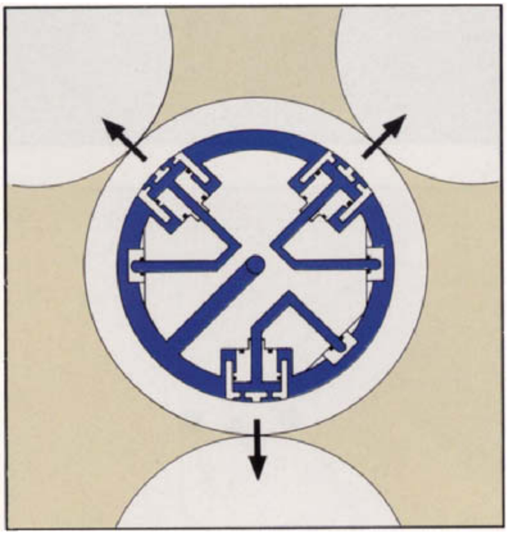

Fig. 2: Triple zone pressure diagram with Nipco roller (Kleinewefers KTM).

in a triangular arrangement can be particularly effective in equalizing the pressures applied by the three counter rotating rollers using hydraulic rams (Fig. 2).

Triple weft carpets Woven carpets in which each row of knots is bound to three wefts.

Triple(zone)filter photometer → Colour measuring instruments.

Triple zone method → Colour measurement using a triple-zone filter photometer.

Tripolyphosphates → Phosphate, condensed.

Tris- (from Gk. tris = three), prefix for organic compounds made up of three identical ("complex") substituents, for example → Tris(1-aziridinyl) phosphine oxide.

Tris(1-aziridinyl) phosphine oxide $(CH_2–CH_2–N)_3P=O$; Aziridinyl compound for permanent flame-retardant finishing using, for example, → THPC.

Tris(2,3-dibrompropyl) phosphate Since the mutagenic and carcinogenic properties of this substance have been established, products based on tris(2,3-dibrompropyl) phosphate are practically no longer commercially available as flame retardants.

Trisilicate So-called "neutral" → Water glass ($SiO_2 : Na_2O = 3.3$) as opposed to alkaline water glass ($SiO_2 : Na_2O = 2.0$).

Trisodium phosphate (TSP) (tertiary or tri-basic sodium phosphate), Na_3PO_4; density 2.536; calc. as dust-fine powder; cryst. as white powder, flakes or needles; non-hygroscopic; freely soluble in water. Aqueous solution strongly alkaline (1% solution pH 11.3) due to the formation of sodium hydroxide: $Na_3PO_4 + H_2O \rightarrow Na_2HPO_4 + NaOH$. The solution alkalinity lies between that of sodium carbonate and that of sodium hydroxide at comparable concentrations. Hardness elements are rapidly precipitated as insoluble salts, and fats and oils are emulsified. Use: water softener for boiler feed water for complete or residual softening, also used as a descaler; alkali factor for oxygen bleaching; washing and degreasing agent; builder for detergents and cleaning agents.

Trisodium phosphate water softening process Water-hardness elements are precipitated out by adding → Trisodium phosphate (TSP). Softening achieved down to 0.1°d. Mainly used as an additional method to the → Lime-soda water softening process. For security reasons, trisodium phosphate is often added to completely softened boiler feed water and distilled water for high-pressure boilers (corrosion).

Tristimulus values Standard colour values (x, y, z) are numbers which fully characterize the colour stimulus specification (→ Colorimetric measures). When a bundle of parallel white light rays meets a triangular prism, it is split up into its components and can be separated precisely into colour lines (Fig.).

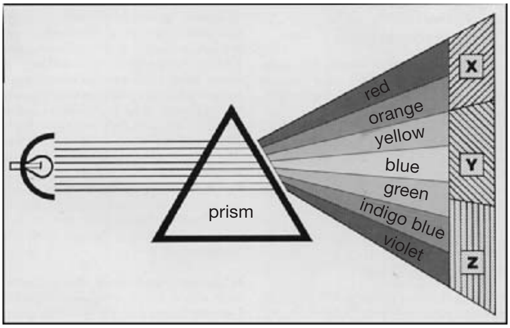

Fig.: Prismatic splitting of white light.

Tritik (Plangi-Tritik, crimped batik). → Plangi technique, in which yarn, threads or bast is drawn into the fabric in rufflets corresponding to the pattern and then gathered before dyeing, in order to produce resists during the dyeing process.

Trivinyl According to the → EDP key system for fibres made from three different vinyl monomers (acrylonitrile, chlorinated vinyl monomers and a third vinyl monomer).

Tropical Light worsted yarn goods in linen or Panama weave, plain or patterned (yarn or colour-effect patterns); up to 300 g/running m; with napless finish. Used for men and boys' outerwear and women's outerwear summer clothing. → Fresco.

Trough doctor (screen printing) Used to apply the coating of lacquer during → Screen making.

Trough roller Ball-bearing-mounted roller in a trough for unwinding rolls of fabric at the feed end of fixing machines, steam calenders, folding machines and inspection machines, etc.

Trough type fabric store A device for storing goods by folding in zigzag fashion in cross pleats on a trough-shaped base. → J box.

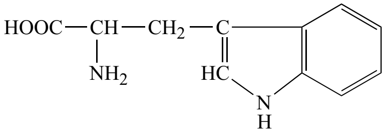
Trubenizing (trubenizing process), for the purpose of chemical stiffening of men's laundry (without using finishing products). Method for stiff collars: a lining which has been soaked with cellulose acetate and swollen with solvent (acetone) is inserted between the outer fabrics beforehand and then bonded to them using a hot iron. This type of collar is soft when wet, washes well and always achieves its original stiffness again (without the use of a finish) after ironing.

True solutions These are solutions in the strictest sense. Their component particles exist in monomolecular form in contrast to → Colloidal solution.

Trypsin An → Enzyme (→ Proteinases) produced by the pancreas which breaks down proteins. Unlike pepsin, the hydrolytic decomposition of protein leads to free amino acids which means that even → Polypeptides are attacked (behaviour similar to that of papain). It is most effective in the weakly alkaline range pH 8–8.7. Amorphous trypsin only attacks proteins in the presence of a protein-type activator which is not required in the case of crystalline trypsin. Trypsinogen is a crystalline trypsin precursor. Pure trypsin is a yellow to grey powder which dissolves in water to give a turbid solution. Crystalline bovine trypsin has a molecular weight of 34 000.

Tryptases → Proteinases of the trypsin type.

Tryptophan A cyclic → Amino acids (2-amino-3(-indolyl)propionic acid).



TS,
I. Titre fluctuation, → TS-type
II. Turk. Standardlari = Turk. Standard.

Tsatlee silk Chinese Grège yarn from live cocoons, products from the cottage industry, non-uniform.

T screens Rotary screens for printing → Transfer printing papers. They have a particularly smooth surface and 80 mesh size to compensate for the sensitivity of transfer printing to any unevenness in the screen due to low absorption capacity of paper. – Manuf.: Stork.

TSE Turkish Standards Association; → Technical and professional organizations.

T-Shirt Formerly a short-sleeved vest; today, this is a term used for a multitude of different fashionable casual shirts, with or without sleeves (short or long sleeved), coloured, printed, and decorated with motifs, etc.; made from knitwear.

TT (dyeing) process → Thermofixation and thermosol process.

TTZ (cloud point index) → Cloud point index.

Tub dyeing machine To shorten the liquor ratio in yarn dyeing, the dyeing volume (otherwise a dyeing boiler) is sectionalised into a number of tubes. A dye column is dyed separately in each tube (Fig.). Associated with this method of dyeing is an adapted finishing method which, under certain circumstances, is carried out by robots.

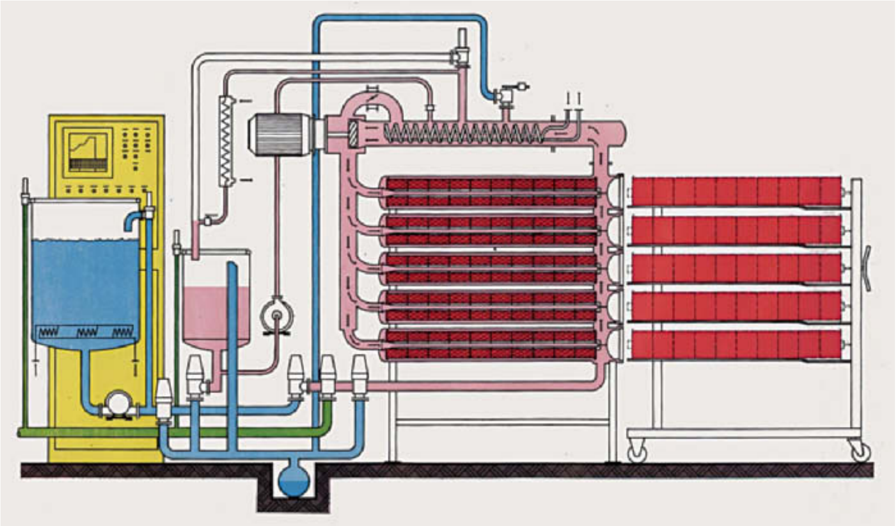


Fig.: Reduced liquor-to-goods-ratios through yarn dyeing in pipes by OBEM ("API/O").

Tubeless cross-wound yarn package Wound packages without a batch centre (dyeing tubes). Promotes better penetration of dye.

Tubular fabric dye padder Padder for the continuous dyeing of tubular cotton wear with reactive dyes according to the CPB method. After impregnation of the tube which is width guided through, it is blown up like a balloon by air-injection nozzles and then squeezed out. A warping device is used to lay the edges of the tube marked by the squeezing process. Special place for depositing goods: → Tubular fabric dyeing range.

Tubular fabric dyeing,

I. Term from piece dyeing which is used for fabric or knitwear with the edges sewn together to form a tube and dyed on the winch as an effective way of countering selvedge curling.

II. Dyeing of tubular knitwear.

Tubular fabric dyeing range The essential purpose is to prevent creases. The main application is reactive dyeing according to the cold-pad batch dyeing method, coupling naphthol dye by padding up fast colour salts, continuous dyeing with vat dye followed by the steamer. Mainly tubular cotton wear is impregnated in the padder economy trough, blown up like a balloon after the squeeze nip and the balloon squeezed for the optimum distribution of liquor (liquor pick-up 130–140%). Then the edges creased by the squeezing unit are laid using a turning device and plaited down in small dwell packages. For thermo-dwelling using heated panel cars; enclosed in plastic film to prevent partial drying. Fabric speed: 25–35 m/min.

Tubular fabric mercerization → Mercerizing tubular knitwear.

Tubular fabric mercerizing machine Tubular knitwear which has not been cut open should be mercerized without fixing the fold creases. For this reason, the impregnated hose is blown during stabilisation in the following steps (Fig. 1) : A = roller-vat type impregnation zone using the squeezing unit; B = mercerization cartridge with controllable lateral and longitudinal tension and end squeezing unit; and C = wash, neutralizing and rinsing step.

The machine in Fig. 3 is ideal for the mercerizing of all types of knitted fabrics such as single jersey, inter-

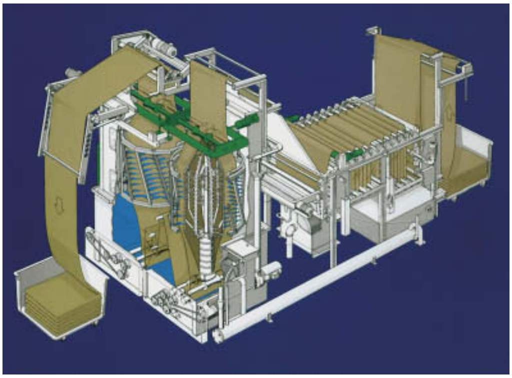

Fig. 2: Tubular mercerizing for knitwear: technical drawing of the Dornier Ecomerc mercerizing range.

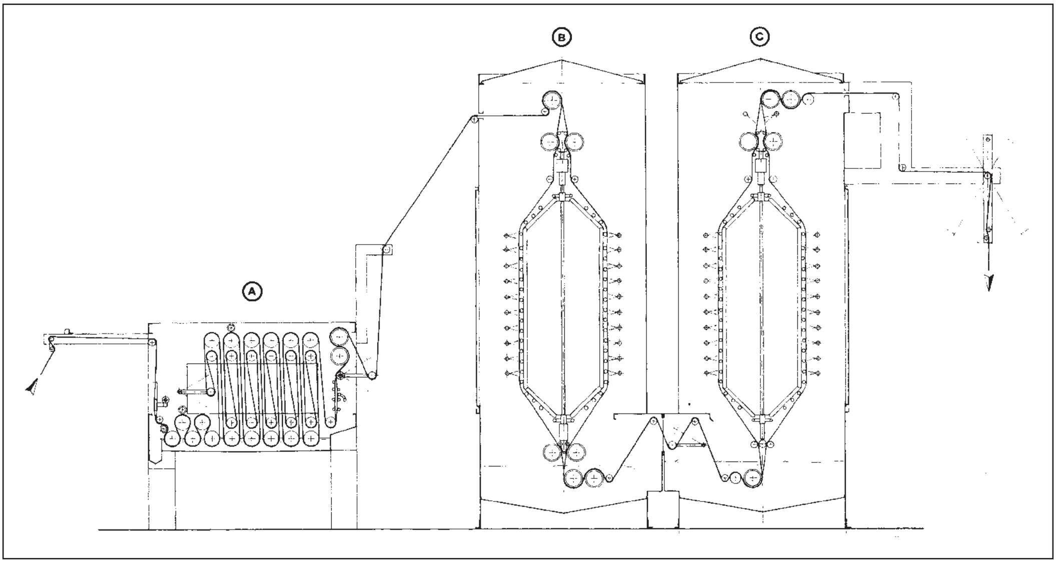

Fig. 1: Tubular fabric mercerizing machine according to Sperotto Rimar with the processes A = impregnation; B = stabilization; C = rinsing.

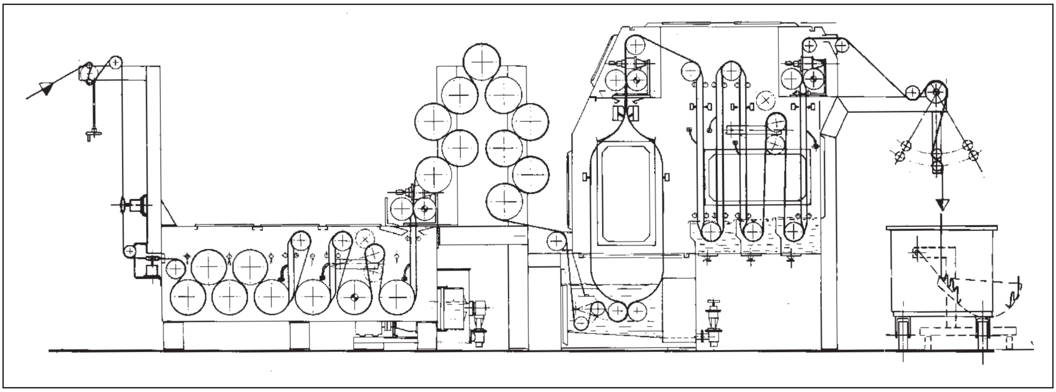

Fig. 3: Tubular mercerizing for knitwear (MCS).

lock, fine rib and pique in cotton or its blends. Not only high-grade fabrics of fine, combed cotton twist but also medium grades in short-staple cotton yarn undergo an appreciable boost to their quality as a result of this process. Aside from outerwear and sportswear, the main applications for fabrics treated in this way include the more upmarket underwear. The Dornier system (Fig. 2) featuring its patented power-adjustable circular expanders in the stabilizing, washing and neutralising sections ensures the cost-efficient mercerizing of tubular knit fabrics for all such garments.

Tubular fabric singeing Tubular knitwear can be passed through a circular burner so as to cause uniform singeing of the goods (Fig.).

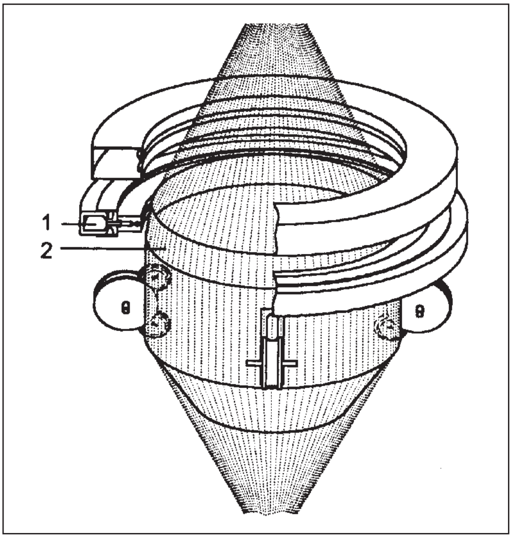

Fig.: Osthoff tubular fabric singeing.
1 = circular burner; 2 = circular tube opening.

Tubular fabric slitting machines (tube openers). They are used to slit open tubular knitted goods to expose the surface of the fabric to the finishing process. The slitting process can be achieved using burners (welding) or cutters. A cut thread or → Separating course is provided for this purpose and is picked up by electronically controlled units (Fig.). The tube slitting machine detects the separating course using a photo-electronic device and opens the tubular wear automatically. The tubular wear runs over a fabric guide cage,

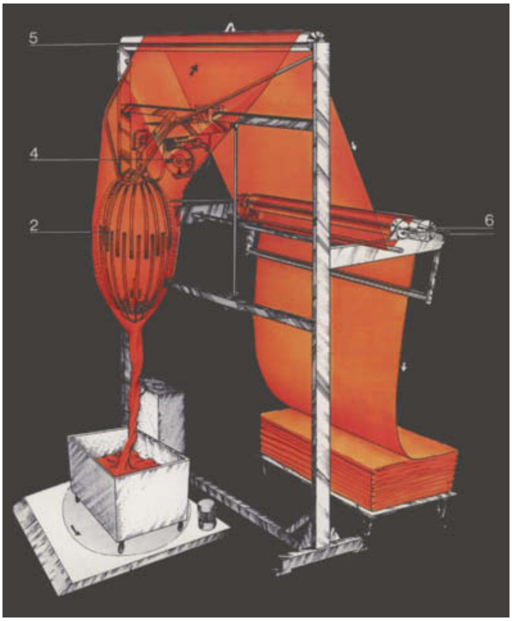

Fig.: Sperotto Rimar tubular fabric cutting machine.
2 = fabric guidance frame; 4 = cutting device; 5 = powered draw-off roller; 6 = powered run-off roller.

which is manually adjusted to the size of the tube, and on to the photoelectronic detector. Amplified signals turn the guide cage via a d.c. drive motor so that the separating course runs exactly under the circular knife of the slitting machine. Also used for slitting tubular goods is the → Calender crease (instead of separating course).

Tubular fabric turning machine Device for turning tubular knitwear using aerodynamics. The tubular wear is pushed on to the turning tube (length 3 000 mm, ∅ 180 mm). The end of the piece is drawn into the tube opening aerodynamically and this turns it at the same time. Fabric speed is 600 m/min (loading) and 300 m/min. (unloading) (see Fig.). – Manuf.: Sperotto Rimar.

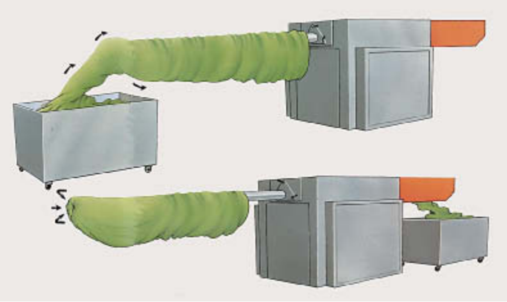

Fig.: Tubular fabric turning machine from Sperotto Rimar.

Tubular felt (felt sleeves). Industrial wool felt in the form of continuous woven or nonwoven pressed felt for covering rollers (lapping), for sizing and finishing machines, calenders, for transferring printing in roller printing, etc. also used as an underlay for machine foundations and seals, etc.

Tubular gauze Tubular fabric made from screen gauze used on nickel screens in rotary-screen printing.

Tubular knitgoods A tubular knitted fabric, generally knitted in tubular form to be cut open subsequently.

Tub washing machine,

I. American design of domestic washing machine with vertical wash tub and wash agitator (cyclically oscillating wash paddle or rotating agitator). There are significant differences in washing technology because of this (as opposed to Europe where most are → Drum washing machine): by connecting to a domestic hot water supply, washing temperatures are usually below 60°C (instead of perborate, chlorine bleach solution is used as required), shorter washing times (approx. 15 min.) relatively higher proportion of wash liquor to laundry (liquor ratio approx. 1 : 20), less detergent (approx. 1–2 g/l) for generally lower water hardness (on average 7° d = approx. 130 ppm) and only one rinse cycle, approx. $^{1}/_{4}$ water consumption for the same amount of laundry.

II. Used for washing printing pastes or dyes from batch containers (Figs. 1 + 2). The effluent must be fed to a controlled disposal unit.

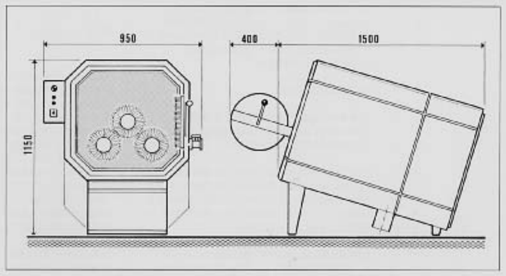

Fig. 1: Diagrammic representation of a tub washing machine (van Wyk).

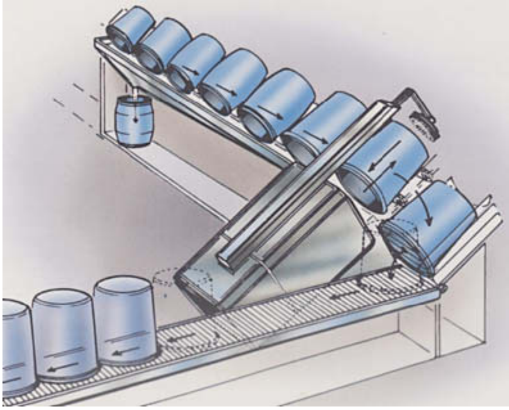

Fig. 2: Tub washing machine (van Wyk) functional principle.

Tuft A bundle of fibres, yarns, etc.

Tufted carpets → Carpets with sewn-in pile loops, using the tuft anchorage process (tufting, → Tufted textiles), in which pile yarn in the form of loops are inserted into a finished woven fabric with the aid of needles (sewing machine principle) (Fig. 1) and then fixed with adhesive on the back.

There are two types of tufted carpets, loop pile type with closed or upright loops and velours (Fig. 2) with cut, open pile loops (cut pile). In contrast to the manufacture of pile loop or wire loom carpets with → Pile loops woven into the fabric, "sewn-in" pile loops in tufted carpets have practically no firm hold in the fabric. They are therefore glued on the reverse side (→

Backcoating of carpets) in order to fix the pile loops and increase the stability and comfort underfoot.

Tufting can either be carried out with dyed pile fibres, or the carpet piece dyed prior to backcoating. When developing designs for tufted carpets or multicoloured carpet yarns, it is essential to obtain computer-generated patterns, in order to check whether the specifications and the degree of patterning are adhered to. In the case of cross-over techniques, in which needle bars can be moved in different ways, the effects of the different movements can be represented by the use of a computer program. In the case of the usual tufting techniques, computer simulation of multicoloured yarns can be used to check whether the colour spaces are long enough and whether negative effects such as barring or patterning arise. Relatively simple computer programs can be developed for the cross-over techniques, but large-scale simulations are necessary for standard tufting techniques. These require the programming of a comprehensive carpet yarn process model.

Depending on the tufting process, carpet widths of e.g. 4.50 m can be produced mechanically (simultaneously with 1000–1200 pile loops) and approx. 2–3 linear m per minute (10–20 times faster production speeds possible in comparison with woven carpets). Manufactured increasingly with natural tufts (i.e. undyed), otherwise in single shades, marl, melanges or mottled. The backing fabric is mainly polypropylene, although jute is sometimes used; all carpet fibres used for the pile material can be tufted. The main ones used, however, include polyamide, polyacrylonitrile, polyester, as well as wool and cellulose.

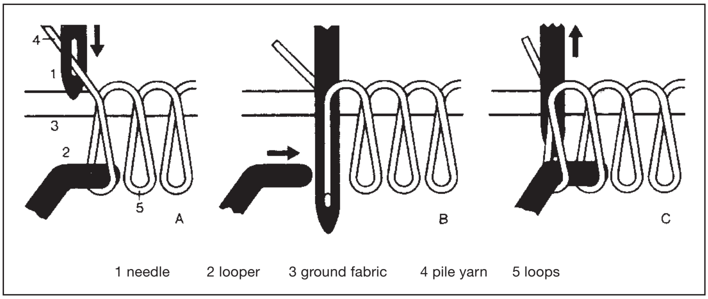

Fig. 1: Manufacture of a tufted carpet.

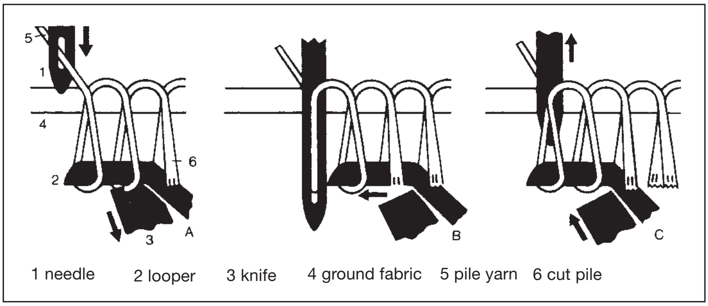

Fig. 2: Pile cutting in a tufted carpet.

The grey goods are submitted to a carpet finishing plant in rolls, which are sewn together as they enter the plant. Intensive cleaning removes lint and threads. The carpets can then be dyed and the dye fixed in the fibres in a saturated steam atmosphere. Non-fixed dye is washed out in a washing unit; then the carpet is dried to a residual moisture content of 50% by extraction. Like continuous dyeing, there is no final drying stage. In place of dye, the carpet can also be impregnated with an anti-static finishing agent. The fixing also takes place in a saturated steam atmosphere. In this process, too, a final residual moisture content of less than 50% is ensured by extraction. A further auxiliary agent can then be sprayed on. For the straight backcoating process it is possible to stop all process stages after cleaning, so that, as in classic coating methods, the carpet is offered

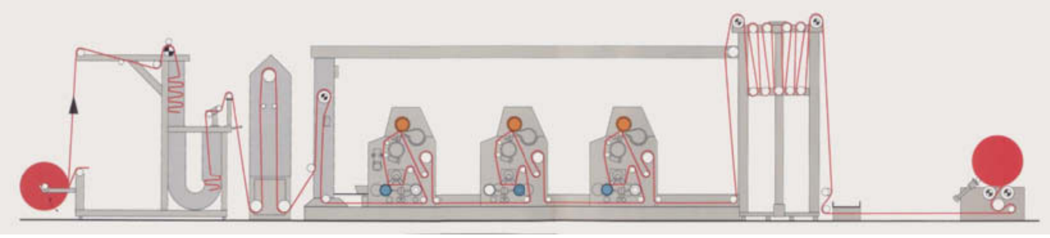

Fig. 3: Tufting shearing range (Menschner).

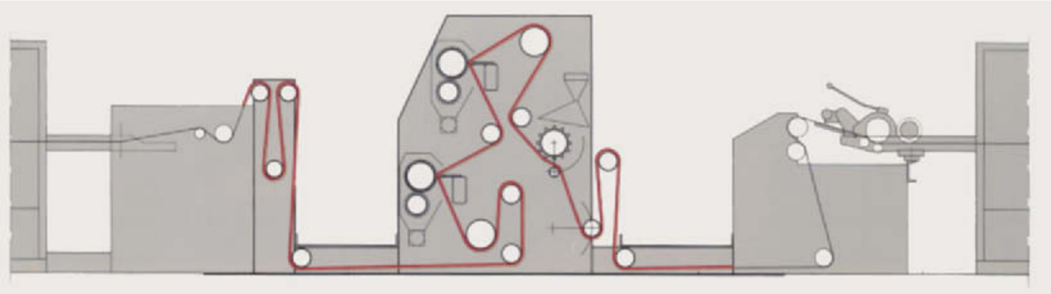

Fig. 4: Tufting pile raising (Menschner).

for latex coating when dry. In all other cases a residual dampness of 50% or less must be achieved before latex coating.

After latex coating, which is necessary for binding the fibres to the backing material, the carpet is dried with hot air. Now, either the foam is applied and gelled in the infrared zone or the adhesive and secondary backing applied. The necessary drying or vulcanization is also carried out with hot air. Specific patterns can be achieved by shearing (Fig. 3) and/or pile raising (Fig. 4).

Tufted textiles In accordance with DIN 60 000, these are fabrics which are made by inserting yarns, into a usually textile backing, using one or more needles, forming loops (pile loops). The loops may be cut and/or fixed to the backing using an adhesive or by heat sealing.

Tufting The manufacture of → Tufted textiles, in particular → Tufted carpets, using the tufting technique.

Tulle A net-like fabric of honeycomb 6 or 4 sided (→ Bobbinet) cells with diagonal weft, used for dresses, blouses and (usually embroidered: florentine tulle) for net curtains.

Tumble drier A drying machine with a rotating, perforated drum, in which the material is spun loosely, without tension, and discontinuously (Fig. 1) or continuously (Fig. 2). The first tumble drier (Passat) came onto the market in 1967. The load weight of a tumble drier is between 6–3000 kg, and they are used both as drum or transfer driers (semi-/fully automatic), for surface finishing (e.g. for imitation lambskin, goatskin or Persian lambskin effects, imitation leather grain, for the preparation of cut-plush fabrics, for the shrinkage of looped plushes and terry cloth goods, the tumbling of tufted garments, the crinkling of yarn hanks, the relaxation of knitted goods, etc.) and for drying cut-plush fabrics, tights, socks, fully-fashioned articles, knitted articles, terry goods, bath mats, etc. (→ Continuous tumbler).

These are processes for establishing quality profiles for drying, relating to handle improvement, voluminosity, relaxation and dimensional stability. The fact that the goods being dried in the rotating drum fall loosely and unimpeded and therefore are not forcibly guided results in a relatively high energy consumption. In contrast, a → Recirculating tumble drier results in almost >70% energy savings. Advantages: reduced drying time (approx. 15–20 min) with maximum material protection. Heating by electricity, steam or gas.

With the Henrikson tubular goods tumble drier, a knitted tube for T-shirts is sewn together as an endless

Fig. 1: Obermaier discontinuous tumble drier.

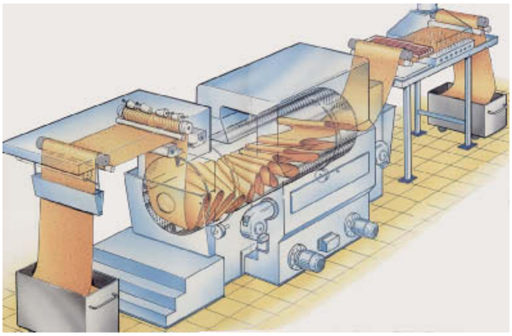

Fig. 2: Obermaier MTM-O continuous tumble drier.

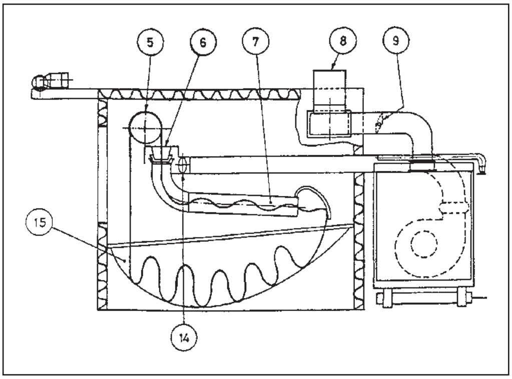

Fig. 3: Henrikson tubular knitgoods tumble drier.
5 = winch; 6 = fabric infeed; 7 = air-heat exchange zone with impact plate; 9 = throttle flap for fresh air access to the fan; 8 = heat exchanger; 14 = control for air access into the Venturi tube; 15 = dwell trough.

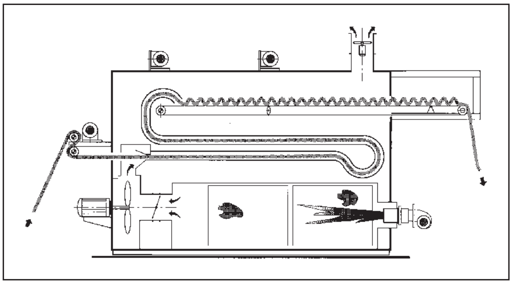

Fig. 4: Thies Tumbler T310 for open width fabrics (woven or knitted).

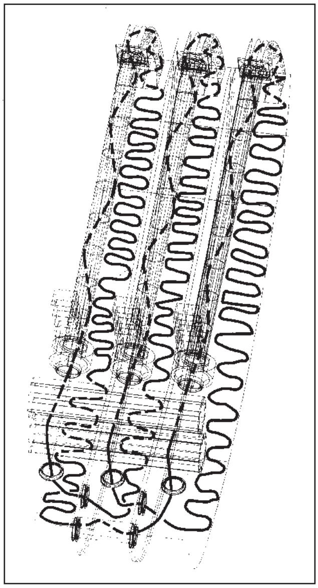

Fig. 5: Rope tumbler.

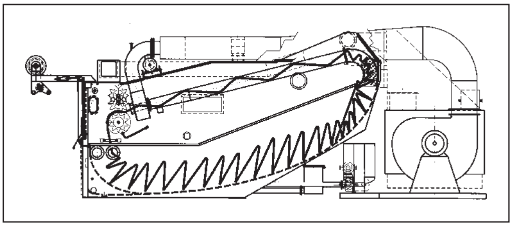

Fig. 6: Flainox Multifinish.

fabric and dried with hot air by the jet principle (Fig. 3).

A tumbler is especially suitable for bulk fabrics such as Nicki, terry towelling and certain qualities of plush, velvet and corduroy. Even the handle of most of the wovens e.g. trouser cloth made from PES/Cel can substantially be improved.

The fabric is treated in open width (Fig. 4) by an air flow whilst running through rectangular wave-shaped channels. These wave-shaped channels perform an intensive motion of the fabric, as well as very fast heating-up and drying by the positive air circulation. The construction of the driving and fabric transport systems are designed in such a way that no longitudinal tensions are effected. Due to the high fluff building whilst tumbling pile cloth, large filter sieves are installed which are easily accessible for cleaning. The advantages of a tumbler are tensionless fabric transport, high mechanical effects and possible steam atmosphere during drying, improved quality, better handle, volume, good pile and residual shrinkage values (Fig. 5–6).

Tumble-dry Drying with hot air in a tumbler, the usual term for the drying method used when testing the fabric smoothness of resin-finished textiles after household washing (→ Wash-and-Wear Standards).

Tumbler drier → Tumble drier.

Tumbler finishes Aftertreatment agents for washable textiles, for the application of active substances (finishing, anti-static, fragrance) during the drying process in the tumble drier or drum drier. Form of application: as foam spray (carrier: cloth/item being washed), spray (carrier: drum walls), pad impregnated with active substance (fixed by adhesive to tumble drier paddles) and → Sheets. Because of the specific difficulties encountered with tumbler application (consistency of viscosity, ease of prefabrication, storage stability), in comparison to fabric softeners, tumbler finishing agents have had to be re-formulated wholly or partially having regard to suitability for specific emulsifying systems. Examples include distearyl, di-coconut alkyl, tallow alkyl, imidazoline compounds, polyamines (partially quaternized to a greater or lesser extent). Proven significant emulsifiers in combination include polyoxethene, oxethylized fatty alcohols, alkyl-phenol polyoxythene and oxethylized fatty amines.

Tumbler shrinkage Unwanted shrinkage which can arise when items of clothing made from heavy cotton fabrics are dried excessively in a tumble drier after washing.

Tungsten (W), atomic weight 184. A grey heavy metal. Melting point 2700–2940°C. Possesses extraordinary hardness and resistance. Application: when smelted with sodium = richly-coloured tungsten bronzes, components of tungsten steel (→ Stainless steel), filament of tungsten lamps, (durability, low power consumption).

Tunnel shrinking machine → Shrink-finishing tunnel.

Tunnel steamer → Arch steamer.

Tunnel test → Steiner Tunnel Test.

Turbidity measuring instrument → Turbidity meter.

Turbidity meter (nephelometer, Tyndall meter). A unit for the determination of the concentration of cloudy solutions from the intensity of laterally diffracted Tyndall light (→ Tyndall effect) and also for the measurement of the light which penetrates cloudy solutions. It is used for the determination of fine dispersed precipitations, for the detection of colloidal changes of state, for the investigation of the growth of micro-organisms, etc. Thus the photoelectric universal colorimeter is, itself, useful for measuring cloudiness which can barely be detected with the eye. Measurements by different observers with different units can be compared using a second measurement with cloudiness standard meters, opaque glass rods, which are used in the nephelometer container with distilled water. Suspension particle size or cloudiness can also be determined using the sedimentation process, in accordance with the time taken to clarify as they sink to the bottom of the container. However, a better way of determining particle size is to use a photoelectric sedimentometer. Particle size detection can also be used for synthetic resins for finishes. The intensity of the light diffused from the suspension or solution is measured in the range from 40–150°. In addition, turbidity meters are also used in → Fluorimetry.

Turbodynamic principle A process in the wet treatment of textiles, in which the bath is set in intensive motion (turbulence), in order to achieve uniform results in a short time.

Turbo mixer A unit in which mixing takes place at high rotational speeds (up to 6000 rpm) by a mixing head with rotating blades, similar to a turbine, around which a guide ring is fitted in order to control the centrifugal forces. This construction creates strong suction on the surface of the fluid, which draws the substances to be mixed from the sides, continually propelling them to the centre of the vessel, thus whilst maintaining a level liquid surface and without splashing, a thorough mixing and compounding of even viscous elements can be achieved.

Turbo spray washer for rotary screens Intensifies rotary screen washing in the vertical screen washing cabin, particularly for the purpose of removing printing pastes of high viscosity and tackiness. Connected to the central washing water supply within the screen. There are polyamide fibres on the rotating element which are spun onto the insides of the screen by centrifugal force, thus mechanically intensifying the cleaning effect of the sprayed water.

Turbostapler yarns High-bulk yarns (strongly textured yarns). Manufactured on a turbostapler. A tow made up of high-shrinkage fibres of varying lengths is passed through electrically heated plates then stretched, thus gaining high residual shrinkage. Around 60% of the slivers entering the turbostapler are then relaxed in the turbosetter by a controlled vacuum vapour process at 1.7 bar and 115°C. The vapour process has a marked effect on the subsequent ease of dyeing, as a difference in temperature of only 2.5°C can result in a completely different dyeing shade to the finished fabric. The non steamed (high shrinkage) and steamed (low shrinkage) slivers are combined for the subsequent spinning processes.

Turbulent flow Water flowing in a river bed displays various types of flow: in the middle the water flows freely. At the banks, some of the water is held back by the embankments (→ Laminar flow). The transition zone displays increasing eddy formation, or turbulence, towards the middle of the river. Using this principle in the wet finishing of textiles, the fibre bulk is comparable to the bank (→ Flow mechanism in dyeing). The finishing chemicals diffused by the laminar layers in the fibre bulk must be dispensed by turbulent flow.

A textile finishing operation can be compared to stirring: the finishing chemicals in the liquor concentrated in one place on the outside of the fibre should be homogenized, i.e. introduced to the fibre in such a way that they can be adsorbed into the fibre surface and removed from the mix. “Stirring” is a mixture of liquids which are soluble one in the other (areas of the liquor with high concentrations in comparison with areas of the liquor which have given up their finishing chemicals by adsorption into the fibre surface). Stirring has the objective of a specific degree of homogeneity. Minimum effort in this process means a short mixing time Θ and a low agitator rotation speed n. The mixing time by stirring is calculated with the aid of the mixing time characteristic, in which the dimensionless reference quantity “n · Θ” (“mixing time”) is plotted using the Reynolds number.

$$\left(\frac{n \cdot d^2 \cdot \rho}{\eta}\right)$$

In the turbulence zone the mixing coefficient “n · Θ” is constant. In the laminar area near the sides of the mixing vessel (in the textile finishing process, close to the fibre, and in the interstices of the fibre bulk inaccessible to the “mixing process”), a constant reduction in the mixing coefficient can be seen. If the Reynolds numbers in laminar flow are small and increasing, then the mixing coefficient falls with an increase of Reynolds number. With Re > 10^4 in the turbulent zone the mixing coefficient “n · Θ” is practically constant, i.e. concentration balances happen quickly. Close to a surface the concentration reduces in the absence of flow (mixing), so that the non-homogeneous substance A (Fig.) can only diffuse there with difficulty.

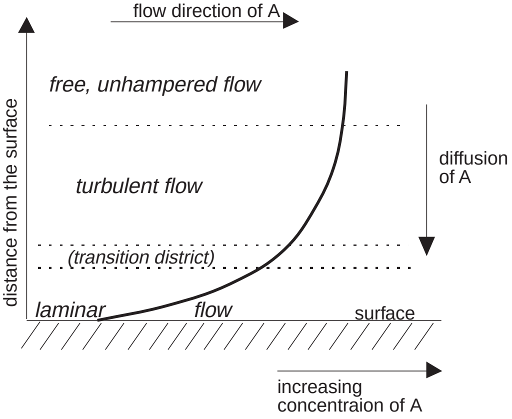

Fig.: Model presentation of turbulent flow in the fibre mass.

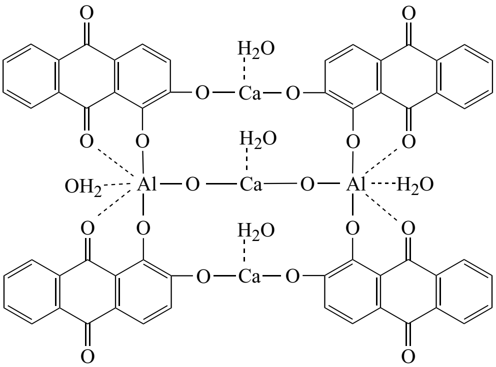
Turka fibre → Kendyr fibre.

Turkey red (adrianople red). Among the oldest organic dyes, and according to tradition was used back in the 17th century as a mordant dye. The dye was formerly obtained from the natural alizarin in the madder root. At the beginning of the 18th century Turkey red was used as a classic old red dye, also in Germany, especially in Wuppertal. By 1868 the natural alizarin was replaced by the purer and cheaper synthetic alizarin. The working methods it involved were difficult and led to an alizarin-calcium dye lake with a complicated structure:



Turkey red is now merely of historical interest, having been replaced by naphthol dyes.

Turkey red oil (red oils, T’ red oils). Consist of → Sulphonated surfactants and similar products. Used as wetting, dye penetration and levelling agents.

Turkish carpets → Oriental carpets from Anatolia and Asia Minor. Original with traditional patterns of flowers stylised to a greater or lesser extent (tulips, daffodils, hyacinths). Introduced to Europe from 15th century and used in particular as wall hangings and table covers.

Turpentine oils Distillation product of the balsams of various types of pine (Balsam turpentine oil) and of resinous wood waste (wood turpentine oil including → Pine oil) which belong to the group of → Terpenes. Density 0.86–0.89; boiling point 152–200°C. Colourless to slightly yellowish liquid, smell like colophony (American) or juniper berry (French), sharp and abrasive taste, easily stirred, rapidly volatile, becomes resinous when exposed to air (store in well-sealed container); highly inflammable; vapours explosive; mixable with alcohol, ether, chloroform; not harmful to fibres or dyestuffs. Imitations: petroleum, pine-wood oil, resin spirit, etc. Used in stain removing agents (for asphalt, resin, varnish oil, pitch, car lubrication, stains etc; but creates clean areas with sharply-defined edges, removable with petrol); used cleaning cloths, left lying about, can self-ignite.

Turpentine resins Natural resins of fir trees, some of the main representatives of which are → Colophony and, for example, → Dammar resin and Mastic.

Turpentine substitute Mixture of colourless hydrocarbons which are generally covered by the term white spirit or lacquer benzine. Mostly with high-boiling point with flame point over 21°C. Occasional addition of etheric oil in order to conceal the smell of petrol or petroleum. Used in solvents and stain removing materials as a substitute for turpentine oil (with its advantages, without its disadvantages).

Tussah silk (tasar, tusser, tussor). → Wild silks obtained from the caterpillars of the Indian (Antheraea mylitta), Chinese (Antheraea peruyi) or Japanese (Antheraea yamamai) tussah silk worms found in the wild and rarely cultivated. Due to the high tannin content of the caterpillars' food (oak leaves), tussah silk always has a light-to dark brown colour. → Silk.

Tutorette process A mechanical shrinking process for cotton/polyester blend fabrics, licensed by Bancroft Far East Inc. in Japan and using the Everest Shrinking Machine (Manuf.: Hunt & Moscrop). Tutorette textured seersucker is a finished crêpe. The regular pattern of the textured surface is achieved by a flatbed embossing calender. An artificial resin finish is used to fix the embossing.

TV → Trivinyl, → EDP Code abbreviation.

TVI German abbreviation for the textile finishing industry.

Tweed Originally the term for hand-woven fabrics of hand-spun yarns with a small colour pattern effect (→ Homespun). More generally applied to ground weave or twill carded yarn cloths, hand-woven in character, which have a mottled, hairy surface (→ Harris tweed) with knops, or which are patterned by varying the colours in the warp and weft (→ Donegal) or some other small-scale pattern.

Twill A general term for a variety of fabrics with diagonal stripes in twill weave (→ Weave). General term for all twill weave fabrics, recognised by the distinctive diagonal ridge pattern.

The term can loosely be applied to all twill weave fabrics (→ Serge). In the wool sector twill is used above all to denote those fabrics which have a coarser or more pronounced twill rib. Usually the woollens are based on the 6-thread even-sided twill. The term twill is only used for worsted yarn, not carded yarn cloths. The term is similarly used in the cotton and silk sectors.

Twill carpet → Flat carpet, woven from coarse yarns in twill weave (Dutch carpets, Parisian, Sayette runners).

Twill ridge The diagonal ridge in twill weave fabrics.

Twill weave One of the 3 basic weave types (→ Weave); the smallest repeat is 3 threads. Different types include one-sided and even-sided, narrow and broad, single-line and combined twill, warp and weft twill.

Twilo yarn A twist-free yarn, ribbon-like in appearance (viscose staple fibre, HWM-, polynosic fibres) of good uniformity from wet-drawn fibre bundles, bonded with hot-water soluble adhesive or polyvinyl alcohol binding fibres (5–11% by weight). The fabric possesses substantial covering property. Once the binding agent is washed out the yarn strength in the fabric decreases. Twilo yarns possess good strength, covering property, softness, sheen properties.

Twin-pole system Rope dyeing plant in which the ropes are treated whilst hung on 2 poles. The hank length can be changed, during treatment, by raising the lower pole.

Twinset In the clothing industry, a term for a fashionable combination of ladies' pullover and cardigan.

Twin star dyeing machine A star dyeing machine, in which piece goods are fixed into 2 stars and thus rotated through the treatment liquor.

Twin-tail chemistry A wide range of variations can be achieved with finishing effects obtained from fluorine chemistry. For example, by means of chemical reactions or compounding by the introduction of additional components. With these variations, effects such as a soft handle and special adaptations to suit different substrates and finished articles can be achieved. Tailor-made solutions to problems are possible. A very specific term, "twin-tail chemistry" refers to spatially close perfluoralkyl chains (see Fig.). The resistance properties, particularly in the case of cotton and blends, are therefore good.

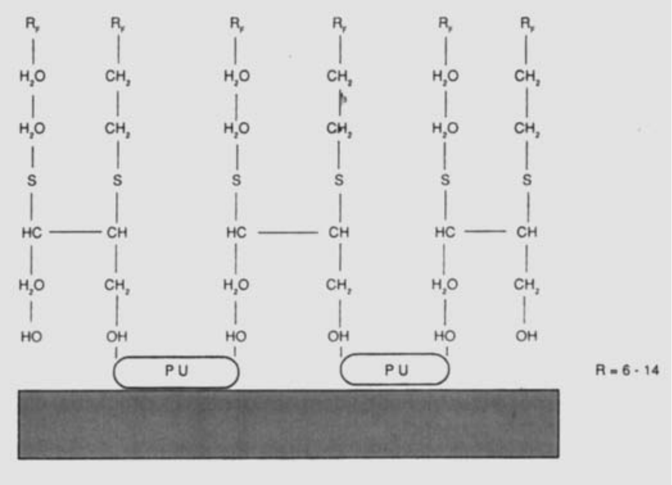


Fig.: Twin-tail chemistry.

Twist,

I. A yarn of cotton, linen, viscose, also cotton/viscose blends with even twist. Different types include water (tight twist), medio (medium) and mule (loose) twist. Reference should also be made to darning twists. These are usually multi-ply (usually 6-ply) cotton twists, which in contrast to the twists in the wool industry are only loosely twisted, have almost no turns and are used for darning household items. They are particularly thick and soft.

II. In the wool industry, twist usually denotes worsted or carded yarn cloths, which consist wholly or predominantly of mouliné yarns in the warp and weft and are usually produced in simple weaves (linen, panama, twill weave). A particular feature of these fabrics is their lively colouring (flecked) and also the fact that they are usually stiffer in feel, due to the higher turn count of mouliné twists. The finish is usually unnapped or in the case of carded yarns, clear. Of the two yarn types, the worsted yarns are superior.

Twist factor at break According to Krais, → Torsional strength.

Twisting (doubling). Starting from single yarn, the production of twist yarn involves 2 stages:

1. bringing the yarns together (on the doubling machine) = plying;
2. twisting the yarns (on the twisting machine) = twisting.

→ Plying is an essential process for the production of 3-fold and multiple-fold yarns with the two-for-one or Topham box twisting machine. For two-fold yarns, two different processing techniques have established themselves in two-for-one twisting (Fig. 1):

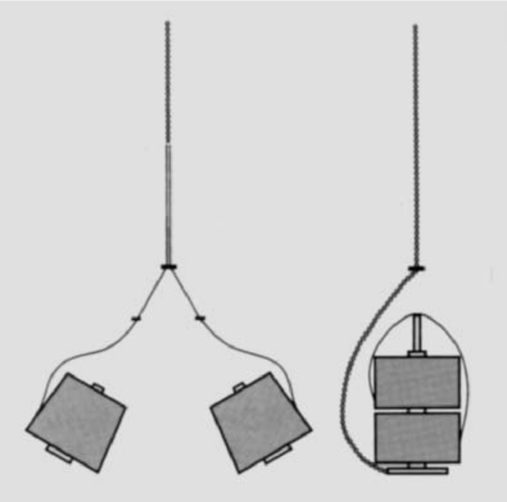

Fig. 1: Twisting with doubling packages (left) and twisting with direct feed packages (right).

- the traditional method with doubling yarn supply packages
- the so-called direct feed with two packages of single yarns positioned one on top of the other.

A perfect twist yarn is characterized by the individual component yarns being twisted together symmetrically. By contrast, a covered yarn is made by feeding one yarn component under a controlled degree of tension (without twisting) through the axis (or axes) of one or more revolving spindle carrying the other wrapping (covering) yarn component (Fig. 2). In this latter case, the quality-enhancing effect is lost since one yarn can slip against the other. Yarn wrapping can take place if a high tension is applied to one yarn and a low tension to the other during the twisting process. There is no possibility for the taut yarn to become deformed in twisting, so that the loose yarn wraps itself around the taut yarn.

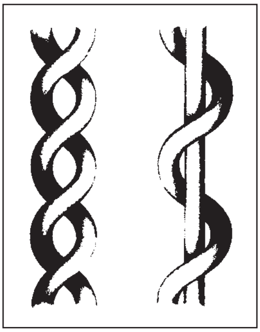

Fig. 2: Two-fold twist yarn (left) and covered yarn (right).

The folded yarn supply packages on two-for-one twisting machines are drawn off through a twisting flyer (campanello) so that the combined yarn components do not separate. The flyer rotates at the same speed as the yarns rotate during their take-off overhead. The rotational speed as the yarn delivery point moves down the package is not the same as that during its upward movement (Fig. 3).

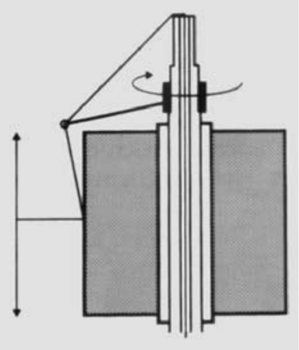

Fig. 3: Upwards and downwards movement of the yarn delivery point on two-for-one twisting machines.

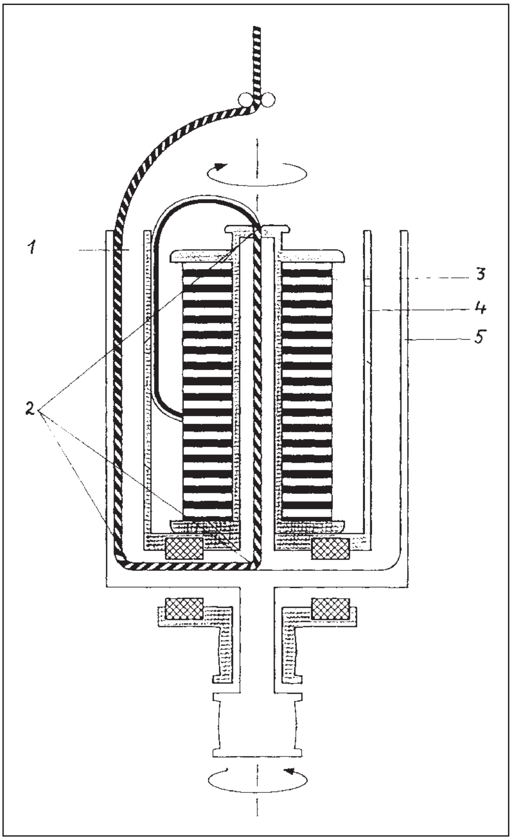

Fig. 4: Cross-section of a two-for-one twisting machine (“Tritec” Twister of Saurer).
1 = open yarn guide; 2 = optimized deflection points;
3 = yarn supply package; 4 = inner yarn guide device;
5 = outer yarn guide device.

The functional principle of two-for-one twisting machines is illustrated in Fig. 4. They consist of two rotating systems mounted on bearings. The outer system with the spindle centre shaft and the inner system which serves as a carrier for the yarn supply package rotate at the same speed in opposite directions. Both systems are fitted with a cylindrical yarn guide. The yarn is thrown off the supply package by the rotation of the inner system and forms a self-regulating spiral-shaped accumulation in the guiding device. Subsequently, the yarn is led through the hollow spindle in which two turns of twist are inserted due to the opposing movements of the fixed point (i.e. insertion of two turns of twist for each revolution of the twisting element). A further accumulation of yarn is formed on the outer guide device and receives a third turn before it is drawn off by the delivery system.

Another method of inserting twist is the cabling process which, from a textile technology standpoint, represents a special kind of covering process. The essential feature of this process lies in the fact that the individual components (inner and outer yarns) are only subjected to a false twist operation. After the cabling process, both yarns have no twist in themselves although they are wrapped around each other. For this reason, the process is particularly suitable for the production of two-fold, symmetrical, tyre-cord constructions. With this technique, the laborious preliminary twisting and twisting at the head, as required for conventional twisting processes, are dispensed with. As a result, only a single operation with a spindle is required in order to produce a perfect tyre cord with zero turns in the individual yarns. This only applies, however, to cases where the supply yarns contain no turns and a two-fold tyre cord is being produced. The production of

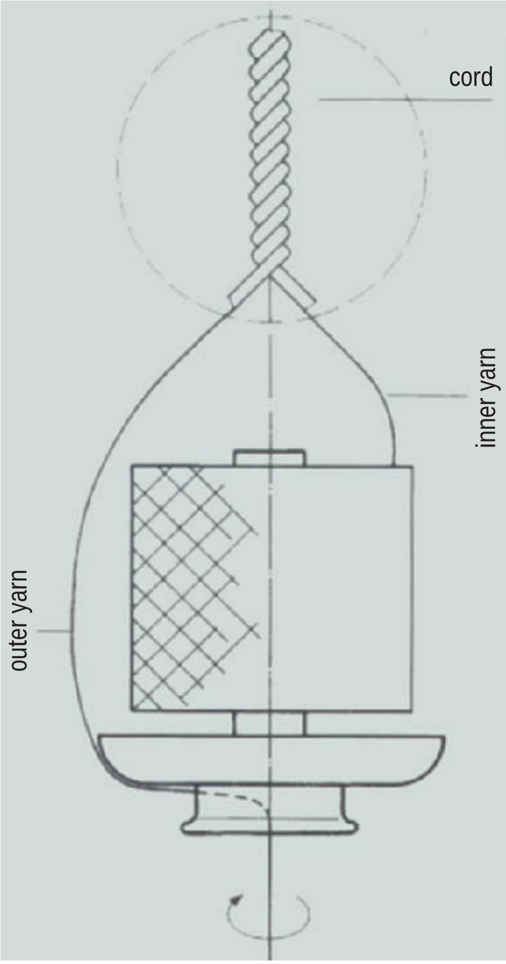

Fig. 5: Principle of cabling (Saurer Alma).

multiple-fold yarns is not possible with the cabling process.

From its constructional features, a cabling machine resembles a two-for-one twisting machine (Fig. 5). In terms of the spindle construction, in particular, they are virtually identical. The inner yarn comes from the yarn supply package which is located on the stationary head of the spindle and is led directly in an axial direction upwards to the point at which it is joined by the outer yarn. The outer yarn comes from the creel and is led into the bottom of the rotating part of the cabling spindle, emerges again from the accumulator disc forming a balloon of yarn and wraps round the inner yarn above the package can.

Twist of spun yarns The twist of spun yarns denotes the amount of twist applied to a yarn (twist) to fix the bundle. The direction is denoted by S- (right-hand) and Z-twist (left). The number of turns (degree of rotation) relating to 1 m yarn length (T/m) depends on the fineness, raw material and ultimate application of the yarn to be spun and the spinning process. The relationship between twist, raw material and fineness is expressed by the formula T/m = α_m R(Nm).

Twist-texturing A texturing method in accord-

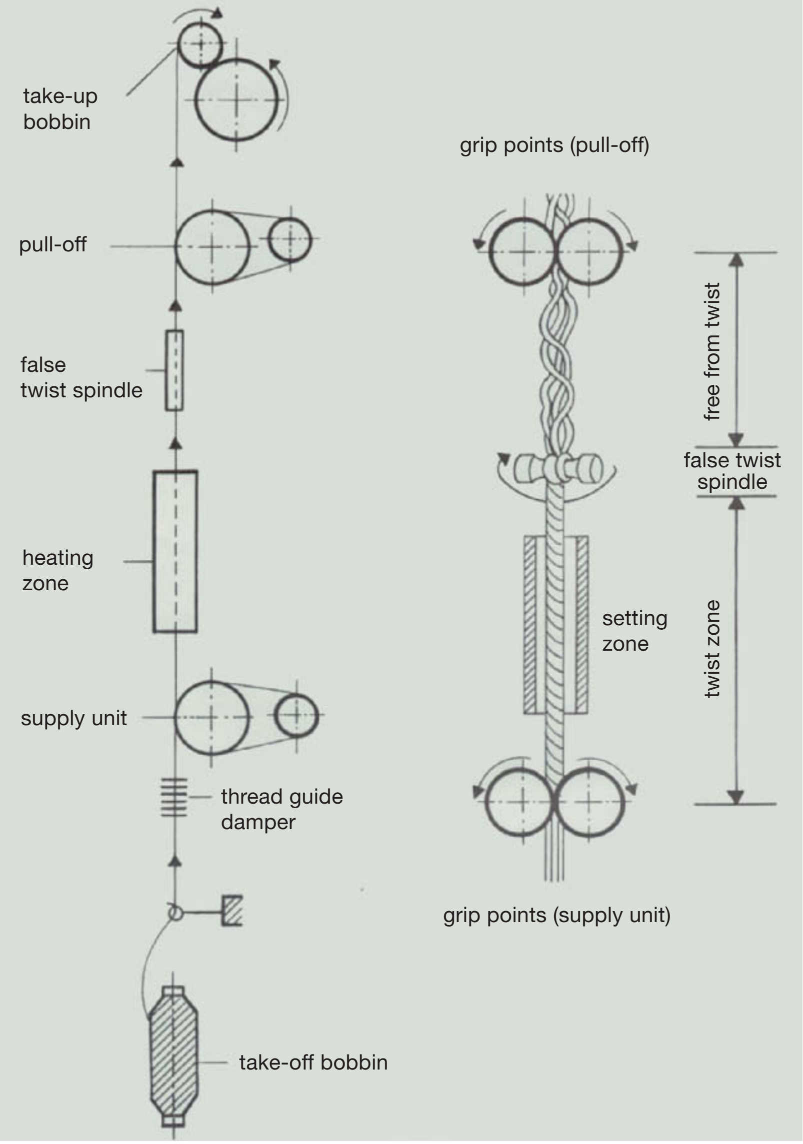

Fig. 1: Twist-texturing (false twist).

ance with the mechanical/thermal principles; the two different processes are torsion crimping and friction texturing. The following phases are followed as a continuous process during manufacture:

- high-twisting,
- heating and cooling to fix the twist,
- downtwisting (doubling).

The process is essentially based on the twist principle, although it is not only two (or more) yarns being twisted together, but a multifilament being twisted around its own axis. The high-twisted fibres are thermofixed and the twist again applied (Fig. 1). This gives rise to high bulk yarns.

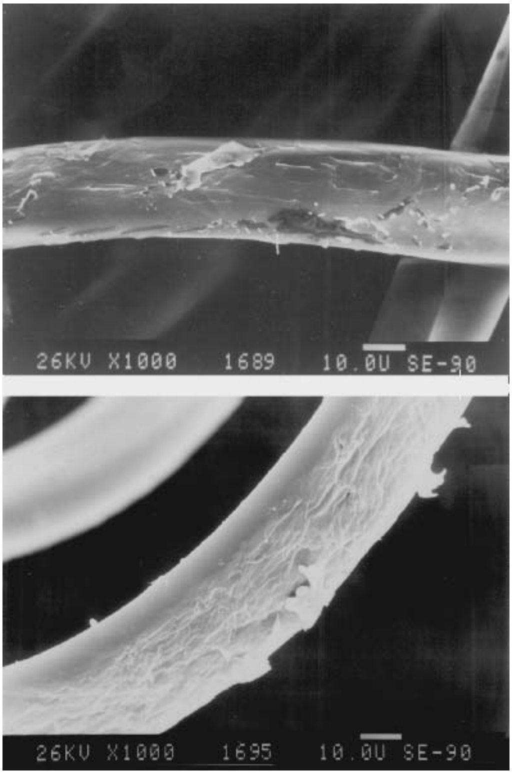

Fig. 2: SEM photographs of twist-textured polyester filament surfaces (by Cerasiv).
Top: slight fibre damage: bottom: heavily damaged fibre surface.

During the process the material is subject to high mechanical forces. The resultant friction means the filament surfaces may be roughened (Fig. 2), and fibres may be abraded. Yarns damaged in this way are more matt when dyed, whilst undamaged yarns have a clearer, brighter dyed appearance. This effect can be minimized by selecting appropriate materials for the friction disks.

Two-bath pad-batch process for reactive dyes A semi-continuous principle: goods are padded with neutral dye solution, dried, padded with alkali and salt, batched up and given several hours' dwell time.

Two-bath pad-steam process Another term for the → Pad-steam process. A continuous dyeing process, in which the goods are padded in the 1st bath with dye, in the 2nd with the chemicals necessary for fixing, and then briefly (max. 60 s) fixed in steam. Examples: for vat dyes, caustic soda and sodium hydrosulphite, for reactive dyes a saline alkali or sodium silicate solution.

Two-bath process Working with two baths in series. For example, in the case of polyester/wool blends, the polyester content is dyed first in one bath, with overdyeing of the wool in a fresh bath. Opposite: → Single-bath process.

Two-component mixing jets Liquor application technology to date consists of the three processes occurring in series:

1. application of the treatment liquor to the goods;
2. metering of the liquor (removal of excess);
3. application of energy to the liquor and goods to achieve the prerequisites for the interaction between substrate and chemicals (reactions).

In the case of application technology using two-component mixing jets, these three processes do not take place in series, but the application, the metering and the energy supply occur simultaneously. This is achieved using steam/liquor mixing jets. The liquor is applied to the goods through the jet in the desired quantity in atomized and heated form. The aerosol is already activated when it makes contact with the textile goods.

Two-component mixing jets have the following properties:

- The liquor flow is independent of the steam flow, i.e. the flow of the treatment liquor may be varied according to the speed of travel of the goods and the desired liquor application, depending on the fabric weight.

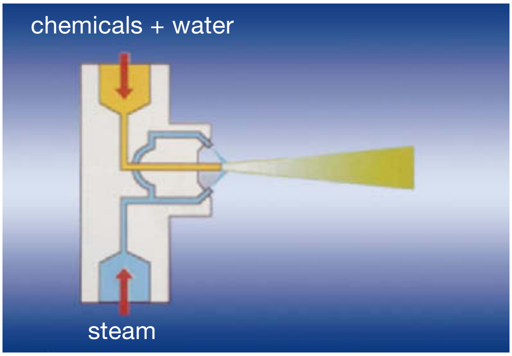

Fig. 1: Two-component mixing jet with external mixing (by Kleinewefers KTM).

Fig. 2: Two-component flat spray mixing jet (by Kleinewefers KTM).

- In the control zone of the jet an even distribution of the volumetric flow and droplet distribution can be achieved across the spray range.
- The jet is operated under 3–4 bar steam pressure and can thus be used by the majority of textile finishers without additional generation of steam.

The jets are supplied with external mixing, as shown in Fig. 1. “External mixing” means that the inter mixing of steam and liquor takes place outside the jet unit. As can be seen from Fig. 2, a flat spray is thus formed.

Two-component system for polyurethane coating Consists of the two components polyol with low molecular weight and isocyanate. Post-curing is necessary after coating.

Two-phase flash-age process In this variation of the → Two-phase printing process, goods printed with alkali free reactive dyes are fixed in a flash ageing plant which consists of a pad, preferably a Mini-Fluid, and a flash ageing steamer.

Fixing involves application from the pad of either an alkaline saline liquor of varying composition or sodium silicate or a combination of sodium silicate and caustic soda (Fig.).

Two-phase laminating process For the laminating of synthetic → Secondary backing for tufted carpets, enabling sufficient adhesive strength to be achieved without blistering across a full carpet width of 4–5 m. The range of the adhesive properties is similar to that of jute backings. The tuft anchorage is unaffected, being principally determined by the quality and manufacture of the base/primary coat. Method: application of primary coat (latex compound with 300–500% chalk filling), lightly dried (application quantity 600–900 g/m^2), application with doctor blade of 400–500 g/m^2 of a less filled, foamed laminating compound (using a foam mixing unit with foam weights of 600–700 g/l) and finally the application of the second backing, which is pressed into the laminate compound thus forming a sandwich.

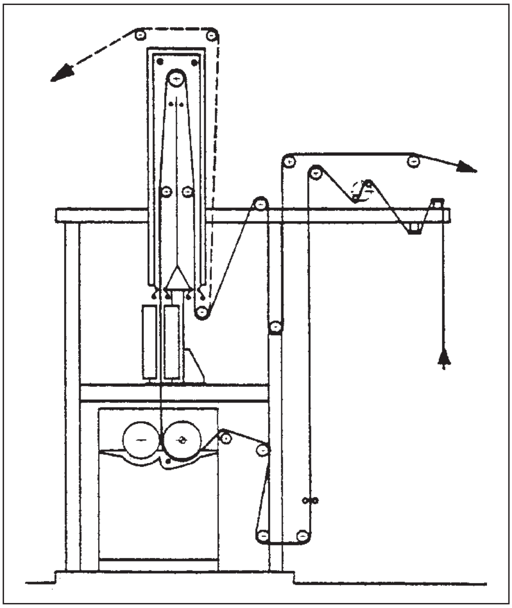

Fig.: Flash ager (Hoechst System) for two-phase printing.

Two-phase mercerizing process A process whereby in the 1st phase cotton is impregnated with 24–25% caustic soda and in the 2nd phase with dilute alkaline solution of approx. 11%.

Two-phase printing process A special printing process in which the chemicals necessary for dyeing and fixing are applied to the goods separately, and the dye is fixed by steaming. The preferred method for vat dyes (→: Colloresine process; Flash ageing) and reactive dyes. Principle: print on the printing dye paste, dry, pad with fixing chemicals (for vat dyes: alkali + electrolyte), then steam, usually without interim drying (100–140°C, 20 s up to 8 min) and wash (Fig. 1). Particular advantages include: unlimited fastness of the dye pastes and prints on printed materials, extremely quick fixing of dyestuffs, low energy consumption for fixing. Disadvantage: high chemical consumption.

The main distinction from the single-phase process with vinyl sulphone dyes is that in the single-phase process the urea and the alkali are already added to the printing paste, whereas in the two-phase process the printing paste dye simply contains thickener and pigment, and the alkali required for the dye/fibre reaction is applied in a second stage. The different processes shown in Fig. 2 can be used for the fixing of reactive prints in the single- and two-phase processes.

In the single-phase process, saturated-steam fixation predominates, whilst in the two-phase method the more widely-used flash ageing process is preferred to the cold pad-batch method, which is limited to cotton

Two-phase printing process

fixation	time	temperature	pH
1 phase process			
saturated steam	7–10 min	102°C	buffer salt NaHCO3 Na2CO3
superheated steam	5 min	150°C	
hot air	5 min	150°C	
2 phase process			
flash ageing	10 s	125°C	NaOH silicate
cold-dwell process	4–12 h	20–40°C	
wet fixation	10 s	95°C	

Fig. 2: Fixation for reactive dyes in textile printing (by Hoechst).

(viscose to a limited extent). The cold pad-batch method (Fig. 3) provides an opportunity for fixing dyes with very little energy consumption. The cold pad-batch method also involves the application of reactive dyes without the use of alkalis or urea; the alkali is applied in a second phase and the print fixed by dwelling (4–12 hours, depending on alkalinity of the fixing liquor) at room temperature. The versatility of the vinyl sulphone system makes it possible to build up a largely interchangeable palette for printing and dyeing. This provides considerable dye stocking and storage advantages.

The two-phase method results in substantial savings when formulating the printing paste, both manually and automatically, as neither alkali nor urea need to be added. The life of the paste for the two-phase process is practically unlimited due to the absence of alkali. With the single-phase process the life of the printing pastes can lead to problems. This is particularly apparent if

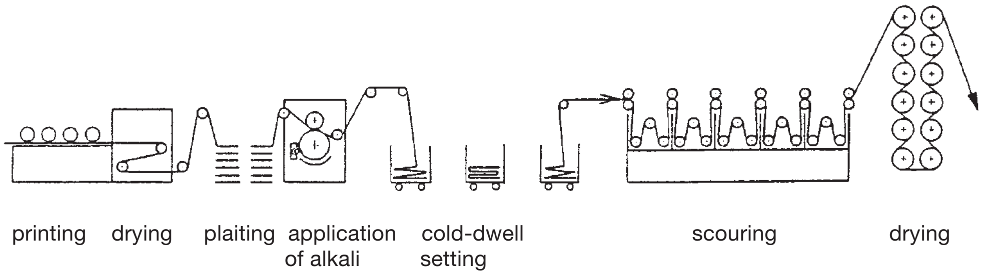

Fig. 3: Cold pad-batch technique with alkali face-padding (by Goller).

alkali quantity and alkali type are not carefully adjusted to suit the reactive dye (anchor) used (Fig. 4) and the quantity by weight of the dye. In addition the effect of temperature should not be underestimated. This is particularly the case with light and medium shades consisting of blends of different dyes. Here, it is not just the depth of colour which varies, but as a result of the variation in alkali stability of the individual dyes, the shade of the printing paste can alter significantly if left standing for a long period. Additional costs, losses and reproducibility problems also arise in relation to the reuse of surplus dye paste. Figs. 5 + 6 show this clearly in relation to light to medium shade depths for monochlortriazinyl dyes.

Whilst in the single-phase process the presence of urea gives rise to a substantial thermal pre-setting, the resultant print is not noticeably affected due to the absence of alkali and urea (Fig. 7).

Moreover, the use of urea has two major disadvantages which should not be underestimated:

1. High drying temperatures mean the risk of sublimation of the urea and its products by decomposition in the drying lofts. The cleaning is time and labour intensive.
2. Urea contributes to an increase in the nitrogen levels of waste water and represents a potentially serious ecological problem.

Saturated steam usage (single-phase process), as required for the fixing of reactive dyes, is rare (Fig. 8).

residues in the production plant usually varies according to the drying conditions, other pattern steaming moisture content conditions and absence of pattern (Fig. 9).

In the two-phase method the absence of alkali and urea has a similarly positive effect on the production plant. In addition the patterns are completed substantially quicker using the two-phase method, leading to

fewer machine stoppages (Fig. 10). The use of a special pattern steamer enables the pattern to be applied quickly, reliably and inexpensively.

Two-phase vat discharge prints The discharge dyeing of direct and reactive dyed backgrounds using vat dyes is only possible using the classic vat printing method with sodium formaldehyde sulphoxylate, which requires long fixing times; with two-phase vat discharge printing the advantages of the → Two-phase printing process can also be of benefit to discharge printing. The goods to be printed are padded with reactive dye of the alkali free vinyl sulphone type, dried, and then overprinted with vat-dye paste, which, apart from the dye, only contains formaldehyde sulphoxylate. The alkali necessary for both dye types is padded on and the discharge print completed using the → Two-phase flash ageing process. The desired rapid decomposition of the formaldehyde sulphoxylate is achieved by a heavy metal complex catalyst, e.g. cobalt dimethylglyoxim, which is added to the printing dye paste.

Two-phase wet fixation process (Hoechst system), for reactive dyes (→ Wet fixation process, Caustic shock process). Fixing in the two-phase wet fixation process is carried out in the wet fixation trough, a simple, inexpensive device, available in various sizes. It contains extendable roller casings, consisting of a feed roller at the upper end, then a pair of nip rollers, and at the bottom end a diversion roller, with a variable feed unit in between. The fixation liquor, consisting of a strong alkaline saline solution or, as has proved preferable, 600 ml sodium silicate 38–40°Bé and 200 ml 33% caustic soda, heated indirectly to 95–105°C. Fixation of the goods under these conditions takes approx. 10 s. Used liquor is transferred to a high-level container for subsequent addition. Manuf.: Goller.

Two-sided effect In the case of textiles made from blended fibres, provided two-tone or → Multicolour effects are not required, all fibres are dyed by means of tone-in-tone dyeing. Otherwise the goods would have an uneven appearance. In the case of certain fabric types, each side of the fabric has a different shade.

Two-sided effects by vertical migration A coloristic variant, which uses the generally undesirable effect of → Vertical migration to achieve a design. This is a continuous dyeing process, which is particularly suited to polyester and/or cellulose fibre fabrics. Two fabrics are padded double with slightly increased liquor pickup (Fig. 1).

Then they are dried at between 160 and 200°C; the best methods are stenter or cylinder drier. The effect of steaming on the outside and the dye migration in the flow of liquid gives the outside a deeper colour than the inside. The result is a light/dark effect. An interesting variation is the two-tone effect. This is achieved by dyeing again in a similar manner; usually in a contrasting colour. The lengths of fabric are turned first. The deeper dyed sides now lie together, the lighter sides turned outwards. When drying, the migration process once again takes place. The dye applied during the second phase again migrates to the outside, and the insides with the deeper colour from the first phase retain their shade (Fig. 2).

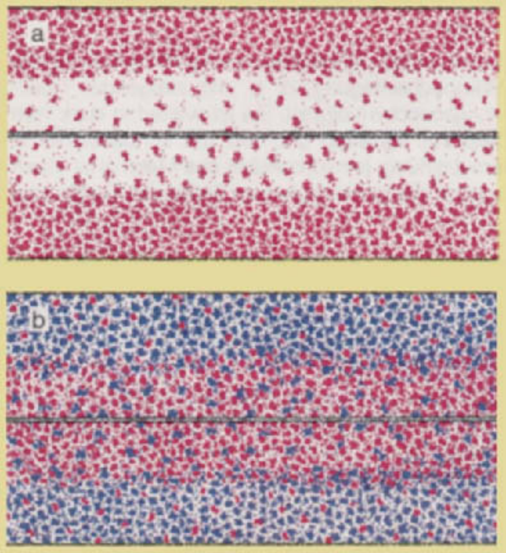

Fig. 2: Dye distribution through migration when dyeing double-laid fabric lengths.

The extent of migration increases with heat transfer, i.e. increased drying speed. It is also strongly dependent on the substrate and is more clearly seen the more hydrophobic the material. The technological characteristics of the fabric are also significant. In general migration increases more sharply, the heavier and thicker

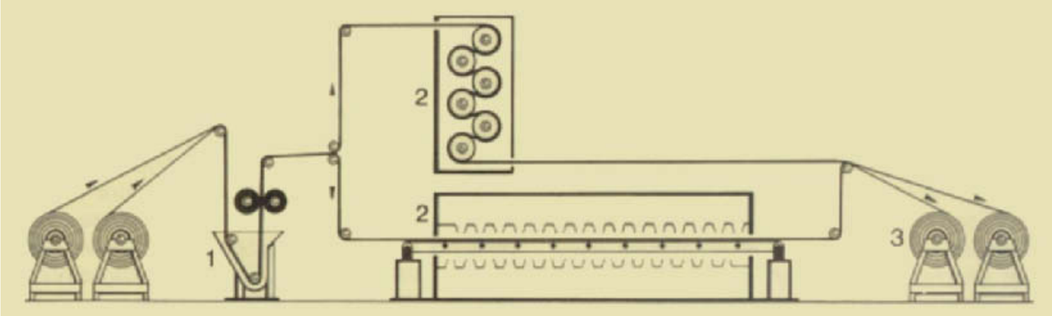

Fig. 1: Diagram of the process: padding (1), drying (2), batching (3).

the fabric and the higher the dynamic water content in the capillaries. A further criterion for migration is the dye itself. Wherever possible, dyes should be used which have low affinity and high microdispersion. Finally, higher quantities of surfactants, i.e. the usual wetting and dispersion agents, can significantly increase the tendency of a dye to migrate (according to Bayer).

Two-tone effects E.g. on fabrics (woven, knitted goods) which fashion requires should contain two colours (for more colours → Multicolour effects), distributed evenly or randomly; e.g. jaspé, melange, vigoureux, changeant (two different-coloured yarns in warp and weft), thread-by-thread (double twill), mouliné twist.

Tying up The division of hanks by means of tie threads, which are usually of a different colour and enable the immediate recognition of e.g., individual and overall titre and degree of twist.

Tyndall effect Named after an Irish physicist; the phenomenon known as the "milky band" of a ray of sunlight (or beam of a headlamp) falling into a dark space or through fog. In these cases dust particles or water droplets in the air cause a lateral deflection of the original direction of light, i.e. light scatter due to diffraction. In accordance with the same principle, in an ultramicroscope a strong beam of light directed through a drop of colloidal solution against a dark background generates individual punctiform diffraction patterns of colloid particles, the number and size of which can be determined. Thus at an angle of 90° to the beam of light, turbidity measurements can also be taken. Turbidity meters and colorimeters can also be used to examine fluorescent solutions (→: Turbidity meters; Fluorimetry), in particular in weak concentrations.

Tyndall meter Used as a → Turbidity meter.

Type of colour Colours of the same type are those in the shade series (e.g. → Grey series) which each represent a point on the same level of the colour triangle (→ Chromaticity diagram). Such a colour group is defined by shade and density and can be distinguished by its brightness. The colour type is defined by the chromaticity coordinates x, y. The colour type of a colour/dyeing is made up of shade and density.

Typha fibres Strong, woolly fibres belonging to the → Bast fibres group, obtained from the leaves of the reed mace. Only of localised significance. Spun alone, or (usually) with flax (tow), jute, recovered wool, etc. Used as a replacement for jute and hemp, or for coarse woven fabrics.

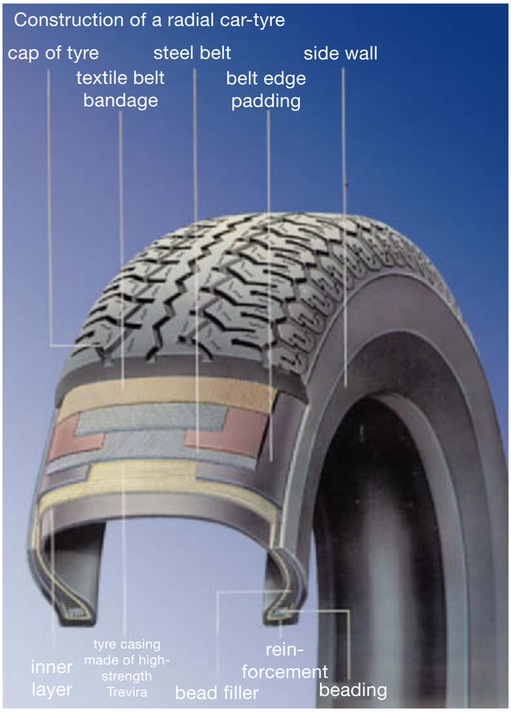

Fig.: Construction of a car tyre from tyre cord layers, made composite through vulcanization of layered rubber (Hoechst).

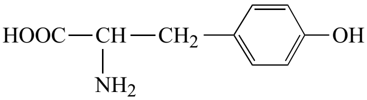
Tyre cord A special insert material forming the carcass of motor vehicle tyres, etc. Consists of a continuous filament tyre yarn (Fig.). Contains a latex preparation to increase the adhesion to rubber, because the tyre cord polymer and the rubber polymer would otherwise be incompatible and repel one another, which could lead to increased risk while in motion.

Tyrosine A cyclic → Amino acids, contained in wool at 5.8% and in silk at 10.6%. In wool tyrosine is found in wool keratin and in the spindle cells, but not in the scale layer. This forms the basis of the Pauly Diazo Reaction, an important tendering detection test.



U

U Symbol for the chemical element uranium (92).

Ubiquitous Distributed or present everywhere (e.g. in traces: dioxin, formaldehyde, silicone).

UBS Abbrev. for → Urea-Bisulphite solubility.

UCMTF French Union of Textile Machines; → Technical and professional organizations.

Ulbricht sphere photometer → Ball reflectometer.

Ulster,

I. A heavy, fulled, rough woollen winter coat material of coarse yarn (often pure virgin wool, but also an admixture of shoddy and rayon) with a Melton finish, usually with a woven-in lining, named after an Irish province. The weave of the outer fabric is usually twill and herringbone; that of the inner fabric is 4-ply evenly spanned twill.

II. A large winter coat with a broad collar and largish lapels made from heavy, soft material; a classic Ulster is double-breasted, modern sport and short Ulsters are single-breasted.

Ultimate shearing strain (shearing stress) → Rheology.

Ultra- (Lat.), beyond, on the other side of, in excess of.

Ultracentrifuge Used in colloidal chemistry to determine molecular weight and sedimentation rate of particles suspended in either liquids or gases. It can attain a centrifugal force of 260 000 to 1 million g (motor driven at approximately 30 000 rpm).

Ultrafiltration A membrane extraction process (→ Permeation) using membranes or cellulose film to separate colloidally dispersed dissolved substances from molecularly dispersed substances. Pore diameter from 1–1000 nm. Ultrafiltration suitable for cleaning waste water from the dyeing and textile industry. An ultrafiltration plant was specifically developed for the important application of size recovery (Fig. 1). For example, rinsing water containing polyvinyl alcohol is continuously cycled through a circulation tank until a predetermined concentration is reached, e.g. 7% polyvinyl alcohol (→ Reverse osmosis). Ultrafiltration is usually carried out in tubular systems (Fig. 2).

Ultrafiltration in size recycling. Ultrafiltration is an extraction process whereby a solid is separated from a solution by means of semi-permeable membranes. The size is almost entirely washed out and the recovered bath is concentrated at a membrane with microscopic

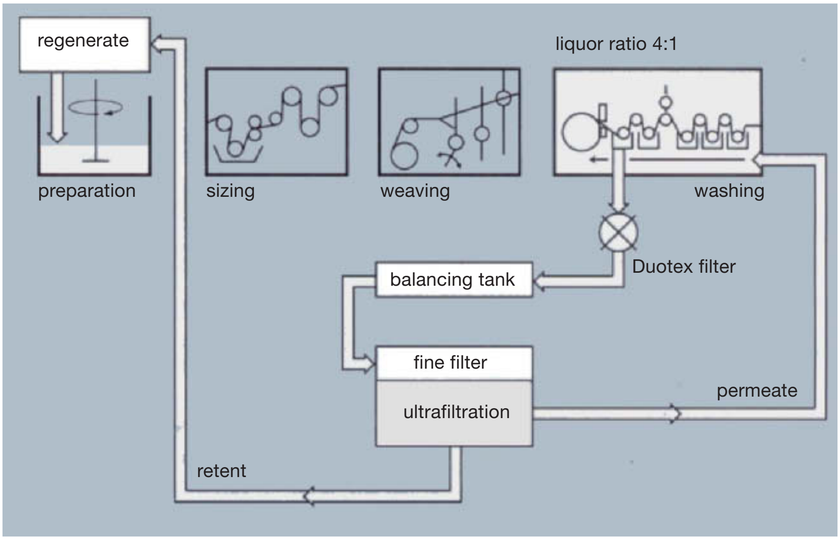


Fig. 1: Through ultrafiltration the sizing-desizing becomes a closed, effluent-free system (Hoechst).

Ultrafiltration

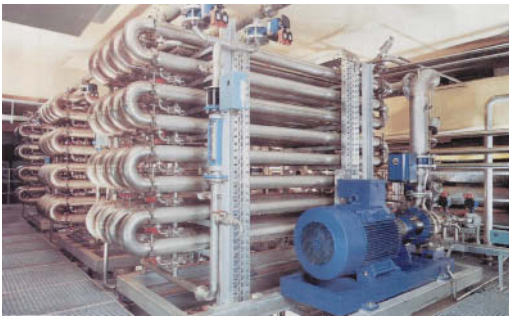

Fig. 2: Typical pipe system of an ultrafiltration plant (by GTV).

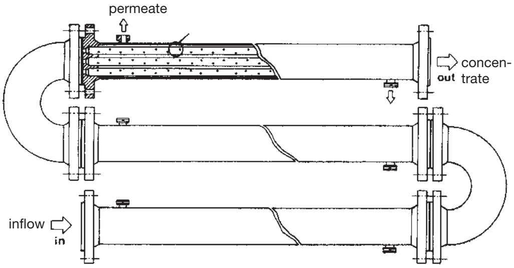

Fig. 3: Schematic illustration of a pipe membrane in an ultrafiltration plant module with effluent inlet, permeate outlet and concentrate outlet.

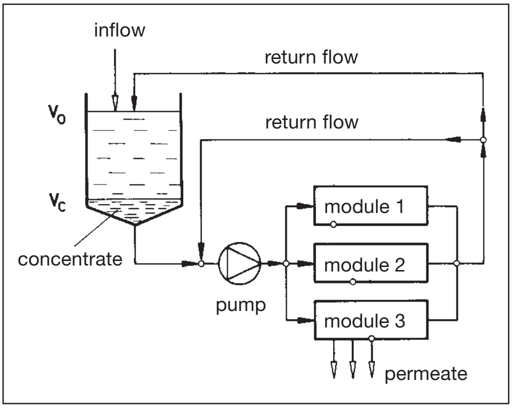

Fig. 4: Batch process ultrafiltration.

pores. The pores of the membrane are so small that the macromolecules of the size are held back while the water can pass through. To achieve this, the liquid to be filtered must be subjected to high pressure.

The concentrate remains within the pipe while the permeate drains out of the pipe (Fig. 3). Short chain molecules are separated out with the water, so there is a constant loss of material known as the permeate loss. This permeate loss gives rise to a particular aspect of the size recovery process: since only short chain molecules are lost from the size, this explains why recovered size is at least as effective in sizing as is the original size. In order to regenerate the ultrafilter, batch processing may be desirable (Fig. 4).

The principle requirement is that the size is soluble in water without thereby changing its characteristics. As a result products are unsuitable if, as starch, they

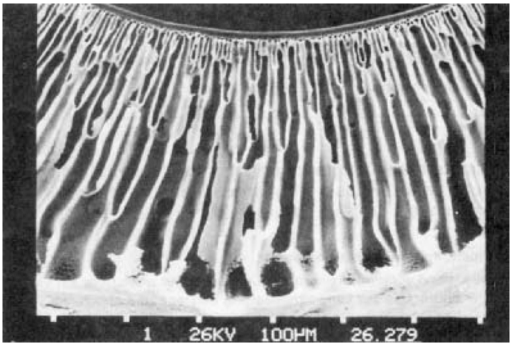

Fig. 5: Section through an asymmetrically structured ultrafiltration membrane.

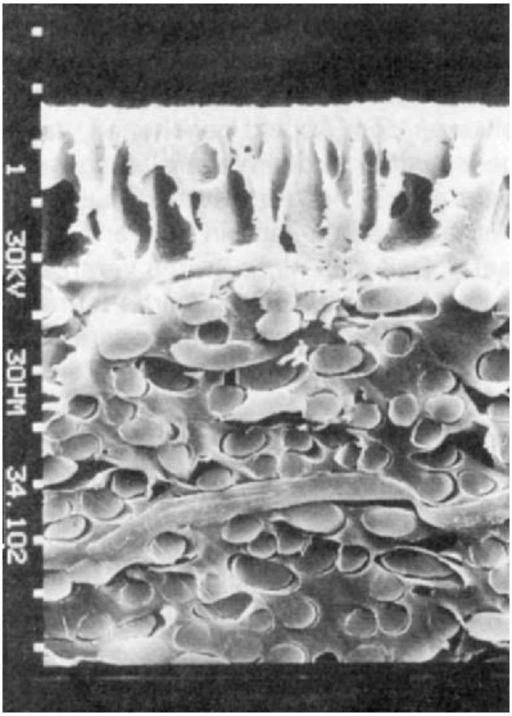

Fig. 6: Membrane, applied to a nonwoven base.

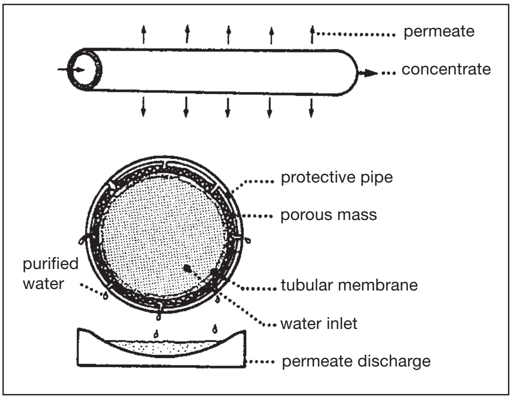

Fig. 7: Tubular ultrafiltration membrane.

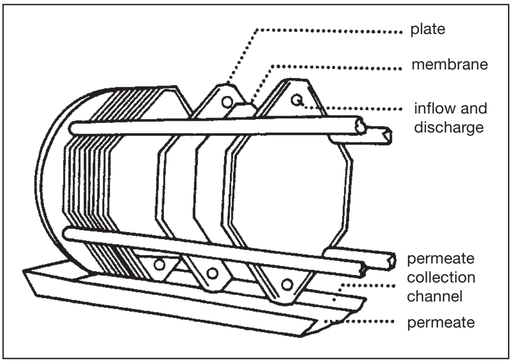

Fig. 8: Ultrafiltration plate module.

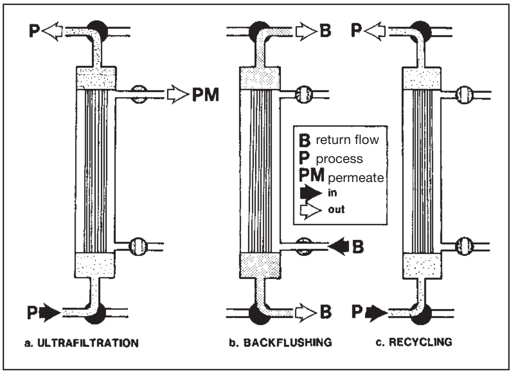

Fig. 10: Hollow fibre module with three ultrafiltration operations.

must be broken down enzymatically, or if they can only be dissolved with the aid of chemical additives. Each class of size substances include some that are water soluble: modified starch/CMC/PVA/PAC. In addition to water solubility a further characteristic is required: stability. Recovered size must not break down chemically while being stored prior to re-use.

Ultrafiltration facilities make use of microporously layered membranes attached to fibrous substrates (Figs. 5 + 6) which are used in a variety of modules:

- tubular module (Fig. 7),
- plate module (Fig. 8),
- spiral module (Fig. 9),
- hollow fibre module (Fig. 10).

Ultramarine (-blue, blue powder, washing-blue). Mineral dye obtained by heating together kaolin, sodium carbonate, sulphur and charcoal. A fine brilliant blue powder (of variable composition), also blue-green, violet and red. Insoluble in all solvents. Fast in the presence of light, air and soap, it is bleached by acid (giving off hydrogen sulphide), which reaction can be used to prove the presence of or to destroy ultramarine

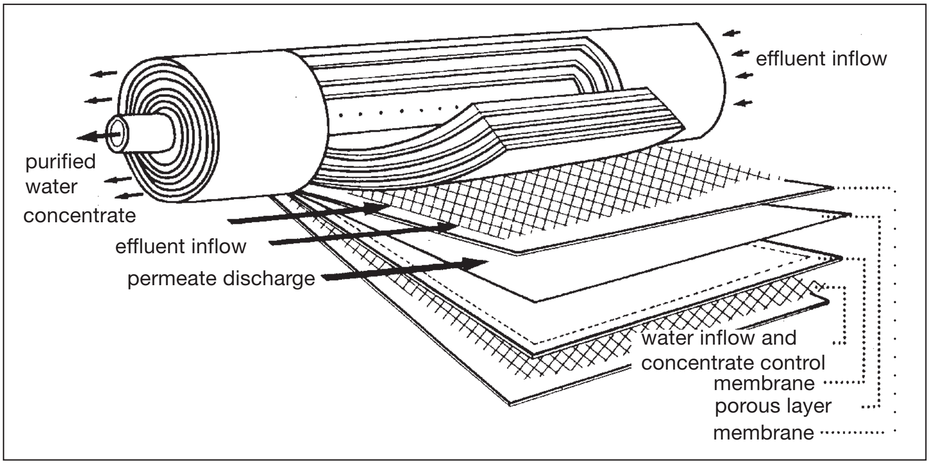

Fig. 9: Spiral ultrafiltration membrane.

marking dyes. However, acid resistant ultramarine does exist. In common with zinc oxide, ultramarine is highly reflective to infrared (therefore use in camouflage colours). Usage: component of white conditioner in printing; frequently used in the blueing of bleached goods, underwear, feathers, etc.; dyeing of plastic, rubber, wax cloth, leather, paper; as marking dyes, etc.

Ultra-rapid accelerator → Vulcanization accelerator.

Ultrasonic cutting Thermo-mechanical contact process. In this case, textiles and other planar objects are not melted by applying ultrasonic sound energy, but instead the oscillations activate a chisel-shaped tool. The principle is similar to that of a pneumatic chisel, but uses oscillations in the region of 20–40 kHz. Cutting is generally done by means of pliers, whereby the material is introduced between one jaw and an opposing jaw suitable for the particular purpose. The ultrasound frequency is modulated such that an acoustic resonance is created between the two jaws. The material is modulated by the sonotrode, causing its fibres to vibrate at the resonant frequency. Heat is created by friction and melting begins. The ultrasonic oscillations are dampened by the thermoplastic fibres, which therefore limits the melting process to a narrow zone.

Ultrasonic cutting has several notable advantages compared with thermal cutting:

- Virtually all materials can be cut, e.g. glass fibre, natural fibres, synthetic fibres, aramid fibres, metal fibres. This depends merely upon the generator power, the working parameters and the form of the cutting tool (sonotrode).
- However, a welded edge is produced only in the case of thermoplastic material containing up to 35% other materials (as in thermal cutting). Firm welded edges of good appearance are produced with either narrow or wide melting zones.
- No noticeable heat is generated and the cutting tool remains completely cold. The maximum irradiated temperature does not exceed 50°C, therefore both combustion of the product or the risk of burns to the worker are out of the question. As a result, thick and voluminous material may be cut in this way.

Since the clothing industry is beginning to recognise a market demand for single or low-number cuts, ultrasonic cutting presents an alternative to rapid water jet cutting. In contrast to previously available cutting techniques, this technique offers increased performance over mechanical means. The maximum blade cutting speed is indeed 60 m/min, but because of mechanical friction between blade and material a somewhat lesser speed is possible than that for water jet cutting. Compared with conventional cutters, ultrasonic cutters are approximately twice as fast for the same quantity of material.

Ultrasonic energy application → Laminating.

Ultrasonic flowmeter The ultrasonic measuring process can be described as follows. Sound propagates through a fluid at rest at a velocity which is dependent upon the elasticity and the kinetic properties of the fluid. If the fluid is flowing, the propagation velocity of the sound decreases or increases in proportion to the velocity of flow, depending upon whether the sound is transmitted with the flow direction or against it.

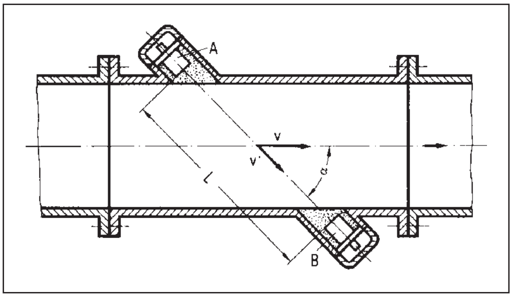

Fig.: Operational diagram of an ultrasonic flowmeter. A = transmitter and receiver; B= transmitter and receiver; L = distance between transmitter A (B) and receiver B (A); n = average flow rate of the measuring material in the measuring tube. n' = n · cos a (velocity component of the average flow rate, in terms of the transmitter/receiver direction).

The Fig. shows the way in which this works. Pulses of ultrasound are sent alternately from transmitter A to receiver B and then from transmitter B to receiver A. The time taken for each transmission is measured, represented as a frequency, and the two frequencies are subtracted one from the other. The difference in frequency is proportional to the flow.

Ultrasonics Higher than audible sound with a frequency above approximately 16 kHz up to approximately 10^6 kHz.

infrasound	up to 16 Hz
audible sound	16–16 000 Hz
ultrasound	above 16 000 Hz.

Ultrasonics is a specialist area of more general acoustics, which studies the behaviour of mechanical oscillations in solid, liquid and gaseous media (→ Sound). In reference to the characteristics of the human ear, high frequency and no longer audible oscillations are termed ultrasound or hypersound.

There are many ways to generate ultrasound. The best known ultrasonic transmitters are whistles and sirens of various forms, as well as piezoelectric and magnetostrictive generators. As a rule ultrasonic generators driven by compressed air are used as these most easily allow the required acoustic pressure level to be reached. Typical values range from 140–165 dB. Whistles and sirens, because of their mechanics, permit an optimal coupling of the generated ultrasound with the

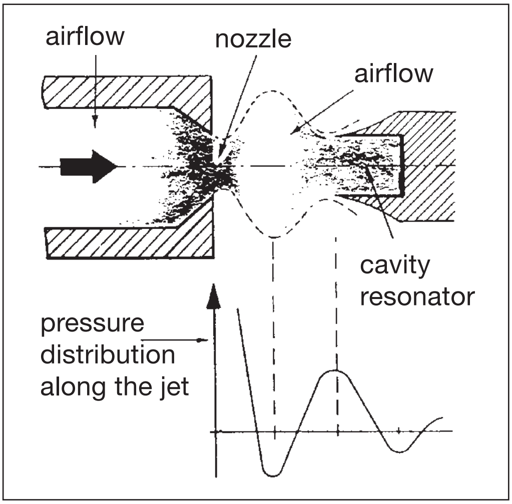

Fig.: Schematic illustration of a Hartmann generator.

surrounding air mass. Magnetostrictive and piezoelectric ultrasound emitters create only low amplitude oscillations inside the generator itself and coupling with gases is poor.

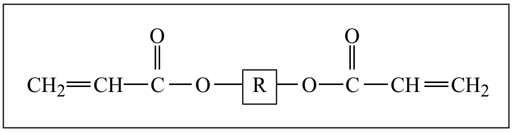
Generation:

I. Mechanical: Ultrasonic oscillations may be generated in gases and liquids by means of whistles, whereby gas or liquid streaming over a blade gives rise to separating vortices, which then excite resonant spaces or resonant bodies into oscillation. Well-known examples are the Galton whistle and its further development, the Hartmann generator (Fig.). The Siemens ultrasonic whistle (for exciting liquids) produces a relatively high ultrasonic output. Ultrasonic sirens (for exciting air) produce ultrasound by blowing a jet of compressed air through a rotating aperture.

II. Electrical: emission of frequencies by tubular transmitters, translation of an alternating electrical voltage into ultrasound (mechanical oscillations). This requires transformers operating on the following principle:

a) Magnetostriction, i.e. alternate lengthening and shortening of a laminated nickel rod according to the rhythm of a magnetic field generated by electrical oscillations (in a surrounding coil).
b) Electrostriction, i.e. alternate compression and extension of an oscillating quartz crystal (piezoquartz; → Dielectric) according to the rhythm of an alternating voltage known as piezoelectricity. The frequency created may be as high as is desired (only 50–200 kHz for a quartz rod, but 200–30 000 kHz for a quartz disk).

Ultra-violet curing of polymers Polymer systems capable of being cured by irradiation need not have a complex structure and may comprise only a single chemical substance. For reactive components such as acrylates, the energy level of accelerated electrons is high enough to begin radical polymerization. However, if UV light is used as a source or irradiation a photoinitiator is usually required in order to generate sufficient radicals to start the polymerization reaction. For practical reasons polymer systems to be cured by irradiation usually comprise more than one component. Each major component normally contains reactive groups (usually acrylate or vinyl groups). The main components can be ordered into two sets: pre-polymers and diluents. The pre-polymers (Fig. 1) are oligomers such as polyurethane, polyester and polyether, possessing acrylate groups at the ends of their chains. In contrast, reactive diluents are simpler molecular components such as the monomers in Fig. 2. Typical examples are glycol acrylate, N-vinyl-pyrrolidon and styrol. These compounds are used in order to manipulate viscosity, improve characteristics in solution and optimize coatings to be applied. Additives may also be incorporated in a mix in order to improve specific characteristics such as colour. If an additive contains a reactive group it may take part in the reaction and become an incorporated component of the polymer network. If it does not, the additive will be enclosed within the polymer network.



$$CH_2{=}CH{-}\overset{\overset{O}{\|}}{C}{-}O{-}\boxed{R}{-}O{-}\overset{\overset{O}{\|}}{C}{-}CH{=}CH_2$$

Fig. 1: Pre-polymers with 2 reactive groups.

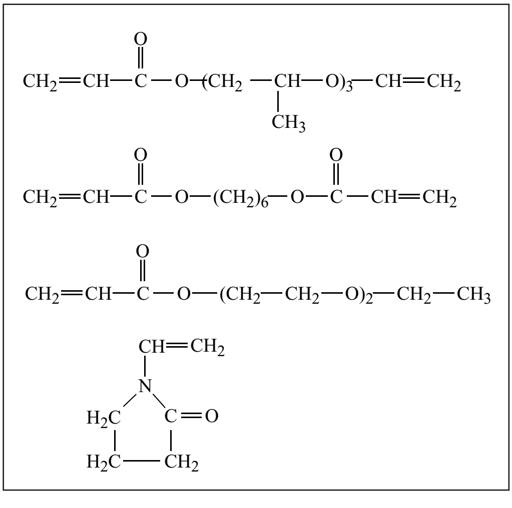


Fig. 2: Examples of typical monomers as reactive diluents.

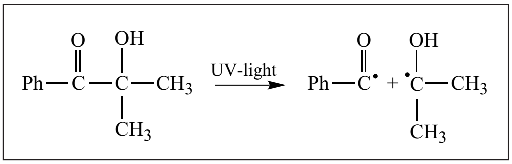

Fig. 3: Generation of radicals through photo-degradation.

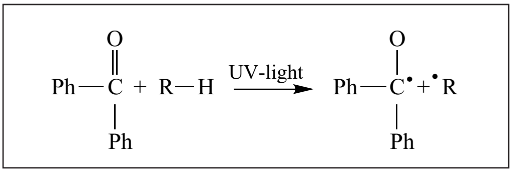

Fig. 4: Generation of radicals through dehydrogenation.

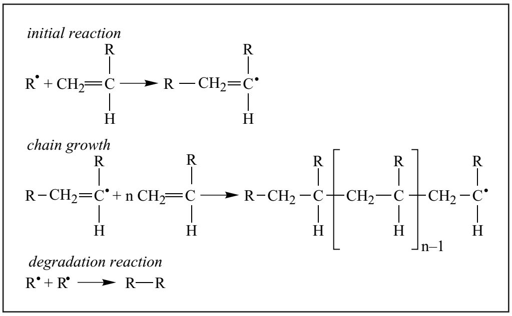

Fig. 5: Radical polymerization (initial reaction, chain growth, degradation reaction); R = alkyl, acyl.

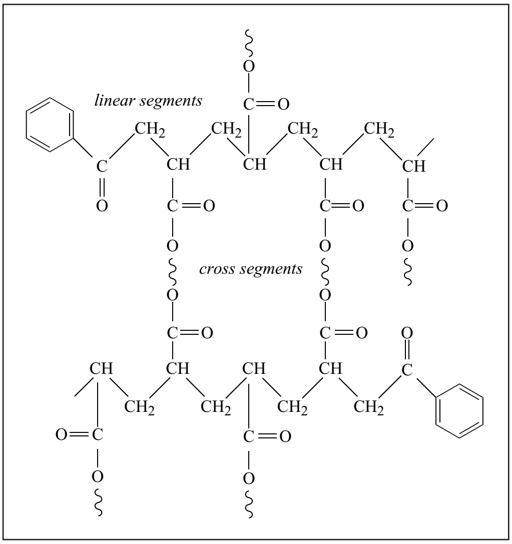

Fig. 6: Crosslinked polymer.

In the case of UV-cured coatings, photo-initiators are used to provide the energy required in order to generate radicals which then initiate the polymerization reaction (Fig. 3). If the concentration of photo-initiators is too low the excitation will not be sufficient to produce a fully polymerized product. If the concentration is too high, the greater proportion of the UV-light is absorbed by photo-initiators in the outer layer of the film and the layer below receives insufficient light to achieve complete curing. In order to ensure that the desired degree of curing is achieved throughout the thickness of a coating an optimal concentration of initiator is essential.

In recent years a great number of photo-initiators have been developed which generate radicals either through photo-degradation or dehydrogenation (Fig. 4). Examples of photo-initiators which release radicals under irradiation by UV-light (Norrish type, Fig. 3) are benzol derivatives, acetophenon derivatives, hydroxyalkylphenons and acylphosphinoxides. The second main group of photo-initiators generates radicals by dehydrogenation, as shown in Fig. 4; this category includes aromatic ketones such as benzophenone and thioxanthrone. The hydrogen donator is generally a tertiary amine such as methyldiethanolamine.

The basic form of radical polymerization by which an irradiation-cured coating is built up is shown in Fig. 5. Long side chains are built from pre-polymers while monomers give rise to short side chains. Since a pre-polymer or a monomer generally contains more than one reactive group, irradiation often results in a crosslinked polymer (Fig. 6) (according to Luiken).

Ultraviolet fluorescence of textiles Fibres emit → Fluorescence in the ultraviolet region, e.g.:

faintly yellowish, whitish	(USA) cotton
pale yellowish	cotton, mercerised and bleached
straw yellow	viscose, unbleached
sulphur yellow with blue shadow	viscose, bleached
intense yellow	polyester
yellowish green	polyacrylonitrile
blue-green	polyvinylchloride
bluish violet, brightly luminous	acetate
reddish white, milky	cuprous
bluish white	wool, unbleached; silk, scoured; casein
pale bluish, whitish	wool, bleached.

→ Luminescence analysis.

Ultraviolet lamp (quartz lamp, quartz-mercury lamp, mercury lamp). Artificial source for the generation of ultraviolet radiation. For lamps used in analysis the visible component of light from such sources is removed using a special filter, e.g. for use in → Luminescence analysis.

Ultraviolet radiation (UV radiation). Includes light of a wavelength from approximately 140 nm to 360 nm. Ultraviolet radiation is present in sunlight but is nevertheless invisible to the human eye since it lies beyond the violet portion of the visible spectrum. → UV Excimer radiator.

Umbrella fabrics A thick, light fabric (often printed) made from yarn-dyed polyamide threads and made water repellant.

UMIST English textile research organisation in Manchester; → Technical and professional organizations.

UNARI Burmese standardization association; → Technical and professional organizations.

Unbalanced mass Unevenly distributed mass within a rapidly rotating machine, e.g. because of unevenly distributed wet articles in a centrifuge or tumble drier. The frame of the machine (its base) must be so constructed as to accommodate the effect of the unbalanced mass.

Unbleached linen (Écru linen, raw linen). Naturally coloured, unbleached → Linen.

Unboiled silk → Écru.

UNCO Una Norma Colombiana, Colombian standard.

Uncollapsed cake Rewound cake in crossed layers of yarn, mechanically stronger with improved dyeing characteristics (package and pin up system).

Undecane (Lat.: undecim = 11) Containing 11, e.g. → Undecanoic acid is an amino acid which contains 11 carbon atoms.

Undecanoic acid (11-amino-undecanoic acid) $NH_2\text{–}(CH_2)_{10}\text{–}COOH$ has an important role in the manufacture of polyamide 11. The starting point for the process is castor oil. The production is outlined in principle as follows (the basis is ricinic acid):

$$CH_3(CH_2)_5CHOH\text{—}\ CH_2CH{=}CH(CH_2)_7COOH$$

$$\xrightarrow{\text{overheat}} CH_2CH(CH_2)_8COOH \qquad \textit{undecylenic acid}$$

$$\xrightarrow{+\,NH_3} NH_2(CH_2)_{10}COOH \qquad \textit{11-amino-undecanoic acid}$$

$$\xrightarrow[-\,H_2O]{\text{polycond.}} [NH(CH_2)_{10}CO]_n \qquad \textit{polyamide11}$$

Under exposure of photosensitive screens In order to manufacture a printing screen, the photosensitive screen, which lies either on or around the stencil gauze, is illuminated at those points which are not coloured black on the transparency sheet which covers it. The rays of incident light penetrate both the photosensitive screen and the gauze threads. Because of a difference in refractive index, or due to reflection at the surface of the thread, the gauze threads cause a degree of scattering of the light, which in turn leads to under exposure of those parts of the photosensitive screen which are exposed by the transparency. Remedy: dyeing the gauze threads yellow leads to absorption of the photochemically active violet and UV radiation. Under exposure can also result from light falling at an angle upon the transparency and the photosensitive screen.

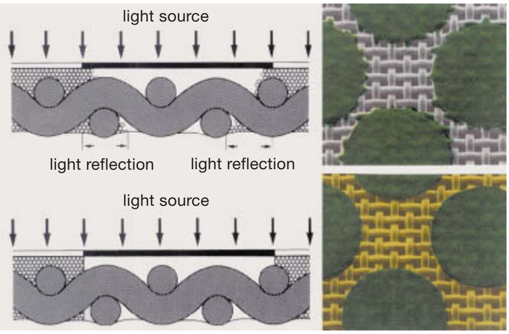

Fig.: Result of under exposure with white gauze (above) and avoidance thereof using coloured screen gauze (below) (Swiss Silk Bolting Cloth Factories, Thal and Zürich).

Undercoat hairs (down hairs, wool hairs). Shorter and finer hairs forming the inner layer of an animal's coat, usually unmarked, soft/elastic, curled with good felting quality.

Underfloor/elevated machine siting Term used for the positioning of a machine above a production floor (elevated) or below the floor level in e.g. a pit (underfloor) (see Fig.). Underfloor positioning can be of advantage with respect to tooling/equipping if a machine incorporates a product feed or output at high level.

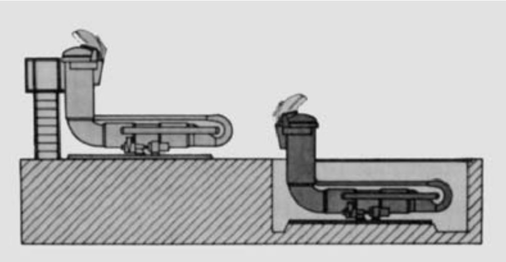

Fig.: Diagrammatic comparison of the siting of an elevated (left) and underfloor machine (right), Alphorn model (Scholl).

Underground biological digestion Process for → Waste water treatment. In this process waste water is

Underground biological digestion

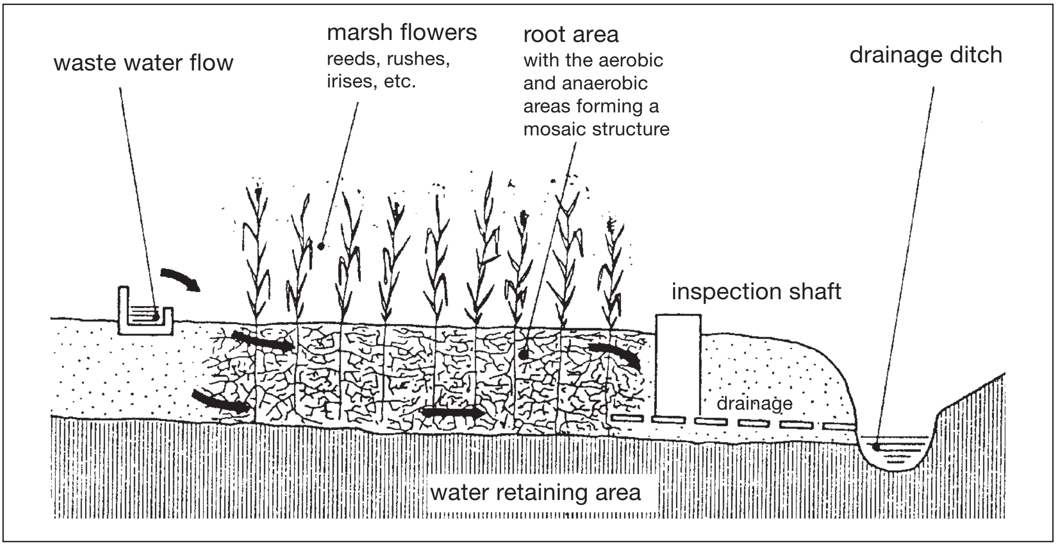

Fig. 1: Section through the ground in underground biological digestion.

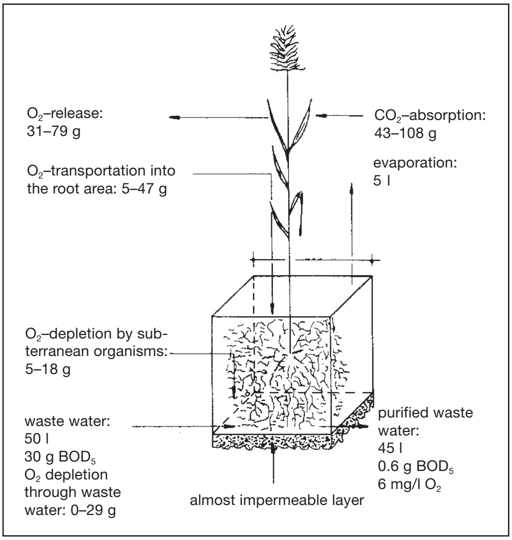

Fig. 2: Structure of the drainage system in underground biological digestion.

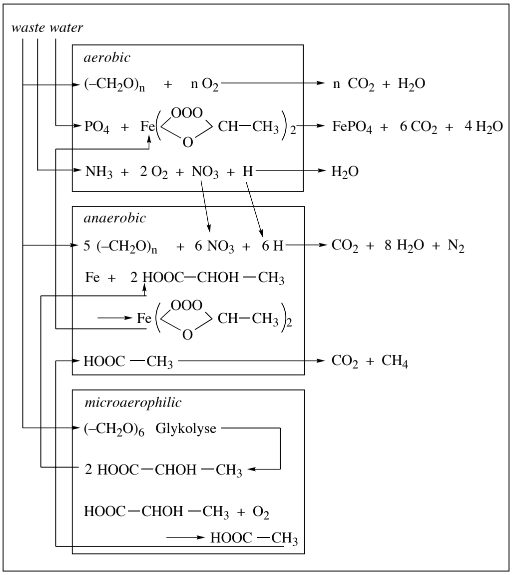

Fig. 3: Combination of aerobic and anaerobic fermentation in underground biological digestion.

allowed to flow horizontally underground, above an impervious layer, through a flow zone which has been dimensioned precisely to match the nature of the waste water and of the soil, and then into an open drain (Fig. 1). The sediment is planted with reeds (Fig. 2) which, in addition to other important physiological benefits for effluent treatment, deliver oxygen from the air to the roots within the saturated sediment. This gives rise to an aerobic-anaerobic mosaic matrix (Fig. 3) which permits waste water recovery other than the usual purely oxidizing or reducing purification processes.

One of the basic requirements of conventional oxidation-based waste water technology is to deliver the waste water to the treatment works in the freshest possible state, i.e. as quickly as possible. If water is delivered in a partially stagnant state, this can lead to smells and to corrosion problems in the enclosed space above the flowing water. Even normal waste water smells are considered unpleasant by many people. Waste water containing sulphur gives rise to largely unacceptable smells and undermines the sense of well-being. It is therefore an important aspect of underground biological digestion that such facilities are constructed decentrally, i.e. well away from residential areas (according to Kickuth).

Underwear Clothes worn directly against the skin and covered by other textiles. Underwear is intended to absorb the moisture emanating from the skin through perspiration and release this to the outer air. If the rate of absorption is greater than that of evaporation, the textile remains wet against the skin and this leads to an unpleasant sensation (→ Clothing physiology).

Functional knitted goods work in such a way that sweat is removed from the body as quickly as possible as it occurs, this being due to the special construction of the textile. Such a textile may be, for example, a two-layered knitted item with an inner layer composed of hydrophobic synthetic fibre and an outer layer of cotton or modal fibre. Most fine-fibrillar synthetic fibres (polypropylene, polyester or polyamide) transport moisture rapidly through the capillary spaces between the fibres and release it to the absorbent outer layer without themselves taking up moisture (the same principle applies if absorbent textiles are worn over simple synthetic fibre underwear).

Such a clothing system only functions if the absorbency of the construction is optimal. Layers of hydrophobic synthetic fibre usually loose their absorbency after dyeing, and this can only be restored with the application of an appropriate hydrophilic agent. This consideration should be included in the design in all cases.

UNE Spanish standards association; → Technical and professional organizations.

UNESCO United Nations Educational Scientific and Cultural Organization (headquarters in Paris) whose "International Organization of Standardization" (→ ISO) is, among other things, responsible for the standardization of colour fastness in dyes.

Uneven dyeing for fashion effects,

I. Interesting fashion effects are achieved by dyeing ready-made goods with the use of stones (stone dyeing). For this purpose selected direct, reactive or acid dyes are used. This method of finishing is characterized by not being energy intensive while remaining simple, and is suitable for the treatment of goods made from acetate fibres or from an acetate/synthetic mix.

II. An irregular dye pattern can, for example, be achieved by spraying dye solution onto a moving band of fabric by steam, while at the same time applying suction to the fabric (→ Space dyeing).

III. Due to a variety of processes, textiles may be treated with special liquid crystals, or else with thermochromatic pigments made from particles of a specific size suspended within a binding agent. Textiles finished in this way react with a change of colour to changes in temperature.

IV. Hoechst AG has patented a process for uneven colouring (a batik process for use on textiles made from synthetic fibre). A reserving agent is applied to the fabric. Once dry, the material is mechanically "broken" and subsequently heat set.

V. Sandoz has developed a technology for uneven dyeing or etching. The continuous finishing process involves spraying stones or porous material from above with one or several dyestuffs, while these stones or this porous material also come in direct contact with one side of a moving textile band.

VI. Equally widely used is a process which makes use of enhanced dye uptake at various locations along a textile band. After dyeing, pronounced two-colour or multicolour effects are achieved.

VII. Technologies are widely established which make use of stones in the processing of finished goods in order to achieve a worn and washed-out effect. The stone wash process has the effect of mechanically removing the dye from the surface of the textile, e.g. in the case of → Denim, so that a subsequent "lightening" can under certain circumstances be attained by treating with hypochlorite. Stone wash technology depends in principle on chemically washing with stones impregnated with potassium permanganate. This technology can be used on knitted goods to produce an interesting fashion effect, since the surface of the fibres is simultaneously roughened to a degree, lending the goods a slightly satin or peach-skin appearance. A series of different technological processes have been developed for this method of finishing, whereby the textile is fretted using either stones or pumice or treated in a bubbling stream of sand. → Enzymes are also used for this purpose.

VIII. A washed-out appearance may also be achieved by spraying the textile with a bleach bath or by chemically washing it in a dilute NaOH or KOH solution.

UNI Italian standards association; → Technical and professional organizations.

Uniflow principle in drying The internal airflow system within a drier can essentially be either a uniflow or a counter-flow system: in uniflow, the driest portion of hot air flows in the same direction as the goods (Fig. 1). The uniflow principle entails central airflow, central automatically regulated exhaust, and a heat transfer medium (air) which moves in the same sense as the fabric band or goods line, and may be employed for the following reasons (Fig. 2):

1. During drying the upstream zones can operate with circulating air at a higher temperature, which increases the evaporation effect. Downstream zones operate with circulating air at lower temperatures.

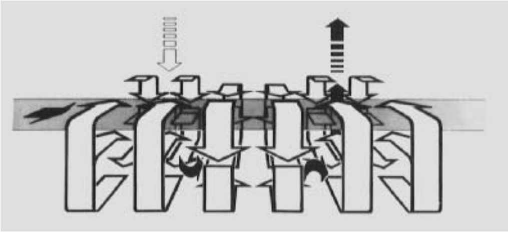

Fig. 1: Uniflow air control (Babcock).

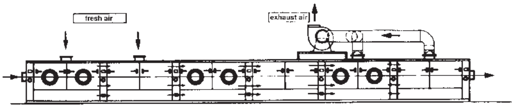

Fig. 2: Fresh air and exhaust air control with the Econ-Air system (Babcock).

Since air is only extracted downstream, the lower temperature means reduced heat loss.

2. During drying the goods attain a higher temperature downstream. This increases the diffusion rate of water on the surface and improves drying efficiency, as shown in both theoretical investigation and practical tests.
3. During curing any softener fumes which may be given off are drawn out of the drier in the direction along which the temperature of the goods increases, thus avoiding condensation on the goods.
4. During combined drying and curing, softener fumes do not penetrate into colder drying zones and form droplets there.
5. During combined drying and curing, the humidity of the circulating air in the downstream zones is higher, thus reducing the risk of yellowing.

Uniformity The most important determining factor when assessing goods according to → Quality, e.g. in terms of pattern, finish, weight, length, thickness, section, strength, stretch, etc. Calculated as: % U (uniformity) = 100 – deviation in % (→ Deviation).

Unipolymerisate Product of → Polymerization resulting from basic building blocks of only one type.

Unisyn concept Universal desizing technique for water soluble synthetic size. The desizing in practice of water soluble sizes is usually dependent on the product used. Water soluble sizes of all types can be washed out cost effectively on a continuous wash production line using the Unisyn technique (BASF) with the application of:
1 g/l wetting agent,
2 g/l dispersing agent,
3 g/l sodium hydroxide.
The particular value of the process lies in the fact that all generally used water soluble sizes can be dealt with in this way (according to Rüttiger).

UNIT Instituto Uruguayo de Normas Tecnicas, Uruguay Institute for Technical Standards; → Technical and professional organizations.

Unitary (Lat.: una = together, combined), refers in chemistry to a molecular structure comprising atoms of only one kind, e.g. O_2. →: Binary; Ternary.

Unit of force Within the → SI System of Units force is no longer a fundamental dimension, but instead the SI unit of force, the Newton (N), is derived from three fundamental dimensions (length, mass, time). 1 N corresponds to the force required in order to impart to a body of mass 1 kg an acceleration of 1 metre per second: i.e. $1\ N = 1\ m\ kg/s^2$. The unit used earlier, the kilopond (kp), is no longer accepted.

$1\ N \approx 100\ p$
$1\ kp \approx 10\ N = 1\ daN$
$1\ p \approx 0.01\ N = 1\ cN$

Unit processes Single processes which recur regularly within larger processes. A unit process must be self-contained and obeys only one law. A unit process cannot be realised in itself. Unit operations, unit procedures or discrete operations are clearly defined in chemical process engineering as physical unit processes which lead to a change of state. They are divided into mechanical, electrical, magnetic and thermal unit processes. Mechanical and electromagnetic unit operations essentially take place without heat transfer or the transportation of molecular material. In the case of thermal unit operations, on the other hand, forces which instigate flux place the central role in the change of state. In this way, for example, both a concentration gradient and a temperature gradient can give rise to diffusion (simple diffusion and thermal diffusion). In this sense relaxation processes are also counted as thermal unit operations, since locational changes of the polymer segments within a fibre are necessary in order to increase or reduce tension.

Within a general technical system inverse pairs of unit functions may be formulated as follows:

flow	inverse of	isolate
fuse	“	split
group	“	disperse
combine	“	divide
rectify	“	oscillate
conserve direction	“	change direction
store	“	discharge
mix	“	separate
enlarge	“	reduce
transform (change)	“	untransform (change back)

Chemical processes by which substances change are described as unit processes. These processes fall within reaction technology. They are divided according to whether they are thermal, electrochemical, photochemical, mechanological, biochemical reactions and so on.

Unit processes within textile manufacturing are, for example:

a) mechanical: passing, compressing, brushing, abrading, stretching, storing, crushing;
b) thermal: diffusion, calendering, mixing, wetting, swelling, relaxing, shrinking, diluting, vaporizing, dwelling;
c) chemical: addition, hydrolysing, condensing, oxidizing, reducing, crosslinking.

The unit processes are formally described in terms of unit functions within textile manufacture. They are characterized by the fact that the input and output conditions of the respective system have not yet been finally determined.

Units → SI System of Units.

Units of measurement → SI System of Units.

Unit time (time per unit). Processing time required for a single unit (single item of a commodity) =

$$\frac{\text{completion time}}{\text{number of units}}$$

→ Completion time is a mutiplication of unit time by the number of units. → Basic time and → Allowance.

Universal loop steamer → Steamer, in which knitted goods are transported through the steam chamber suspended in long loops and thus are not under tension (Fig.). An externally heated standard universal loop steamer, accepting goods with a width of 2.6 m and accommodating a length of 200 m, requires approximately 1700 kg steam/hour to supply heat from the external source to its steam chamber when operating with superheated steam (180°C) in order to fix dyes after printing. In contrast an internally heated universal loop steamer (Artos) of the same size and capacity requires only approximately 560 kg/h when operating with superheated steam. For technical reasons hot air operation of externally heated steamers is either impossible or very difficult to achieve. Internally heated universal loop steamers, on the other hand, permit hot air operation provided they are equipped with a fresh air intake system. Hot air operation allows an almost complete avoidance of the costs incurred for steam.

Unlevel dyeings Faults occurring in the dyeing of textiles of all varieties. The dyestuff is not level (→ Levelling properties) but instead is spread unevenly over the textile material. Unlevel dyeing may be caused by, among others, any of the following factors: omitted or inadequate pre-treatment, packing too tightly in apparatus, a too weak or a too strong dye bath circulation, inappropriate or faulty dyeing conditions, inappropriate choice of dye.

For example, during the heating up phase while dyeing either polyester yarn or beam dyeing polyester piece goods, the glass transition temperature is exceeded. When this occurs, the substrate begins to draw the dissolved dyestuff from the adjacent liquid. If it were the case that the dyestuff was instantly replenished through a process of diffusion or dissolving from dispersed particles, then the concentration of dissolved dyestuff would remain equal at every point above the substrate surface and would match the solubility of the dyestuff. The sorption rate would be everywhere the same and the resultant dyeing would be exactly level. This limiting sorption rate is determined solely by the diffusion process taking place within the substrate.

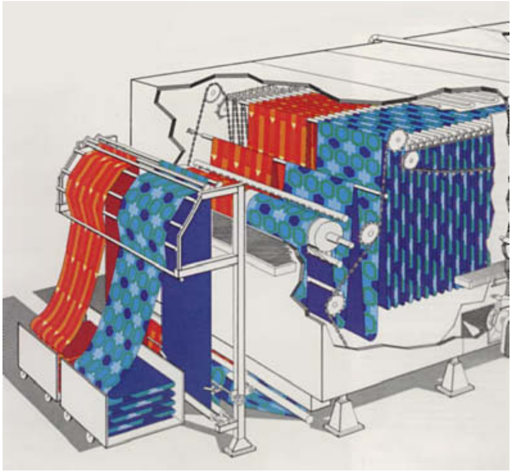

Fig.: Universal loop steamer (Babcock).

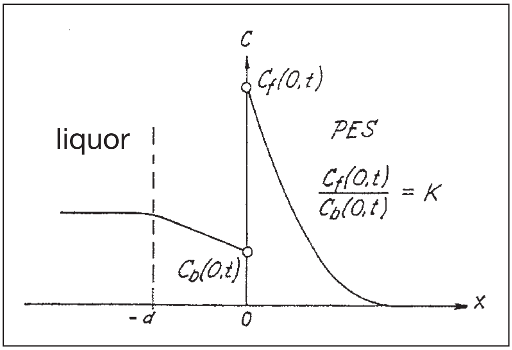

Fig.: Liquor-substrate concentration profile on the suface.

However, since the replenishing of dissolved dyestuff takes place only at a limited rate, the boundary layer above the substrate becomes depleted (see Fig.).

This depletion causes on the one hand a reduction in the sorption rate and on the other a simultaneous increase in the delivery of dissolved dyestuff to the boundary layer. The concentration of dissolved dyestuff C_b (0, t) at the boundary between dye bath and substrate (x = 0) adjusts itself constantly such that sorption rate and replenishment rate remain in balance.

If the depletion of this boundary layer is slight a level dyeing may be expected. In such a case the replenishing of dissolved dyestuff is not significantly influenced by local current effects. If, however, the depletion is greater, replenishment becomes strongly dependent upon the thickness of the laminar boundary layer, in other words upon local currents. This results in the sorption rate being no longer independent of location and unlevel dyeing begins to develop.

Unlevel dyeing is a consequence of a depletion of dissolved dyestuff in the boundary layer. The ratio between the limiting sorption rate and the replenishment rate of dyestuff (UK) is a measure of this depletion and thus offers a criterion for levelness.

$$UK = f\left(\frac{C_f}{C_s}\right)$$

The dimensionless levelness criterion UK has a different value at every moment during the heating up phase because both the quantity of dyestuff absorbed C_f and the dyestuff's solubility C_s are temperature dependent. The greater the value of UK at any particular moment during the dyeing process, the more level the sorption of dyestuff by the substrate at that moment (according to Gerber).

UN number So-called classification number for "hazardous substances" the transport of which involves particular dangers (→ Hazardous substances act). An international cataloguing and classifying system of types of hazard which is largely uniformly implemented. Its basis is the recommendations of an expert commission of UNO. Transport of chemicals in the Federal Republic of Germany requires a special permit (brown-bordered form) and accompanying papers (safety information sheet).

Unrolling of liquid droplets The separation of a flattened and spread-out oil droplet from the surface of a textile material (e.g. when washing with surfactants). As the unrolling process proceeds (see Fig.) the thin film of oil first flows together to form a hemisphere and then develops into a sphere which separates from the surface. This process can be measured optically by observing the angle of contact between oil droplet and surface.

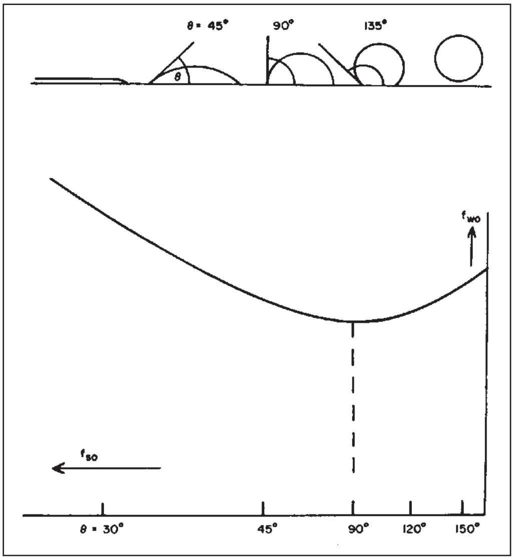

Fig.: Separation of an oil droplet from a solid foundation (e.g. textile substrate), as nearly the opposite of wetting, shown as size f_{wo} of the boundary layer liquid/liquid (ordinate) in relation to the surface area f_{so} (abscissa).

Unsaturated organic compounds Compounds in which not all available carbon atom bonds (depending upon → Valency) are saturated with hydrogen atoms (or oxygen atoms, etc.) and are therefore still free and capable of addition; e.g. acetylene C_2H_2 → H–C=C–H.

Unsaturated steam → Superheated steam (→ Steam).

UNSCC United Nations Standards Coordinating Committee; → Technical and professional organizations.

Unused colour paste recycling using colour measurement Unused colour pastes are segregated according to variety and approximate dye colour differences in minimum quantities of approx. 50 kg.

Printing paste preparation:

1. colour strike-offs made on the substrate to produce calibration values for the computer.
2. store strike-off data in the computer.
3. measure the pattern.
4. using a computer, calculate the recipe that is required to adjust the old dye paste to match the required sample.
5. recipe selection criteria: number of dyes, quantity of dye, price, type of dye etc.
6. prepare old dye paste as per the recipe, control strike-off, re-use.

Upholstery crêpe A woven crêpe made from cotton, usually printed.

Upholstery fabric finishing is aimed towards the quality standard (Fig. 1). The fact that the conventional types have no clearly distinctive crystal structure, but that the fibre structure is always in a range between

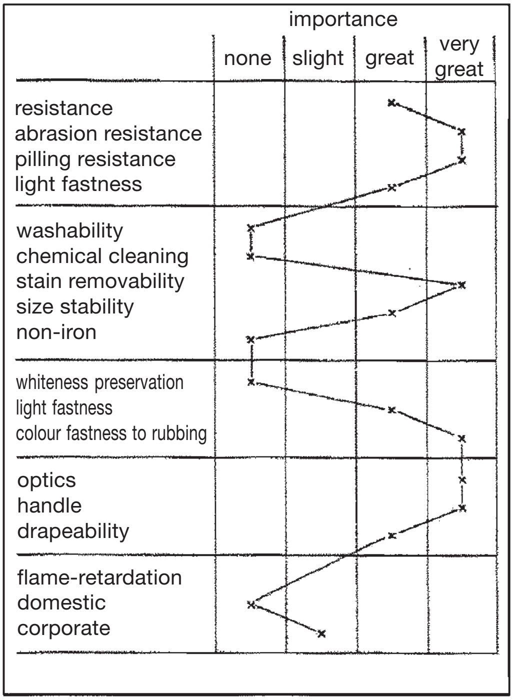

Fig. 1: Requirements profile of upholstery fabrics.

amorphous and crystalline, which is the reason for the good deformability of the material, is what has made the use of polyacrylonitrile fibres in furniture velours preferred and appealing from the start. The pile loops can be placed in any desired position depending on result; crimping (crinkling) of yarns, whirled, crushed and embossed designs can be achieved relatively easily. As the glass temperature of polyacrylonitrile fibres is generally between 70–80°C, the temperatures necessary for deformation can be reached easily in textile finishing. Plasticizability occurs much earlier in damp heat or in hot water than in dry treatment with heat. The temperatures essentially depend on the continuous amount of material, exposure time, shade of colour and on the desired degree of deformation. Darkly coloured fibres take up temperature more quickly than light dyeings. Wool crimped velours formerly in fashion in the 50 s were redeveloped from polyacrylonitrile fibre yarns. Crimping (crinkling) occurs in both materials in the knit-deknit method. The position of the pile loops has a critical effect on the appearance and handle of upholstery velours. Design effects are already possible due to so-called layer weaves, which result in the familiar shaded velours.

Planographic printing, roller printing, rotary printing and heat transfer printing are suitable for printing of polyacrylonitrile upholstery velours. There are two main types of polyacrylonitrile fibres as regards dyeability: firstly the types dyeable using cationic dyes and secondly those, which are dyed using acid dyes. The polyacrylonitrile fibres predominantly used are those which can be dyed cationically. The combination of both types facilitates piece dyeings using dyeing and design effects similar to those of yarn dyeings, with which the piece dyeings combine simplification of layout, production and stocking of spare parts.

In velour manufacture polyacrylonitrile yarns are to an increasing extent combined with yarns made from other raw materials, e.g. with cotton, polyester, or viscose, amongst others. Not only in yarn-dyed items are attractive effects produced by this, but also in piece dyeings, for which not only raw white yarns but also super dye fast dyed yarns are used for special effects.

Whirled designs are produced by means of rotating or traversing brushes (Figs. 2–7) with or without a screen and with subsequent design setting. “Setting” is also normal for polyacrylonitrile fibres, but it does not mean the same as in crystallites, e.g. polyester. For polyacrylonitrile fibres this means the production of a permanent structural change, which is not reversible, e.g. the triggering of a shrinkage or residual shrinkage. The drawing of pile fibres by heat and mechanically for

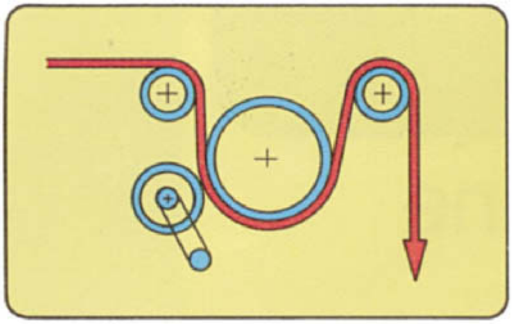

Fig. 2: Embossing upholstery velour fabrics.

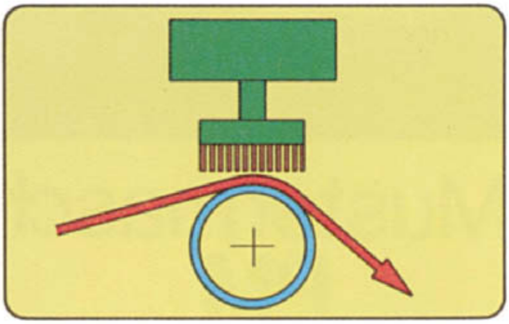

Fig. 3: Whirled pile finishing of upholstery velour fabrics with round brushes.

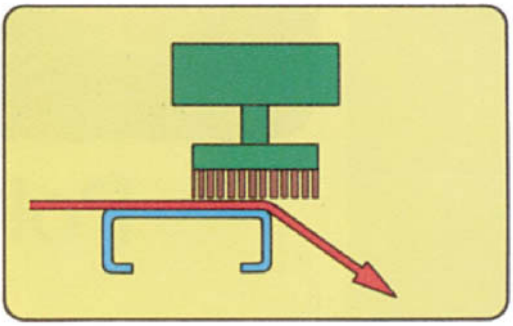

Fig. 4: Flat-table whirled pile finishing of upholstery velour fabrics with round brushes.

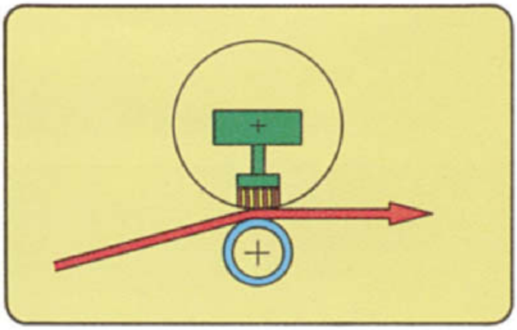

Fig. 5: Screen drum whirled pile finishing of upholstery velour fabrics with round brushes.

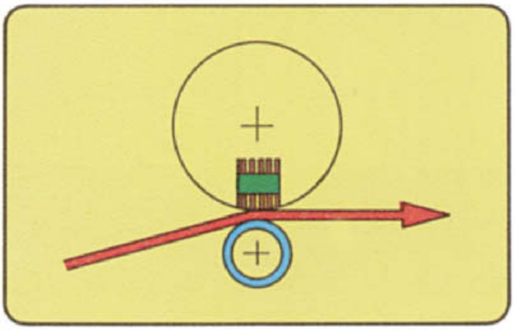

Fig. 6: Screen drum cross-brushing of upholstery velour fabrics with a brush bath.

the purpose of partial or complete uncrimping also results in a certain determination of this state, as the fibre crimping in velours may still be returned into a very small part again. The piece good is actually deformed in a tumbler by heat recovery, above the glass temperature to produce crush-effect designs. Embossed designs in wool and viscose fur fabrics already existed before the production of polyacrylonitrile fibres, but they have

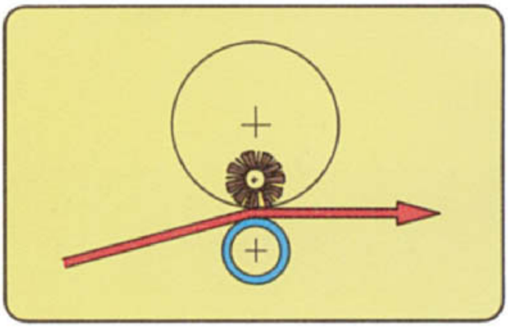

Fig. 7: Screen drum long-brushing of upholstery velour fabrics with a brush roller.

only been made more seriously available on the polyacrylonitrile velour market in recent years since it became possible to keep the surface temperature of embossing rollers almost constant within narrow limits. All types of polyacrylonitrile velours can be supplied with embossed designs and new, versatile designing possibilities are added. This does not only concern the copying of woven designs, but also fantasy designs.

The upholstery market demands especially highly inflammable fabrics. This objective cannot, however, be achieved by using highly inflammable fibres in the pile, otherwise modacrylics could possibly help, but these lack versatility in supply and usability. The back design and/or behaviour of the entire material plays an equally important role, which is why velour manufacturers are either forced to process highly inflammable fibres into the rear yarns or to finish the velours with suitable chemicals or to combine both options (according to Hoppenz).

Upholstery fabrics As woven, warp-knitted, raschel-knitted fabrics and stitch-bonded fabrics in wool, polyamide, polyacrylonitrile, cellulose and blends. Collective term for covering, hank stretching and padding fabrics of different type and composition, e.g. upholstery brocade, cord, damask, gobelin, moquette, plush, rib fabrics, etc.; partly also as → Furnishing fabrics and hemmed for couch and table cloths. Exceptionally complex market. Anti-soiling finishes, no pilling, high light fastness, good colour fastness to rubbing (wet and dry) are demanded.

Upholstery velour fabrics – development of lustre in use A typical property and characteristic of all velour qualities which manifests itself during use are variations in the lay of the pile which are visible to a greater or lesser extent and which are associated with differences in light reflection. The development of lustre in use, therefore, is not an indication of defective quality nor does it signify any deterioration in the serviceability of the article.

UPN Urad pro Normalizaci a Mereni, Prag;

Polish Office of Standardization and Metrology; → Technical and professional organizations.

Upper knife Part of the cutting gear on → Shearing machine.

Upright pile finish Plush fabrics with pile made from cotton fibres are impregnated with synthetic resin, brushed, dried and set. The pile stands up again after being pressed down.

Upright pile velvet Raised fabric with velvety appearance. The napped fibres stand vertical (opposite → Nap velours). → Pile lifter.

Uranium (U), atomic weight 238.07. Element of pitchblende. Is of importance as the basis of atomic nuclear energy.

Urea (carbamide, urea), $CO(NH_2)_2$. Molecular weight 60.12; density 1.335; melting point 133°C. Long crystals, colourless and odourless; easily soluble in water or alcohol, neutral solution. Properties: dye dispersing and releasing force; methylol compounds (→ DMU) of the urea are important resin finishing agents, self crosslinking resins. Use: addition in wool vat dyes (printing); manufacture of slip resistant, crease-resistant and shrink-proof finishings, delustrings, special processes, etc. Urea causes better accessibility of cellulosic fibres to reactive dyes and accelerates their diffusion into the fibre core (= improved full penetration dyeing). Predominantly less substantive reactive dyes and polyamide dyes are suitable for this machine-intensive continuous process due to shorter diffusion and setting times. Work with urea is accompanied by a less pleasant appearance though, as it decomposes at temperatures > 133°C:

$$H_2N–CO\boxed{–NH_2 + H–}NH–CO–NH_2$$

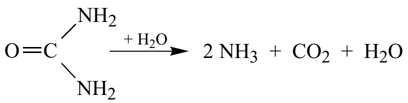
$$\longrightarrow NH_2–CO–NH–CONH_2(I) + NH_3\uparrow$$

$$OC(NH_2)_2 \longrightarrow NH_3(II)\uparrow + NCOH$$

$$3\ NCOH \longrightarrow (NCOH)_3(III)$$

Urea decomposition products form smoke in the setting machine, which can have a disturbing effect. → Dicyandiamide is therefore used as a urea substitute in the → ATE process.

Urease Urea-breaking enzyme, belonging to →: Hydrolases; Amidases. Gradual degradation into ammonia and carbonic acid results with water absorption:



$$O{=}C(NH_2)_2 \xrightarrow{+H_2O} 2\ NH_3 + CO_2 + H_2O$$

in which partially decaying ammonium (hydrogen) carbonate forms again. Urease was of great importance in wool finishing with urine (wool washing, indigo vat). Manufacture in purely crystalline state from the jack and soya bean since 1926. 1 g of urease splits almost 60 g of urea in 1 min at 20°C. Urease is inactivated by low quantities of heavy metal ions (Cu) (immobilisation of active groups through complex formation), which can be reversed again by adding cyanides or hydrogen sulphide.

Urea-Bisulphite solubility (UBS, Ger.: HBL), UBS reaction, was developed in order to determine the alkali damage to wool without costly mechanical tests and, for example, to differentiate from acid damage. The UBS is changed depending on the treatment of the wool (steaming, alkaline influences, heating, etc. reduce the UBS, however acidic and oxidative influences increase it). Especially important for comparison between untreated and treated wool (degree of damage). Implementation:

1. Determination of the dry weight m_1.
2. Place second wool sample in a 65°C solution, which contains 50 g of urea and 3 g of sodium pyrosulphite ($Na_2S_2O_5$) in 100 ml and has been adjusted to pH 7 using NaOH. Therein treat for 1 hour, filter and determine dry weight m_2 of the residue.
3. Calculation of the dry weight m_1 for 2 from 1 in g.

$$\text{UBS in \%} = \frac{m_1 - m_2}{m_1} \cdot 100 \quad \text{for acid free wool}$$

$$\text{UBS} = (\text{UBS} - S) \cdot \frac{100}{100 - S} \quad \text{for wool containing acid}$$

S = acid content in % of the dry weight.

The UBS is based on the reductive breaking of cystine bridges using hydrogen sulphite ions. 1 mole cysteine and 1 mole cysteine-S-sulphonates (bunte salt) are thereby formed from 1 mole cystine.

$$>CH–CH_2–S–S–CH_2–CH< + HSO_3^-$$

$$\longrightarrow >CH–CH_2–SH + >CH–CH_2–S–SO_3^-$$

The new crosslinkages formed from the cystine in alkali effect on wool are not broken by a sulphitolysis. Treatment of wool in alkaline baths may result in a considerable acceptance of the UBS, which is normally 40–50%. The extent of the reduction in solubility is thereby in direct correlation with the newly formed crosslinkages and provides an indication of the degree of alkali damage.

Urea-formaldehyde compounds Condensation products made of urea and formaldehyde (→ Dimethylol urea), partly also etherised with methanol (→

Dimethoxymethylurea); → Self crosslinking resins. Used as finishing agents amongst other things.

Urea-formaldehyde Resins → Urea-formaldehyde compounds.

Urea-free printing (→ Urea in textile printing). Dye manufacturers try to replace urea as a hydrotropic agent with low molecular surfactants. Since the spray technique using rotor damping may in the meantime be described as technically dated, the use of this device has proved to be more successful than a print steamer on a semi-technical scale in order to fix reactive prints on viscose without using the waste water problematic urea. In normal setting yields of 60% effectively fixed dye (referring to the dye used, the K/S value is = 100%) the best colour yields are achieved at approx. 30 % rotor damping before entering the steamer: The reactive group of the dye has a certain influence on the print result in so far that MCT dyes with 0 % moisture without urea hardly react (K/S value = 30%), against which spraying with water in the absence of urea achieves an improvement in colour intensity.

Vinylsulphone dye produces a K/S value of 126% under these conditions, while the dichlorotriazine dye is 110%. Speculation should not be made about the reasons for successful urea-free reactive print on viscose. It is however valuable for printing practice that there is a possibility of satisfying extensive environmental requirements.

Urea in textile printing There are official measures to discharge nitrates from drinking water. These are produced in excess due to the ground water being overloaded with nitrogen compounds via the natural nitrogen circulation and their equilibrium transfer. That is why the elimination of urea from printing recipes or at least the reduction of its concentration in the waste water from after-print washings is striven for. But for reasons of print technology and colloidal chemicals, the elimination of urea from the recipes is not easy. Dried prints are usually steamed after a certain intermediate storage period with a low moisture content. Special viscose fibres collaborate so much in deswelling during drying, that re-swelling during steaming is aggravated as a pre-condition for the inner diffusion of the dyes. Because swelling is an exothermal process, fibres as well as the dried out thickener should be swollen before steaming at room temperature if possible. The transmission of dyes from the print paste onto the fibre requires humidity for diffusion in most dye classes. Part of the water quantity required is obtained from steam condensation on the “solid fabric” when the dry fabric enters the steamer. The condensate quantity is determined by the specific heat of the printed fabric and by the temperature difference between the fabric entering the steamer and the boiling point of water under the prevailing steam conditions. The specific heat of cellulosic fibres and natural thickeners is approx. 1.26 kJ/kg · °C (0.3 kcal/kg · °C), that of the printing auxiliary at 0.42 kJ/kg · °C (0.1 kcal/kg · °C). Moisture on the fabric has a specific heat 4.2 kJ/kg · °C (1 kcal/kg · °C). So the presence of water influences the condensation of steam considerably more than the printed textiles. On the other hand, the steam composition in the steamer possibly varies considerably. Dry steam occurs if there is insufficient steam supply, and saturated steam conditions cannot always be evenly adjusted in the steamer, which is why a constant high temperature of 102°C is demanded by “good” steamers.

A careful selection of reactive dyes from the point of view of “compatibility” is beneficial in preventing yield differences (and therfore the shade variations from batch to batch) as a result of temperature/humidity fluctuations in the steamer. Circulation steamers with moisture injection also increase the reproducibility of the printing result, in particular in reactive dye printing on cellulosic fibres, and with the printing performance. Above all the addition of urea to the reactive stock colour pastes (besides the quantity of alkali) reduces the demands on the steam quality as regards the fixation of different reactive dyes. This is because urea with the condensed steam forms a “melt” on the fabric, which only releases the water again at temperatures above 115°C. But the use of urea should not only be optimised for ecological reasons mentioned at the start, but also from the point of view of the ability to store the dried fabric. The composition of the reactive stock colour pastes as regards quantities of alkali and urea is usually a compromise, which is determined by the reactivity of the dyes and by their sensitivity to hydrolysis compared with moisture (absorbed by the urea in dried printing).

Thickeners can only bring their flow properties to bear when they are swollen with water. But even during the steam process the polymer thickeners, which were deswollen by drying, have to swell quickly again, i.e. the dried thickener film (micelles, networks) have to be expanded and separated if the diffusion of dyes and chemicals from the print paste film is to be eased into the fibre. To what extent the solute cases of a thickener are constructed and decomposed, amongst other things, essentially depends on the chemicals, which promote the thickener being absorbed in water. Urea promotes water absorption during steaming in varying ways depending on polymer thickener for example. The hydration spheres of the urea molecules taken up onto the polymers are the amino groups directed outwards. The hydrophily of the polymers is therefore increased by the amino groups; but the take up can also promote the swellability of the polymers without increasing hydration if the cohesion of the macromolecules is reduced. In addition, urea functions in the dried on print paste (also in the preparation of the print paste) as a hydrotropic agent. As a water-soluble compound itself, urea increases the water solubility of the dyes broken down in the dried print paste, depending on the quantity used. In order to overcome the intermolecular forces (due to the short liquor-to-goods-ratio during printing and steaming) of less soluble dyes, a third, solution-conveying component is required, which introduces dissolving properties together with water. The surface tension of the water should firstly be reduced in the course of this before hydrogen bond interactions can come into force in the ternary system.

The hydrophilic amino groups of urea reduce the surface tension of the water and so cause the structure of the water in direct proximity to the solid dye to be dissolved, which promotes the dissolving process. The carbonyl group on the other urea dipole end has (in contrast to the amino groups with their hydrogen donor properties) an affinity for electrons: both carbenium C atoms and semipolar absorbed oxygen appear as a mesomeric restricted form, which is why energy exchange is possible with other organic reaction partners (the chemically diverse dyes). Under these circumstances, the question arises as to whether urea can be dispensed with in the formulation of dyes, in the fixation of prints in the steamer and also in the printing area (when the screens have a tendency to addition). On the one hand, it is difficult to define where the hydrotropic character of a compound stops and, for example, its surfactant character begins. On the other hand small surfactant molecules also have typical dissolving properties in water and have already been tested as alternatives in order to replace urea.

Urea peroxide → Carbamide peroxide.

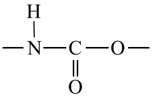
Urea reagent is used to identify urea (derivatives) in textile materials finished with relative synthetic resins. Is based on red dyeing of hydrolytically released urea through furfural in the presence of acetone. Reaction is regarded as specific (possible fault in dyed goods by acetone soluble dye). Sensitivity 0.5 mg (2g/l of urea can certainly still be identified). Urea reagent production (always fresh, will only keep for 2-3 hours, colour yellowy gold initially, then changes to brown) made from 20 ml acetone, 20 ml water, 10 ml concentrated hydrochloric acid and 1 ml furfural. Mode of operation: heat to boiling approx. 10 cm^2 testing section in the reagent glass with 5-6 ml of freshly produced urea reagent, leave to stand, orange to red dyeing after a few minutes. Melamine resins do not give this reaction.

Ureides Organic acid derivatives, related to → Acid amides, whereby instead of the NH_2 group the urea radical $-NH–CO–NH_2$ is joined in the carboxyl group (–COOH). Example: acetic acid ($CH_3–COOH$) → Acetic acid ureide or acetyl urea ($CH_3–CO–NH–CO–NH_2$).

Urena fibres → Bast fibres (e.g. aramina fibre, congo jute) from many tropical countries (Brazil, Madagascar), similar to → Rosella as a jute substitute.

Urethane elastomer → Polyurethane elastomer fibres.

Urethane group Basically weaker compared with the → Carbamide group (–NHCO), affinity only to disperse and selected acid dyes (below pH 2).



$$-\overset{\overset{\displaystyle H}{|}}{N}-\underset{\underset{\displaystyle O}{\|}}{C}-O-$$

Urethane rubber → Polyurethane rubber.

Urethanes (carbamates, ester amides). CO(OR)(NH_2), the compounds of carbonic acid intended here can be interpreted as esters of → Carbamic acid. Due to their chemical relationship to urea they are called urethanes (of → Urea), whose structural principle is represented in → Polyurethanes.

Urone (urone ethers), as an N,N'-Bis (methoxymethyl) compound used as a reactive resin; → Dimethoxymethyluron.

Useable area Useable layer in fitted carpets, in accordance with DIN 61 151: the surface of fitted carpets needed in use.

Used Equipment Worldwide Guide Trilingual directory for used equipment from more than 1000 dealers. Trade publications from the International Institute for Used Machinery.

Useful life of working The time required for using the production resources in the → Processing sequence. In the case of their use one talks of machine time (main machine time, secondary machine time), in contrast to idle machine time (processing sequence dependent, decommissioning, fault-dependent, work-dependent).

U-shaped curved tubes Material carriers for hank yarns for dyeing in liquor, especially using sulphur, vat dyes and similar.

UV Absorber Substances, which absorb → Ultraviolet radiation and protect such fibres, dyeings and/or skin. Term, which in the broadest sense also includes → Fluorescent brightening agents. In the narrower sense, however, UV absorbers are understood to mean those organic compounds (with carbonyl and hydroxyl groups), which protect from and/or make inactive harmful, especially UV, contents of solar radiation (important for example in polyurethane fibres). This does not happen via emission (light radiation), but via light absorption and is usually expressed in the appearance of complementary yellow shades of colour. The light protection effect can be controlled by preserving the tear strength, for example, and/or the degree of polymerisation. According to the present level of experience, UV absorbers can be washed off more or less quickly (loss of light protection effect).

UV calibration device Supplementary device for measuring fluorescing white samples with spectrophotometers and triple zone devices with sample lighting similar to daylight. Is used for the regular compensation of lamp alteration and resultant reduction of radiant energy in the UV range. It is a prerequisite that when using new lamps a UV excess is available first. Until now only possibility for measuring fluorescent brightening with good long-term reproducibility and/or elimination of differences in the white rating using various measuring instruments.

UV Excimer radiator UV rays belong to the spectrum of electromagnetic waves. They belong to the short-wave part of visible light and extend to the other side up to the ionising rays (X-ray radiation, γ radiation). Usually a range of 100–400 nm is given, which is further subdivided into UV-A, UV-B and UV-C for practical considerations. The conventional division of the UV spectrum in the FRG is (Fig. 1):

UV-A:	315–400 nm
UV-B:	280–315 nm
UV-C:	200–280 nm
VUV:	100–200 nm

Industrial processes use UV radiation for
- drying paints,
- harmful pollutant degradation,
- photochemistry,
- medical treatment,
- depositing of thin metal, insulator and semiconductor layers.

Only a few powerful UV radiators had been used for these processes until now. These include electrically powerful arc discharges in xenon and mercury/inert gas mixtures. It is common to both that they have a broad emission spectrum. Besides the desired UV radiation, UV radiation of other wavelengths, visible light and IR radiation is also emitted. In contrast, selectively intensive UV radiation can be produced at a certain wavelength using excimer UV radiators. The excimer formation known from UV lasers is thereby used in certain gas mixtures to produce incoherent UV radiation.

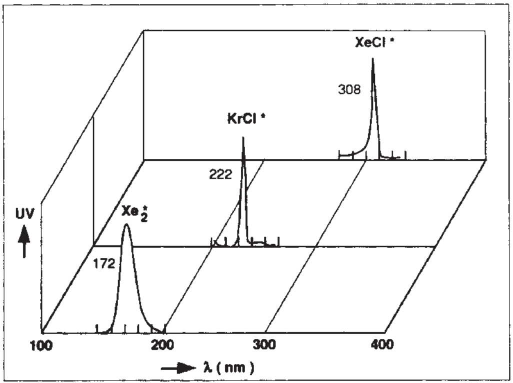

Fig. 2: Emissions spectra of some excimer radiators (according to Heraeus).

Fig. 2 shows the narrow-band emission spectra of a xenon excimer radiator (λ = 172 nm), a krypton chloride radiator (λ = 222 nm) and a xenon chloride radiator (λ = 308 nm). A large number of excimers is well known so that a suitable gas mixture can be selected virtually for every desired wavelength range. Com-

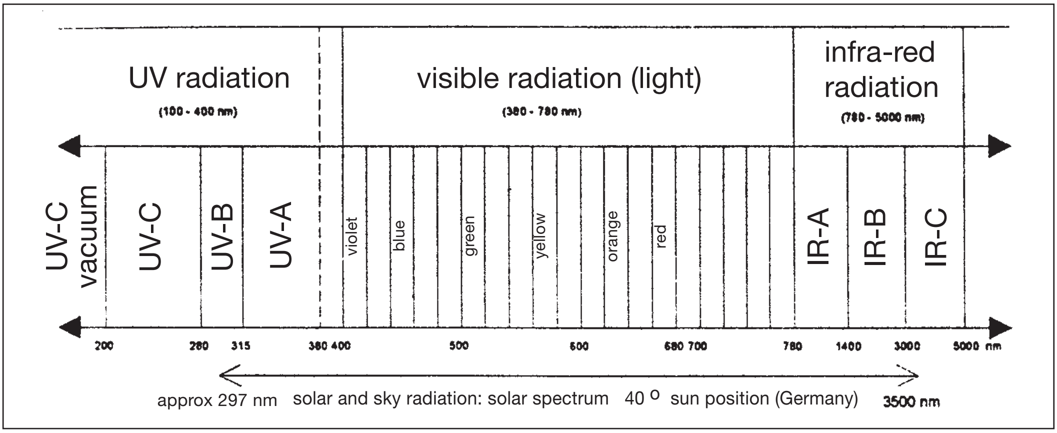

Fig. 1: Electromagnetic optical radiation wave spectrum.

pared with other UV sources, extremely high radiation doses can also be achieved in the VUV using the excimer radiators. The advantages of excimer radiators are:

- monochromatic, not coherent,
- wider range of achievable wavelengths,
- simple structure,
- variable geometry,
- high degree of efficiency in the deep UV, no heat influence from the radiated material,
- immediate start, re-ignitable, pulsable,
- no electrodes in the discharge area,
- ozone-free model possible.

A simple model of excimer radiators consists of two coaxial, cylindrical quartz tubes, which are gas tight connected. The excimer gas is in the gap between the tubes; the electrodes are located outside the discharge area (Figs. 3 and 4).

Besides the cylindrical discharge geometry, low UV sources and special geometries can also be achieved for photochemical reactors. The flexible geometric arrangement of excimer radiators can be extensively adapted to the object to be radiated in many cases.

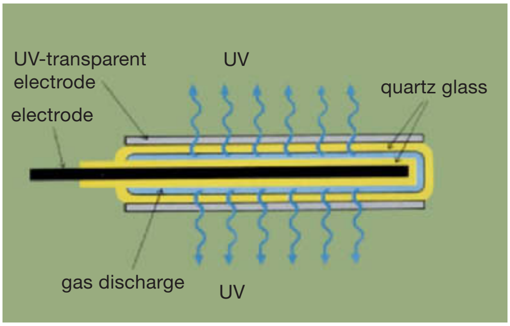

Fig. 3: Excimer radiator structure (according to Heraeus).

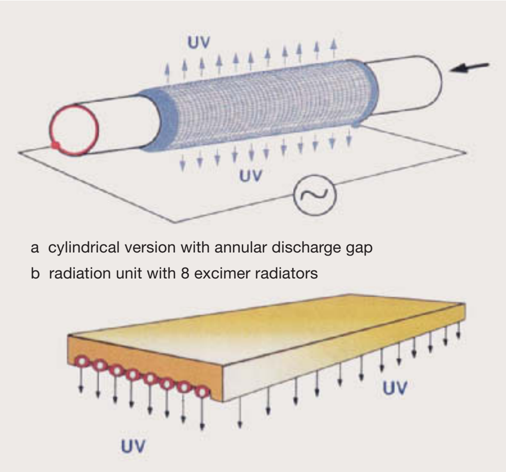

Fig. 4: Schematic structure of the new excimer radiator (according to Heraeus).

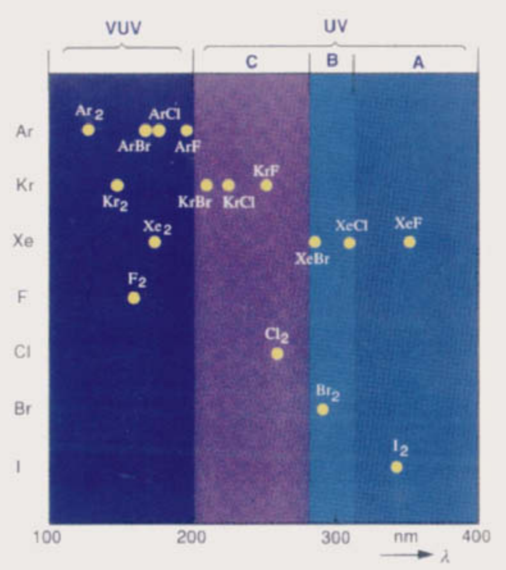

Fig. 5: Emissions wavelengths of various excimers (according to Heraeus).

A number of gases are available, which can be activated to form excimers in this way (Fig. 5).

The excimer formation is carried out in a so-called “still” and/or dielectrically obstructed discharge. The discharge area is hermetically sealed by a dielectric (quartz glass); the electrodes are outside the discharge area. Still discharges are carried on using alternating voltage. The current flows in many micro discharges, short airflows each of only a few nano seconds duration. The excimer formation takes place exclusively during these discharges. Free electrons are present, due to the short current pulses, in order to stimulate the atoms of the molecules of the gas emitted during charging. During this surge process (Fig. 6 a) an atom or molecule assumes almost the entire energy of an electron in fractions of a nano second and is thereby transferred into an excited state (Fig. 6 b). The electron, which flows after the surge with a much reduced speed, must be accelerated in the dielectric field again in order to be able to excite another atom. The excited atom may however then collide with the numerous neutral atoms present and so form an excimer (Fig. 6 c):

$$e + Xe + Xe \rightarrow e + Xe + Xe^* \rightarrow Xe_2^* + e$$

The excimer molecule is not very stable. It decays within a few nano seconds and delivers the excitation energy in the form of a UV proton (Fig. 6 d):

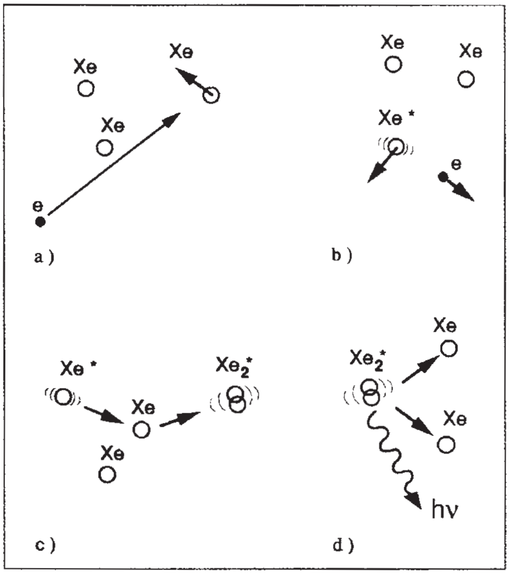

Fig. 6: Diagram of the excitation process of excimer formation and UV production.
Xe = xenon in its normal state; Xe = excited xenon atom; Xe_2^* = xenon excimer; e = electron; hv = UV photon.*

$$Xe_2^* \rightarrow 2\,Xe + \text{UV photon (172 nm)}$$

(according to Heraeus).

UV fluorescent dyes → Fluorescent dyes in combination with UV irradiation. Application → UV marking pen.

UV-induced oxidation of waste water Oxidation is a process for waste water treatment. It is used for decontaminating hazardous substances such as cyanide and nitrite and for decomposing organic substances, which are recorded by the summation parameters COD or BOD. Oxidizing agents can be used for all these reactions, whereby they frequently contribute to the formation of substances harmful to the environment or contain such substances. Hydrogen peroxide, oxygen and ozone are considered by preference, as they make no contribution to the salt accumulation in the water. Oxygen only reacts in an activated and/or atomic state in the desired manner.

Oxidation occurs when electrons are extracted from the substance being oxidized. It should not be characterised by the uptake of oxygen. How easily or how difficultly a substance can be oxidized and how strongly an oxidizing agent works (standard potential) is decisive for oxidation. The more positive this is, the stronger is its oxidizing effect. All substances, whose standard potentials are more negative than one of those given in the Tab., can be oxidized by the respective oxidizing agent. This illustration shows that hydroxyl radicals still exceed the high oxidation affinity of ozone. A hydroxyl radical has the positive standard potential of all oxidizing agents both in the acidic range (+ 2.8 V) and in the alkaline range (+ 2.0 V).

Radicals are changeable compounds or atoms, which are only produced by expending energy. After interrupting the energy supply they immediately turn into stable inert or non-reacting compounds, by releasing energy. But as radicals they are capable of reacting severely with other partners. If they have an oxygen balance such as the OH radical, this occurs via oxidation of other substances.

OH radicals are produced by electrolysis through discharge of OH ions on the anode, by the effect of UV radiation on ozone in the presence of moisture and by the irradiation of solutions containing hydrogen peroxide with UV light. Of these three possibilities the last mentioned should be preferred, as the oxidation of substances using OH radicals takes place in a homogeneous medium. The technical reaction difficulties do not thereby occur as they are present in the heterogeneous reactions (reaction on the solid/liquid interface as in anodic oxidation or on the gaseous/liquid interface, as in ozone reaction).

The activating influence of the energy from electromagnetic radiation on different kinds of substance is well known. Its effect thereby extends from the stimulation to rotation and oscillation in the molecular range by IR radiation via the stimulation of electrons in the molecular and atomic range due to radiation of the vis-

oxidizing agent	redox reaction*	E° in V*
oxygen (atomic)	$H_2O \rightleftharpoons O + 2\,H^+ + 2e$	+ 1,229

** in an acid medium; the standard potentials E^0 are smaller in alkaline media.*

ible and ultraviolet light, to the ionizing effect of electromagnetic radiation of even shorter wavelengths. If radiation of a particular frequency meets with a response in the molecular and atomic range, it is expressed in the fact that the radiation is absorbed. The absorbing substrate is thereby in an excited, high energy state, in which it reacts with another substance more easily and/or the radiated energy is sufficient to convert the substrate itself (photochemical reaction).

Hydrogen peroxide absorbs electromagnetic radiation in the short-wave UV range, the so-called UV-C range (200–280 nm). So a photochemical reaction occurs, which divides the hydrogen peroxide molecule into two OH radicals.

$$H_2O_2 \longrightarrow 2\,\dot{O}H$$

Due to their high oxidation potential, these radicals are capable of oxidizing substances, which cannot be oxidized using other oxidizing agents. They are also in a position to react with themselves in reverse of the equation and using hydrogen peroxide by forming O_2H radicals (hydrogen peroxide radicals). Oxidizing agents are always formed again with the exception of the reaction of OH with O_2H radicals, which by breaking chains results in water and oxygen.

Depending on the wavelength and/or the frequency (ν) of the light, a very specific amount of radiation energy is required to convert a molecule (quantization of the light). The unit of this light energy is called Einstein (E).

$$E = h \cdot \nu$$

h = Planck's actuating constant ($6.63 \cdot 19^{-33}$ *Js).*

In order to convert 1 mole of a substance using photochemical reaction, $6.02 \cdot 10^{23}$ E is required provided that each photon scores a hit on a molecule. This can be considered as a chemical reaction partner due to the quantization of the light. But as not every photon hits, the quantum yield is smaller than 1, and is smaller, the smaller the concentration of hydrogen peroxide is to be converted. So this is referred to as the quantum yield φ. This is the ratio of photons, which result in a photochemical reaction (hit), to the photons irradiated into the solution, which could trigger a photochemical reaction. The material turnover is larger, the higher the radiation output of the light source and the larger its UV-C yield to the OH radical formation.

The reaction finished products in the oxidation of organic compounds are carbonic acid, water, nitrate, sulphate and chloride. The oxidation consists of the photochemical reaction and the kinetic reaction. The reaction curves show, as long as there is still sufficient oxidizing agent (hydrogen peroxide) due to the radiation of constant light energy at the start a straight characteristic of a zero order reaction,

$$\frac{dc}{dt} = k_0$$

dc/dt describes the material turnover; k_0 is the velocity constant of a zero order reaction. The following oxidation reaction runs as long as the concentration of the substance to be oxidized is still relatively large and spontaneously so that the straightness of the reaction curve does not change at the start. If the concentration of the oxidizing agent is small at the end, the quantum yield is also low and the reaction is dependent on the concentration of OH radicals formed. The oxidation is at the same time also dependent on their concentration due to weakening concentration of the substance to be oxidized. The entire reaction then turns into a higher order pseudo-reaction as it is dependent on the concentrations of two reactions.

$$\frac{dc}{dt} = k_n \cdot c^n$$

k_n is the velocity constant of an nth order reaction; c the concentration of the substance to be oxidized. An odd number between two and three can be expected for n.

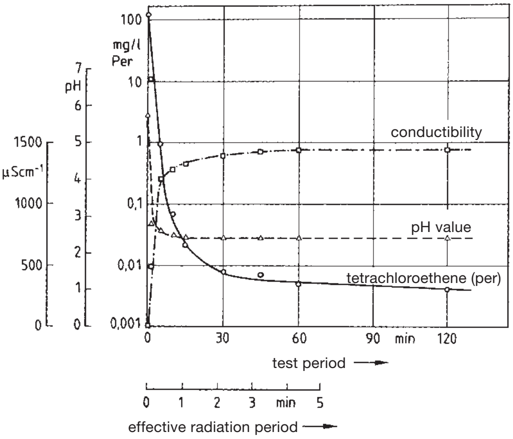

Fig. 1: Oxidative destruction of tetrachloroethene with hydrogen peroxide under the effect of UV radiation (according to Götzelmann and Hartinger).

A corresponding process for waste water treatment (Fig. 2) is suitable for the degradation of tetrachloroethylene in water (Fig. 1) (in accordance with Götzelmann and Hartinger).

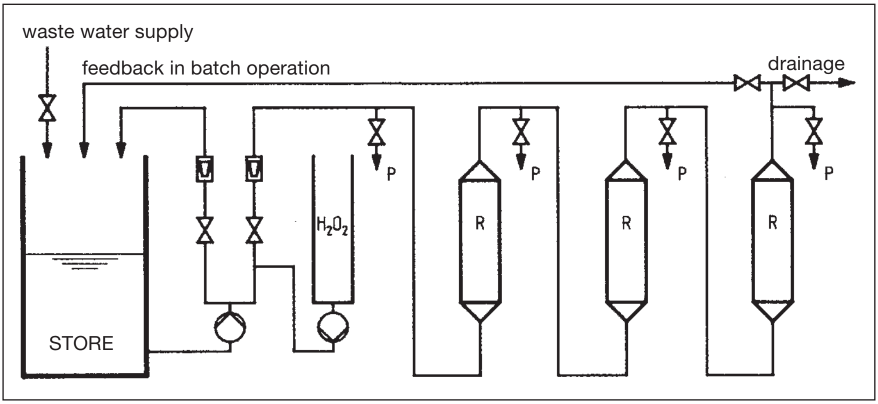

Fig. 2: Diagram of a waste water treatment plant (Goemalux) with three reactors for batch or continuous operation in series connection.

UV Lamp → Ultraviolet lamp.

UV marking pen Is used for the invisible labelling of material faults and pre-programmable material positions (combination using UV irradiation), also for valuable fabrics (carpets, fleeces, furs, etc.) for invisible sighting using recognition features. Constructed on a wax basis and in the form of → Retouching pencils. The fabric spot to be marked must be ironed so that UV dye penetrates into the fabric. Chiefly used for wool and wool blend fabrics, as cotton and synthetics do not absorb any wax.

UV radiation → Ultraviolet radiation.

UV sun protection of the skin UV light results in cell damage and creates inflammations on human skin. The most obvious consequence of the inflammation is the formation of an erythema (sunburn). Depending on the wavelength of the UV light, an erythema develops in accordance with widely varying absorbed radiation doses. The reciprocal value of these critical doses is called erythema effectiveness (EW(λ)). The harmful dose for each wavelength is the product of EW(λ), the sunlight output (P(λ)) for this wavelength and the time. The entire harmful dose is the total of these products.

Sun protection agents (sun cream or garments) absorb a part of the UV radiation and so reduce the amount of light hitting the epidermis and with that the harmful dose resulting in sunburn. The sun protection factor (SF) is defined as a quotient of the harmful dose without and harmful dose with sun protection. It can be calculated from EW(λ), P(λ) and from the wavelength-dependent transmission of the sun protection agent. The transmission of fabrics in the UV range can be strongly reduced by applying UV absorbers, i.e. the SF is increased (in accordance with Reinert).

UV transmission of textiles The transparency of cotton, silk, polyacrylonitrile and polyamide fibres is very high for UV radiation so that dressed skin is damaged by intensive sun irradiation. With UV absorbers, these fibres and/or the products manufactured from them can be given a high sun protection factor.

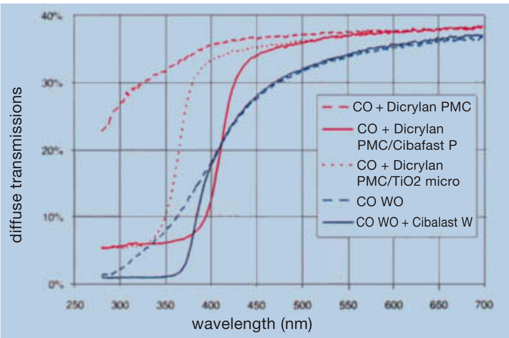

Fig.: Transmission spectra (diffuse light) of CO fabrics and CO/WO fabrics (intimately blended 50 : 50), with and without UVA. The CO contains the UVA in finishing (according to Reinert).

The Fig. shows the transmission spectra of cotton and cotton/wool fabrics. Small transmission values in the UV range correspond to a good screening from UV radiation or, expressed differently, a good sun protection effect.

UV/VIS Concerns → Spectroscopy in the ultraviolet/visual (= visible) range. Range of electromagnetic spectrum 200–800 nm.

V

V,

I. (Chem.). The symbol for vanadium.

II. (Phys.). The symbol for volt; the SI unit of potential difference, electrical potential and electromotive force (emf).

Vacuole (Lat.: vacuus = empty), a cell cavity found especially in plant and algal cells, including vegetable fibres, which takes up a large part of the cellular volume; fibre cavities, intermicellar regions, → Crystallites.

Vacuum (Lat.: vacuus = empty), virtually air-free space, negative pressure. Although, literally, a vacuum is defined as a space totally devoid of any matter, which does not exist on earth, the term is used loosely for an enclosed space within which the pressure of a gas or air lies below that of air at the normal atmospheric air pressure of 1 bar. For practical purposes, a vacuum is produced by means of → Vacuum pumps (single stage up to 95–99% vacuum). In textile finishing a vacuum is applied, e.g. in the printing of carpets on screen printing machines, to suck print paste through the carpet pile and achieve better penetration. In dyeing (→ Vacuum dyeing), attempts have been made to improve dye penetration on textile fabrics which are difficult to penetrate by saturating the material with dye liquor with the aid of a suction slot (see Fig.). In dry cleaning plants a vacuum is applied, e.g. in the still, as well as the machine system, when working with chlorinated fluorocarbons, (the use of these solvents is banned in the Federal Republic of Germany).

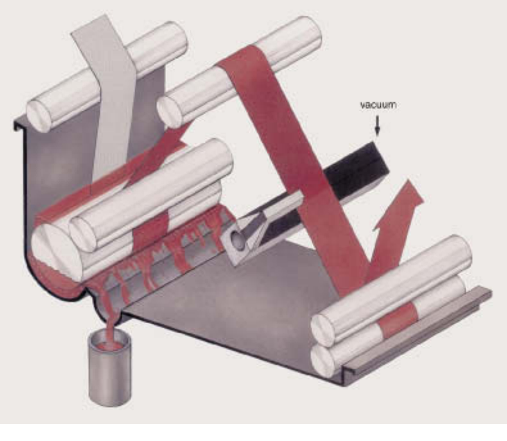

Fig.: Vacuum application in continuous dyeing by Evac-Küsters.

Vacuum breaker A ventilating valve for steam-heated equipment (e.g. feed water tanks) to protect the tank/unit against the build-up of excessive vacuum pressures. A vacuum is formed, e.g. in the feed water de-aerator by the choice of superheated steam to raise the water temperature and introduction of cold water at the same time, due to condensation of superheated steam which is still present. To prevent the build-up of excessive vacuum pressures, therefore, a flow of air into the de-aerator must be ensured by a suitable device as soon as a negative pressure develops in order to equalize the pressure.

Vacuum drier This type of drier is based on the principle of a → Suction-drum drier and has been designed particularly for drying yarn on packages or in the form of hanks at temperatures of only 40–70°C. The 3-phase vacuum drier (Fig.) works intermittently by alternating cycles of heating up under pressure and evacuation to allow vaporization at a lower boiling point. When boiler I is under vacuum, boiler II is heating up. Heating air is circulated by a fan (3), then passed through the heat exchanger (4) and into boiler II where the relative humidity of the air increases as heat energy is transferred to the wet textile material. During the second phase, the moist air is recirculated without cooling down to the heat exchanger (4) where it is heated again to penetrate the textile material. Thus, air with a relatively high moisture content is used to warm up the yarn, and this is also maintained towards the end of the drying process by steam injection. Air flow is automatically controlled by built-in multiple valves in the bottom of the boilers. When the heating phase is complete, boiler II is connected to vacuum. The change-over flap (1) closes, and the vacuum flap (8) opens. Vacuum pressure produced by vacuum pump (10) lowers the boiling point to 40°C and the moisture in the yarn is evaporated by heat energy contained in the yarn which is then condensed in the vacuum condenser (9). The cooling unit (5) cools the air during the first drying phase and also eliminates any rise in temperature from the heat of compression in the fan.

Vacuum dyeing

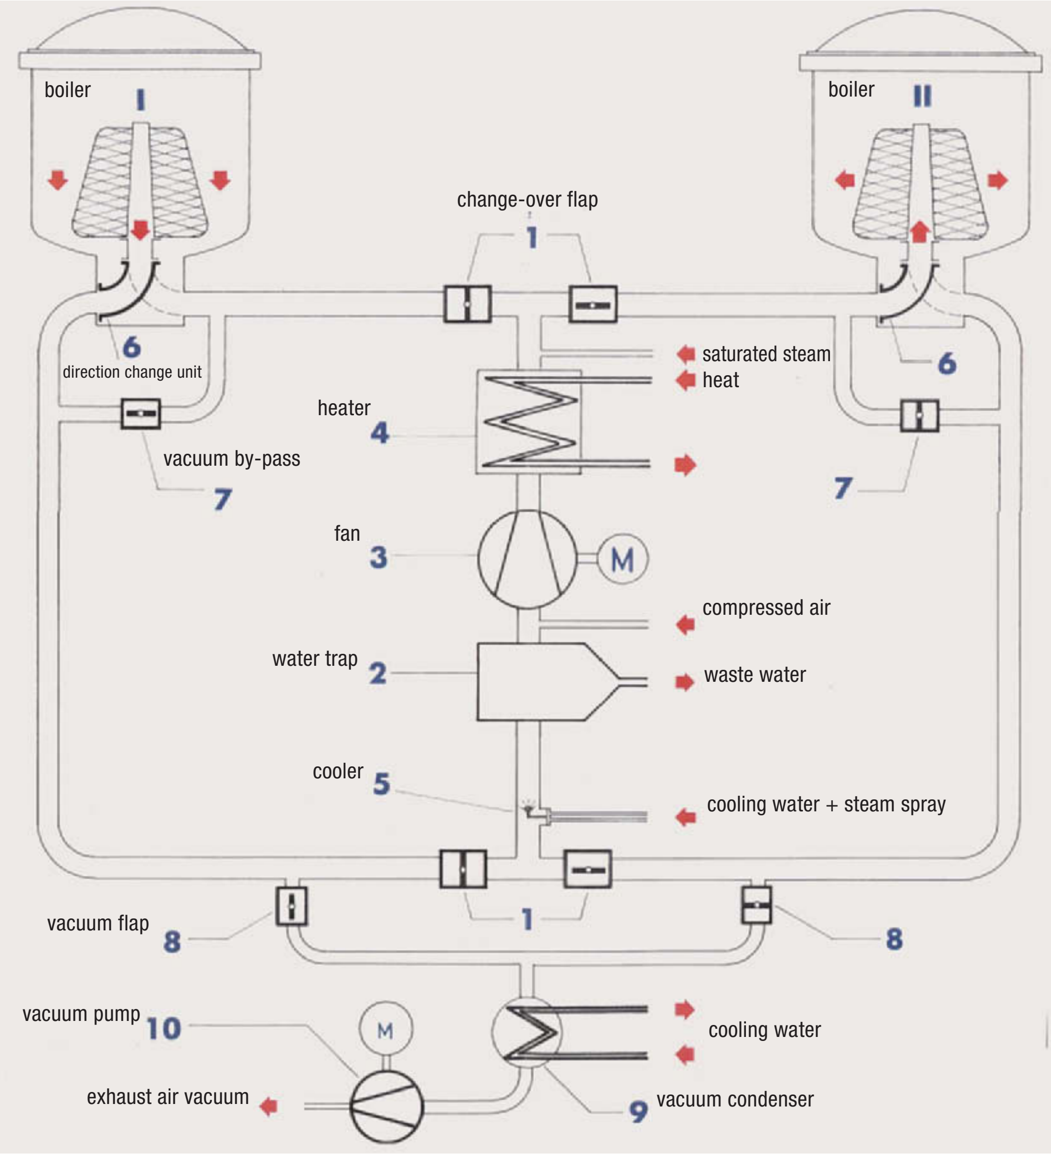

Fig.: Vacuum drier (MTM Obermaier).

Advantages of vacuum drying include: gentle drying conditions with no thermal damage to the fibre; no overdrying; uniform residual moisture content throughout the dried yarn; no migration of aftertreatment chemicals and softeners; no yellowing of the yarn; energy savings of up to 60% are possible when compared to conventional driers. Manuf.: MTM Obermaier.

Vacuum dyeing Fibres from which all the air has been removed in a vacuum wet out more rapidly and penetration of dye liquor into the material is more complete. Enclosed circulating liquor dyeing machines are suitable for this technology in exhaust dyeing. The technique is of particular interest for vat dyeing in view of the absence of air. Machines specially designed for pad dyeing applications are illustrated in Figs. 1 + 2.

After passing over a suction extraction cap via a draw roller to remove air, the fabric is run directly into the processing liquor. The vacuum unit consists of a suction cap, adjustable control system, vacuum pump

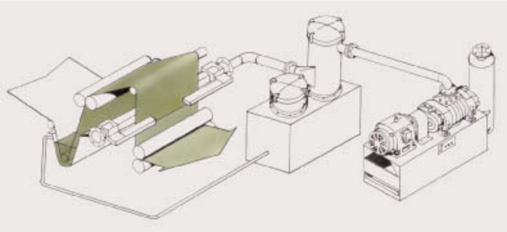

Fig. 1: Evac-Küsters vacuum impregnation plant.

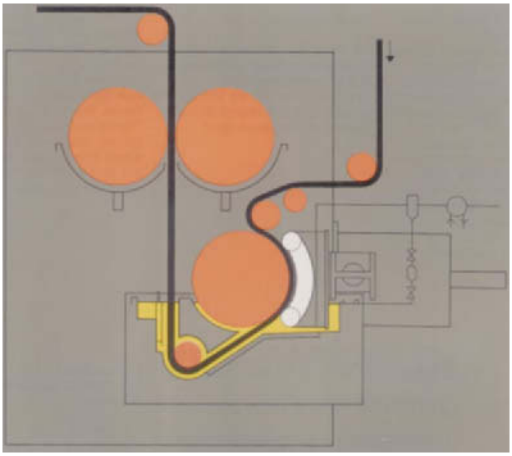

Fig. 2: Kleinewefers KTM Vacupad.

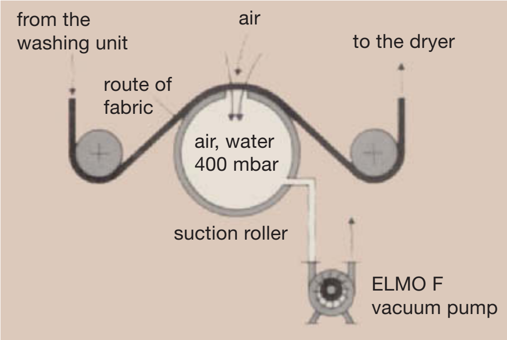

Fig. 1: Suction slit for vacuum extraction (ELMO).

Fig. 2: Tube-Tex-Jet-Extractor (vacuum extraction) for knitgoods.

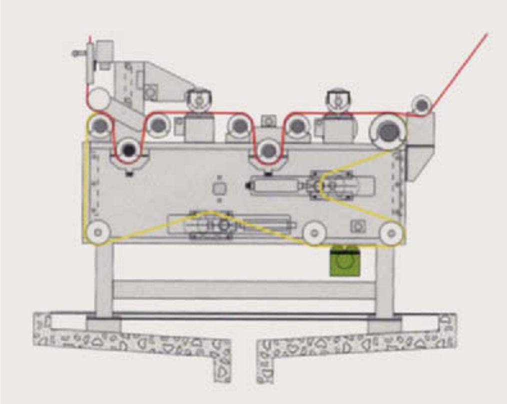

Fig. 3: Evac Ultraknit in diagram form.

and a draw roller. In the suction cap zone, air is removed from the fabric by a vacuum of 3325 Pa. The cap is sealed against the rotating draw roller. Control of vacuum pressure during the process is not necessary. Sealing of the suction cap and the liquid vacuum pump ensure a constant vacuum of 3325 Pa is maintained even during continuous operation. The driven draw roller is ground cylindrically. As with the suction cap, its dimensions are such that no deformation occurs under load. For fabric entry, the vacuum cap allows the fabric to leave the draw roller approx. 170 mm horizontally. The resultant impregnated fabric is squeezed off in the nip of a 2-bowl padder with deformation-resistant bowls. Up to 30% higher liquor pick-up is possible with vacuum impregnation.

Vacuum extraction of piece goods Surface water adhering to woven fabrics is easily removed through suction extraction by exploiting the principle of gas kinetics with the aid of a vacuum. In this process, the wet fabric passes over a suction slit (Fig. 1).

For knitgoods, on the other hand, finer suction slots are required such as those employed in the Tube-Tex-Jet-Extractor. In this system, superheated steam is passed through the wet fabric from above which then becomes saturated with water and is extracted underneath the fabric by means of a vacuum (Fig. 2).

In the Ultraknit machine of Evac-Küsters, wet fabric is transported through the unit on a conveyor so that vacuum extraction with high-performance suction slits is also possible (Figs. 3 + 4).

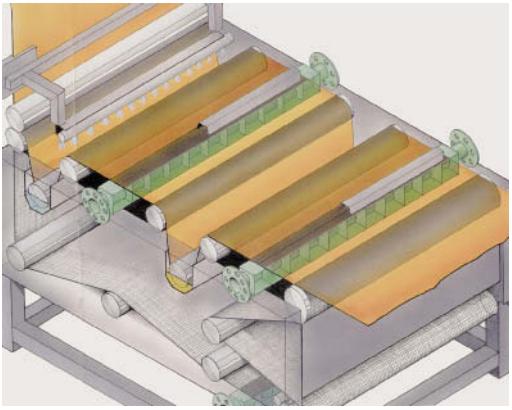

Fig. 4: Evac Ultraknit range.

Vacuum extractor for yarn packages A device for extracting water from yarn packages with a branch circuit to a vacuum station and an interrupter valve. The rapid intermission frequency developed by the latter produces shock-like suction pulses which entrain the bound water. Residual moisture content after extraction is approx. 100%.

Vacuum impregnation An impregnation technology for applications on the padder which removes the air present in the fibre's intercapillary spaces by means of a vacuum (3325 Pa) immediately before entry into the liquor (Fig. 1). After leaving the liquor, the fabric enters the air again. The penetration of liquor is more rapid and complete due to the extraction of air before immersion. Application of the vacuum principle offers savings in liquor consumption compared to conventional padders as well as reduced drying costs. The removal of air can also be achieved with steam. Besides its application in fabric pretreatment and mercerization, the technique is also used mainly for the application of dye liquors to circular-knit cotton fabrics, where savings of up to 20% dye are possible as well as more uniform dyeings (Fig. 2).

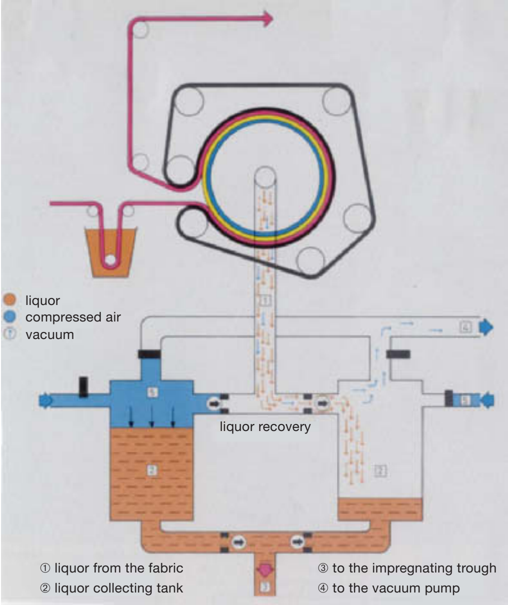

Fig. 1: Monforts Matex-Vac impregnation machine.

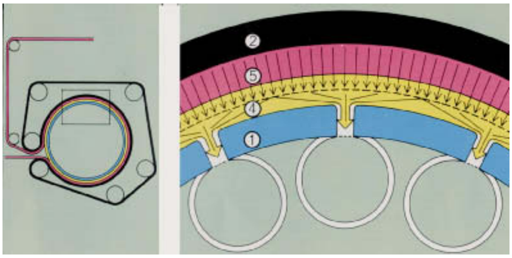

Fig. 2: Vacuum application and capillary active dehydration (Monforts).
1 = cylinders for vacuum; 2 = cover band; 4 = fabric; 5 = viscose nonwoven.

In the Farmer Norton vacuum impregnation unit the fabric is transported between an endless polyester film belt and a coarse mesh rotary screen. The vacuum and liquor tube assembly are mounted inside the screen as shown in Fig. 3. As the screen rotates it carries the fabric progressively under a high vacuum slot (A), then a slot filled with liquor to be applied (B) and finally a second vacuum slot (C). The endless belt prevents loss of vacuum and the screen prevents the fabric being

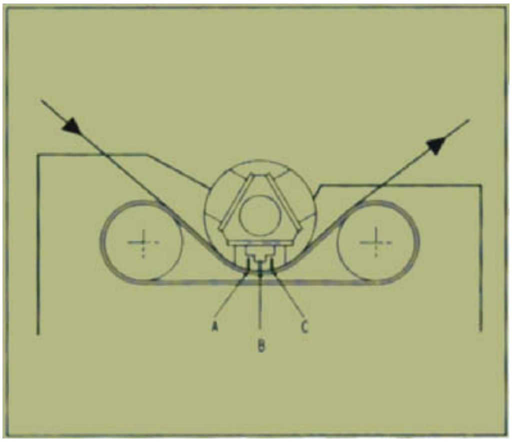

Fig. 3: Vacuum impregnation (according to Farmer Norton).

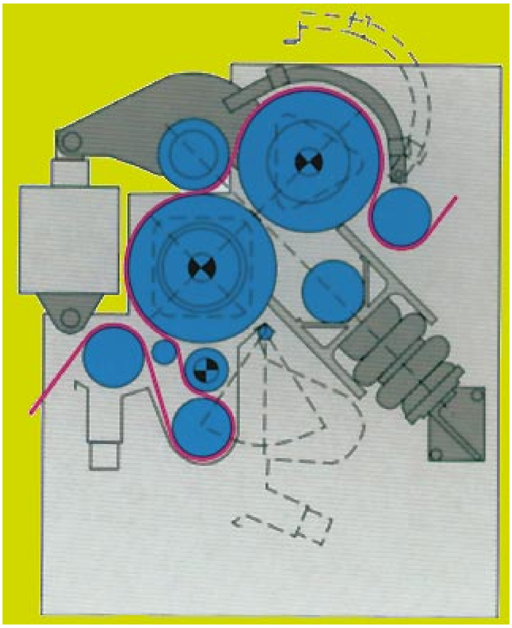

Fig. 4: Evac-nip.

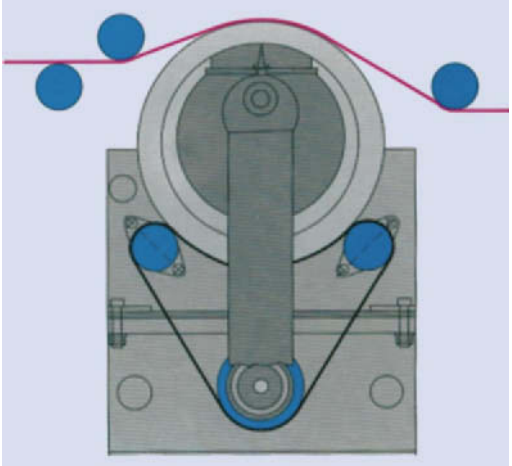

Fig. 5: Evac-roll for knitted good.

drawn into the vacuum slot. Consequently, the fabric is not subjected to any tension or drag. The flexibility of VAS-200 is achieved by independantly adjusting the level of vacuum applied to slot (A) and (C). In this way it is possible to adjust the amount of liquor first applied and then extracted from the fabric. This control allows the liquor pick-up to be adjusted from 35%–200%, as is nearly also the case in Küsters Evac-nip (Fig. 4) and Evac-roll (Fig. 5) for knitwear.

Vacuum mercerization → Vacuum treatment during mercerization.

Vacuum metallizing → High-vacuum metallizing.

Vacuum pumps → Vacuum technology pumps.

Vacuum sieving machine A → Print paste sieving machine which operates on the vacuum principle.

Vacuum strainers High-speed → Print paste sieving machine for sieving print pastes and thickeners with a sieving cycle of 1–3 min. These strainers are equipped with a liquid ring vacuum pump to ensure a long trouble-free life. Their function is to remove small particles of dust and other foreign matter from print pastes in order to prevent streaking or blocking of printing screens.

Vacuum suction device An open-width suction unit (Fig. 1) designed to reduce the liquor content of a textile fabric before drying, and before or after the application of chemical liquors (wet-on-wet treatment) for the removal of unbound water. Savings in drying energy are achieved. Vacuum suction units can also be retrofitted to existing machines. The use of an underliquor vacuum suction unit allows, e.g., the desizing of tightly woven airbag fabrics (Fig. 2).

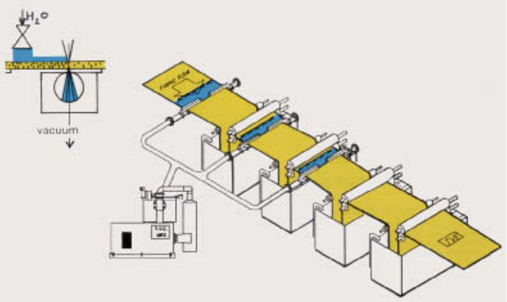

Fig. 1: Liquor spray vacuum suction process for rinsing the textile fabric after every roller vat treatment (TVE).

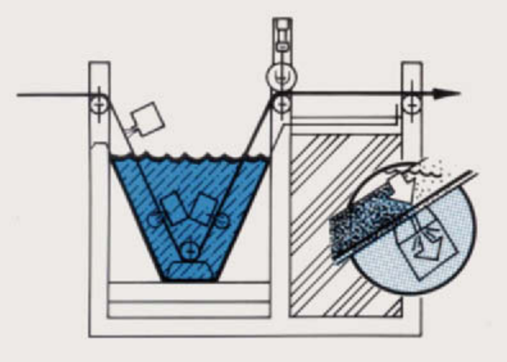

Fig. 2: Under-water suction with vacuum for intensive throughflow of especially thick fabrics (TVE).

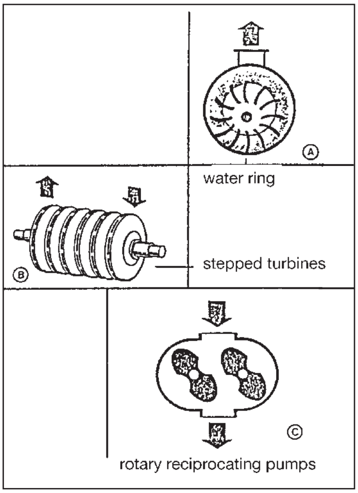

Fig. 1: Vacuum technology pumps.

Vacuum technology pumps The choice of pump system to produce a vacuum is determined by the field of application (Fig. 1). The following types of pump are used:

- water ring pumps,
- stage turbine pumps,
- rotary positive displacement pumps.

For the dewatering of carpets, water ring pumps appear to be the most popular choice.

Pumps are designed to displace gas against a pressure. In a typical vacuum pump an electric motor drives a paddle-wheel on a shaft which transports air regulated by a cam plate (Fig. 2). The intake valve is installed on the suction side of the system being evacuated. → Pumps.

Fig. 2: Exploded view of a vacuum pump (Siemens Elmo F) a) side casing; b) cam plate; c) impeller; d) floating ring seal; e) pump housing; f) motor.

Vacuum transfer printing machine The objective of this type of transfer printing machine is to achieve higher production speeds and improved print quality. It is essential that the air-permeable stainless steel conveyor, textile fabric and transfer paper are transported together before entry into the vacuum zone in order that the fabric passage can be checked and corrected if necessary without any intervention in the vacuum zone (Fig.).

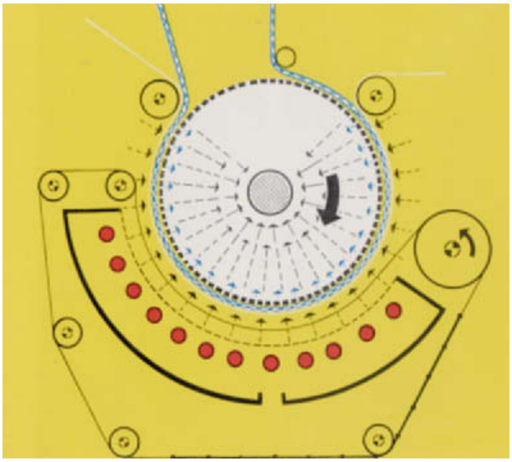

Fig.: Kannegießer Vacumat for continuous transfer printing.

Vacuum treatment during mercerization A method which requires the installation of a vacuum unit at the entry of a mercerizing machine in order to express air from a textile fabric before immersion in the mercerizing liquor. With an overhead caustic impregnation compartment this process offers some savings in floor space. Immediately before impregnation, entrained air is evacuated from the textile material which allows cold NaOH liquor to be forced into the still unswollen interior of the fibres by external overpressure during immersion. The vacuum cap is an essential machine element here.

Vacuum yarn steamer With automatic dosing of chemical additions. This type of steamer can be preprogrammed from 50–150°C in increments of 1°C with steaming times of 2–120 min (punched card controller). → Yarn steaming.

Vagabondo effect In addition to the “stone wash” treatment of denim articles to obtain various effects (e.g. “snow wash”, “moon wash”, “gold wash”, etc.) as well as sand-blasting to produce a fine, velvety handle, another process designed to give denim articles a modish character has established itself. This process, which is used to produce a so-called “vagabondo effect” on cotton goods, involves four stages:

1. Cationization of the cotton.
2. Dyeing with water-soluble sulphur dyes or selected reactive dyes. A pronounced ring-dyed effect is obtained due to the cationization treatment.
3. Enzyme treatment with cellulases to achieve an irregular and lighter colour.

4. Final finish to obtain the desired handle and other utility effects.

The enzyme treatment should be carried out in a drum washing machine (analogous to the “no stone” technique) in order to obtain an optimum “washed out” and “used look” effect.

Vagrant currents (stray currents). Stray electrical ground currents which are not infrequently responsible for severe electrolytic → Corrosion of underground water pipelines.

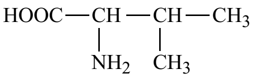
Val A derivation from equivalent weight which, expressed in grams, corresponds to 1 val of a particular substance. Thus, 1 val of a substance dissolved in 1 l of water = $^1/_1$ normal solution. $^1/_{1000}$ val = 1 millival (abbrev. 1 mval).
Terminology:

	val		mval
1 l	$^1/_1$ normal solution	= 1	= 1000
1 ml	$^1/_1$ normal solution	= $^1/_{1000}$	= 1
1 ml	$^1/_2$ normal solution	= $^1/_{2000}$	= 0.5
1 ml	$^1/_{10}$ normal solution	= $^1/_{10\,000}$	= 0.1, etc.

Consequently, 1 ml each of a $^1/_1$, $^1/_2$ and $^1/_{10}$, etc. normal solution corresponds respectively to 1, $^1/_2$ and $^1/_{10}$, etc. mval.

Valency The combining power of an → Atom or radical, equal to the number of hydrogen atoms that the atom could combine with or displace in a chemical compound (hydrogen has a valency of 1). →: Atomic bond; Chemical bond; Saturated organic compounds and Unsaturated organic compounds. Example: in one molecule of water H_2O, two atoms of hydrogen H combine with one atom of oxygen O: i.e. H–O–H. Therefore, H is monovalent and O is bivalent. Some elements can also have different valencies, e.g. copper (Cu) is usually bivalent and seldom monovalent. Similarly, iron (Fe) is trivalent in iron (III) chloride, $FeCl_3$, and bivalent in iron (II) chloride, $FeCl_2$. By analogy, groups of atoms (→ Radicals) also have their own valencies. A knowledge of valency therefore simplifies the understanding of chemical formulae and the representation of reactions in chemical equations. A distinction is often made between positive (metals) and negative valency (non-metals).

Valine → Amino acids (α-aminoisovaleric acid). A monoamino-monocarboxylic acid present in wool (4.72%) and silk (3.20%).



$$HOOC-\underset{\displaystyle NH_2}{\underset{|}{CH}}-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_3$$

Valves Shut-off devices to control the flow of liquids, superheated steam and gases under high pressure through pipes. Operated by means of a hand wheel and a threaded spindle (the valve is always opened slowly otherwise a risk of bursting exists).

I. Globe valves (two-way valves) with drip catcher, valve cone, annular ring and valve seating.

II. Piston valves (plunger valves) with cylindrical piston and two gasket rings (upper and lower, liquid enters through louvres).

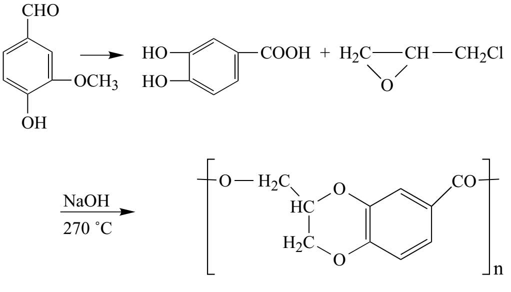
Valves are designed in various shapes and sizes according to the particular application, e.g. a) as shut-off, relief and overflow, bottom or dump, and dispensing valves (for mobile and highly viscous media as well as steam); b) electrically or thermally-controlled valves (for heating units, air compressors, cooling water pipes); c) piston slide valves (for steam); d) plastic valves (for acids, bases, salt solutions, various solvents, hydrogen peroxide: suitable for working temperatures up to 130°C); e) diaphragm valves (e.g. with exchangeable thick-walled rubber linings; positive operation; suitable for water, acids, corrosive liquids); f) pressure reducing valves (→ Reducing valves); g) self-closing and non-return valves (close automatically under back-pressure); h) acid valves (hard lead, iron-silicon, chromium-silicon); i) float valves (closed by a float-ball in an elbow joint); k) safety valves designed to operate with different safety loads or springs; used to prevent unacceptable increases of pressure in steam boilers, pressure pipes, water-heating systems, etc. and lastly as shuttle valves, forced safety release (on boiler shut-downs); l) glandless valves; m) feeler valves (with instantaneous shut-off for the humidification of textiles), etc.

Vanadium (V). A silvery-white ductile metallic element, atomic weight 50.95. Used as a hardening component in alloy steels and in the manufacture of vanadium compounds, e.g. → Vanadium dichloride.

Vanadium dichloride (vanadous chloride). VCl_2, molecular weight 122. Derivation: from ammonium metavanadate. Used as a catalyst in the dyeing and printing of aniline black (in solution 1:1000).

Van der Waals forces Weak attraction forces between molecules or crystals named after the Dutch physicist and Nobel Prize winner, J. D. van der Waals (1837–1923). They vary inversely as the sixth power of the interatomic distance and are due to momentary dipoles caused by fluctuations in the electronic configuration of the molecules. These forces are somewhat weaker than hydrogen bonds and far weaker than interatomic bonds. They are the forces responsible for the non-conformity of gases to the ideal gas laws and for the lattice energy of molecular crystals. The term is also used sometimes to include → Hydrogen bonds. Van der Waals forces are usually divided into two main groups, known respectively as polarization (or electrostatic) and dispersion forces. The former represent interactions between the electrons and atomic nuclei of different molecules lying in close proximity to one another. They involve incompletely compensated electrostatic attraction forces, i.e. intermolecular active residual valencies which are left over after saturation of principal valencies as so-called → Secondary valency forces, the function of which may be attributed to cross-cohesion between macromolecules. The reason why substances condense to form liquids or solidify to form solids at sufficiently low temperatures has also been attributed to the action of van der Waals forces. Likewise, the boiling point of a substance can be regarded as a measure of the strength of molecular excitation necessary to overcome van der Waals forces. These forces increase to some extent with increasing molecular weight. It therefore follows that heavy molecules are more strongly attracted than lighter ones. However, van der Waals forces only play a significant role if the molecules are quite close to one another. They only act over a very short distance and have a relatively strong action over a distance of approx. 0.5 nm. From monatomic molecules, (e.g. rare gases) it is known that on doubling the distance from 0.5 nm to 1 nm, the effect is to reduce the attraction force by less than one hundredth. Van der Waals forces are also involved in dye/fibre bonding and are particularly important in the case of substances with a detergent action where they appear to function as solution-promoting forces alongside → Ionic bonds. In terms of energy, however, their strength is only one tenth that of interionic bond forces. Despite this, they are responsible for colloidal properties and the formation of micellar colloids in particular.

Vanillin (poly) ester fibre A polyester fibre produced from vanillin (3-methoxy-4-hydroxybenzaldehyde) derived, among other things, from wood lignin (1 kg wood gives 0.5 kg lignin), then converted to protocatechuic acid and subsequently to a condensable oxy acid with epichlorohydrin. Filaments are spun from the polycondensate:



Vantean process A finishing process to produce a high lustre on wool fibres. It involves a preliminary impregnation (mordanting) with a nickel catalyst which, after an intermediate wash, remains in the endocuticle. Subsequent chlorination is accelerated to such an extent that the exocuticle peels off resulting in a smooth fibre surface.

Vapour phase process → Gas phase crosslinking.

Vapour pressure (evaporation). A vapour pressure exists wherever molecules leave their associated state in a liquid since they possess sufficient kinetic energy (at the surface of liquids, i.e. the boundary interface for the process of evaporation). The energy necessary to evaporate 1 mole of a liquid is known as the molar heat of evaporation.

The most important vapour in nature and technology is water vapour or steam. The vapour itself is not visible but rather the finely distributed water droplets held in suspension due to their charge. Steam in a two-phase system in which steam and condensate are in a state of equilibrium at the same temperature and pressure is described as saturated steam. Steam fulfils several functions in textile processing: it transfers heat and moisture to a textile substrate through condensation. In many cases, the steam also dissipates the heat of reaction and condensation as well and maintains moisture in the textile which is absolutely essential for fixation processes. Moreover, undesired decomposition products released during fixation processes, as well as spin finishes, etc. are transported away by the exhaust steam.

The process of vaporization or evaporation involves a combination of heat transfer and mass transfer between a moist surface and the air flowing over it. For heat transfer the following formula applies:

$$Q = \alpha \cdot F \cdot (t_{Wo} - t_L) \text{ [J/h]} \approx \text{evaporative capacity N}$$

Q = quantity of heat transferred [J/h],
α = heat transmission coefficient,
F = surface area for heat transfer [m^2],
t_{Wo} = temperature of water at the boundary layer [°C],
t_L = temperature of the air [°C].

Apart from physical characteristics, the heat transmission coefficient α is dependent above all on the flow conditions. By applying similarity considerations, useful formulae are obtained via dimensionless variables which allow α to be calculated for a respective application.

A similarly derived equation has been introduced for the determination of mass transfer:

$$W = \delta \cdot F \cdot (x_s - x) \text{ [kg/h]}$$

W = quantity of water evaporated [kg/h],
δ = rate of evaporation [kg/m^{2}h],
x_s = saturation content corresponding to the temperature of the water surface t_{Wo} [kg/kg],
x = moisture content of the air [kg/kg],
F = surface area for heat transfer [m^2].

Dalton’s law of evaporation states that the quantity evaporated is proportional to the vapour difference between a wet surface and the air.

Just as a temperature difference is the driving force for heat transfer, mass transfer involves differences in moisture content. Without external expenditure of energy, heat is always transferred in the direction from higher to lower temperature regions. The 2nd main law of thermodynamics states correspondingly that heat cannot be transferred from a colder body to a hotter one of its own accord. In a similar manner, the mass transfer of water vapour takes place from regions of higher to those of lower concentrations. Mathematical formulae to determine the rate of evaporation δ lead via similarity considerations, as in the case of the heat transmission coefficient α, to dimensionless constants where flow conditions are again of decisive importance.

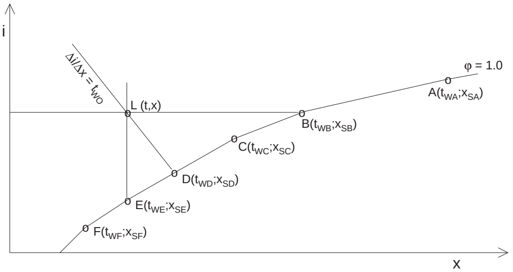


Fig.: I-x diagram to explain the relation between heat transfer and mass transfer during the volatilization process.

The i-x diagram (Fig.) is particularly helpful as a visual aid for understanding the combined effects of heat and mass transfer in the evaporation process. In the schematic diagram, L represents a specific state (t, x) which should not change by transfer from the air flowing over the evaporation surface. The saturation state x_s immediately on the surface of the water is found on the saturation line $\varphi = 1.0$ and should be able to change by the influence of the water supply from A to F. As long as the temperature of the boundary layer t_{Wo} lies above the temperature of the air t_L, heat is transferred from the water to the air (state A). After cooling down to B, the temperature of the water surface and the air temperature have become the same ($t_{Wo} - t_L = 0$) and, correspondingly, no more heat is transferred ($Q_B = 0$). Below B, the direction of heat flow is reversed: from now on the air is warmer than the water and gives up heat at the boundary layer. At C, D, E and F the temperature difference gradually increases and more and more heat is released from the air.

If care is taken to ensure that the evaporation vessel is sufficiently well insulated so that no heat can transfer from the surroundings, then the water supply at state A will cool down through the release of heat into the air. It could now be assumed that after reaching state B, the cooling process is ended and that heating up would occur below this point through heat supplied from the air. However, the water still continues to cool even below B due to the superimposition of mass transfer on the heat transmission.

The driving force for the mass transfer ($x_s - x$) is greatest at state A and decreases through B, C and D until at state E it is zero ($x_{sE} - x = 0$, $W_E = 0$). E is the dew point of air corresponding to state L; no further mass transfer takes place after cooling the water supply to the dew point. With a further decrease in the water temperature, ($x_s - x$) is negative; i.e. no more water evaporates but moisture thaws out of the air (point F).

If both transfer flows are considered in context, then an intensive release of heat is to be expected from the water (at state A) which not only gives up heat to the colder air but which, the same time, has supplied the entire heat of evaporation for the evaporation process. When no heat flows from the surroundings, i.e. when the process proceeds adiabatically, the water will cool down to a great extent. Even at B the release of heat has not ended since the water supply still has to carry the entire heat of evaporation. Below B, the air begins to give up heat to the surface of the water and the heat contribution of the water to the evaporation process can decrease correspondingly. At the same time ($x_s - x$) has become smaller (state C). A boundary state has now established itself at which the heat supply from the air can just compensate for the heat of evaporation necessary for the decreasing mass transfer. An “adiabatic steady state condition” is then said to exist (indicated by D).

An adiabatic equilibrium is only reached when no heat transfer takes place with the surroundings. If heat flows into the water supply then inertia occurs above D (with heat extraction, below D). In a state of adiabatic equilibrium, the air exchanges heat for water vapour. Its total enthalpy, which is related to liquid water at 0°C, is increased as a result so long as $t_{WD} > 0°C$. State D is found in the i-x diagram at the point where the mist isotherms $\Delta i/\Delta x = t_{WD}$ are drawn through L. Since the lowest temperature is obviously reached at D at which point the water can be cooled down by air under the given conditions, it is described as the dew point temperature. The dew point lies appreciably below the air temperature.

The evaporation enthalpy (also known as heat of evaporation) corresponds to the amount of energy which must be supplied to a material, e.g. water, with a mass of 1 kg to convert it from the liquid to the gaseous state at the boiling point and vice versa.

$$r = h'' - h' = u'' + p\,(v'' - v')$$

r = evaporation enthalpy,
h = enthalpy,
u = internal energy of a system,
’ = state variable for water,
” = state variable for water vapour,
p = pressure,
v = volume.

The enthalpy of evaporation therefore consists of an internal energy component Δu to overcome molecular forces and an external component of volume work $p \cdot \Delta v$. The external component is needed for expansion of the water volume to the water vapour volume.

If the evaporation entropy is calculated from the enthalpy of evaporation at the boiling point for various substances

$$\Delta S_{\text{evap.}} = \int_{n=0}^{1} \frac{\Delta H_{\text{evap.}}}{T} dn = \frac{\Delta H_{\text{evap.}}}{T}$$

values are obtained which are dispersed around a mean of 88 J/K/mol. This statement is known as the Pictet-Trouton rule. Considerable deviations from this rule are often found, however, which can be attributed to molecular chemistry.

All substances with evaporation entropies greater than 88 J/K/mol exhibit associations through hydrogen bonds in the liquid state, e.g. H_2O. Associated H_2O molecules possess less freedom of motion which results in a lower entropy of H_2O and consequently a greater entropy of evaporation.

Compounds with an entropy of evaporation ($S_{\text{evap.}}$) smaller than 88 J/K/mol are not only associated in the liquid but also in the vapour phase. Association through hydrogen bonding, e.g. in organic acids, results in dimeric molecular complexes which are also present in the vapour phase. The smaller $S_{\text{evap.}}$ value is because the single molecular weight and not the molecular weight of the molecular complex has been used to calculate the entropy of evaporation. Consequently, the entropy of evaporation is only half as big.

Liquids which obey the Pictet-Trouton rule are independent of specific molecular structures, and deviations can be attributed to a change in the kinetic energy of the evaporating molecules (according to Häussler).

Variable temperature dyeing processes Dyeing methods on the basis of drawing out at different dyeing-bath temperatures. Varying degrees of drawing effectiveness are demonstrated at individual temperatures, temperature ranges or stages, i.e. the substantivity, degree of fixation and drawing speed react differently in different temperature ranges. There are temperature stage-dyeing processes using increasing and decreasing temperatures. → Vat dyeing.

Variable-tension rolls A system of rolls to adjust fabric tension by changing the wrap angle of the fabric around guide rollers or guide rods. When variable tension rolls are installed at the entry to a continuous processing plant, they are also sometimes described as the fabric feed system (consisting of 2 tubes only).

Variance In → Statistical analysis, variance is a measure of the dispersion of the distribution of a random variable. The square root of the variance is called the → Standard deviation (s), and is the most widely used measure of variability.

Variance comparison The difference between target and actual values (regulating variables) in closed control loops. This difference is called the standard tolerance. It is a measure of the quality of regulation and is used by a controller (automated control unit) as an input quantity. → Automatic control systems.

Varnish (oil-based varnish). A varnish consists of → Drying oils (usually linseed oil with turpentine and resins if desired). Its rate of drying is increased by the addition of a drying agent. Varnish produces an elastic hard smooth coat (oil film). When applied as a thin coating, varnish hardens by oxidation within 11–24 h.

Varnish stains These stains are tacky when fresh; hard and brittle with blurred edges when old. Removal: it is advisable to loosen the varnish film mechanically first before treating the material in a suitable solvent, e.g. a) chloroform-carbon disulphide (or ethyl ether) 1 : 1; b) turpentine followed by gasoline (benzine); c) concentrated benzine soaps/ethanol/trichloroethylene; d) benzene/acetone 1 : 1; → Grease stains.

Vascular bundle A discrete strand of cells in the stems of some plants for the transportation of sap. → Flax stem structure.

Vase carpets → Oriental carpets with coloured representations of flower vases surrounded by palmettes and stylised floral motifs.

VA steels → Stainless steel.

Vat,

I. An alkaline sodium dithionite bath either without dye (blank vat) or with → Vat dyes (dye vat). In the latter case, the vat dye is present as the soluble → Leuco compound of the water-insoluble parent vat dye and is able to exhaust on the fibre in this form (→ Vat acids).

II. The term “vat” was originally used to describe a wooden tub used for the fermentation of indigo.

Vat acids The leuco compound of a vat or sulphur dye which, in this (water-soluble) form, possesses affinity for the fibre. A vat acid is a very weak acid. Principle: all vat dyes contain the characteristic >C=O group (keto group). In an alkaline sodium dithionite vat, the addition of hydrogen (= reduction, hydrogenation) takes place first of all to form the >C–OH group which corresponds to the leuco form as the vat acid. However, due to the presence of caustic soda in the vat, H and Na are exchanged and the sodium salt of the vat acid >C–ONa is formed which represents the actual state of vatting.

Vat dye fine dispersions The development of the → Pigment dyeing process with vat dyes and its continuous variants was made possible mainly by the preparation of special fine and ultrafine dispersed vat dye pigments having a particle size of approx. 0.2–6 µm which are suitable for this type of application. These dispersions guarantee accelerated fixation in textile printing and better penetration and levelness in (pad) dyeing (especially on thick materials). Particularly recommended for continuous processes.

Vat dyeing In general, dyeings produced on textiles with vat dyes have the highest colour fastness although one and the same dye cannot always satisfy every colour fastness requirement at the same time. Consequently, dye manufacturers have classified their dyes into 3 groups, i.e. for washable goods (e.g. uniforms), interior furnishings and all-weather articles. Indigo, which can be regarded as the first vat dye, has now lost much of its former importance in cotton dyeing. It is still used for special articles such as "blue jeans" which are only considered to be "fast" if they have been dyed with indigo or when a range of different fashion effects is desired. Chemically, vat dyes are classified into two main groups:

– indigoid vat dyes: derivatives of indigo and thioindigo which give leuco compounds of relatively low affinity.
– anthraquinonoid vat dyes: based on anthraquinone, the leuco compounds of which are taken up rapidly and completely by the fibre.

In terms of overall colour fastness, the anthraquinonoid vat dyes are superior to indigoid vat dyes. With the exception of indigo, therefore, the latter class of vat dye is only used for textile printing in the main. A peculiarity of vat dyes used to be the various physical commercial forms available in the market. Nowadays, the dye maker generally limits his production to a single commercial form suitable for all applications in view of the trend in dyehouses to move towards liquid forms. The unsurpassed wet fastness of vat dyeings is due to the complete insolubility of these dyes in water. In order to apply vat dyes to the fibre, therefore, they must first be converted into their water-soluble leuco salts which then behave in a similar manner to substantive dyes. As a rule, the reduction (vatting) stage is carried out with sodium dithionite in alkaline solution and the dyes are converted back to their insoluble state on the fibre after dyeing by oxidation in air or with substances capable of liberating oxygen.

1. Vatting: sodium dithionite reduces vat dyes very rapidly at 50–60°C. With certain dyes there is already a risk of over-reduction at temperatures above 70–80°C. Sodium dithionite solutions decompose in the presence of oxygen which is why reduced dye liquors (vats) have to be protected from exposure to the atmosphere. 1 l of air alone consumes approx. 3 g sodium dithionite. In HT dyeing, more stable reducing agents are used, but more is necessary to maintain the state of the vat; sodium dithionite is still used to reduce the dyes, however. The vatting time is dependent on the dye constitution and the particle size (commercial form). In order to achieve satisfactory dyeings, the concentration of sodium dithionite in the dyebath must be checked at appropriate intervals during the dyeing process. For anthraquinonoid types, the pH of the vat is approx. pH 13, and for indigoid and thioindigoid dyes a pH of approx. 10 is used. If the pH falls below these values there is a risk of the vat acids separating out. Apart from sodium dithionite, sodium borohydride (sodium tetrahydroborate) and thiourea dioxide can also be considered as reducing agents for vat dyeing in theory. Whilst the first of these has achieved no success in practice, neither alone nor as an additional stabilizing element, thiourea dioxide has gained some importance in Europe, since it inhibits the biodegradability of organic substances in waste waters to a far less extent than sodium dithionite. It also has a high reducing power and is more stable.

2. Oxidation: after dyeing, the leuco dye present on the fibre is reconverted to the insoluble pigment form by oxidation. Depending on the particular dye, this is carried out in the rinse bath (direct rinsing dyes) or by a special treatment (non-direct rinsing dyes). The latter category applies above all to the so-called cold-dyeing types of low affinity. With these dyes, it is recommended to remove the vat as completely as possible mechanically by squeezing-off, suction extraction or centrifuging in order to avoid non-uniform migration of dye in the rinse bath. The rate of oxidation is dye-dependent. Oxidation already begins to take place when the dyed material is exposed to the air. It occurs most rapidly at pH 10–11. To achieve the most favourable pH value, carbonic acid can be fed into the first rinse bath (a method which has found favour in the USA) or, alternatively, the vat can be neutralized with sodium bicarbonate after dyeing has been completed; a process which is recommended for cold-dyeing types with low affinity. For those dyes which oxidize rapidly, oxidation is completed in the rinse bath. For others, oxidation takes place in an additional bath with hydrogen peroxide after rinsing. In principle, sodium perborate, percarbonate or persulphate, as well as sodium bromate, can also be used. For ecological reasons, however, the use of potassium dichromate should be avoided. In some dyehouses, acetic or formic acid is added to the bath for neutralization after oxidation is complete. Under no circumstances should neutralization be carried out before oxidation since otherwise the difficult to oxidize or no longer oxidizable vat acid is formed.

So-called shock oxidation by the addition of sodium hypochlorite to the first rinse bath, which must however be restricted to vat dyes with adequate colour fastness to chlorine, is also used in practice. To achieve complete development of the shade and optimum colour fastness, dyed materials must be given a soaping treatment at the boil after oxidation. The duration of this treatment varies and a few minutes is sufficient for many dyes; a minority, however, require up to 0.5 h. The soaping treatment removes the excess dye loosely adhering to the fibre and also brings about a rearrangement of the dye molecules from the amorphous to the crystalline state or an aggregation to larger particles. A vat dyeing which has not been soaped, or which has been soaped insufficiently, will therefore not exhibit its correct shade and will not have maximum light fastness. On the other hand, a soaping treatment which is too intensive can impair colour fastness to rubbing. For economic reasons, many dyers now carry out the soaping process with suitable products in the spent oxidation bath at pH 6–6.5 thereby saving a separate bath. Oxidation with organic oxidizing agents is also possible, e.g. sodium m-nitrobenzenesulphonate.

I. Exhaust processes: the exhaust process with its many variants is of chief importance for yarn dyeing (package dyeing) and the dyeing of knitgoods. It is less important for woven fabrics where applications on the padder are preferred. In the exhaust process, the dye is either vatted in a concentrated bath (stock vat) or directly in the dyebath. The latter method is the most frequently used in practice. Only shading additions are still vatted in the stock vat as a rule. In some cases, vat dyes in most dye makers' ranges are quite different in their constitution and therefore have different properties as well. For example, different temperatures and quantities of caustic soda and sodium dithionite may be necessary for vatting. If the recommended vatting conditions are not observed, partial destruction of the dye and defective dyeings are likely to occur.

Variations in the properties of vat dyes have led dye makers to classify them into 3 groups. The allocation of individual dyes to these groups is not easy; some dyes may be dyed equally well by two different methods. For reasons of colour fastness, the so-called cold-dyeing types are no longer of any commercial importance and nowadays the warm and hot dyeing types are no longer treated differently from a processing point of view. In order to shorten the dyeing times and still achieve level results, dyers have switched more and more to higher temperatures. Since the vatted dye exhausts very rapidly (90% of the end state is reached after approx. 10 min), special measures have to be taken to obtain level dyeings. Diffusion and migration behaviour differs from dye to dye (in general, the difference is relatively small but increases with rising temperatures). In order to retard the rate of exhaustion, auxiliaries have been developed whose main effect is based on aggregation of the dye molecule (products with dye affinity). Aggregates formed in this way exhaust more slowly on to the fibre and break down again during the course of dyeing.

Control of the dyeing temperature and state of the vat, i.e. the alkali and sodium dithionite content, is necessary. At the end of dyeing, the dyebath must still contain sufficient reducing agent. Appropriate instruments are available for monitoring the redox potential of dyebaths. The consumption of reducing agent in a dyebath depends on the type dyeing machine, the textile material (entrained air) and the temperature. Enclosed machines are therefore particularly important for vat dyeing. The use of nitrogen as a protective gas in winch dyeing machines, for example, has already been recommended. Recently, BASF have begun to supply already vatted indigo solutions under nitrogen as a protective gas in special containers. Additions of ammonia above the bath can likewise provide protection against atmospheric oxygen. Further variants of the exhaust process include:

a) Dyeing with decreasing temperatures (rapid dyeing process). The bath contains the vatted dye. Dyeing begins at 80°C and is maintained at this temperature for 30 min in the case of pastel shades and 10 min for medium to dark shades. This is followed by a 20 min cooling down phase to 50°C. After a further 20 min, exhaustion is complete.

b) Incremental temperature process: the bath is presharpened at a temperature no higher than 15°C, i.e. alkali and sodium dithionite are added followed by the stock vat. With a temperature rise of 1°C/min, the dye exhausts slowly on to the fibre. This process is only suitable for warm and hot dyeing dyes.

c) High temperature process: dyeing is carried out according to the normal recipe and, during the course of dyeing, the temperature is increased to 115–120°C to improve levelling and increase the rate of diffusion. Only selected vat dyes can be dyed under these conditions. However, many dyes can be stabilized by additions of sodium dithionite, glucose, formaldehyde and formaldehyde-liberating products, e.g. methenamine (hexamethylenetetramine). Besides sodium dithionite, which is unstable at high temperatures, different types of reducing agent can be used to maintain the vatted condition of the dye. The HT process has found particular favour for the dyeing of unscoured cotton yarn in pastel shades.

d) Pre-pigmentation process: the unvatted dye has no affinity for cotton. By using finely dispersed commercial brands, it is therefore easy to achieve a uniform distribution of the dye in yarn packages (cross-wound packages). The finely dispersed dye is taken up by the material from a warm bath with additions of sodium sulphate (Abbot-Cox process) or special auxiliaries. The dyeing is then developed in the same or a fresh bath with caustic soda and sodium dithionite at the recommended temperature. This process can be easily controlled with modern control systems. According to one variant, special additions are dispensed with and the pre-pigmentation bath is heated to 90°C followed by addition of caustic soda and sodium dithionite after a certain time, and the temperature is then allowed to fall to 50–60°C. With some dyes, pre-pigmentation with dye and alkali together can lead to undesirable coarsening of the dye particles and filtering out problems. Only selected dyes are suitable for this process variant. At low temperatures, on the other hand, the dye, alkali and sodium dithionite can be applied together. The bath is then heated slowly to 60–80°C, during which time the dye is gradually vatted and taken up by the fibre. This process is described as the semi-pigmentation process. In principle, it is possible to increase the temperature to 110–115°C in the pre-pigmentation process (as in the HT process) so long as appropriate additions are made. Levelling agents recommended for the normal exhaust process can also be used to advantage in this process (Fig. 1). For all pre-pigmentation processes, finely dispersed commercial brands must be used without exception. These processes are not suitable for dyeing woven fabrics on beam dyeing machines.

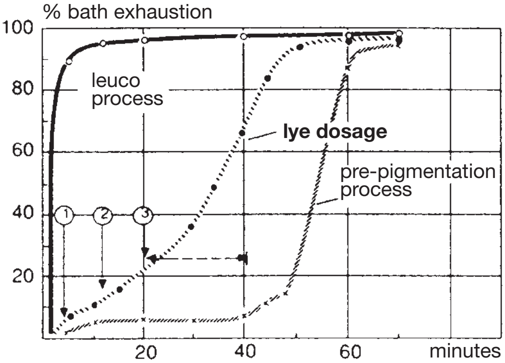

Fig. 1: Absorption behaviour of Indanthrene Brilliant Violet 3 B in different processes on cross-wound yarn packages; (VP = pre-pigmentation process).
4% dyestuff, 2 g/l of Dekol SN (BASF), 25 ml/l of caustic soda (38°Be), 10 g/l of sodium dithionite, Obermaier laboratory dyeing machine, liquor ratio 10 : 1, cotton yarn, cross-wound yarn packages inside to outside.
Lye dosage: 1 = dye, auxiliary agent, sodium dithionite, 3 g/l of sodium carbonate calc.; 2 = sodium dithionite; 3 = in a 4 minute cycle: 1, 1, 1, 2, 5, 15 ml/l of caustic soda (38°Be), 20 min at 30°C, in 25 min up to 60°C, 35 min at 60°C.

II. Padding processes: continuous dyeing processes are very important in piece dyeing. They guarantee high rates of production, good penetration and solid dyeings. A distinction is made between 2 process methods, i.e. padding with vatted or unvatted dye. The latter method has found the widest application in practice.

a) Processes with vatted dye: the high affinity of the leuco dye and the instability of the vat are the main reasons why this process has not achieved any success in practice. At one time, it was believed that the ”Standfast” or ”molten metal” process in which a textile fabric was impregnated with a vatted dye in a small pad trough had a promising future. Dye fixation was achieved by subsequent passage through a bath containing a molten metal alloy. The process only proved successful for loosely woven fabrics produced from loosely twisted yarns. A further development in this area was the “rapid dyeing” or “flash dyeing” process which had also been promoted in England: in this case, the dyebath is prepared cold with all additions and, shortly before running in the very small pad trough of a padder, it is heated to 90°C by an inlet-controlled water heater. The fabric, preheated to 90–95°C, runs through the bath within 0.6–2 s. In this case also the penetration of densely woven fabric qualities is problematic. Another process used in former times is the so-called vat-acid process. This involves vatting the dye and converting the leuco compound thus formed into the vat acid by addition of an acid. After application on the pad, development was carried out in a warm blank vat with caustic soda and sodium dithionite.

b) Processes with unvatted dye: these methods of application only became possible after finely dispersed commercial brands with a satisfactory mean particle size distribution had been developed. The dye dispersion, which has no affinity for the fibre, is applied on the padder and, after a possible intermediate drying, it is vatted in a second stage. By far the most important methods are the pad-jig and pad-steam processes. Pad troughs with liquor circulation, i.e. continuous liquor circulation from and to the stock tank are not recommended for padding with unvatted dyes where the action of pumping can cause the dyes to agglomerate. Opinions are divided concerning the absolute necessity of an intermediate drying stage before vatting. As experience has shown, however, the constancy of shade within a batch is more reliable when an intermediate drying stage is given. It is, of course, true that intermediate drying involves higher costs and a risk of dye migration when driers are used with non-uniform heating. Modern driers are, however, designed with air circulation systems to ensure uniform drying. Cylinder driers in which the fabric is dried on both sides are also used but at least 3 independently-controlled groups of cylinders must be available. Typical temperature settings for the different groups of cylinders are:

1st group:	70°C
2nd group:	80°C
3rd group:	120°C
4th group:	150°C

There is a risk of clip marks when drying is carried out on stenters. The tendency of a dye to migrate is dependent on the particular fabric (fibre type, fabric construction), fabric pretreatment, the dye and its particle size as well as any necessary additives. Thickening agents are not sufficiently effective in preventing migration. Products which become insoluble at high temperatures and cause the dye particles to aggregate are more effective for this purpose. In pad-jig dyeing, the discontinuous vatting of pigment-padded fabric in the full bath of a jigger can, under certain circumstances, cause end-to-end variations in shade since some of the dye is transferred to the blank vat from the fabric. This defect can be avoided by making suitable additions of pad liquor to the bath at the beginning and end of the 1st passage. The correct quantity of pad liquor to use demands appropriate experience on the part of the dyer. Continuous vatting in a full bath, e.g. in a so-called "Williams unit" consisting of a roller vat with minimum liquor content, gives rise to shade variations within the batch, which is why this process is hardly ever used nowadays. The pad-steam process (Fig. 2), on the other hand, is capable of producing uniform dyeings over the entire length of a batch by continuous vatting and involves impregnation of pigment-padded goods in a blank vat (caustic soda and sodium dithionite) followed by subsequent steaming (30–60 s). A continuous plant of this type is expensive and only intended for high production. Smaller pad-steam plants capable of dyeing small production lots economically are also now available. The individual stages are carried out in the following order:

1. pigment padding.
2. drying.
3. cooling.
4. padding with blank vat.
5. short steaming.
6. open-width washing machine for oxidation and aftersoaping.

The extreme sensitivity of sodium dithionite to atmospheric oxygen requires a continuous excess of the product in the bath and continuous monitoring by automatic titration is recommended. The blank vat is usually applied from a padder immediately in front of the steamer. However, some pad-steam dyeing ranges also have a small trough (booster) installed inside the steamer itself.

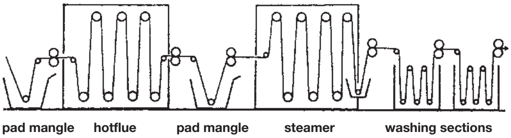

Fig. 2: Diagram of a pad-steam line.

Vat dyeing faults Some typical defects which occur in vat dyeing and their most likely causes are listed below:

- Unlevel dyeings: dyebath heated up too quickly; salt addition too high at the beginning of dyeing as well as inadequate oxidation.
- Poor penetration: dyebath heated up too quickly (= dye is only deposited on the surface of the fibres).
- Dull shade: dyeing temperature too high with too much sodium dithionite at the same time (= over-reduction).
- Formation of stains: unsatisfactory vatting of the dye; inadequate rinsing of vatted batches before oxidation (= localized concentrations of dye liquor); inadequate movement of dye liquor or textile material.
- Poor rub fastness: unsatisfactory vatting; incorrect after-soaping; too much dye on the substrate. This defect must not be confused with inadequate wet rub fastness which can be attributed to abrasion of the external layers of cellulose.
- Incorrect shade: aftersoaping treatment too short or carried out with too little energy.
- Poor light fastness: inappropriate dye selection, especially the use of unsuitable dye combinations (→ Catalytic fading).
- Fibre damage: → Vat dyes and fibre damage.

Vat dyeings, oxidation of An important stage in the development of correct shades in vat dyeing. After dyeing, the leuco vat dye which is present in its water-soluble reduced form (enol form) must be reconverted into its insoluble keto form again. In exceptional cases this can be achieved by aerial oxidation (e.g. by hanging in air); as a rule, however, the oxidation stage is carried out in baths containing suitable oxidizing agents. The rate of oxidation is dependent above all on the constitution of the dye as well as on the type and concentration of oxidizing agent used and the temperature and pH of the oxidation bath. The most favourable pH for oxidation is from 10–11. The excess alkali after dyeing must therefore be reduced as closely as possible to this value. The oxidation procedure varies according to the type of dye: e.g. vat dyes with leuco compounds of high substantivity (IN/CI dyeing types) can be rinsed directly after dyeing by the exhaust process. In order to save rinsing water, however, the material is often squeezed-off or suction extracted beforehand. For dyes with less substantive leuco compounds (IW/CII and especially IK/CIII dyeing types), the material must be squeezed-off or suction extracted first, otherwise considerable losses in yield and unlevel dyeings will result. The most favourable pH is achieved by an addition of sodium bicarbonate to the rinse bath. Under no circumstances should excess alkali be neutralized with acid otherwise the vat acids may be formed which can no longer be oxidized. The concentration of oxidizing agent and the conditions of oxidation (temperature and time) should be kept to the minimum required in order to prevent damage to the fibre.

Vat-dye instability A loss of colour caused by the decomposition of printed vat dyes due to storage of printed goods at high temperatures and high humidities before steaming. Other possible causes include steaming with air present in the steamer or poor steam circulation, and premature oxidation of a vatted dye by exposure to air. Loss of colour in discharge prints is due to the loss of reducing agent through atmospheric oxidation when printed goods have been stored too long before the reducing agent can be activated during the steaming process.

Vat dye printing Besides reactive dyes, vat dyes represent the fastest dye class for the printing of cellulosic fibres. They are used for printing articles which have to meet the highest standards of colour fastness. Vat dyes are supplied either in solid form (powder or granules) or as liquid brands.

The reduction process necessary for the fixation of vat dyes on the fibre can be carried out in two ways:

1. Potash process (“all-in” process): in this case the print paste contains both a reducing agent (e.g. sodium formaldehyde sulphoxylate) and an alkali (potassium carbonate = potash). In some cases, potassium carbonate may also be substituted with sodium carbonate. Starch-tragacanth was for many years the standard thickener for vat dyes. However, since this thickener is difficult to remove in the print afterwash, more readily soluble thickeners are also used nowadays such as starch-ethers, locust bean gums, alginates, etc. The fabric must be dried immediately after printing since otherwise the reducing agent would decompose on exposure to atmospheric oxygen during storage in the wet state and the dye would no longer be capable of vatting in subsequent steaming. A steaming time of approx. 12 min is usual. Care has to be taken to ensure that the steamer is completely air-free, otherwise the reducing agent would be consumed prematurely. During steaming, the shade of a vat dye changes to its so-called vatted colour, e.g. a blue may change to yellow or a green to red (usually the complementary colour is formed). After steaming, the printed fabric is finally oxidized and soaped. Oxidation can already be achieved with atmospheric oxygen but, in order to speed up the oxidation process in practice, hydrogen peroxide is usually added to the first wash bath. A final hot soaping treatment is absolutely essential in order to wash out loosely adhering, unfixed dye pigments from the surface of the fibres and thus achieve optimum colour fastness. Both direct prints as well as discharge prints can be produced by this process.

2. Two-phase process: this method is only possible for prints on white (i.e. undyed) fabric and offers optimum process reliability. The water-insoluble vat dyes are printed first as pigments. Thickeners capable of undergoing coagulation are used to prepare the print pastes, e.g. locust bean gums and their modifications. In this case, the printed fabric can be stored indefinitely before development which is a considerable advantage compared to the “all-in” method described above. The prints are finally developed by impregnation in a bath containing reducing agent/sodium carbonate or sodium dithionite/caustic soda followed immediately by steaming. This bath also contains sodium tetraborate which coagulates the thickener and prevents the vat pigments from bleeding out of the thickener film, thus ensuring sharp printed outlines. Excess liquor is squeezed off through a nip and the printed goods are steamed immediately to reduce the vat dyes to their soluble leuco compounds, in which form they can penetrate the fibre. Finally, the printed goods are oxidized, soaped and washed off as in 1 above.

Vat dyes These are water-insoluble dyes containing at least one keto group >C=O. Most are quinone derivatives (quinone group $O{=}C(C_4H_4)C{=}O$) which undergo molecular rearrangement in alkaline solution with a reducing agent, e.g. sodium dithionite (vat) to hydroquinone-like compounds $HO–C_6H_4–OH$ (vat acids) and their sodium salts ($NaO–C_6H_4–ONa$). In this form (i.e. so-called leuco compounds) vat dyes are water-soluble and have an affinity for textile fibres (cellulose, wool, silk). Vat dyes can be applied by exhaust and pad dyeing methods as well as by textile printing. Nowadays, vat dyes are available in a variety of commercial forms: e.g. the usual fine or microdisperse powders as well as paste or liquid forms. After they have been taken up by the fibre, vat dyes are converted back to the insoluble quinone form again by re-oxidation. The well-known, outstanding, high wet fastness properties of vat dyes are due to their insolubility in water. A final aftersoaping treatment is necessary for correct development of the shades and achievement of optimum colour fastness. Vat dyes are classified according to their constitution into anthraquinonoid and indigoid types; the latter are of relatively little importance nowadays.

Uses: for dyeing and printing textiles where the highest colour fastness requirements are demanded, especially colour fastness to light, weathering, washing at the boil, as well as for coloured articles required to withstand bleaching. The application of vat dyes to cotton, regenerated cellulose and linen is of greatest importance in practice. Their application to wool, silk, polyester and polyester blends, as well as the printing of acrylics and polyamide is relatively unimportant. Vat dyes are also used in the mass coloration of man-made fibres.

Vat dyes and fibre damage A few vat dyes (in the yellow, orange, brown and red sectors) can act as catalysts under certain conditions during oxidation processes, which results in the partial degradation of cellulose. A distinction can be made here between dyes which cause tendering during bleaching, dyeing and exposure to light. An individual dye does not have the same effect in all 3 categories. Dyes with a tendering effect in bleaching are only active in the bleaching of coloured wovens if sodium hypochlorite is used at a $pH < 7.5$

only or when the bleached material is exposed to direct sunlight. Dyes with a tendering effect in dyeing are only active if the dyed material is exposed to sunlight in open machines and the dyeing oxidizes due to repeated shortages of sodium dithionite and has to be reduced again. There is no remedy for dyes which cause tendering on exposure to light. Such dyes should be avoided and only those dyes specifically recommended by reputable dye makers as suitable for curtains and all-weather articles should be used.

Vat dyes in direct printing,

I. All-in method: the print paste contains vat dye, potassium carbonate (or sodium carbonate), reducing agent (usually sodium formaldehyde sulphoxylate) and thickener. After printing, the fabric is thoroughly dried and steamed (in air-free saturated steam at 101–104°C). During steaming the dye is reduced and converted to the soluble leuco compound, in which form it is taken up by the fibre. During oxidation in the subsequent washing-off stage the vat dye is restored to its original insoluble form again. This is followed by an aftersoaping treatment.

II. Two-phase methods:

a) → Colloresine process.
b) → Flash ageing.

In both the above two processes, the vat dye is printed without chemicals and the dye is only fixed after subsequent padding in a solution containing alkali and reducing agent followed by a steaming treatment. These two processes differ in the composition of the pad liquor, steaming time and temperature.

Vat dyes in discharge printing,

I. As dyeings: local destruction of the vat dyes was formerly achieved with oxidative discharges and nowadays exclusively with strongly alkaline reductive discharges.

II. As coloured discharges: vat dyes are the preferred choice of dye class for the production of coloured discharges on grounds dyed with direct or reactive dyes and naphthols.

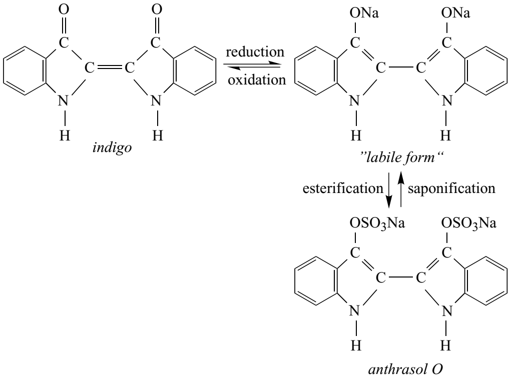
Vat dyes in resist printing This technique is no longer practised to any significant extent. Vat dyeings can be resisted by preprinting the fabric with substances having a mechanical and/or chemical resisting action: e.g. by preprinting with oxidizing agents, heavy metal salts with an oxidizing action, or metal salts with an alkali-binding action, either alone or in combination.

Vat-Flashage-discharge process→ Two-phase vat discharge prints.

Vat leuco ester dyes (solubilized vat dyes). The leuco compounds of → Vat and → Sulphur dyes are unstable unless special measures are taken. Dyeing with vat dyes is often accompanied by levelling problems since water-insoluble pigments are involved, which have to be made water-soluble by the addition of appropriate chemicals in order to dye the substrate. Vat leuco ester dyes, on the other hand, are already water-soluble products which produce very level dyeings. In most cases, these dyes have only slight substantivity and are used for dyeing and printing cotton as well as other cellulosic fibres. These products are not dyes in themselves and have to be developed on the fibre after dyeing to form the vat dye. In principle, they are vat dyes which have been esterified by chemical reaction and thus rendered soluble.

The dyeing procedure is generally as follows: a dyebath or pad liquor is prepared with the required vat leuco ester dye and a calculated quantity of sodium nitrite. Textile material is then dyed or padded with the solution, squeezed off and run into a second bath containing sulphuric acid, taking care to protect the goods from direct sunlight. The vat leuco ester dye on the fibre is then saponified to the leuco vat dye and the sodium nitrite, which is converted to nitrous acid by the sulphuric acid, oxidizes the leuco compound to the original vat dye. The textile material is then neutralized, soaped and finished as usual. Dyeings produced in this way are no different from vat dyeings produced by the conventional route.

Single-bath process: in this method, textile material is dyed with a vat leuco ester dye, sodium nitrite and sodium sulphate. When the correct shade has been achieved the vat dye is finally developed on the fibre by portionwise additions of sulphuric acid. For continuous dyeing, the individual baths can be arranged in succession.



Printing methods:

a) Nitrite process: the most popular method, which involves printing the vat leuco ester dye together with the oxidizing agent. The print paste contains: dye, solvent, sodium nitrite (oxidizing agent), water and thickener. After steaming (5–10 min), the printed fabric is passed through a hot developing bath (60–80°C) containing approx. 20 g/l sulphuric acid which then oxidizes the dye. Safety precautions are necessary, since the nitrous gases liberated during acid development are injurious to health.

b) Steaming process: in this method a different oxidizing agent is applied in the print paste. Since oxidation takes place in an acidic medium an appropriate acid-liberating salt must also be present. The print paste recipe for the steaming process is as follows: dye, solvent, water, ammonium thiocyanate (acid-liberating salt), sodium chlorate (oxidizing agent) and ammonium vanadate (oxygen carrier). A steaming time of 5–10 min is sufficient to develop the dye. Printed fabric still awaiting development after printing is sensitive to acidic vapours and direct light and must be carefully covered to protect the dyes before development. This sensitivity has been exploited in the so-called Photonprint process in which a textile fabric is padded with the aqueous dye solution and exposed to direct light (sunlight or carbon arc) after passing through a negative film which develops the colour. Dye in the unexposed and therefore undeveloped areas of the print is removed on washing off the fabric.

Vat leuco ester dyes in direct printing,

I. Processes involving wet development:

a) Nitrite process: the thickened dye solution is printed together with sodium nitrite, dried, and given a short steaming treatment if necessary. The dye is finally developed by passing the printed fabric through a hot bath containing sulphuric acid and sodium sulphate. Transparent prints can be produced in a developing bath with a higher concentration of sulphuric acid.

b) Dichromate process: the thickened dye solution is printed, dried and given a short steaming treatment if necessary. The dye is finally developed by passing the printed fabric through a hot bath containing sulphuric acid and sodium dichromate.

c) Iron nitrate process: the thickened dye solution is printed, dried and developed by passing the printed fabric through a hot bath containing sulphuric acid and iron nitrate followed by a treatment with oxalic acid during the final wash off.

II. Processes involving steam development:

a) Ammonium thiocyanate process: the thickened dye solution is printed together with ammonium thiocyanate, sodium chlorate and ammonium vanadate, dried, steamed and washed off.

b) Chromate process: the thickened dye solution is printed together with a neutral solution of sodium chromate, dried, steamed in acid steam and washed off. As an alternative to steaming, wet fixation with sulphuric acid is also possible.

c) Diethyl tartrate process: as process a) but replacing ammonium thiocyanate with ammonium chlorate together with diethyl tartrate. The colours are fixed by a short steaming treatment or by hanging in air.

Vat leuco ester dyes in discharge printing,

I. As dyeings: → Vat dyes in discharge printing.

II. As illuminating colours: this process is seldom used and can be considered as an alternative whenever difficulties are encountered in discharge printing with conventional vat dyes. The process involves printing a thickened solution of the vat leuco ester dye together with a reducing agent (with or without alkali depending on the dyeing) followed by drying, steaming and a passage through a hot bath containing sodium nitrite/sulphuric acid (the quantity of nitrite is increased and a longer dwell time is given since some undecomposed reducing agent is usually still present). The fabric is finally rinsed and afterwashed.

Vat printing → Vat dye printing.

Vatting The process of converting → Vat dyes from the water-insoluble (pigment) into the water-soluble substantive form (→ Leuco compounds) by reduction, usually with sodium dithionite and caustic soda.

Vatting condition When a → Vat has the correct composition it is described as a ”satisfactory vat”. If the quantities of sodium dithionite or caustic soda (or both) are deficient, partial oxidation occurs and some of the dye may begin to separate out under certain circumstances and the vat appears dull, i.e. the vat is said to be “unsatisfactory”. Even if the dye does not separate out, an “unsatisfactory” vat results in unlevel dyeings.

Vatting test An unreliable test for hydro-, oxy- and photocelluloses. Cellulose which has been chemically damaged has reducing properties which are sufficient to convert Indanthren Yellow G (flavanthrene) in alkaline dispersion into its blue leuco compound. Procedure: treat the sample in an alkaline bath with the dye. Formation of a blue colour indicates chemical damage.

Vat yellow paper → Indanthren yellow paper.

V-belts (Vee belts) → Transmission belts, drive belts with a tapered cross-section which run in the corresponding vee-tapered grooves of pulleys. V-belts are usually made of a rubber composition reinforced with V-belt cord. To transfer higher forces, several identical V-belts are used parallel to one another. Advantages: minimum possible distance between shafts, less wear, non-slip characteristics.

VCRS Abbreviation for the Swiss Federation of Dry Cleaners (Verband Chemischer Reinigungsanstalten der Schweiz); → Technical and professional organizations.

VdCh Abbreviation for the former (1887–1945) German Association of Chemists (→ Verein Deutscher Chemiker); → Technical and professional organizations.

VDF Abbreviation for the Society of German Dyers (Verein Deutscher Färber); → Technical and professional organizations. Today → VDTF.

VDI Abbreviation for the Society of German Engineers (Verein Deutscher Ingenieure). A German professional organization. Publication: VDI Nachrichten; → Technical and professional organizations.

VDMA Abbrev, for the German Machinery and Plant Manufacturers Association (→ Verband Deutscher Maschinen- und Anlagenbau e.V.); → Technical and professional organizations.

VDTF since 2000 union of VDF and VTCC.

Vector dye media for multicolour printing The usual colour solids conceived as colour ellipsoids can also be represented more simply as colour polyhedrons resp. as polyhedral colour lattices with defined colour edges and corners as colour vectors, e.g. in the form of four, five, six and seven vector colour solids. The seven vector colour solid has, e.g., 448 different coloured edges and 128 coloured corners. It is used for calculating mixing ratios of the yellow, magenta and cyan primary colours employed in typography.

VEGAT Abbrev. for the Federation of Swiss Yarn and Tricot Finishers (Verband Schweizerischer Garn- u. Tricotveredler); → Technical and professional organizations.

Vegetable (Lat.), of plant origin (when used as an adjective) as in vegetable fibres (e.g. cellulosic fibres) or vegetable impurities in wool.

Vegetable colloids These products are used as stiffening agents for textile sizes and finishes, e.g. →: Starch; Mucilages; Vegetable gums.

Vegetable dyes → Natural dyes.

Vegetable fibres →: Natural cellulosic fibres; Cellulosic fibres, regenerated; Natural fibres; Fibres.

Vegetable gums (natural gums). Carbohydrate high polymers insoluble in alcohol and other organic solvents which are obtained as dried exudations from various African and Asian trees and shrubs mainly of the acacia type in tropical areas. They are amorphous substances with very complex polysaccharide constitutions and are generally soluble or dispersible in water to give solutions with adhesive characteristics. They are coagulated by aluminium and chromium salts and are often used as thickeners in textile printing (especially in discharge and resist printing; unsuitable for mordant dyes) as well as for thickening pad liquors in dyeing. Also used in sizing (for this application it is recommended to use vegetable gums together with soluble starch). Formerly, they were also used in textile finishes to achieve a full handle. The diverse range of product names on the market is easier to understand from the following classification based on their main components of →: Arabin acid; Bassorin or Cerasin:

I. Gums containing predominantly arabin: →: Feronia rubber; Arabic gum; Cape gum, Mahagoni and Senegal gums.

II. Gums containing arabin + approx. 35% cerasin: → Rosaceae gum.

III. Soluble varieties of II marketed as so-called → Industrial rubber.

IV. Gums with a high bassorin and low arabin content: Bassora gum, Chagual gum and Gum Tragacanth.

Vegetable hair fibres Single cell seed hairs (→: Cotton; Akund) or fruit wall fibres (→ Kapok) of various plants the original purpose of which is to disseminate or protect the seeds. →: Natural cellulosic fibres; Fibres.

Vegetable horsehair → Crin d'Afrique.

Vegetable impurities The main impurities in the fleece, e.g. wool grease, dung and sand are removed in raw wool scouring. Burrs, seeds, leaves, bits of straw and wood, which become entangled in the fleece during the time when the sheep are at pasture, remain so obstinately attached to the wool that they seriously impair the appearance of wool fabrics. This particularly applies to piece dyed goods since the burrs are undyed by wool dyes. These various impurities of vegetable origin are generally described as vegetable matter.

The nature and frequency of occurrence of such vegetable matter in raw wool is dependent on animal husbandry and the country of origin of the sheep as well as on climatic conditions, e.g. the predominance of dry or wet weather and the associated growth of plant life. If manual removal is not practicable only chemical separation, i.e. a carbonizing treatment, is suitable for removing the vegetable matter from wool piece goods. In the case of worsted materials, however, a large proportion of the vegetable matter is removed during combing.

The carbonizing process involves an acid treatment followed by heating. When the material is dry, the carbonized and degraded cellulosic components "dust out" and are separated from the wool by mechanical means. The process of carbonizing is based on the different behaviour of animal and vegetable fibres in the presence of strong acids. Unlike wool protein, the vegetable matter is degraded hydrolytically by mineral acids. This vegetable matter contains in addition to 60–70% cellulose, 30–40% lignin which is not degraded by the carbonizing process. The next most important factor determining the wool price after fibre diameter and yield is the content of vegetable matter. This is because the vegetable impurities have to be removed during the course of wool processing, which incurs fibre loss as well as extra process time and an increased number of process stages.

The carbonizing process is mainly applied to loose wool in carded wool spinning. The non-uniform distribution of vegetable matter in loose wool requires a high acid content so that some fibre damage is unavoidable, which again leads to reduced yields, reduced fibre strength and problems in the subsequent processing of textile fabrics. These problems can be avoided to some extent by carbonizing in the piece, which is hardly ever applied to worsted fabrics any more but may be carried out on carded wool fabrics.

The content of vegetable impurities in Australian wool has been remarkably constant for a long time. As

application	type of error	vegetable impurity contamination level	basic vegetable impurities content	percentage of the shear [%]
worsted yarn	FNF B + S errors C + L errors D errors	none light medium heavy	< 1.0 1.1–3.0 3.1–7.0 ≥ 7.1	49.1 25.5 10.4 1.7
carded yarn	Y, carbonizing + waste during carding and combing	light to heavy	< 1.0 up to ≥ 7.1	13.2

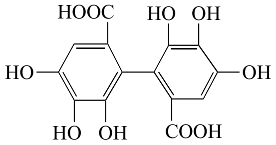
Tab. 1: Distribution of vegetable impurities in Australian wool for the 1988–89 season.

a result, the outcome of one season could also be taken as an example for a longer period of time with confidence. Tab. 1 shows that approx. 49% of the clip has a basic vegetable matter content of less than 1% and approx. one quarter of the clip has a vegetable impurity content of 1–3% which, with an improvement in the elimination rate, could be reclassified into the high-quality end-consumer category.

In worsted yarn manufacture, vegetable impurities are specifically separated during the carding and combing stages. Nevertheless, losses are incurred in all processing stages and particularly during spinning. A typical example for the elimination of vegetable matter is given in Tab. 2; the performance has been measured in order to estimate the level of impurities in wools with the given types and content of vegetable matter in the card sliver and tops. The values reproduced in the table show that wools containing burrs with a maximum vegetable matter content of 1% and a length of more than 10 mm correspond to normal commercial standards. Wool containing seed and vegetable matter residues with a basic content of 1% is acceptable but if this increases to 5% then the wool can no longer be used for high quality end uses.

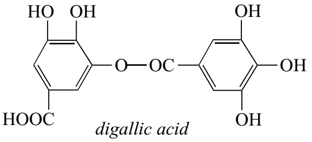
Vegetable silk → Akund.

Vegetable tanning A considerable number of plants and bark woods offer technically economic yields of tanning agents on extraction. Most of these vegetable tanning agents are extracts from horse chestnut trees, wattle, quebracho bark, oak woods, mimosa bark, oak barks, valonia acorns, myrobalan fruits and other plants rich in tanning agents. These vegetable tanning agents are complex compounds of high molecular weight with numerous phenolic hydroxyl groups. In chemical terms, vegetable tanning agents may be classified into two main groups, i.e. the pyrogallol and the pyrocatechol tanning agents. Hydrolyzable pyrogallol tanning agents are readily decomposed by ferments with the formation of ellagic acid (a valuable tanning agent).

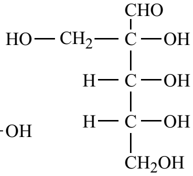


ellagic acid

They also form gallotannins and depsides, esters of phenolic carboxylic acids and hamamelose.

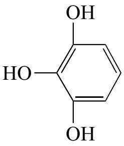


digallic acid



hamamelose

On heating to 180–200°C, the hydrolyzable tanning agents yield pyrogallol.



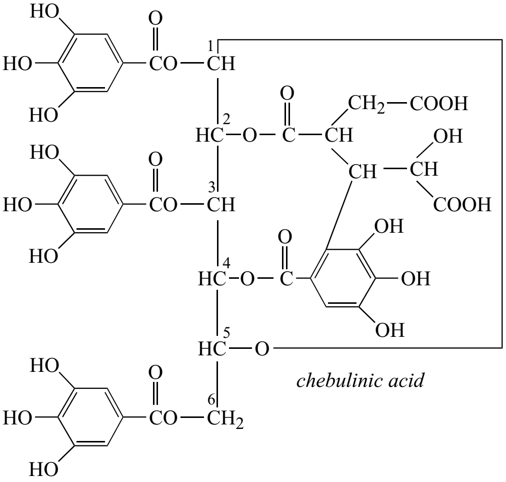
pyrogallol

The benzene nuclei in the tanning agent molecule, which are linked together by oxygen atoms to form large complexes, are another characteristic of such compounds.

type of vegetable impurity	basic vegetable impurity content [%]	secretion during carding [%]	occurrence of vegetable impurities in the card sliver (number of particles per kg > 10 mm)	secretion during combing [%]	occurrence of vegetable impurities in the combed top	usual commercial standards
					number of particles per kg > 10 mm)	
burrs burrs	1 5	95 95	833 4165	99.6 99.6	3 15	10 10
seeds/shives seeds/shives	1 5	85 85	2500 12500	99.6 99.6	10 50	20 20

Tab. 2: Secretion of vegetable impurities in carding and combing.

Pyrocatechols are more resistant to fermentative exposure and have a pH of 4.5–5 in solution. They form phlobaphenes in solution which again form pyrocatechol on heating to 180–200°C.



In the condensed pyrocatechol tanning agents, a large number of polyvalent phenols (pyrocatechol, pyrogallol) is fused together through carbon atoms, chain ether compounds or heterocyclic structures from furane, pyrane, or other types, to form high molecular weight polyphenols (Fig. 1).

Tanning with vegetable extracts involves the formation of crosslinks between the polypeptide chains (–CO–NH) through hydrogen bonding with the phenolic OH groups of the tanning agent (Fig. 2).

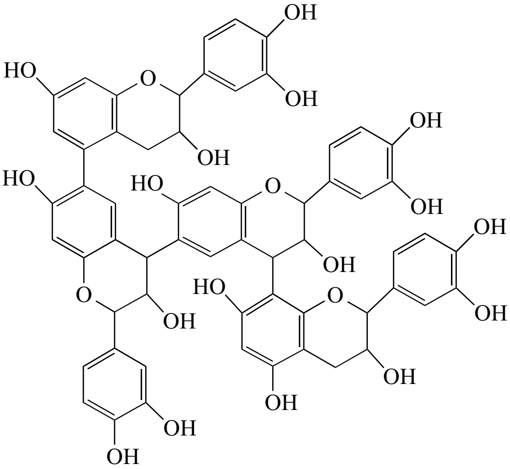


Fig. 1: Tetraflavonoid tanning agent from rhus lancea.

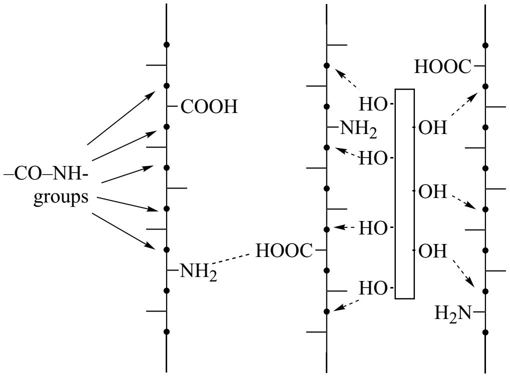

Fig. 2: Diagram showing crosslinking of the collagen chain by vegetable tanning agents.

Ionization and the formation of electrical charges on the skin and tanning agent is necessary so that the electropositively charged free amino groups in the skin cause the electronegatively charged particles of the tanning agent to be discharged thereby resulting in a mutual precipitation.

Vegetable tannage gives leather the characteristic colour of the corresponding tanning agent and a low shrinkage temperature at the same time. Vegetable tanning agents tend to be used as aftertanning agents. Starting products for the production of aromatic syntans include aromatic polynuclear hydrocarbons such as naphthalene and diphenyl, as well as mono and polynuclear phenols such as phenol, cresol and diphenyl ethers as simple aromatic ethers (Fig. 3). The production of synthanes with active tanning properties proceeds through sulphonation of the starting products to condensation with formaldehyde, urea or dimethylol urea.

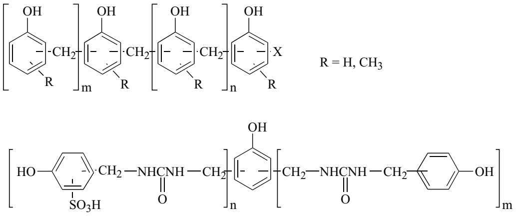

Fig. 3: Structural principle of synthanes.

The water-soluble sulphonated products are linked by bridging groups (–CH_2–) or (–O–CH_2–O–) and become tanning active substances by an additional adjustment of the concentration, pH and acid value.

Vegetable waxes are used as components in textile finishes and sizes, e.g. →: Japan wax; Carnauba wax.

Veining Long incompletely drawn nodules in spun filaments, e.g. in finished polyamide fabrics caused by soiled polyamide starting materials in spinning. These nodules dye much darker than normal filaments.

Velour, warp A French word derived from the Latin vellosus = “hairy”. Velour is a general term for → Warp velvet (→ Velvet). The pile is formed by an additional warp thread system, i.e. two warp thread systems are used, the ground warp and the pile warp, and one weft thread system. Velour is produced as wire and double velvet. Wire velvet can be produced as cut velvet (velour-coupé) with cutting wires, as curled velvet with an uncut pile (velour-frisé) as well as mixed velvet (with alternating cut and uncut pile). Patterned warp velvets are also produced. Numerous modifications exist, e.g. with transverse stripes (velour-chiffon), transparent (velour-transparent), so-called mirror velvet (velour-moiré), or additionally patterned with a swivel embroidery stay. Metal or Lurex threads are frequently used as embroidery threads (velour-broché), etc.

Veloutine,

I. A French dress fabric with a napped finish produced with a thick wool warp that forms cords and a soft merino weft.

II. A lightweight weft-pile fabric with a pronounced twill effect mainly used for linings.

III. A fine cord fabric produced from a silk warp and a wool weft.

Velvet,

I. A pile fabric with a dense short pile. A distinction is made in the case of woven velvet between plain and twill weave velvets (ground weave). The anchored pile loops can have a V-shaped or a W-shaped form. In the nature of things, the W-form is more firmly anchored. A distinction is also made between warp velvet (→ Velours) and weft velvet. Both types of velvet require different finishing treatments. Woven velvet is already cut from the loom, whereas weft velvet is cut only after a pre-preparation in velvet cutting. A large number of special machines are required for finishing weft velvet. Continuous production lines are used for efficient resin finishing. A typical production line consists of a padder with double immersion and an immediate brush roller, a pre-drier with a downstream drum drier, and a beating and raising machine.

Warp-knitting also offers the possibility to produce good velvet qualities which are of particular interest as far as production costs are concerned. An automated warp-knitting machine can produce between 8 and 50 m of grey fabric per hour depending on the article and the speed of the machine. Velvets produced on automated warp-knitting machines are of chief importance as furnishing fabrics, outerwear velvets, trimmings and case linings. The finishing of warp-knitted velvets differs considerably from weft, warp, raschel and other velvets. Unlike the latter, warp-knit velvets are dyed or aftertreated in the still unopened state. The velvet pile is only produced after the drying process by cutting the floating threads on a raising machine followed by subsequent shearing. This has the advantage that the pile cannot be broken or distorted during wet processing. The problem of “shadings” cannot arise under these circumstances. Moreover, loss of pile need not be feared since the pile yarns are firmly anchored in the loop structure of the knitted fabric. Loss of pile can occur, however, if the pile yarns are subjected to abrasion on the back side of the fabric. With outerwear velvets, this sometimes occurs during wear unfortunately. The problem is also not unknown even in the case of woven velvets.

II. A so-called weft velvet with a dense short pile (the term “velvet” is also used for cotton warp-plush). The weft pile yarns are inserted into the stable warp in such a way that they float on the face side of the fabric. These weft pile yarns are then cut in the stretched material and the resulting pile is opened and aligned by brushing.

Velvet carpet (velvet tapestry), a → Plush carpet very similar to a → Tournay carpet but produced by printing.

Velvet/corduroy cutting machines Special cutting machines in which the cutting arm with its extremely low mass inertia follows every lateral or vertical movement of the fabric without backlash. An angle adjustment with a scale on the cutting head enables a reproducible inclination of the knife to be obtained in the cutting channel. With the machine shown in the Fig. particular attention has been given to parallel guidance of the velvet tips to the weft channels. During operation, the main element is guided automatically and requires no further monitoring by the machine operator.

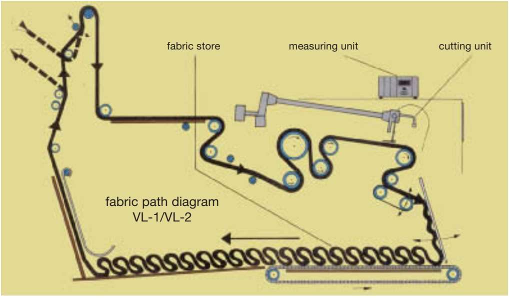

Fig.: Sucker-Müller velvet cutting machine fabric path diagram.

Velveteen A cut weft-pile fabric, usually of cotton or cotton blend, in which the cut fibres form the surface of the fabric to resemble true velvet. The effect is produced by cutting the weft floats after weaving. The finished fabric may be dyed or printed and has a smooth surface covered with short cut pile not exceeding 3 mm in length. Uses: bedspreads, children's wear, draperies, menswear, womenswear, upholstery, trimmings.

Velvet pile carpets A collective term for carpets produced by various methods of manufacture with a cut plush-like pile. → Cut-pile carpets.

I. A cut-pile carpet made in the same manner as tapestry carpets, but substituting cutting wires for looping wires.

II. A non-jacquard carpet with the same construction as a Wilton carpet.

Vented hood All open machines where steam or exhaust gases are produced should be fitted with vented hoods (see Fig.) in order to collect and vent these vapours outside the workplace.

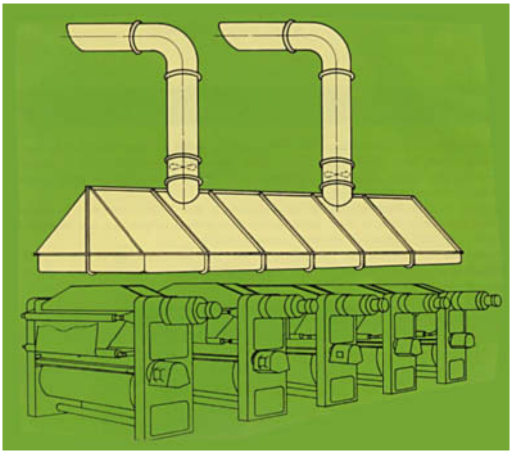

Fig.: Vented hood by Windel.

Ventilation systems → Extractor fans and → Radial fans are used for air extraction and ventilation, to control fresh air input, etc. (for high pressure; → Compressors). Ample air volume requirements/person are as follows: approx. 60 m^3/h for factories and 100 m^3/h for unhealthy working conditions; correspondingly more (+ 25 m^3/h) where gas flames are present. In cases of moderate evolution of harmful vapours or dusts, a complete change of air is recommended 4–6 times/h). The size of extractor fans and radial fans is determined by the quantity of air to be moved and the required air pressure. The latter is mainly dependent on the necessary length of the air ducting. Where suction extraction is carried out from different locations at the same time, the sum of the suction openings must correspond to the cross-section of the main ventilation duct (adjustable shutters are recommended on individual openings).

Ventilation systems in driers Through-flow, jet-flow and parallel- flow ventilation. →: Drying systems; Drying technology.

Venturi (venturi principle, tube, jet). A short tube with a) a narrow throat in the middle to give a constricted cross-section and b) a final section which gradually widens out (so-called diffusor). Fluid or gas passing through the tube speeds up as it enters the throat and the pressure drops, i.e. with the development of a so-called Venturi gradient. The pressure differential is used to measure and control the rate of flow of material passing though the tube (gas, compressed air or liquid). The pressure rises again in the diffusor (b).

Verband Deutscher Maschinen- und Anlagenbau e.V. (VDMA), Frankfurt. German Machinery and Plant Manufacturers'Association. → Technical and professional organizations.

Verdigris Green basic copper (II) carbonate formed on the surface of copper exposed to moist air (patina).

Verdigris stains These are typically blue-green in colour and are often only present on the surface of a textile material. Removal: 1. Ammonia 10–15% (and a fatty alcohol sulphate) warm, followed by hydrogen peroxide 3%. 2. Fatty alcohol sulphate/formic acid 15% warm to hot. Repeat if necessary. 3. Potassium bifluoride 10%.

Verein der Textilchemiker und Coloristen (VTCC, Union of Textile Chemists and Colourists). German professional organization for practitioners and scientists. It continues the tradition of the earlier IVCC with cooperative research, practical and scientific lectures, discussions and summarising reports as well as through furthering the exchange of ideas with like-minded foreign organizations. Cooperative member of the → IFVTCC. Business address: Heidelberg. Official publication: Melliand Textilberichte (textile reports). → Technical and professional organizations. → VDTF.

Verein Deutscher Chemiker (VDCh, Union of German Chemists). Defunct general professional organization (1887–1945) whose traditions have been continued since 1946 by the Gesellschaft Deutscher Chemiker (Society of German Chemists) → GDCh. → Technical and professional organizations.

Verein Deutscher Textilveredlungsfachleute (VDTF). Since 2000 union of → VDF and → VTCC.

Verein Österreichischer Textilchemiker und Coloristen (VOeTC). Austrian Association of Textile Chemists and Colorists. An Austrian organization, which is a cooperative member of the → IFVTCC, → Technical and professional organizations.

Verein Textildokumentation und -information e.V. (VTDI, Association for Textile Documentation and Information). Founded in Frankfurt towards the end of 1980 as a new body in the FRG to house the Textile Documentation and Information System →

TITUS, it commenced operation on 01.01.1981. The founding members are, in addition to the VDI which can no longer itself house the system, the Gesamttextil (Gesamtverband der Textilindustrie in der Bundesrepublik Deutschland e.V.) and the Fachgemeinschaft Textilmaschinen im VDMA (both associations for firms using the system), as well as textile research institutes (producers of information) and specialist publishers (disseminators of information). The hope is that this cooperative undertaking, which is unique in the FRG, will be able to support companies in taking up the results of research and development more rapidly into actual industrial practice.

Vertical company A fully-integrated manufacturing company, e.g. a textile company that undertakes all the processing stages from the fibre to finished product including spinning, weaving or knitting, finishing and, in many cases, garment manufacture as well.

Vertical drier A sieve-drum drier of vertical design based on the through-flow principle which offers the highest heat transmission coefficient and maximum drying performance in the smallest space. Heat recovery is determined by the machine construction. The specific heat losses in this type of drier are low due to its compact design and effective heat insulation (without thermal bridges).

Vertical finisher Whilst a commission finisher must have a wide range of flexible machinery at his disposal in order to be in a position to carry out all the necessary finishing processes and satisfy a variety of customer requirements, a vertical finisher (owner-operator or integrated finisher) tailors the development of his merchandise to whatever machinery and process technology is available to him. The vertical finisher therefore has an advantage (see Tab.) over the commission finisher who receives his goods horizontally (i.e. at the same level as the company placing the order) → Organizational structures in textile finishing.

Commission finisher	*Vertical finisher*
Finishing process tuning singeing, desizing, bleaching, mercerising rope treatment, open-width treatment, relaxing, stabilising, dyeing, printing, finishing	Tuning, grey fabric, fibre, yarn spinning process, setting of the weave size

On the finished fabric Width, weight, degree of whiteness, dyeing, accuracy of shade, fastnesses, residual shrinkage, reproducibility	On the finished fabric (width, length, shrinkage, appearance, accuracy of shade, fastnesses)

Tab.: Differences in commissioner and vertical finisher product development.

Vertical flammability test → Flammability test.

Vertical migration (selective migration). The variable rate of migration of a dye combination through the cross-section of a textile fabric. This behaviour is exploited intentionally for the production of → Two-sided effects by vertical migration between the face and back sides of a textile material to give either a different colour on each side (two-colour effect) or different depths of the same shade (dark/light effect). → Migration.

Vertical open-width washing machine A machine with a series of open-width compartments (see Fig.) for washing off or impregnating fabrics with chemical liquors (e.g. in pretreatment). → Roller vat.

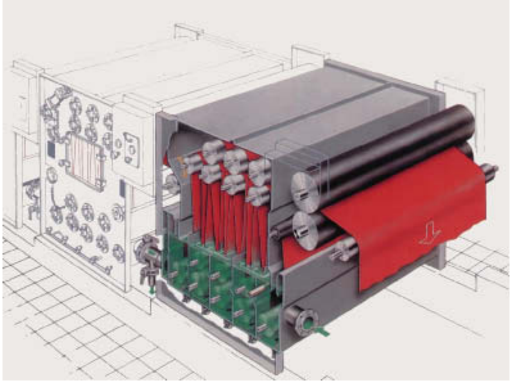

Fig.: Vertical open-width washing machine (Kleinewefers KTM).

Vertical padder A → Padder with a vertical arrangement of squeeze rolls.

Vertical roller printing machine A roller printing machine formerly produced by Saueressig (Germany) with a vertical arrangement and an individual pressure roll for each engraved printing roller or rotary screen. The colour boxes, doctor blades and furnisher rollers are all mounted on a hinged sub-frame which can be swung to one side (like a gate) thereby offering the advantage of easier and quicker servicing compared to conventional roller printing machines. Specially constructed pressure rolls adapt themselves automatically to any bending distortion of the engraved printing

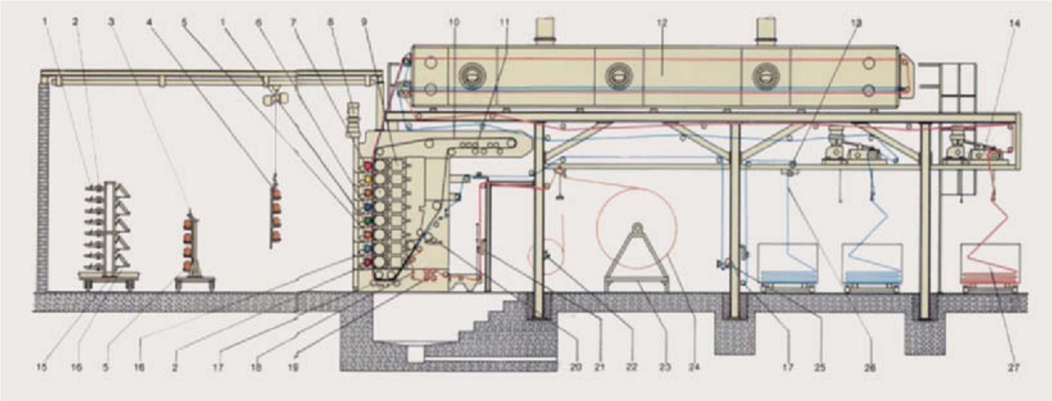

Fig.: Saueressig vertical roller printing machine (portal roller printing). 1–10 = printing zone; 11–20 = periphery; 21–27 = passage of fabric.

rollers. Print paste is fed to the printing heads automatically (see Fig.).

Vertical space-dyeing printing unit A development for → Space-dyeing (Micro-Space) with vertical fabric transport from bottom to top and up to 6 pairs of printing rollers (print stations) as modular units. Splashing of print pastes at high speeds is prevented with this system and the practical application of lint doctors is possible.

Vertical star dyeing machine An upright star dyeing machine where vertical movement of the loaded star frame in the dye liquor is actuated by a cam.

Vertical sueding machine (sanding, emerizing). A surface finishing machine for the → Sanding and → Emerizing of knitted and woven fabrics. The fabric runs tangentially against the sanding resp. emerizing rollers.

VI,

I. → Viscose fibres, → Standard abbrev. for textile fibres according to the → EDP Code; → CV.

II. Abbreviation for → Viscosity index.

Vi → Vicuna, → Textile fibre symbols, according to DIN 60 001 until 1988, from 1991 → WG.

Vibraire process A continuous felting process for yarns and slivers co-developed by the Fibre Research Institute TNO Delft and the IWS England. The yarn is passed, together with the felting liquor, through a tube which is subjected to intense vibrations (also known as the Periloc process).

Vibrating open-width washing machine An open-width washing machine consisting of a series of roller vats (countercurrent principle) which uses vibrating elements between the ascending and descending fabric web (see Fig.) to achieve a more intense washing and rinsing effect.

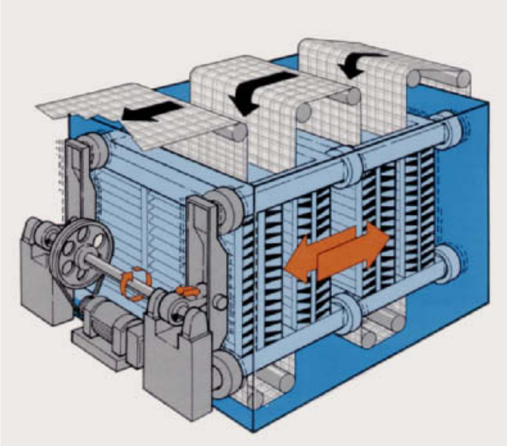

Fig.: Vibrating open-width washing machine (MAT).

Vibrating steamer A steaming device for the relaxation of elastic materials which utilizes the combined action of a short steam shock and intense vibration. The treatment makes it easier to handle such materials in cutting and garment making.

Vibrator units Special vibrating elements designed to achieve more rapid movement of processing liquors and/or a textile fabric in order to intensify the washing effect in, e.g. open-width washing machines (see Fig.).

Vibratory felting machine A machine for the production of plate felted (technical felts) from wool.

Vichy,

I. A cotton dress fabric generally made with two different coloured yarns.

II. A gingham fabric with a stiff finish frequently made in large checks and plaids in Spain, Chile and Bolivia.

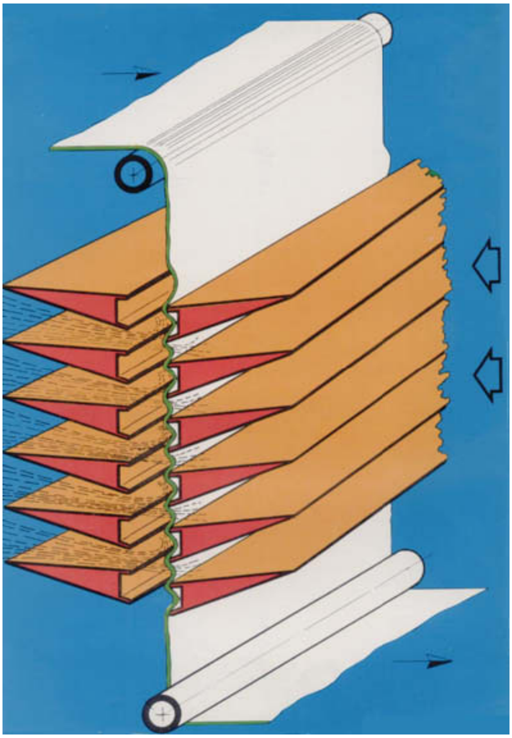

Fig.: Vibrator device on a continuous washing machine (MAT).

III. A fine gingham produced in Serbia.

IV. An inexpensive gingham and yarn-dyed cotton plaid produced in Turkey usually with a stiff starchy finish.

Victoria Blue 4R (CI 42 563). Victoria Blue 4R colourings are used to distinguish between different man-made fibres, particularly regenerated cellulose fibres, and for improving the visibility of fibre structures under the microscope when no dark-field illumination is available.

Victoria Blue B test (Sieber test). Cationic blue dye for examining raw and bleached vegetable fibres. The reduced fibre sample is boiled in 3% solution for 0.5–1 min. This is then thoroughly rinsed with distilled water repeatedly and dried. Raw cotton turns deep dark blue and bleached cotton turns pale blue.

Vicuna South-American fine → Animal hair fibres from the vicuna, related to the llama and the guanaco (Peru and Bolivia). Only the undercoat hair is processed – deep yellow to reddish brown, soft, silky-glossy, curly and fine (10–20 µm, around 84 scales/mm).

Vienna chalk Finely milled pure dolomite which consists of calcium magnesium carbonate $CaCO_3 \cdot MgCO_3$, density 2.8–2.95. Source: Dolomites, German Mittelgebirge and similar places. Examples of use: in working up chlorinated hydrocarbons (neutralization); where there is no free acid, Vienna chalk causes alkaline corrosion of non-ferrous metals and → Blue water phase on copper (also decomposes relatively solid N compounds).

Vigoureux printing (tops printing). Diagonal or transverse striped printing of combed wool tops (using relief rollers). The twisted and drawn (Fig. 1), essentially homogenous blends produce mixtures of different-

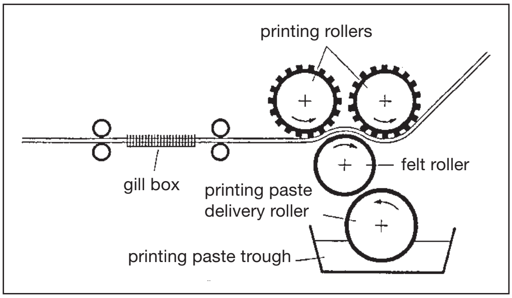

Fig. 1: Diagram of classic vigoureux printing on wool tops.

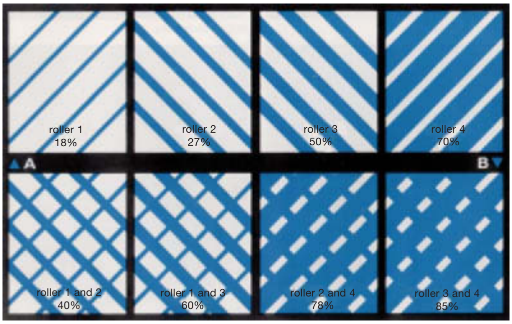

Fig. 2: Vigoureux printing rollers print formats with strips of varying width (A) and twin roller print possibilities (B). The percentages indicate the printed area of the combed top (according to Bayer).

Fig. 3: Typical vigoureux patterning on combed tops (Fleissner).

coloured fibre. In most cases, black is used for printing which gives grey colour-blend effects depending on the depth of colour in the mixture and cover in non-printed areas. Printing with metal-complex and chrome dyes is preferred on combed top wool but is also carried out on polyester with dispersion dyes and polyacrylonitrile with cationic dyes. Zebra-striped patterns (Figs. 2–3) are produced which blur after drawing and spinning.

Vigoureux yarn Mottled yarn which is made by printing stripes in a single colour on combed top in → Vigoureux printing and then doubled and stretched several times.

Vinal American generic name for polyvinyl alcohol fibres (→ Vinylon) containing at least 50% vinyl alcohol, i.e. more than 85% by weight vinyl groups. According to DIN 60 001: a minimum of 85% by weight vinyl alcohol or vinyl acetate.

Vinyl Abbrev. for → Polyvinyl chloride.

Vinyl acetate (acetic acid vinyl acetate). Colourless liquid with characteristic smell, $CH_3COOCH{=}CH_2$; melting point –93°C; boiling point 72°C; glass transition temperature 29°C. Industrial manufacture is carried out by the addition of acetic acid to acetylene:

$$\underset{\textit{acetylene}}{HC{\equiv}CH} + \underset{\textit{acetic acid}}{CH_3COOH} \xrightarrow{Hg^{2+}} \underset{\textit{vinyl acetate}}{CH_3COOHC{=}CH_2}$$

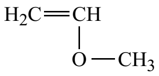
In the presence of heat, light and peroxides, vinyl acetate easily polymerises to → Polyvinyl acetate. Acetates exist which are based on pure vinyl acetate polymers (homopolymers) or on superficially softened polyvinyl acetate dispersions, i.e. dispersions containing softeners. Vinyl acetate polymers freely dissolve in organic solvents. Vinyl acetate copolymers are used in various adhesives, binders, coating agents and film formers, etc.

Vinylal According to DIN 60 001, generic name for fibres based on → Polyvinyl acetate, i.e. acetylated, making the polyvinyl alcohol fibres insoluble in water (→ Vinal).

Vinylbenzene → Styrene.

Vinyl cyanide → Acrylonitrile.

Vinyl ether Colourless liquid (manufactured by reacting acetylene with alcohols at high temperature and pressure) such as vinyl methyl ether. Resistant to alkalis. Hydrolyses completely on heating with dilute acids. Reacts with the hydroxyl groups on cellulose. Starting material for → Polyvinyl ethers.



$$H_2C{=}CH{-}O{-}CH_3$$

Vinyl group $H_2C{=}CH{-}$. Component of vinyl derivatives and polyvinyl derivatives.

Vinylidene chloride $CH_2{=}CCl_2$, identical to asymmetrical → Dichloroethylene.

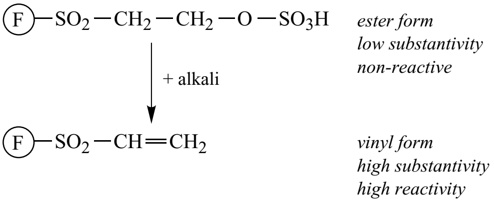
Vinylidene fibre → Polyvinylidene chloride fibres.

Vinylidene group $CH_2{=}CR_2$, → Polyvinylidene group.

Vinylon Since 1948, generic name for polyvinyl alcohol fibres made in Japan (→ Vinal).

Vinyl resins →: Polyvinyl alcohol; Polyvinyl acetate; Polyvinyl chloride.

Vinylsulphone dyes As a Sulphatoethylsulphone dye, the commercial form contains a protected reactive group. In this ester form, they only have moderate substantivity. The actual reactive dye, vinyl sulphone, is not released until the required alkali is added for dyeing to take place. In this form, the dye is now reactive showing high substantivity.



Although automated, progressive alkali dosing offers advantages in the case of all reactive dyes, due to the chemical structure of vinyl sulphone dyes, they are particularly suitable for this method. One application variant consists of initially adding a relatively weak alkali, such as sodium carbonate, to start the process and not adding the stronger alkali until a high level of fixing has already been achieved. The quantities of alkali added and the periods between the additions should be maintained exactly to ensure a high level of reproducibility. Obviously, methods such as these are labour intensive and, therefore, oppose the trend towards increasing efficiency and quality.

Collaboration between Adcon AB in Sweden and Hoechst AG in Germany has resulted in the develop-

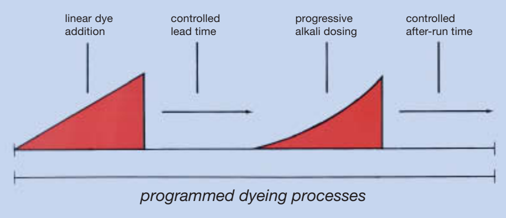


Fig.: Dosing programme in dyeing with vinylsulphone dyes (Remazol Automet, Hoechst).

ment of dosing equipment and a method which can be used to control and optimise the fixing behaviour and eliminate the disadvantages of conventional dyeing methods. The principle used in this method relies on the automated, progressive addition of alkali at the dyeing temperature. It is a constant-temperature dyeing process which operates at 40°C, 60°C or 80°C. The process operates the same way at all three temperatures (Fig.).

In principle, all alkalis usually used in reactive dyeing can be used. Out of economic considerations and because of handling, caustic soda solution is used in preference. In the case of pale shades only, it is buffered by small amounts of sodium carbonate or replaced with the latter. Corresponding recommendations for alkalis are available in the form of alkali diagrams when dyeing at 40°C, 60°C and 80°C, both in the case of mercerised cotton or viscose and in the case of non-mercerised cotton.

Vinylsulphone group $–SO_2–CH=CH_2$. Reactive group which reacts with the OH groups of cellulose: $–SO_2–CH_2–CH_2–O–Cell$ in the presence of alkali. Important compound with masked vinylsulphone group, for example:

$$–SO_2–CH_2–CH_2–O–SO_3H \rightarrow –SO_2–CH=CH_2.$$

Bifunctional compounds used as high-grade finishing aids are known as: → Divinylsulphone compounds; → Vinylsulphone dyes.

Vinyon American generic name for polyvinyl chloride fibre with at least 85% by weight vinyl chloride.

Virgin wool,

I. Commercial name derived from the method of recovery of wool which has been shorn from live sheep and has not yet been spun or filtered or been subjected to a recovery process which damages the fibres. In contrast to this is → Skin wool (fellmongered wool), →: Pelts; Fallen wool; Recovered wool or → Reclaimed wool. The quality symbol for virgin wool is the → Woolmark. Virgin-wool blend tolerances: for visible decorative effect, 5% (in the case of woolmarked products) or 7% (according to the textile labelling regulations), for unavoidable extraneous fly fibres 0.3%.

II. (South Africa), expression analogous to pure wool.

Viscoelastic behaviour → Rheological behaviour of solutions.

Viscoelasticity Property of a substance which, when subjected to shear, compressive and tensile stresses, shows both viscous and elastic properties (→ Viscosity, → Rheology). Plays a decisive role in textile printing. As the polymer molecules are subjected to increased stress, the viscosity of the swollen thickener spontaneously drops and increases again as the stresses are relaxed.

Viscometers Instruments for measuring → Viscosity.

I. Capillary viscometer. This type of viscometer is filled with the fluid which is to be measured, as shown in Fig. 1. When the small bulb on the left hand side is filled with the liquid, the fluid level should be approximately in the middle of the bulb on the right. The time taken (t) for the fluid level to fall from the upper mark S_1 to the lower mark S_2 is then measured. The bulb on the right must be large enough for the increase in the level of the fluid inside it to be negligible when the level in the other side falls. In order to calculate the viscosity from the equation below, it is necessary to know the pressure ΔP due to gravitational force.

$$V = \frac{\pi \cdot r^4 \cdot \Delta P}{8\,\eta\,l} \cdot t$$

This is obtained from the density of the fluid ρ, the acceleration due to gravity g and difference in height h of the two levels of fluid. $\Delta P = \rho g h$. Using this relationship, the equation for viscosity becomes:

$$\eta = \frac{\pi g r^4 h}{8 l V}\,\rho\,t.$$

The parameters, acceleration due to gravity and parameters associated with the specified set-up measurements are represented in the experimental constant:

$$C = \frac{\pi g r^4 h}{8 l V}$$

to give:

$$\eta = C\,\rho\,t.$$

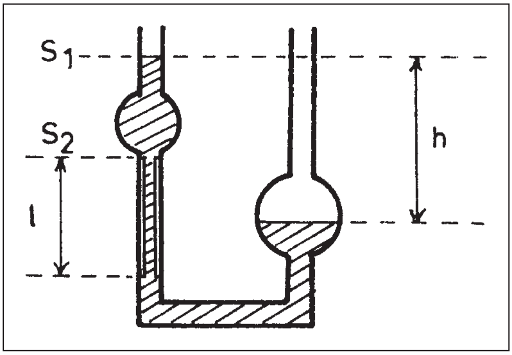

Fig. 1: Diagram showing how a capillary viscometer works.

The experimental constant for the viscometer is obtained by calibrating it with water at 20°C ($\eta = 1.0002$ mPa s), the flow time being determined several times over. An Ostwald viscometer essentially consists of a U-tube, one arm of which is in the form of a capillary. Bulbs are situated above and below the capillary. The volume of the top bulb is bound by two marks. Disadvantage: not suitable for determining intrinsic or non-Newtonian viscosity (→ Rheological behaviour of solutions). Instruments: Ostwald, Ubbelohde and Bingham, etc. Measurement range 10^{-3} to 10^{11} Pa s. Sucker viscometers are suitable for monitoring liquor viscosities where the viscosity varies with differential pressure.

II. Flow cup: the time taken for a given quantity of fluid to flow through a tube at test temperature is measured and compared with the behaviour of a standard fluid (water). Disadvantage: the fluid level and, therefore, the magnitude of the shear stress continually changes throughout the measurement. Conversion of the measurement units into Pa s is only possible for Newtonian fluids. Measurement range 10^{-} to 10^{11} Pa s. Known instruments are the Engler, Ford and DIN flow cup instruments.

III. Falling-ball viscometer: the viscosity is determined by measuring the time taken for a ball to fall in a tube filled with the test fluid. The results obtained are precise and reproducible. Data in Pa s is only possible for Newtonian fluids (while taking density into account). The shear stress cannot be measured. This method is not suitable for measuring non-Newtonian viscosity. Instruments: Höpler viscometer, etc. Measurement range 10^{-5} to 10^{11} Pa s.

IV. Rotary viscometer (Fig. 2): various shaped impellers rotate in the fluid. Measurement range 10^{-4} to 10^{11} Pa s. It is easy to understand how this measurement system is derived from the Newtonian parallel plate model by imagining the level parallel plates bent as inner and outer cylinders. A substance found in the circular gap can be subjected to a defined shear force as in the Newtonian model.

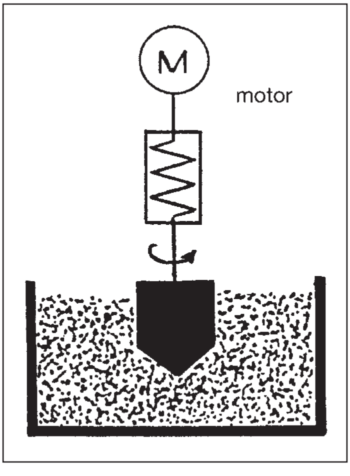

Fig. 2: Rotary viscometer without defined slot.

There are two different ways of realizing this geometry in viscometers:

1. A defined shear force is imposed on the inner or outer cylinder (using a defined torque) while the other cylinder is at rest. A certain shear rate or characteristic speed is measured which is defined by the resistance of the sheared substance due to its viscosity.

2. The shear rate is applied (inner or outer cylinder rotates with defined speed) and the shear force determined by the viscosity of the substance acting on the walls of the inner cylinder is measured. Most viscometers operate using the second measurement principle. This can be classified into two types as follows (Fig. 3):

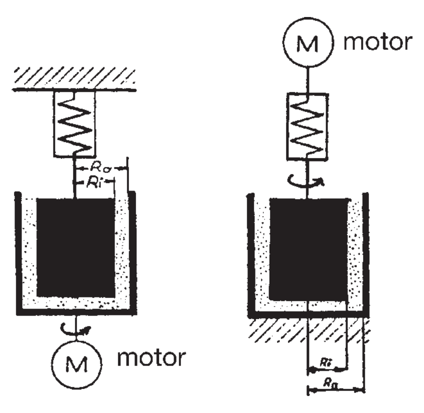

Fig. 3: Rotary viscometer with defined slot: Couette system (left) and Searle system (right).

a) The Searle system: In this case, the inner cylinder rotates at a constant or variable speed while the outer cylinder is at rest. The rotating cylinder causes the substance to flow and the resistance exerted by the substance being sheared is proportional to the viscosity-dependent torque or effective shear stress. The measuring element for this torque is a distorted steel spring located between the drive motor and the axle of the inner cylinder. The spring distortion is a direct measure of the viscosity of the test substance.

b) The Couette system: In contrast to the Searle system, the outer cylinder is rotated causing the fluid to flow while the effective shear stress is transmitted to the inner cylinder, which would rotate with the outer cylinder if it were not prevented from doing so. The torque on the inner cylinder is measured by determining the counter force required to prevent it from rotating.

The Searle system is the method which is most frequently adopted in the manufacture of viscometers. The reason for this is the ease with which the temperature of the test substance can be controlled and the many different ways in which it can be used. Thus, viscosity ranges from low to extremely high can be measured. However, there is one restriction: the measurement of very low viscosities leads to non-laminar flows (< 3 mPa s), so no sensible values can be expected.

V. Vibration viscometer: relies on the determination of the damping effect of the fluid on the vibration of the vibrator. It is suitable for testing viscoelastic behaviour (→ Rheological behaviour of solutions). Measurement range 10^{-8} to 10^5 Pa s.

VI. Compression or extension viscometer: viscous media are compressed or stretched between two plates. Deformation is measured relative to time. This method is suitable for determining the viscoelastic properties of high polymers. The measurement range is from 10^3 to 10^8 Pa s.

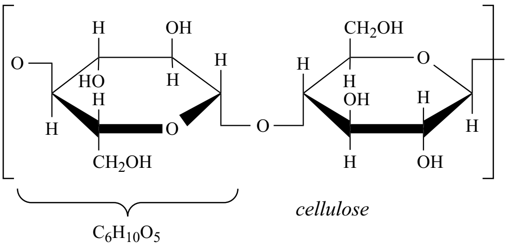
Viscometer, torsion type (visco printogram). Used to determine the → Viscosity of printing thickeners; → Viscosity of printing pastes.

Viscose,

I. Spinning paste, thick, viscous, made from alkali cellulose and carbon disulphide dissolved in caustic soda solution. Starting material for → Viscose fibres.

II. Short for → Viscose fibres.

Viscose fibre properties in comparison to other cellulosic fibres Cellulose fibres are classified into native cellulose fibres (cotton) and regenerated-cellulose fibres (viscose and modal). The chemical structure of both types of fibre is identical:



cellulose

Chemical reactions with the cellulose fibre take place on the cellulose molecule. For example, a reactive dye reacts with the functional groups on the molecule, which in the case of cellulose, are OH groups. In preference, a dye will react with primary groups (the –CH_2OH groups on the outside of the molecule). Only 1% of the OH groups on the cellulose react in reactive dyeing, but this is sufficient for deep dyeings. The differences between cotton, viscose and modal are due to their different physical structures, i.e. the fine structure of the different types of fibre. The fine structure of the fibre is determined by the combination of monomers and chain molecules, the way they are bundled into crystalline and amorphous zones and the fibrils which usually lie parallel to the fibre axis.

Each fibre is characterised by highly ordered crystalline zones, non-crystalline, i.e. amorphous zones and non-crystalline, semi-amorphous zones of chain molecules.

The amorphous zone in cotton is identified by its reversible swellability in water. In contrast to its reversible swelling property in water, in caustic soda, the whole fibre structure swells irreversibly as the crystal lattice is converted from cellulose I to cellulose II.

The crystal lattice of viscose fibre is cellulose II. The non-crystalline chains are significantly disoriented as the fibres are spun from solution and crystallise out of solution. At the same time, when a viscose fibre is dried and then made to swell again in water, the cellulose molecules in the non-crystalline zones take on a rather randomised structure which hardly changes. In contrast to the regenerated cellulose, the number of hydroxyl groups in the non-crystalline zone of cotton make themselves noticeable by the effect that moist cotton fibres with the cellulose I lattice are more solid than dry fibres.

In the case of cotton, this phenomenon is explained by the randomised molecular chains in the non-crystalline zones becoming ordered, albeit reversibly, as the water molecules penetrate into the structure. When the quantity of water reaches a critical level, the hydrogen bonds are broken and internal stresses in molecular chains are removed. This behaviour of cotton differs from that of regenerated cellulose as native cellulose crystallises out from the liquid crystal state. The amount of water bound to cotton is again subdivided (unlike viscose) into 19.8% "non-freezable" and 2.2% "freezable" water.

The regenerated modal fibres of the high-wet modulus types (HWM) represent a special case in comparison to conventional viscose. During the development of modal fibres, the most important criteria was to achieve reduced swelling and a reduced tendency to shrink. Investigations have shown that the disadvantages of conventional viscose mentioned are due to a wet modulus which is too low. The modulus describes the amount a fibre stretches under a given load (the relationship between bad and extension) – the smaller the extension for a given load, the higher the modulus and the greater dimensional stability of the textiles manufactured from these fibres. Such fibres may only be called modal fibres if the amount they stretch under a load of 22 cN/tex in the wet state does not exceed 15% which, according to the definition, is the same as having a high wet modulus.

Another characteristic difference is the essentially higher average degree of polymerisation (DP) of modal spinning solution in comparison to that of viscose.

While a drop in the DP to 280 must be accepted when producing standard viscose fibres, the values achieved for high wet modulus types exceed 500. Coagulation of the spinning solution takes place in the precipitating bath with significantly reduced sulphuric acid and sodium sulphate concentrations and is relatively slow. This means that high drawing is possible which causes the cellulose molecules to be highly oriented.

The following differences may be summarised for the different types of fibre, cotton, viscose and modal:

Conventional viscose fibres have lower strengths and higher stretching properties than cotton. The DP of viscose is lower, as is the degree of orientation, which is 30–40% lower than that of cotton (50–60%).

Compared with cotton, modal fibre does have a weaker tensile strength/extension ratio in the wet state. Its other properties, however, such as water retention values, which range from around 60–70%, are very similar to those of cotton. In comparison with cotton, modal and viscose fibres have the following advantages which are mainly the result of their being regenerated fibres: uniform quality, large capacity for variation with regard to staple length and titre, high purity and therefore better spinnability and a soft silky handle.

The advantages of modal fibres over viscose fibres are found in their essentially high strengths in the conditioned and wet state, higher wet modulus, lower water retention values, reduced swelling properties and higher resistance to alkalis.

Due to the variation in the additions in the spinning solution and spinning bath, a DP of 180–280 is achieved for standard viscose fibres (cotton type) and 250–380 for modal fibres (high wet modulus type), although the DP of both the starting cellulose (800–1200) and the spinning solution (300–700) is the same for both types of fibre.

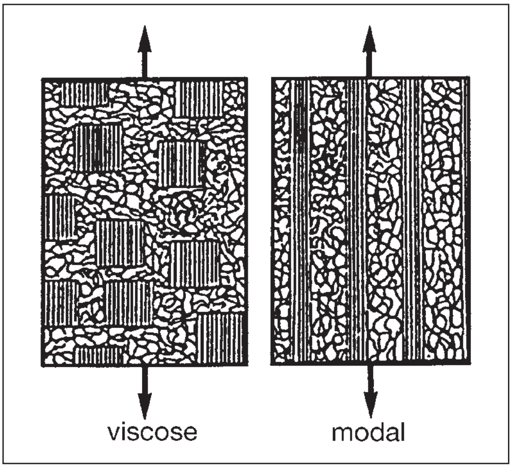


Fig.: Difference in the sub-microscopic structure of crystalline and amorphous areas of viscose and modal fibres.

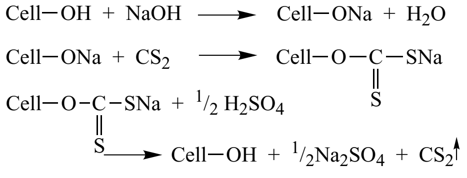
The differences between viscose fibres and cotton can be explained by their different crystal-lattice structures. This results in a weaker load/extension ratio for viscose fibres, both in the conditioned as well as the wet state. Other characteristics typical of viscose fibres are pronounced swellability, high moisture absorption, lower shape retention as well as the need for improvement in breaking strength and abrasion resistance.

The regeneration process has been so well mastered that it is possible to alter the morphology, degree of orientation and orientation of the fibre at will. Based on this knowledge, cellulose fibre groups can be developed which are very similar to those of cotton. Representatives of these modal fibres are the polynosic and high wet modulus types. Polynosic fibres have good shape retention, increased linear strength and are easier to mercerise in comparison to standard viscose fibres. The high wet modulus types have around 50–70% higher lateral strength; thus, under certain conditions they are also easier to mercerise, are less resistant to bending and do not fibrilate. At 60–70%, their water-retention value is of the same order as that of cotton. The properties listed predetermine these fibres for use in mixed processing with natural and man-made fibres.

The difference in the structure of regenerated fibres from that of cotton (Fig.) results in their having different properties. Thus, conventional viscose fibres have lower strengths, higher water-retention, a greater susceptibility to creasing and a higher stretching ability than cotton.

Viscose fibres Regenerated fibres made from the renewable raw material "cellulose" can only be wet-spun as filaments in precipitation baths with the aid of special solvents for the base polymer. The compounds shown in Fig. 1 are used for the classical solvent-precipitation bath system.



$$\text{Cell}-\text{OH} + \text{NaOH} \longrightarrow \text{Cell}-\text{ONa} + H_2O$$

$$\text{Cell}-\text{ONa} + CS_2 \longrightarrow \text{Cell}-O-\underset{\substack{\| \\ S}}{C}-\text{SNa}$$

$$\text{Cell}-O-\underset{\substack{\| \\ S}}{C}-\text{SNa} + {}^{1}/_{2}\,H_2SO_4 \longrightarrow \text{Cell}-\text{OH} + {}^{1}/_{2}Na_2SO_4 + CS_2\uparrow$$

Cellulose is immersed in approx. 18% caustic soda solution where the alkali cellulose is formed, a greatly swollen but non-solubilised material. The alkali cellulose is brought into contact with gaseous or liquid carbon disulphide to form the cellulose xanthate, an unstable compound which dissolves in caustic soda solution. It is spun into an aqueous solution containing salt and acid. The salt promotes coagulation and the acid neu-

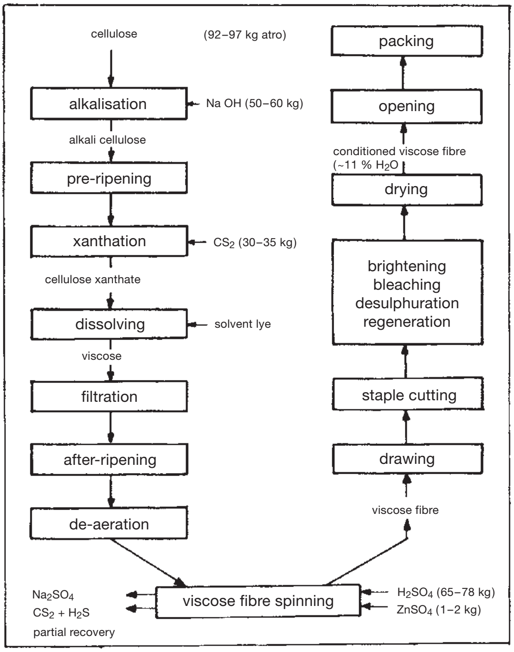


Fig. 1: Diagram of viscose staple fibre production (consumption in kg/100 kg of conditioned fibre).

tralises the alkali and decomposes the xanthate. This process regenerates the cellulose in the form of continuous fibres which are known as viscose fibres.

While the cellulose is regenerated, sodium sulphate and carbon disulphide are formed, the latter being released in the form of a gas. Some of this carbon disulphide is condensed and recovered. The carbon disulphide which is not condensed is washed out and the components with an unpleasant smell are removed.

During the stage when the xanthate is formed, a side reaction takes place during which the carbon disulphide partly reacts with the sodium hydroxide in the alkali cellulose. This produces sodium trithiocarbonate via various intermediate steps.

$$3\,CS_2 + 6\,NaOH \rightarrow Na_2CO_3 + 2\,Na_2CS_3 + 3\,H_2O$$

The characteristic orange colour of viscose is explained by the presence of the sodium trithiocarbonate.

It cannot be overlooked that the production of regenerated cellulose fibres is associated with significant shortcomings, i.e. the poor ecology of the most commonly used viscose processes due to the emission of CS_2 and H_2S. This problem has been known for some time, so a considerable amount of work is being undertaken to

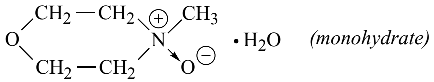
a) increase the safety of the viscose process at higher productivity by improving the industrial technology (for this, there are examples which are effective for production)
b) look for alternative solvents for cellulose and develop new processes.

A series of new aqueous and non-aqueous solvents has been discovered for cellulose (Tab. 1).

The “Newcell” process uses N-methylmorpholine oxide (NMMO) as a solvent for cellulose.

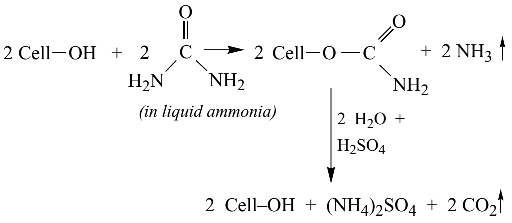
Amine/dimethyl sulphoxide	NH_3/NH_4SCN
N-methyl morpholine-N-oxide	Phosphoric acid
$(HCHO)_x$/dimethyl sulphoxide	$ZnCl_2$/water
N_2O_4/dimethyl formamide	LiOH/water
LiCl/dimethyl acetamide	
LiCl/urea derivatives	

Tab. 1: Unconventional solvents for cellulose (left), with precipitating bath (right).



A stabiliser is added to reduce the interactions of the redox system which is produced (cellulose is reducing and, at high temperatures, N-methylmorpholine oxide is oxidizing).

The “Celca” process is based on the dissolution mechanism and precipitation reaction:



CS_2-free processes for the production of regenerated cellulose fibre are

- the process for producing tencel fibres which was developed by Courtaulds;
- the Akzo process for spinning newcell fibres;
- the Lenzing process for spinning lyocell fibres.

These fibres have completely round cross sections, smooth surfaces and modified cohesion properties, high wet modulus, high dry strength as well as a pronounced tendency to fibrilate.

Viscose fibres

Cellulose triacetate dissolves in trifluoroacetic acid (or in the cheaper and less toxic alternative, concentrated nitric acid). The 30–50% solution is anisotropic, i.e. liquid crystals are formed in the solution, which after a sharp increase in the viscosity, at the critical point, leads to a subsequent decrease in viscosity. When spinning these types of high-concentration but low-viscosity liquid-crystal solutions using "air gap" technology, triacetate fibres can be spun which then yield regenerated cellulose fibres after saponification.

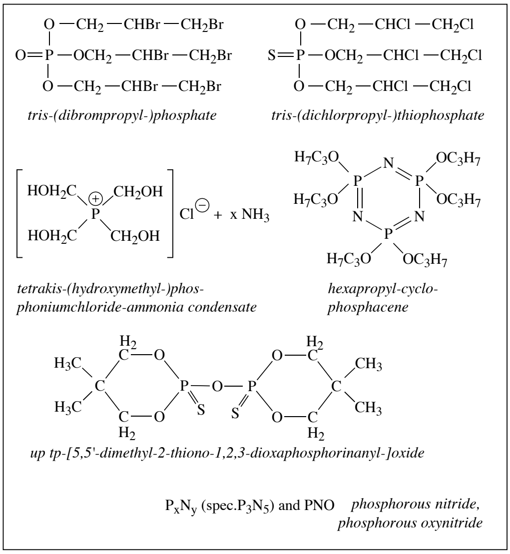


Fig. 2: Examples of core spun agents for flame retardation of viscose fibres.

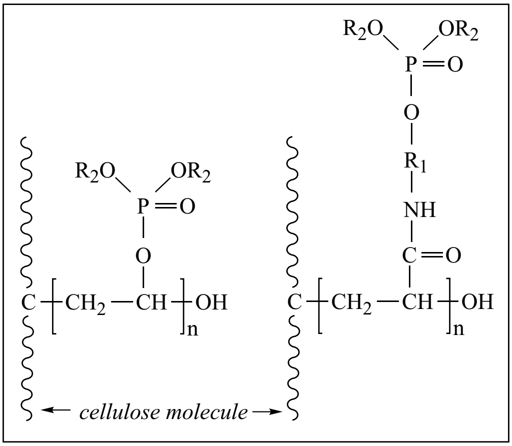

Fig. 3: Examples of achieving flame retardation of cellulose fibres through graft modification.

Flame-resistant viscose fibres can be produced in the cellulose xanthate by adding phosphorous compounds (as well as graft polymers) to the melt (Figs. 2–3).

Cellulose exists in different crystalline configurations of which the most important are cellulose I and cellulose II.

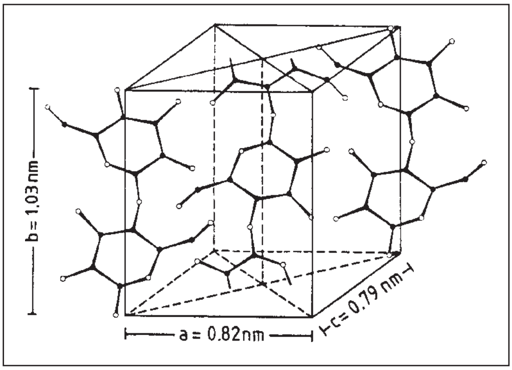

Fig. 4: Layers in cellulose I linked by hydrogen bonds in the elementary (unit) cell (radioscopic) according to Fengel.

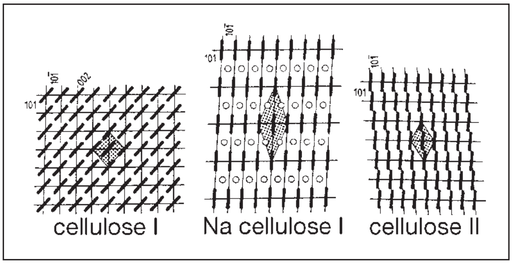

Fig. 5: Transition of cellulose I into cellulose II.

While the natural product is characterised by cellulose I, cellulose II appears in regenerated cellulose products. In comparison to cellulose I, cellulose II is thermodynamically more stable. An intramolecular hydrogen bond exists on both sides of the oxygen atom in cellulose I (Fig. 4) linking the two neighbouring anhydroglycose units. Apart from this, there are also intermolecular hydrogen bonds. In the arrangement of cellulose II (Fig. 5) there is only one hydrogen bond parallel to the oxygen atom link. Thus, the number of intramolecular bonds found in cellulose II is only half that found in cellulose I. As the intramolecular hydrogen bonds contribute to the rigidity of the polymer chain and their number is only half that of cellulose I, their contribution to the rigidity of cellulose II is lower. Thus, the theoretical modulus (a measure of stiffness) of cellulose II is lower than that of cellulose I. With their cellulose II configuration, viscose fibres have a lower modulus than that of natural cellulose fibres such as cotton, jute, hemp, flax and ramie, etc.

It is generally accepted that the polymer chains in cellulose I run parallel to each other and that in cellulose II they have a stable anti-parallel arrangement. In cellulose II, the chains are arranged in parallel in a particular plane in the crystal lattice. On the next plane, however, they are oriented in the opposite direction, i.e. they run non-parallel to the first plane. This gives rise to the problem that this material swells significantly when cellulose I is immersed in a caustic solution, although it continues to remain in the solid state. Nevertheless, it appears as if the cellulose structure transforms itself into the crystal lattice of cellulose II on regeneration. This means that all the lattice planes in the solid state have switched round by 180°, which is difficult to explain.

The shape and arrangement of the molecules are also decisive, apart from the length of the chains which is determined by the DP. In the case of viscose, the macromolecules are oriented axially during production due to stretching. At the same time, the chains are in a position to form sub-microscopic crystallites. High-strength fibres result from a high level of orientation, an ordered zone involving a bundle of 40–60 macromolecules. X-ray analyses have shown that 40% of the fibre substance in the case of viscose fibres and 70% in the case of cotton is found in crystalline zones which alternate between amorphous segments. The molecular chains are partly folded (Fig. 6) and form a so-called fringed fibrila structure.

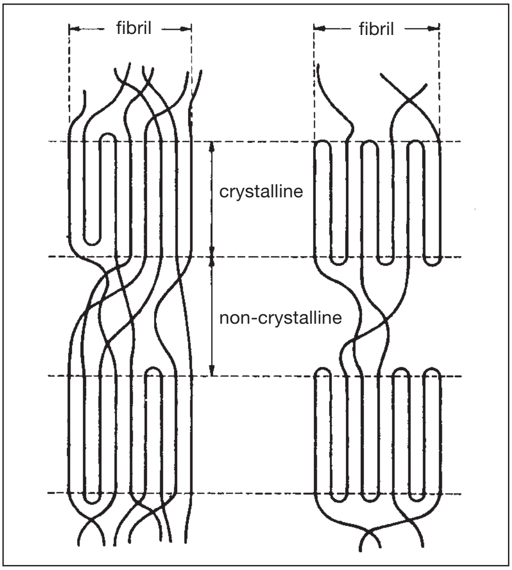

Fig. 6: Structural model of a drawn fibre (with chain overfolding).

The extension and swelling of viscose fibres depends on the number, size and distribution of crystalline and amorphous zones. The finishing processes only affect the amorphous part of the fibre material in which water penetrates as the hydrogen bonds split up. But even in the amorphous zones, not all OH groups are available to react because, for example, some of the dye molecules are too large and are so sterically inhibited that reaction is impossible. Apart from axial orientation, lateral arrangement is also important for the fine structure of the fibre. As the viscose enters the precipitation bath, a tiny skin is first formed by coagulation and this acts as a membrane. Thus, the viscose fibres receive a denser outer layer, the so-called “sheath”. Inside the fibre, the conditions for forming crystallites are less favourable as fewer crystallisation centres are available there. In the so-called “core”, an irregular network of larger crystallites develops which are separated by large amorphous zones. The sheath, on the other hand, has a homogeneous structure composed of many small crystallites. The structural differences between the core and the sheath are made easily visible under a microscope by staining.

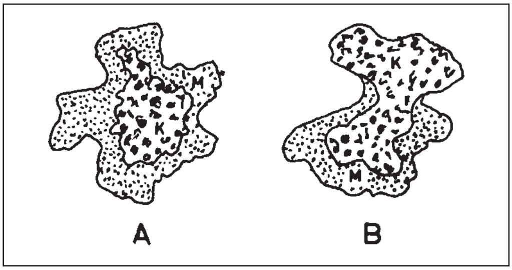

Fig. 7: Cross-section structure of a normal viscose fibre (A = sheath core structure) and a highly crimped viscose fibre (B = “two-component structure”).

The crimp is an extremely important property of the spun fibre. It is necessary for good workability and optimum spinnability, giving strength, volume and uniformity to the yarn and a good appearance, surface coverage and handle and pleasant wear behaviour to the fabrics and knitwear produced from it. The usual types of regenerated-cellulose-based spun fibre have long been know in crimped forms, even if hardly crimp-resistant. New techniques have been developed which are based on special coagulation, regeneration and drawing conditions. These produce viscose fibres which have a “live” crimp which can be regenerated. The special spinning method causes the primarily formed outer sheath of freshly spun fibre to break out in small areas during the fibre formation and drawing process, and the fibre core, while it is still plastic, can reach the fibre surface through the fibre capillaries. This produces a kind of "two-component structure", in which the stretching and swelling properties caused by the different fine structures of the core and sheath zones provide a basis for latent crimping as well as crimp recovery. Fig. 7 is a schematic illustration of this "two-component structure".

Moisture absorption and swelling behaviour of viscose fibres: viscose is very hygroscopic, i.e. it rapidly absorbs moisture from the surrounding air and reacts more sensitively to fluctuations in climatic conditions than man-made fibres. This behaviour is of great importance during further processing. Under standard atmospheric conditions (20°C and 65% relative humidity), the following moisture absorptions are observed for viscose and cotton:

- viscose 13–14%,
- cotton 7–8%.

The dependence of moisture absorption on the relative humidity is shown in Fig. 8.

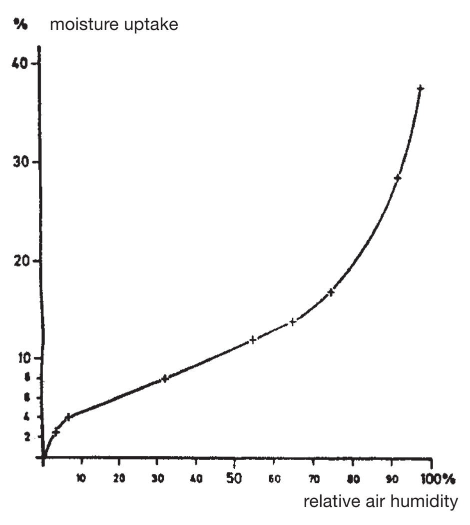

Fig. 8: Moisture uptake of viscose relative to relative air humidity.

As the drawing properties are strongly dependent on the moisture content, the fibre can easily be over-drawn during processing as the climatic conditions fluctuate and this may become noticeable in the form of contraction variations in the goods (bagginess and bands in the finish).

The degree of swelling during moisture absorption is one of the most important properties of viscose. The percentage of water retained by the fibre serves as a measure of its swelling capability. The following are found for viscose and cotton:

- viscose 80–115%,
- cotton 45–50%.

Although the ability of the fibre to swell is not lost during drying, the water-retention value decreases with each drying. How this changes with intermediate drying after each finishing stage and can be seen in Tab. 2.

The disadvantage is that swelling in the case of viscose is always associated with loss in strength as the effect of the hydrogen bonds between the chains is removed by their bonding with water. The relative wet strengths for viscose and cotton are as follows:

- viscose 42–50%,
- cotton 100–113%.

The consequences of this are felt during treatment in the wet state in particular. The decrease in strength is also associated with an increase in stretch. Tab. 2 also shows that the filament number is important for strength in relation to fineness. Yarn with fine filaments has a higher relative wet strength because the finer filaments have a higher proportion of crystalline sheath structures. The yarn therefore does not swell so much.

count (dtex)	84 f 24	84 f 30
individual filament count (dtex)	3,5	2,8
strength (cN/tex)		
dry	18,4	16,7
wet	7,7	8,0
relative wet strength (%)	42	48
stretch (%)		
dry	12,5	18,0
wet	23,5	26,0
water retention capacity (%)		
sized and dried	88,8	83,2
washed and dried	82,3	78,7
bleached and dried	79,5	–
dyed and dried	75,8	74,7

Tab. 2: Strength and water retention capacity of viscose filament yarns (Enka).

As the limited degree of swelling in water is reversible, none of the changes in the fibre properties remain. The behaviour of cellulose in alkali solutions, on the other hand, has more impact. Alkalis produce significantly more swelling than water, as intermicellar swelling turns into intramicellar swelling. Accessibility to the hydroxyl groups and, therefore, the reactivity of the cellulose is increased significantly by alkaline treatment. It is important to find the right measure and not exceed the target.

Cellulose can be dissolved by converting it into sodium cellulose using caustic soda solution. The highest possible alkalinity for the compound is achieved with:

1 Mol caustic soda to 1 Mol glucose.

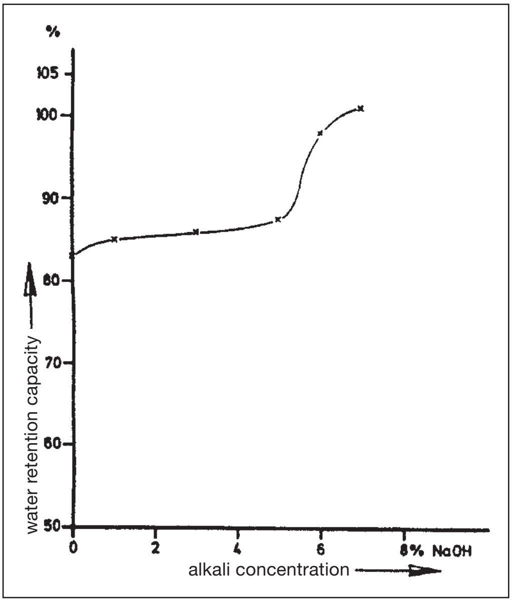

Fig. 9: Change in the water retention capacity of viscose due to caustic soda treatment.

Solubility in caustic soda solution is dependent on both the concentration and temperature and reaches a distinct maximum at a concentration of 10%. Regenerated celluloses dissolve in 10% caustic soda at –5°C. Providing the NaOH concentration remains below 5%, the amount of viscose fibres dissolved is negligible. At room temperature, they are resistant to alkali solutions up to 1%, almost without any change to the water-retention value. When viscose is treated with 4–6% caustic soda solution, there is a clear increase in the dye affinity and corresponding differences in colour. This is made use of when causticizing with caustic soda solution between 6 and 8°Bé. The change in the water-retention value, particularly the sharp rise at 5%, is shown in Fig. 9.

Caustic treatments at concentrations above 5% NaOH significantly loosen up the crystalline fibre structure.

The swelling effect is different for different alkali-ion solutions and depends on the atomic volume of the alkali ion. This increases in the following order:

$$K^+ < Na^+$$

This explains why a caustic potash solution is less dangerous to viscose than a caustic soda solution at the same concentration.

A typical finishing process for viscose fibre fabrics would have the following sequence:

- singe,
- desizing with enzymes using the CPB method,
- after washing, intermediate drying,
- caustic treatment (8°Bé Na0H),
- wet-in-wet-pad-steam-peroxide-bleach,
- intermediate drying,
- CPB reactive dyeing,
- acidulating on the padder with intermediate drying,
- resin finishing (padding-drying-condensation),
- sanforizing.

This finishing procedure produces crease values such as those shown in Fig. 10 for coarse- and fine-titre viscose fibre fabrics in comparison to cotton (according to Shaumann, Krässig, Vollbrecht, Berger und Morgenstern).

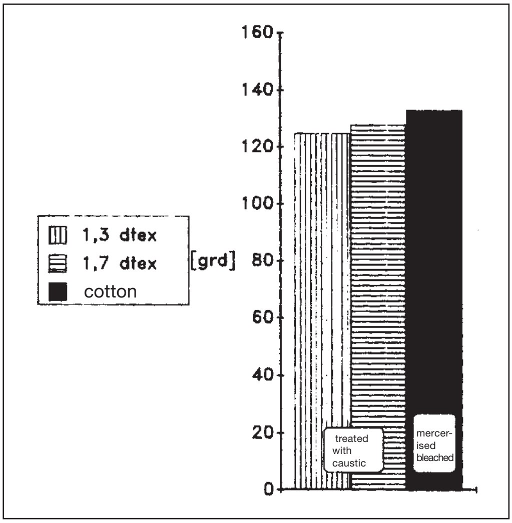

Fig. 10: Effect of count and pre-treatment on crease recovery angle (mean value K/S after 30 min) of viscose in comparison to cotton.

Viscose fibres, finishing Following the general trend, viscose articles are manufactured from very fine yarns. Yarns up to Nm 60–80 as well as those of Nm 100/2 are used. The weight of these goods, which are predominantly printed with large-area patterns, range from 80 to 120 g/m^2. In order to achieve high elasticity, finishing is carried out using urea-formaldehyde resins (resin finishing agents). The disadvantage of these finishes is the extremely high proportion of free formaldehyde which leads to high levels of odour pollution. For this reason, viscose articles are also finished using low-formaldehyde DMDHEU crosslinkers. However, in order to achieve a formaldehyde level as low as that for cotton, note must be taken of the following points:

- viscose has a higher proportion of amorphous zones in which there will be alkali residing from pre-treatments and dyeing processes carried out beforehand.

This disrupts the catalytic effect and prevents complete crosslinking.

- The alkali can be neutralized by adding 1 ml/l acetic acid (80%) to the finishing liquor.
- Increasing the amount of catalyst by 30–50% and intensifying the condensation conditions also have a positive effect on the formaldehyde content. At the same time, the negative effect on the strength is essentially lower for viscose than it is for cotton.

An elastic finish is achieved by combining the DMDHEU crosslinker with a polyurethane product, while a silicone elastomer can be added to increase it further. Due to the surface structure of the viscose and the general trend towards a softer finish, the risk of impaired non-slip properties for this article group increases. For this reason, it is advisable to add an anti-slip product. Whether it is crêpe, staple goods or smooth articles with high-twist yarns, it is really the causticization which produces the desired effects, i.e. the handle, the brilliance of the colours and the fall of the fabric.

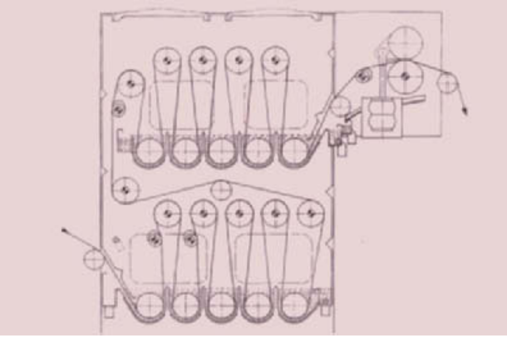

Fig.: Wet-caustic causticizing machine for viscose fabrics (Wet-Tex).

Theoretically, causticization is simple to carry out: the substrate is soaked with caustic solution for a certain period of time (caustic soda solution at 5–8°Bé and temperature approx. 15–25°C). The caustic solution is then washed out of the textile. Not only is the material intensively wetted with the caustic solution at the desired concentration during the treatment, the absence of tension must be maintained throughout the entire process. In practical terms, various procedures are usually adopted:

a) Batch treatment in wide form: it is only possible to causticize on the jigger if shrinking of the goods is to be avoided. Jigger-treatment is, therefore, not appropriate for most viscose articles which are tension-sensitive.

b) Semi-continuous method: the semi-continuous method using an impregnation device and batching station offers a good ratio between the textile mass and amount of caustic soda solution used. The tension required for the goods in the pad roll or pad batch methods for secure reeling prevents the goods from shrinking. Thus, the desired improvements with regard to fabric breakdowns are not achieved.

c) Continuous method: good results are achieved with the long-loop method. The system is limited by the maximum possible fabric speed. The fabric, wetted with a caustic solution, must be soaked in the treatment bath using a special device. The liquor stream must only flow at a certain velocity, otherwise the turbulence in the dwell bath make the smooth conveyance of the long loops into the dwell bath more difficult.

Often, the conventional open-width washing machines used for the occasional causticization of viscose cannot operate at the minimum fabric tension. As the warp shrinks, the length of the weft threads change at the same time. The rapid change in the width of the fabric produces a number of small “waves” in the direction of the fabric run and these can join to form rope creases which cannot be repaired. The fabric tension in relation to this problem can be better controlled in a short-loop roller vat (Fig.) (according to Fornelli and Meyer).

Viscose fibres, reactive dyeing One of the main factors which affect reactive dyeing of viscose filaments in the exhaustion process is the substrate or its properties. On the one hand, the high swelling capability of viscose, particularly in alkaline dyes, must be taken into account and on the other hand, it is the dye pickup which has to be considered. When dosing with solid salt, it is possible to compensate for the high affinity of the material by slowly increasing the substantivity of the dye.

The relationship between pH and fixing temperature and the possibility of dosing with alkali can be used to

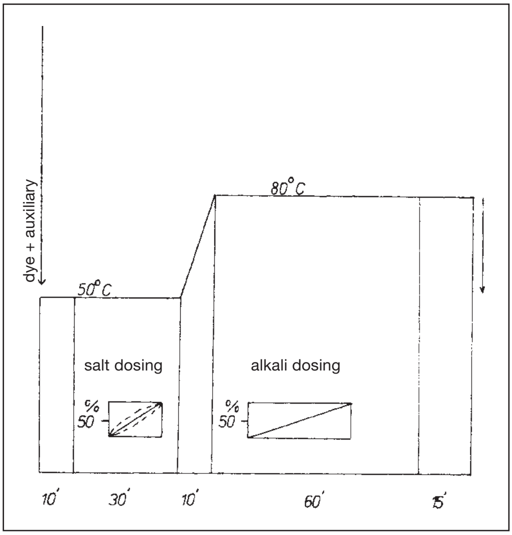

Fig. 1: Dyeing method 1 for viscose dyeing.

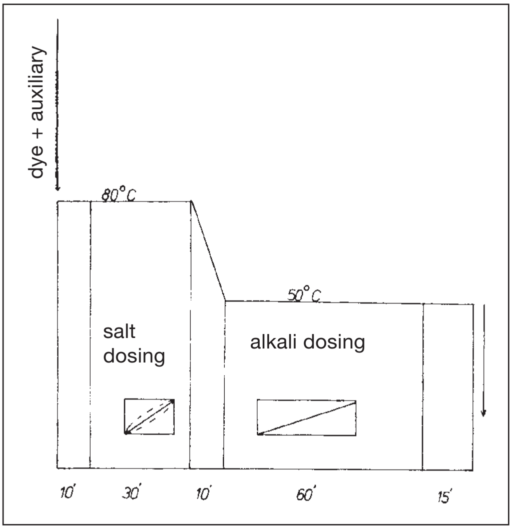

Fig. 2: Dyeing method II for viscose dyeing.

reduce the swelling properties. Based on this principle, five dyeing methods are available which are suitable for dyeing viscose filaments (Figs. 1–5).

Method I corresponds to the conventional migration process, except that the salt (for increasing the substantivity) and alkali are dosed. In spite of the slow increase in substantivity, it is possible that the flow through the wound packages will be disrupted due to the swelling of the viscose filaments, particularly in water at lower temperatures. Consequently, dosing salt delays the absorption of the dye but the requirement that the dye be distributed uniformly before fixing begins is probably not fulfilled because the flow of liquor through the packages is impaired.

In the case of method II, the salt is dosed at a higher temperature. Swelling is limited at higher temperatures and the diffusion and migration of the dye improved. The probability of uniform dye distribution during the substantive phase is greater than it is for method I.

Cooling and fixing in the cold bath could have a negative effect on the final levelling. The substantivity of the dye increases as the temperature of the total quantity of electrolyte in the dyebath decreases. The dye fills up as the equilibrium shifts in the direction of the fibre. By adding alkali to the cold bath, three factors effect each other and cause increased swelling of the material and, therefore, impair the flow of the liquor through the packages:

- an increased tendency to swell due to the low temperature,
- an increased tendency to swell in alkaline solutions,
- lower fixing temperatures require stronger alkaline conditions to achieve the final fixing value. Swelling increases with increasing amounts of alkali.

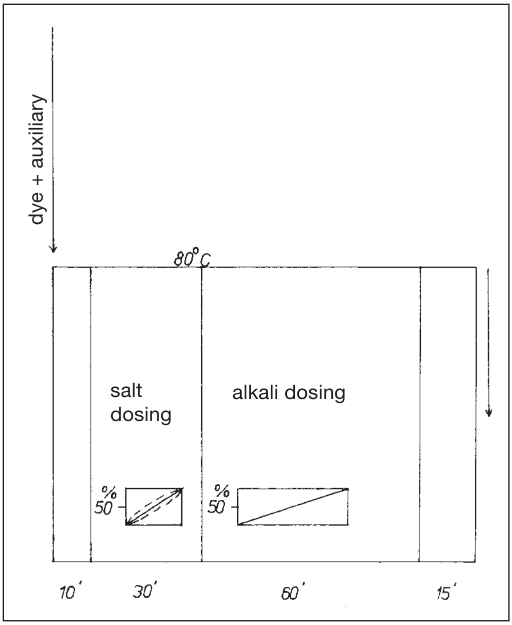

Fig. 3: Dyeing method III for viscose dyeing.

Judging by the dyeing profiles, the isotherm method III is the most suitable for achieving level dyeing, taking into account the lowest degree of swelling for the material and associated even flow through the packages. Based on uniform temperatures, non-uniform filling of the dye (as assumed in the case of method II due to cooling of the bath) is not to be expected. The fixing conditions are milder in line with the higher bath temperature, and this has a positive effect on the swelling state.

In the case of dyeing method IV, high temperatures

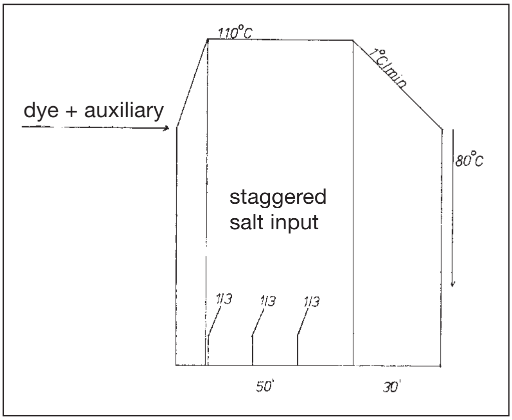

Fig. 4: Dyeing method IV for dyeing viscose filaments with substantive dyes.

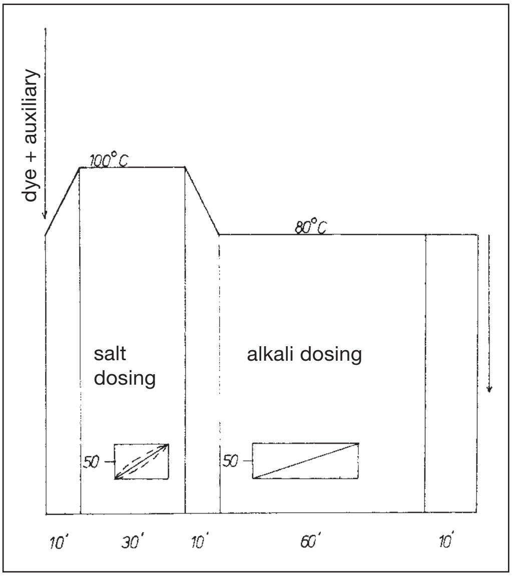

Fig. 5: Dyeing method V for dyeing viscose filament packages with reactive dyes.

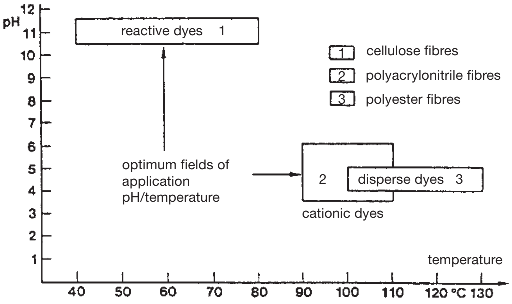

Fig. 6: Problem with the exhaustion dyeing of synthetic fibre/cellulose blends with the use of reactive dyes (Bayer).

are selected mainly to ensure better flow of liquor through the dye packages due to the reduced tendency to swell at high temperatures. When using reactive dyes, particularly in the case of the high-reactive type, these high temperatures cannot be achieved as dye fixing and increased hydrolysis takes place within this temperature range even in the absence of alkali (pH around neutral).

The dyeing profile of method V is suitable for reactive dyeing. At the selected temperatures, the reactive dyes have a high diffusion rate, whereas the substantivity only increases slowly after the bath has cooled in a defined manner and salt has been added. The dye is also fixed at high temperatures. Thus, it is possible to work with milder alkalis or with smaller amounts of alkali. The main factors (temperature and pH) which affect the swelling of the material are chosen to favour reduced swelling and, therefore, uniform flow of liquor through the packages.

A problem peculiar to the dyeing of viscose-polyacrylonitrile blends arises from the conflicting absorption and fixing conditions for the classes of dye used for the cellulosic or man-made fibre (Fig. 6).

A single-bath procedure using reactive and cationic dyes cannot be achieved because of the risk of agglomeration which exists between the two classes of dye.

cationic dye$^+$ + reactive dye → dye-dye

A two-bath procedure must, therefore, be used, making sure that the polyacrylonitrile in the blend is always dyed beforehand, exactly to the shade, as it is almost impossible to dye it with cationic dye afterwards.

Viscose high tenacity fibres (rayon cord, supercord, all-skin fibres and modal fibres), developed with the aim of increasing strength, dry modulus, fatigue resistance and dimensional stability, etc. This aim was realized to a limited extent using older spinning meth-

ods (such as the Lilienfeld and Lanusa principle and stretch spinning similar to cupro). By modifying viscose (→ Modified fibres) the production of high-strength viscose fibres with thickened → Covering layer and super-strong viscose fibres in all-skin structure with high-strength and high elongation (Tab.).

Use: as a filament for industrial fabrics, tyre cord, fabric linings, conveyor belts and drive belts. As a staple fibre: alone or in a mixture for rainwear, uniform fabrics, work clothing and protective clothing.

Viscose high wet tenacity fibres → Modal fibres.

Viscose modified fibres → Modified fibres.

Viscosity (Lat.: viscum), thickness, internal friction, internal resistance of a fluid against the relative movement of two neighbouring layers, i.e. the resistance a substance offers to flow.

A distinction is made between:

1. Dynamic viscosity η (→ Rheology; Rheological behaviour of solutions):

$$\eta = \frac{\text{shear stress } \tau}{\text{velocity or shear gradient D}} \quad [\text{Pa s} = \text{Ns/m}^2 = \text{kg/m s}]$$

2. Kinematic viscosity ν:

$$\nu = \frac{\text{dynamic viscosity } \eta}{\text{density}} \quad [\text{m}^2/\text{s}]$$

Both parameters “shear stress” and “velocity gradient” are defined using the parallel plate model (Fig. 1). In this model, two flat plates are arranged in parallel at a distance y to each other, the lower plate being stationary and upper plate being in motion. Both plates have an area A and the viscous substance is divided into laminae between the plates. If a force F now acts on the upper plate (in the direction shown), then this plate moves with a constant speed in the direction of the force and the substance begins to flow. The quotient of force F and the boundary area A of the substance underneath is called the shear stress τ.

$$\tau = \frac{\text{F(force)}}{\text{A(area)}} \quad [\text{N/m}^2 = \text{Pa}]$$

The shear force is responsible for the flow velocity of the substance which also depends on the internal resistance of the substance acting against the flow (viscosity).

Between the two plates, there is a velocity gradient where the substance has a velocity v_{max} at the upper plate and velocity 0 at the lower plate.

In the model presented, the fluid is divided up into laminae so the model is examined in terms of laminar flow. Laminar flow means a continuous stack of thin laminae of fluid in relative motion parallel to each other. The velocity gradient is established from the differences in velocity of two neighbouring laminae of substance divided by the distance between them and is defined by the following differential quotient:

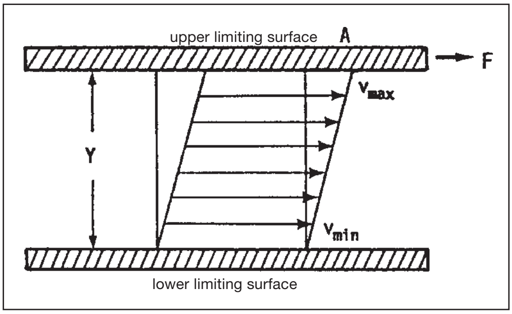

Fig. 1: Parallel plate model.

$$D = \frac{dv}{dy} = [\text{cm/s/cm} = \text{s}^{-1}]$$

The equation for dynamic viscosity is found by applying Newton’s law of viscosity:

$$\eta = \frac{\tau}{D} \quad [\text{N/m}^2 \cdot \text{s} = \text{Pa} \cdot \text{s}]$$

The unit of viscosity is the Pascal second (Pa s). The older unit, Poise, is still frequently used and is related to the new unit as follows: 1 Pa s = 10 Poise. There are two different types of flow or viscosity depending on whether the fluid is Newtonian or non-Newtonian. The first case covers all substances which behave according to Newton’s law of viscosity, as follows:

$$\tau = \eta \cdot D; \eta = \text{const.}$$

In this case, the dynamic viscosity is a constant for the substance which can be seen from the flow or viscosity curves. The relationship between shear stress and the velocity gradient D is shown graphically by the flow curve (Fig. 2), where τ is the ordinate and D is the abscissa. A corresponding relationship to the flow curves is found in the viscosity curves where the viscosity η is plotted against the velocity gradient (Fig. 3).

The flow curves of Newtonian substances appear as a straight line passing through the origin with a gradient α. The viscosity curve appears as a straight line parallel to the abscissa.

From Figs. 2 and 3, it can be seen that curves for non-Newtonian substances have a fundamentally dif-

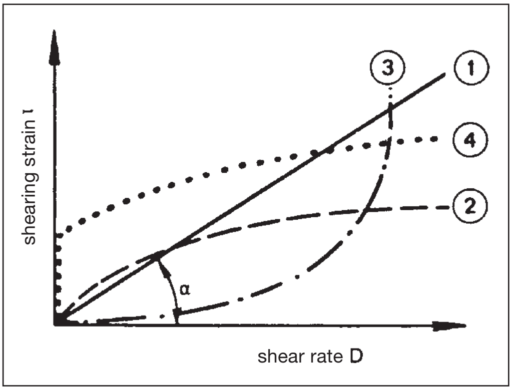

Fig. 2: Flow curves.
1 = Newtonian liquid; non-Newtonian fluid; 2 = structural viscous liquid; 3 = dilatant fluid; 4 = intrinsically viscous fluid with a flow limit = plastic fluid.

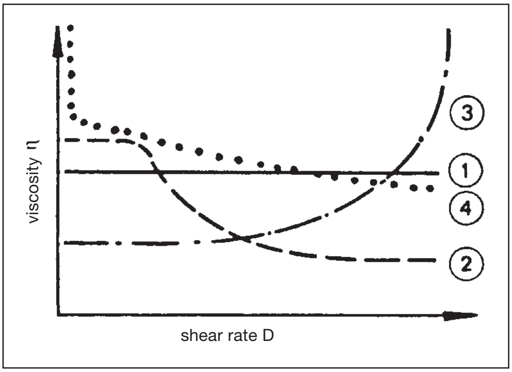

Fig. 3: Viscosity curves.
1 = Newtonian liquid; non-Newtonian fluid; 2 = structural viscous liquid; 3 = dilatant fluid; 4 = intrinsically viscous fluid with a flow limit = plastic fluid.

ferent shape. In this case, the viscosity does not have a substance-dependent constant but a dependent variable. In the following, the different flow characteristics will be described in more detail. In regard to viscosity as a function of velocity gradient, there are two different kinds of flow: dilatant and structurally viscous flow. If the viscosity increases with increasing velocity gradient, this is described as dilatant flow. If the viscosity decreases with increasing velocity gradient, this is structural viscosity or pseudo-plastic flow.

When the viscosity is dependent on the velocity gradient producing a yield limit τ_0, this is described as plastic flow. Substances showing this type of behaviour, apart from a yield limit, also show structurally viscous behaviour in most cases.

Viscosities which are dependent on D and time t:

a) If the viscosity increases with shear time, this is rheopexy flow.
b) If the viscosity decreases with shear time, this is thixotropic flow.

Most thickeners are non-Newtonian fluids and show more or less pronounced structurally viscous behaviour (Fig. 4); a few have a yield limit and are, therefore, plastic. The rheological behaviour of foam is also structurally viscous flow.

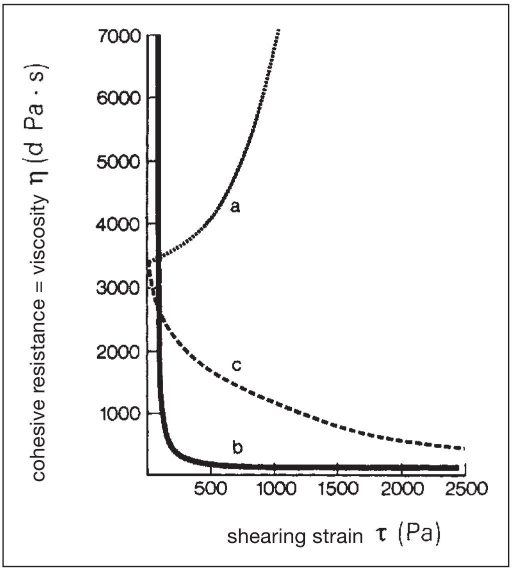

Fig. 4: Intrinsic viscosity of thickeners b and c; a is not to be used for printing thickeners.

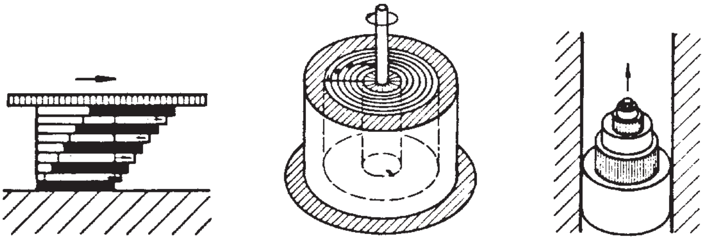
For absolute viscosity measurement, values obtained must be based on the measurement of the fundamental physical parameters force, length and time. It must be possible to calculate the test substances mathematically, i.e. their flow measurement system must correspond to one of the four types of flow profiles shown in Fig. 5.

Another essential prerequisite is that it must be possible to calculate the shear force and velocity gradient exactly. In addition to this, the following boundary conditions must be fulfilled:

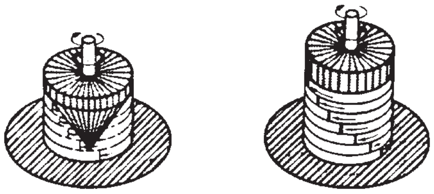
– Laminar flow: the shear must only generate laminar flow.
– Stationary flow state: in Newton’s viscosity equation, the shear stress applied is proportional to the velocity gradient. At the same time, the shear stress is only in a position to achieve constant velocity flow. Thus, the energy required to accelerate or retard flow velocity cannot be recorded.
– Wall adhesion: the effective shear stress must be



a) Flowing between two parallel flat plates

b) Flowing in the annular gap between two coaxial cylinders

c) Flowing through capillaries, sheet dies, tubes or pipes



d) Flowing in the annular gap between a cone and a flat plate or flowing in the gap between two plane-parallel round plates

Fig. 5: Different flow profiles.

transferable. If there is no adhesion between the layer of fluid and the two walls, i.e. moving and stationary, then it is not possible to produce a meaningful viscosity measurement.

- Homogeneity: when measuring mixtures, there must be no sedimentation of either component, otherwise the measurement will be distorted by the changes in the composition of the mixture.
- No chemical or physical changes: in order to characterize a sample using viscosity measurement, these effects must be excluded. On the other hand, if it is necessary to record the changes in viscosity caused by chemical or physical reactions, then this can be achieved by using a special experimental arrangement where the viscosity parameters (type of substance, temperature of substance, pressure, velocity gradient and shear time) must be kept constant.
- No elasticity: for substances which show viscoelastic flow behaviour, the measurements can no longer be regarded as due to viscosity if there is a large increase in the elastic component.

Viscosity index η is boundary value of the relationship between the specific viscosity η_{sp} and the concentration C, if the latter tends to zero:

$$[\eta] = \lim_{C \to 0} \frac{\eta_{sp}}{C}$$

The specific viscosity of a dilute solution of the fibrous material in a solvent is determined using a capillary viscometer. The viscosity index is a characteristic of the quality of the material and, through this, a measure of the reduction in the molecular weight, i.e. the reduction of viscosity index. The viscosity η_0 of a solvent is raised to the value η by the dissolution of a given amount of polymer. The quotient of η and η_0 is called the relative viscosity:

$$\eta_{rel} = \frac{\eta}{\eta_0}$$

Furthermore, the increase in relative viscosity, i.e. the difference between the η and η_0 in relation to η_0, is called the specific viscosity:

$$\eta_{sp} = \frac{\eta - \eta_0}{\eta_0}$$

As proportional factors, both η_{rel} and η_{sp} are dimensionless. For their determination, therefore, it is sufficient to measure only one parameter which is proportional to the viscosity η or η_0.

A measure for viscosity is obtained by running the diluted polymer solution through a capillary and measuring the time for it to stop at time t. A corresponding value is obtained for the pure solvent at time t_0. According to the Hagen-Poiseuille law, the viscosity is proportional to the flow time. The flow times can, therefore, be substituted by viscosities:

$$\eta_{sp} = \frac{t - t_0}{t_0}$$

The viscosity of fluids is strongly dependent on the temperature and the measurements must, therefore, be carried out at a defined temperature under temperature-controlled conditions. Einstein showed that, for a solution or dispersion of spherical particles, the specific viscosity η_{sp} is directly proportional to concentration c and inversely proportional to the particle density ρ:

$$\eta_{sp} = 2.5 \frac{c}{\rho} \quad \text{or} \quad \frac{\eta_{sp}}{c} = \frac{2.5}{\rho}$$

η_{sp}/c is called the reduced viscosity. A macromolecule in solution, however, is not a sphere but forms a statistical coil in solution. ρ is, therefore, not the density of pure polymers but of the coil, the solution contained within the coil not being taken into account. Strictly speaking, the corresponding relationship only applies to infinite dilution where the dissolved particles no longer have any effect. As η_{sp} determinations can only be sensibly made for finite dilutions, measurements are carried out at several concentrations and the reduced viscosity η_{sp}/c is plotted against c and extrapolated to concentration c = 0 (see Fig.). Where the line cuts the ordinate is designated the intrinsic or limiting viscosity or the viscosity index or even the Staudinger index and is given the symbol [η]. The coil density is not a constant for the substance but depends on the molecular weight M. Finally, from this relationship comes the Kuhn-Mark-Houwink-equation:

$$[\eta] = K \cdot M^a$$

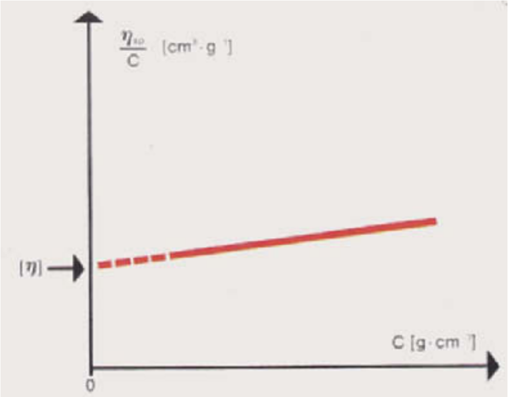


Fig.: The viscosity index [η] is obtained through extrapolation of η_{sp}/c against c = 0.

In this, K and a are constants when polymers, solvents and temperature are known. The value of a lies between 0.5 and 1 but is frequently in the vicinity of 0.8.

Viscosity of print pastes The rheological behaviour of print pastes plays a part in textile printing which is not insignificant. Apart from tensile loads, shear forces in particular act on the pastes (→ Rheology in printing and coating). However, so far, measurement techniques have not asserted themselves in printing practice. In most cases, assessment is subjective – tack-tests judged by the flow of paste from a rod. However, viscosity measurement has been introduced into printing practice indirectly as thickener manufacturers use the flow properties to characterize thickeners and then use this information in formulation recommendations.

Investigations into the relationships between the rheological properties of a printing paste and its printing behaviour show the limits of viscosity measurement. As a single parameter, viscosity measurement cannot offer an adequate prognosis on the printing result. However, if the rheological behaviour is used in relation to other parameters, then the characteristic behaviour of each printing paste can be established and the printing process controlled.

In the case of foam printing, viscosity measurement is a fixed component of certain printing systems because the reproducibility of foam production is directly related to the starting material (the liquor feed is calibrated to a particular viscosity value of the starting paste).

Voile,

I. Material (grenadine and veiling): light translucent, thin and loosely woven cotton fabric (and wool) made from hard-twist in linen weave, the hard-twisted, fibreless yarns giving the fabric a granular feel and slip resistant properties. The following distinctions are made:

- full voile: warp and weft ply yarn,
- semi voile: warp ply yarn and weft simple yarn,
- imitation voile: warp and weft simple yarn (Indian mull),
- silk voile: warp and weft natural silk.

In addition to these, there is marquisette voile, etamine voile, brocaded voile and ondulé voile. Voiles are used in curtain making, decoration and cloths.

II. Yarn: fine, hard-twist (gas-singed) cotton or worsted ply yarn.

Volatilization,

I. Change of state from liquid to vapour/gas (opposite → Condensation). Arising from molecular movement, based on the fact that molecules of high velocity escape from the surface of the liquid, the liquid being depleted by its fastest moving molecules.

II. The progressive change from a liquid to a gaseous state without heat input. Example: evaporation of volatile organic solvents such as benzene.

Voltage ranges According to the VDEW (Vereinigung deutsche Elektrizitätswerke e.V.) [Association of German Electricity Generating Stations]:

– low voltage	< 1 kV
– medium voltage	1–6 kV
– high voltage	60–150 kV
– extra-high voltage	> 150 kV

Voltammetry In voltammetry, the shape of the current/voltage curve is dependent on the type of voltage excitation (E vs. t), of the mass transfer to the electrode and on the degree of reversibility of the electrochemical reaction producing the signal.

Apart from the Ohmic resistances in a solution at rest for a given chemically stable species "Ox" (oxidized form) or "Red" (reduced form), the diffusion of the substances participating in the reaction is of prime importance for the transport of the electroactive substance to the electrodes. "Convective diffusion" applies when the solution or the electrodes are not at rest. A step-shaped current/voltage curve is observed under stationary conditions. As the signal increases, the kinetics of the electron transfer is the determining factor. Mass transfer dominates when each of the electroactive molecules or ions is converted as it reaches the electrode. This means that a limiting current is reached which is independent of any further increases in voltage.

$E_{1/2}$, the half-wave potential, is the potential at which half the value of the limiting current is reached (Fig.). The $E_{1/2}$ is used to describe the process and, in any given medium, is characteristic of the electroactive substance in question, i.e. it is qualitative. Limiting currents i_{gr} are used to determine the concentration of the electroactive substance in question, i.e. they are quantitative. If the reduction potentials are far enough apart from each other, voltammetric measurements can be taken of several substances together at the same time.

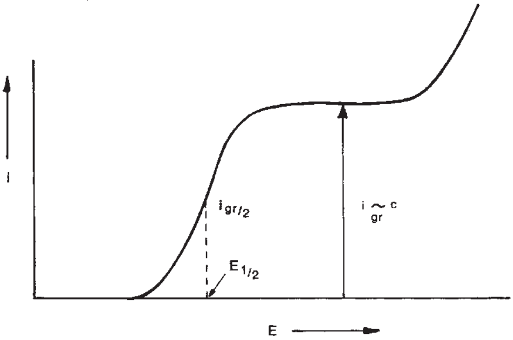

Fig.: Current potential curve in the case of stationary measuring methods.
E potential vs. reference electrode, $E_{1/2}$ half stage potential, i_{gr} marginal current.

For a simple electrochemical conversion, the magnitude of the Faraday current that can be achieved depends on the following parameters:

- the concentration of the electroactive substance,
- the number of electrons participating in the reaction per molecule or per mol.
- the transport mechanism of the substance (for example, the diffusion coefficients)
- the electrode surface.

The magnitude of the current arising from the electrochemical conversion is calculated from Faraday's and Fick's laws of diffusion; it also may be necessary to take into account the convection of the solution. For all methods listed below, a clear relationship is obtained between the measured current signal for the solution concentration being determined and the parameters of the measurement technique.

Voltammetry = the measurement of current in relation to voltage:

- current signal caused by electrochemical conversion of a substance (reduction/oxidation) at the electrodes,
- current (usually) proportional to the solution concentration of an electroactive species,
- voltage (in relation to reference value) corresponds to the energy in the electrochemical reaction (voltage x faraday constant = energy per mol), can be used for selective substance determinations.

Several types of current can be observed in voltammetry:

- faraday current i_{far}, arising from the electrochemical substance,
- kinetic currents i_{kin}, for example, affected by the rate of preceding equilibrium reactions of an outgoing inactive species A (A → Ox)
- currents arising from the adsorption of products of electron transfer and capacitance currents which arise from the molecular structure of the phase boundary electron conductor/ion conductor.

(according to Knittel et al.).

Volumetric analysis → Titration.

Volumetric weight of textiles The volumetric weight of yarns cannot be accounted for by the density of the type of fibre in question alone as it is generally significantly less. This is because the pore volumes and air content can fluctuate strongly depending on how the materials have been processed. The volumetric weight of textile fabrics is calculated as follows:

$$\frac{\textbf{weight (g/m}^2\textbf{)}}{\textbf{1 000} \cdot \textbf{thickness of fabric (mm)}}$$

Vulcanization accelerator A distinction is made between ultra-rapid accelerators (thiocarbamates, thiuramide sulphide and xanthogenic acid derivatives), semi-ultra-rapid accelerators (aldehydamine derivatives, derivatives of 2-mercaptothiazols and thiur ammonium sulphides), medium-strength accelerators (di- and triphenylguanidine) and weak accelerators (thiouria derivatives, 1.6-diaminohexane and formamide).

Vulcanized fibre Cellulose-plastic (plasticized using zinc chloride solution; paper webs "welded" by roller pressure) in the form of slabs, rods and tubes. Horn-like, tough, hard to leather-like soft and pliable. Absorbs little water (also water-proof impregnated). Resistant to oils and hydrocarbons, etc. Low flammability. Can be machined in any way to make gearwheels, sealing washers and suitcases (and the like).

Vulcanize, to Rubber or plastic coatings are produced by vulcanizing polymers with sulphur, which contain double bonds (such as natural rubber).

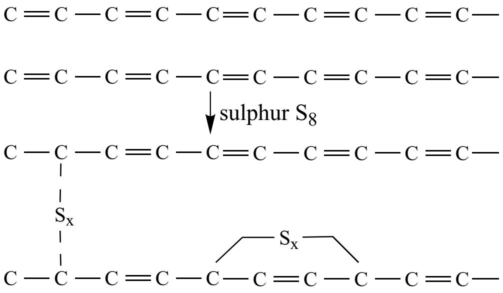
Natural rubber has a molar mass of 200 000–400 000 (Tab.), which corresponds to a structure containing 3000–5000 isoprene units of a basic monomer with a molecular weight of 68. In the case of "synthetic natural rubber", polyisoprene, it is possible to produce molecules containing 1–1.5 million units (even as many as 2.5 million units). The molecular weight and the molecular weight distribution, in particular, essentially determine the processing behaviour of the rubber.

Goodyear discovered the reaction of natural rubber with sulphur under heat in 1839. He called the reaction vulcanization after the Etruscan-Roman God of fire Vulcanus. As sulphur exists in the form of an eight-

rubber	abbreviation	molar mass
natural rubber	NR	200 000 to 400 000
styrene-butadiene rubber	SBR	250 000 to 800 000
polybutadiene rubber	BR	250 000 to 350 000
polyisoprene rubber	IR	1 000 000 to 2 500 000
ethylene-propylene rubber	EPDM	200 000 to 300 000

Tab.: Molar mass of rubbers.

membered ring, this must be broken open during vulcanization so that it can then form links with the fragments via the double bonds of the rubber molecule.



Sulphur is incorporated as the link S_x in all molecule lengths from S_1–S_8. The type of link formed depends on the vulcanization temperature, the duration of vucanization and, above all, the vulcanization activators. The length of the sulphur links determines or affects the properties of the vulcanized product. Thus, during the ageing process, it can be assumed that bonds break, the chain length changes and free sulphur links bond again to other carbon atoms.

The most important vulcanizing agent for sulphur crosslinking is elemental sulphur of 99.5% purity. This exists in colloidal form in the vulcanization pastes. As sulphur exists in the form of an S_8 ring, it is slow to react and requires approx. 270 J/mol to open the ring. Vulcanization does not start, therefore, until a high temperature has been reached or a vulcanization accelerator has been added. These are in the form of mercaptans, dithiocarbamates, disulphides and metal oxides (such as ZnO). The S_8 ring is opened by ionic or free-radical reaction or opened thermally at high temperatures. With latexes, ionic or free-radical reactions are used for opening, depending on the vulcanization accelerator.

Ring opening by ionic reaction: $^{+}$S:S:S:S:S:S:S:S:$^{-}$

Ring opening by free-radical reaction: .S:S:S:S:S:S:S:S·

Bases, such as amines, open the ring in the ionic form and dithiocarbamates open the ring in the radical form. The activated sulphur then reacts with methane groups or the double bonds to produce intra- and intermolecular bonds.

When crosslinking using metal oxides and synthetic resins, intermolecular bonding of the macromolecules is carried out via monomers with reactive groups, which have been incorporated in the polymer for this purpose. Crosslinking converts the polymer from its plastic rubber state into its elastic rubber state.

A schematic representation of the behaviour of long-chain filamentary molecules during plastic deformation under heat and elastic deformation after vulcanization is shown in Fig.

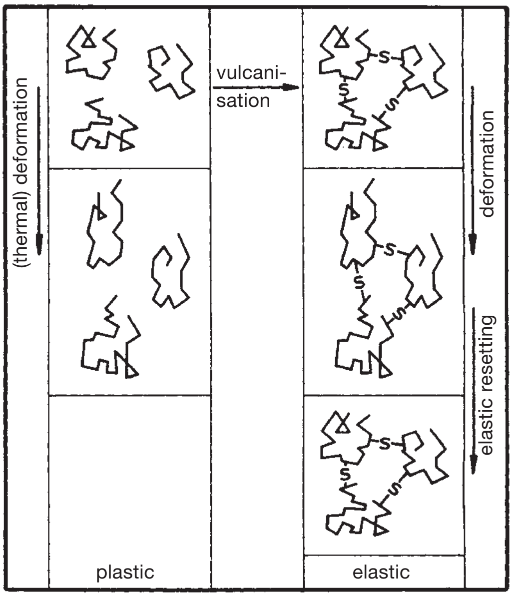


Fig.: Diagram showing plastic deformation with heat, vulcanization and elastic deformation (stretching).

The term “crosslinking” is often used instead of vulcanization. Originally, there was a difference between the two terms. Vulcanization stood for all molecular bondings using sulphur or sulphur-donating compounds. Crosslinking stood for other bonding mechanisms without sulphur (such as radiation energy or peroxide), which are no longer commonly used.

The production of natural rubber, originally from wild plants discovered in Middle and South America (Brazil), in particular, was stabilised to a certain extent, after Wickham 1876, on a detour via England, laid out plantations in Eastern Asia. Nevertheless, rubber still remained a speculative commodity with frequent peaks in price. As Staudinger clarified the chemistry of high polymers in chemical research at around the turn of the century, rubber was soon to be synthesized. The name Staudinger, especially, is associated with the development in structural analysis, as are the names Faraday and Williams with the search for basic building blocks. In regard to the synthesis of rubber, these names are joined early on by names such as F. Hofmann (methyl rubber, 1906–1909) and Harries (butadiene with alkali, 1910). Technical solutions were developed at Bayer’s dye works in Germany (Zahlenbuna = sodium butadiene, 1926) and by Carothers at DuPont in the USA (chlorobutadiene, chloroprene and neoprene) and finally, there are the solution polymers according to Ziegler/Natta (polybutadiene, polyisoprene, ethylene propylene rubber, around 1960) (according to Zeppenick).

VY → Vinylal, symbol according to the → EDP key system.

W

W,

I. Abbreviation for → Watt.

II. Element symbol for tungsten (74).

WA → Angora, → Textile fibre symbols in accordance with DIN standard 60 001 T4/08.91.

Wadding Cotton wool type raised frieze interlining and stuffing material (providing filling and warmth) for dresses, ladie's and gentlemen's suits. Wide-meshed woven or knit fabric consisting of loosely processed wool (black in colour), wool mixes, cotton, viscose; also in the form of textile composite fabric with strengthened thread interlining and quilted (quilt wadding).

Wadding component Component of → Padding, stuffing, specifically for the perfection of form stability in the chest/shoulder area. It is used as an integral wadding component for strengthening wadding in the shoulder and armpit areas.

WAK (Ger. abbrev. for "waschaktive Komponente" = wash-active components), rarely used term referring to synthetic detergents. WAK consists of a percentage of sulphonates (alternatively a percentage of sulphonated ester or phosphonated ester); also a percentage of → Fatty acids as in soaps. For example, 100% wash-active substances if liquid triethanolamine is used, contain 64% WAK, in the case of potassium salt, 88% WAK, with common sodium salt, 93% WAK, and 94% WAK with ammonium salt in the case of dodecylsulphonate. Non-ionogenic detergents do not form this type of salt, which is why there is, apparently, no great difference between wash-active substances and WAK.

Walk test,

I. Method of testing wear resistance, such as soiling properties and pile firmness in textile floor coverings. The sample is spread out in an area where people frequently walk, usually together with a comparable carpet that has known properties. Soil pick-up, wear, colour change, etc. are monitored over several months.

II. Test to establish the electrostatic properties of textile floor coverings (DIN 54 345, Section 2).

Wall hangings Wallpaper or carpets for decorating and/or providing acoustic insulation on walls. Wall hangings can be divided up into smooth and those having a textured surface. Nonwoven wall hangings are usually pinned with lustred fibres. In general wallpaper is hung wet, i.e. affixed to the wall with a water-based paste. This is taken into account when nonwovens are used for wallpaper, by laminating it with special wallpaper paper. If the wallpaper has been sintered with thermoplast powder, transfer printing and laminating can be carried out in a single process.

Smooth nonwoven fabric that has been slightly prepinned, for instance 100% polyester fibre with a weight of 80 to 100g per m^2, is coloured by means of transfer printing with transfer paper. If it is necessary to cut out the separate paper sintering phase to enable online production, a powder dispersal system is installed before the transfer calender, which disperses the thermoplast powder as required on the reverse side of the nonwoven or wallpaper.

This method is used not only to colour nonwovens made of polyester fibre, but also nonwovens based on cellulose fibre, although they have to be chemically bonded first, using polyurethane dispersions, for instance. This is because this binder takes up transfer dye with a high yield, in the reverse process.

Wall-to-wall carpeting A term for carpets that are laid from wall to wall (fitted carpets). → Contract carpet.

Ward-Leonard control In continuous production lines, electrically driven machines which operate in series are synchronized using the Ward-Leonard control via compensator roll potentiometers (see Fig.).

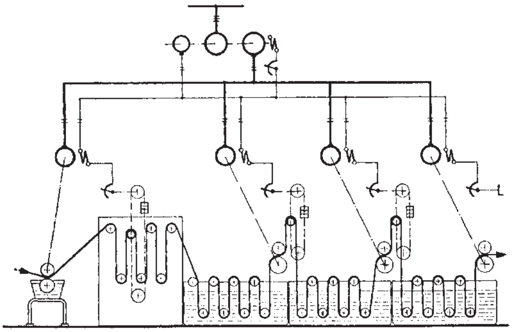

Fig.: Leonhard multi-motor drive with compensator roller control for an open-width washing machine.

Wardrobe Clothing, in particular outerwear, dresses, general outer garments, in French it also applies to underwear.

Warm-dyeing vat dyes Vat dyes that act in a heated environment on the basis of the → IW dyeing method.

Warming up time The time required by measuring devices from switch-on until calibration stability is achieved.

Warning devices → Alarm and indicating equipment.

Warning limits Variation limits marked on → Control charts, which may only be exceeded under certain conditions. → Control limits.

Warp,

I. In weaving: all the parallel threads running in a longitudinal direction of a woven fabric. The yarn used for this is known as warp yarn. Woven warps consisting of spun fibre yarns are usually yarns with a higher twist, which have also been (warp) sized prior to weaving, so that they will withstand the stress to which they are subjected during the weaving process. Ply warps are not usually sized.

II. In warp-knitting: the yarns that are wound onto the warp beam and serve to form stitches.

Warp beam (warp-wound bobbin). Roller-shaped device that holds the warp yarn ready for weaving. Perforated warp beams are used for bleaching or dyeing the warp (or the fabric) on → Beam dyeing machines.

Warp beam centrifuge Centrifuge for beam dyeing machines or card lap beams, usually upright rather than horizontal.

Warp dyeing process This process is used for the manufacture of warp patterned carpets. Pile yarns are wound in parallel onto drums with dye liquor application systems, they are dyed in stripes, and finally the dye is set using steam.

Warp ends → Warp.

Warper-Sizer-System The warp yarn runs from the warping reel frame straight into the sizing machine with no sectional warping process. This means that each thread in the multi-thread warp is sized individually. This system is particularly suitable for warp preparation of untwisted synthetic fibres (e.g. fine titre of polyamide and polyester threads).

Warping Whereas warp threads with the required sett are wound individually onto the sectional drum or a sectional warp beam in → Sectional warping, there is also a type of warping where the warp yarn is wound onto warping beams to the intended weaving width but with a reduced sett. More and more beams of this type are being consolidated into a standard warping beam. This technique is primarily suitable for long warps of a single colour. Multi-coloured yarns are usually warped sectionally.

Warp-knit → Warp-knitted fabrics.

Warp knit nonwoven pile fabric Nonwoven knitted fabric consisting of a basic material with additional nonwoven fibre. The nonwoven fibre is bonded into the basic material by forming it into pile loops.

Warp-knit stitch-bonded nonwovens (stitch-bonded nonwovens). Nonwoven knits consisting of fibre fleece, bonded by means of a row of sliding needles with tongues that are pushed into and pulled out of the fabric, causing loops of fibre (stitches) to be formed.

Warp-knitted fabrics Textile fabric manufactured from one or more thread systems by forming stitches. Warp-knitted fabrics, unlike → Weft-knitted fabrics or knitgoods (single-thread knits), are formed into stitches from several adjacent threads (warp) at the same time. The process of forming stitches is less time-consuming than in weft-knit manufacture, and it is not possible to chafe the fabric. → Knitted fabrics.

Warp patterned carpets Multi-coloured machine-woven carpets in which the pile yarns are dyed using the → Warp dyeing process.

Warp printed carpet A true warp printed carpet is a wire carpet. The pattern is created before weaving, using the → Warp printing technique on the pile warp yarns. This type of warp printed carpet (tapestry or velvet-type carpets) typically exhibits settled patterning. In contrast to this, multi-coloured printed carpets have a certain degree of pattern bleed after weaving.

Warp printing (Chiné printing). Printing the warp thread system of woven fabric with thin print pastes (complete print penetration), drying, and then, in most cases, weaving immediately (to avoid extreme pattern displacement). Dye setting and washing processes are carried out once the fabric has been woven. Small pattern displacements are inevitable, and they produce the characteristic blurred and slightly jagged appearance. This technique is used in particular for articles where complete print penetration is required (e.g. curtains). Two-phase print processes are frequently used for warp printing.

Warp printing process Variant of → Space dyeing.

Warp rib tricot → Tricot with ribs running in the direction of the warp (lengthways). The opposite of this is → Transverse tricot.

Warp size naphthol preparing Dyeing process using naphthol dye from sizing, for cotton and polyester/cellulose warps. Preparation takes place on the sizing system.

Warp sizing Sizing of the warp in wovens in preparation for the weaving process. The evenness is particularly useful in practice for reasons relating to technology and economy. For this reason the aim is to reduce unevenness in the sizing along the warp. Control systems are available that reduce the variation in warp size application, for example in the slow/fast transition phase. The advantage of a control system to keep

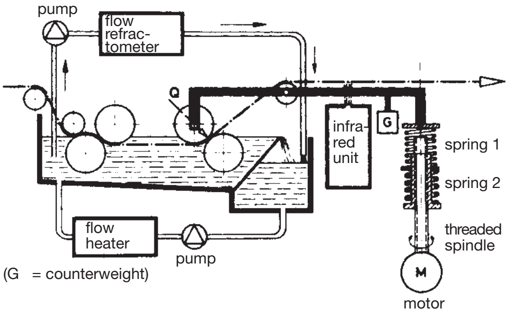

Fig.: Warp size application with bath control (refractometer) and liquor application control (infra-red etc.) (Sucker-Müller).

the degree of sizing constant (see Fig.) is that the effects of all influential parameters are summarized and sizing variations are regulated by varying the squeezing pressure. Use of a closed loop control circuit has the added advantage that the degree of sizing is returned to the target parameter after a control deviation. A computer continuously evaluates the signals measured with an IR device (to analyse H_2O) and a throughput refractometer, with which it calculates the target warp sizing parameter.

Warp sizing and dyeing Process for dyeing cotton warp during sizing. Only used for a few types of fabric, such as denim, blue jeans.

Warp smoothness A special type of warp wax for coating the warp in weaving. It enables the warp to "run" better, minimizes yarn breakage and loom outtime, as well as improved weaving performance. From a practical point of view it is only suitable for fabrics that are washed directly without singeing, or for multicoloured fabrics. Non-existent or poor saponification properties usually mean uneven dyeing. This type of damage can be tested easily by ultra-violet (low luminance).

Warp velvet (wire velvet, velours). Smooth or patterned → Velvet, in which the pile layer consists of an additional warp system (pile warp). Wires with a lancet-type blade on one side are inserted into the velvet on a specially designed loom after the pile warp threads have been lifted. When the wires have been pulled out (still on the loom), the loops formed are cut open. In warp velvet, these loops are held by the weft, as opposed to → Weft velvet where the tufts of fibre are held by the warp. The depth of pile is determined by the thickness of the wire. Plush and velours carpets are also manufactured using this technique.

WAS (abbrev. for wash-active substance). A pure, organically effective component of → Synthetic detergents or → Soap (→ Surfactants). The WAS content is stated in %, e.g. 30% pure alkylarylsulphonate or alkylsulphonate or fatty alcohol sulphonate, etc. Although WAS content plays an important part in the effectiveness of → Washing agents, it would be wrong to assess the quality of the detergent on this basis alone, or even to try to calculate it. There are significant differences even between WAS products of the same raw materials group. There are also WAS mixes in which the individual components have the effect of mutually increasing wash-active properties (synergetic), or of reducing them. Finally there are further components (→ Builders) that contribute to greater effectiveness. Objective washing or cleaning experiments are important for carrying out objective quality tests, by means of → Soiling tests.

Washable goods Washable textiles, divided into the following categories: → Coloured articles wash; Delicate articles; Laundry for 100°C wash. →: Wash and Wear; Machine-washable wool. → Care labelling of textiles provides information regarding washability.

Wash-active component → WAK.

Wash-active substance (active material, active substance) → WAS.

Wash and Wear (W & W), textile property, usual term for easy-care textiles. The garment is so smooth after washing that it can be worn again with virtually no ironing. → Wash and Wear Finishing.

Wash and Wear Finishing Cotton, viscose, linen and mixes containing these materials with synthetic fibres are fibre types that are important on a worldwide scale. All attempts to achieve comparable finishing effects using mechanical finishing processes alone, targeted action on the fibre or specific use of the article, have not resulted in the same quality as chemical modification using appropriate finishing products. Resin finishing agents, catalysts and additives, applied using low-cost process techniques combined with mechanical finishing phases still ensure the best wash and wear finish (→ Resin finishing). Obviously ecological changes have taken place during the past 10 years, particularly in industrialized countries, which have meant that it was necessary to re-think and re-organize the approach to wash and wear finishing, among other things. Consumer requirements with regard to textiles are more demanding and more quality-orientated and the emphasis is on function and variety. Fashion trends mean that alterations to articles have to be carried out at short notice more and more frequently. Increasing operating costs mean that high requirements apply to existing production capacity, and mean that rational process techniques are necessary. It is becoming more and more complicated, detailed and specific to take into account ecology and toxicology and the constraints associated with them.

1. Formaldehyde crosslinkers: in today's state of wash and wear finishing, N-methylol compounds are still used. These compounds are the most significant product group of → Resin finishing agents (Fig. 1).

Wash and Wear Finishing

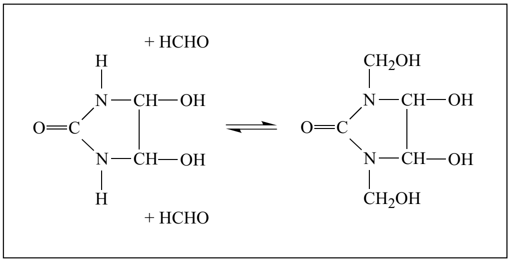

Fig. 1: *Methylolation/glyoxal urea.*

At least 95% of all processed crosslinkers used for wash and wear finishing (at least 100 000 t worldwide) contain formaldehyde in bonded form. Using the functional N-methylol group, reactant crosslinkers cause the known modification of cellulose (Fig. 2), thereby producing the required wash and wear effects. →: Low-formaldehyde resin finishing; Formaldehyde-free finishes.

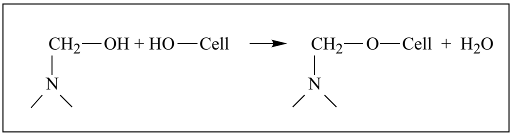

Fig. 2: Part of the crosslinking reaction.

As well as the intended crosslinking reaction with cellulose, there is a range of possible auxiliary reactions in the finishing liquor and on the fibre, which cause formaldehyde to be released (Figs. 3 and 4). This released formaldehyde presents problems of a toxicological and ecological nature.

The risks associated with formaldehyde, which are detrimental to health, have resulted in legally defined limitations in many countries, applying to finishing products, the workplace, exhaust and formaldehyde levels on textiles.

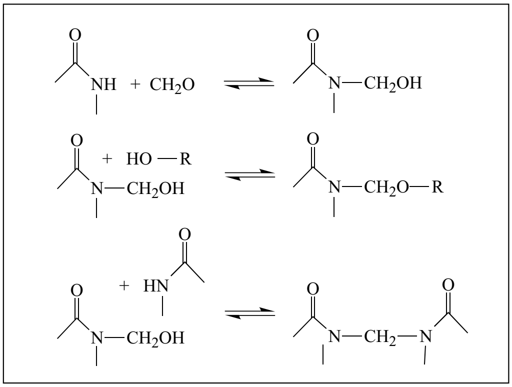

Fig. 3: Free and bonded formaldehyde in crosslinked cotton articles or in the finishing liquor.

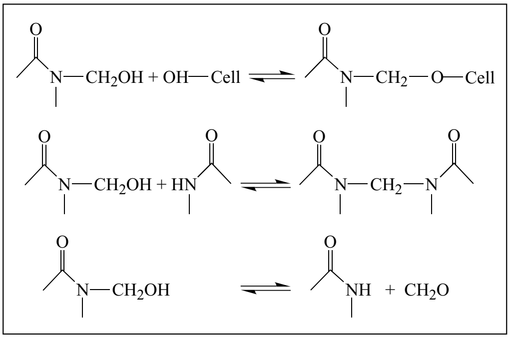

Fig. 4: Cellulose crosslinking reactions and formaldehyde self-crosslinking and splitting.

In many countries, the maximum concentration applying to the working environment (threshold limiting value TLV) for formaldehyde is subject to law. In Germany for example, the TLV for formaldehyde is 0.5 ppm, a low TLV value, that, in practice, can cause problems. Other industrialized countries are aiming to halve the current TLV value, which is usually 1 ppm. Japan was the first country several years ago to legislate set limits for formaldehyde on textiles. In Germany, textiles with a free formaldehyde content higher than 0.15% have been subject to identification regulations since 1988. As well as legal limitations (which by now exist in several countries), there is a range of involuntary regulations specific to each company relating to formaldehyde on textiles. It is not just well known retail and storage operations that set limits for their articles; the textile finishing industry itself is striving towards taking responsibility for low-formaldehyde finishing. The formaldehyde problem in textile finishing is no longer just restricted to the working environment and the textiles themselves, but in many countries these regulations also apply particularly to the exhaust from drying and condensation systems. Complex measurement and monitoring becomes necessary.

2. Low-formaldehyde crosslinkers: the necessity for low-formaldehyde crosslinkers in the textile finishing industry is constantly on the increase, and always involves higher requirements relating to free formaldehyde. Methylolglyoxal ureas (Fig. 5) are the most commonly used crosslinkers for low-formaldehyde finishing. The most frequently encountered are methylolglyoxal ureas modified with methanol, and increasingly with diethylene glycol.

3. Formaldehyde-free crosslinkers: the chemical industry, by developing low-formaldehyde crosslinkers,

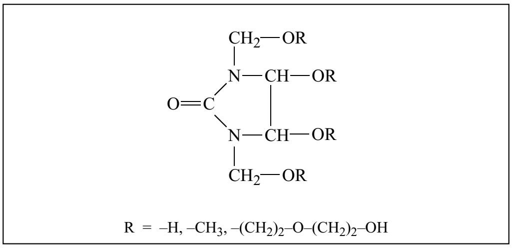

Fig. 5: Modification of the N-methylol group.

and the textile industry with purpose-orientated technologies for production, have made a significant contribution towards dealing with the formaldehyde problem. The problem could only be solved completely if formaldehyde-free crosslinkers were available that provided a comparable finishing quality at the same cost, and were also harmless from the point of view of ecology and toxicity. However, unfortunately that has not been the case so far. Formaldehyde-free crosslinkers such as chlorohydrines, vinylsulphones and acrylamides, which were used for a variety of applications in the 1960s, also constitute a toxicological risk. All these would do is to shift the current problem to a different category of hazardous substances.

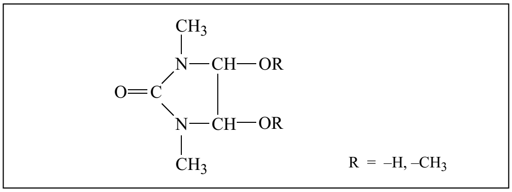

Fig. 6: Dimethylglyoxal ureas.

The formaldehyde-free crosslinkers that are currently available to the textile finishing industry in the form of commercial and trial products are almost exclusively reaction products of glyoxal. The conversion products of glyoxal and dimethylene urea (Fig. 6) are the most widely used in practice, and which can sometimes be etherized with methanol. Furthermore the conversion product of glyoxal, ethylene urea and methanol is described. Conversion products of glyoxalic acid are also under discussion.

It has also been suggested many times that glyoxal itself could be used for formaldehyde-free crosslinking of cellulose (Fig. 7). At the moment it is really only practical to use glyoxal conversion products as formaldehyde-free crosslinkers. Wash and wear effects can be achieved that are near in quality to standard reactant crosslinkers. The level of whiteness is not usually quite as good as it is when standard crosslinkers are used. The disadvantage is the high cost of finishing, which is three or four times as expensive. There are no particular points relating to application for dimethylglyoxal urea-based crosslinkers. Pad-drying takes place on the padder, and crosslinking occurs in the presence of catalysts at, for example, 150°C within 2–4 min. A specific post-wash process is not necessary.

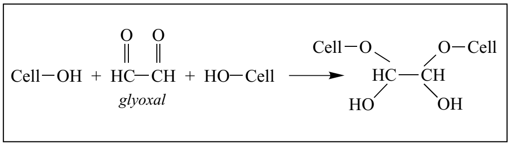

Fig. 7: Crosslinking with glyoxal.

4. Additives: the attempts to create alternative products to crosslinkers for wash and wear finishes resulted in selected polymer dispersions based on polyacrylate, polysiloxane and/or polyisocyanate (Fig. 8). However they did not constitute a comprehensive solution for a high-quality wash and wear effect in all cellulose fibres with regard to formaldehyde release and minimal fibre damage. Polymer dispersions have no effect on shrinkage stability. Crease resistance is only significantly better with polyester/cotton; however wash and wear fastness is not achieved.

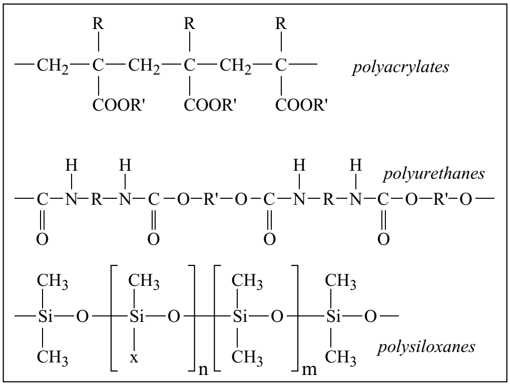

Fig. 8: Various polymer dispersions as additives.

However, in the form of so-called additives in combination with crosslinkers, the polymer dispersions described are becoming more important. A significant optimization of the effect can be seen even on cotton. The creasing properties are improved without further detrimental effect to the fabric strength.

5. Creating the handle: the current handle favoured throughout Europe is still extremely soft. High quantities of softeners, up to 60–90 g/l, are used on wovens

and in particular on knitgoods. Silicon softeners are becoming increasingly popular. Amino-polysiloxane micro-emulsions are especially sought after because they create a cotton-type, particularly soft handle, they have good washing stability, and they have a positive influence on sewability (according to Seidel).

Wash and Wear Standards Photographic and three-dimensional standards for the assessment of wash and wear properties. AATCC 124-1973: Smoothness of textiles. AATCC 88B-1973: Appearance of garment seams. AATCC 88C-1973: Appearance of ironed creases on garments, in each case after domestic washing. Samples for testing of specified sizes are washed under defined conditions, dried (drip dried, spin dried, tumble dried) and allocated the grades relating to the comparative standard (1–5). 1 is the lowest grade possible, and 5 is the highest (Monsanto crease photographs).

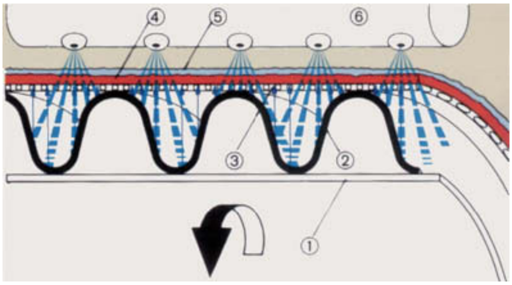

Fig. 2: Active wash principle with ribbed drum (Kleinewefers KTM)).
1 = closed drum body; 2 = groove profile; 3 = perforated belt; 4 = fabric; 5 = outer liquor film; 6 = spray pipe.

Wash compartment A specific washing principle, which is independent of other wash compartments, is applied in the wash compartment of an open-width washing range. The layout of the washing elements in the wash compartment is dependent on the fabric to be treated in it (Fig. 1). If a drum washer is used, it may be necessary to construct high-volume wash compartments, because for instance a ribbed drum (Fig. 2) has a very large diameter. If water savings are to be achieved in a single wash compartment, the collection of the wash water draining off the fabric is relocated external-

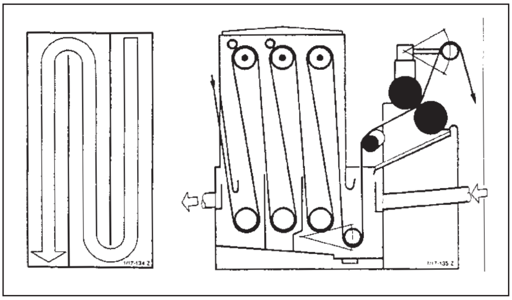

Fig. 4: Dividing plates in the Convi-Tex wash compartment (Babcock). Left: plan view; right: side view.

ly (Fig. 3), and only the necessary water for running the pump is retained within the wash compartment.

Dividing plates (Fig. 4) in the wash compartment also guide liquor flow opposite to the fabric direction, alternately from the right to the left side of the wash compartment and then left to right, i.e. at right angles to the fabric direction. This transverse flow directs the entire liquor specifically at the fabric, thereby preventing part of the liquor flowing past unused. At the same time it has the effect of ensuring that the fabric is evenly rinsed across its entire width.

In Fig. 4, feeder rollers can also be seen in addition to the upper rollers. The purpose of these is to hold back the liquor carried on the surface of the fabric. In conjunction with the dividing plates this has the effect of an additional separation of the liquor within the compartment. There is also a spray line with flat beam jets between compartments, which is charged with fresh water, to ensure liquor separation. The final component of a wash compartment is a squeezing system, which also ensures liquor separation.

Wash creases in fabrics containing polyester texturized yarns After washing this type of fabric, washing creases can be observed again and again. These creases run transversely or longitudinally depending on the type of washing machine, and are still visible when the finished fabric is tensioned at higher temperatures. Microscopic inspection shows that these crease markings are primarily caused by distorted crimping. In order to avoid wash creases of this type, the fabric should be opened out and crease-free when it is introduced to the wash liquor. The structural alterations must have finished taking place before the creases are removed and mechanical processing starts. The time taken to process crease-free fabric depends both on the temperature of washing and the initial material/construction.

Washfast finish → Permanent finishing.

Washfastness testers Mechanical instruments for measuring washfastness. Consist of a water bath, in which sealed stainless steel or glass containers rotate on a horizontal axis. The containers hold the sample with the prescribed test solution, and possibly a set number of steel balls. Usually also suitable for testing other types of fastness (e.g. peroxide washing, hypochlorite washing, milling fastness, dry cleaning fastness, etc.).

Washfastness testing Test to establish the resistance to all types of industrial and domestic washing. The specimen is treated together with control fabric samples in a suitable mechanical washing device. After the test is completed, the specimen is rinsed twice in cold distilled water, squeezed, rinsed for 10 min in flowing water, the specimen is opened on 3 sides, dried at max. 60°C and then assessed (using grey scales to check the colour change and level of bleeding).

Washing Process in which heavy or slight soiling is removed and transferred to the water in the form of a solution or dispersion. Washing has the effect of cleaning surfaces. The resulting effect is several physical/chemical processes (→ Washing process).

Washing and cleaning constitute a complex process, during which soiling is removed by means of physical separation, with or without substance conversion, from a substrate.

Industrial washing processes can be categorized as solution washing, dispersion washing and reaction washing.

1. With solution washing, the substances to be removed from the fibre are soluble in the washing liquor. Examples of this type of solution washing are the removal of salts, bleaching chemicals and synthetic sizes by means of washing.

2. In the case of dispersion washing, the substances to be removed from the fibre are not soluble in the washing liquor, i.e. disperse systems are created during the washing process. This means the more or less fine distribution of one or several substances in the dispersion agent (washing liquor). If the system is solid/liquid, it is known as a suspension, if it is liquid/liquid it is

called an emulsion. Examples of this type of washing process are the removal of pigments, fat, wax, oils and print thickeners by washing.

3. Reaction washing renders it necessary to distinguish between washing processes with and without degradation. In reaction washing with degradation, the substances to be removed from the fibre are not soluble or dispersible in the washing liquor. It is only after a chemical or biological conversion that soluble or dispersible substances are created. A typical reaction washing process with degradation involves the removal of starch sizes. Reaction washing processes without degradation are for instance, where an excess of alkali or acid is removed not by means of thinning, but by neutralization, and the excess is removed subsequently by means of solution washing.

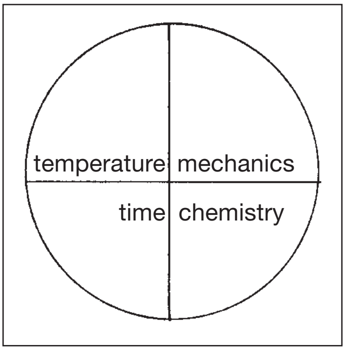

Fig. 1: The Sinner Circle for representing washing performance.

The → Washing process is essentially dependent on four factors, which can be represented as sectors of a circle (Fig. 1). All washing processes are based on these four factors, with only the influence of the individual factors varying from process to process. The Sinnerscher wash circle is frequently extended by water as a solvent. The liquor ratio is one significant parameter in the washing process. It influences the concentration gradient of the soil from the fibre to the washing liquor, and regulates the strength of the mechanical forces. The washing process can be divided up into four steps: The first step is the wetting of both the substrate and the soiled surface with the washing liquor by reducing surface tension. During soil detachment, the second stage, differentiation is made between pigment soiling and oil-based soiling. In the case of pigment soiling, soil release is based on increasing the equal negative electric charges of the soil and fibre in the wash liquor, and on raising the propogation pressure in the adsorbed layers between the soil and the fibre, which is manifested as nip pressure. In the case of oil-based soiling, the reduction of interfacial pressure by means of surfactant adsorption followed by a rolling process and rewetting of the fibre are particularly important. Further stages of the washing process are using surfactants to keep the soil particles in suspension in the wash liquor, and removal of the soil by the free-flowing wash liquor.

The → Surface tension is a parameter relating to the state which identifies the energy properties of the surface to distinguish them from internal properties. In the case of water/air, this value is $\sigma = 72.8 \cdot 10^{-3}$ N/m. This figure corresponds to the work that must be done in order to bring molecules from inside the water to the surface against cohesion pressure. On the same principle, the → Surface tension (interface tension) between two phases can be defined. Interface tension of this type occurs for example between a gaseous and a liquid phase (air/water) or a liquid and liquid phase (oil/water) or a solid and liquid phase (pigment/water or fibre/water). Fig. 2 depicts the surface tension. The electrical forces of attraction between the molecules of a liquid (in this case water) generate an interface tension, which helps to prevent foaming of the liquid. Molecules deep inside the liquid are attracted equally strongly in all directions by the adjacent molecules as a result of van der Waals forces. For this reason molecules at the surface are subject to a unilateral force from the inside. Because of this, energy is necessary for a molecule to reach the interface surface against this force. Interface tension is a measurement of the endeavour of a liquid to keep its surface as small as possible.

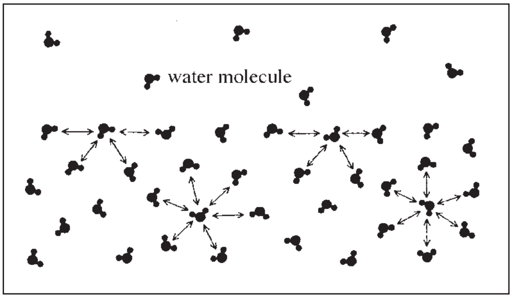

Fig. 2: Electrical forces of attraction between the molecules of a liquid.

→ Wetting means the lowering of surface tension between a liquid and a solid body, where the phase limit solid/gaseous is suppressed by the solid/liquid system, by reduction of the free surface energy.

As shown in Fig. 3, the → Wetting angle is a measurement of wetting. If this angle is greater than 0° but less than 90°, wetting is spontaneous. If the angle lies between 90° and 180°, then wetting is involuntary. As the surface and interfacial tension can be varied significantly through the use of surfactants, it is easy to see that

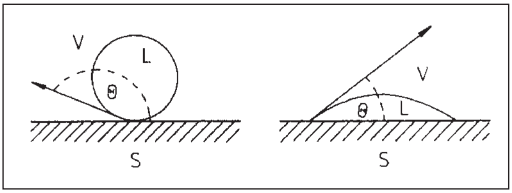

Fig. 3: Wetting illustration.
V = gaseous phase; L = liquid phase; S = solid phase;
θ = wetting angle.

surfactants are important for wetting problems, such as the wetting of textiles during the washing process.

The → Washing mechanics, as one of the four factors in the Sinnerscher wash circle, is based on the current generated as a result of textile or wash liquor motion. It can be assumed that the particles of dirt are picked up by the current generated in the wash liquor, and shaken out of their stationary position. This is dependent on the particles being large enough and standing out from the stationary layer of liquid adhering to the substrate (adhesion layer).

As shown in Fig. 4, the current generated during the washing process causes not only free-flowing wash liquor, but also flow boundary layers. The adhesive layer is created as a result of the fibre's forces of adhesion, so that there is a strong interactive effect between the water molecules and the fibre. The second layer is the diffusion boundary layer. In this layer the flow is slowed by interactive effects between the water and the fibre. The flow boundary layers are dependent on the type of textile. These layers become important during the washing process, as they cause an extreme reduction in the capacity to wash out soiling. Although the soil has already become detached from the fibre, it is still in the flow boundary layers in the case of smaller particles, and can therefore not be carried away. From this it can be concluded that the phase of the washing process that determines the speed is the slow diffusion of the soil particles out of the diffusion boundary layer; in other words it is diffusion-controlled. This means that stronger washing mechanics (flow) lower the diffusion boundary layer and result in a faster washing process.

Washing activity Specific properties relating to the removal of → Soil (with significant involvement of surface or interfacial activity) of wash-active substances (→ WAS).

Washing activity of surfactants This is mainly in relation to the → Surface activity and the characteristic molecular structure of → Surfactants. Because of their binary character, they can convert hydrophobic substances that are not soluble in water into hydrophilic water-soluble substances by means of surface adsorption. The first requirement for a good washing effect (→ Washing) is adsorption of the surfactants by the soil as well as the substrate, resulting in a reduction of the → Surface tension and changes in the interfacial potential values. It is essential that adsorption takes place to ensure that wetting occurs during soil detachment. In the case of liquid soiling, oil (for instance) is forced from the surface, and the substrate is rewetted. The washing liquor comes out of the fibre surface in the context of wetting at the same time as the oil-based soiling. Surfactant adsorption causes the oil to form droplets. In this process the increase in cleavage pressure is caused by the hydrate shell of the surfactants in the limit area. The consequence is further surfactant adsorption at the interface between the washing liquor/oil, which leads to complete detachment of the oil-based soil, which is then carried away. This process of removing oil-based soil is known as unrolling of liquid droplets. Detach-

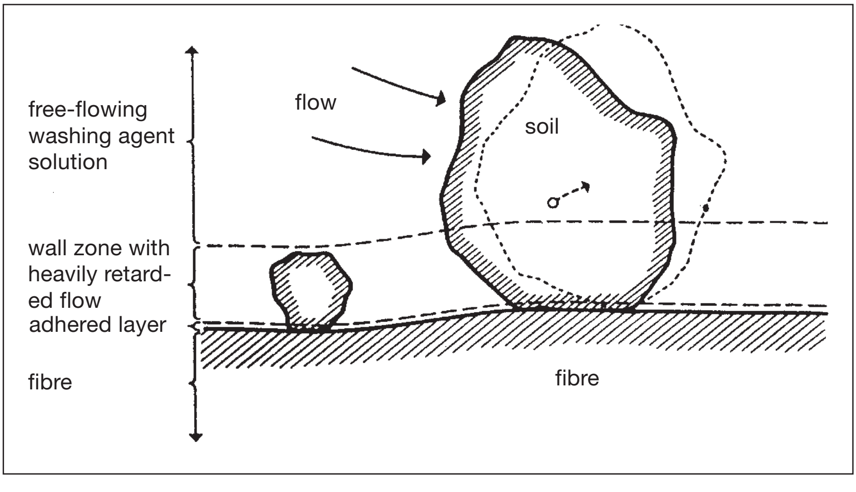

Fig. 4: Diagram of the dispersion of soil particles through wash liquor flow dependent on the particle size.

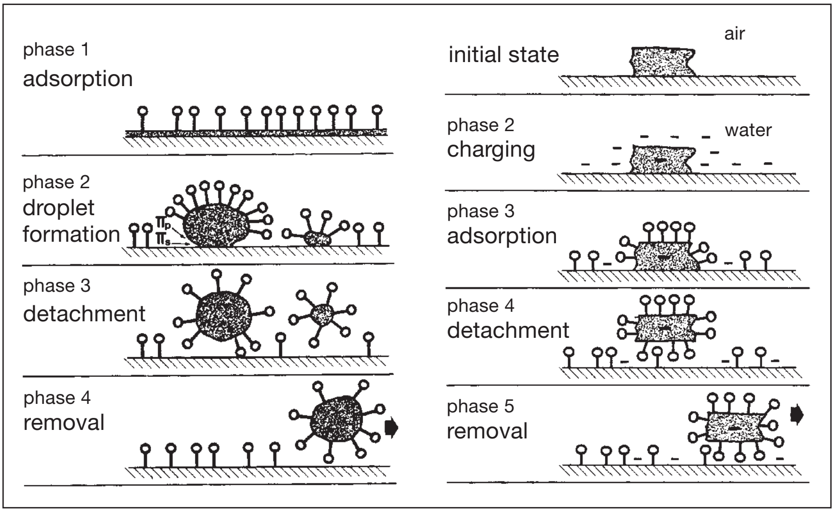

Fig. 1: Diagram showing the effect of surfactants on the detachment of oily soilings (left) and of pigment soil.

ment of pigment-based soiling using surfactants is dependent firstly on an increase in the negative solid body charge (→ Zeta potential), which can be achieved using anionic surfactants. As both the textile fibre as well as the attached soil pigments have a higher negative charge as a result of surfactant adsorption, a higher level of repulsion occurs. This makes soil removal easier, and the washing effect increases. In addition there is pronounced spread pressure in the adsorbed layer, and the soil particles are infiltrated by adsorbing surfactants and the bonding energy between the substrate and the soil particles is reduced. This causes the pigment soiling to be detached and carried away. Soil detachment of pigments and oil-based soil using surfactants is shown in Fig. 1.

Another function of surfactants in the washing process is the soil suspending property or dispersion of detached soil in the washing liquor. The dispersion process with anionic surfactants can be partially explained by the fact that their adsorption by soil pigments or oil droplets, because of the negative charge that has formed, results in increased repulsion between the different particles. This prevents agglomeration or coalescence, and therefore also prevents re-absorption onto the clean fibre surface. The dispersion or solvation effect of non-ionogenic products is so strong that particles surrounded by a shell do not conglomerate even if there is a negligible electric charge. The washing effect of non-ionogenic surfactants can be explained by the fact that they have a larger hydrate shell than anionic surfactants.

When cation-active surfactants are used in washing, the soil particles are charged positively; the negative charge of the fibre under normal conditions is reduced without going to the extreme of converting to a positive charge, because the charge of fibres is difficult to change by this method. Under these circumstances it is difficult to detach the soil, which means that it is not practical to use cation-active surfactants for washing.

The way in which surfactant effects can be blocked by soil has been sufficiently researched with regard to hardness salts such as calcium, magnesium and even iron compounds, which are present in natural soiling. For instance it has been discovered that soap is converted to lime soap if calcium ions are present that bond with the carboxyl group in the soap. The soap loses its properties of interfacial activity and precipitates. A second type of washing activity blocking where surfactants are used can be explained by the fact that surfactants form aggregates (micelles) above a certain concentration, which are responsible for the soil suspending properties. The soil suspending properties are limited. The soil particles that are already detached form “micelle germs” in the washing liquor with which surfactants are bonded. For this reason they are then no longer available for detaching soil components from the textile. The more the soil suspending properties are utilized, the more a wash liquor is “saturated”, and consequently the cleaning effect is worse. Extinction measurements, with water-soluble dyes instead of soil, can be used to show that once the dye concentration exceeds a certain level, the consequence is saturation of the micellary solution.

The electrokinetic phenomena that occur when textile fibres come into contact with water and aqueous solutions at the phase boundary show that a charge distribution must be present. The positive charge can be allocated to one phase, and the negative charge to the other. Helmholtz provided an initial theory to explain this principle, the theory of the electrical dual layer. According to his theory, there is a drop in electrokinetic tension at the phase interface between solid and liquid, between the dispersed particles and the dispersing agent. The concept of the electrical dual layer at the interface between fibre and solution proves that a monomolecular layer of counter-ions, the so-called star layer, is adsorbed at the fibre surface, which (in pure water) always exhibits a negative charge. The diffuse Gouy-Chapman layer is adjacent to this, which contains the necessary counter-ions for complete compensation at the fibre surface as well as co-ions; the internal solution connected to this layer is known as the bulk phase. The interface between the star layer and the Gouy-Chapman layer is known as the external Helmholtz layer, and the potential that occurs there is called star potential (Fig. 2).

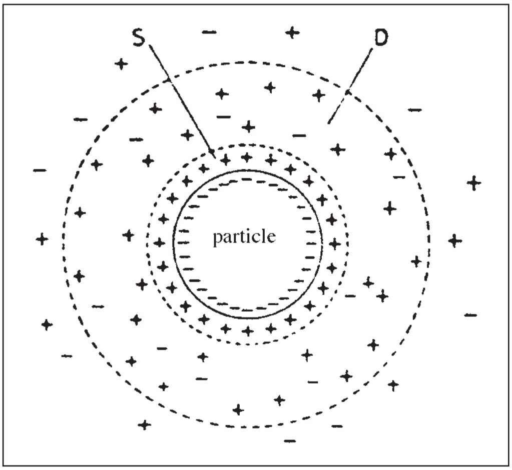

Fig. 2: Construction of the electrochemical dual layer.
S = Star layer of securely adsorbed ions with so-called surface potential or equilibrium potential (towards the particle) and so-called star potential (towards D).
D = diffuse layer (Gouy-Chapman dual layer).

For a dual layer to be formed, the surface must carry a charge. The source of the charge can be traced back to functional polar groups, molecular dissociation, ion adsorption because of ions dissolving out, and friction-generated electricity. Micelles also have a dual layer. Conductivity tests show that without a particular bond being present between the surfactant ion and counter-ion, about 80% of the counter-ions are bonded to the micellary surface, while the remaining counter-ions are distributed in the aqueous phase in free motion. This means that the micellary surface of ionic micelles is charged in comparison with the aqueous phase; the charge density can be calculated from the aggregation index and the level of dissociation.

Zeta potential (ξ potential) is a term applied to the galvanising tension in the diffuse part of the electrical dual layer at the interface between two phases that can not be mixed (e.g. between fibre with adsorbed soil particles and the wash liquor). Zeta potential is defined as the potential drop along the Gouy-Chapman layer, in other words from the external Helmholtz surface to the bulk phase. There are various methods available for measuring the zeta potential. Of these, the method that has proved to be the best for characterizing solid substances is the current potential method. The zeta potential (ZP) can be calculated from the current potential measured using the Helmholtz-Smoluchowsky formula:

$$ZP = \frac{4\pi\eta}{D} \cdot \frac{E}{p} \cdot \lambda \ [V]$$

η = viscosity of liquid phase
p = pressure difference
D = dielectrical constant
E = current potential
λ = conductivity of liquid phase

The strength of the electrical dual layer and therefore the level of the zeta potential is dependent on polarity, as well as the tendency of the interface to form hydrogen linkages with water. Furthermore the zeta potential decreases as the electrolyte concentration increases (Fig. 3).

The pH-dependent negative zeta potential is increased by the adsorption of anionic surfactants; cati-

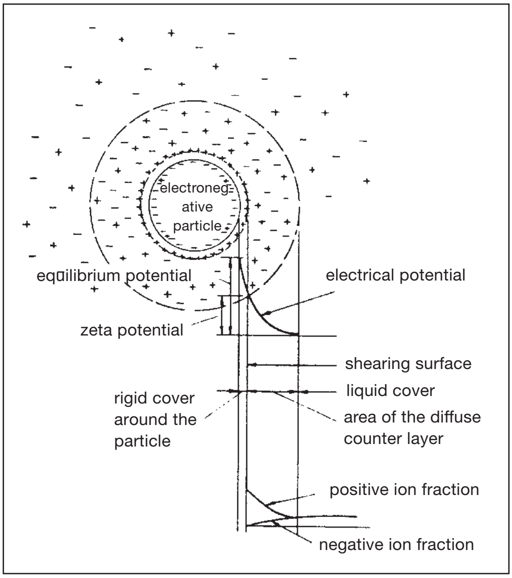

Fig. 3: Zeta potential diagram.

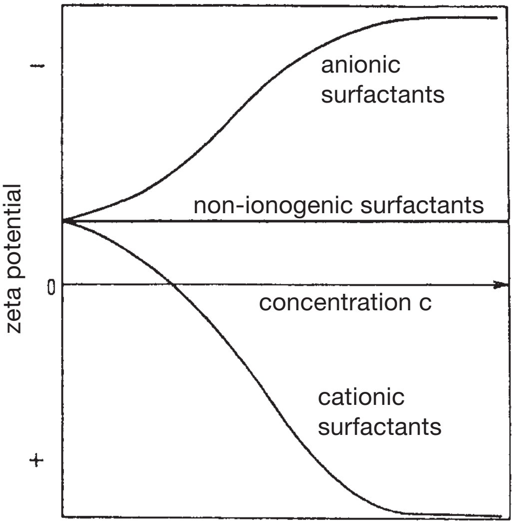

Fig. 4: Diagram showing the change in the zeta potential of textile fibres and pigment soil after surfactant addition.

onic surfactants compensate for it, while non-ionogenic surfactants do not influence it (Fig. 4).

The effectiveness of anionic surfactants in the washing process has several reasons, including the increase in the negative zeta potential of the fibres and soil particles, and the repulsion between the two that results from it. Experiments on fibres soiled with soot and mineral oil depending on zeta potential have shown that only surfactant concentrations up to the critical micelle formation concentration (cmc) of the surfactant in question result in an increased wash effect. This means that the micelle forms of the surfactants therefore have no influence on the zeta potential.

The equation gives the instantaneous contamination concentration c_s in the wash liquor.

$$c_S = c_\infty - (c_\infty - c_0) \exp \left[- \beta 0 \left(\frac{1}{V_c} + \frac{1}{V_S}\right) t\right]$$

c_∞ = equilibrium concentration after an infinite dwell period of the fabric in the liquor,
c_0 = initial liquor concentration,
β = substance exchange factor,
0 = substance exchange surface,
V_c = liquor volume carried within the textile,
V_s = liquor volume in the machine,
t = dwell time in the liquor.

The → Detergency efficiency is defined by the ratio of the residual and initial charge of the textile being washed, and therefore the time-dependent changes in concentration of the impurities to be washed out that are in the liquor c_s. c_∞ depends on the ratio of the initial charge of the fabric to the liquor volume. c_0 is given. The exchange factor β is usually unknown, and is defined by the machine construction and settings, as well as the textile, the impurities themselves and the washing liquor. The exchange surface 0 and the volume V_c are factors that are known, and depend on the textile and machine settings. In the same way, V_s is a known factor dependent on machine construction and settings. The detergency efficiency that can be achieved during a wash process is therefore essentially dependent on the unknown substance exchange factor, which can be estimated. In a single washing bath, the detergency efficiency decreases with the progression of time, i.e. with the quantity of textile being washed. On the other hand, washing machines that are set up in series with counterflow between the textile and washing liquor reach equilibrium after a certain length of time, so that the residual charge remains constant. The point in time at which equilibrium is reached is in turn dependent on the exchange factor and machine settings. Because of this it is important to be aware of these factors in order to enable process control resulting in cost-effective production with a consistent finishing result.

Washing aftertreatment auxiliaries These have the task of returning laundry to its original state after washing, which is one of the decisive factors for consumers when purchasing. → Fabric softener; Fabric softeners can be used for this purpose. → Soft handle treatment.

Washing agent additives The increasing differentiation in textiles, and as a result, washing programs, but also for instance the efforts to produce alternatives that save on packaging and that space, and are also environmentally friendly, have resulted in a range of detergents that is constantly increasing. In line with this, the performance features vary throughout the market.

For universal detergents suitable for all temperatures, textiles and types of soiling, the washing power is the factor of primary importance. Universal powder detergents that contain bleach exhibit optimum performance at 60–95°C, have powerful fat/pigment soil removing properties, are efficient at removing bleachable soiling, and are particularly suitable for washing the cotton and cotton-mix fabrics that dominate the market. There is a definite tendency to omit the pre-wash cycle when using powder-type universal detergents. With liquid universal detergents this trend has already been taken into account. They exhibit optimum performance in the low temperature range at 30–60°C, particularly with all types of soiling containing fat. As yet there are no liquid detergents on the market worldwide that contain integral bleach-active substances. Even without a bleaching agent, liquid detergents remove bleachable stains at low temperatures to a standard comparable with universal powder detergents. However in the higher temperature range (60–95°C), detergent chem-

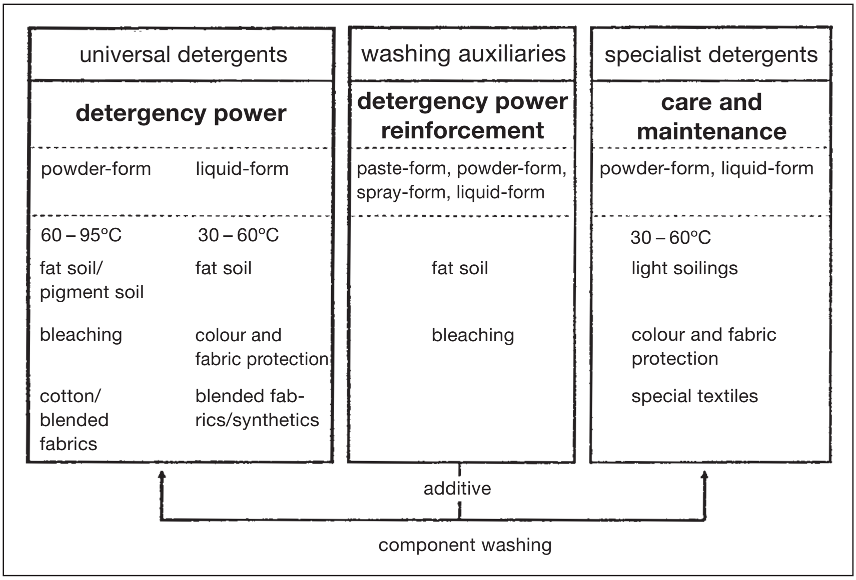

Fig. 1: Main use and benefits of classical detergent types (according to Puchta).

ists have the difficult task of achieving the same effect as universal powder detergents by incorporating suitable bleaching agents. On the other hand, the missing bleaching agent has the advantage that liquid products are more gentle on colour and fibre. The differentiation in performance (Fig. 1) between the two universal detergent categories demonstrates why the liquid versions are considered more as complementary rather than alternative products to powder options.

With specialist detergents, care and mildness of textile treatment are the primary factors. Use of detergent for specialized textiles, such as coloureds and delicate fabrics, for wool, curtains, etc. implies not only low washing temperatures (30–65°C), but also specially adapted formulae. Specialist detergents are, for the most part, free of bleaching agents and optical brighteners, for instance. Sometimes it is necessary to have specific pH levels, or in some cases the addition of softeners causes the laundry to have a soft handle. Washing auxiliaries are available for specific requirements of washing performance. These auxiliaries can be used specifically depending on the type or level of soiling, to attack fatty soiling (fat boosters), bleachable stains (bleach boosters), or both types of soiling (universal boosters) as additives to a universal or specialist detergent. Bleach boosters (scouring salts) in particular have recently taken on greater significance, because from an environmental point of view they are only used in combination with bleach-free specialist detergents and liquid universal detergents only in situations where a specific bleach-

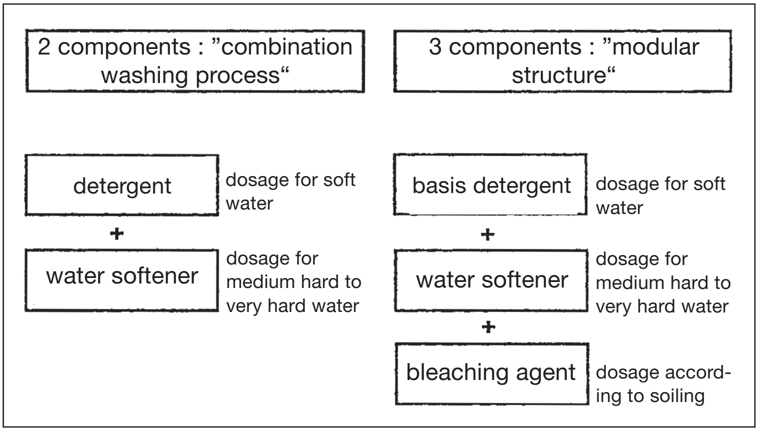

Fig. 2: Component washing systems (powder).

ing performance is required. This means that component washing is possible using traditional types of detergent. Under the general term “component washing systems”, independently of the combination of classic detergent types, new types of washing systems are increasingly being launched onto the market (Fig. 2).

In the combination washing process a detergent dosed for soft water is combined with an additional water softener for medium to very hard water. The modular system incorporates a separate bleaching agent as well as a bleach-free basis detergent in concentrate form and a water softener. This process is intended to make it possible to minimize on chemical additives in domestic washing, using only chemicals for a specific purpose. The future of this type of washing system will certainly be influenced by the development of compact detergents, which were introduced at about the same time. Compact detergents also feature minimal and highly efficient use of chemical additives.

Compact detergents, also known as detergent superconcentrates (Fig. 3), can be identified by their high weight per litre, which saves on packaging and space, and by a concentration of washing performance due to elimination of bulking substances and the use of more efficient raw materials. Perborate monohydrate for instance, which is usually used in compact detergents, is about 50% more effective than perborate tetrahydrate, which is usually used in conventional powder detergents.

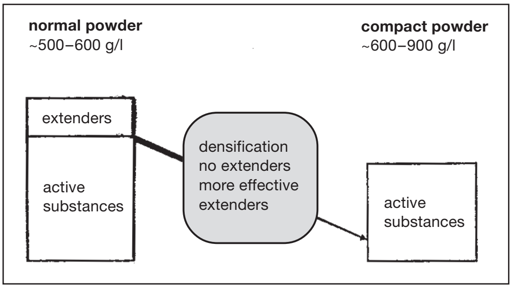

Fig. 3: Principle of a compact detergent (“superconcentrate”).

One reason why it is possible to use relatively small measures of phosphate-free compact detergent is because of the high level of reliability in the performance of the phosphate-free softening system. With products containing phosphate, especially reduced phosphate, a precise balance of softener concentrate with respect to water hardening salts (calcium, magnesium) is necessary to prevent phosphate precipitation, which means that a higher quantity of detergent is necessary if the water is harder. Opposed to this, phosphate-free detergents containing zeolites can be administered in relatively low doses even in hard water, without causing increased deposits on textiles and washing machines, which would be relevant in practice. This discovery is confirmed by the example of a phosphate-free branded detergent currently on the market. In the case of phosphate-free detergents, and even more so with the compact varieties, the quantities recommended for each wash are decreasing. At the same time the graded dosage of phosphate-free detergents, dependent on the level of hardness, is becoming increasingly less important. On the other hand, detergent quantities are differentiated more according to the level of soiling, because in the same way as products containing phosphate, the degree to which soiling is removed is significantly dependent on the amount of detergent used. This action is a good idea from an ecological point of view, and falls in line with the requirements of the Detergent and Cleaning Agent Law (Ger.: Waschmittelgesetz) relating to minimal use of detergent (§ 1).

compact detergents (phosphate free)	↔	modular-system (phosphate free)
● low dosage		● low dosage
● adaptable for the best possible results from every wash		● selective dosage depending on soiling
● easy to use (only 1 washing component)		● independent combination of the individual components

Fig. 4: Comparison of compact detergents and modular system.

Phosphate-free compact detergents and modular systems make it possible to use the smallest quantity of detergent. Compared with modular systems, compact detergent (Fig. 4) represents the universal type because of its complete composition, and it guarantees highly reliable performance because of the optimally balanced effect of all components in each wash cycle. It is easy to use and does not pose problems for the consumer. With modular systems, a specific measure of detergent can be used depending on the soiling, or individual detergent components can be combined. As is the case with component washing using traditional detergent types, these detergents are aimed particularly at consumers who have knowledge of washing technology.

An example of a basic formula of a modern phosphate-free universal powder detergent (Fig. 5) shows that the percentage of individual ingredients can vary extremely. With some ingredients this can be partially explained by the differentiation between conventional

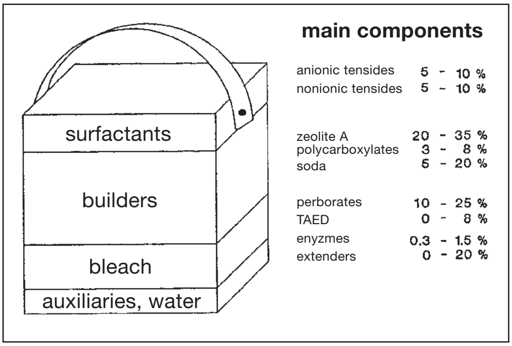

Fig. 5: Contents of phosphate-free powder universal detergents.

and compact powder types. Compact detergents are noted for their lack of bulking substances and a correspondingly relative proportion of active substances. But there are also examples of conventional powders that contain practically no bulking substances.

Certain washing agent additives can be found in the waste water from domestic washing machines, as shown in Tab. 1.

The evaluation criteria for the ecological behaviour of detergent and cleaning agent additives originally concentrated mainly on primary biodegradability in the case of surfactants. The German Detergent and Cleaning Agent Law as well as EC guidelines including the relevant legislation were restricted until now to the requirement for a minimum degradability of 80 or 90% for anionic and non-ionogenic surfactants. To limit the liming effects of detergent phosphates, the quantity of phosphate used was controlled by means of the directive concerning maximum phosphate levels.

The debate on the environmental impact of detergents and cleaning agents clearly shows that an increasing range of criteria has an extreme eco-political significance. The possibility should not be ruled out that a requirement for legislation on this matter will be recognized in the foreseeable future. The following general criteria or aspects are being considered and debated:

- aquatic toxicity for fish, daphnia (water fleas) and water plants,
- total decomposition of organic detergent additives,
- formation of toxic metabolites,
- complex forming properties and remobilization properties for metals,
- enrichment processes in the soil in agricultural sludge recycling,
- bio-accumulation (enrichment in the food chain),
- fertilizing effects in lakes, ponds, etc.,
- unwanted supply of salts in the form of Na^+, SO_4^{2-}, SiO_4^{3-}, BO_3^{3-} ions in surface water.

There is a current trend, not governed by the law, towards surfactants that biodegrade completely. Completely biodegradable means that the surfactant decomposes rapidly under any environmental conditions (in the presence and absence of oxygen), without any residual molecule fragments that do not biodegrade easily. A second general trend is the increasing importance of → Surfactants on the basis of raw materials that can be regenerated (Fig. 6).

contents of heavy-duty washing agent	percentage %	Waste water concentration (mg/l)
Surfactants:		
anionic surfactants	10	14
non-ionic surfactants	5	7
special soaps (behenates)	3	4.2
Builders:		
Tripolyphosphate	20	28
Na-Al silicate	24	33.6
Bleaching agents:		
Na-perborate	20	28
Bleach activators:		
TAED	2	2.8
Other contents:		
CMC	2	2.8
Na-sulphate	10	14
Na-silicate	3.6	5.0
enzymes	0.4	0.56
optical brightening agents	0.2	0.28
perfume oil	0.2	0.28

The calculation is based on a specific washing agent consumption of 28 g and a waste water output of 200 l (both per person per day). This corresponds to a total content of ≈ 140 mg/l of washing agent additives.

Tab. 1: Specific waste water concentrations of washing agent additives.

Despite this general trend, the most important surfactant from a quantity point of view will for many years continue to be an anionic surfactant based on mineral oil, known as LAS (linear alkylbenzol sulphonate). It is expected that fatty alcohol sulphate (FAS) will increasingly take the place of LAS as a detergent additive. The raw materials of FAS can be regenerated, and it is fully biodegradable. In the case of non-ionogenic surfactants a trend towards low-ethoxylated alcohols can be observed, which improve the removal of fat-based soiling during washing, particularly at low

temperatures. In this instance too the use of raw materials that can be regenerated, i.e. fatty alcohol ethoxylates (Tab. 2), will increase. Alkyl polyglucosides constitute a particularly interesting category of surfactants, which are obtained by condensing fatty alcohols with glucose, e.g. from starch. These surfactants are not only completely biodegradable, they are also gentle on the skin, and also have a performance that is comparable to standard surfactants. Alkyl polyglucosides are used in universal liquid detergents, in particular for liquid dishwasher detergents.

The development of detergent builders (Fig. 7) is generally identified by the increasing spread of phosphate-free detergents in Europe. As a consequence, zeolite use and requirements will increase, while phosphates will continue to become less significant. This development can be seen by the intensive development of zeolite capacity on a worldwide basis, for example in countries such as Spain or Great Britain.

tripolyphosphate can be achieved. The co-builders most commonly used in Europe (Tab. 3) are sodium carbonate and polycarboxylate, a co-polymer based on maleic and acrylic acid. Although this polymer is eliminated to about 90% by adsorption in purification plants, and as yet no ecological disadvantages have been discovered, the insufficient biodegradability is always under debate. For this reason, priority is given to a search for substitutes with better biodegradability. Examples of substances with good biodegradability are citrate, which has been known for a long time, and tartrate succinate. These raw materials apparently have limited use in Europe and overseas. NTA (nitrilotriacetic acid) could represent an alternative co-builder. However this substance, which has been known for a long time, gained a bad reputation in the past because of its alleged poor degradability, and it was feared that it had heavy metal remobilization properties. For this reason, the textile industry subjected itself to restrictions regarding NTA use in Germany, for example. NTA is not used in any household detergents in Germany. Extensive experiments and an extended monitoring program have proven that the misgivings expressed in the past were unfounded. NTA biodegrades very efficiently under environmental conditions. However it is still questionable whether these positive findings will be sufficient to restore the reputation of NTA. Crystalline sodium layered silicates are a new development in builder products. The substance “SKS-6”, which bonds hardness ions, falls into this category. Because this compound is so unstable above a wash temperature of 60°C however, its use is presumably limited to specialist applications or perhaps as co-builders in combination with zeolite A.

Bleaching components (Fig. 8) are also undergoing significant changes as a result of the ongoing tendency towards low washing temperatures and compact detergents. Because of this, the proportion of perborate monohydrate instead of perborate tetrahydrate will increase in parallel with the development of compact detergent.

Perborate is added to full detergents in a ratio of 10–25%, which makes it one of the most important detergent additives as regards quantity (Tab. 4). It exerts an intensive bleaching effect because the peroxide releases active oxygen. Since the perborate has a boron con-

tent of approx. 7%, a specific boron level in waste water of 250–300 mg can be calculated per inhabitant per year. At a specific waste water level of 200 l per head, the result is a mean waste water concentration of 1.25–1.5 mg of boron per litre, but in practice the value measured in the purification plant flow is 0.9–1 mg/l.

The discharge values indicate that in principle boron compounds can not be eliminated by means of conventional waste water purification processes, i.e. neither physical/chemical processes nor biological processes result in complete removal of boron. This means that boron is discharged unaltered into water in the form of boric acid or borate ions. If the waste water is diluted at a ratio of 1 : 10 in the drainage, in theory the maximum water concentration to be expected is 0.12–0.15 mg/l. However boron has a low acute toxicity towards water organisms (Tab. 5).

Perborate has been used in European detergents for over 80 years. Since an alternative to perborate that is comparable in detergent stability and ease of use has not yet been found, perborate is likely to remain the most significant bleaching component for the next few years. Percarbonate on the other hand became a bleaching component in washing auxiliaries (scouring salts), and as part of a modular system. Organic per acids, such as diperoxydodecandic acid (DPDDA) or phthaloylaminoperoxycapronic acid (PAP) exhibit good bleaching effects at low temperatures. Bleach activation is essential at low temperatures. For this reason the use of bleach activators will increase. TAED (N,N,N,N,-tetraacetylethendiamine), with a current annual capacity of approx. 60 000 t, clearly dominates the European activator market. There are competitors, such as pentaacetyl glucose (PAG), diacetyldioxohexahydrotriazine (DADHT), and nonanoyloxybenzene sulphate (NOBS), but they are not used in Europe, or only play a very minor role.

The use of bleach stabilizing components, i.e. heavy metal bonding substances such as EDTA (ethylene diamine triacetic acid) and phosphonates, is regressive. EDTA, which is not easily biodegradable and has heavy metal remobilizing properties, is no longer used in domestic detergents in Germany, for example. It

seems that an alternative has recently been found with better biodegradability for some applications. This alternative is isoserin diacetic acid (ISDA).

Other detergent ingredients that are now considered almost indispensable are enzymes (Fig. 9). Proteases constitute the most important category of enzymes by a long way. Their important contribution is to remove soiling with protein content. It can now be observed that after decades of 1st generation protease use, most powder detergents have now switched to 2nd generation proteases, i.e. more effective proteases, in particular in a highly alkaline environment. There are also so-called 3rd generation proteases with further improved stability on the market, which in future will be used in detergents. The use of amylases, which act against starch-based soiling, will remain restricted. Currently amylases can be seen mainly in liquid products in combination with proteases. New specialist enzymes, such as lipases which act against fatty soiling, or cellulases, which clean and maintain cotton fibres, are already used globally in some detergents. Since their spectrum of effectiveness is limited, particularly compared with the other components of detergent, such as surfactants, these new enzymes are likely to be used only on a limited basis in detergents. After all, these enzyme developments can contribute towards the removal of soiling, particularly at low temperatures, and therefore restrict the use of surfactants even though they are not rendered superfluous.

Where foam inhibitors are concerned, a further decline in the use of soap is to be expected, and it will be replaced by foam inhibitors containing silicon oil or paraffin. The greying inhibition function of cellulose derivatives has now been mainly superseded by other detergent components, such as polycarboxylates, and therefore a further reduction in cellulose derivatives is expected. No immediate change of any significance is expected in optical brighteners (Tab. 6), in other words their use will continue to be restricted just to the category of universal detergents. Bulking agents, primarily sodium sulphate, will be practically eliminated as compact detergents come to the fore (according to Upadek and Krings, as well as Brüschweiler, Felber, Schwuger and Huber).

Washing agent dosing Because of the chemical industry's self-imposed commitment to ecology and the economic pressure to conserve raw materials and energy, it is essential to rethink optimization of detergent formulae and recommended dosage constantly, as well as domestic laundering care methods.

During the 1980s, the general population became much more aware of environmental issues. Many households in Germany claim to be environmentally orientated. Detergents and environmental tolerance are subjects constantly under debate. Much has happened in the past few years in the way of improvement. This is illustrated by the fact that phosphates in detergent have

Tab. 6: Chemical structure and ecological properties of detergent components: other possible additives.

been completely replaced by raw materials that are compatible with the environment, in particular sodium aluminium silicate of the type zeolite A, or the introduction of compact detergent systems. Both legal requirements and the requirements of consumer organizations and environmental associations continue to aim for an overall reduction in detergent use, even though detergent dosage has fallen within the past 20 years to one-fifth of the original quantities (Fig. 1).

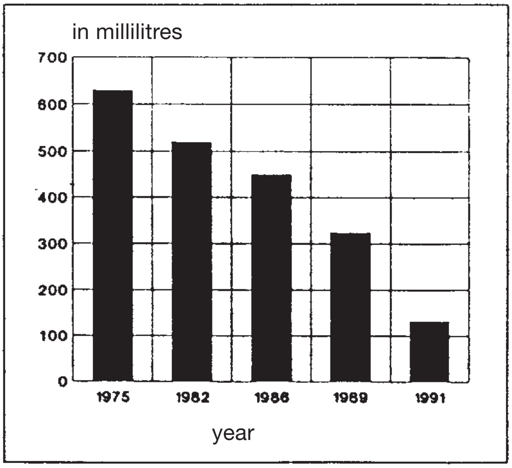

Fig. 1: Reduction of washing agent dosing, demonstrated from the Persil example: over 16 years the Persil dosage fell from more than 600 ml to less than 100 ml per wash (recommended dosage for water hardness range 3).

Environmental protection and washing performance are equally important to the detergent manufacturer. The environment should be subject to as little burden as possible. At the same time, detergent dosing should be orientated towards achieving the required cleaning performance and the necessary care of laundry and washing equipment. The consequences of under-dosing are frequently not only insufficiently cleaned laundry and reduced hygiene, but also damage to the textile being washed and to the washing machine. The correct solution in order to conserve the environment is to use the lowest dosage, which fulfils both these conditions.

For this reason, a constant objective of detergent development is establishing the specific minimum dose for the current detergent formula. In order to establish the required dosages, application-orientated tests are usually carried out on domestic laundry. The textile being washed is treated with a variety of different naturally occurring soil types, such as fats (skin grease, make-up), protein (milk, egg, blood), pigment soil (dust, mud), or bleachable stains (coffee, tea, fruit and vegetable juice, red wine). Various different quantities of detergent are used. The amount of soiling is assessed before and after washing, by means of visual examination or objective methods such as optical measuring processes. The smallest quantity of detergent that still results in an acceptable wash effect is used to define the minimum dosage.

The main additives in the detergents used for domestic washing are surfactants. The most commonly used universal detergents contain surfactants in standard form or as a compact powder, or also as a liquid formulation. Surfactants improve the wetting properties of water; they reduce its surface tension. Pure water has very high surface tension, and is poor at wetting the laundry or other hydrophobic surfaces. If surfactants are added, the surface tension of the solution becomes lower and the laundry is penetrated by the liquid. For this reason, if a hydrophobic surface is available to a surfactant solution, e.g. a textile fibre surface with fat and particle soiling, the surfactant molecules will be deposited on it. During this process they affix themselves with their hydrophobic residue into the fat. The hydrophilic head remains in the water. As further surfactant molecules are deposited, all the fats gradually become detached from the surface in the form of small particles surrounded by surfactants. Depending on the melting temperature of the fats, these particles can be liquid or solid. The detachment process is assisted by the washing machine mechanics (rotary movement of the washing drum), the heat supply (washing temperature) and the duration of the wash cycle. The fat particles are only stable in water because they are protected by the surrounding surfactant shell. The case of pigment soil particles is similar to fat-based soiling; surfactant particles are also deposited on their surface. They even penetrate into the tiny cleavages between the particles and the fibre surface. This causes the entire soil particle to be completely surrounded by surfactant molecules, so that it can then be rinsed off with the water.

There are other additives in detergent that support surfactants. There are substances known as builders that soften the water – which constitutes an essential condition for a good wash result. Further additives raise the alkaline level in the washing liquor, which makes soil detachment easier. Detergent enzymes also make soil detachment easier, by hydrolyzing protein or fat-type soiling into small fragments. For example protease ensures easy removal of protein; lipase assists the washability of fatty soiling. In order to remove soiling as fully as possible, the washing liquor must contain enough surfactants, i.e. sufficient reserves of detergency power. At the beginning of the washing process, all surfactants dissolve rapidly in the washing water. Gradually a proportion of these deposit on the surface of the textile fibres. The other surfactants lift soil from the fibre and hold it in a stable situation in the washing liquor. With both of these surfactant groups, the original total quantity is “lost” since it no longer contributes to further cleaning: the detergency power reserve decreases.

The properties of “hard water”, which can be damaging, are well known. Only about one-fifth of drinking water is “soft”, i.e. only has a low level of water hardness. Water hardness is caused by small amounts of calcium and magnesium salts, which are present in all drinking water. When the water is heated, the salts precipitate as carbonates in the form of insoluble lime. Lime deposits would also occur in washing machines and on laundry if modern detergents did not contain a sufficient proportion of softeners, which fix the hardness in the water. Where phosphates were a necessary additive in detergents for the complex fixing of water hardness, nowadays in phosphate-free detergents, the problematic calcium and magnesium salts are removed from the washing liquor by zeolite A, which is insoluble in water.

Lime also has an unfavourable effect on the washing effect of a detergent. Since some of the calcium and magnesium salts can form insoluble compounds with some surfactants, wash-active substances are removed from the detergent. The wetting properties and wash performance are reduced.

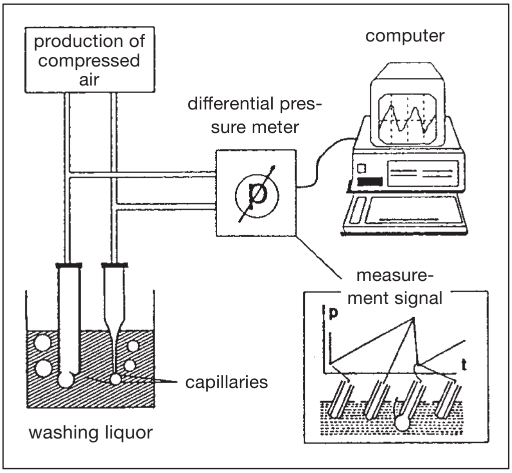

Fig. 2: Construction of an online tensiometer: compressed air flows through two capillaries of different widths into the washing liquor. The pressure difference between the capillaries is recorded electronically (by Henkel).

An online tensiometer can be used during washing for direct analysis of the ratio between the quantity of surfactants still available or “free”, and the amount deposited on fabric and soil, i.e. “used”. The online tensiometer is a sensor to detect surfactants, and functions on the principle of the maximum bubble pressure method (Fig. 2). Small quantities of air are pumped through two thin capillary tubes, which are immersed at the same depth in the washing liquor. Air bubbles form constantly on both capillaries. The pressure required to form bubbles varies because of the different diameter. The higher pressure is measured in the narrower capillary. The pressure difference between the two capillaries now only depends on the surface tension of the liquor. This parameter is in turn directly linked with the surfactant concentration in the washing liquor.

Pure water has a high surface tension. The more surfactants there are in the water, the more the surface tension drops. The level of surface tension can be used to determine the surfactant amount. The only surfactants measured are those that are still free in the solution and can therefore still exhibit surface-active properties. In other words these are the surfactants which are in the form of individual molecules or micelles. An exception to this is the surfactants that are already attached to the fibre surface or soil particles. For this reason an online tensiometer records the quantity of surfactants in the washing liquor and the wash reserve, which is particularly important in practice, by measuring the dynamic surface. This method is particularly easy if the differential pressure measured is compared directly with the prescribed dosing of the detergent. This produces a calibration curve (Fig. 3), which can be used to work out an unknown concentration of detergent in a washing liquor if all other influential parameters are kept constant.

An online tensiometer measurement taken from the washing liquor discharged from a simulated wash cy-

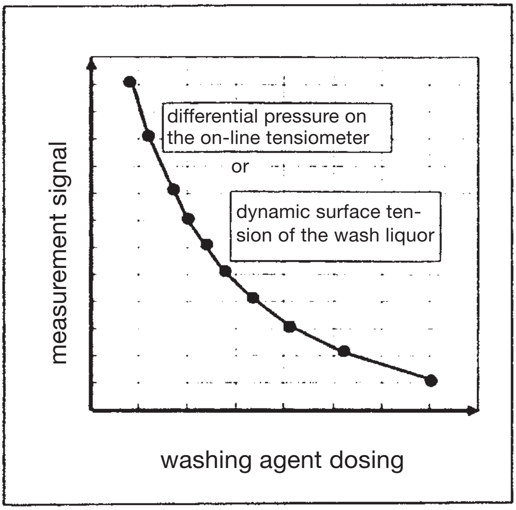

Fig. 3: The online tensiometer as a surfactant sensor: connection between the washing agent dosing and the measuring signal of the online-tensiometer or the dynamic surface tension of the wash liquor (by Henkel).

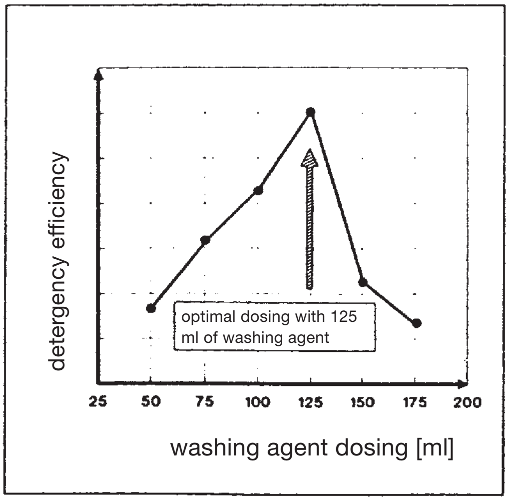

Fig. 4: Maximum detergency efficiency at optimal dosing: if the optimal dosing is maintained, there is a maximum of washing agent action. The overdosing avoided guarantees the minimum of environmental pollution (by Henkel).

cle, shows that the quantity of wash-active surfactants and therefore the detergency power in the washing liquor as a result of increasing amounts of laundry and soil in the wash liquor, is actually reduced. The online tensiometer can be attached directly to the washing machine. In practical tests for example 3.5 kg of normally soiled domestic laundry is washed at 60°C in the main wash cycle without a pre-wash. If there is a constant water flow of 20 l per wash cycle, there are varying initial concentrations of detergent in the washing liquor depending on the dosing. Dosing varies in another area. At the end of the wash cycle, the actual surfactant concentration (and therefore indirectly the concentration in the detergent) can be measured with the online tensiometer. If the detergency efficiency is calculated from the values measured, the optimum dosing can be seen in graphic format. The detergency efficiency reaches its maximum at the exact point at which the detergency power reserve and the quantity of "used" surfactants are at optimum compatibility (Fig. 4) (according to Krings, Smulders and Müller-Kirschbaum).

Washing agent enzymes Detergent enzymes have a high resistance to alkali and thermostability at approx. 60–65°C. Towards the end of the 1960s, the technical production of detergent proteases underwent rapid expansion. In 1968 the first heavy duty detergent with microbial → Proteases was manufactured by Henkel. In 1969, about 80% of detergents in West Germany had enzyme additives; in 1975 this figure stabilized. The most popular detergent enzymes in 60°C detergents are microbial proteases, bacillopeptidases and → Amylases (→ Enzymes).

Washing agents Washing agents or Detergents remove fat and soiling substances from textiles. In the context of textile finishing, detergents are specially adapted to suit each finishing process, e.g. for raw wool scouring, washing after dyeing and printing, etc. Laundry and domestic detergents are specifically included under the category of detergents. Domestic detergents can be classified depending on their use into the following categories: →: Heavy duty detergent; Mild washing agents; Special washing agents. Depending on the method of manufacture, detergents can be classified as mix and spray (cold and hot sprayed) products. Depending on consistency there is a distinction between detergents in powder form and liquid products.

	[%]
anionic surfactants (LAS)	5–10
niosurfactants (alcohol ethoxylates)	1– 5
foam regulators (soaps, silicon oils)	3– 5
builders (zeolite, polycarboxylates, NTA)	30–40
bleaching agent (sodium perborate)	20–30
extenders (sodium sulfate)	0–10
bleach activators (TAED)	1.5– 4
stabilizers for perborate (EDTA, Mg-silicate)	0.2– 2
enzymes (proteases)	0.3– 1
greying inhibitors (CMC)	0.5– 1
optical brightening agents (stilbene and pyrazoline derivates)	0.1–0.3
aromatics	0.2

Tab.: Universal washing agents.

→ Surfactants (WAS) form the product basis, as well as preparations made from surfactants using → Washing auxiliaries or builders, boosters, as well as other additives or bulking agents (Tab.). → Washing agent additives.

Washing and hydroextraction machine Multipurpose machine used as a washing machine, hydroextraction machine, and agitator (loosener). The drum construction is usually divided in a Y shape for side or front loading, also available in the form of a → Front loading washing machine (loading/unloading can be manual or mechanical). Operates on the multi-bath principle. The revolutions for washing/agitating is 20–30 rev/min, for the final spin it is 500–1000 rev/min. Load time is 40–50 min. Residual moisture 50–60%. Capacity 9–800 kg.

Washing auxiliaries (→ Builders), improve the effectiveness of detergents. In the textile industry these are usually colloids, such as cellulose derivatives, and also water correction agents, organic solvents, etc.

Washing blue → Ultramarine.

Washing carriage in screen printing After printing, the printing blanket is washed with rotating brushes and water. During this process, washing carriages run on tracks that are also intended for the → Printing carriage. It can be powered manually or electrically.

Washing detergent analysis → Surfactant analysis.

Washing detergents Products manufactured from →: Surfactants; Phosphates; Perborates or alternative products and other complementary components as specified by the → Detergent and Cleaning Agent Law. They act in conjunction with water to produce a cleaning effect, or are intended for cleaning (according to an additional suggestion: or products that can be used as additives and auxiliaries in washing and cleaning processes), which can finish up in environmental waters after use. The definition also includes particular textile and leather auxiliaries and industrial cleaners.

Washing in hard water,

1. Dependent on the presence of soap, the formation of insoluble, wash-inactive calcium and magnesium soaps (→ Water hardness salts).
2. If sodium carbonate is added (before soap and during heating), only partial softening occurs.
3. High-molecule → Polyphosphates in a quantity appropriate to the hardness enable the detergent to be utilized fully; can not be used in boiling baths.
4. → Lime soap dispersant only prevents flaky lime soap secretion by forming colloid dispersing particles (clouding of washing liquor) with no detergency power.
5. Although synthetic ionogenic detergents are usually resistant to lime, they have a lower detergency power in hard water at 10–30°d (fatty alcohol sulphates, fatty acid condensation products), or they frequently require 3 to 4 times the quantity of the product than would be necessary in the case of water at 0°d to achieve the same washing effect.
6. Synthetic non-ionogenic products have better detergency power than ionogenic products.

Depending on water hardness (particularly in the presence of heat, where inactivation additives are only effective under certain conditions), there are always excesses of detergent. The value of the detergent should always be weighed against the cost of → Water softening.

Washing lubricants → Textile lubricants.

Washing machines There are two different types of washing machine:

I. Washing machines for laundry care (domestic washing machines, laundry washing machines).

II. Industrial washing machines for pretreatment or after-washing, e.g. after-print washing of textiles.

In the case of pretreatment washing machines, discontinuous systems (Fig. 1) are available for small batches, and continuous systems (Fig. 2).

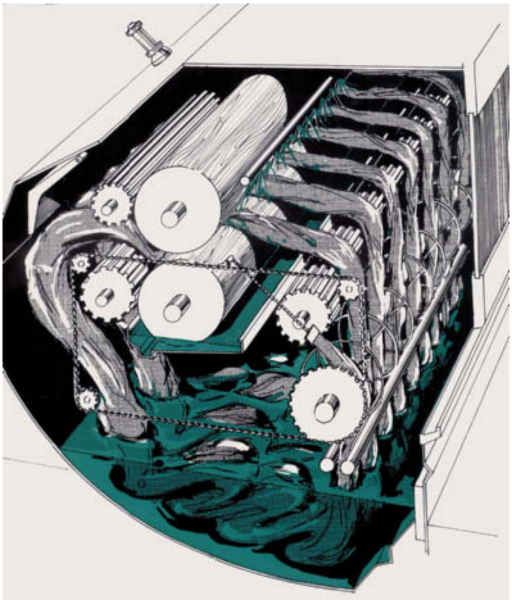

Fig. 1: Discontinuous rope washing machine (Hemmer) for the pretreatment of woollen fabrics.

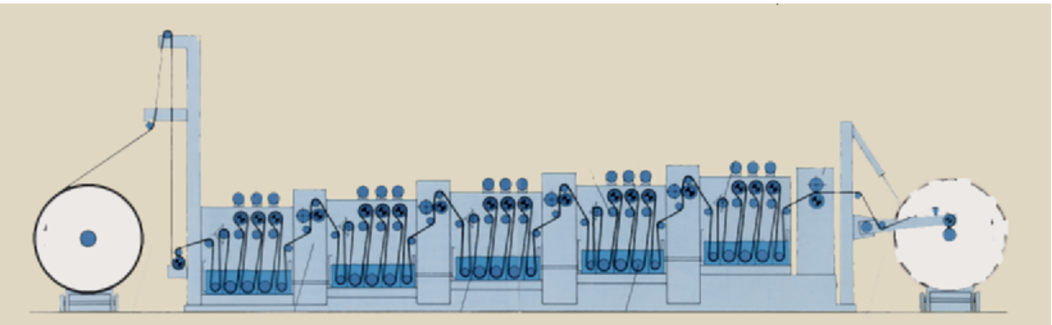

Fig. 2: Continuous open-width washing range for the pretreatment of fabrics (Kleinewefers KTM).

Washing machines

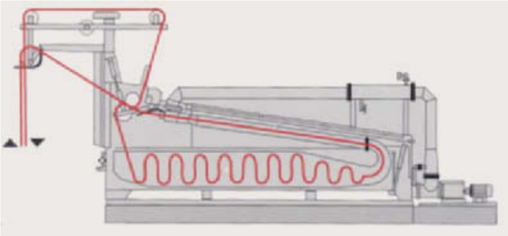

Fig. 3: Continuous rope washing machine (Küsters).

Depending on the type of fabric/thread, washing can be carried out in rope form (Fig. 3) or open-width. Open-width washing machines can be sub-divided into roller vat types (Fig. 4) and drum washing machines (Fig. 5).

Machines designed for continuous open-width washing usually consist of individual washing systems, which are considered as modules of a plant, each having washing functions. The sequence of these systems within a machine is variable. The individual systems in a plant can be distinguished, sometimes significantly, in their management of textiles and washing liquor. The washing liquor in the individual washing systems is either changed in charges, or is transferred from one system to another against the direction of the textile. Combinations between so-called standing baths and constant liquor change occur within a plant. A counter-flow between the liquor and yarn can be implemented while the yarn is still in the system, particularly when multiple liquor separation is carried out.

Yarn guiding can be fixed or non-fixed. When it is non-fixed, there are two different types – plaiting down without folds, or with folds or loops. Plaiting down without folds is done rarely because of the length of the bath or dwell period that would be required if plaiting with folds is not indicated because of the danger of fold marking. Plaiting down in folds can be done horizontally in a trough, on a belt, roller bed, chain or sieve. Alter-

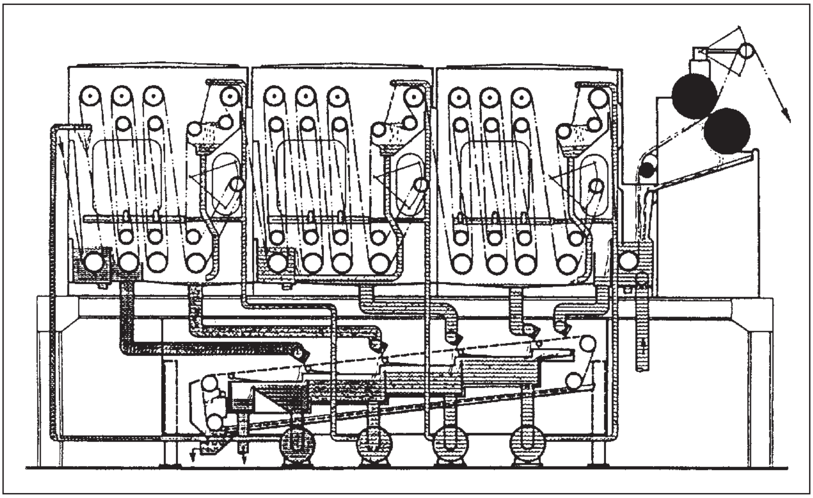

Fig. 4: Econtex roller vat (Babcock).

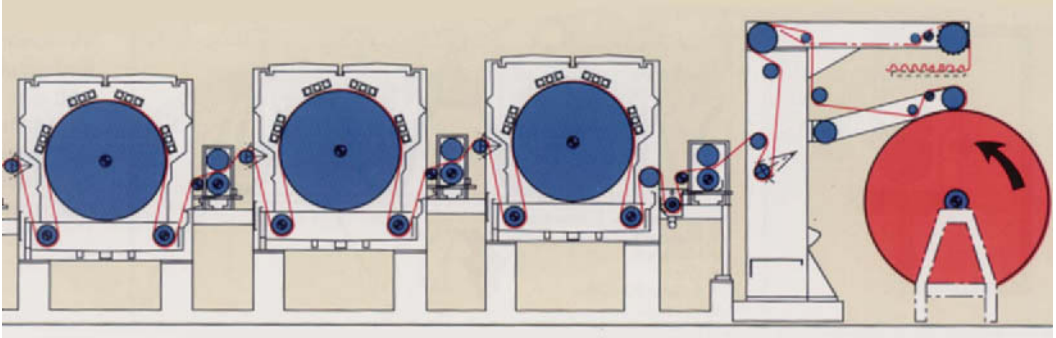

Fig. 5: Trikoflex-2000 drum washing range (Kleinewefers KTM).

natively it can be done vertically in a J-box or trough. During this process, the fold marking is more intensive the higher the pressure on the fold and the more intensive the structural change is during the dwell period in the liquor. The pressure on the fold is at its lowest with hanging loops and at its highest in the J-box. Fabric transport occurs either independently as a result of gravity, or it is forced by the liquor impulses, as well as milling elements or the motion of the plaiting elements. The mechanics acting on the yarn are designed to aid relaxation and soil detachment.

Rotating sieve drums constitute a transition between non-fixed textile guiding to fixed methods. The rotating sieve drums are in a flooded state, and they use pulsation or constant suction so that the liquor flows through the textile.

The simplest example of fixed textile guiding is the roller vat washing machine. Its washing effect is firstly improved by liquor separation using individual compartments as well as squeezing units and strippers. Secondly the liquor exchange is intensified with the aid of overflow weirs or gutters, spray tubes, beating and vibration elements, as well as air blowing, double yarn thread-up and associated liquor turbulence. Under optimum conditions with regard to machine construction and condition, the textile tension is affected by friction with the liquid rather than with roller bearings. Other guiding elements can be used instead of rollers, such as winches and corrugated rollers.

To achieve maximum liquor separation, the objective is to keep the liquor as short as possible, for example by employing several squeezing units in series with spray tubes or overflows between. The squeezing units can be arranged around a central cylinder or above one another in a tower, to avoid a long free yarn path. A high level of liquor separation and textile throughflow can be achieved in non-flooded systems with horizontal guidance and counter-flow. In special cases the detergency efficiency can be improved by increasing liquor exchange with the textile by using suction and pressure jets. In addition, continuous washing can be carried out under pressure at temperatures in excess of 100°C. In order to do this, it is essential that the washing system is purpose-designed and sealed.

Washing machines for disinfection laundry Functionally standard drum washing machines that operate discontinuously, which are used for a disinfection washing process. However they have a built-in separator for the clean/dirty section (side for clean laundry/side for soiled laundry) and accordingly there are separate openings for loading and unloading, which each have to be locked on both sides so that it is impossible to open both at the same time. This type of machine is specifically required by the Federal Health Office in Germany.

Washing mechanics One of the four factors of Sinner's wash cycle (→ Washing). It refers to the flow ratio caused by the movement of washing liquor or textile. In the case of a → Laminar flow, all parts of the flowing medium move parallel to the sides of the tube, so that the speed is highest at the middle point, and towards the sides it drops off to zero. This is because the layer adjacent to the side adheres as a result of surface forces. However if a specific critical speed is exceeded, or if the tube cross-section is larger, swirling effects occur, and at Re > 2300, the laminar flow becomes a → Turbulent flow or swirling flow. The limit layer theory applied to laminar flow, permits simplification of the differential equation of the flow and diffusion field to such a degree that in this case it can be solved exactly. For laminar and parallel flow to and over a plate, the flow velocity can be broken down into components Wx and Wy on a vertical axis, which are constant with respect to time. The mass flow of the substance passing over can be calculated in the same way. The differential equation of the concentration boundary layer is derived from the second → Fick's law of diffusion. Furthermore the continuity equation is valid for the speed component.

If the differential equation is simplified so that the friction and inertia forces of flow are only effective in the direction x, and transport of the substance in this direction only occurs by means of free convection, the solution for localized substance transport is:

$$\mathrm{Sh} = 0.664 \cdot \mathrm{Re}_x^{0.5} \cdot \mathrm{Sc}^{0.33}$$

In this situation,

$$\mathrm{Re}_x = \frac{w_\infty \cdot x}{\nu}$$

represents the Reynolds number Re formed with the unobstructed approaching flow velocity W_∞ and x (distance). The concentration and velocity profiles are of the same type. If D (diffusion coefficient) and υ (viscosity) have the same numerical value (i.e. Sc = 1), then both profiles are congruous. The most important characteristic of these profile curves is the disappearing curve at the side, at which substance transport occurs only by means of diffusion. Since the profiles decline asymptotically to the values of the unobstructed flow, the thickness of the boundary layer can be defined as the distance from the side up to which an unobstructed flow velocity or solution concentration of up to 99% is reached.

The flow velocity and the run distance (= flow path over the surface) influence the thickness of the boundary layer (δ) and the substance transport number (β) the opposite way around, i.e. $\beta \sim {}^{1}/\delta$.

Reynolds recognized that there is an analogy between impulse exchange and substance transport in turbulent flows where the flow velocity and concentration fields are congruous (Reynolds analogy). Prandl and Taylor expanded further on this analogy to the higher values of the Schmidt number. These theories are based on the assumption that the turbulent boundary layer near to the side becomes a laminar sub-layer because the velocity drops on a linear basis towards zero.

The Reynolds analogy is used to calculate the resistance correction value for an even surface in a turbulent flow where $c_W = 0.074\ Re_x^{-0.2}$.

The resulting substance transport value in a turbulent flow is $\beta \sim w_\infty^{0.8}$. According to this, the influence of speed on the substance transport is significantly greater in turbulent flow than in laminar flow. It is often the case in turbulent flow that the resistance correction value is independent of the Reynolds number, and therefore according to the analogy, substance transport is not dependent on viscosity.

Five different flow types are possible:

1. liquor approach flow in the direction of textile travel (parallel flow).
2. liquor approach flow in the opposite direction to textile travel (counter flow).
3. Liquor approach flow vertical to the direction of textile travel (stagnation point flow or impact flow).
4. liquor approach flow transverse to textile surface and direction of textile travel (transverse flow).
5. liquor approach flow through textile (throughflow).

None of these flow types occur exclusively in an open-width washing machine. For this reason it is difficult to make quantitative statements and calculations in the context of substance transport and flow mechanics.

In order to discuss the link between substance transport and flow mechanics, a further distinction must be made between forced convective and free convective substance transport. In the case of forced convection, the substance transport is characterized by the substance transport parameter β and the diffusion coefficient D, and the flow process is distinguished by the velocity of the fluid and its kinematic viscosity. A further factor is “l”, which is needed to identify the geometric size ratios.

According to the Buckingham theories, these five influential factors are used to produce three dimensionless indices. From this the substance transport for forced convection can be calculated (Sherwood number)

$$Sh = f\,(Re_x, Sc)$$

Free convection is caused by gravity as a result of varying densities that occur in the layers near to the side between non-saturated and saturated solutions (washing liquors). As opposed to forced convection, the velocity of the flowing fluid must be replaced by the gravity coefficient S. In this way, the Grashof number Gr is calculated instead of the Reynolds number. In this way, the following equation can be applied to substance transport in forced convection:

$$Sh = f(Gr, Sc)$$

Calculation formulae derived from traditional flow theory can be used to calculate substance and heat exchange for the five flow forms in simple individual cases. These formulae produce a solution in the case of laminar flow.

Washing off The removal of scrooping agents, preparations, sizes, chemicals, textile auxiliaries, non-set dyes and finishing agents. Washing off has a high level of influence on water use, and therefore also on costs and the problem of waste water. With discontinuous washing off, the textile stays in a machine and the washing and rinsing liquors are added or exchanged. Keeping the liquor ratio as short as possible lowers water consumption. With continuous washing off, the textile runs through several individual machines or sections, and the rinsing liquor is directed in counter-flow, i.e. there is a fresh water supply at the point at which the textile leaves the machine. Turbulence is used to ensure that the liquid lamella between the textile and the liquor is constantly broken up (increasing kinetic energy). The number of washing baths should be kept as low as possible (see Fig.).

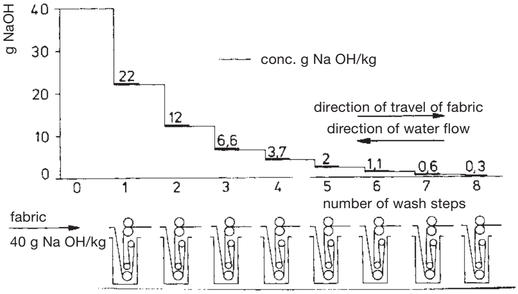

Fig.: Washing off 40 g caustic soda liquor/kg fabric with 4 l water/kg fabric.

Washing of printed goods Printed articles usually need to be washed after setting (with the exception of pigment and transfer prints). Washing serves to remove thickeners, chemicals and non-set dye, in order to achieve optimum fastness. Each washing process is dependent on the substrate and the type of dye that has been applied. Depending on the arrangement of each particular plant, the process can be carried out either continuously or discontinuously. → After-print washing.

Washing of woollen goods,

I. Raw wool: removal of lanolin, sweat, soil, e.g. Leviathan (Belgian process) using soft water and soap (calculated according to the wool; poss. 10–20% substitution with lime-resistant synthetic detergents, which makes clear rinsing in the final baths easier), ammonia or soap + sodium carbonate, poss. + fat solvent soap (in the case of pitch tips). Final rinsing in soft water. The impurities that are washed out precipitate to form a solid sludge. → Raw wool scouring.

II. Wool yarn: removal of spinning oil and size (→ Desizing). Sodium carbonate or higher alkaline levels should be excluded if possible with yarns that felt easily. Carded yarn is washed using soap or synthetic detergent + sodium carbonate calc. or ammonia. Worsted yarn with up to 1% fat content is usually washed with synthetic detergents, poss. + ammonia, and rinsed thoroughly.

III. Hairy yarn: mainly any melted-on mineral oil that requires removal. In certain circumstances difficulties can arise, in that the use of a highly effective synthetic detergent is urgently recommended. Technique (→ Salt wash is also possible), depending on soiling and fat content, using detergent (poss. + sodium carbonate calc. or ammonia). Subsequent rinsing is carried out, twice warm and once cold, until the water is clear. Lustre and handle can be influenced by subsequent acid treatment in a bath containing formic acid or acetic acid.

IV. Piece goods:

a) Worsted yarn, light ladies' goods, wool union goods, etc. usually using hank or open-width washing machines. Usually only a light wash is carried out, with soap + ammonia (poss. sodium carbonate if olein has been used as a lubricant, then with slight alkali excess with a significant alkaline reaction), after "kick-off" there is a further wash with synthetic detergent + ammonia (for the purpose of clearer fabric appearance). Light textiles are washed only with synthetic detergent (to avoid felting). In general the final rinse is lukewarm, then cold. Washing and milling are frequently combined (favourable effect on handle and lustre), particularly for cloth with "grease milling".

b) Carded yarns: mainly the removal of fat used in spinning (fatty acid or olein), so-called "wool scour", using sodium carbonate solution. A significant alkaline reaction should be expected, poss. + synthetic detergent, followed by lukewarm and cold rinsing. Generally speaking, the addition of water correction agents in a final rinse is recommended for soft water and rinsing with hard water. If hard water is being used for washing, less synthetic detergent + sodium carbonate is used, and after the first wool scour has started, further synthetic detergent is added (complete removal of soap). If melted or broken-down mineral oil is present, further fat solvent additives are required. →: Acidic washing; Solvent scour process for wool.

Criteria: the following points should be borne in mind when wash batches are being put together:

a) The machine should not be overloaded, otherwise soil removal becomes more difficult, roller pressure becomes lower, soil drains off less easily, felting hazard, risk of crease formation.
b) Batches of pure wool, wool union or worsted and carded yarn should not be mixed.
c) Batches of wool, yarn and piece-dyed articles should not be mixed because of varying dye pigment soiling and varying levels of tension.
d) Individual articles should only be processed using the same washing period. Loosely woven articles should not be washed together with heavy weaves, since the latter require a longer period of treatment and the former would become too narrow and felting would be extreme if this washing time was used.
e) In general the weight and thickness of articles should be carefully monitored. A thinner article running between thicker textiles is not subjected to enough roller treatment. If necessary, thick articles can be processed on one side of the machine and thinner ones on the other side.
f) Batches of the same colour shade should be washed at the same time, because light, dark or different coloured articles can bleed and cause colour changes.
g) Care should be taken that the level of soiling is the same (this is frequently a decisive factor in selecting the correct detergent type).
h) If possible, articles should be of the same length (± 2 m).
i) It is practical to exercise the same quality arrangements for all articles.

Washing pH In practice, the most efficient detergency power of soap (→ Electrokinetic interfacial potential) is achieved when the pH is 10.7 = 3 g/l of soap with a fatty acid content of approx. 30%. Many detergents contain significantly less fatty acid (up to 5%). The following washing alkalis in g/l result in pH 10.7: 1–1.5 g sodium metasilicate or 2–3 g sodium carbonate calc. or 5–8 g sodium carbonate cryst. or 20 ml ammonia.

Washing powder Specific term for → Washing agents in powder form.

Washing process Washing is a chemical-physical process, during which the combination of a multi-phase system consisting of fibre, oil-based soiling, solid soiling, washing liquor and air re-groups to form a new multi-phase system (Fig. 1).

As long as there is no total shielding of one phase, a system like this features contact between three phases. In addition, the washing liquid should not be regarded as a homogeneous phase, since detergent in the concentration used in practice does not form pure solutions. Instead it forms a system of micelles that has unequal

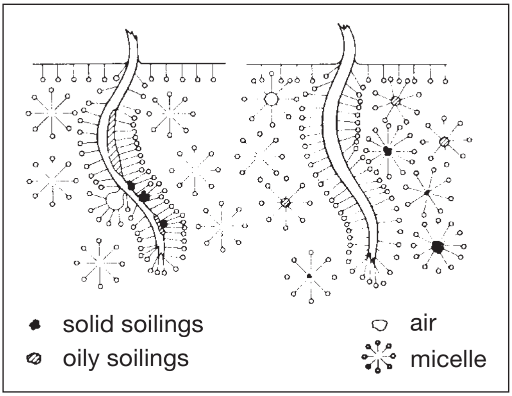

Fig. 1: Phase change in the wash process.

concentrations, which should, at least, be regarded as a two-phase system. The washing process itself is a dynamic process, at the end of which the fibre is soil-free, possibly surrounded by a shell of detergent adsorption layers, and a liquid multi-component phase with mutual equilibrium (thermodynamic). Furthermore the formation of an unstable system at the end of the washing process is possible, which exhibits a change in enthalpy as a result of energy absorption. At the end of washing, there is a much larger proportion of interfaces. Since each interface has a higher energy charge compared with its internal volume, the formation of the liquid phase after washing is linked with energy absorption. In a three-phase system, either forces of attraction or forces of dispersion predominate; under certain conditions an equilibrium of both forces must be present.

The principle of the washing process is based on the removal of substance deposits from a solid body, for which primarily an aqueous medium or washing liquor is used. It is essential that the substance deposits have the potential to be transported in the washing liquor, or can be made capable of being transported in a detachment process beforehand. Furthermore, the transportable deposit must be taken over by the washing liquor and removed from this, or thinned to such an extent that the purpose of washing has been fulfilled. The conditions stated apply to all types of treatment, whether it is the removal of dye hydrolysates from dyed textiles, the removal of print thickeners after printing, or the removal of soil.

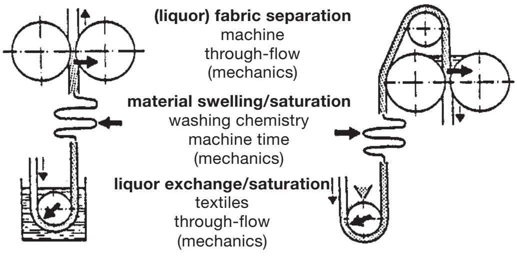

Fig. 2: Separate steps in the washing process (according to Kretschmer).

Fig. 2 shows the three aspects of the washing process, using an open-width washing machine as an example. The three aspects are:

– liquor exchange and charging,
– swelling and dissolving,
– separation of the substance.

Liquor exchange ensures that the concentration on the fibre surface is reduced, and that detached substances are transported away from the fibre surface. A high liquor flow velocity in textile loading is important for reducing the concentration at the fibre surface, because the thickness of the flow boundary layer is dependent on this, and therefore the length of the time-related diffusion path. In contrast to this, the liquor flow velocity is practically insignificant for removing transportable deposits, since the substance transporting properties of the liquor is ten times more powerful than the released substance flow at the fibre surface.

Swelling and dissolving constitute a time-orientated process. This process is accelerated by temperature, which also causes improved diffusion in the flow boundary layer and shortening of the diffusion path in the flow boundary layer. The time-orientated swelling and dissolving process is a decisive factor for the definition of the length of the washing machine, and its fixed costs have a significant influence on the cost of washing. Diffusion occurs according to the following formula:

$$C_t = C_0 \cdot e^{-\frac{\gamma}{V_0} t}$$

C_t = concentration as a function of time (g/kg),
C_0 = initial concentration (g/kg),
γ = substance transmission coefficient (m/s),
V_0 = volume of liquor involved in the washing process per textile area (m^3/m^2),
t = time (s).

The (liquor) substance separation has a central significance for washing treatment. It occurs in open-width washing machines in the squeezing unit with paired rollers. For each thinning process, the proportion of liquor that is subject to liquor separation must not be thinned further. The effect of the nip between the squeezing rollers is not simply limited to liquor separation. In addition, the high speed at which the liquor flows out of the roller nip causes an effective reduction in the flow boundary layer on the fibre surface, and therefore an increase in intensity of substance transport, which is after all the objective of any washing process.

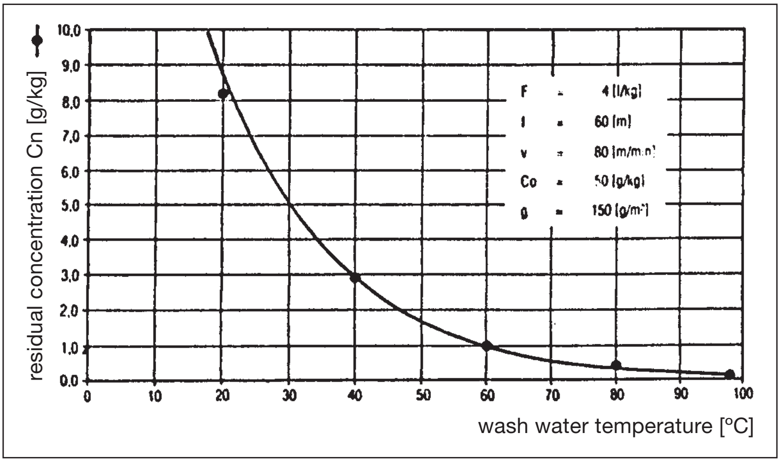

Fig. 3: The effect of water temperature on residual concentration when rinsing away caustic soda liquor (according to Paulsen).

The washing off result is dependent on several factors:

- temperature,
- textile weight and structure,
- quantity of washing water,
- duration of wash, number of textile circuits and textile speed.

As the temperature increases, the viscosity of the water changes. In the temperature range 20–100°C it drops by about a factor of 4. The lower viscosity of water means that textile wetting and throughflow are more efficient. Furthermore the textile expands at a higher temperature, which improves the washing off process. Fig. 3 shows the influence of the water temperature, using the washing off of a caustic soda solution as an example. It can be seen that compared with the result at 20°C, the residual concentration at a liquor temperature of 60°C is reduced by a factor of 8 and at a liquor temperature of 98°C, it is reduced by a factor of approx. 40. The temperature has a direct influence on the substance transmission coefficient γ, and therefore on the washing off process.

The substance transmission coefficient γ can be defined as follows:

$$\gamma = \frac{D}{h} = \frac{k_B \cdot T}{6 \cdot \pi \cdot \eta \cdot r \cdot f}$$

γ = substance transmission coefficient (m/s),
D = diffusion coefficient (m^2/s),
h = diffusion path (m),
k_B = Boltzmann constant (J/K),
T = temperature (K),
η = dynamic viscosity (Pa s),
r = radius of diffusing molecule (m),
f = correction factor.

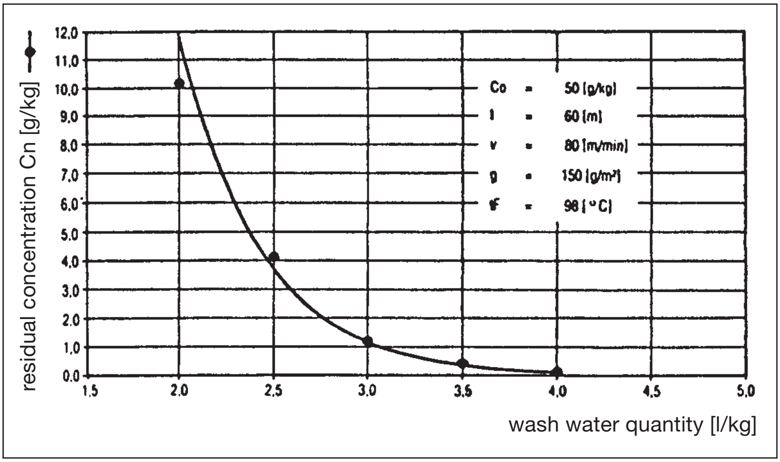

Fig. 4: The effect of wash water quantity on residual concentration (according to Paulsen).

Washing process

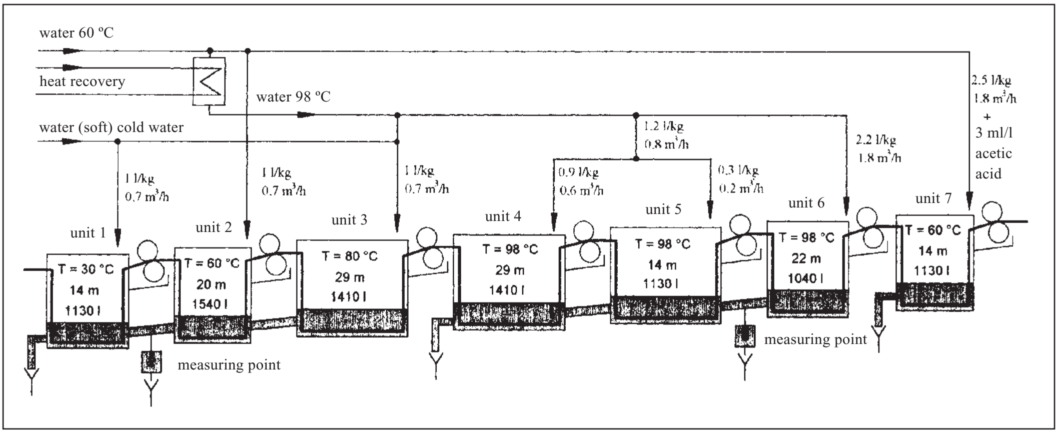

Fig. 5: Open-width washing unit for dyeing and printing aftertreatment.
Example: 100 % cotton article; fabric weight 720 kg (225 g/m); fabric speed 50 m/min; water consumption 6.4 m³ (8.9 l/kg).

Since the thickness of the textile increases in line with the weight (and therefore also the diffusion path), the throughflow properties of the textile decrease, causing a reduction in washing effect. The accessibility of a textile is dependent on its structure. In a thread with a heavy twist or a densely woven fabric, the liquor flow will reach the fibre surface less efficiently than in the case of an open weave or loose twist.

The quantity of fresh water used has a strong influence on the quality of the washing process, since it has a direct effect on diffusion. Fig. 4 shows that the quantity of fresh water increases sharply in proportion to the depth of the residual concentration of the substance to be washed off (in this case caustic soda solution). In order to save water, the permitted residual concentration must be scrutinized carefully.

Washing duration, number of textile circuits and textile speed are directly linked with each other, and are incorporated directly into the diffusion equation. At a high textile speed, the washing time is reduced, and therefore the dwell time. However, since diffusion is a time-dependent process, the textile speed must not be excessive, thereby shortening the washing time, in order to guarantee an optimum washing result.

Fig. 5 shows a conventional open-width washing machine, in which the individual washing compartments in the textile direction are set up in the form of basic elements that increase like a flight of steps. This means that the water is directed against the textile by means of a natural slope. Open-width washing machines of this type are usually arranged to comply with the prescribed initial and final concentration of the substance being washed off. Additional information regarding textile properties and machine constants is then used to define the machine properties (e.g. number of washing compartments) and operating parameters (e.g. textile speed). After one water change, two-thirds of the substance being washed off has been removed. The remaining interval until complete equilibrium is reached can be calculated as follows:

$$R = 100 \cdot e^{-n}$$

After one water change the interval to complete equilibrium (complete removal of substance being washed out) is only 36.8% (Fig. 6).

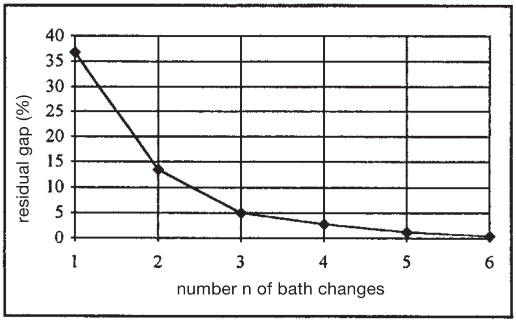

Fig. 6: Percentage residual gap of complete levelling.

The calculation of transient response in a washing compartment can be derived from the following example: two containers of water at different temperatures are mixed in one container. The new temperature can be calculated using the following formula:

$$T_3 = \frac{m_1 \cdot T_1 + m_2 \cdot T_2}{m_1 + m_2}$$

m_1 = water content of 1st container,
m_2 = water content of 2nd container,
T_1 = temperature of 1st container,
T_2 = temperature of 2nd container,
T_3 = combined temperature of T_1 and T_2.

In the same way, this formula can be used to calculate the transient response in a water trough containing dye (Fig. 7) with a permanent water supply, if the parameter concentration c is inserted for the temperature. The time response is recorded by inserting mass flow (kg/s) and time (s). The current trough contents at a given time can be calculated from the mass balance for a washing trough.

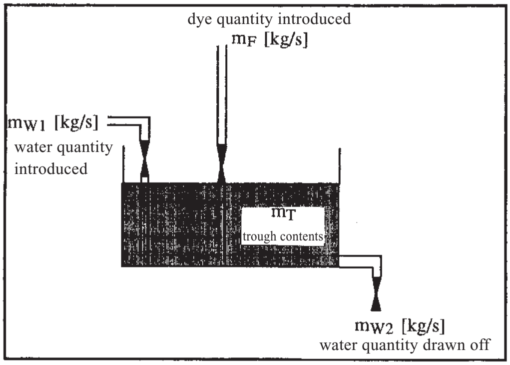

Fig. 7: Water trough mass flows.

A specific quantity of dye (defined concentration) and a specific quantity of fresh water are continuously supplied to a water trough of a defined size. The sum of the quantity of dye and fresh water is taken out of the trough again. The new concentration each time in the trough can then be calculated as follows:

$$c_{T2} = \frac{(m_{W1} + m_F \cdot c_F - m_{W2} \cdot c_{T2-1}) \cdot dt + c_{T2-1} \cdot m_{T-1}}{(m_{W2} + m_{F1} - m_{W2}) \cdot dt + m_T}$$

m_{W1} = water supply quantity (kg/s),
m_{W2} = quantity of water taken out (kg/s),
m_F = dye supply quantity (kg/s),
c_F = concentration of dye infeed (–),
m_T = trough contents (kg),
c_{T1} = old concentration in trough (–),
c_{T2} = new concentration in trough (–).

Washing process temperature Kretschmer divides the washing process into three sub-categories:

- In the substance detachment zone, the substances adjacent to the fibre are dispersed or dissolved so that they can be transported by the washing liquor.
- In the substance transmission zone, the substance flow occurs mainly by diffusion, since the convective flow is not effective in the boundary layer near to the substrate.
- In the substance removal zone, the convective flow causes intensive substance transport.

In the substance detachment zone, the transport of substances occurs mainly as a result of diffusion and only slightly by means of convection where the flow is parallel to the textile. The diffusion coefficient can only be influenced by temperature, while Kretschmer advocates the use of washing auxiliaries to cause acceleration. The liquor flow in the transition zone is responsible for substance transport, because the liquor flow can reduce the thickness of the diffusion boundary layer and therefore shorten the length of the molecular substance transport path (thin diffusion layer), or increase it (thick diffusion layer). An increase in temperature can have the effect of reducing the thickness of the diffusion layer by reducing the viscosity of the liquor.

In the substance removal zone, Kretschmer does not envisage any great problems. In this zone, the only point to watch is that a sufficient concentration equilibrium should be maintained in the washing liquor transverse to the fabric run. →: Washing; Washing mechanics.

In a washing process, washing in the final compartment of a washing machine frequently takes place using cold water to avoid interim storage problems before drying, such as edge drying, migration, etc. This meth-

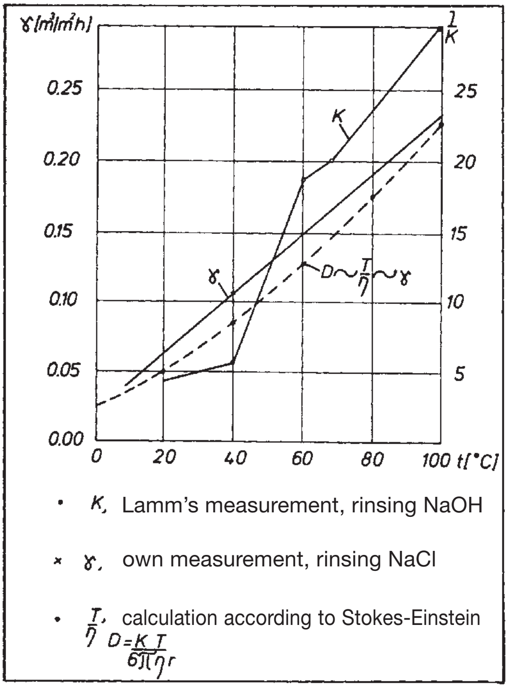

Fig.: Effect of temperature on washing (Tischbein).

od of process management has three significant disadvantages:

The washing effect in the final compartment is relatively poor. In order to wash as effectively as possible, it is essential to aim for a high substance exchange number γ(m/h) and a high concentration difference according to Fick's first law.

Fick's 1st law:

$$g = \gamma \cdot (C_{textile} - C_{liquor})[kg/m^2h]$$

The substance exchange number γ can essentially only be influenced by temperature. An increase in temperature from 20°C to 100°C has the effect of increasing the value of the substance exchange number by a factor of 4 (see Fig.). The concentration difference between the textile ($C_{textile}$) and the washing liquor (C_{liquor}), which also improves the washing effect, is usually low in the final compartment of a washing machine because the concentration in the textile has already become low and the counterflowing washing water still has a concentration of $C_{liquor} = 0$. For this reason, a high washing liquor temperature is particularly important in the final compartment. The investment in this washing compartment is only properly utilized if a good washing effect at a high temperature is achieved.

Washing shrinkage A change in physical state is understood to be the change in physical structure of a fibre as a result of swelling, crystallization and increasing/decreasing tension, causing properties to be altered during and after washing. A change in fabric thickness caused by contraction, volume development or material flattening is usually linked with shrinkage or stretch in a transverse or longitudinal direction.

A textile fabric shrinks during washing if the tension caused during fibre, yarn or fabric manufacture can be partially or totally reversed. Tension applied as a result of purely mechanical processes during secondary spinning, twisting, weaving and knitting, also known as "cold deformation", can be reversed even at temperatures at which the first molecular motion processes within the fibre are triggered. This temperature range (glass, freezing or thawing phase) is dependent on the steric arrangement of the macromolecules and the bonding forces between the molecules, and varies from fibre to fibre.

In the presence of solvents that diffuse into the fibre, preferably water in the case of hydrophilic fibres and organic solvents for hyrdophobic synthetic fibres, this tendency towards motion is increased further. A liquid medium acts as a kind of "molecular lubricant", causing the "thaw temperature" to drop, the frozen tension to be released, and to be converted into a shrinkage path. This proportion of shrinkage is known as substance shrinkage. It can be triggered in a range of fibre types even in cold water. For this reason, cold deformation usually occurs fully in the washing phase.

On the other hand, tensions that are generated during thermic or hydrothermic processes (primary spinning, texturizing, steaming and sizing), which are blocked by a physical network of crystallites, are only triggered by temperatures that are equivalent to the "effective temperatures" of the preceding thermic processes. In the same way, the temperature required to release the blocked tension, which, depending on the fibre type and arrangement, can be reduced to a greater or lesser degree by the effect of the washing liquor, analogous to the reduction in melting temperature of fibre in water.

Substance shrinkage increases in all fibres as the washing temperature rises, however it is inhibited by external tension acting on the fabric during the washing process. Substance shrinkage can also be less effective if the yarn has a higher number of bonding points in the fabric, i.e. when there is increased fibre-on-fibre friction. In this situation, the friction coefficient can be reduced by mechanical means and/or by adding a lubricant. A shrinkage process is mainly completed within a short time if there is minimal tensile stress and tension caused by friction; longer periods result in a level of shrinkage that is only minimally higher. The shrinkage speed also increases as the temperature of treatment rises.

Any natural or manufactured crimp present in the textile is also associated with latent internal tension, known as flexion tension, to a greater or lesser degree. This type of tension is triggered in the same way as substance shrinkage tension, and the crimping effect is made more extreme by tension-free washing treatment. Shrinkage associated with crimping is called crimp shrinkage. However crimp shrinkage can only become effective if relaxation shrinkage is triggered, i.e. if the crimping that has been pulled out during a mechanical process is reversed. As the washing temperature is increased, the bulking effect increases, which is linked with the shrinkage. If mechanics are used during the washing process, it is not only possible to encourage relaxation shrinkage by suspending the friction within a fabric, the crimp shrinkage is also continued inasmuch as the crimps are pushed into each other by hooking together. This causes the material to become denser in the same way as felting in wool, which is associated with further increasing shrinkage but worsening elastic properties. Pronounced crimps and loosely woven fabric provide ideal conditions for the hooking principle.

Crimp development is inhibited by substance shrinkage, which can occur in varying degrees and usually acts along the fibre at the same time. The released shrinkage tension chooses the path of least resistance, i.e. the shrinkage occurs in the non-fixed crimps, causing the crimp to flatten out. In that situation, extra volume can not even be developed as a result of intensive mechanical processing. The crimp volume therefore represents the difference between overall shrinkage and substance shrinkage.

With crimp development, time is an extremely secondary parameter in comparison with temperature and mechanics. For knitgoods made from texturized polyester, the shrinkage after 10 s of mechanical washing is greater than after 1000 s without mechanical washing.

Crimp development can be ruined if the textile tension is too high within the washing phase. Although tension-free treatment is quite possible in the weft direction, quite a significant distortion can occur in a warp direction, for instance when pulling the wet fabric out of the hot washing liquor. Because of the material buoyancy in the relatively high liquor, there is a favourable fabric tension ratio in Mezzera-type open-width washing machines; however the washing effect is minimal. On the other hand suction drum washing machines have a good washing effect; however tension is exerted on the material as a result of high liquor circulation.

Excessive stretching can be avoided in the washing phase if the material is pre-stabilized in the first phase of the washing process with a low level of tension, and not below the prescribed wash temperature. Care should however be taken that the textile run remains crease-free. This method of treatment permits the application of higher processing tension levels after 5 s. As a result, less crimp is pulled out than would have been the case if higher process tension had been applied at the point of immersion in the liquor. The tendency towards deformation during the washing process decreases as the stabilization temperature rises. This effect also causes sized fabric to have an insufficient crimp volume after desizing at an increased development temperature, if the yarn crimp was pulled out during sizing and this state was then set by the size film. For this reason, desizing is frequently carried out in a cold state of structural development in a hot washing liquor, i.e. the process is discontinuous.

This phenomenon also plays an important role in crease marking during washing, even if it is only localized on the crease fold. A fabric made from polyester crimp yarn, exposed to a boiling water treatment spread out and at low tension for only a few seconds, results in a finished fabric that is crease-free with no dye markings after a subsequent fold operation in the same washing solution.

If specialist yarns are used in fabrics, crimping or specific patterned reliefs can be created, which do not appear until washing. These yarns are known as “producer texturized yarns”, and they have the advantage that smooth yarns are easier to make up into fabric than crimped yarns. These include:

a) High bulk yarns, made of mixed fibre yarns that are smooth in their raw state of a non-crimped nature and/or synthetic spun fibres with varying shrinking properties;
b) Mixed filament yarns that are folded or twisted from synthetic filament yarns with deviating shrinkage;
c) Yarns made from dual component fibres, where two polymer components with varying shrinkage are combined by spinning into a single filament.

Fabrics made from these yarns, where the required crimp volume is compensated for by a lower raw material density, should be washed as recommended by the yarn manufacturer. Usually this involves consecutive stages where the temperature is gradually increased, so that the blocked tension in the yarn is not suddenly released, causing the fabric quality to be barky.

The high bulk yarns or mixed filament yarns contained within fully-shrunk fabrics can be differentiated from texturized yarns by the fact that the component with more extreme shrinkage tendencies is flush with the yarn twist, whereas the components which shrink less or not at all are pressed into small loops at the edge of the yarn. As is the case with texturized yarns, area shrinkage is the objective, combined with an increase in thickness. This causes an increase in specific volume, which exerts a favourable influence on the physiological properties of the clothing material.

Shrinkage and volume development are not only dependent on the fibre structure of the textile used, but also they depend on the construction of the yarn and the fabric made from it. In fabrics made from flat filament yarn or spun fibre yarn, usually only surface shrinkage takes place during washing, which is dependent on the level of substance shrinkage in the fibre type used, and is limited by the fibres’ freedom of movement within the yarn, or the yarn within the fabric. For this reason, substance shrinkage can be less effective in fabrics made with ply yarn and with short thread floats. The fabric actually tends to become more compact and stiff because the torsion tension in the yarn or twist increases, as do the forces of friction between the bonding points of the yarn in the fabric. If this blocked tension is not balanced out during the washing phase using mechanical means and lubricants, then additional released tension will accumulate during the drying and setting phase. It is only during washing care that the blocked tension is successively released by the constant cleaning, washing and tumble-drying mechanics, leading to what is known as “progressive shrinkage”.

The bowed nature of the yarn within the fabric, and therefore the fabric thickness, is only marginally increased as a result of surface shrinkage in fabrics made with smooth yarns. An increased ply twist in crimped yarn has a negative effect on crimp development.

In knitgoods, as the stitch size decreases, whether deliberately for practical reasons or because of thread shrinkage, the flexing tension levels are increased, and therefore also the energy content of each stitch. Because of this, stitches that gradually become smaller are increasingly difficult to distort and always attempt to revert to the ideal round shape if there is an opportunity to balance out the tension. For this reason, fabric often becomes shortened in one direction during the washing process, at the same time widening in the other direction.

Shrinkage and volume development should only be encouraged in the washing phase to the extent permitted by the prescribed final width. On this principle, shrinkage should not take place in excess of the final width, because this will mean that width tensioning will be necessary during setting or final finishing, which is again associated with flattening of the fabric and increased residual shrinkage. However if too little shrinkage is released in the washing phase, it is not then possible to compensate for the lost shrinkage in the drying and setting phases.

Excessive shrinkage in the washing phase can be avoided by lowering the temperature or increasing tension, i.e. by means of dimension-controlled washing, or stabilization of the required dimension by steaming or hot air treatment prior to washing.

Usually 60–70% of overall shrinkage is triggered in the washing phase.

Finally, when washing fabrics made from polyamide and wool, a change in physical state should be taken into account, even if it is reversible. This change in state is known as “hygral expansion”, which means stretching during water treatment that reverts completely to its normal state after drying. This effect can cause run creases if the fabric is not stretched out mechanically before feeding onto the rollers (according to Berndt and Heidemann).

Washing wool fabric → Washing of woollen goods.

Wash-liquor softener application Articles that are potentially suitable for wash-liquor softener application need to be inert to the substances present in → Washing agents. The objective of preparatory treatment and application testing is to produce substances with fibre affinity for temporary wash-liquor softening effects and fibre-active bonds for semi-permanent and permanent scrooping effects according to the following principle of categories:

constitution	*type*
	with fibre affinity
	reactive
	reactive

Wash-off factor (C_0/C_n), this refers to the fact that the chemical/soil concentration C_0 is taken into account at the point of fabric infeed, and the residual concentration C_n at the point of fabric exit. C_n is reduced by the concentration of substances to be washed off the fabric in the machine to the value.

$$C_n = \frac{\text{initial concentration}}{\text{wash-off factor}}$$

Wash-out jeans Denim garments that change in appearance after a domestic wash cycle. One variant of the pigment dyeing process is the wash-out finish. This consists of pigment dyes to shade depth that are manufactured using reduced quantities of binders. Fabrics are only subjected to a washing process (mill-wash, stonewash) when they have been partially made up into a garment, but usually this is not done until the garment is fully made up. The formulae for these articles, in particular washing methods, vary from firm to firm, and are usually trade secrets.

Wash (process) The process of → Washing (rinsing).

Wash/rub test Test for pigment dyes and prints, by rubbing with the washing solution to check the adhesive properties of the binder.

Wash test →: Washfastness testing; Wash testing; Wash tests for dye identification.

Wash testing Artificially soiled test fabrics are used to assess the cleaning effect of detergents and washing processes. These soiling models are widely used, for example for the following: by detergent manufacturers for the development and improvement of detergent formulation, by the manufacturers of detergent base materials for carrying out assessment of different surfactant types, detergent components, complexing agents, enzymes etc, and by washing machine manufacturers to test wash programs. The test materials are suitable for developing water-saving detergent products or wash programs that use energy economically. Soiled and non-soiled test fabrics are also used as control samples in laundries, for carrying out consumer testing and in institutes for comparative quality testing.

The washing result depends on a variety of influential factors determined by detergent, water, washing machine, soiling level of the washload, and textile type. The factors that influence the wash result are itemized in the Tab.

When testing detergents and washing processes for their cleaning effect on textiles, it is practical to limit

1. Detergents

washing agent dosing

surface-active compounds
anionic surfactants
non-ionic surfactants
soap
cationic compounds

inorganic constituents
washing alkalis (sodium carbonate, silicates)
phosphates (sodium tripolyphosphate)
ion exchangers (sodium aluminosilicate)
bleaching agents (sodium perborate)
stabilizers (magnesium silicate)

organic constituents
complexing agents (NTA, citrate, etc.)
polymeric polycarboxylic acid
fluorescent brightening agents
solvents (alcohols)
enzymes (proteases)
bleach activators (tetraacetyl ethylene diamine, etc.)
greying inhibitors (carboxymethylcellulose, hydroxyethyl cellulose, etc.)

2. Water
water quantity
water hardness, Ca^{2+} Mg^{2+} ratio
purity, heavy metal content

3. Washing machine
washing temperature (initial temperature, heating-up rate, maximum)
washing time
washing mechanics (rotation speed of the washing drum, drum run time and drum useful life, drum diameter, wash load, liquor quantity, dimensions and weight of the textiles, fabric-on-fabric friction, foam formation);
pre-wash, main wash, rinses

4. Laundry soilings
degree of soiling
various laundry soilings

5. Textiles
fibrous materials
natural fibres (cotton, wool, etc.)
man-made fibres (polyester, polyamide, etc.)
synthetic fibres (viscose, acetate, etc.)
fabric type (woven fabrics, knitwear, etc.)
finishing, dyeing
garment manufacturing (dimensions, weight, etc.)

Tab.: Factors affecting the washing result.

the tests on usual washing conditions and areas of use, and to incorporate standard detergent, washing processes and textiles into the experiments. If the appropriate experiments are set up, it is possible to obtain results that provide useful information. In this way, detergents belonging to different product categories, such as phosphate-free or perborate-free washing powder, powders containing these substances, and liquid detergent, can be differentiated clearly in their effects, using washing machines with different washing programmes, pre-wash/main wash, economy wash, load levels, etc. Specific test conditions must be used for more subtle differentiation, which is necessary for developments within a product group or a washing program, and to optimise detergent and washing processes.

As well as the primary wash effect, i.e. the removal of soiling and staining after a single wash, it is also important to take into account the secondary washing results after several washes during technical washing tests. The secondary effects include greying (re-depositing of soiling), calcium deposits (loss of tensile strength, chemical damage), for which a non-soiled test fabric is available as a control sample.

For residual soiling, soil removal (ΔS) occurs proportionally to the logarithm of the washing time (t), using the formula

$$\Delta S = a \cdot \log t + b$$

In this formula the factor a is dependent on the type of pigment soiling, the effective chemical/physical factors and the washing mechanics, and b is primarily dependent on the washing temperature. At different washing temperatures the remission parameters for increased washing times, are virtually parallel (Fig. 1). The effective factors (chemicals, temperature, time, washing mechanics) are mutually interchangeable to a large extent, to ensure that the same washing result is achieved.

Washing experiments using artificially soiled fabrics should be carried out as comparative tests using

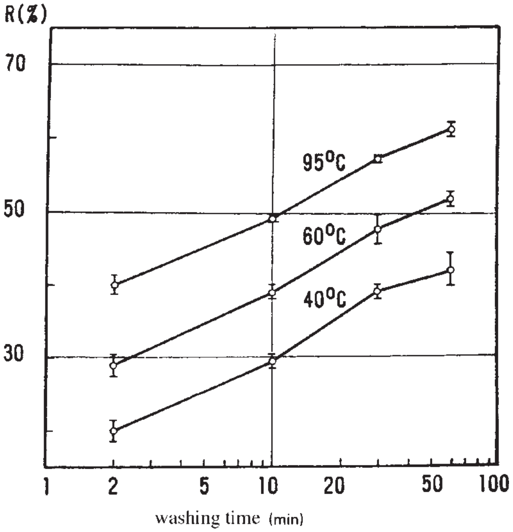

Fig. 1: Washing effects (remission parameters) on carbon black/oil soiling (EMPA, Art. 101). Washing at constant washing temperatures of 40, 60 and 95°C in a drum washing machine.

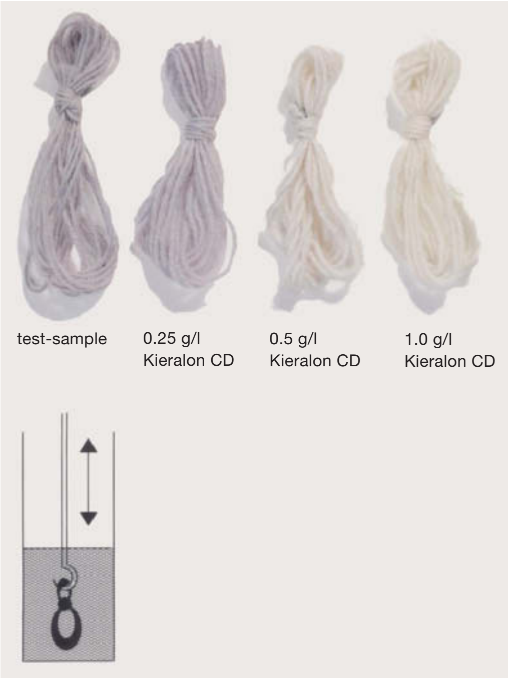

Fig. 2: Take a wool length impregnated with dyed oil, wash for 15 min at 45ºC, then rinse and assess (BASF).

fabrics in the same soiling batch, with standard detergent and standard washing processes under precisely specified conditions. A wool hank impregnated with dyed oil (Fig. 2) could for instance be used to test the fat washing effectiveness of a surfactant (Brüschweiler).

Wash tests for dye identification The purpose of this is to provide information complementary to the → Dye class identification on fibres.

I. + II. On fibres of plant or animal origin: interweave the test material with white wool and white cotton. Immerse in a cold solution of 5 g/l soap + 3 g/l sodium carbonate. Slowly bring to the boil (observe the colouring of white wool, white cotton, test material, washing liquor). Rinse and dry after 1 h.

1. Dyed wool: at first intensive (not or only slightly with cotton), almost complete decolorization during boiling, test sample usually completely decolorized: Cationic dyes. Counter-sample: a) when dabbed with acetic acid, the test material and wool revert to a weaker form of the original colour shade; b) in chlorine solution 1°Bé: decolorization; c) tannin test.
2. Dyed cotton: At first intensive, also wash liquor, wool also not later, after 1 h almost the same colour depth as the test material: Direct dyes. Counter-sample: new test material + conc. sulphuric acid: usually shade change (usually shade reversion during rinsing). Or: wool/cotton dyes: in this case the wool is often more decolorized (magnifying glass) (additionally: → Ammonia test (for dyeings).
3. Dyed wool and cotton: frequently decolorized at the start, after 1 h test material is usually completely decolorized. Acid dyes (additional ammonia test). Delayed and weakened appearance: metal complex dye, dye with milling fastness, etc. Particularly delayed appearance: metal complex dyes (additionally: →: Copper detection in fabric dyeing; Chrome test for dyeings), chroming dye (sometimes also reduced washfastness, then confusion with simple acid dyes: chrome test. New sample + conc. sulphuric acid: usually colour change, reverts during rinsing.
4. Undyed wool and cotton/low soiling level: fast dyes (additionally →: Paraffin test for dyeings on cellulose and protein fibres; Chlorine test for dyeings on cellulosic fibres; Hydrochloric acid test); black staining: mineral dyes (chrome/paraffin test).
5. Reactive dyes: non-reactively bonded dye bleeds. With repeated wash sample, usually no bleeding or only slight bleeding of white samples.

III. On acetate fibres (according to): 5 g/l soap, 80°C, 15 min treatment time.

1. Cationic dyes: intensive colour bleeding, woven-in acetate takes up dye. → Benzene test positive.
2. Dispersion dyes: considerable bleeding, white sample takes up dye. Benzene test positive.
3. Diazotizable dyes: slight bleeding, white sample at worst slightly soiled. Benzene test negative. Paraffin test slightly positive.
4. Naphthols: no bleeding or only slight bleeding, white sample not colorized. Paraffin test extremely positive.
5. Pigment dyes: microscopic test on fibre cross-section. Even distribution: Spinning bath dyeing; only on fibre surface: binder setting.

IV. On polyamide fibres: 5 g/l soap + 4 g/l sodium carbonate calc., boil for 20 min.

1. Cationic dyes: extreme bleeding. Benzene test positive.
2. Acid and dispersion dyes: extreme bleeding. Benzene test negative (acid dye) or positive (dispersion dye). Paraffin test definitely positive (dispersion dyes).
3. Substantive dyes: extreme bleeding. Benzene test negative.
4. Metal complex dyes, vat dyes, development dyes: no bleeding or only slight bleeding. Additionally see I + II. 4.

Waste → Textile wastes from manufacturing and processing, which are usually re-processed after appropriate treatment.

Waste disposal Considering that disposal is becoming more difficult, the textile finishing industry must aim to re-use or re-process residual substances by optimizing processes and formulae. Even then residual substances that cannot be recycled will be generated, and for these disposal methods must be developed that generate a low volume of waste. It should after all be permissible to burn certain residual substances in order to make use of recyclable heat energy that the substances contain, or to purify water in a treatment plant for substances in waste water that have low toxicity and have a good level of biodegradability.

Compared with the overall annual waste volume of a medium-sized textile finisher, the proportion of liquid/paste waste originating from sludges, residual paste and residual preparation liquors in textile finishing is currently still categorized as "of little significance". However these residual substances will become more significant in future as a result of the regulations contained in Appendix 38 of the German Administration Regulation of Waste Waters (Abwasser-Verwaltungsvorschrift). This also applies to residual finishing liquors. Waste disposal considerations are already practised within limitations for reasons of economy. This includes organizational measures such as consolidation of batches, tightening up on the number of formulae and the type and quantity of auxiliary used. In the past, great efforts were made to keep the contents of the padder trough as low as possible by installing displacers and introducing alternative processes such as nip padding, foam application or spraying techniques. However there is one thing in common to all techniques and processes and even the best organization: there will be residual substances consisting of aqueous dispersions and finishing chemicals with a greater or lesser concentration level. The quantity of residual substances can be reduced even more using automatic finish equipment so that there are no superfluous preparations left over. However the quantity of finishing chemicals required for the immersion line means that there will be a residue, in the same way as liquor used for spraying and foaming, which by definition will remain in the system.

If the residual finishing liquor can not be re-used or re-processed, then in future differentiated disposal must be implemented. Possible reasons for this are because of progressive crosslinker reactions leading to a negative effect on quality, because bleeding dye in the finishing liquor makes recycling impossible, or because using certain formulae for fashion garments means that preserving the substances is impractical for time reasons. Textile off-cuts from leader cloths that are no longer usable, edge off-cuts and ends are hardly ever re-processed. They are "used". They can possibly be used as cleaning cloths, which (when smeared with oil) must be disposed of separately, as they are considered to be "waste requiring particular monitoring". When exhaust air is cleaned, the substances removed from the exhaust either precipitate directly as a condensate, or when the droplet separator is cleaned. This is also considered to be "waste requiring particular monitoring", consisting of oils, fats, paraffin carbohydrates and cracked products from thermal processes. The same applies to the condensate from flame backcoating. There are extra problems associated with unavoidable clippings that are composites from different textiles and foam, for instance, which excludes them from being recycled.

It is frequently the case that there are insufficient internal strategies for residual substance collection, which at least would enable all the residual textiles to be put into a recycling process. Sometimes the good will that is present founders because of the requirement to separate textiles according to their raw material type. It is not possible to put together a complete summary of the most important waste products generated during textile finishing, but it is becoming apparent how specific the subject of residual substances is becoming. From a volume point of view, one large group of waste is the empty finishing agent containers, which can not always be completely cleaned of the residual substances adhering to them. This means that they also become "waste requiring particular monitoring". Many companies now have internal regulations to deal with the complex subject of empty packaging, so that internal sorting can be carried out.

Much of the waste generated in companies requires monitoring, so that there must be accompanying documentation when it is disposed of. Some high-volume waste occurring in plants does not fulfil the classification criteria for depositing above ground; the active

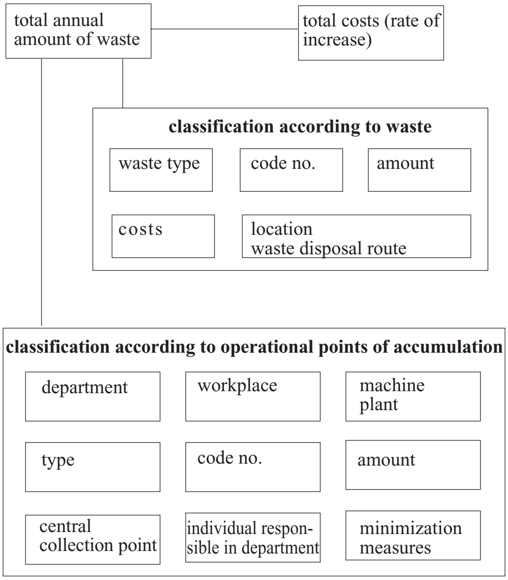

Fig.: Waste register for waste disposal.

substances they contain need to be sorted. As it would seem uneconomical to store these substances in a container initially for subsequent sorting, the residual substances generated in plants are collected separately at source, which is more practical. To do this, an exact quantitative analysis of residual substances generated internally is necessary, which should also contain allocation of disposal costs to individual parts of the company, plants or even processes. This network of residual substance ratios should finally be applied to the waste register diagram (see Fig.) for all areas of the finishing company. In this way it will be possible to enforce a remarkable reduction in the volume of domestic-type commercial waste in the future, because more than 90% of the residual substance mix consists of plastic film, textile off-cuts, packaging and waste paper. However the conditions required for economical recycling of these residual substances still need to be established (according to Marzinkowski).

Waste disposal considerations The principle of environmental protection in an industrial environment is based on the sequence: avoidance, reduction, recycling (see Fig.). The first principle is avoidance or minimization, then re-processing, and only the residual substances that can be reduced no further are disposed of. This hierarchy should be adhered to during planning, among other reasons because the optimization suggestions in the first two points (with the exception of the automatic finish boiler) can be implemented relatively fast and without great expense. A disposal process of any type will always incur costs for setting up the necessary infrastructure, operating costs and in some circumstances extra personnel. Appendix 38 of the German Administration Regulation of Waste Waters (Abwasser-Verwaltungsvorschrift) is effective (regarding waste water from textiles); a detailed system of regulations will also be enforced governing indirect discharges by the textile industry, which will make it essential to take internal avoidance and reduction action, applying in particular to textile finishers. In this context, textile finishers have not only to pay attention to the emissions from their production, but also of the contents of the waste water from the preliminary textile stages. The most important strategies are to avoid waste by means of re-using or re-processing residual liquor, to use auxiliaries sparingly, and to substitute potentially harmful auxiliaries and dyes. Further emphasis in future will be placed on water recycling strategies. The concentrated residues that still remain from treatment solutions constitute an increasing waste problem if it is not possible to introduce low-waste disposal techniques.

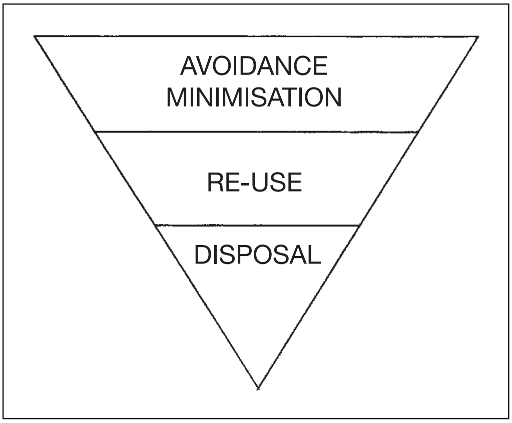

Fig.: The optimal residual matter pyramid.

Waste disposal site Supervised, ordered depositing of waste substances. Domestic and industrial waste as well as sludge from purification plants is normally taken to waste disposal sites if incineration or storage of special waste at specialist waste sites is not necessary. The law governing preservation and recovery of natural resources gives environmentally active authorities the opportunity to monitor the dumping of hazardous waste. At the same time, the authorities can issue specifications for the filling of above-ground waste disposal sites. These specifications are precisely defined, and set standards for the compatibility of covering materials and waste. In this context, advice relating to design and operation to ensure that these sites are properly secured and sealed is important. The basic objective is to store the waste as economically as possible and in a controlled way, solid waste being deposited at waste disposal sites and liquid substances in pools. Lining with sealant as well as synthetic fibres in the form of woven material, nonwoven fleece or even a superimposed yarn layer is an important aspect of waste site construction at landfill sites and above ground dumps. The use of technical textiles has opened up new opportunities with anticipated success in the construction of waste disposal sites, as a way of setting up specific barriers to prevent uncontrolled leakage.

Barriers are constructions that are intended to provide a secure boundary to an area. The area should be for the purpose of storing solid or liquid materials, either permanently or temporarily. Barriers have two main purposes: they must hold the mechanical pressure of the stored deposits, and they must also prevent potential hazardous substances from escaping underground or reaching the water table. The types of barrier commonly used are dams made of earth or from concrete, wood, cast iron segments or sheet pile walls. They are constructed according to criteria stemming from mechanical strength analysis. However these barriers have limited suitability when it comes to holding back potentially hazardous substances. The penetrability coefficient of concrete, for instance, is $10^{-9} < k < 10^{-7}$ m/s, and the value for compressed clay with a Proctor optimum water content is $10^{-10} < k < 10^{-8}$ m/s. For this reason geo-membranes are used to reduce the seepage and to control the volume of seeping liquid so that the leakage rate is as close as possible to zero. In some cases the seepage is collected between two geo-membranes and stored in containers for subsequent treatment. Penetrability coefficients have been measured for geo-membranes with a range of $10^{-14} < k < 10^{-12}$ m/s.

In dams made of earth, geo-membrane linings are often installed in conjunction with geo-textiles to protect them from puncture. If geo-membranes are spread out on rough ground and subjected to the pressure of the rising water table, geo-textiles can be used for specific purposes relating to improving adhesion to the ground, drainage, filtration and the separation of fine and coarse materials.

The last phase of the waste disposal strategy (→ Waste management) is depositing it in long-term or permanent storage. A waste disposal site is a bioreactor in which biological, physical and chemical processes occur, mostly in an uncontrolled manner. It is not likely that these processes will be able to be controlled in the immediate future. The critical factors are environmental compatibility and long-term characteristics of the deposited waste. Many textiles do not contain any hazardous substances, in particular substances that are hazardous to water. For this reason they can be deposited at domestic waste sites. Waste from lining fleece for example is only partially biodegradable. In order for → Biodegradation to be possible, substances must have the following properties: they must be hydrophilic and as amorphous as possible (not crystalline), have a low molecular weight, linear polymer structure, as well as having as great a surface area as possible, and they must not be crosslinked. These criteria are only fulfilled by some of the raw materials used.

1. Viscose fibres and some surfactants, for instance, have a good level of biodegradability.
2. Polyamide fibres, polyamide fusible fibres, ethylene vinylacetate binders and other wetting agents, thickeners and softeners are partially biodegradable (even though it is a difficult process). This group constitutes the highest proportion of the overall quantity.
3. Polyester fibres, polyester fusible fibres, polyethylene fusible fibres, pigments, crosslinked polyacrylate binders and silicons are not biodegradable.

Waste management The concept of waste is described in law as follows: waste according to the AbfG (Abfallbeseitigungsgesetz – German Waste Disposal Law) is constituted by “movable items of which the owner wishes to rid himself, or which should be disposed of properly in order to preserve general welfare, particularly in order to spare the environment”. According to paragraph 1 of this law, recycling of substances is of equal status to converting them into energy. Potential waste should be inspected at source to establish whether or not it could be avoided in the future. Organizational and technical action can be taken in this context (Fig. 1). Residual waste with the potential to be re-used undergoes a recycling process. Waste disposal can take place in the form of thermal treatment (waste incineration) or as a physical-chemical treatment process (waste disposal site with or without biodegradation). Special waste, which can not be disposed of in this way because of its hazard, is disposed of at special waste sites or treated by means of special waste incineration (Fig. 2).

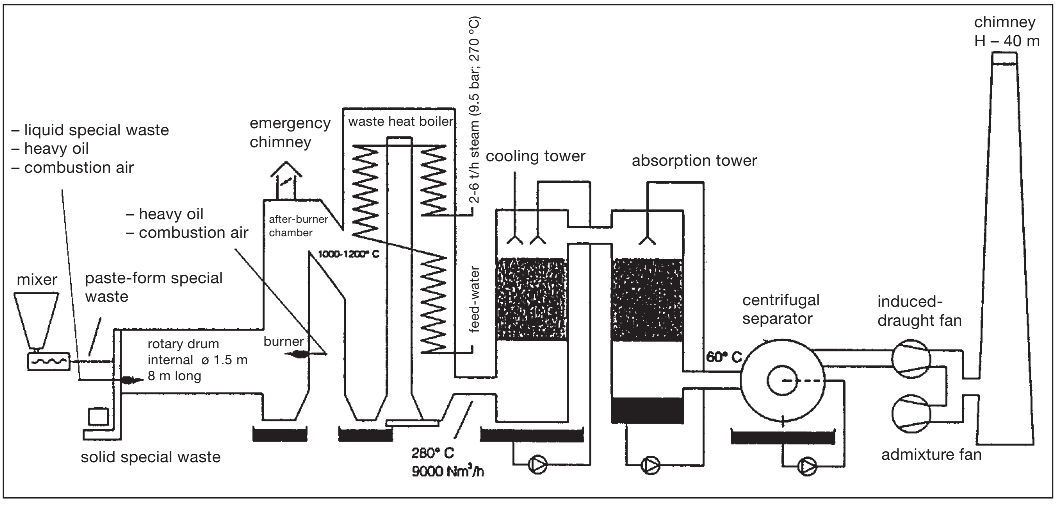

Fig. 2: Special waste incineration plant.

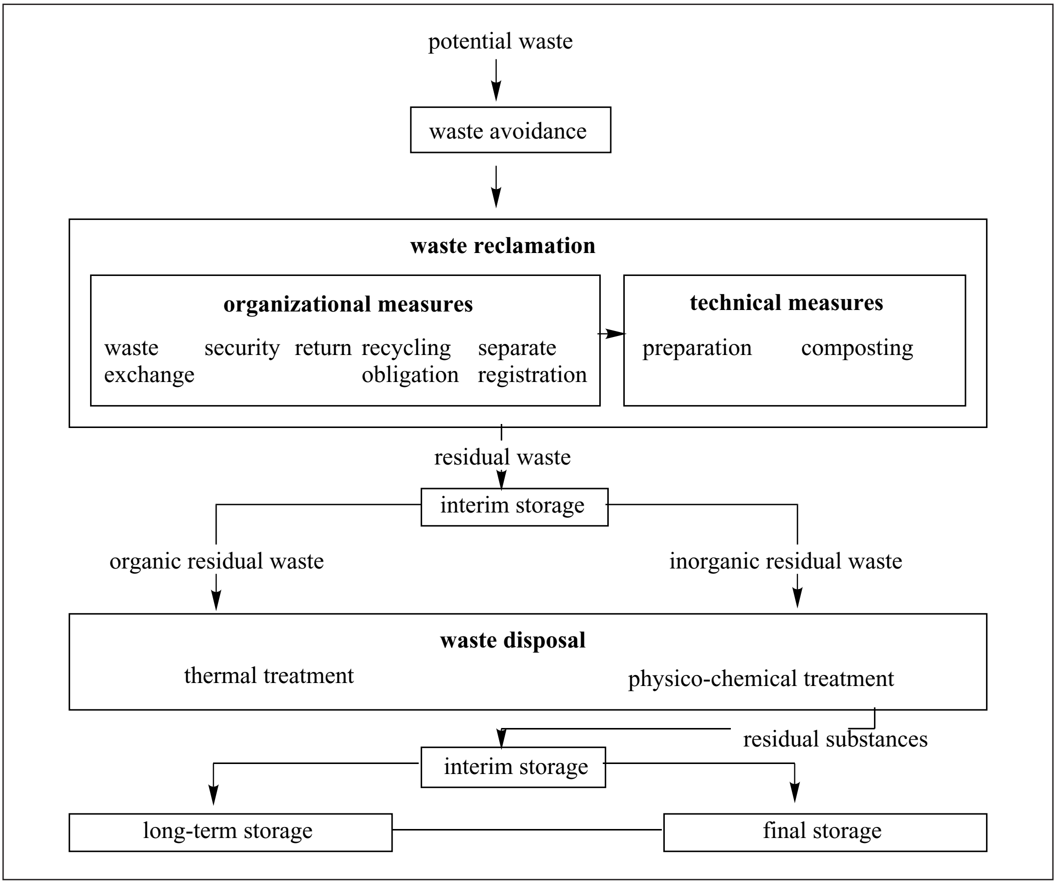

Fig. 1: Waste reclamation flow chart in terms of waste management.

Waste water Strictly speaking, water that is soiled by domestic, commercial and industrial use, as well as drain precipitation water from built-up land (roofs, roads), contains impurities in solute, colloid and solid forms. The characteristics depend on origin, e.g. communal sewage waters have a like composition in comparison with the great differences between commercial and industrial waste water. Most of the waste water generated by the textile finishing industry (see Fig.) contains primarily organic substances (fibre particles, dyes, fats, surfactants, phosphates, textile auxiliaries, proteins, carbohydrates, etc.) as well as inorganic salts, acids, alkalis, chlorine, etc. A permit is required for releasing waste water into open water, and is subject to certain conditions according to the terms of the German Water Resources Law (WHG – Wasserhaushaltsgesetz). Experience has shown that even where toxins are actually being specifically withheld, the cumulative effect of waste water pollution should be considered so great, that in time a negative effect on the ecological equilibrium must be expected. In particular non-toxic organic substances that consume the oxygen dissolved in the water to enable them to biodegrade should be kept away from the drainage system. Nowadays it is no longer sufficient to carry out corrective treatment at the end of waste water production, because a new concept for the textile finishing industry is required that incorporates an environmentally friendly preventive ideology (→ Ecological problems in textile dyeing, printing and finishing).

It is essential to monitor industrial systems that produce waste water. It is self-evident that problem factors such as unclear pipework management, leak points, etc. must be identified and alleviated. The systems relevant to waste water in question that are found in textile finishing plants, for instance as polluters, are shown in the Fig. In this situation there is a practicable possibility to reduce the quantity of waste water by reducing water consumption. It is possible to minimize the quantity of fresh water using automatic fill level control and over-

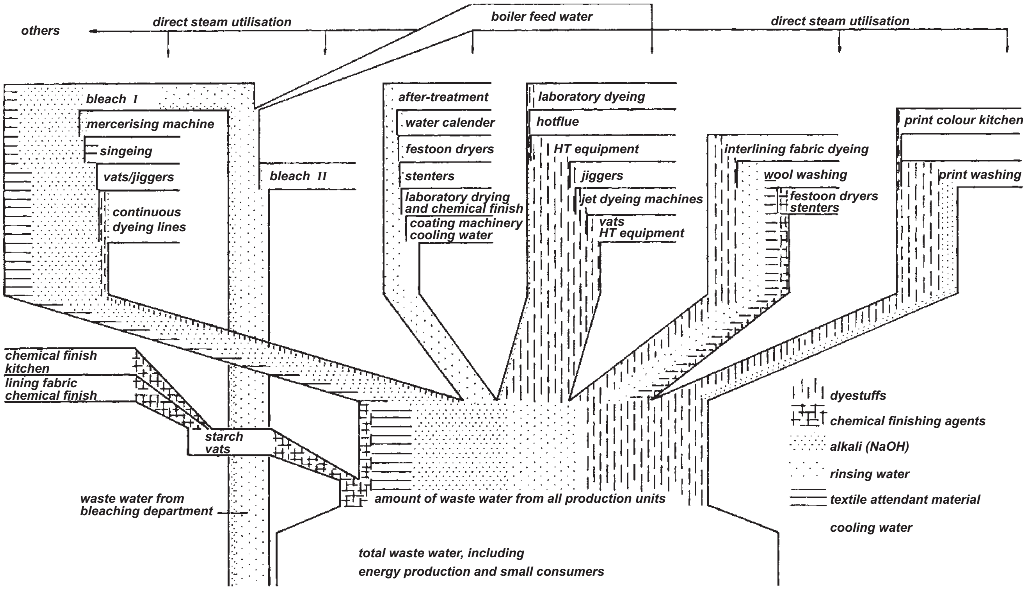

Fig.: Important textile plant waste water initiators.

flow barriers, counterflow washing arrangements, coolant circuits, condensate backfeed systems, padder displacers. A remarkable amount of water and chemicals can be saved using partial process circuits, e.g. by feeding polluted water back to different sections of mercerizing machines.

Waste water analysis →: Summation parameters; Waste water evaluation.

Waste water automatic analysis Used for continuous monitoring of water or waste water. The concentration of sulphate, nitrate, phosphate, ammonia, chlorine, iron, etc. can be continuously monitored.

Waste water balance This can be construed as the material balance in the complex of waste water, for example sub-divided as follows:

- Raw water supply (R value): quantitative definition for energy centre, quantitative definition for manufacture;
- Waste water all-in pollution (A value): Quantitative definition, qualitative investigation;
- Waste water purification plant complying with German Water Resources Law (Wasserhaushaltsgesetz) (W value) in drainage.

Since the initial and final values must balance, as soon as the values of R and A are known, the following target for value W, which can be specified, is set as close as possible to the R value. Processes that involve partial treatment before the waste water flows into communal sewage plants cause the most problems as a strategy directive, because communal plants are never in a position to cope with an uncontrolled inflow. Many synthetic fibre substances are non-biodegradable, or only to a certain extent, which means that they are not eliminated in biological treatment plants. Biological plants have a biodegradation rate of approx. 90–93% because of the BOD. Dyes (up to approx. 10% of waste water) and other non-biodegradable substances pass through this type of plant unchanged. Flocculation and precipitation means that a proportion of up to 40% of non-biodegradable substances can be eliminated. However that is by no means enough, because waste water should be almost colourless. This means that an extra chemical-physical phase is necessary to remove dyes, metallic ions and other non-biodegradable substances before it can be diverted to the biological plant.

Waste water dye removal Dyes are not very biodegradable, they colour the waste water even in extremely small amounts and therefore have a visually disturbing effect. For this reason the incidence of dye baths in waste water should be limited as far as possible.

The following processes are available for the removal of dye:

I. Chemical precipitation using flocculating additives such as iron or aluminium salts, possibly in combination with calcium oxide. An adsorption effect takes place, which means that pseudo-dissolved dyes are not affected by the precipitation agents. In most cases they have to be destroyed by a reduction agent such as caustic iron (II) chloride solutions or sodium hydrogensulphide. Azo dyes can be split using reduction agents.

II. Filtration can often be a suitable process for decolorisation.

III. Biological purification can lead to decolorization if there are no toxins present in the waste water.

IV. A combination of chemical precipitation and biological purification leads to a satisfactory result in many cases.

Waste water evaluation The crucial notification for waste water contributions will contain control values for the damage parameters A, COD and G_F that should be mean values and maximum values that should under no circumstances be exceeded. Any hazards in water taken from open water can be considered existing pollution and deducted. For all textile finishers who do not cause pollution directly, harmfulness units can be grouped together per m^3. Companies that are liable for these levies have to carry the costs of measuring the levels of harmfulness themselves. The following formula has been suggested for calculating the pollution index using the analysis data (possibly with regional variations).

For soiled water and water from mines, the following formula can be used (as an example) to establish the level of pollution at peak pollution times:

$$B = \frac{Q}{0.15}\left[0.40 + 0.25\,\frac{A - 0.3}{6.0 - 0.3} + 0.35\left(0.5\,\frac{BOD - 20}{250 - 20} + 0.5\,\frac{COD - 80}{500 - 80}\right)\right]$$

B = pollution count per head of population,
Q = quantity of water supplied in m^3/day (not including precipitation water),
A = sediment in ml/l (excluding carbon),
BOD = biochemical oxygen demand BOD_5 in mg/l for the deducted sample,
COD = chemical oxygen demand in mg/l for the deducted sample.

I. Definition of the water quantity Q: the water quantity can usually be established from the level of water consumption if no private water supply is present. Alternatively, flow measuring devices can be used to establish the quantity of waste water from the cross-section of the outfall. Representative sampling is a particularly awkward problem if the analyses are expected to give a precise conclusion, because the sample must represent the mean value of the waste water properties. This can certainly not be guaranteed if random samples are taken only occasionally. It is essential to take water samples continuously using the appropriate devices over a long period of time, particularly during operation, which will automatically generate a good mean value. Authority testing should only take place at the outfall and not at the machines.

The harmfulness of the pollutant waste water is recorded in the form of pollution indices, which take into account the following:

a) sediment (A),
b) the chemical oxygen demand (COD),
c) the level of toxicity (G_F).

II. Sediment (A): sediment consists of solid substances that settle on the bottom within 2 h. The harmfulness is not only clouding and the formation of sludge, but also the negative effect on the oxygen content. It is also possible to analyse the harmfulness of the sediment by its weight instead of volume if the annual volume in cubic metres is more than five times as large as the annual weight in tons of the dry substance. This is almost always the case in the textile finishing industry, where the factor is usually in excess of 20. This calculation is carried out on application. Settling mineral substances are rated lower than organic sediment. After the weight of the dry substance has been established, the proportion of organic sediment can be established by further analysis of the glow reduction. Evaluation:

a) sediment where the organic proportion is at least 10% 1 pollution index per m^3 annual quantity or in tons as an annual quantity,
b) sediment where the organic proportion is less than 10% 0.1 pollution index per m^3 annual quantity or in tons as an annual quantity.

This method can be used to analyse sediment with a concentration higher than 0.05 ml/l. Analysis should be carried out as soon as possible after the sample has been taken, using the entire range of samples. One litre of the sample is shaken well and placed in an Imhoff sediment glass. This is shaken several times jerkily. The volume of sediment is read after 2 h. Any undissolved substances that have not formed sediment can be gravimetrically analysed when the liquid is siphoned off by filtration. Flaky or fibre-type solids prevent straightforward precipitation.

III. Substances that can oxidize (COD): substances that can oxidize can be found in waste water that has been subjected to the action of oxidizing agents. They are measured using the chemical oxygen demand (COD) after the sediment has been removed. Analysis is carried out using the dichromate process, with silver sulphate as a catalyst. Evaluation: DIN 38 409 (12/1980) or process H41. Oxidizable substances in chemical oxygen demand 2.2 pollution index 100 kg annual quantity (COD). Ag_2SO_4 is used as a catalyst. $HgSO_4$ bonds the chlorine ions (because mercury is so toxic, the use of $HgSO_4$ should be avoided. Instead Cl_2 should be fully oxidized and this should be taken into account during calculations).

IV. Toxicity towards fish: aquatic organisms exhibit varying reactions to substances in water. The law defines a test fish, which is debatable because of possible adaptations, and also it is designed for analysing the effects of toxicity by using waste water thinned to varying levels. There is no provision for neutralization of the water.

Toxicity (G_F): the effect of toxicity in waste water on fish is analysed by testing the effects on the test fish, a golden orfe. The thinned waste water that no longer has a toxic effect is measured. Further regulations relating to the way the test is carried out, such as test time, can be found in the legal administration directives contained in the AbwAG (Abwasserabgabengesetz – German Waste Water Discharge Regulation), which relates to waste water levies. Analysis of toxicity towards bacteria has not been included. Evaluation: DIN 38 412 (12/1980). Toxicity towards fish (G_F) 0.3 · G_F · pollution index 1000 m^3 annual waste water quantity. G_F is the thinning factor at which waste water no longer has a toxic effect in the fish test. Where $G_F = 2$, zero is used.

V. Biochemical oxygen demand (in 5 days) BOD_5 and biodegradability: the measurement of the biochemical oxygen demand during aerobic, microbial oxidation in principle covers all water-soluble organic substances, and evaluation can be done in the same way as the natural biodegradability and self-cleaning of water; DIN 38 409, (5/ 1987). The higher the level of organic impurities, the more nutrients are present for the bacteria, causing the oxygen demand to increase. It is assumed that the oxygen consumption is caused only by the metabolic activity of the bacteria. However it can be the case that waste water contains toxic substances, for instance, which destroy the bacteria and therefore cause a falsely low BOD reading. The substances themselves have by no means degraded, and have a high oxygen demand. The BOD value measured however leads to an incorrect conclusion. The 5 day BOD value was introduced to provide comparative values as a basis, on the assumption that a certain level of environmental adaptation would have taken place within 5 days. A further disadvantage is the fact that only the oxygen consumption that is needed by the bacteria to biodegrade is measured, and the chemical reactions are not taken into account. As well as the biological oxygen demand, biodegradation test processes allow precise conclusions to be drawn regarding chemical processes.

VI. Analysis of oxygen consumption: the analysis of BOD_5 only provides values after a period of 5 days. For this reason, BOD_5 is as little suited to regulating a biological purification plant in a way that is appropriate to the quantity of pollution, as the analysis of COD or TOC, because these values only describe the pollution load relatively precisely if external conditions remain constant. It would appear to be more practical to use the measurement of consumption as a gauge for the quantity of pollution. The advantage of this process is that the measured values are ready within 10 min, and the instruments used to measure this are of a relatively convenient size and can be installed directly in the sludge activation chamber or the return sludge line. Construction and function: with the valve closed, the medium is transported to the pipe reactor from the container that is immersed in the medium to be measured. After a few circuits, the valve is opened. The medium circulates through the reactor, and consumption measurement begins.

Waste water harmfulness The level of harmfulness expressed as a → Pollution index (effluent) according to the waste water levy law.

Waste water heat exchanger It is necessary to make a basic differentiation between cold and hot waste water when planning heat recovery plants in the textile finishing industry. This thermal separation should be fully automated at approx. 60–70°C, because otherwise it has been found in practice that if all waste water is mixed, the max. mixed temperature is approx. 45°C. However, despite the high heat content of this mixed waste water, heat recovery would be inefficient because of the high quantity, since the fresh water could only be heated up to about 40°C. Older equipment can also be used to separate hot and cold liquors without great expense by installing thermostats and control valves in the run-off system of the dye machinery. However, individual checks must be carried out to establish which liquor temperatures can still be used in the heat exchanger, and which liquors are drained off directly.

For this application, the following are the best heat exchangers in practice, and have different types of construction as follows:

1. Plate heat exchanger (Figs. 1 + 2).

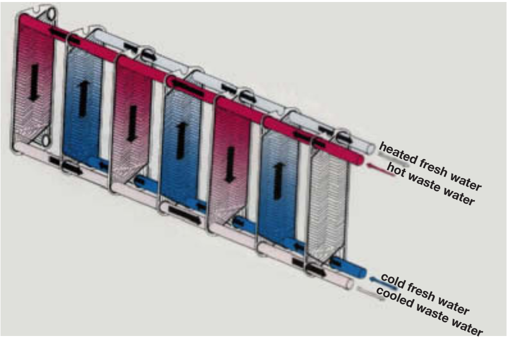

Fig. 1: Plate heat exchanger (W. Schmidt KG).

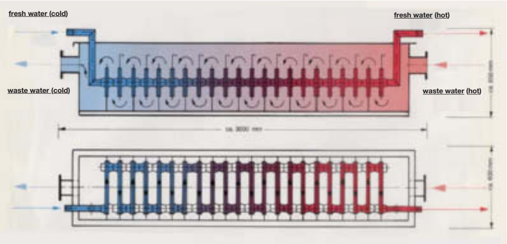

Fig. 2: Menzel waste water heat exchanger (6000 l/h capacity).

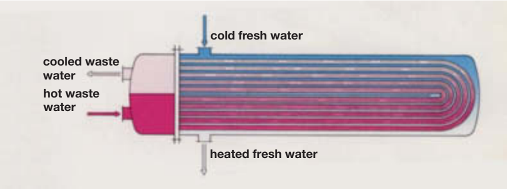

Fig. 3: Shell and tube exchanger (bundle heat exchanger).

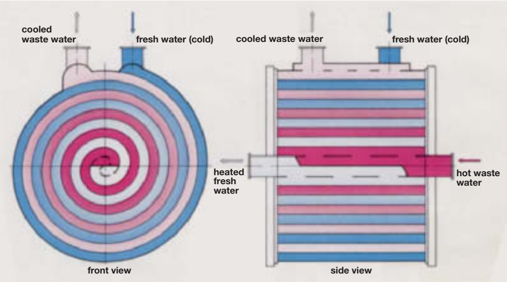

Fig. 4: Spiral heat exchanger.

2. Tubular heat exchanger as
   a) double-tube heat exchanger,
   b) tube bundle heat exchanger (Fig. 3).
3. Spiral heat exchanger (Fig. 4).

Waste water load Amount of impurities. Pollution in flowing water containing substances that consume oxygen (→: Waste water; Waste water pollution; Summation parameters). Calculated as a quotient of the limiting value per head of population and low water drainage.

Waste water measuring probe → pH/redox probe.

Waste water neutralization Alkaline waste water (e.g. from cotton or wool pretreatment) can be neutralized using acid, or acidic waste water (e.g. from wool dyeing) with alkali. Acidic and alkaline waste water from textile finishing processes can neutralize each other in a neutralization bath if none of the individual water requires specific treatment.

Waste water oil separation and adsorption This process is for cleaning waste water containing oil and fat, such as washing water emulsions, fat removal baths, etc., where the oil content is approx. 0.5–1.0% and surfactants are present to ensure stability. Oil emulsions can be broken up within a few minutes by adding separating agents, and the oil released is separated by silicic acid. The flakes of separating agent with adsorbed oil are filtered out of the purified waste water. The filtered oil cake is incinerated at a suitable incineration plant. Silicic acid, which is ecologically neutral, remains as ash. Low investment costs.

Waste water partial stream pollution A partial stream of waste water is considered to be concentrated waste water from the starting liquor. Some limit parameters are expected in Appendix 38 (textile manufacture and finishing) of the German Framework Administration Regulation of Waste Waters (Rahmen AbwVwV – Rahmen-Abwasser-Verwaltungsvorschrift) in line with paragraph 7a of the Water Resources Law (WHG – Wasserhaushaltsgesetz), which apply to a selection of auxiliaries and dyes.

1. Colour: the spectral adsorption coefficient is stipulated as follows:
   - 436 nm (yellow range) $7\ m^{-1}$
   - 525 nm (red range) $5\ m^{-1}$
   - 620 nm (blue range) $3\ m^{-1}$

   Colour is only included for aesthetic reasons. Also the limiting values (almost) correspond to clear water.
2. AOX: The source of AOX is hypochlorite bleach, and also (in unfavourable situations) chlorite bleach. Further sources are reactive dyes containing halogens with different reactivity in the reactive group in certain circumstances, as well as dyes that contain halogens in the form of auxochromic groups. This means that the AOX value can be controlled by increasing the dye yield and by means of process technology. A further source is the chlorination of wool for antifelt finishing and print pretreatment.
3. Sulphide: can be extremely toxic to bacteria in certain situations. The limiting value forces the textile industry to rethink the use of sulphur dyes, i.e. a transition to low-sulphur dyes and reduction agents, e.g. pre-reduced dyes and glucose as a reduction agent.
4. Heavy metals: these originate from metal complex dyes and afterchroming of wool, aftercoppering of substantive dyes in the case of cellulose and the cotton itself. Zinc salts are catalysts in resin finishing, however it is possible to replace them with NH_4 and Mg salts. Tin salts are used as reduction agents in textile printing, and they can also be substituted.
5. Surfactants: the recommendations relating to relieving the strain on waste water should be taken seriously, this also applies to products containing surfactants that are not included in paragraph 2 section 1 of the German Detergent and Cleaning Agent Law (WRMG – Wasch- und Reinigungsmittelgesetz). These must fulfil the legal requirements defined on the basis of paragraph 3 of the Detergent and Cleaning Agent Law from the point of view of biodegradability. Texturizing auxiliaries are exempt from this. The set requirements regarding biodegradability also have to be fulfilled by a large number of textile finishing auxiliaries. Furthermore, the following is required:
   - treatment of screen and print blanket washing water, as well as the washing water from print machinery cleaning, to be re-used as washing water.

- separation of dyeing and washing liquors with a high concentration of dye for special treatment.
- washing of barrels and packaging only when concentrates have been removed.

The following short-term strategy for the textile finishing industry can be derived from Appendix 38:

- checking individual formulae using the avoidance principle. It would be helpful if dye manufacturers would provide information regarding heavy metal and AOX content;
- checking process methods in the plant; multi-use of process water, e.g. rinsing water (dependent on temperature and dwell time);
- consistent introduction of measurement techniques;
- construction of a waste water installation system that fulfils the requirements of the partial streams;
- installation of sampling systems to check that the limiting values are adhered to;
- installation of a collection and neutralization basin;
- installation of a sampling system at the point of transfer to the communal purification works (Venturi shaft);
- checking economical and ecological compliance.

It is essential that the mid-term and long-term targets of the textile industry are subject to scientific processing with respect to their ecological responsibility. In the medium term, the following theories among others are particularly important:

- in future, the functional mechanism of textile auxiliaries must be highly efficient and biodegradable in a process;
- development of specific purification methods for partial stream cleaning; if this can not be regulated, aerobic or anaerobic disposal should be the objective;
- circulation of process water;
- measurement/control techniques should be suited to the individual components;
- all biotechnological opportunities should be used to full advantage.

(according to Schollmeyer).

Waste water permanganate consumption The → Chemical oxygen demand (COD) of a sample of waste water, expressed as a weight of potassium permanganate (in mg), which contains reducing components and oxidizes under certain reaction conditions in 1 l of waste water. According to the normal values that apply in Germany, mechanically purified domestic waste water should have a potassium permanganate consumption of less than 200 mg/l, and for biologically purified waste water the value should be below 100 mg/l. These values are exceeded by far in waste water from the textile industry, at 300–30 000 mg/l (where the normal value for surface water is 10–30 mg/l).

Waste water pipes The best type of pipes for aggressive waste water are formed pieces internally enamelled with no internal bushings: having the hardness of glass, mirror-like, with high resistance to acid, alkali and other aggressive substances; extremely resistant to temperature. Sealing sleeves made from ethylene propylene terpolymer rubber or nitrile rubber are used as connectors.

Waste water pollutant load Calculation of → Waste water pollution x waste water quantity/unit time. Conventional value is the → Population equivalence.

Waste water pollutants are aggressive, toxic and inorganic and organic compounds as well as their ions which impede biodegradation (→ Waste water pollution). Given as a concentration in mg/l. Permitted waste water threshold limit values for discharging waste water pollutant are aimed at the required protection of the sewerage system, biological → Waste water treatment and the outfall channel.

Waste water pollution,

I. Contaminants accumulating in waste water. Stemming from textile finishing substance burdens in the waste water: dyes (absorbable, non-absorbable), acids, alkalis and neutral electrolytes, oxidants (chrome compounds, bleach liquors, nitrites, nitrates, etc.), reducing agents (sulphur compounds), plastic emulsions/dispersions, finishing agents (e.g. fermentable starch products), metal salts, especially salts from heavy metals (toxic substances) such as copper, chrome(III), chrome(VI), mercury, lead, zinc, zirconium and such ions. Textile auxiliaries/wetting agents, surface-active substances, thickeners, lubricants/oils, sequestering agents and phosphates, tannin-like products amongst others → Waste water pollutants.

The waste water pollution of a finishing business (Tab.) approximately consists of the following: 46% sizing, 39% preparation, 15% dyeing and finishing.

	Pollution g of COD/kg	Waste water accumulation l of water/kg
Coloured CO fabric	100–150	100–180
Printed fabric	180–250	140–200
Knitted fabric (coloured)	80–100	80–140
Yarn dyeing	70–100	100–140
Coloured PA fabric	60–100	60–100
Carpet dyeing		
– exhaust process	25– 60	50– 80
– continuous process	35– 60	50– 80
Carpet printing	35– 60	60– 90

Tab.: Special characteristic numbers of some textile chemical finishing processes (calculated to 1 kg of textile product). CO = cotton; PA = polyamide.

II. Results from domestic, technical and agricultural water consumption as well as polluted rainwater. The degree of pollution is measured in settleable solids (ml/l), ignition loss, as oxygen consumption in the oxidation of contaminants in chemical or biochemical methods and as organic carbon content. →: Oxygen demand; Waste water pollutants; Waste water pollutant load; Population equivalence.

Waste water pollution from dyehouse effluents Each phase of the dyeing process contributes to waste water pollution to a greater or lesser extent depending on composition (see Tab.).

	COD value (mg O_2/l)	g of COD/kg of fabric
Dye liquor before dyeing	982	19,6
Dye liquor after dyeing	995	19,9
1st rinsing bath	233	4,6
2nd rinsing bath	74	1,5
3rd rinsing bath	55	1,1
Total pollution according to individual liquor measurements	(1357 : 4) = 339	27,1

Tab.: Waste water pollution from wool dyeing with acid dyes (20 : 1 liquor ratio), relative to the liquor and to the fabric.

The pollution values can be calculated using the following formula:

$$\frac{\text{COD value}}{1000} \cdot \text{liquor ratio} = \text{g COD/kg fabric}$$

These values correspond with the figures in the last column of the Tab. The second-last column, the so-called mixed waste water value results from the COD values of the liquor mixture. The arithmetic mean of the mixed waste water value provides good insight into how efficient the addition of the COD values of the individual liquors is with respect to the overall value. As a complement to this, the waste water pollution of acidic wool dyeing used as an example in the Fig. is shown as a function of conductivity, COD value and extinction.

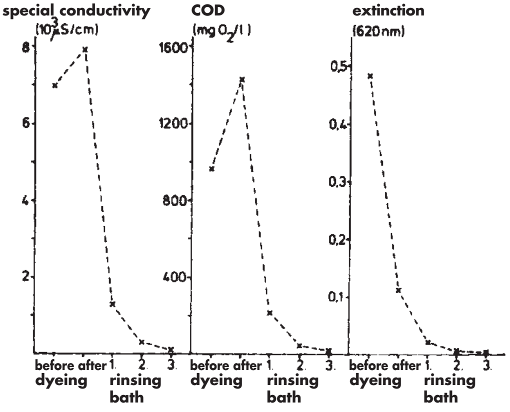

Fig.: Fall in typical waste water values with rinsing time.

It is apparent that the conductivity (measured with a conductivity gauge) and the COD value in the dye liquor increase after dyeing (in comparison with the dye liquor before dyeing), which is linked with the acetic acid feeding liquor. On the other hand the extinction, which is dependent on dye uptake, decreases. Then all three values drop successively during subsequent rinsing. Regarding the level of pollution, the dye bath before and after dyeing and the first rinse are considered to be heavily polluted, and the second and third rinsing baths as slightly polluted.

Waste water pollution sources,

I. Direct pollution sources are those which drain directly into the outfall channel of a works sewerage system and works waste water treatment plant. Minimum requirement in accordance with § 7a of the German Water Resources Law (WHG – Wasserhaushaltsgesetz).

II. Indirect pollution sources are those which drain into a public sewerage system to a municipal waste water treatment plant and from there indirectly into a body of water.

Waste water, potassium dichromate consumption → Chemical oxygen demand.

Waste water pretreatment Hydrocarbons and colloidally dissolved dyes as well as some auxiliaries can be flocculated by the addition of electrolytes, e.g. iron or aluminium salts. The pH should also be controlled to complete the precipitation and a suitable flocking auxiliary added. The costs of such a pretreatment are, relative to the water volume, often considerably higher than those of biological cleaning. So, such a pretreatment is only appropriate if it is essential for the protection of the subsequent waste water treatment plant. Main source of hydrocarbons in textile waste water is grey fabric; this mainly concerns auxiliary substances from preceding processing stages, e.g. spinning preparations, sizing waxes, etc. The following product groups are considered in finishing:

- scrooping agents,
- synthetic thickeners,
- dust extraction agents (powder dyes),
- benzine (in printing).

Waste water in textile finishing mainly contains aliphatic hydrocarbons (liquid or wax-like paraffins); textile waste water contains ecologically and toxicologically questionable aromatic hydrocarbons to a lesser extent, as, e.g. in motor spirit for automobiles. Hydrocarbons disrupt the operation of local authority waste water treatment plants only in higher concentrations; a lower recommended parameter is therefore being discussed in the new version of the ATV/Work sheet A115 (ATV – Abwassertechnische Vereinigung – German technical association for waste water). Hydrocarbons are present in emulsified form in textile waste water; simple mechanical removal is therefore not possible. A precipitation/flocculation process is required to break the emulsion; not only is the mineral oil concentration reduced, but the COD value and the AOX concentration are also considerably lowered at the same time. Some businesses already have the appropriate plants today. It can be expected that more firms will be subjected to pressure from the authorities to segregate highly polluted flows from physical/chemical treatment systems before discharging into the public sewerage system. However, a segregated stream treatment is particularly problematic especially in textile finishing, as the possible segregated streams neither occur continuously nor (due to the frequent lack of strict assignment of machine and process) always at the same site.

Waste water quantity As m^3/day in the hazard formula (→ Waste water evaluation).

Waste water regulations In 1976 § 7a, amongst others, was introduced into the German Water Resources Law as the 4th law on the amendment of the → Water Resources Law, with which demands on the introduction of waste water into public bodies of water (Tab. 1) should be controlled (→ Water protection). The objective read: "In order to protect the bodies of water from contaminants, only waste water introduction consistent with § 7a, paragraph 1, clause 1 of the German Water Resources Law (WHG – Wasserhaushaltsgesetz) may continue to be permitted, if quantity and hazards of the waste water are kept as low as possible when using methods in accordance with technological regulations." The Federal Government established so-called minimum requirements for different types of waste water in the form of General Administrative Regulations (VwV – Verwaltungsvorschriften) for the execution of the law. These VwV were prepared by committees from the State Working Group for Water (LAWA – Länderarbeitsgemeinschaft Wasser) with more or less strong involvement of representatives from industry and associations. The VwV for the textile manufacturing industry was issued in 1984 (38th Abw.VwV – Abwasserverwaltungsvorschriften – Waste Water Administrative Regulations) and amended in 1994.

In § 7a, WHG, "dangerous substances" are described as follows: "substances or substance groups, which due to the concern that toxicity, durability, accumulation ability or a carcinogenic, fruit-damaging or genetic altering effect can be considered as dangerous". This long-winded, unclear definition is open to many possible interpretations.

The 38th Abw.VwV (Abwasser-Verwaltungsvorschrift – German Administrative Regulation of Waste Waters) applies, as all other Administrative Regulations in accordance with § 7a WHG, only to direct pollution sources, of which there are very few left in the

Tab. 1: Minimum requirements for textil manufacturing and textile finishing waste water according to § 7a of the German Water Resources Law – Wasserhaushaltsgesetz (by DTNW).
a = requirements according to common engineering standards; b = state of the art requirements; c = applies to the yellow, red or blue zone; d = from the sample.

textile industry in the old states of the Federal Republic of Germany. This is more so, however, in the new states of the Federal Republic of Germany. It can be assumed that some municipal waste water treatment plants are subject to these VwV provided that a textile firm provides most of the pollutant load in the local authority in question. It is stated in the 38th VwV: this VwV "is valid for waste water which is introduced into bodies of water whose pollutant load essentially comes from the processing and treating of textile fibres and yarns and textile finishing." The question as to how the word "essentially" should be applied could not be explained until now. It would be justified if at least 50% of the pollutant load, but at any rate 75% of the average pollutant load from the municipal waste water treatment plants, came from one or several textile firms. There are such examples in several places in Germany without the authorities having applied the 38th VwV until now.

Meanwhile the Federal Government ordered the LAWA committees to revise the requirements. Some of the new minimum requirements for other branches of industry have meanwhile been issued and this is as a rider to the amended General VwV, which henceforth applies to all waste water treatment plants, from which waste water is introduced into bodies of water and is with additional minimum requirements, depending on the type of, or the industrial undertakings, from which the waste water mostly comes. The appropriate rider for the textile industry exists as appendix 38 in the draft of 25 May 1990. The minimum requirements are referred to in the middle column of Tab. 1. A whole series of parameters was recently incorporated, which increases requirements for most parameters already listed. The trend in pollution control legislation can be recognised from these measures. Waste water experts comment on the existing minimum requirements in the draft, to the effect that some of the requirements mentioned are scientifically unjustified, many measures cannot be achieved in accordance with technological regulations or state-of-the-art, and many lack relevant parameters.

Besides the requirements of laws pertaining to water and waterways, the water protection regulations contain detailed provisions on dealing with water threatening substances. The neighbouring countries of Germany do not have a similarly dense network of overlapping laws, regulations, guidelines or statutes in accordance with the provisions of the state of the art. While in Germany, demands on the discharge of waste water are partly stipulated in an industry-specific way (in accordance with the regulation of origin), in other European countries they usually apply to all areas. From there it is only comprehensible that, for example, Spain has meanwhile introduced a wealth of individual monitoring parameters, which are comparable with German ideas with regard to their results. Belgium has laid down partly specific and sectoral standards for industrial waste water. Nevertheless as a result of separate information, up to 30% of textile waste water is directly discharged into the outfall channel without considerable treatment. In France it is up to 45% of all textile waste water. The Netherlands, however, consistently pursue the way of load limits also frequently demanded in Germany.

Sometimes only vague advice exists on the issue of self-checking, which indicates that the extension of municipal or supra regional state monitoring organisations is not yet intended or was not yet concluded. It can certainly be confirmed that state controls are being revoked and there is an increasing desire to introduce self-checking. It is quite different in the federal constitution of Germany. The competing legislation (embedded in clauses 72 and so on of the Basic Law) is taken literally in the German states and results in vying competition. The German regional water laws authorise the regulatory body to decree self-checking regulations, which were introduced into the old states of the Federal Republic of Germany, sometimes in a very different form. These generally apply to public waste water plants and other waste water plants with a low limit of, for example, 8 m^3 per day or less than 60 inhabitants. Self-checking and/or self-monitoring is committed to the following measures:

- installation of control and measuring devices,
- keeping an operating diary,
- seal-tight tests for waste water channels and pipes,
- storage of resetting samples,
- reporting of stoppages,
- preparation of an annual report.

Extent and frequency of the checks are dependent on the type of waste water plant and the daily waste water accumulation, in which distinctions are made between plant and production-related checks. The following checks should be carried out first and foremost by textile finishing companies:

- general type (independent of waste water accumulation),
- general parameters
- certain substances regularly occurring in textile waste water.

Bavaria has "practically revised" the EKVO (Emmissionskonzentrationsverordnung – Emmission Concentration Regulation) of Baden-Württemberg in the Waste Water self-monitoring Regulation (AbwEV – Abwassereigenüberwachungsverordnung), reduced the low limit and production-related self-checks, which should be used for the formation of a waste water register, but not incorporated. The municipalities are in principle responsible for waste water treatment. It is their task to build waste water treatment plants of sufficient dimensions and to operate properly. These requirements (as "generally accepted technological regula-

Size classification of waste water treatment plants	Chemical oxygen demand (COD) [mg/l]	Biochemical oxygen demand in 5 days (BOD_5) [mg/l]	Ammonium nitrate (NH_4-N) [mg/l]	Total phosphorus (P_{tot}) [mg]
Class 1 less than 60 kg/d BOD_5 (raw) Qualified sample or 2 h mixed sample	150	40	-	-
Class 2 60 kg/d or more BOD_5 (raw) Qualified sample or 2 h mixed sample	130	340	10 (>300 kg/d BOD)	2 (>3000 kg/d BOD)

Tab. 2: Waste water threshold limit values (local variation in COD down to 20).

tions") are fulfilled if the empirical values of the cleaned waste water correspond to the values mentioned in Tab. 2. If they are exceeded a punishable offence exists in principle as regards § 7a WHG (and/or the similar regulation in the state law).

The discharger must pay a tax in accordance with the German Waste Water Discharges Regulation (Abwasserabgabengesetz) for discharging the waste water in bodies of water. The law intends that an evaluated quantity of harmful pollutant is calculated on the basis of data in the content of COD, settleable solid pollutants in waste water, certain heavy metals, AOX and fish toxicity, which is summarily deposited each year at an outfall channel. This is described as a damage unit. A waste water tax is calculated for each damage unit by multiplying the damage unit by DM 40.00 per damage unit. Roughly calculated one damage unit corresponds to approx. the cleaned waste water of 10 inhabitants. For a small town with approx. 10 000 inhabitants with 100 000 damage units in the raw sewage and (90% cleaning performance of the waste water treatment plant assumed) 10 000 damage units occur in the waste pipe. A waste water tax of DM 400 000/year results. If the cleaning performance fulfils all the specified conditions and corresponds with the normal standard of the purification technology, i.e. the generally recognised technological regulations, only 50% of the calculated tax, i.e. DM 200 000, should in fact be paid. If, however, faults occur and these are recognised by the supervisory authority, the reduction does not apply. In particularly efficient waste water treatment plants, which clean in accordance with the state-of-the-art, the attainable reduction is even 80%, i.e. in the case of a fault the tax to be paid can in fact be increased fivefold. This not inconsiderable reduction is less a concession but more a motivation to encourage the waste water treatment plant users to operate their plant carefully, to discover possible causes of faults amongst the indirect polluters and to cause a change in their behaviour.

The regulations on minimum requirements for waste water treatment plants and the size of the waste water tax firstly only concern the direct discharge of waste water, i.e. those institutions, which discharge their waste water directly into a body of water after successful cleaning, e.g. the municipalities. Laundries are normally not direct polluters, as they mostly discharge their waste water into municipal waste water collection systems. The waste water tax must always be paid as well as the costs of the waste water treatment by the associated indirect polluters. That is why indirect polluters always pay a waste water charge, which covers the costs of the waste water tax, the channel operating system, the operation of the waste water treatment plant and the waste water monitoring. The type of charge is different depending on the region. There are often fixed prices per m^3 of waste water with no consideration for the content of the pollutant. But a lot of local authorities have introduced so-called waste water coefficients, which assess how high the pollution of the waste water actually is, using analysis data. They then calculate a charge corresponding to the pollution. But also compulsory waste water threshold limit values, which should not be exceeded, exist for indirect polluters independent of this charge issue. The effective regulation of these threshold limit values (Tab. 2) lies with the local authorities, who draw up so-called local waste water statutes. The criteria recommended by the German Technical Association for Waste Water (ATV – Abwassertechnische Vereinigung) in worksheet A 115 are normally assumed in these (in accordance with Gode, Reetz and Schulze-Rettmer).

Waste water situation textile finishing Investigations have revealed that from 1000 kg of cotton fabric, substances reach the waste water, which, determined as COD (→ Chemical oxygen demand), have values of 130–150 kg. This COD component consists of:

51% sizing agents,
25% fibre degradation products,
11% chemicals
13% resultant products of dyeing and finishing.

This is the reason that a search for methods for reducing waste water loads, mainly in sizing and desizing, was suggested. For instance the following picture results as regards fabric; values for COD are compiled in accordance with water treatment at 100°C (1 hour) (10 g of textile material was used each time; liquor-to-goods-ratio 1 : 10) [mg O_2/l]:

– cotton fabric, sized (starch)	7350
– cotton fabric, desized	2740
– cotton fabric, peroxide-bleached	2140
– cotton jersey knit good	1780
– polyester fabric, carrier-free dyeable	760
– polyester fabric, cotton type	1130

The waste water situation is characterised by:

- quantitative waste water accumulation,
- a series of the most varied materials, alkalis, acids, in part high salt quantities, diverse finishing agents, low-molecular paraffin hydrocarbons, surface-active substances, polymers, natural and synthetic oxidizing agents, reducing agents, etc. Decomposition products of the fibres: hemicelluloses, pectins, waxes, oligomers, dyes and optical brightening agents,
- pH and temperature fluctuations,
- potential toxic effects,
- discolorations, odour, cloudiness, foam,
- sludge and its production during extensive elimination of waste water materials.

Waste water technology embraces all technologies of → Waste water treatment.

Waste water treatment Reserves of dirt, poison or re-usable substances, which are contained in waste water, as well as separate waste water and separate sludge treatment.

Waste water treatment methods are classified as follows:

I. Physical (mechanical): a) sedimentation, b) filtration, c) distillation, d) sorption, e) freezing out.

II. Chemical: a) neutralization, b) ion exchange, c) oxidation, d) reduction, e) catalysis.

III. Biological: a) aerobic treatment, b) anaerobic treatment, c) activated sludge process, d) fungus treatment.

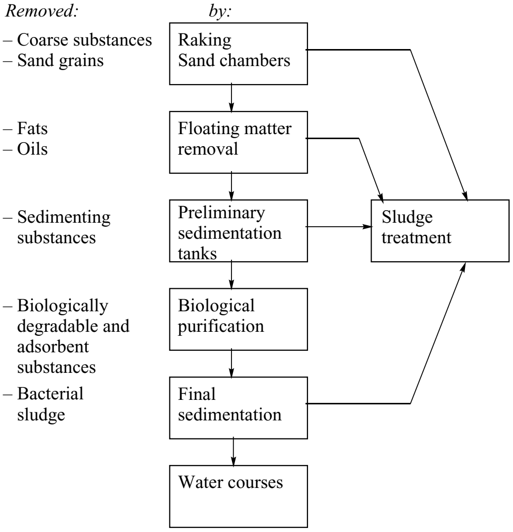

Fig. 1: Diagram of a communal waste water treatment plant.

IV. Physical/chemical: a) flocculation and precipitation (coagulation), b) ventilation, c) activated carbon filtration, d) foam fractionation, e) solvent extraction, f) combustion, g) osmosis, h) electrolysis.

Depending on the type of treatment carried out, a distinction is made between treated or so-called clarified waste water, which is either re-used or introduced into an outfall channel. The sludges are re-used, stored, re-structured or burnt. Most municipal waste water treatment plants have a mechanical and a biological cleaning stage; the technique is sophisticated and is also used successfully in large industrial plants. Such a plant is constructed schematically as follows (Fig. 1):

a) arithmetic processing unit: for coarse substances;
b) sand trap: for grains of sand (protection of pumps, seals);
c) floating material separator: for oils and fats;
d) sedimentation tank: for settleable solid pollutants in waste water;
e) sludge activation tank or percolation filters: for biologically degradable and adsorbable substances;
f) secondary settling tank: for bacterial sludge.

Fig. 2 shows in detail which waste water loads are reduced, degraded or eliminated (sorption in sludge) by certain waste water treatment methods.

The following processes run in the actual biological stage (sludge activation tank or percolation filters):

Bacteria degrades organic substances by the consumption of atmospheric oxygen, in which firstly CO_2 and water and secondly new bacterial mass develops. Filter candles, injectors or aeration tanks, for example, are used for ventilation. At the same time the bacterial sludge is in a position to extract substances from the

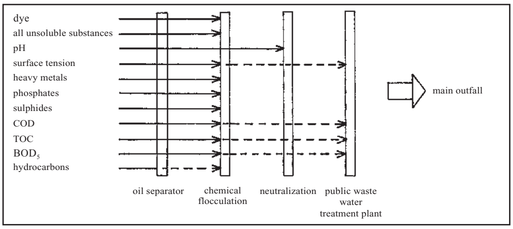

Fig. 2: Treatment of waste water of a textile finishing manufacturer by oil separator, chemical flocculation with iron hydroxide and calcium hydrate, neutralization and biological oxidation.

waste water through adsorption; this includes most textile dyes, for example.

Water and sludge are separated in secondary settling tanks; the cleaned water drains through an overflow channel. The sludge is extracted on the floor of the basin. The larger part of the sludge flows back into the sludge activation tank as return flow sludge in order to inject the newly added waste water. The excess sludge, approximately 10–50% of the removed organic substances, must be disposed of and/or further treated. It is firstly thickened, whereby the dry content of approx. 0.1–1% is increased to approx. 5%. In municipal plants, a decaying process is possibly connected, i.e. an anaerobic biological sludge treatment, in which part of the organic mass is converted into methane and carbon dioxide. As a result of the decaying the sludge is at the same time transported in a perfectly hygienic state; after draining the humus-rich material can be used to improve soil in agriculture (in accordance with relevant regulations). Sludges from industrial waste water treatment plants are normally burnt after conditioning or sent to a disposal site.

In catchment areas of inland lakes phosphate reduction is required after the mechanical/biological waste water treatment in order to avoid an uncontrolled algae growth. The necessary chemicals, e.g. iron or aluminium salts, can be added at various process stages (Fig. 3).

- pre-precipitation in sedimentation tank,
- simultaneous precipitation in the sludge activation tank,
- post precipitation in a separate 3rd stage.

In the first two processes, costs arise only for the chemicals; an additional third stage, however, requires high investment costs, though it also results in an even better phosphate elimination. In the pre- and/or simultaneous precipitation the danger exists moreover that not enough (dissolved) phosphate is available in the sludge activation tank for biodegradation; but if a third stage is to be avoided, metering the precipitate in the outlet of the sludge activation tank is also considered. The mechanical/biological waste water treatment outlined, (possibly supplemented by a precipitation stage) is also the most convenient process, economically and ecologically, for waste water from textile finishing; this applies particularly to mixed water from municipalities and the textile finishing industry.

I. Mechanical (physical) waste water treatment: is based on physical properties and includes the separation of coarse disperse solid substances from the liquid phase and their stabilization. Is used as pre-treatment for easing the subsequent waste water treatment processes, especially the biological stage.

1. Coarse substance precipitation with rakes, screens and filters.
2. Gravitational precipitation via:
   - flotation plants,
   - oil and fat separators,
   - sand traps,
   - settling basins: rectangular basins, round basins, two-storey settling basins (Emscher tank), slat-type settling basins and vertical throughflow settling basins.
3. Balancing reservoirs are plants, which cause a mixture of different qualities and concentrations of

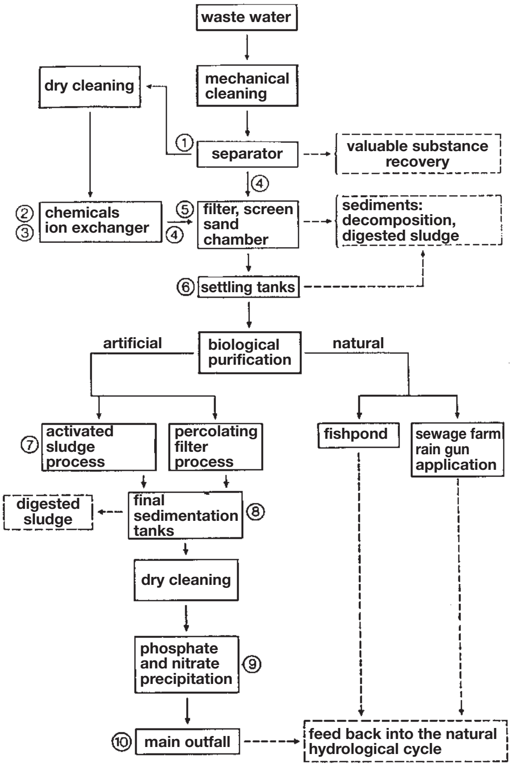

Fig. 3: Model of a 3-stage waste water treatment plant, including artificial or natural biological decomposition with valuable substance recovery (top, right). The figures describe the waste water treatment sequence in a public waste water treatment plant.

waste water to drain by mechanical processes. Ponds or specially built basins are used as balancing reservoirs. Balancing reservoirs are designed and built with horizontal, vertical or tangential charging machines.

II. Chemical waste water treatment: comprises the retention or the conversion of the settleable, suspended and dissolved matter through the use of chemicals. The processes are based on purely chemical or physical/chemical reactions and are used to achieve the following effects:

- neutralization of acid or alkali drains,
- separation of solid matter, which cannot be removed by simple mechanical waste water treatment,
- elimination of colloidal, usually organic matter and some dissolved inorganic matter,
- removal of the residual amounts of fats and oils,
- improvement in the waste water treatment effect of flotation and filter plants,
- reduction in radioactivity of contaminated waste water,
- through use of chlorine and chlorine oxygen compounds, achievable effects such as: disinfecting, controlling algae growth, maintaining water freshness, decontamination, odour prevention, decolorizing, oxidation and controlling fly larvae in percolation filters.

1. Neutralization: is required before the introduction of acid or alkali waste water into an urban sewerage system. The following groups of neutralization processes are common nowadays:
    - use of the buffer properties of the outfall channel,
    - mixing of acids with alkali waste water,
    - addition of chemicals, which react as alkalis, such as NaOH, $Ca(OH)_2$, etc.,
    - filtration through neutralization of filter material, such as with $CaCO_3$, etc.

   During the neutralization process, a pH shift occurs, which often results in flocculation of colloidal constituents of the waste water. An after treatment in a settling plant is necessary in such cases.
2. Flocculation and precipitation: the substances, which are present in the water in colloidal form, are transformed into larger agglomerates through addition of appropriate auxiliaries. The flakes thereby are in a state and a size, which make them capable of forming a sediment, capable of flotation or filterable, through which extensive mechanical separation of the suspended matter from the water is possible. The generic term flocculation and precipitation is understood to mean both coagulation and flocculation. Both inorganic and organic substances as well as in combination are used as flocculation agents. The most important inorganic ones are aluminium salts, iron salts and calcium hydrates; the organic ones are polymers with a long chain length, manufactured from natural substances (algae, starch) or by a synthetic process.
3. Adsorption of dissolved materials in the water on the surface of, e.g., activated carbon particles and thus their elimination from the treated water flow. Another possibility for adsorption is sand filtration, in which the suspended particles are adsorbed on the particle surface. Activated carbon is the most important technical adsorbent, which can be so varied in its porous structure through appropriate control of the manufacturing process, so that an optimum adsorption of certain substances is facilitated.
4. Extraction using solvents: the capability of some substances (solvents) to dissolve in certain liquids is used in this connection but not in the waste water. The liquids can consequently be separated and recovered from the dissolved substances which are to be removed from the waste water. Butyl acetate, isopropyl ether and other similar products are used as solvents, for example. The extraction processes may be varied dependent upon how the solvents came into contact with the waste water, for example, with single or repeated contact, counter-current, etc.
5. Membrane separation (ultrafiltration, reverse osmosis): dissolved substances can be removed from aqueous solutions and electrolytes through membranes. In contrast to conventional filtration (treated waste water and adsorbed substances on dry sludge), hyper and ultrafiltration of the volumetric flow is separated into two segregated streams, one enriched with dissolved substances and one depleted of dissolved substances. Hyperfiltration and ultrafiltration are differentiated by their operating pressure and also by the membranes used as well as by the systems to be processed.
6. Distillation: as the mineral and organic matter are not easily vaporized, distillation is based on the change of state of the waste water through evaporation of the liquid and then condensation. High energy costs and greater technical expenditure are disadvantageous.
7. Oxidation: is used in waste water, which contains hydrogen sulphide, mercaptans amongst other sulphide compounds. The most commonly used oxidizing agents are atmospheric oxygen and chlorine. Atmospheric oxygen is used for the oxidation of organic substances with low reducing property. The following are thereby distinguished:
    - pressure oxidation with oxygen (at 110°C; $3.5 \cdot 10^5$ Pa),
    - wet combustion (225–347°C, $150 \cdot 10^5$ Pa).
8. Reduction: for waste water, which contains easily reducible, harmful constituents. Chrome acid can be reduced, for example, using sulphuric acids, their

salts or using bivalent iron salts in waste water containing chlorine by means of activated carbon.

9. Ion exchange process: certain ions in this process are absorbed from an electrolyte solution and an equivalent quantity of other ions are exchanged with the solution. Similar to adsorption, ion exchange also results in the reversible bond of material in waste water with an auxiliary, with whose regeneration a phase low in foreign matter, but concentrated, precipitates the material. Most ion exchangers are polymers, on the framework of which certain substances are absorbed. Besides the synthetic resin exchangers, there are also inorganic-based exchangers (zeolites). The following are used in waste water treatment:
   - cationic exchangers, resins with sulphonic acid and carboxylic acid groups. They bond copper ions, for example, and release sodium or hydrogen ions.
   - anionic exchangers, resins with amino groups, for example, bond sulphates or cyanites in exchange for chloride or hydroxyl ions. (→ Ion exchanger).
10. Other physical/chemical treatment processes:
   - flash steam,
   - ventilation,
   - fumigation with carbonic acid or flue gases,
   - evaporation,
   - freezing processes,
   - crystallization,
   - electrolysis,
   - dialysis.

III. Biological waste water treatment: is carried out mechanically on treated waste water by fixed or moving lattices of oxygen containing micro-organisms.

1. Soil and/or dynamic filters: levelled off soil (easily permeable, not too fine a sand) with at times waste water back up and breaks in atmospheric oxygen absorption. 300–750 m^3 daily output per hectare. The water table should be a maximum 2 m below the surface; sealing required; poss. after spraying.
2. Drip process: percolation filters are cylinder or polyhedron-shaped vessels with filling of sand-free, weatherproof, broken stones, mineral pieces, lava tuff, burnt pieces or plastic filling. The waste water is distributed across the surface by sprays, rotary sprinklers, channels, etc. and drips dependent on load, under gravity, in 20–60 minutes via a 2–3 m high percolation filter. A type of film develops on the broken filling, which is formed by the mineralising micro-organisms from the matter in the waste water. The films and/or the micro-organisms living in it, also referred to as “biological grass”, adsorb and mineralise the matter contained in the waste water. A distinction is made between low-polluted (containing sludge) and high-polluted (flushing-) percolation filters. Waste water pollution of a percolation filter is understood to mean the quantity of waste water, which is distributed on a m^3 filter material in a certain unit of time (expressed in m^3 waste water/m^3 filter material · day = $m^3/(m^3 \cdot d)$). In the low-polluted case, dead bacterial films are mineralised and then repelled; in the high-polluted case, immediately rinsed out; in both cases a post waste water treatment is required. The percolation filter rating is not in accordance with the quantity of water, but in accordance with the quantity of soil. A volumetric pollution of 200 g $BOD_5/m^3 \cdot d$ and/or 5 E/m^3 for low-polluted and 600 g $BOD_5/m^3 \cdot d$ and/or 15 E/m^3 for high-polluted percolation filters is expected; the latter require a surface coating of at least 0.8 m^3 water per m^2 surface for the maintenance of the rinsing force (E = population equivalence, d = days).
3. Stimulation processes: waste water treatment with stimulated flocks (activated sludge), which are produced by biochemical oxidation of organic contaminants. Besides oxygen, a nutrient ratio of $C : N : P = 5 : 1 : 0.15$ is required. Activation plant usually has a higher degree of treatment than percolation filters, but produce more sludge containing a lot more water; a good settling plant should be connected. Mixing of the activated sludge with waste water as well as oxygen input are carried out in the sludge activation tank: compressed air basins, Haworth channels, oxidation trenches, basins with rotary scoops, Dessener basins and mixer basins with added air. Activated sludge is precipitated in the after waste water as return sludge and is mixed as return sludge with pre-treated waste water in the sludge activation tank. Excess sludge produced is usually removed from the pre-treatment together with sludge. Volumetric pollution of 500 g $BOD_5/m^3 \cdot d$ and/or 12 E/m^3 (low-polluted activation) up to 1000 g $BOD_5/m^3 \cdot d$ and/or 25 E/m^3 (full treatment) are necessary to rate activated sludge. Higher levels of pollution only result in a partial treatment. In addition, there are other important pollution parameters such as ventilation periods and sludge load, i.e. the ratio of daily BOD_5 volumetric load to the sludge quantity operating in the sludge activation tank. Oxygen supply at full treatment in compressed air basins should be 1.2–2 Nm^3 air/E · d and in basins with surface ventilators 1.2–2.0 O_2/g BOD_5. An O_2 content of 1–3 mg/l must be guaranteed from the air supply in all parts of the ventilation basin.

Other waste water treatment processes: →: Activated sludge process; Electro-m-process; Ion-exchange processes; Katox-system; Methanation in the biogas process; Reverse osmosis process.

Waste water treatment by plant biology Biodegradation of municipal waste water can be achieved with the aid of marsh plants (rushes, reed, irises, etc.). A promising alternative to the conventional waste water treatment technique presents itself for areas difficult to develop infrastructurally. With low maintenance costs, little care needed, the long residence times, the high biodegradation rates and the almost complete avoidance of problematic residual matter (sludge), this process presents an alternative solution. In this method, the waste water is transported into special plant beds, which are sealed against the subsoil, similar to a foil basin. Optimisation of the sediments is required, on whose composition the efficiency of energy use of degradation is crucial. The physical, chemical and biological processes take place in the ground including the metabolic activity of micro-organisms. The plants are first and foremost responsible for the reliable performance (hydraulics) of sediments and for the absorption of degradation products. The natural degradation mechanisms can be used to extract phosphorous or nitrogen compounds, for example, via the structure of organic materials (plants and micro-organisms) and the immobilisation on the substrate of the sediments of the waste water chain. The large area required, the feed of the plants to be harvested (due to possible contamination with heavy metals), the reduced degradation performance in the cold season (→ Waste water treatment plants) as well as possible odour nuisance are all problematic.

Waste water treatment plants degrade waste water materials biologically, adsorb or filter harmful pollutants in the waste water or allow untreated waste water to run through into the outfall channel (body of water). The drawing off of textile waste water to a central waste water treatment plant using a biological stage and common treatment with domestic waste water is the norm. Insufficient effluent values with regard to TOC, DOC and surface tension usually ensue from washing and rinsing agents, complexing agents amongst other textile chemicals difficult to degrade.

In the field of biodegradability (besides the actual degradation, the term "biological elimination potential" also includes adsorption processes) a satisfactory uniformity in the test methodology is still lacking. Nevertheless a fundamental discovery is almost generally accepted: the "real" elimination, which includes the substance in question along with its possible conversion and partial degradation products is, for example, ascertained with the aid of DOC evaluations in the water phase of activated sludge, and is important. On the other hand, only one so-called primary degradation is recorded with the traditional "detergent criteria" MBAS (methyl blue active substance) and BIAS (bismuth-active substance), namely that first degradation stage, which is normally shown in detergents by the disappearance of disruptive foam formation.

The waste water supplied to the waste water treatment plant has a certain pollution from organic/chemical matter. The Tab. gives an overview and obligatory approximate figures. The terms TOC (Total Organic Carbon) and DOC (Dissolved Organic Carbon) are observed by name. TOC is a measure of the total contents of organic/chemical compounds in the sediment; but not filtered waste water. DOC on the other hand, is for the contents of purely dissolved organic/chemical compounds (membrane filtrate) (→ Summation parameters).

cumulative parameters		I	II
BOD_5	mg O_2/l	200–400	50– 500
COD	mg O_2/l	300–600	200–2000
TOC	mg C/l	100–200	70– 700
DOC	mg C/l	50–150	50– 500
MBAS	mg MBAS/l	2– 10	2– 20
BIAS	mg BIAS/l	0.2– 3	0.2– 10
OSP	mN/m	38– 50	35– 55

Tab.: Cumulative parameters for the analytical evaluation of effluents and effluent content substances (OSP = surface tension).

The current state-of-the-art increasingly determines the demands put on waste water treatment plants. Particular waste water structures force related problems to be solved, which also require external measures from time to time, besides classical treatment processes. This can and should return to basic product manufacture. A significant objective of future waste water treatment will consist of avoiding and/or substituting retardants of toxic and biodegradation processes. The short-term degradability and the consideration of possible intermediate degradation products should be increasingly considered in the choice of chemicals and

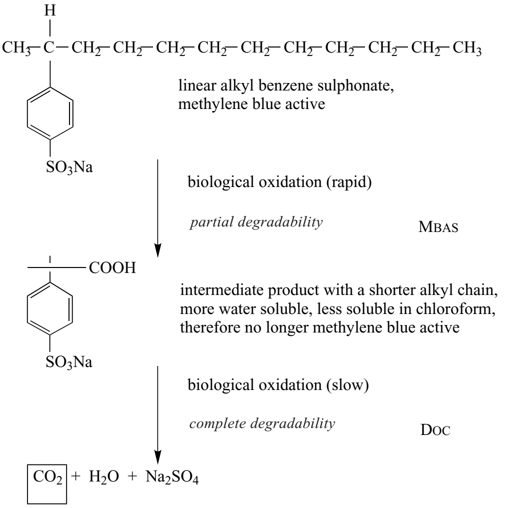

Fig. 1: Diagram of partial and complete degradability.

production processes. Pretreatment measures should be efficiently co-ordinated with waste water treatment plants and should be operated in a co-ordinated way. Total treatment with several treatment stages mounted side by side is state-of-the-art, but results in above average increases in costs. Economically tenable solutions should be sought in combination with textile finishing processes. A large proportion of textile waste water mixed with domestic waste water results in some moves for joint treatment. The biocoenosis operating in an aquatic medium can be adapted to particular waste water structures within certain limits. Extreme values (temperature, pH, etc.) which are too high result in restraints, with losses in performance up to the prevention of the aeration activity.

The essential features of textile waste water compared with domestic waste water are shown in the varied parameters in the following list:

temperature
pH
P and COD load
heavy metal portions
hydraulics
chloride
AOX
dye
surfactants
phosphonates
nutrient ratio
sulphate

While the unbranched alkyl chain is degraded quickly from the chain end by micro-organisms, the aromatic ring reacts in a resistant way. An organic/chemical intermediate product remains in the water despite an “outwardly” good degradation reaction. The MBAS method indicates “complete” degradation, the DOC determination in the same test medium compares with incomplete degradability in reality (Fig. 1). Both cases are quantitatively represented by Fig. 2 (top and bottom curve). The middle curve also indicates the DOC elimination, but with the distinction that activated sludge was used with its known high elimination performance, instead of the very diluted bacterial suspension.

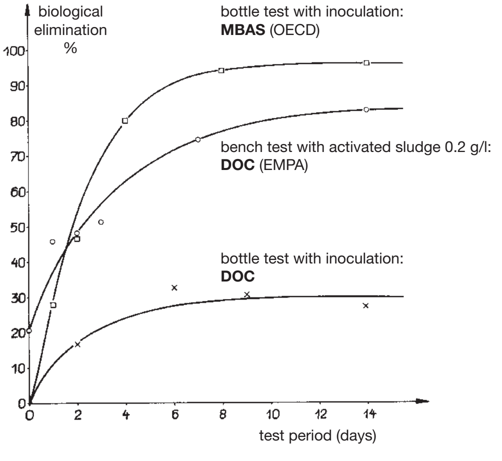

Fig. 2: Biological elimination in accordance with three different test methods.

The choice of the biological test medium, which either, as in the OECD “selection test”, may consist of an inorganic nutrient solution, inoculated against bacteria (bottle test), or activated sludge following the event in the waste water treatment, is unclear. Finally the activated sludge method can be carried out as a flow test or, with similar results, simplified, as a level test (→ Waste water evaluation).

The textile expert, who is responsible for the performance of the operational waste water on the biological waste water treatment plant, will generally fall back on the flow or level test with activated sludge in order to come as close as possible to the ratios in practice (in accordance with Schefer).

Waste water treatment plants are always multi-stage (Fig. 3). The associated waste water treatment process stages in a waste water treatment plant consist of:

a) mechanical operating stage,
b) biological operating stage,
c) chemical operating stage.

Fig. 3: Large-scale waste water treatment plant.

In the interests of an optimised total performance each treatment stage has a special industrial task to perform. Possible waste water treatment process stages should be briefly explained. As a comprehensive examination of all waste water treatment processes would be too costly, the processes, which are most often used, should be examined more closely.

I. Various functions can be led to the surge tank within waste water treatment, which may have a supporting effect on the waste water treatment process and may consequently increase the efficiency of the entire waste water treatment plant. Firstly, the surge tank performs a mixing and buffer function, secondly, a reduction of the contaminant load may already take place in the surge tank. Textile finishing waste water accumulates in varied ways in quantity and concentration conditioned by the production rhythm. At first, concentrated dye liquors accumulate, for example, during the draining off of a dyeing machine; on the other hand, in the following rinsing processes waste water has a decreasing concentration. Moreover this waste water accumulates spasmodically, only on completion of a process. So firstly the function of the surge tank is to absorb the waste water surges and secondly to mix the high and low concentrated waste water, so there is a dual function with regard to quantity and concentration. Such a comparison may be of great importance for an associated biological waste water treatment stage. A constant waste water residence time is guaranteed within this by a constant stable inflow to the biological stage. A contraction of the residence time through a spasmodic, strong hydraulic loading, along with a falling degradation performance in the biological stage, is avoided by connecting a surge tank in series. This also applies with regard to the concentration of the waste water. By comparison, an almost constant supply of nutrients is safeguarded to the biological stage. No shortage and/or excess supply of nutrients occurs due to fluctuations in concentration; this also secures a stable degradation of the waste water materials. The surge tank has a supporting role in the process stability of a biological waste water treatment stage connected in series. There is a definite possibility of the reduction in the contaminant load already in the surge tank. As the most varied chemicals are used in textile finishing, a compensation of chemical reaction properties already takes place in the surge tank, for example, electrolytes neutralize acids, and reducing agents and oxidizing agents are mutually eliminated. If the parameters of temperature and pH are considered in addition and kept in the physiological range, it is possible to settle bacteria in the surge tank. These bacteria can then produce a certain degradation in the contaminant load during the storage of waste water. As most processes in biological waste water treatment run under aerobic conditions (in the presence of oxygen), a sufficient supply of oxygen should be guaranteed in the surge tank.

With heavy bacterial activity, the surge tank should therefore be ventilated, or otherwise a high oxygen depletion causes the occurrence of anaerobic conditions and unpleasant odours. With bacterial activity, activated sludge accumulates due to aggregation of micro-organisms, which should inevitably be removed from the surge tank in order to avoid a complete silting up. An extraction or ploughing device should therefore be included in the design when building such mixed reservoir. The use of a surge tank to reduce contaminants can also be carried out by innoculation with special bacteria for the elimination of certain waste water materials. In addition, the creation of aerobic and anaerobic zones is possible using a selective ventilation of the surge tank (e.g. only the upper part of the tank is ventilated). Besides oxidative, i.e. aerobic degradation processes, the metabolism of such waste water materials, which are degraded via a reductive step (i.e. under anaerobic conditions), is also already facilitated in the surge tank. If the entire waste water flow from a textile finishing is not treated, but only their segregated streams, the mixture drops in the surge tank.

II. In mechanical waste water treatment, the dissolved matter, which can be removed mechanically, should be so removed from the waste water. Firstly, the coarse solids are removed from the running waste water by fixed or movable equipment, such as rakes, screens, gravel filters and similar. Secondly, the difference between the specific weights of the material to be removed and that of the water is used for precipitation and removal via settling and flotation processes. This is the case in sand traps, which are used for the removal of dense mineral material (e.g. sand, stone), in precipitation plants for the removal of floating material (oil, fat, benzine, etc.) and in sedimentation tanks for the removal of suspended sediment. The method of mechanical waste water treatment used depends on the waste water composition and the demands on the complete waste water treatment system.

III. The chemical processes for waste water treatment are essentially understood to mean methods, which are based on chemical or physical/chemical reactions. They are thereby in conflict with, or supplemented by, biological treatment processes, in which the purification effects are, to a large extent, conditioned by bacterial, enzymatically catalysed metabolic reactions. Moreover inorganic matter is only slightly (≈ 5%) eliminated in the biological system, while chemical processes facilitate a removal up into the trace range. Such processes are stable and insensitive to poisons and fluctuations in concentration and quantity as far as the system is concerned. Biological waste water treatment processes have limitations and are therefore sometimes ruled out for the treatment of industrial waste water on the basis of its complex waste composition as well as a high rate of pollution, which is not biologically ascertainable. Great importance will be given to the chemical waste water treatment processes in the future for safeguarding the aquatic part of the ecosystem for the same reason. These processes are often used in conjunction with other waste water treatment processes. In chemical waste water treatment processes, distinctions are made in principal between reactions with and without material conversion.

a) The following basic operations include the undissolved matter:
   - sedimentation,
   - filtration,

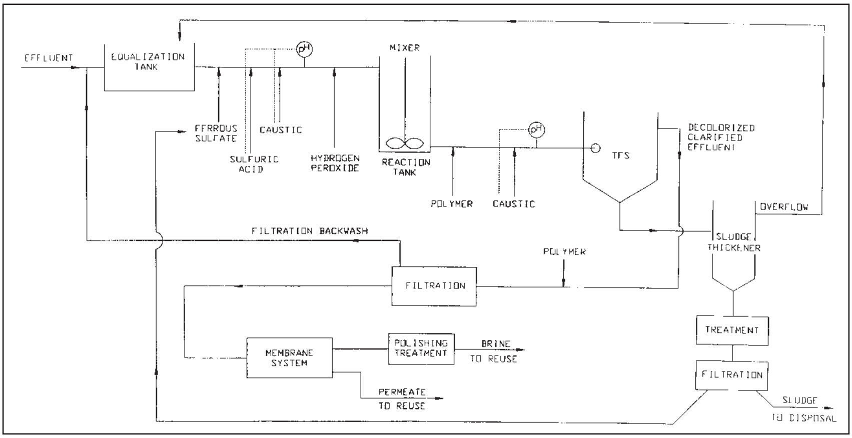

Fig. 4: Textile Dyeing Effluent Reuse-Flow System (Gaston County) (TFS = Tangential Flow Separator).

- flocculation and precipitation,
- adsorption,
- flotation.

b) The following basic operations, which are essentially based on physical/chemical reactions, are used to include the dissolved matter without material conversion:
  - adsorption,
  - extraction,
  - membrane filtration,
  - distillation.

c) Basic operations to include the dissolved matter including chemical reactions with material conversion are:
  - neutralization,
  - precipitation,
  - oxidation,
  - reduction,
  - ion exchange.

Through the specific combination of the above-mentioned basic operations it is possible to construct waste water treatment processes (Fig. 4), which actually make any approach to a problem soluble. The different basic operations are described in the reactions below. The operations with material conversion are described first.

- Neutralization: Acid waste water is adjusted to around the neutral point with basic reaction agents and alkaline waste water, with acids to a given pH range (i.e. in waste water technology between pH 6.5–9). This pH range is required for the introduction into sewerage systems, waste water treatment plants and bodies of water.

  Example: $HCl + NaOH \rightarrow NaCl + H_2O$

- Precipitation: not easily water-soluble material, which is precipitated as sludge and detached. It is produced by chemical conversion during precipitation.

  Example: $Fe_2(SO_4)_3 + 3\ Ca(OH)_2 \rightarrow 2\ Fe(OH)_3 + 3\ CaSO_4$

- Oxidation: certain waste water materials can be removed by chemicals acting as oxidants (chlorine, permanganate, ozone and similar). An example is the reaction of cyanides with chlorine.

$$\begin{aligned} NaCN + HOCl &\rightarrow NaOH + CNCl \\ CNCl + H_2O &\rightarrow HCNO + HCl \\ 2\ HCNO + 3\ Cl_2 + 2\ H_2O &\rightarrow 2\ CO_2 + N_2 + 6\ HCl \\ HCl + NaOH &\rightarrow NaCl + H_2O \end{aligned}$$

- Reduction: the conversion of 6 valency to 3 valency chrome is called an example of reduction, because only in the 3 valency form does chrome form a product insoluble in water.

$$2\ CrO_3 + 3\ SO_2 \rightarrow Cr_2(SO_4)_3$$

  The Cr(III) ion formed from alkaline additions can then be precipitated as a hydroxide.

- Adsorption: these operations with no material conversion, but with phase change cannot be formulated so simply, as they are based on complex thermodynamic or electrochemical processes, whose complete sequence consists of several increments. Essentially concerns adsorption effects and/or diffusion through boundary layers. The adsorption can be represented schematically as follows:

$$[\text{water + contaminants}] + \text{chemicals} \rightarrow \text{water} + [\text{chemicals + contaminants}]$$

  The contaminants do not experience any chemical change; they are merely adsorbed onto the surface due to their charge and the adsorptive force of the chemical. The contaminants may be dissolved or undissolved in water; they may be solid, liquid or gaseous. The adsorbent, e.g. activated carbon, is in solid form and has an extremely large surface area.

- Chemical flocculation and precipitation: a special case of the industrial structuring of adsorption is chemical flocculation and precipitation, whereby the adsorbent is formed from a chemical reaction with material conversion in the water. The reaction occurs in two stages:

1. Formation of the adsorbent:

$$FeCl_3 + 3\ NaOH \rightarrow \underset{\text{adsorbent}}{Fe(OH)_3} + NaCl$$

2. Adsorption process:

$$[\text{water} + \text{dye}] + Fe(OH)_3 \rightarrow \text{water} + [\text{dye} + Fe(OH)_3]$$

The reaction product in this example is an adduct of iron(III) hydroxide flocks and dye.

- Flotation: in chemical flocculation and precipitation the adducts of flocculation agent and contaminant have a larger specific weight than water and are separated by sedimentation. In flotation, the adducts are specifically lighter than water, due to a deposit of micro-fine air bubbles, float and can be removed from the surface.
- Extraction: without altering the chemical composition, the specific material from the aqueous phase changes into a non-aqueous liquid phase, in which it has a greater solvent power.

Other processes: oxidation processes are mentioned as further processes of chemical waste water treatment, which are initiated by chemicals with an oxidizing effect, and/or cannot be regarded as biological oxidation processes. With pressure oxidation and wet combustion the organic waste water materials are oxidized into carbon dioxide and water with atmospheric oxygen, at high temperatures (150–250°C) and pressures between 20–150 bar. By this method “wet” combustion of oxidized substances is achieved. Oxidation using ozone has still not become very widespread in waste water treatment because of the technical complexity and associated costs. It is simply mentioned here, as it is used repeatedly in the textile industry in a process developed by the Scholl Company. The “Scholl process” represents a combined oxidation/flocculation and precipitation process, in which waste water materials are oxidized by air enriched with ozone (in which an extensive decoloration is usually achieved) and are then subject to flocculation and precipitation. Oxidation by chlorine is frequently used in waste water containing cyanide from plating works. Besides the cyanide oxidation, ammonium is also removed. With the aid of oxidation through chlorination, disinfection, destruction of dye and odourous material, decontamination and maintaining waste water freshness are striven for on the other hand. Reduction processes are seldom used in chemical waste water treatment. They are possible if waste water contains easily reducible harmful constituents, as may be the case in waste water from plating works, if it contains a lot of chrome. Chrome reduction is necessary, in which sulphuric acids and their salts such as iron(II) ions, among others, are possible reducing agents.

IV. The biological treatment of waste water is the norm in waste water treatment. The microbial degradation of organic substances, widespread in nature, is used as the basis for the biological and/or biochemical treatment technique. This process of natural self-treatment of surface waters is imitated in biological treatment processes, in which the process is essentially accelerated by increasing the concentration of bacteria, etc. and by oxygen supply in the form of air. The microbial degradation of organic substances is chiefly carried out under aerobic conditions and may thus be regarded as an oxidation, and thereby, elimination of waste water materials via atmospheric oxygen, with the exchange of micro-organisms. Two groups can be distinguished in micro-organisms:

a) primitive forms, the prokaryotes (cells without a nucleus) such as bacteria and blue-green algae;
b) higher developed forms, the eukaryotes (cells with a nucleus) such as fungi, algae and protozoa.

Prokaryotes have the advantage that they are insensitive with regard to external effects such as high temperatures and that they have a conspicuously high rate of growth. Organic waste water materials are partly mineralised into carbon dioxide, water and inorganic salts (chiefly nitrate, sulphate and phosphate) and partly enlisted for the construction of new cell substance and as an energy provider. Adsorption of the organic substance on the cell mass is intrinsic to the actual oxidation process. The oxidation process can be described approximately by the following reaction equation:

$$\begin{aligned}&\text{organic substance} + n\ O_2\\ &\rightarrow CO_2 + H_2O + NH_4^+ (\rightarrow NO^-{}_3) + SO2^{-}_{4}\\ &+ \text{new cell mass} + \text{energy}\end{aligned}$$

The aerobic biodegradation of waste water materials is carried out in two stages. The degradation of carbon compounds is performed first and only in the second stage does the nitrification of nitrogen compounds take place. The metabolism of micro-organisms represents combined degradation (dissimilation) and construction (assimilation) processes. The oxygen consumption of micro-organisms, which directly refers to the physiological recycling of the nutrients introduced to the cell from outside, is described as substrate breathing. If there are not enough organic substances for further cell construction, the bacteria consume their own, likewise organic cell substance on demand of oxygen. The resulting oxygen consumption is described as endogenous breathing. The metabolic processes are branched and multiple combined systems of separate biochemical reactions. The transition of the waste water materials is carried out in many smaller steps, in each of which the surmounting of an energy threshold is required in order to transfer the reacting substance into a reaction-ready state. In addition, enzymes are formed from the micro-organisms for intracellular and extracellular reactions, which catalyse the processes. This enzyme-catalysed reaction can be described as follows: Organic substances contained in the waste water enter into a complex with the enzyme, whereby it is transferred into a reaction-ready state. This facilitates the decomposition of the substrate. The enzyme is not consumed as a typical catalyst in the reaction. Favourable living conditions exist for micro-organisms if the necessary nutritional salts (nitrogen and phosphorous) are present. If they are missing, as is frequent in industrial waste water, they must be compensated for. There should be a minimum ratio

BOD : N : P = 100 : 5 : 1 in waste water
BOD : N : P = 90 : 5 : 1 in sludge.

The demand for trace elements is so small that it can usually be covered by the waste water itself. Moreover the biological waste water treatment is tied to a particular BOD_5 : COD ratio. The following should apply:

for domestic waste water ≈ 0.5
for commercial waste water < 0.5

Small values of this ratio indicate that organic matter is contained in the waste water, which is accessible for the micro-organisms only with difficulty or not at all. The number of chemical compounds which can be converted by micro-organisms is large, provided that the natural bases of life remain. The following are prerequisites:

a) sufficient quantity of oxygen;
b) sufficient quantity of food;
c) favourable living conditions, for example, moisture, settlement areas, as well as temperature and pH in the physiological range (pH ≈ 5–9);
d) no bacterial poisons.

It is noted for d) that adaption phenomena in bacteria, even in extreme waste water compositions, can result in adequate treatment performance. For example, cyanide in a concentration of 1 mg/l normally has a highly toxic effect; biological plants with adapted micro-organisms can, however, definitely tolerate cyanide in a concentration of 50 mg/l.

Anaerobic bacterial work, i.e. work without access to air, is applied in waste water treatment only in special cases, e.g. in denitrification. The anaerobic conversion of organic waste water materials has great status in the decoloration of waste water because most dyes used in textile finishing can be classified as persistent under the conditions of aerobic biological treatment. The breaking and thereby decolorizing of most dyes is carried out via a reductive step, in which the chromophore group is split. The degradation products resulting from this step can therefore be extensively oxidatively degraded in the subsequent reactions. The decolorizing performance of aerobic biological processes can therefore be seen primarily in the adsorption of dye molecules on the biomass. The actual process of decolorizing is carried out in later sludge decaying, which takes place under anaerobic conditions. The technology of biological waste water treatment processes has meanwhile achieved a high level. These processes are chiefly used in the treatment of municipal waste water, however endeavours are made to use biological processes exclusively for the treatment of industrial waste water. Two possibilities essentially exist for biological treatment:

1. Natural processes, which are generally based on agricultural waste water exploitation and use of waste water ponds.
2. Technical processes such as activated sludge biologies or, more correctly, activation processes and carrier-fixed biologies.

The biological treatment is carried out with “activated sludge” in waste water activation plants. The activated sludge mainly consists of flock-forming micro-organisms, which are concentrated in an enormous number in a small space. Their surface area is 2000–10 000 m^2/m^3 ventilation space. Artificial ventilation ensures that the bacteria have adequate oxygen at their disposal and the flocks are kept in balance. The bacteria would die if the sludge was deposited on the floor of the basin. An oxygen content of 2–3 mg O_2/l is regarded as optimum. The biological treatment of waste water is carried out in two stages. To obtain energy a part of the organic contaminants is oxidized first and new cell matter is formed at the same time. In a second phase the bacteria are gathered together into easily settleable flocks. The flakes of the activated sludge consist of a slimy element, in which bacteria and protozoa live. Carbon, nitrogen and phosphorous are built in approximately in the ratio 5 : 1 : 0.5. The oxygen demand of an activation plant follows the BOD_5 degradation and the ventilated quantity of sludge. If there is so much air that the degradation ability of the activated sludge can be fully developed, the oxygen consumption is dependent on the sludge pollution. Sludge pollution is understood to mean the quantitative ratio of contaminants in the waste water to the bacteria in the activated sludge. With lower sludge pollution endogenous breathing predominates; with higher sludge pollution the substrate breathing prevails so that so much new cell matter is produced that a part of it has to be removed from the system as superfluous sludge. The reproduction of the bacteria can be accelerated by an oversupply of food, but the bacteria would not withstand the reproduction of the food supply, and a partial treatment of the waste water would be the result. Activation plants normally consist of preliminary sedimentation tanks, ventilation or sludge activation tanks and a secondary settling tank.

Preliminary sedimentation tanks are usually settleable basins, in which the solid contaminants are settled in a one to two-hour period. In the subsequent sludge activation tank the water is mixed by air with the activated flocks or the “activated sludge”, which is pumped back as return sludge to a secondary settling tank. The dwell time is approximately 8 hours in this stage. In the secondary settling tank, the sludge added to the waste water is precipitated again by settling, removed and either drawn off as surplus sludge or re-used as return sludge. Despite intensive construction of mechanical/biological waste water treatment plants, the pollution of rivers and lakes with various contaminants is still increasing. Plant nutrients such as phosphorous and nitrogen, non-easily degradable organic matter, suspended matter, toxic substances amongst other water-harming substances can often only be reduced effectively with more extensive treatment stages. The increasing water pollution from already treated waste water reveals three areas:

a) Eutrophication of the body of water: eutrophication phenomena can only be avoided and/or kept under control by reducing the supply of nutrients. For waste water treatment this means the targeted elimination of algae nutrients, phosphorous and nitrogen.
b) Oxygen economy of the body of water: the oxygen-feeding load of already mechanically/biologically treated waste water can chiefly be put down to suspended matter in the waste water treatment plant run. The oxygen economy of bodies of water can be clearly eased by extensive retention of residual suspensions. Such material can be included via the BOD_5.
c) Accumulation of refractory organic substances: refractory organic substances are not accessible to any biological processes. Biological processes do not alter their concentration in the body of water so that there is a continuous accumulation. Refractory matter can be summarily included via the chemical oxygen demand (COD) and the carbon content (TOC).

Water H_2O. Molecular weight 18. Clear, colourless, odourless, tasteless, chemically neutral (pH 7); freezing point 0°C, boiling point 100°C (both at 1 bar pressure). Greatest density of 1 at + 4°C. Density above and below this temperature is lower (e.g. ice = 0.9168). Liquid/solid transition means volume increase by $^1/_{11}$ in closed vessels (tubes, containers, and fissures in buildings), therefore pressure effect (burst pipe) from freezing. The viscosity at 0°C is approx. 8 times greater than at 100°C. Mean specific heat between 0°C and 100°C = 1 (temperature increase of 1°C = 4.1868 joules), from ice at 0°C = 2.093 joules, from water vapour at 100°C (and constant pressure) = 1.934 Joules. Heat of fusion and/or solidification at 0°C for 1 kg (ice-water or vice versa) = 334.944 joules. Heat of vaporisation per kg (water at 100°C, steam at 100°C) = 22 483.1 joules. Steam pressure (equilibrium pressure of water/water vapour) at 100°C = 1 bar (saturated steam), greatly increasing with increasing temperature. Steam with higher (than normal) pressure is supersaturated, with lower pressure, unsaturated. The electric dipole character of the water molecule (→ Dipoles) is technically important; it partly decays (dissociates) into its electrically charged molecular constituents (ions) and is (theoretically): $H_2O \rightarrow H^+ + OH^-$ (but practically: $2\ H_2O \rightarrow H_3O^+ + OH^-$) because the unstable hydrogen ions are combined with a neutral water molecule in the formation of H_3O ions. The molecules of water exist in the main as multimolecules $(H_2O)_n$ stored together (cluster, → Iceberg structure of water).

Water absorption of porous substrates A typical curve for the weight increase of a macroporous film through water deposits is shown in Fig. 1. Such a functional correlation can be described by the following equation:

$$c_t = c_\infty \cdot \left(1 - e^{(-k_a \cdot t)}\right)$$

whereby the weight at any moment is described by c_t and the weight after the time $t \rightarrow \infty$ by c_∞. The speed constant of water absorption is k_a. The dimension c_∞ corresponds to the max. water absorption of the macroporous film. The following expression is obtained by converting the equation:

$$-\ln\left(1 - \frac{c_t}{c_\infty}\right) = k_a \cdot t$$

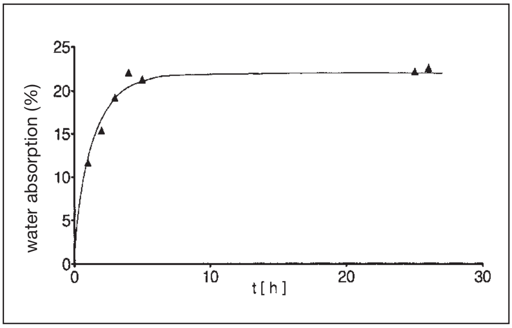

Fig. 1: Water absorption of a polyurethane film (PU 555), out of which starch (1%) was released, as a function of time (according to Schollmeyer).

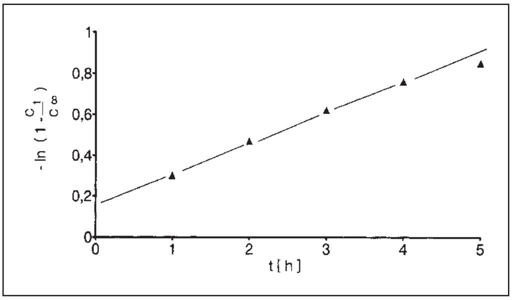

Fig. 2: Application of $-\ln(1-c_t/c_\infty)$ against time t to determine the speed constant k_a of the water absorption of a polyurethane film (PU 555), out of which starch (1%) was released, as a function of time (according to Schollmeyer).

A straight line, whose gradient is k_a, is obtained by applying $-\ln(1-c_t/c_\infty)$ compared with the time t. In Fig. 2, the experimental data shown in Fig. 1 is applied in accordance with the equation.

Independent of the size of the pores, which is determined by the molecular size of the various substrates dissolved out, it is observed that the speed of water absorption is smaller with increasing substrate concentration in the film (in accordance with Schollmeyer).

Water and oil repellents Finishing agent for →: Waterproofing; Oil-repellent and/or → Soil-resistant finishing.

Water as finishing medium Water is one of the essential production resources in textile finishing. This is already apparent in the descriptions used for one task or another:

- material to do work as steam,
- coolant for the dissipation of the heat of condensation of steam or for temperature control of machines,
- heat carrier in liquid or gaseous form for energy control and for heating in the industrial sector,
- reaction medium and solvent in liquid form.

In addition, it is used for treatment activities, in the sanitation area as washing and drinking water and as water for fire extinguishers. The properties of water in the form of liquid and vapour as well as the properties of water as regards pressure and temperature should be observed to safeguard a faultless plant operation. The variation of state occurring in the course of a finishing process, the change in the aggregate state during steaming and condensing, the interactions with the design materials as well as the contact with the fabric during open circulation thereby play a special role. Appropriate demands for the quality of the water used and the steam produced are necessary in the operational practice in view of the operating parameters, the design layout of the plant and the use of materials. The expenditure required for processing as well as the limited quantities available, demand an economical use of water, which can above all be achieved by extensive circulation control.

A considerable portion of the relatively low known reserves of freshwater is used industrially in modern social systems (Fig. 1). While the large part of the coolant quantities required for energy generation, up to the higher temperatures, hardly pollute the environment, other industrial waters are more or less mixed with materials, which must be removed before the water is put back into natural circulation.

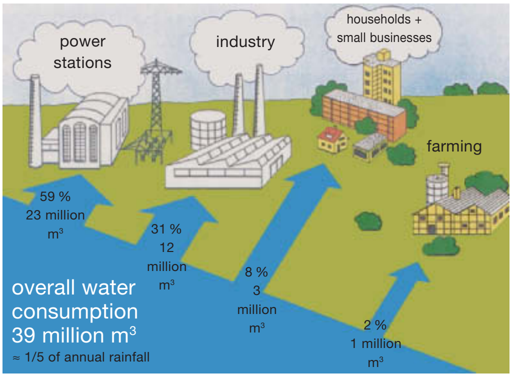

Fig. 1: Water demand in the former West Germany (1989) (according to Röhm).

There is practically no known industrial process, which is not dependent directly or indirectly on water. Besides the costs of obtaining water, the question is therefore also put for each industrial operation in accordance with the costs for → Waste water treatment, as leakage of untreated waste water must be ruled out. Many industrial operations therefore make a special effort to control the water in circulation. But this circulation control, on the other hand, again has the disadvantage that the residual quantities of waste water are thereby extremely highly polluted and the treatment processes necessary are especially complex and expensive. Endeavours are therefore made to start waste water treatment at the root cause, in industry (Fig. 2). The mixing of different types of sewage from different industrial undertakings immensely aggravates the waste water treatment. Waste water treatment is therefore chiefly carried out as follows:

1. Pretreatment at the cause, i.e. separation of undissolved, suspended solid matter of inorganic or organic type.
2. Chemical/physical treatment for the separation of dissolved inorganic or emulsified organic materials.
3. Treatment of dissolved organic contaminants using aerobic and anaerobic biological processes.

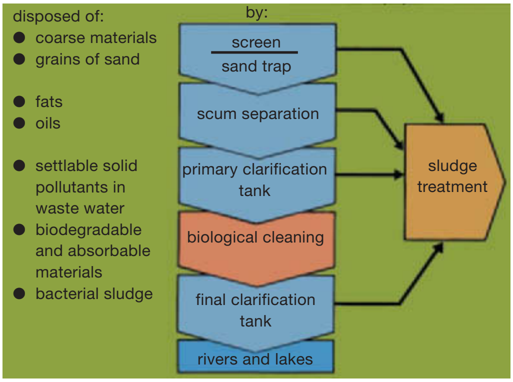

Fig. 2: The technique of waste water treatment (according to Röhm).

4. In future, public waste water treatment plants will be retrofitted by a so-called third stage (N elimination).

Viewed thermodynamically, water has a certain heat content per mole (enthalpy H). The change in heat energy as a result of a chemical reaction of the water can be expressed as the difference between the heat content of the reaction educts and the heat content of the reaction products.

$$H_2O\ (g) \xrightarrow{1000\ K} H_2\ (g) + {}^1/_2\ O_2\ (g)$$

$$\Delta \bar{H}_{reaction} = (\bar{H}_{H_2O\ (g)}) - (\bar{H}_{H_2\ (g)} + {}^1/_2\ \bar{H}_{O_2\ (g)})$$

$$\Delta \bar{H} = 272\ \text{kJ/mole water vapour}$$

The representation of heat transfer in reactions by ΔH is described as catalytic combustion, which is positive for endothermic (heat absorbing) reactions and negative for exothermic (heat producing) reactions. The signs of the heat transfer are altered by reversing the reaction direction:

$$H_2\ (g) + {}^1/_2\ O_2\ (g) \xrightarrow{1000\ K} H_2O\ (g)$$

$$\Delta \bar{H} = -272\ \text{kJ/mole}$$

Whether a reaction is endothermic or exothermic depends on several factors. Sodium chloride is dissolved in water endothermically, caustic soda liquor exothermically, however. On the one hand energy will be expended in this dissolving process in order to separate the ions oppositely charged in the crystal from each other (lattice energy, ΔH_{git}). Energy is released however if the ions separated from each other are taken up around polar water molecules (Fig. 3) (hydration energy, ΔH_{hyd}). The molar solution heats are not sufficient to account for the relative solubilities of different compounds in water; endothermic solution processes would be impossible if the heat transfer was the sole driving force for the reactions. Just as each chemical reaction is linked to an enthalpy change ΔH, an entropy change ΔS also occurs with it. The entropy change can be simply established for some processes: If water evaporates at constant pressure, the heat, which is supplied to the system in order to achieve this conversion, corresponds to the heat of vaporization ΔH_d. As this process runs endothermically, ΔH_d is positive. The change in entropy for this process can be described by the relation

$$\frac{\Delta H_d}{T} = \Delta S$$

ΔS is positive in this process, as the probability of a highly random gas phase is greater than the probability of the more strongly ordered liquid phase. As the temperature is directly linked with the molecular weights, the entropy change ΔS in the system with the same enthalpy change ΔH, should be larger, the lower the temperature at which the heat effect occurs. The entropy S of a system is larger, the higher its temperature. At low temperatures the disorder of the systems is small and a phase transition such as evaporation causes a large entropy change. At high temperatures the systems, however, have such a great disorder due to the thermal movement of the molecules that a phase transition means a much lower change in the disorder or entropy.

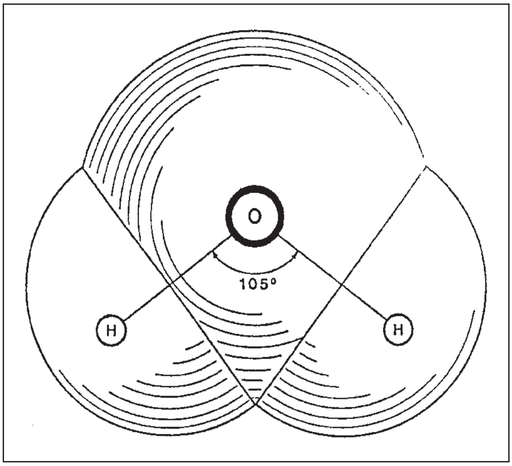

Fig. 3: Water molecules possess a dipole due to their angled arrangement.

Gas molecules move more quickly and have more energy (and enthalpy) than molecules in a liquid. The same heat energy is released if water vapour condenses:

$$H_2O(g) \rightarrow H_2O(l) \qquad (\Delta H = -42\ \text{kJ/mole})$$

The formation of H bridges in water is considered as a predominantly co-operative phenomenon, which is why in most cases, if an H bridge develops, others are immediately formed due to resonance effects and vice versa. If an H bridge breaks in the cluster, it decays immediately. The life of the cluster is very short, 10^{-10} to 10^{-11} s. The image (Fig. 4) of a high frequency, structural flicker (flickering clusters) is consequently produced.

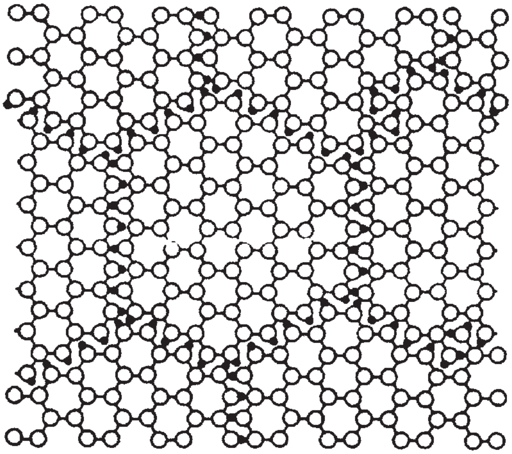

Fig. 4: Cluster structure of water in liquid form at 0ºC.

Tab.: Number of water molecules of average cluster size in H_2O (very idealized).

T [°C]	cluster size
0	700
100	50
200	10
240	8
310	4
370	1–2

An idealised structural image of the water, which probably corresponds well to reality, is shown in Fig. 4. The oxygen atoms are represented by open circles, the bridge-combined protons by lines and the free, unbonded protons by filled circles. Assuming that the free OH groups are located on the surfaces of the cluster, the temperature dependency of the cluster size was estimated (see Tab.). Formation and decay of hydrogen bridges in the water represent an equilibrium reaction. The position of the association equilibrium is described by the change in the free enthalpy ΔG_{ass}. Signs and sizes of ΔG_{ass} are essential for the value of the association constant K_{ass} and decide whether the association equilibrium is on the part of the association (negative ΔG_{ass}, $K_{ass} > 1$) or the monomers (positive ΔG_{ass}, $K_{ass} < 1$). In most hydrogen bridge equilibria K_{ass} is < 100, but possibly even smaller than 1, so that ΔG_{ass} adopts small negative or positive values. When the temperature is increased, the association constant K_{ass} decreases in accordance with the principle of Le Chatelier, as a consequence of the increasing kinetic energy of the molecules, which results in the gradual break up of the association. For an isothermal process the size ΔG_{ass} is combined with the association enthalpy ΔH_{ass} and the entropy change ΔS_{ass} by the thermodynamic basic logic function:

$$\Delta G_{ass} = \Delta H_{ass} - T\Delta S_{ass}$$

H bridge formation is an exothermal reaction, i.e. ΔH_{ass} is always negative. The position of the association equilibrium is however not only determined by the H bridge enthalpy, but also by the association entropy. The equilibrium is on the part of the associates (negative ΔG_{ass}) if $T\Delta S_{ass}$ is < ΔH_{ass}. As the atomic state of the system increases in the formation of H bridge complexes, ΔS_{ass} assumes negative values in accordance with the second law of thermodynamics. While the energy content of the water shows the actual states of the particles for individual temperatures and explains the macroscopic type of state, the representation in the p/T graph (also referred to as phase, state or vapour pressure graph) facilitates ease of measurement of accessible state variables, pressure and temperature. The lines of the graph (Fig. 5) indicate the conditions under which two phases are in equilibrium next to each other at any one time. The following appear as characteristic:

- triple point, for which all three aggregate states are next to each other at the same time; the values are p = $0.61 \cdot 10^{-3}$ MPa and = 0.01°C

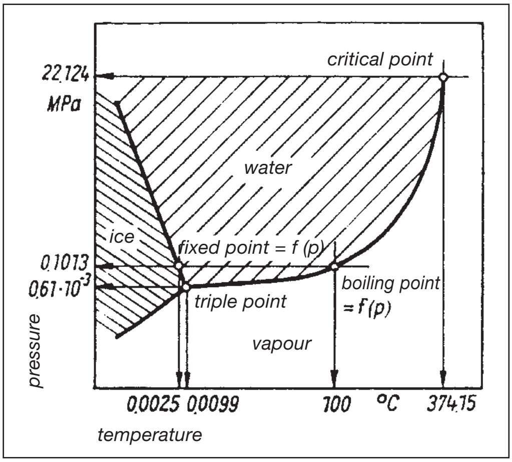

Fig. 5: p/T diagram of water.

- critical point, whereby a (gas) phase still exists above the accompanying critical temperature (ϑ = 374.15°C) independent of pressure. The critical pressure is p = 22.124 MPa.

Phase transitions are always equilibrium processes. Heats of vaporization, heats of fusion and heats of sublimation (ΔH_d, ΔH_{sch} and ΔH_{sub}) always have positive values. Condensation and solidification occur if heat is extracted from the output phase. Melting, vapour pressure and sublimation occur if heat is supplied to the output phase. Because water stores a high amount of energy with vapour pressure, water vapour is a common energy carrier; the molar heat of vaporization ΔH_d is 40 700 J/mole. The statement of ΔH_d = 40 700 J/mole refers to the evaporation process of one mole of H_2O (l):

$$H_2O\ (l) \rightleftharpoons H_2O\ (g)$$

A quantity of heat ΔH = –40 700 J is released again during the condensation of a mole of H_2O (g).

$$H_2O\ (g) \rightleftharpoons H_2O\ (l)$$

Analogous to the definition of the heat content, each material has a certain entropy S and the change in entropy of a reaction is equal to the entropy of the products minus the entropy of the reaction partner. For example, the molar change in standard entropy for the dissociation of water vapour is given by the following relation:

$$H_2O\ (g) \xrightarrow[1.013\ \text{bar}]{25\ ^\circ C} H_2\ (g) + {}^1/_2\ O_2\ (g)$$

$$\Delta \overline{S}^\circ = (\overline{S}^\circ_{H_2\,(g)} + {}^1/_2\,\overline{S}^\circ_{O_2\,(g)} - \overline{S}^\circ_{H_2O\,(g)})$$

Absolute order will rule at the absolute zero point (0 K) in an imagined ideal crystal, and the entropy of such a system is equal to zero. Processes, which comprise an increase in the entropy (ΔS > 0), are favoured or are more probable than processes, in which the entropy decreases (ΔS < 0). The entropy will increase in the following reaction:

$$H_2O\ (g) \rightleftharpoons H_2\ (g) + {}^1/_2\ O_2\ (g)$$

ΔS > 0, as more product molecules of the reaction partners are available in this process.

The efforts to achieve a max. heat emission and the efforts to attain a max. increase in entropy are both driving forces in the chemical reaction, also in the cycle of phase transitions in the water (Fig. 6). A combination of change in enthalpy and change in entropy must determine the course of the phase transition in the water (Fig. 7), which can be used for the prediction of the position of the equilibrium of a chemical system: the change in the so-called free enthalpy or even Gibb's free energy.

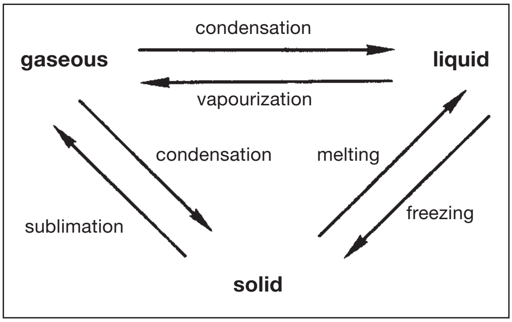

Fig. 6: The cycle of the phase transitions.

$$\Delta G = \Delta H - T\Delta S$$

At constant temperature the change in free energy ΔG is equal to the change in enthalpy minus the change in entropy, multiplied by the absolute temperature TΔS. It can be understood that a reaction is spontaneous when the free energy decreases altogether, whereby it plays an independent role with enthalpy and entropy at any one time. Spontaneity is only achieved by the interaction of H and S. Ice has an entropy of 41 J/K/mole, liquid water of 63 J/K/mole and water vapour of 188 J/K/mole. The energy is consumed in the transition from liquid to gaseous water (ΔH > 0). This endothermic process is nevertheless carried out voluntarily at temperatures above 100°C. The increase in entropy clearly outweighs the loss in enthalpy. With increasing temperature (in K) the importance of the difference in entropy is growing. Both laws of thermodynamics concerning enthalpy and entropy were summarised by Clausius around 1865 as follows: "The energy in the world (cosmos) is constant; the entropy in the world strives (in the long term) for a maximum".

The solubility of a substance in water depends on the change in the free enthalpy of the system, which is connected with the solution process. Polar substances are either constructed from ions or have a polarised electron pair bonding. If the solution of a sodium chloride crystal in water is considered as an example: the water dipoles are taken up with their charge centres by the crystal surface by oppositely charged ions. The ions are hereby released from the grid lattice. The dielectric constant of the water is approx. 80, i.e., the Coulomb attraction force in water is still only $^1/_{80}$ of the Coulomb force in the ionic crystal. The water molecules enclose

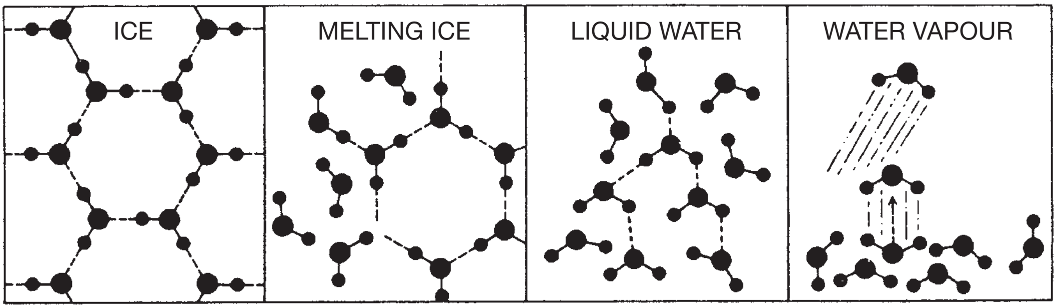

Fig. 7: The disorder increases from ice to liquid water to water vapour: more water vapour bridge-type bonds are dissolved and water molecules start moving past each other freely.

the released ions (hydrate envelope, general solute case): the ion is hydrated (general: solvated). The process is connected with a change in energy. In the case of water, it is called hydration energy and/or enthalpy and general solvation energy and/or enthalpy (sometimes also hydration and solvation enthalpy). It corresponds to ΔH in Gibb's equation. The solvation enthalpy depends on the charge concentration of the ions, i.e., it is directly proportional to the ionic charge and inversely proportional to the ionic radius. It decreases with growing radius for equally highly charged ions. Small, highly charged cations and anions are therefore strongly solvated, e.g.

$Na^+ \rightarrow [Na(H_2O)_6]^+$
$\Delta H = -418.6$ kJ/mole; radius 97 pm
$Al^{3+} \rightarrow [Al(H_2O)_6]^{3+}$
$\Delta H = -4605.4$ kJ/mole; radius 51 pm

Ions are always surrounded by a hydrate envelope in water (aquo complexes). The solvation enthalpy is dependent on the polarity of the solvent and it is inversely proportional to the temperature.

Only a part of the water, which is found in solid polymers, corresponds to liquid water. Thermoanalytical methods, nuclear magnetic resonance and other processes all show that water, which is found in polymers, essentially forms three states, namely so-called non-solidifying, bonded, but solidifying and finally free water. The water molecule layers, which are found on internal or external surfaces of polymers, are no longer entirely free, but "linked" via hydrogen bridges and polar forces of the polymer. For this reason this water can partly no longer enter the ice-like, "frozen" state when cooled below 0°C. A series of investigations has revealed that the mobility of chemical compounds is severely slowed down in this bonded water.

In Fig. 8 the state of the water in polyacrylonitrile fibres was determined calorimetrically (DSC method). The curves described with f_{wf}, f_{wb} and f_{wi} represent the proportions of the three types of water in polymers mentioned above. The results on the vertical broken lines of both graphs are important for the water content under dyeing conditions. It is thus recognised that only approx. 60–66% of the water is released onto both fibres. Only in this proportion is diffusion carried out by dye molecules and ions just as quickly as in aqueous free solution. For this reason, the results of the diffu-

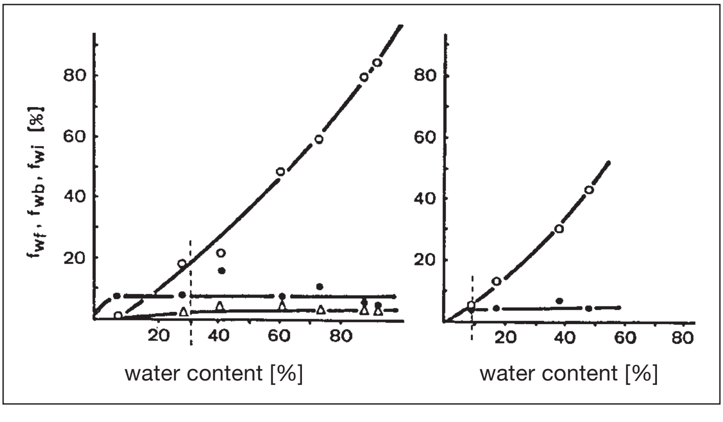

Fig. 8: Proportions of free (O), bonded (·) and "intermediate" (Δ) water in polyacrylonitrile fibres (a) = Dunova; b) Dralon X-100, Bayer) (according to Zollinger).

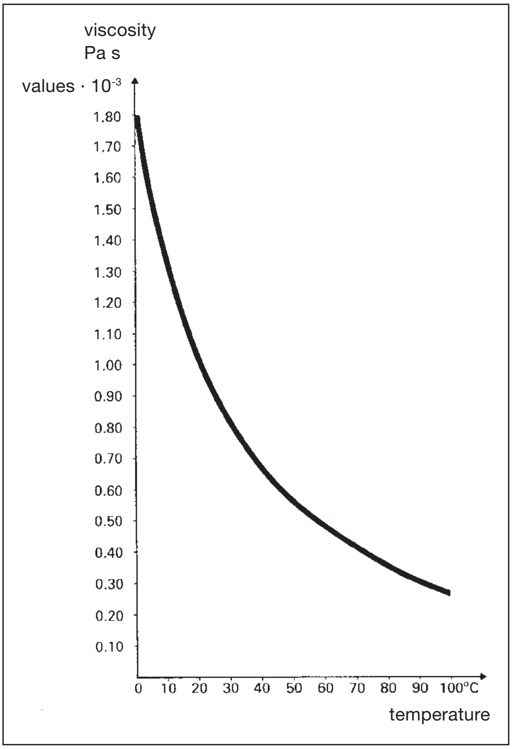

Fig. 9: The effect of temperature on the viscosity of water.

sion of dyes by cellulose membranes also result in calculated diffusion coefficients, which are still somewhat smaller than the diffusion coefficients of these dyes in free water: Cellulose membranes also contain bonded and not solidifying water on the pore walls, in which the diffusion of dye molecules is certainly much slower than in free water (according to Zollinger).

Surface tension and viscosity (Fig. 9) of water decrease with increasing temperature, whereby material to be washed is better moistened and passed through. High operating temperature is given as a reason for this. This also applies to water extraction required by fabrics on the padder. With pure H_2O as the so-called potential electrolyte no ions exist in the solid state. They are firstly formed in the liquid, but also in the gaseous state in interaction with other molecules. This is called a self-dissociation. The following separate steps, which in reality run simultaneously and overlap, are given formally as shown in Figs. 10 + 11.

Ionic formation:

$$H_2O \rightleftharpoons H^{\oplus} + OH^{\ominus}$$

The resulting H^+ corresponds to an atomic nucleus (proton) and is not constant in the presence of other H_2O particles. It consequently forms hydronium ions

$$H^{\oplus} + H_2O \rightleftharpoons H_3O^{\oplus}$$

The H atoms arranged symmetrically around the O atom enable (with other H_2O molecules) the complexes $H_5O_2^+$ and $H_9O_4^+$ to form: the latter is especially stable and further hydrated (Fig. 10).

Very pure water conducts electric current one bil-

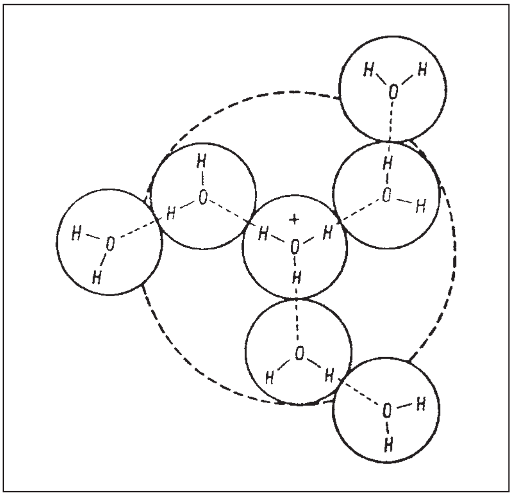

Fig. 10: Hydration of the proton in aqueous solution.

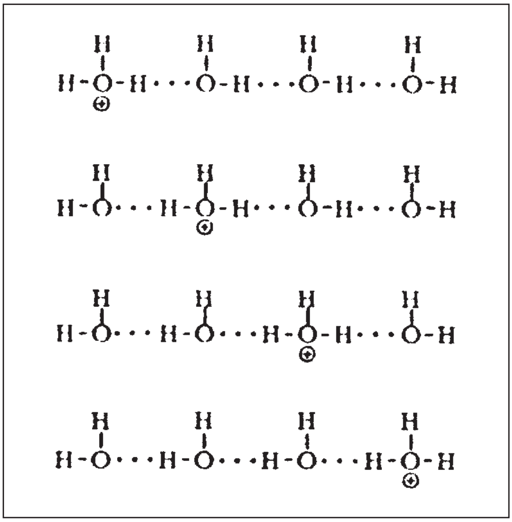

Fig. 11: Migration of a positive charge via hydrogen bonds.

lion times less than strong electrolytes. If its conductivity is measured and correspondingly analysed, it is revealed that approximately every hundred millionth molecule is split into ions. As the concentration of unsplit water molecules is constant due to this very low dissociation, the law of mass action demands that the product of the concentrations of cations and anions is a constant. This is 10^{-14} at room temperature and in water, where both concentrations are equal to each other; the concentration of hydrogen ions is the square root of this, that is 10^{-7} mole/l, a ten millionth of a gram of ions in 1000 g of water. Decimal powers are not readily written out in full, but high-ranking number, i.e. the number of zeros is sufficient. This number is 7 in pure water. Water has a pH of 7. The more acidic an acid solution is, the smaller this number is; it is 0 in normal hydrochloric acid (1 mole/l).

It is found that the ion mobility is much greater than would be expected on the basis of molecular size in the H^+ ion (and/or H_3O^+ ion) and in the OH^- ion. It is therefore assumed that in these cases the ion itself does not migrate at all, but that only the positive and/or negative charge is further transported via hydrogen bridges on the way (Fig. 11).

Water balance Represents the water balance of a finishing business in the most graphic way possible. Besides integrated water support from wells or outfall channels, water from the public supply system may be used. 100% of this fresh water goes (see Fig.)

– for fixed objects,

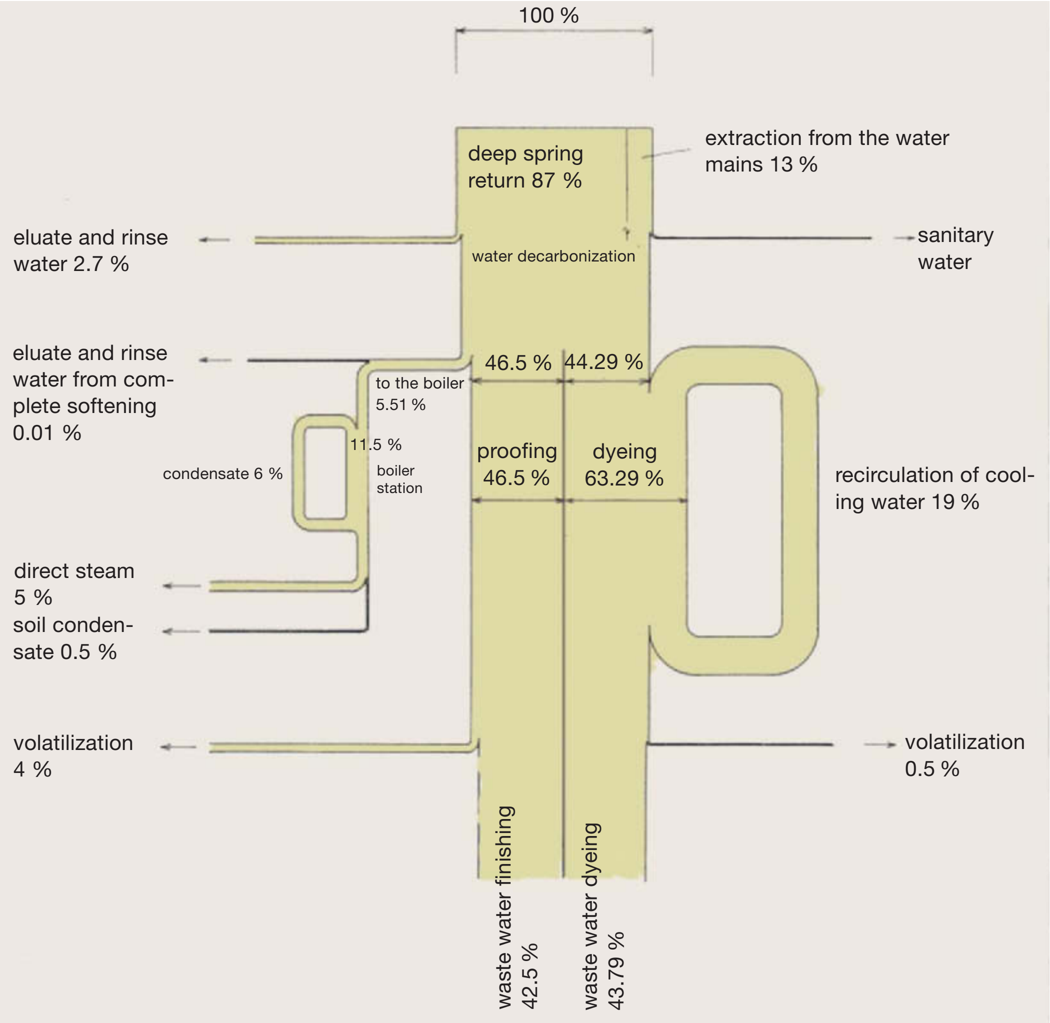

Fig.: Water balance.

- to the boiler house and thus as steam into circulation with return as condensate,
- as evaporation,
- into wet finishing,
- into the dyehouse and printing,
- as cooling water in respective circulation systems,
- as waste water.

Waterborne bacteria →: Iron bacteria; Nitrobacteria.

Water calender → Water mangle.

Water clarification →: Waste water treatment; Waste water treatment plants.

Water consumption averages in textile processing Reduction of the (considerable) water consumption, especially in the cotton sector, but also in wool, is at the forefront of the short liquor technique. The detail of obligatory water demand parameters for the different finishing steps becomes difficult because they are dependent on the technique selected, the age of the mechanical equipment and on the operating staff. A specific water consumption of 120 l/kg of fabric on average was given in the water/waste water survey of 1988. The minimum and maximum values were 18 and/or 375 l/kg of fabric. Waste water quantities are given for different process stages and substrates in the Tab.

It would be wrong to prescribe an estimated reduction of the water consumption, as a reduction of the liquor-to-goods-ratio is not always possible especially for rinsing and soaping depending on article and plant, without having to accept a reduction in quality.

1. piece-dyed woolen fabrics		
pretreating/dyeing/softening		100 – 250
2. piece-dyed cotton fabrics		
desizing/scouring/bleaching		30 – 120
dyeing/softening		50 – 120
	total	80 – 240
3. piece-dyed cotton knit fabric		
pretreating/dyeing		70 – 180
4. printed cotton fabric		65 – 280
5. manufacture of a blanket from flock dyed polyacrylonitrile		
dyeing/softening		30 – 80
washing		10 – 70
	total	40 – 150
6. fabrics and stitch-bonded fabrics made of cotton, viscose fibres and blends thereof with synthetic fibres		
singeing		0.5 – 1
washing		3 – 7
desizing		4 – 8
mercerizing		6 – 12
alkaline treatment		5 – 8
continuous bleaching		3 – 15
continuous dyeing		1 – 25
discontinuous dyeing		55 – 90
printing		3 – 16
aftertreating printed goods		12 – 50
finishing		1
7. carded yarn woollen fabrics and blended with man-made fabrics		
– overcoating		
dyeing incl. washing		172 – 212
– suit and costume fabrics		
continuous washing		5 – 20
dyeing incl. washing		65 – 120
8. worsted yarn fabrics		
– suit, costume fabric and dress fabric 55 polyester/45 wool		
washing		9 – 14
dyeing		75 – 95
finishing		1

These examples produce a standard value of 100 l water/kg of fabric.

Tab.: Values (l of water/kg of fabrics) for optimized water consumption in textile finishing.

Water crimp → Crimp, types of.

Water decarbonization Removal of temporary hardness (→ Water hardness salts) using appropriate → Water softening process, e.g. so-called lime decarbonization via precipitation process or so-called hydrogen decarbonization with ion exchangers, which contain carboxyl groups and work accordording to the principle of desalination. Also as more economical pre-softening, to which a neutral exchanger is connected in series for total softening. Achieved by alkaline decomposition using saturated lime water or milk of lime. Decarbonization plant operates in accordance with the principle (see Fig.): a) process water supply into open reservoir and ventilation/oxidation ; b) sampling of ventilated water; c) filtration via gravel filter; d) treatment in the rapid reactor; e) renewed filtration in further gravel filter.

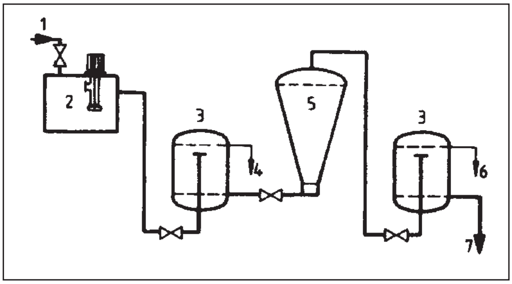

Fig.: Modified water decarbonization unit for yarn dyeing. 1 = water supply; 2 = ventilation/oxidation (FeMn); 3 = gravel filter; 4 = sludge (FeMn); 5 = rapid reactor; 6 = carbonated sludge; 7 = treated process water.

Water degasification Release of dissolved gases: air, oxygen, carbonic acid, etc.

I. Mechanical: watering, vacuum.

II. Thermal (especially for atmospheric oxygen): heating above 100°C (high pressure enclosed vessels or low pressure at 40–60°C). Residual oxygen content approx. 0.5 mg/l, practically no free carbonic acid.

Water demanganizing Manganese content rarely exceeds 1–2 mg/l, but often becomes unpleasantly noticeable in quantities of 0.1 mg/l in mains water. Manganese makes dark brown stains, which are difficult to remove.

I. Iron-contaminated water should have the iron removed and, if necessary, be deoxidised before the demanganizing. In water with a lot of organic matter demanganizing is only possible using aluminium sulphate precipitation.

II. Special manganese filter: with preprepared (potassium permanganate) filter sand or special filters (manganese ore) and/or base exchange filters (manganese permutit, filter regeneration using potassium permanganate). Principle: oxidation of the bivalent to the polyvalent form via oxygen dissipating manganese dioxide hydrate (precipitated on sand layer) and filtering of the insoluble hydroxide.

III. Biological: (carbonic acid up to 30 mg/l harmless). Vertical double gravel filter with iron and manganese retaining algae, water flow under pressure, great activity. Principle: adsorptive deposit and/or bonding of the manganese salts.

Water deoxidation Removal of carbonic acid from water using different processes depending on water hardness, carbonic acid content, iron quantity.

I. Mechanical: a) for hard to medium-hard water (6–8°d): ventilation; b) for hard water with little carbonic acid: trickling flow; c) for hard and soft water with high carbonic acid content: spraying, ventilation, vacuum degassing.

II. Chemical: a) marble filter process for water with degree of hardness below 6°d and above 2°d, unsuitable for water containing iron and manganese; b) magnesite process, for water with degrees of hardness up to 15°d; c) dolomite filter compounds, especially for drinking water; d) calcium hydrate process for hard and soft water containing iron.

Water desalination process → Ion exchanger.

Water discharge legislation Approximately 15% of the process water used during textile manufacture is lost to evaporation, spillage or incorporation with the product. By far the greater portion is discharged by processors into the public sewage system, which means that it is subject to the discharge legislation of the various states on the one hand, and on the other to the waste water bye-laws of the local authorities.

Under the 5th amending statute to the German → Water Resources Law (WHG – Wasserhaushaltsgesetz) and its associated "Appendix 38" concerning the framework AbwVwV (Abwasserverwaltungsvorschrift – Waste Water Administrative Regulation), which is presently under review, measures may in future be required to address waste water treatment according to the "state of the art" with respect to each → Segregated stream. This applies, however, only to those batch discharges which contain hazardous substances. The definition of the term "hazardous substance" is disputed but is crucial to the necessity of treating batch discharges. It thus demands a final resolution in order to avoid unnecessary dispute between textile manufacturers and authorities once the revised Appendix 38 comes into force. → Waste water evaluation.

In recent years the imposition of a major polluter premium by local authorities has led to a drastic rise in costs and thus financial burdening of textile manufacturers. In many cases this cost increase can be traced back to a lack of cooperation between indirect discharger and local sewage works. Any business will of necessity make projections which compare the water supply and waste water costs which fall due if the existing facilities are retained against the capital and operating costs of in-house effluent treatment. If the company is presented with ready-made conclusions by the authorities, it is inevitable that it will do its utmost to reduce its liability to costs. The result is that the discharge ratios at the relevant sewage works will fluctuate, which in turn invalidates the dimensioning parameters applied at the sewage works.

It is also possible that major polluter premiums are not in keeping with the actual cost of dealing with waste water from textile plants. Since such water is usually depleted in both nitrogen and phosphorus, combining its treatment with waste water from other sources may actually result in cost savings. For example, an "excess BOD" (biological oxygen demand) of industry-sourced water may contribute to a reduction in denitrification volume and a saving on aeration costs.

It is fundamental that the biological treatment of textile waste water is to be preferred over all other methods of treatment. Only if such exclusively biological treatment fails to meet the mandatory maximum pollutant levels should additional chemical and physical procedures be considered. This, however, requires that the indirect discharger accepts as self-evident the need to carry out certain preliminary procedures:

- A balancing of both the quantities and the concentration levels of waste water through the use of mixing and holding basins (for weekly adjustment). This has advantages when it comes to accommodating possible errors or faults. Balancing makes allowance for a lower maximum biological treatment capacity.
- Neutralization of pH to between 8.5 and 9 (preferably using flue gases). A lower pH is not to be recommended due to the danger of releasing hydrogen sulphide.
- Recycling weak leaching (alkali) solution following mercerization by means of evaporation.

It is yet to be seen whether waste water from textile plants may be transferred separately to the sewage works using company pipelines. Given the poor state of most public sewers, this may be the preferred option from the point of view of local authorities. If this were done, it would also be possible to site mixing and holding basins at the sewage works in cases where there is insufficient room on the company's own site.

I. Iron-contaminated water should have the iron removed and, if necessary, be deoxidised before the demanganizing. In water with a lot of organic matter demanganizing is only possible using aluminium sulphate precipitation.

If this were done, it would also be possible to site mixing and holding basins at the sewage works in cases where there is insufficient room on the company’s own site.

Water economy in discontinuous (rinse) process

Water economy in discontinuous (rinse) process Technically feasible and technologically responsible, rinsing processes should be carried out with a liquor-to-goods-ratio as short as possible in order to save water. Decisions on the optimum rinsing process can only be taken in each individual case in view of technical and technological conditions and staff and water costs. When considering the expenditure of time and energy, preference should be given to the continuous rinsing process in the short liquor-to-goods-ratio, despite an increased water demand compared with the discontinuous rinsing process. It is advisable to monitor the rinsing process (and water consumption). Considerable reduction in fresh water demand can be brought about by a single discontinuous draining (or even better for example by suction) of the treatment bath. If it has to be rinsed with a long liquor-to-goods-ratio for any reasons, the last mentioned process should be considered because of high water consumption by the continuous rinsing process as well as in view of the increasing number of rinsing operations in the discontinuous rinsing process with increasing liquor-to-goods-ratio. Considerable savings of water and time can be achieved by reducing the liquor backlog (e.g. via suction) after draining.

Water-endangering substances The German water conservancy law → Water Resources Law (WHG – Wasserhaushaltsgesetz) contains special regulations in §§ 19 g–1 relating to the handling of water polluting substances (see Fig.). These federal regulations are further supplemented by regulations of the German states for installations handling water polluting substances (VAwS), which refer back to a standard ordinance of the LAWA (Länderarbeitsgemeinschaft Wasser = state working group on water). Despite this standard LAWA ordinance, regulations in the various federal states differ, especially since the water legislation is linked to building legislation, which also differs in the

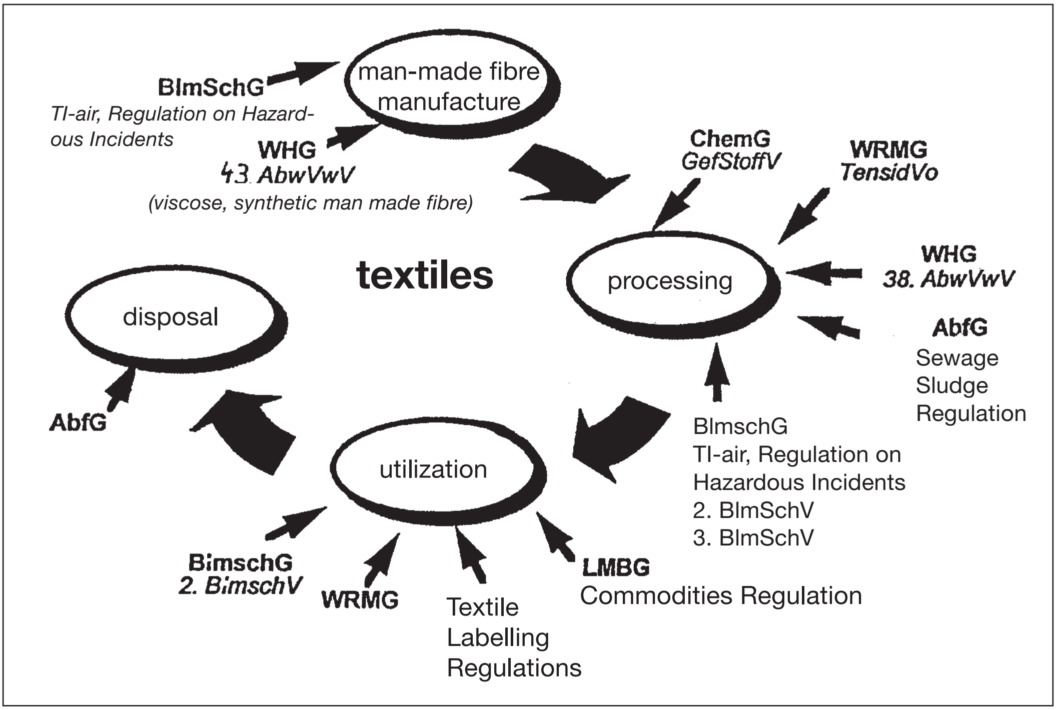

Fig.: Points during the manufacture and utilization of textiles at which water-endangering substances might appear, along with regulations valid in the Federal Republic of Germany for the handling of water-endangering substances.
BImSchG = Bundes-Immissionsschutzgesetz – Federal Immission Protection Law; Störfallverordnung – Regulation on Hazardous Incidents; WHG = Wasserhaushaltsgesetz – Water Resources Law; AbwVwV = Abwasser-Verwaltungsvorschrift – Administration Regulation of Waste Waters; ChemG = Chemikaliengesetz – Chemicals Law; GefStoffV = Gefahrstoffverordnung – Directive for use of Dangerous Substances; WRMG = Wasch- und Reinigungsmittelgesetz – Detergent and Cleaning Agent Law; TensidVo = Tensidverordnung – Surfactant Regulation; AbfG = Abfallbeseitigungsgesetz – Waste Disposal Law; KlärschlammVO = Klärschlammverordnung – Sewage Sludge Regulation; BImSchV = Bundes-Immissionsschutzverordnung – Federal Immission Protection Regulation; LMBG = Foodstuffs and Commodities Law; Bedarfsgegenständeverordnung – Commodities Regulation; Textilkennzeichnungsgesetz – Textile Labelling Regulations.

various German states. §§ 19 g–1 applies to installations for storage, bottling/packing and transhipment, installations for production, treatment and use, as well as pipeline systems which do not extend beyond the limits of an industrial plant. §§ 19 g–1 stipulates that installations for the storage, bottling/packaging, production and handling of water polluting substances, as well as installations using water polluting substances in the commercial business sector and in the area of public undertakings must be so designed that the quality of a water course does not suffer any detrimental change. The same stipulation applies to pipeline systems within the confines of an industrial plant.

For the purposes of §§ 10 g–1, water polluting substances include all solid, liquid and gaseous substances capable of bringing about a detrimental change in the physical, chemical and/or biological properties of water.

Various substances and preparations have been grouped into the following 4 water hazard classes (Wassergefährdungsklassen – WGK) according to their properties:

WGK 0 = substances which, in general, are not water polluting,
WGK 1 = slightly water polluting substances,
WGK 2 = water polluting substances,
WGK 3 = highly water polluting substances.

These classes are based on a classification system introduced by the “Commission for the Evaluation of Water Polluting Substances” which is subject to the Federal Ministry for the Environment, Nature Preservation and Safe Operation of Nuclear Power Plants.

Every installation handling water polluting substances is obliged to submit a suitability declaration (§ 19 h). From this suitability declaration, the authorities are able to certify that installations, or parts of installations, as well as technical safety devices, satisfy the requirements of § 19 g, Clause 1 or 2 of the WHG in an individual case. For installations, parts of installations and safety devices of standard manufacture, this suitability declaration can be substituted by a building permit pertaining to water legislation. Despite this stipulation, there are a number of exceptions here. Suitability declarations are not necessary for installations, parts of installations and technical safety devices of a simple or conventional type. Where installations, parts of installations or safety devices are subject to an industrial building permit or a test of conformity under building legislation, the suitability declaration is likewise dispensed with. As a rule, this applies to installations, parts of installations and safety devices of standard manufacture.

The following are excluded from the obligation to submit a suitability declaration:

– Installations for production, treatment and use where the substances are involved in a process.
– Temporary storage of transport containers.
– Short-term availability or storage of water polluting substances in connection with transport if the containers or packages satisfy the regulations and requirements for transport on public highways.
– Storage in laboratories where small quantities are dispensed by hand.

In § 19 i, Clause 2, of the WHG it is stipulated that the operator has an obligation to monitor the soundness of the installation against leakage and the functional integrity of safety devices. Installations, or parts of installations, where water protection is involved, must only be installed, erected, repaired, maintained and cleaned by specially monitored specialist firms. This applies to the operator’s industrial plant (§ 19 l, Clause 1) as well as to other companies sub-contracted by him (§ 19 i, Clause 1). The operator must allow the proper state of the installation to be checked by official experts, or recognized experts for these purposes, especially before an installation is commissioned, as well as after a significant modification and before an installation is recommissioned after it has been shutdown for a period longer than one year, or to comply with special instructions, or for special reasons and after notification of an inspection has been given. This also applies when the installation is shutdown.

According to the requirements of water legislation in the German states, the operator is subject to additional obligations, such as

– a duty to notify the authorities of any installation, erection and significant modifications for which specific information is required;
– a duty to notify the relevant authorities immediately when any leakage of water polluting substances occurs if there is any risk of these substances entering the sewer system or seeping underground (according to Schäfer).

Water equilibrium Term in dry cleaning for the final state of water distribution between treatment liquor and textile.

Water extraction,

I. (pre-drying), aims at the removal of water from fibre and fabric pores for the relief of high drying costs. Approx. 40–100% water still remains after water extraction. Mechanical water extraction is considerably more economical than thermal drying, which requires approx. 400 times as much energy. Distinctions are made between water extraction processes shown in the Fig 1.

Water extraction can be carried out

– mechanically,
– gas kinetically,
– capillary active,
– thermally by drying.

The advantages and disadvantages of separate processes are shown in the Tab.

The following methods are common:

Water extraction

	mechanical		gas kinetic	capillary active
	discontinuous	continuous	continuous	continuous
equipment and machinery employed	centrifuge	pad mangle with different variants (polyamide fibre rollers, swimming rollers, additional negative pressure etc) continuous centrifuge (staple fibre yarns)	suction pipe, suction roller, Mach nozzle, jet squeezer, venturi nozzle	squeeze-suction method capillary-vacuum process water extraction by continuous nonwoven fabrics
water extraction effect	residual noisture levels near original swelling water value	residual moisture levels approx. 20-30 % higher than centrifuge values	residual moisture figures somewhat lower than by pad mangling on average	reduction of residual moisture values to centrifuge figures sometimes possible in the case of synthetics
quantities affecting the water extraction effect	– type of fibre – speed	– type of fibre – fabric weight – type of construction – machine speed – line pressure in the nip – liquor temperature (recovery feasible under certain circumstances if it can be effected via heat recovery)	– type of fibre – machine speed (e.g. Mach nozzle: at 20 m/min, the residual moisture content of a woven polyester fabric is 25 %, and 45 % at 100 m/min) – fabric air permeability – energy density of the gas flow and installed power	– type of fibre – machine speed – number of passages
advantages	also suitable for sensitive and highly textured fabric	– ease of handling – perfected process – easy roller cleaning	– effect is independent of parameters such as water surface tension, fabric temperature etc – suction machines also suitable for extensible fabric – 2 water extraction operations possible at the same time by roller-jet-squeezer (wet on wet process)	– capillary vacuum system: very good with synthetics; also suitable for warp and weft knitted fabric; easy to extract water from rope and tubular fabric; suitable for structured and pile fabric; water extraction effect very little dependent on speed; – improved liquor penetration – QS technique: also suitable for natural fibres
disadvantages	discontinuous	– relative to the centrifuge, higher residual moisture levels with open fabrics like net curtains etc) – high pressure on the fabric – danger of creasing	– high energy consumption in the case of the suction principle – Mach nozzle unsuitable for extensible fabrics – dye liquor hardly uniformly removed	– unsuitable for extensible fabrics with the exception of the capillary vacuum system and water extraction by continuous nonwoven fabrics – usable only for final processes with the use of nonwoven fabrics (water extraction from heat set and washed fabric) – seam impression in the case of thin fabrics

Tab.: Comparison of water extraction processes.

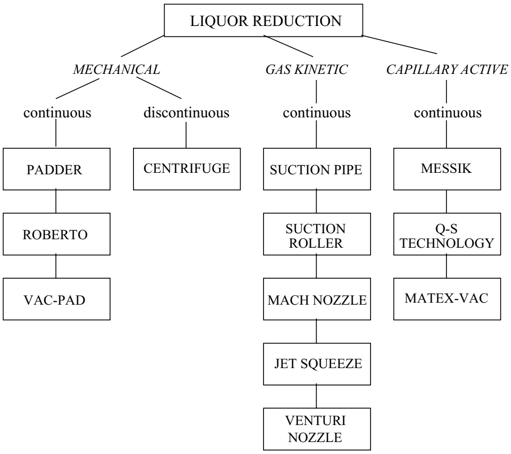

Fig. 1: Water extraction process classification (without thermal water extraction).

1. Squeezing or pressing between squeeze rollers under pressure, usually in the open-width state of the fabric, on so-called wet or water calenders, chiefly for heavy fabrics.

The most efficient removal of water from fabric at the end of open-width washing ranges can be achieved by means of water mangles with swimming rolls (Fig. 2).

2. Centrifuge hydro-extraction: most used process for every type of making up of finished textiles. Performed in centrifuges at approx. 750–1200 rpm. Yarn packages on material carriers in accordance with the hydro-extractor slip-on process are directly centrifuged, also with simultaneous hot air blast (water extraction at 40–50%); in dyeing machines with a vacuum system it is often only sucked and then centrifuged.

3. Suction by vacuum pump: performed for fabrics on so-called suction extractors in the crease-free open-width state by the passage through a tube with suction slots and vacuum connection. Especially suitable for sensitive fabrics.

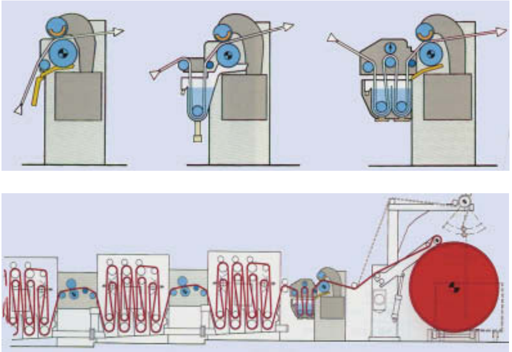

Fig. 2: Water mangle (Küsters).

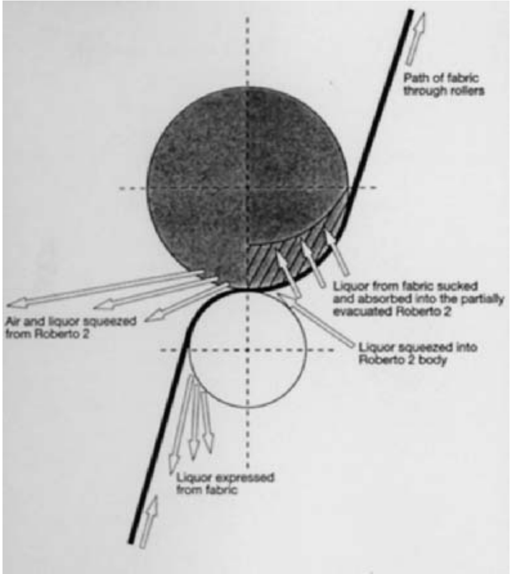

Fig. 3: Hydroextraction by porous roller.

4. During hydroextraction by porous roller excess liquor is removed by the steel and squeezed out by the Roberto as it is compressed (Fig. 3). Then with the fabric still in the nip, the Roberto regains its shape, drawing air through the fabric into the filling of the Roberto and creating a sucking action which removes more liquid from the fabric. Compared to the established Roberto, tests with Roberto 2 show expression increased by an average 12% running against a stainless steel roll. For a tubular knitted or thick pile fabric where two Robertos are recommended, the average increase is 18%. These figures are improvements over a roller which already outperforms conventional rollers by as much as 60%.

II. (f_1), remaining water weight in relation to textile dry weight:

$$f_1 = \frac{g_{ges} - g_{atro}}{g_{atro}} \cdot 100\ \%$$

g_{ges} = water content before drying
g_{atro} = absolute drying.

Water extraction by compressed air (compressed air squeezing system). Device for non-contact water extraction of width fed fabric webs. A compressed air water extraction machine (in contrast to the vacuum suction machine) with perforated passage (moveable top element, e.g. as plate and bottom slot device). Air under high pressure, in which water adhering to the textile web is pressed and blown off, and flows through the operating slot.

Water extraction machines for piece goods Mainly continuously operating systems for mechanical water extraction (→ Squeeze off). Division:

I. Discontinuous: → Centrifuges.

II. Continuous: squeezing units, such as → Water calender; →: Suction roller for textile webs; Water extraction throughflow method.

Attainable residual moisture from water extraction machines is between 30 and 100% depending on fibre and machine type.

Water extraction throughflow method The mechanical energy of a gas (mass) flow is used to release free water from the textile bond.

Water fastness Resistance of dyeings and prints to the effects of water.

1. Light strain (DIN 54 005-73): test sample with adjacent fabrics well moistened (surplus water poured away), 1 hour weighted with 4.5 kg tested at 20°C, separated and dried at 60°C and assessed using grey scales.

2. Heavy strain (DIN 54 006-73): as 1., but tested for 4 hours at 37°C and/or 16 hours at 20 °C. AATCC test: 18 hours. Assessment using grey scales. The perspirometer from AATCC (Atlas Electric) or the hydro test equipment (Schröder) is used as the tester.

Both standards are essentially adapted to ISO 105, issue 1982.

Water filter for turbidity contamination,

I. Slow filter: open (covered) reservoirs, filter material (from bottom to top) gravel, shingle (quartz) sand, filter use (according to process water) a few days to several months. Disadvantages: large space required. Principle: logging of mainly most finely grained suspended sediments. Effect: a) mechanical; b) adsorptive through jelly-like filter skin (being produced during filtering); c) biodegradation (by bacteria settled in the filter skin). Result: clear treated water.

II. High speed filter: for the preparation of boiler feed water. Filter material of rounded quartz sand. Result: deoxidation, iron elimination and fine filtration.

III. High performance filter: with special sludge suction.

IV. Microfilter: material of porous kieselguhr or porcelain, fireclay hollow cylinder, etc.

→ Filter for waste water treatment.

Water fire extinguisher → Fire extinguishers holding 6–12 litres of water (to which salts have been added to lower its freezing point) and containing a riser pipe, a cartridge filled with either dilute sulphuric acid or compressed liquid carbon dioxide, a heavy duty button and a nozzle through which the extinguishing fluid is expelled. Activation of the heavy duty button causes the cartridge to be broken, whereupon the carbon dioxide (released directly or else generated due to the reaction of sulphuric acid with sodium carbonate) forces the water through the riser pipe and the nozzle as a jet, several metres long, which may be directed at the seat of the fire.

Water flow meter Measuring instrument for water flow velocity and flow quantity.

Water glass (→ Sodium silicate), is produced by melting quartz sand (SiO_2) and sodium carbonate, whereby approximately the following ratio exists in the product which is of interest to the textile industry: 8% sodium oxide and 27% silicon dioxide. The exact structure of water glass cannot only be given by 37–40°Bé, but it is well-known that the structures SiO_3^{2-}, a chain structure, and $Si_4O_{11}^{6-}$, a band structure, represent the main constituents. O–Na groups are produced, corresponding to the ratio of alkaline carbonate addition, from a part of OH groups by melting with alkaline carbonates. The free OH groups are capable of bonding further caustic soda liquor. This characteristic results in an excellent buffer power compared with sodium hydroxide. In addition, a salt formation with alkaline earth metals such as calcium and magnesium as well as with heavy metals such as iron, copper and manganese is possible in these OH groups. The polysilicic acid

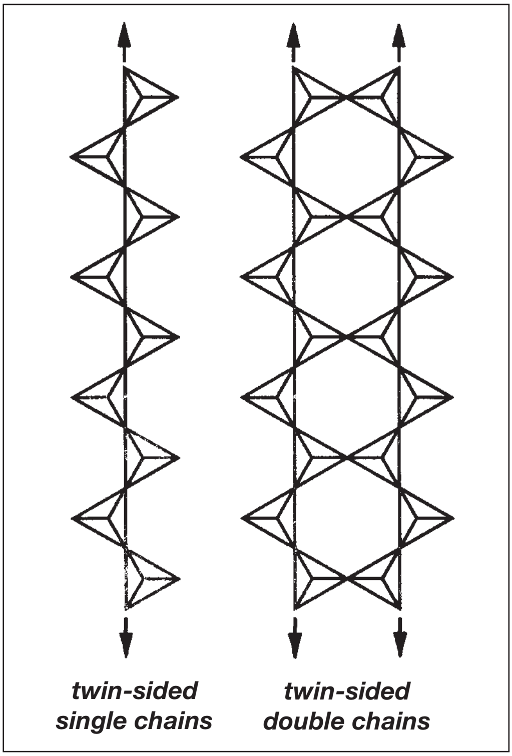

Fig. 1: Polysilicic acid molecules.

molecules (Fig. 1) and their sodium salts are responsible for these positive properties of water glass. Unfortunately these structures are not very stable. Already higher quantities of CO_2, which are brought into impregnating baths by the air, high quantities of alkaline earth salts, chiefly Ca^{2+}, which are input using mechanically harvested grey fabric, as well as heat and pressure result in a dehydration (water release) and in the formation of silicic acid gel and insoluble metal hydroxides as well as insoluble alkaline earth silicates. The heat sensitivity of colloidal silicates can be very easily proven by observations in practice. If, for example, reactive dyeings, whose dye recipe contains 60 ml/l of silicate, are washed off immediately by boiling in the first bath, the machine shows severe silicate encrustations in a short time. If however 20–40°C is selected as the washing temperature in the first bath, the plant does not show any encrustations even after a longer period of production.

If bleach preparation liquors are prepared with water of 8°d and a) 12.5 ml/l of water glass, b) 5.0 g/l of sodium hydroxide, c) 40.0 ml/l of hydrogen peroxide 35 percent by weight, once in the sequence described (beaker A) and secondly in the sequence b, a, c (beaker B), glass A shows an unchanged appearance over weeks; glass B contains a precipitate after only a few hours.

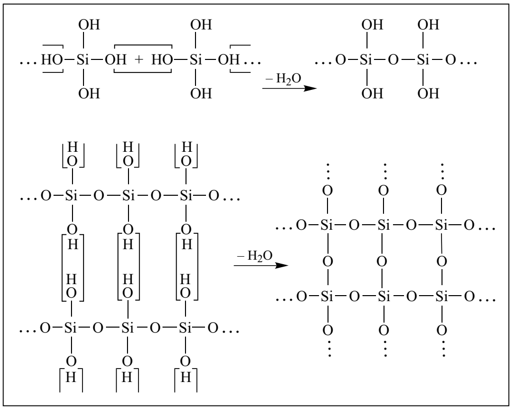

Fig. 2: Dehydration of water glass (according to Ney).

This dehydration (Fig. 2) is responsible for the dreaded deposits on steamers. Rock hard coatings are formed, which are difficult to remove. The phenomenon described may however also be formed in laying the fabric web on excessively heated machine parts. This is shown by a hard fabric handle, as polysilicic acids are difficult to rinse out. The process water plays a crucial role in stabilizing when using water glass. If the water hardness is higher so that it can be bonded as magnesium silicate by the silicate and can be kept in solution by alkali, not easily dissoluble calcium silicates are formed, which break down and are deposited on the fabric. These are also detrimental to the handle and possibly to the fabric appearance of a later dyeing.

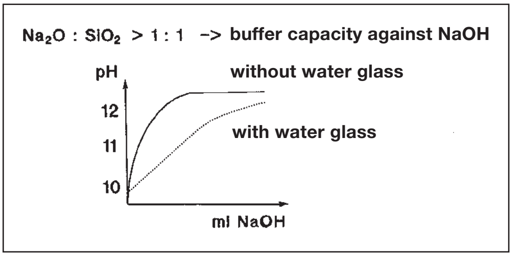

Fig. 3: Buffer capacity of water glass against caustic soda liquor.

Besides its stabilizing properties, water glass has the advantage of reducing and/or preventing the effect of catalytes. Catalytes are understood to mean, above all, in the hydrogen peroxide bleaches, salts from heavy metals and/or heavy metal ions. They have the capacity to decompose the bleach liquor so rapidly that it turns into a spontaneous, uncontrolled discharge of atomic oxygen and acid and causes local fibre damage. During the manufacture and/or processing of textiles, iron compounds can get onto the fabrics so that the risk of catalyte damage from iron is especially large. Iron salts can be eliminated by so-called complexing agents (e.g. ethylenediaminetetra-acetic acid), but most of these auxiliaries are not effective in the strongly alkaline medium of the bleach bath. On the other hand, these complexes are also not stable so that stabilizers, which are constructed on this basis, are far less effective than water glass. In this, the iron is not bonded in a complex way, but “absorbed” like a porous sponge and virtually mechanically removed from the bleach liquor and made ineffective.

Water glass has yet another important function in bleaching. It buffers away the alkali and thereby creates an alkali reserve in the bleach bath (Fig. 3) without concentrating the activation of the peroxide. In this way 2.5 g/l sodium hydroxide is buffered away by 10 ml/l water glass; up to a fourfold quantity of water glass

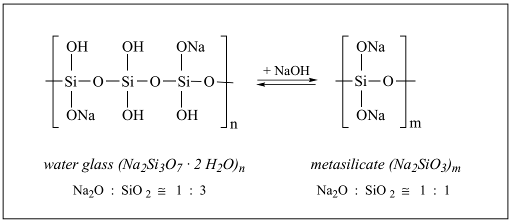

Fig. 4: The buffer effect of water glass.

(in ml/l) can be used compared with sodium hydroxide (in g/l). If this ratio is exceeded to the disadvantage of the water glass, the alkali can no longer be adequately buffered away by the water glass (Fig. 4); the free alkali increases the activation and reduces the stabilization (in accordance with Ney as well as Wurster).

Water glass variant Alternative to → Cold pad batch dyeing (CPB), which necessitates a special aftertreatment on the open-width washing range (see Fig.), so that water glass is properly washed out from the reactive dyeing.

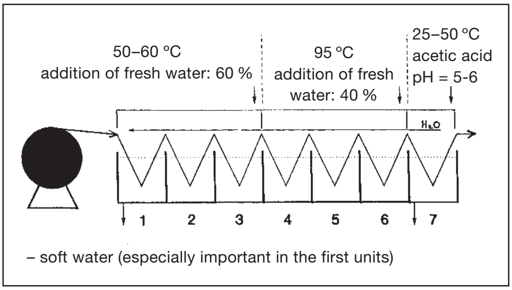

Fig.: Water glass variant (Hoechst) in the CPB process with carefully directed afterwashing of the batch on an open-width washing range (4th + 5th unit: addition of 1 g/l Ladiquest 1097).

Water hammer is produced in steam and condensate return piping by rapidly moving/retarded water drops or by combination of steam and hot condensate with colder condensate. Remedy: Lay old piping with sufficient gradient at the water extraction point; prevent water pockets in piping; drain water from all low points; slowly put evaporation plants into service; all water drainage systems should function well; steam piping and heat exchangers should be empty when out of service; thermostats and pressure regulators should be correctly sized; sufficiently large bore condensate piping; steam or hot condensate of higher pressure should not come into contact with considerably cooler condensate.

Water hardening salts The degree of water hardness means the quantity of calcium and magnesium ions (hardness salts) in the water. They can cause undesired linking of textile auxiliaries and dyes and may therefore result in difficulties in textile finishing. Problems with hardness salts also occur in the household, for example lime soap, lime deposits on the heating elements of washing machines. In Germany, the total hardness of calcium and magnesium compounds in the water refers to the oxides of both alkaline earth metals, although these oxides themselves are not present in the water. 1°d (degree of German hardness) means that 10 mg of calcium oxide is present in 1 l of water. All hardness salts are converted into these reference variables by applying stoichiometry. The hardness can be determined in °d directly with the aid of colour indicators. Free, aggressive carbonic acid (carbon dioxide), released in water, attacks many compounds, in which temperature and time play an essential role. In most cases the bonded carbonic acid predominates in the form of hydrogen carbonates of calcium and/or magnesium. In boiling and/or heating the hydrogen carbonates are decomposed and the insoluble carbonates (boiler scale), which break down and are deposited on machine parts, are produced. Due to this decomposition reaction, the calcium and/or magnesium hydrogen carbonates are described as temporary hardness salts. In contrast to this, the dissolved chlorides and sulphates of calcium and magnesium are permanent hardness salts.

One talks of calcium accumulation if fibrous materials (above all cotton) or textile auxiliaries (e.g. sea salt or rock salt in direct dye dyeings) add additional water hardness to the hardness of the process water. Sequestrene (e.g. EDTA) or polyphosphates can be used together for the binding of water hardness in the dye liquor. Polyphosphates are not completely harmless ecologically and sequestering agents not only bind calcium ions during dyeing with copper complex dyes, but also extract the copper ions from the dye. Thus there is the need for an auxiliary that is completely harmless ecologically, shows no or only a slight complex formation compared with polyvalent cations and prevents the crystal deposits caused by calcium hardness on the dye material. → Water hardness salts.

Water hardness → Water hardness salts.

Water hardness agent remove Removal of the → Water hardening salts by deactivating agents (→ Complexing agent).

Water hardness, degree of → Water hardness units.

Water hardness determination → Complexometry offers a suitable method for total, calcium and magnesium hardness, which works simply, rapidly and accurately (0.05°d). → Water hardness salts.

Water hardness, determination of → Water hardness determination.

Water hardness, microdetermination See → Complexometry with complexing agents (complexometric titration).

Water hardness salts Water-dissolved calcium and magnesium salts (total hardness) cause the "hardness" in water. The hydrogen carbonates break down when boiled by releasing the carbonic acid holding them in solution (temporary, carbonic acid or carbonate hardness). The remainder is resistant to boiling (permanent, mineral acid or permanent hardness). Magnesium salts produce magnesium hardness; calcium salts, calcium or lime hardness. The units of hardness are different depending on the country and are usually given in mVal = millival (→ Water hardness units).

I. Soluble carbonates (of magnesium and calcium) cause (→ Water hardening salts):

1. During boiling, bleaching, soaping, washing, etc. sticky/dirty lime soap precipitates (vessels and fabric), soap and auxiliary losses, stains, yellowing, rancid smell, wetting difficulties, unequal result, worsened handle and promote fibre brittleness.

2. During dyeing: precipitation and sudden change in shade of dyes sensitive to hardness, poor wetting, unevenness, cloudy dyeing, bronzing, stains, reduced colour fastness to rubbing, dye losses, etc.

3. In steam boiler operation: boiler scale formation (chiefly carbonate and sulphate of lime, 1 mm boiler scale layer approx. 15% increased fuel consumption), deposits in pipework (blockages), overheating at the boiler end, corrosion, burning through, tube fractures, explosions, malfunctions, costly repairs and/or boiler cleaning, reduced performance, shortened life of the boiler; increased energy consumption.

II. Soluble non-carbonates:

1. Soluble chlorides, often up to 30 mg/l and more, contaminate water up to 1000 mg/l and more. More than 100 mg/l have an effect in soft (low in carbonate) water metal corrosion (especially with increased temperature and pressure), high chloride content causes ferrous corrosion (sea water) and zinc damage. High calcium carbonate content promotes formation of protective layers inside tubes in water containing chlorides. Reactions occur with mortar/concrete, cracks, loosening of foundations, etc., serious damage only above approx. 200 mg/l.

2. Free chlorine, usually not more than 1 mg/l, may possibly, especially in the dyehouse, cause unwanted failures, possibly also mains damage is caused by "soft" water, low in minerals.

3. Soluble nitrates/nitrites: in finishing: traces have a disruptive effect. High nitrate content has a corroding effect on metal (encouraging rust, sea water) especially in the presence of "aggressive carbonic acid" in the zinc-containing mains system (reduction to nitrites), with low temporary hardness possibly already 50 mg/l damaging to the mains system. Nitrites are especially detrimental in lead pipes, generally increased corrosion in steam boilers (burn-out, explosion hazard).

4. Soluble sulphates (sulphides): a) count in textile finishing, where work is carried out at a higher temperature, to the most damaging hardness salts, as they represent the "remaining residual hardness" (sulphate, calcium sulphate hardness); b) high sulphate content has a rust promoting and zinc corroding effect on the mains water system; c) in steam boiler operation high sulphate content is the most dangerous boiler scale forming agent, which results in the dreaded hydrated calcium sulphate scale. Deposit in solid micro-crystalline form on heat transfer surfaces, not easy to remove, low heat conductivity. Last process is accelerated by decreasing sulphate solubility with increasing temperature; d) lime building materials: not only does free sulphuric acid have a rapid corrosion effect, also neutral water with more than 300 mg/l of bonded acids as well as especially dangerous water low in sulphate (of loam, marl, clays with fluctuating water table) during evaporation and concentrated accumulation. Besides hydrated calcium sulphate, sulphates of magnesium also corrode (seriously damaging due to additionally unfavourable magnesium influence), sodium (potassium). Formation of voluminous calcium sulphaluminate, concrete destruction, pulp transformation (so-called → Gypsum expansion). In addition excretion of gypsum crystals, cracking in foundations, breaks, etc. Sulphides (as well as, if necessary hydrogen sulphide, often in small quantities in ground water containing iron) have a similar effect of metal and mortar corrosion.

5. Soluble silicates, almost in every natural water, rarely more than 10 mg/l, with sufficient magnesium content, the most feared stone-like silicate boiler scale results, lowest thermal conductivity coefficient.

III. Soluble metal salts:

1. Iron, (usually iron II-) hydrogen carbonate sulphate (-hydroxide), frequently 1–3 mg/l. Removal is encouraged with more than approx. 0.2 mg/l, in the air, water often opalescent to cloudy, yellow formation of small flocks, with rapid higher temporary hardness, retarded in especially soft or humus-rich water. Ensuing results: a) water pipes: inner deposits, light silting up, encouraged occurrence of iron-storing algae, blockages and corrosion. In the presence of small quantities of free carbonic acid in water, oxygen/air-free and/or lacking in air, further iron contamination (iron pipes) takes place especially at line ends . There is also corrosion-dissolved iron in water containing sulphate, sulphite, hydrogen sulphide, chloride and nitrite. b) In finishing: in bleaching and washing more than approx. 0.05–0.1 mg/l already has a disturbing effect, no pure white, yellow/dirty brown bonded discoloration, rust stains, catalytic fibre damage, musty smell, etc., with more than approx. 1 mg/l, tendency to stain removal in processes using soaps and metal-sensitive auxiliaries, dyes (sudden change in shade), dull, cloudy dyeing, etc.

2. Manganese, more frequent, an accompanying complex in water containing iron, quantities usually smaller, but often up to approx. 0.3 mg/l; removal (similar to iron) is promoted by manganese-storing algae, pipe blockages are often more serious than with iron. In finishing extensive excess lengths sometimes occurring; brownish black discoloration, more visible in bleaching, strong rubber poison in rubberising.

3. Lead, usually as an easily soluble hydrogen carbonate as well as not easily soluble carbonate and hydroxide. Not in water containing carbonic acid/air-free

water. Less in flow lines, easy to remove by pipe cleaning. Occurrence in corrosion-dissolved form only in atmospheric oxygen, especially also soft water containing air/carbonic acid free/low in carbonate, in soft water (low in carbonate), containing air and chloride also containing air and nitrate in the presence of nitrites, humus acid, etc. chiefly in newly laid lead pipes, especially also using lead alloys (soldered joints). Results: lead soaps, etc.

4. Zinc, corrosion dissolved in respective tubes and containers with water, which contains “aggressive carbonic acid” (with or without atmospheric oxygen), as well as other acids, alkali carbonates, liquors, high content of chlorides or sulphates, even soft water corrodes. Zinc is released from brass pipes under the above conditions. Zinc is initially corroded in galvanised iron pipes.

5. Tin, corrosion dissolved only in strong acid or strong alkaline water (scarcely in water containing carbonic acid/oxygen), however in tinned iron pipes (electrolytically conditioned, are more likely to rust than untinned iron), in lead pipes containing tin (frequently) only lead is dissolved. The feared tin decay (tin pest) occurs especially in tin pipes laid in the ground (average annual temperature + 18°C): big increase in volume, decomposition to grey powder. Then pumped water may possibly contain a lot of tin. Presence of small tin particles.

Water hardness scales, conversion factors → Water hardness units.

Water hardness units → Hardness ranges of water, for determination of the resistance of surfactants to hard water, in accordance with DIN and ISO standards, always used for water with balanced calcium hardness. With the introduction of the international system of units the parameter “German degree of water hardness” (°d) can no longer be retained as the unit of water hardness because it does not correspond to international standards. The necessity to convert into statutory SI units follows. It thereby offers manageable figures for conversion, which are as easy to use as the old °d. In principle two possibilities are given at the same time for details of chemical concentration: details of the mass (in this case in mg) per unit of volume and/or details in mole per unit of volume (e.g. mmol; mole). The graduations quoted in the Tab. approximately apply.

Water-impermeable finishes (→: Water repellent finishing; Solvent impregnation). These are some of the most important textile finishes and offer real value to the consumer, i.e. improved quality, especially if the effects are resistant to washing and dry cleaning.

I. Waterproof and water repellent effects:

1. → Water repellent finishes with no influence on air permeability, suitable for e.g. rainwear such as poplin, gabardine and loden coats, anoraks, sportswear, uniforms, loden fabrics, suitings, dress fabrics, costumes, etc.

2. → Waterproof, finishes resistant to water pressure: the air permeability is greatly reduced or non-existent, especially in the case of finishes produced with coatings. These finishes are used for heavy fabrics such as tarpaulins, tenting, etc. The degree of waterproofing is dependent on the fabric construction, i.e. suitable fabrics must be tightly woven for optimum effects.

3. Combination effects: these finishes are often combined with oil repellent, non-iron and crease-resist finishes (for outerwear and similar fabrics) or in rotproof finishes (tarpaulins, tents, etc.).

II. Basis for good water repellent effects: a woven fabric with a uniform structure and fine capillaries; low-swelling fibres; production of a closed, elastic, hydrophobic film on the textile material; the hydrophobic substance must be firmly bonded to the textile substrate and have a high wetting angle. Fabric construction must be adapted to the field of application. Unless the woven structure is sufficiently tight, the fabric will allow water to pass through it in spite of the water repellent finish. A water repellent finish should have as little effect as possible on the handle and appearance of the treated material (e.g. no dulling of the fabric lustre, hazing or chalking). Water repellent effects resistant to washing and dry cleaning can only be obtained with products capable of combining chemically with the fibre.

III. Fabric requirements: woven and knitted fabrics must be given a thorough pretreatment preferably with products having no affinity for the fibre; only non-ionic textile auxiliaries should be used. The absence of wet-

assessment	old unit of measurement °d	new unit of measurement total alkaline earth (hardness) mmol/m³	mmol/l
very soft	0 . . . 4	0 . . . 716	0 . . . 0.7

quite hard	12 . . . 18	2148 . . . 3222	2.1 . . . 3.2
hard	18 . . . 30	3222 . . . 5370	3.2 . . . 5.3
very hard	>30	>5370	>5.3

Tab.: Classification of water according to hardness (total hardness) regarding of the old and new units of measurement.

ting agents, acids, alkalis and salts is necessary for good water repellent effects. Detergents with a wetting action must not be used in dry cleaning.

IV. Technology: 3 processes are used in dry cleaning establishments:

1. Spray application: minimum concentrations, therefore economical.

2. Application by infusion: the goods are sprinkled with 1–1.2 times their own weight of impregnating solution in the machine which is allowed to run for approx. 5 min, followed by a short centrifuging.

3. Dipping process (standing bath, intracellular process): the goods are treated in a full bath followed by centrifuging. The bath is not exhausted in this process and can be used again up to 10 times after appropriate replenishment.

In all these processes, the treatment should be followed by a slow stepwise drying. The maximum temperature depends on the particular product used.

In textile finishing plants, exhaust methods and continuous application on the padder are possible. Exhaust methods are of secondary importance here. The concentration of impregnating agent in all these processes is dependent on the type of fibre. Synthetic fibres require particularly high quantities in view of the fact that they can only absorb a small amount of liquor.

4. Exhaust methods: the treatment is carried out at a long liquor ratio on winches or jiggers depending on the fabric quality. The impregnating agent is only partially taken up by the fibre and the degree of liquor exhaustion is variable and difficult to monitor. After the fabric has been treated, it is suction extracted or centrifuged without rinsing then dried. Emulsions of single-bath impregnating agents specially manufactured for this type of application are used.

5. Padding processes: a single or two-bath application is possible depending on the particular impregnating agent. For the two-bath method, an intermediate drying may be given if necessary. The impregnating agents are emulsions of water-insoluble hydrophobic substances. These emulsions must be stable during impregnation. Even the smallest separated particles are noticeable as translucent dark stains during drying. Emulsion breakdown is not only due to the influence of chemicals washed out of the material but can also be caused by high mechanical shear stresses (e.g. during squeezing-off between the padder bowls or liquor circulation by pumping).

6. Solvent impregnation.

V. Examples of water repellent impregnations (the examples below are given roughly in order of increasing resistance to washing and dry cleaning):

1. Aluminium salts (aluminium acetate, diformate, triformate). When used alone, these compounds only produce slightly water repellent effects.

2. Aluminium soaps + wax or paraffin: in two-bath methods the fabric is first padded with a soap solution into which wax or paraffin has been emulsified to increase the water repellency effect. It is then passed directly, or after intermediate drying, through a solution of an aluminium salt. This process is repeated if necessary. The procedure is, however, laborious and involved.

3. Single-bath impregnation: suitable products for this type of application contain an aluminium salt, a protective colloid and paraffin in the form of an emulsion. These products are also suitable for application by exhaust methods although such methods are uneconomic.

The water repellent effects obtained in examples 1–3 are not resistant to washing and dry cleaning.

4. Zirconium salt/paraffin wax emulsions: more resistant effects are obtained by substitution of the aluminium salt with a zirconium salt. Padding and exhaust methods are used.

In examples 1–4, no chemical bond is formed between the impregnating agent and the fibre. This not the case with the following examples:

5. Isocyanate basis: esterification with cellulose takes place with isocyanates at high temperatures (above 130°C) to form cellulose urethanes (Cell–O–CO–NH–R) whilst a substituted alkyl urea is formed on wool (Wo–NH–CO–NH–R). Cellulose esterification is also achieved with fatty acid chlorides; solvent application plants are necessary for this method.

6. Stearyl-pyridine derivatives: curing at 150°C. Breakdown of pyridine and formation of the cellulose ether or, in the case of wool, the amine (unpleasant smell).

7. Fatty acid substituted ethylene urea derivatives: fatty acid modified melamine resins. Some of these derivatives can already be cured at relatively low temperatures. Besides a reduced propensity to soiling and good water repellency effects (not as pronounced as paraffin emulsions), these products confer a marked resistance to washing and dry cleaning and are highly effective softeners at the same time.

8. Chromium complex/fatty acid derivatives (chromium stearate): these products give excellent water repellent effects resistant to washing and dry cleaning. Their main disadvantage is, however, the greenish self-colour.

9. Fatty acid modified synthetic resins: apart from the derivatives mentioned in 7 above, other aminoplasts can also be used. After drying, they require an additional curing stage.

10. Silicone derivatives (organopolysiloxanes): these products are also applied in emulsion form and some are applied in combination with heat-curable resins. Organic metal compounds and zinc or zirconium salts are used as catalysts. Such silicone derivatives form crosslinkages with the fibre at high temperatures. They are suitable for all types of fibres. Excellent water repellent finishes (with good soil repellency and usual-

ly a soft handle). Some silicones have excellent resistance to dry cleaning (organic solvents, although this varies in the presence of dry cleaning detergents) and household laundering.

11. Perfluorocarbon derivatives (perfluorinated compounds): oil-repellent effects, above all, are obtained with these products (→ Oil repellent finishing). In order to intensify the water repellent effect, they are mainly combined with the products in examples 7 and 9, where they also function as extenders at the same time. The impregnating agents mentioned in 10 and 11 confer a positive charge on textile fibres which has the effect of attracting oil-based soils since the latter are usually negatively charged.

Water impermeability test The impermeability of a textile fabric to water (i.e. the effectiveness of a waterproof finish) can be determined by the water pressure (hydrostatic head) test described in German Standard DIN 53 886. To carry out the test, a test specimen is mounted in a test apparatus and the underside of the specimen is subjected to increasing pressure from a column of water. The water impermeability of the test specimen may be determined in units of water pressure in mbar or as the height of the water column (mm) and is also known as the "Schopper value" (see Fig.). This value is read off the water column as soon as the first three drops of water have penetrated through different parts of the fabric surface.

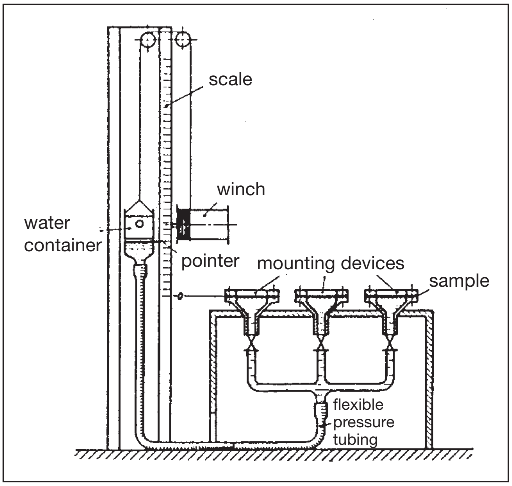

Fig.: Water pressure test as laid down in DIN 53 886.

The rate of increase of water pressure is approx. 10 mbar/min which corresponds to approx. 10 cm water column per minute. → Water repellency of textile fabrics (Bundesmann method).

Water impermeability testing →: Water repellency; Bundesmann; Basin; Burette; Empirical; Permeability bag; Spray; Immersion; Water pressure and Water tap tests.

Water-in-oil emulsions (W/O emulsions) →: Emulsion; Emulsion thickener.

Water jet cutting In garment manufacture, patterns are cut mechanically with knives or saws, or thermally with laser beams. Multiple layers of textile fabric or leather can also be cut into single layers by high power jets of water provided the momentary discharge of water is dissipated with the aid of a suitable backing material (Figs. 1 + 2).

Fig. 1: Typical water jet cutter nozzle.

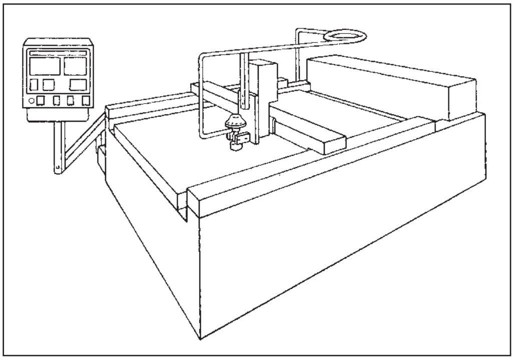

Fig. 2: Water jet cutting machine for garment manufacturing.

Water jet vacuum pump A simple suction pump capable of producing a moderate degree of vacuum, in which air is drawn through the branch of a T-tube by the action of a fast jet of water passing through the straight section. The pump has no moving mechanical parts.

A controllable water jet pump consists essentially of the elements shown in the Fig. Due to the difference in pressure P_{01}/P_{03} between the propulsion flow and the suction flow, the propulsion flow has a higher speed than the suction flow at the exit of the jet and carries it along by the mechanism of turbulent apparent friction into the collector jet. The speeds v_T and v_S of the propulsion and suction flows differ up to the end of the mixing tube. The pressures are equal, however. The Bernoulli equation holds good here

$$P' = P_{03} - h_S \qquad \left(h_S = \frac{\rho \cdot v_S^2}{2}\right)$$

where h_S is the dynamic pressure of the suction flow.

Both flows become mixed together in the mixing tube by the transfer of energy and impulse. Since the impulse decrease of the propulsion flow is smaller than the impulse increase of the suction flow, the pressure in the mixing tube rises. Both flows are so well mixed together at the end of the mixing tube that the speed at that point is almost uniformly distributed throughout the cross-section. The speed decreases in the diffusor and the pressure rises to P_{04} at the end of the diffusor (according to Baelz).

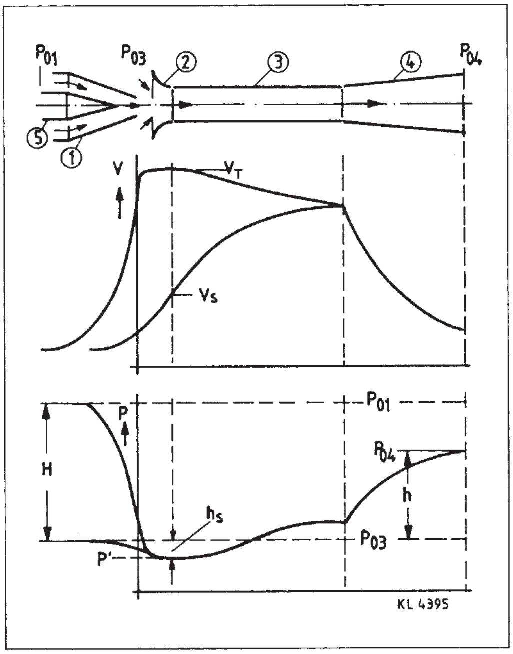

Fig.: Jet vacuum pump in diagram form showing speed and pressure flows.
1 = feeding nozzle; 2 = reception aperture; 3 = mixing tube; 4 = diffusor; 5 = controlling taper.

Water lock The installation of a water seal prior to the delivery of fabric from a steamer ensures an air-free passage of the latter through the steamer, e.g. by immersing the lower exit rollers inside the steam chamber in the liquor contained in the 1st aftertreatment bath (see Fig.).

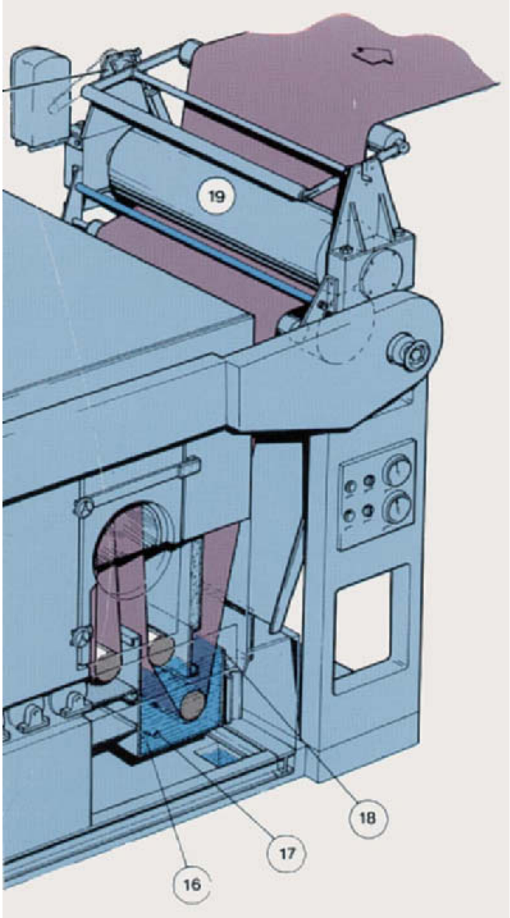

Fig.: Water lock on the run-out of a fabric steamer.
16 = water lock; 17 = fresh water distributor pipe;
18 = water lock overflow; 19 = run-out squeezer.

Water mangle, water calender A mangle with two squeeze rolls for the dewatering (pre-drying) and simultaneous smoothing of textile fabrics. A water mangle is often used before drying piece goods in rope form after pretreatment.

Watermarks,

I. Differences in light reflection from a textile fabric caused by the action of otherwise harmless water sprays or water drops. The effect is due to a temporary swelling which occurs particularly with regenerated cellulosic fibres sensitive to wetting. In most cases, these water marks can be successfully removed with a mixture of alcohol/glycerol 3 : 1 (dabbed on the affected area with a prewetted cloth followed by smoothing and drying. Crêpe fabrics should be covered with a cloth after dabbing on the above solution and dry ironed).

II. Moiré effects caused by the pressure of one layer of fabric on another.

III. Undesired marks due to the presence of wet spots on a textile fabric prior to continuous dyeing (or beam dyeing) which reduce dye uptake in localized areas.

IV. Variations in the pile orientation of pile fabrics causing differences in light reflection.

Water meter A programmable meter which has the function of a summation counter to predetermine and control the total consumption of water in wet processing treatments. Quantities of water for individual process stages can be preselected by means of a rotary switch and are automatically measured as the program runs. Different quantities of water can be preselected.

Water of crystallization (water of hydration). Water which is chemically combined in many crystalline substances. This water may be held in the crystal in various ways. Thus, the water molecules may simply occupy lattice positions in the crystal, or they may form bonds with the anions or the cations present. Hydrates are examples of compounds containing water of crystallization and include such well-known salts as, e.g. sodium carbonate crystals ($Na_2CO_3 \cdot 10\,H_2O$) and sodium sulphate ($Na_2SO_4 \cdot 10\,H_2O$) as the decahydrates which lose their water of crystallization on heating at fairly high temperatures (calcination). Numerous salts exist with different amounts of water of crystallization, i.e. hydrates with a low and a high water of crystallization content such as copper (II) sulphate in the form of, e.g. the monohydrate $CuSO_4 \cdot H_2O$, the trihydrate $CuSO_4 \cdot 3\,H_2O$ and the (normal) pentahydrate $CuSO_4 \cdot 5\,H_2O$. The pentahydrate is converted to the monohydrate at 100°C and only becomes anhydrous (as a white powder) above 250°C. Loss of water of crystallization is accompanied by a breakdown of the characteristic crystalline form.

Water parameters recommended for steam generation Boiler feed water for steam generating purposes must be of a particular quality as far as its chemical make-up is concerned (Tab.).

Water pistols A water pistol is used in textile cleaning operations for the localized dosing of liquid cleaning agents by hand. Such a water pistol may be attached to a flexible hose of any length and the main water supply tap does not have to be opened and closed before and after each application. The water spray (Fig.) stops automatically on releasing the trigger.

Water pockets If batch rolls containing wet fabric in the open-width state are inadvertently kept standing during, e.g. a prolonged machine stoppage in wet

Tab.: Water chemical standard values recommended for the recirculation water of directly or indirectly heated systems.
1) If the provisions of the drinking water ordinance/ drinking water preparation ordinance are to be observed, it is essential not to exceed the pH of 9.5 and the PO_4 ion concentration of 7 mg/l. 2) In continuous operation significantly lower values normally appear. 3) If appropriate inorganic corrosion inhibitors are used, the oxygen concentration in the recirculation water can be up to 0.1 mg/l. 4) For hot water generators with smoke tube heating surfaces, e.g. flue smoke tube boilers, the half maximum value of 2.5 or 5 mg/l of PO_4 ions is to be observed as the lower phosphate concentration. 5) Only for heating systems without direct drinking-water heating.

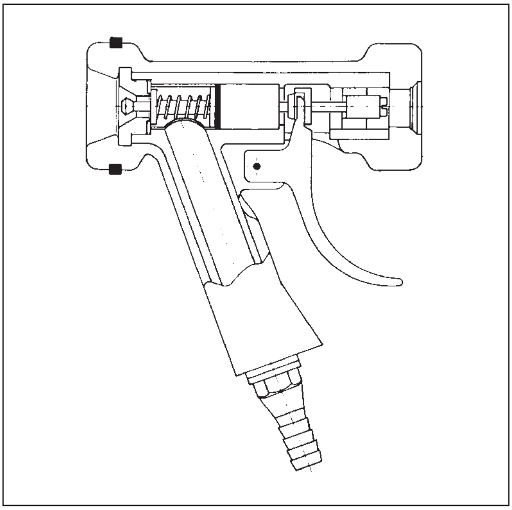

Fig.: Water pistols (van Wyk).

processing, unavoidable concentrations of liquor build up in the lower parts of the batch roll (in the form of a water pocket) due to gravity. The consequences are unbalanced running and unwinding problems.

Water power Water power is little used in the textile industry. Conversion systems designed to exploit the energy contained in falling or flowing water (dams, rivers, etc.) include: a) a simple turbine wheel (rotating about a perpendicular axis, which diverts the water in one direction by means of a fixed wheel with guide vanes); b) a Francis spiral turbine (rotates on a horizontal axis and requires no fixed guide wheel); c) a Pelton wheel (an impulse water turbine in which specially shaped buckets attached to the periphery of a wheel are struck by a jet of water, the nozzle being either deflected or valve-controlled by a governor); d) "overshot" water wheels are now obsolete (low efficiency).

Water pressure resistant → Waterproof.

Water pressure test (hydrostatic head test). A method for testing water-repellent and waterproof finishes on textile fabrics (→ Burette test). The time taken for the first drops of water to penetrate through the material or the quantity of water which has passed through the material per unit time is measured. For the Schopper water pressure test, the following practical guidelines are useful: a textile material resistant to a water column pressure up to 20 cm is regarded as "showerproof", up to 50 cm as "rainproof" and resistant up to 1 h at 50 cm without any penetration of water as "waterproof".

Waterproof A term commonly applied to textile fabrics fully resistant to penetration by water (resistant to water pressure) and "completely impermeable" to air (i.e. the pores of the fabric are closed). Examples include oiled silk with an appropriate finish, ground sheets, tenting, tarpaulins, etc. This term must not be confused with the term → Water repellent.

Waterproofing The production of a → Water repellent finish (analogous to a waterproof or water pressure resistant finish) on a textile fabric. → Waterproof and water repellent finishes.

Water protection Embraces all measures necessary for the protection of surface and ground waters against harmful pollution. The German Water Resources Law (WHG – Wasserhaushaltsgesetz) was amended in 1986 (→ Waste water regulations) with a view towards introducing more stringent requirements for the protection of water as well as to safeguard future drinking water supplies. As a consequence of this amendment, direct polluters (as well as some indirect polluters) are now faced with much stricter demands in terms of the minimum requirements to be met for waste water discharges. If the receiving body, into which waste water is directly discharged, is also used for the abstraction of drinking water, a waste water management plan is prepared which can place even higher requirements on the direct polluters concerned.

The WHG was promulgated in 1957 to protect all surface waters and ground waters on a statutory basis for the first time. The WHG provides, so to speak, the rough outline for the codification of water legislation. First of all, the WHG contains an introductory clause setting out the scope of its application (§ 1). This is followed by general clauses relating to water courses (§ 1a–22: legal consents; old legislation; old utilization; compensation procedures; effluent disposal plans and effluent treatment plants; ground water preservation areas; pipelines; installations for the storage, bottling/packing and transhipment of water polluting substances; compensation; monitoring requirements; the designation of authorized persons with responsibility for water protection; and absolute liability). This is followed by special regulations for surface waters (§§ 23–32; licence-free usage; pollution control; upkeep and consolidation; flood areas), as well as special regulations for coastal waters (§§ 32a, 32b), special regulations for ground water (§§ 33–35), regulations for water management planning and the water account (§§ 36–37) and finally administrative fines and concluding clauses. (§§ 41–44).

According to § 2 of the WHG, the utilization of a water course requires an approval from the relevant authority (§ 7) or consent (§ 8). According to § 3 of the WHG, utilization includes abstraction from surface water courses as well as the discharge or introduction of substances into surface water courses. According to § 7a of the WHG, a permit for the discharge of effluent may only be granted if the quantity and pollution of the effluent are kept as low as possible. In order to give the requirements relating to the discharge of effluent a concrete form, the federal government has issued, with the agreement of the federal parliament, general administrative directives for specific industrial sectors setting out the minimum requirements for the discharge of effluent (e.g. the 38th general administrative regulation for the textile industry) (§ 7a WHG). Licencing as well as monitoring of the required discharge limits is undertaken by the authority responsible for the respective user. The licence is granted by the higher water authority (government president) for discharge quantities greater than 200 m^3/2 h, and by the lower water authority for discharge quantities les than 200 m^3/2 h. These minimum requirements are monitored by the national department for water management and waste disposal in the corresponding administrative district or the responsible department of the environment. In addition, § 21a WHG requires that users of water courses discharging more than 750 m^3 of waste water per day must appoint at least one authorized person (company employee) with responsibility for the protection of water courses. According to § 21b WHG, this person is under an obligation to monitor compliance with the directives, conditions and regulations in the interests of water protection, especially by the routine control of waste water treatment plants in terms of their functional integrity, proper operation as well as maintenance, by measuring the quantites and properties of the waste water discharged and by recording the results of such measurements and controls. This kind of self-monitoring is often carried out several times a year by an authorized body. If required by the Water Resources Law, plans for the management of water courses are drawn up by the German states (§ 1a) which take into account the various requirements for their utilization (management plans) (§ 36b). Such management plans are drawn up especially for those surface water courses to be used as water supplies. The uses to which a particular water course may be put, the characteristics which the water course must exhibit during its passage (e.g. water quality classes) and the measures necessary to realize the required objectives are laid down in the management plan. These management plans can also be declared mandatory for other authorities by state law.

The WHG is subject to continual amendment. The 5th Amendment, which is particularly concerned with improved water protection and therefore places greater emphasis on the interests of water ecology and stricter observance of water saving measures, came into force on 1.1.1987. Not all the changes introduced in the amendments to the WHG will be mentioned here. Only those changes which place much stricter requirements on the operation of effluent treatment plants and which particularly affect the discharge of effluent will be discussed in greater detail. The most important amendment in this regard is the change made to § 7a WHG. The communiqué of 16.10.1976 on § 7a lays down that effluents that contain polluting substances must be avoided according to the best technology available or must be treated properly before they are discharged into a water course (direct discharge) or into a public sewer (indirect discharge). The administrative regulations on minimum requirements likewise correspond to generally recognized standards of technology. The corresponding branch-specific administrative regulations are limited, as a rule, to just a few parameters which take account of the practical properties that have been protected. In the 5th Amendment of 25.6.1986 the WHG imposed considerably more stringent requirements with regard to the provisions of § 7a for limiting emissions. As before, the requirement for minimization exists, i.e. by keeping the pollutant load as low as possible. In addition, however, the regulation now makes a distinction between hazardous and other substances. The discharge of effluent containing hazardous substances is subject to increased requirements for their reduction in conformity with the general state-of-the-art as reflected in the administrative regulations. Effluent which only contains "other substances" is, by contrast, only subject (as before) to requirements for reduction directly in accordance with generally recognized standards of technology. In the new draft of § 7a, such noxious substances are defined as follows: "substances or substance groups which, because of concern as to their toxicity, persistence, bioaccumulation, or

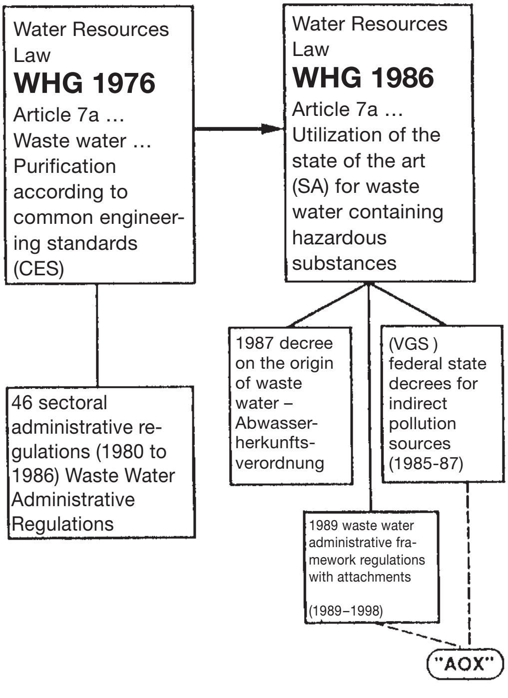

Fig.: Administrative regulations of the German Water Resources Law – Wasserhaushaltsgesetz (WHG).

which have a carcinogenic, fruit-damaging or genetically-mutational effect, are to be rated as hazardous". According to § 7a, the federal government has specified the sources of origin for effluents containing noxious substances in the Ordinance on Waste Water Origins of 3.7.1987 (which includes textile manufacturing and finishing). For branches of industry mentioned in the Ordinance on Waste Water Origins those requirements which, in the opinion of the federal government, can be met by current state-of-the-art procedures have been specified in concrete form within the General Administrative Ordinance on Minimum Requirements for the Framework Administration Regulation of Waste Waters (Rahmen-Abwasser VwV; see Fig.) and are contained in approx. 50 industry-specific annexes. "State-of-the-art" differs from best available technology with regard to the possibilities for reducing the presence of noxious substances with a sufficient degree of certainty by employing advanced, if not yet tried processes, installations or operating methods without involving excessive expenditure. A new development here is that limits for noxious substances have now been fixed not only for direct polluters but also for indirect polluters as well (and even for certain segregated effluent streams so that no dilution within a plant is possible). Individual states are allowed to modify the WHG, provided the result is not less stringent than federal law. It should be noted that state regulations differ slightly but all set specific threshold limits for concentrations and pollutant loads of noxious substances in effluents.

The legally binding 38th former General Administrative Regulation as well as the future 38th Annex to the Framework Administration Regulation of Waste Waters, which currently exists in draft form, apply to effluents discharged into water courses where the pollutant load originates essentially from the treatment or processing of yarns and fabrics and textile finishing. The requirements of the former 38th General Administrative Regulation have now been compared in tabular form with the new definitive requirements which will probably have to be met in future under the new General Administrative Ordinance (see Tab.).

A comparison of the minimum requirements for the discharge of effluent reveals that considerably more stringent limits have been laid down for almost all the parameters. In the requirements according to generally recognized standards of technology, which are only important for direct polluters, the limits for COD and BOD_5 have been virtually halved. In addition to the unchanged limit for ammonium nitrogen, a new limit for total phosphate and a specific denitrification has now been specified. The requirements according to state-of-the-art procedures (applicable to direct and, above all, indirect polluters), are now much more stringent compared to the Administrative Regulation of 1984 as far as the threshold limits for heavy metals are concerned. In addition to these, further limits have been introduced for other parameters (Sn, As, Hg, Cd, AOX, volatile halocarbons) and the colour of effluent is also subject to specified limits. When the future General Ordinance on Waste Water comes into force, the textile finishing industry will have to satisfy considerably higher requirements on the discharge of effluent and these will only be met by pollutant-specific effluent cleaning treatments or pretreatments.

Tab.: Consequences of amendment of the German waste water legislation for textile industry.

Water quality,

I. 1. Temperature: ground and surface waters in particular, as well as piped water to some extent, often exhibit considerable variations in temperature.

2. Chemical reaction: soft waters can be acidic in reaction to approx. pH 5 and hard waters may have an alkaline reaction up to approx. pH 8.

a. Numerous problems in textile wet processing are obviously dependent on other properties related to water composition.

b. All waters can have a corrosive action under certain circumstances: 1) an acidic reaction is mainly due to the presence of humus or other organic and inorganic acids such as carbonic acid (in air-free water), sulphuric acid (especially in swamp water), silicic acid and acidic surface corrosion. Results: formation of soft lime soaps on mortar and concrete foundations, strength losses, hazardous destruction, etc.; 2) a neutral reaction can also lead to the corrosion of metals and mortar building materials, especially in the case of chemically pure water. The presence of atmospheric oxygen causes typical pitting corrosion and is particularly dangerous in half-filled pipes and boilers; 3) an alkaline reaction can also cause metal corrosion under certain circumstances (high ammonia content).

3. Suspended solids (suspended matter):

a. Organic substances (humus products) of a more or less acidic character, various colloids with reducing properties provide favourable conditions for 1) dark-coloured precipitations in dyeing (from soaps, auxiliaries, mordants, dyes), stain-like deposits, dull cloudy dyeings; 2) troublesome precipitations in steam boilers and wall incrustations causing hot spots (accumulations of heat), etc.

b. Oils and greases (from condensate contamination with lubricants). These cause 1) spot-like stains in dyeing and defective dyeings; 2) corrosion of boiler plant and concrete foundations in normal operation due to breakdown into free fatty acids, even small quantities are dangerous (5–10 mg/l), including unsaponifiable mineral oils. There is a tendency to form thin heat-insulating protective layers on the inner walls of boilers (heat conductivity approx. 100 times less than steel); these deposits make boiler scale more impervious to water which results in local overheating, bulging, burst tubes, operational safety risks, etc.

4. Dissolved substances upset the equilibrium of H and OH ions in water and influence the mutual solubility of other dissolved or soluble substances. Consequences: the neutrality of the water usually changes in an acidic or alkaline direction, diverse chemical interactions take place depending on concentration and temperature. Dissolved components sometimes participate energetically and uncontrollably in numerous finishing processes as electrolytes. Dissolved substances also represent a corrosion factor as far as most metal installations and cement-concrete structures are concerned.

a. Water containing air with a high oxygen content can, under certain circumstances, interfere with reductive processes in textile dyeing and finishing due to the sensitivity of the latter to oxidation. Water containing air with a high proportion of chlorides, nitrates or free carbonic acid has lead-dissolving properties. In general, soft water (low in carbonates) with only 4 mg/l of oxygen has a detrimental effect on metal pipes up to approx. 7°d. On the other hand, water with a higher carbonate hardness and 9 mg/l oxygen usually has no detrimental effect. Water containing air is responsible for the much feared pitting corrosion in steam boilers and this has to be prevented by the deaeration of boiler feed water and/or the addition of oxygen scavengers.

b. Water containing free carbonic acid in different states: 1) totally bound carbonic acid (e.g. neutral carbonates such as calcium carbonate $CaCO_3$); 2) partially-bound carbonic acid (e.g. acid carbonates such as calcium bicarbonate $Ca(HCO_3)_2$); 3) free carbonic acid (i.e. not bound to a base, with up to 99% as the gas CO_2). Free carbonic acid serves to maintain the carbonate/water equilibrium. When water is heated, half of the carbonic acid which is present in readily soluble bicarbonates escapes as gas whilst the less soluble carbonates are partially precipitated. The free carbonic acid content rises with increasing temperature.

II. Water for textile dyeing and finishing must have a certain degree of purity if it is to be used as process water. The term ”water quality” is also used in an ecological sense. Even treated waste water which can be recycled for textile dyeing and finishing processes must meet certain water quality requirements if its constituents are not to interfere in various processes.

Element species analysis involves an analysis of the physical and chemical states of elements. The results of this analysis (Fig. 1) allow inferences to be drawn, e.g. on possible sedimentation processes or toxic effects towards aquatic organisms. Copper ions, for example, are considerably more toxic to algae as free metal ions than when they are bound in the form of stable organic copper complexes.

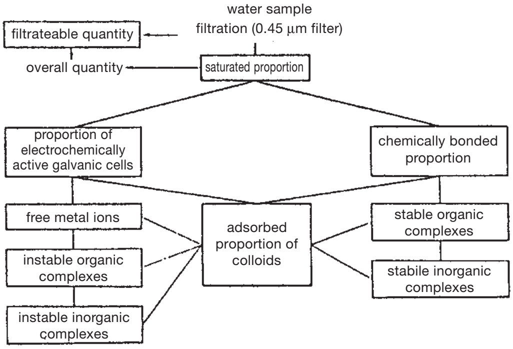

Fig. 1: Diagram enabling galvanic cell species analysis in water.

Water treatment (Fig. 2) or waste water treatment (Fig. 3) is necessary to improve the quality of water. A certain water quality is recommended for recycled waste water for use in dyeing and finishing processes after a cleaning treatment (Tab. 1).

The optimum condition of fresh process water for textile dyeing and finishing is reproduced in Tab. 2. Organic substances are found in surface waters particularly and may be present in a suspended or colloidally dissolved form after heavy rainfall as well as in fast flowing rivers.

The processes frequently used for the treatment of drinking water, e.g. the removal of iron and manganese by aeration, sand filtration or the removal of carbonic

acid by atomizing the water are usually insufficient for the treatment of surface water.

A well-proven process combination for the treatment of river water is the sludge contact process with subsequent sand filtration and the removal of residual hardness by neutral ion exchange.

In the so-called "accelerator" (Fig. 2) a number of processes take place alongside each other. On the one hand, carbonate hardness is precipitated out by the addition of calcium hydroxide according to the formula

$$Ca\,(HCO_3)_2 + Ca\,(OH)_2 \rightarrow 2\,CaCO_3 + 2\,H_2O$$

and partial softening also takes place. On the other hand, suspended organic matter is eliminated by the simultaneous addition of iron (III) chloride sulphate as a flocculant. By adjusting the pH to approx. 10, iron and manganese are precipitated out in the form of their hydroxides. Because of the large reactor volume (approx. 1000 m^3 for a maximum throughput of 800 m^3/h), the plant (Fig. 2) is relatively insensitive to changes in feed quantities and quality. After subsequent sand filtration, the iron content usually lies below the required 0.1 mg/l. Permanganate consumption is also reduced by about 30%. Since the water has an alkaline reaction due to the addition of lime, it is necessary to correct the pH by adding sulphuric acid.

Water treated in this way is optically clear and free of iron and colloidal impurities. This water can be used for cooling purposes and similar dyeing and finishing processes where residual hardness will not give rise to problems. For dyeing, however, the water must be fully softened in an additional ion-exchange treatment stage to obtain a residual hardness of < 0.1°d. As a rule, the water is sufficiently free of organic substances after sand filtration to feed into a full deionization plant. Feed water required for the operation of steam boilers represents approx. 5% of the total water consumption in textile dyeing and finishing.

Even before any process water is used for textile dyeing and finishing, considerable quantities of effluent and residues will already have accumulated during the treatment described above. The quantity of concentrated carbonate sludge from the carbonate hardness removal stage can indeed be just as high as the total quantity of industrial wastes accumulated in a textile plant. Moreover, a significant amount of polluted waste water results from the high salt load due to regeneration of the water softening or full deionization plant. Compared to the quantity of salt removed from the raw water, at least double this quantity accumulates in the effluent due to the salt load from regeneration.

From a waste water standpoint therefore, efforts directed towards the minimization of waste water and wastes should not only be concerned with the use of process water within the dyeing and finishing plant itself but should already begin at the raw water treatment stage. Examples here include the recycling of rinsing water from the sand filters into the accelerator as well as minimizing the consumption of regeneration agent by counter-current and coupled regeneration.

Water quality classification The condition of water is described by objective, measurable data based on chemical, physical and biological parameters, e.g. concentrations of substances, temperature, flow rate, biomass productivity, etc. The biocoenosis is always the result of the physical and chemical environmental conditions. The latter represent the origin of biological activity. The biocoenosis, for its part, can induce secondary changes in the physical and chemical environmental conditions; reactions and interactions always have a role to play here of course. In contrast to the condition of water as determined by objective measurable parameters, information concerning water quality involves subjective considerations. An effective condition of water is thus compared against a predetermined reference condition. Such reference conditions are based on the requirements placed on water courses for specific utilization objectives such as drinking water supplies, exploitation of certain types of fish or aesthetic considerations (bathing quality). The qualities of water courses are therefore dimensionless parameters (comparative values) compared to a reference condition at the same time. For this reason, water classifications are arbitrary gradations in accordance with a freely selected gradient of water qualities. Such classifications are not practically useful or capable of objective interpretation. Even the so-called water "quality" classes are hardly applicable as far as the totality of properties of a particular water course are concerned. Nevertheless, indicator organisms present in a water course can provide information on its saprobic state.

The determination of a so-called "saprobial index" is based on the observation that organisms whose development in water can take up to one year and longer, are constantly exposed to changes in their aquatic environment and can therefore provide an indication of the

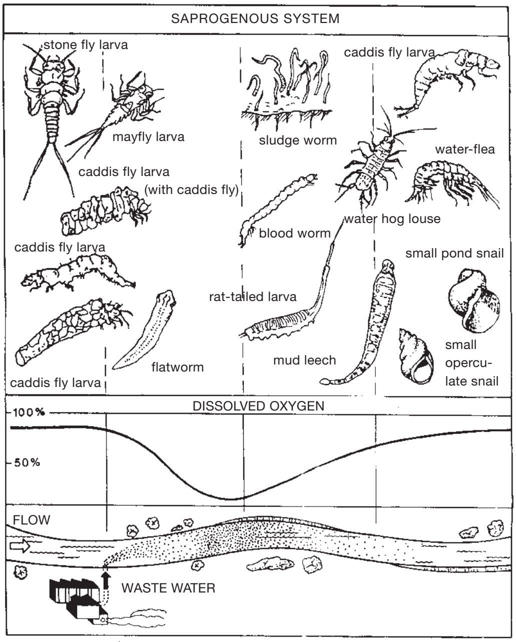

Fig.: Saprogenous system of a body of water before and after waste water discharge into an outfall.

integral condition of the water from only one sampling. The saprobial index describes a typical composition of microorganism species for a particular water course, especially e.g. animal and plant communities living on the bottom of rivers with a specific species diversity and biocoenosis composition. Depending on the degree of pollution, the number of living organisms which can be counted in a specific volume of water is reduced, thus providing a measure of the water quality in terms of its saprobial index (see Fig.).

The German → Water Resources Law describes water pollution from a different standpoint in terms of so-called water hazard classes:

Class 1: water containing unproblematic substances.

Class 2: water containing hazardous substances.

Class 3: water containing particularly hazardous substances (as well as all non-classified substances).

Water recycling Cooling water is unpolluted after use and can be re-used for production purposes. Machines which use cooling water must therefore be provided with the necessary peripheral equipment for recycling (Fig. 1).

Process liquors which have become depleted of essential components during dyeing (Fig. 2) or bleaching (Fig. 3) due to their affinity for the fibre can be replenished again after intermediate storage, e.g. during the rinsing stage, for re-use as starting liquors.

Water repellency test,

I. A severe test method for textiles with a hydrophobic (water repellent) finish. Procedure: a specimen of the textile fabric is lightly stretched over a wooden frame inclined at an angle of approx. 15° (attached to a glass plate with a rubber band if necessary) and placed 50 cm below the outlet of a dropping bottle. Water drops (previously adjusted to a rate of 100 drops/s) are allowed to fall on the same area of the textile specimen until a perceptible wetting occurs (as indicated by a darker colour in the wetted area). Good water repellent impregnations should be able to resist at least 20 of

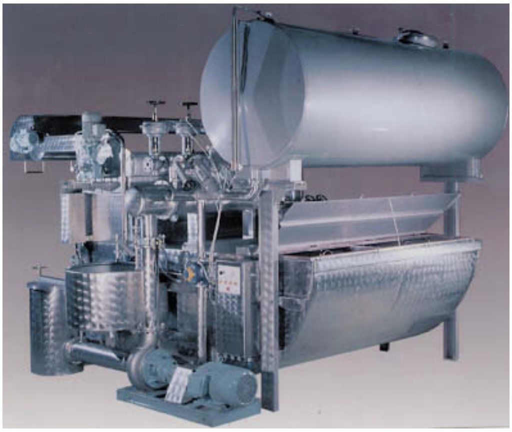

Fig. 2: Recovery (F.A.M.I.T. Ecoflow system) of exhausted polyamide carpet dye liquor in a high container, from which it is re-used as a new feed liquor.

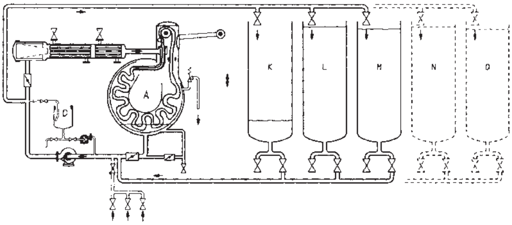

Fig. 3: Scholl Bleachstar: re-use of recycled bleach liquors.

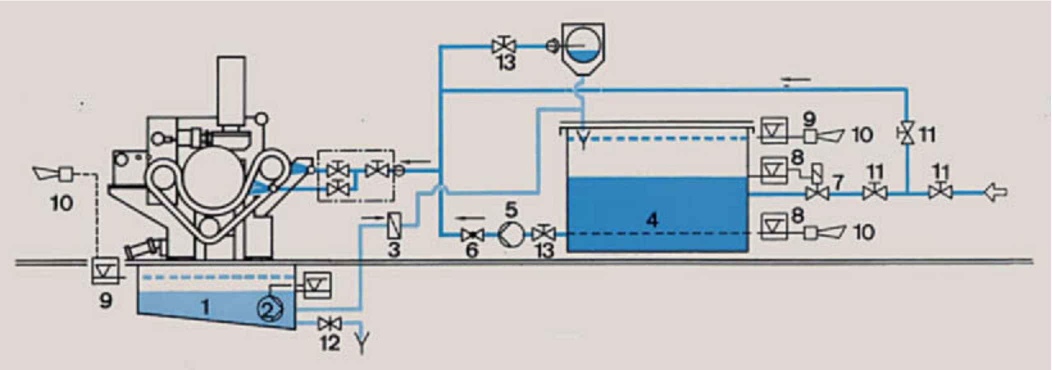

Fig. 1: Cold water recycling reduces water consumption, therby reducing production costs and it is also environmentally friendly (Monforts shrinker).

these drops without any wetting. Alternative: → Spray test.

II. This test method is used for the evaluation of water repellent and waterproof finishes. The test is based on the principle of subjecting a textile test specimen to the action of simulated rain with simultaneous rubbing on the underside of the fabric. The water repellency of the fabric is assessed by measuring the water absorption (%) and the quantity of water which has passed through it (simulated rain values). →: Pfersee-testing instrument; Hydrophobic finishes, evaluation of; Spray test.

Water-repellency testing The Bundesmann rain simulation tester is used to test the water repellency of textile fabrics. A provisional standardization of this test method was already in existence at the beginning of the 1950's and eventually led to the issue of German standard DIN 53 888 in 1965. This standard specifies the procedure for testing water repellent properties for evaluating the effectiveness of finishes intended to improve the water repellency of textile fabrics (Fig. 1). Already at the time of this standardization in Germany, an international standardization of this procedure was also under discussion in the International Standards Organization (ISO).

In order to simulate the action of rain drops, the Bundesmann tester uses a system of 300 identical jets with a drop surface of 4 mm in each case mounted above the centre of the test specimen surface at a height of 1500 mm. The size of the drops falling from the jets is constant and their volume is approx. 0.07 ml. The speed of the drops, and therefore the prescribed quantity of 100 ± 5 ml/min of simulated rain for an exposed surface area of 100 cm^2 is accurately adjusted by means of a pressure reducing valve (coupled to a manometer) built into the water supply line. A cleaning filter with exchangeable inserts is also built into the water supply line to retain mechanical impurities. A swivelling catchment tray mounted immediately underneath the water jets allows the flow of simulated rain to be interrupted immediately at the end of the specified exposure time.

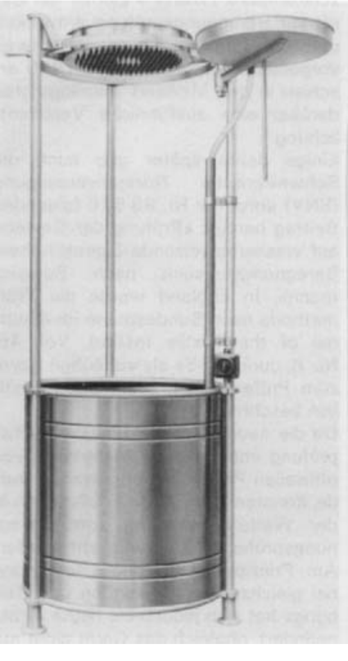

Fig. 1: Water-repellency tester, water-repellency device (according to Bundesmann).

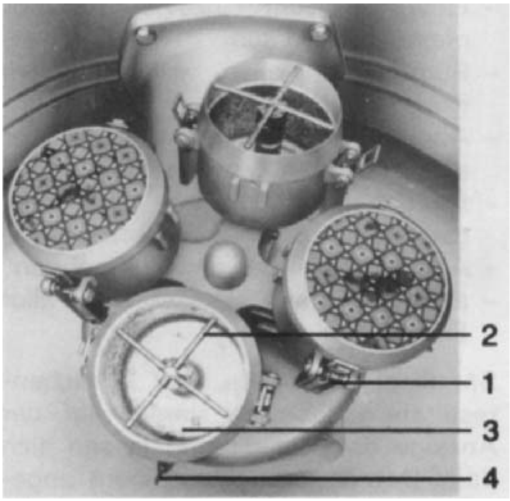

Fig. 2: BP2 water-repellency tester, gauge (according to Bundesmann). 1 = bevelled tension device; 2 = rotating cross-member; 3 = collecting cup; 4 = outlet tap.

During the discussions in ISO on the acceptability of the Bundesmann method, Great Britain proposed its own simulated rain test. However, it was not only the opinion of the German side that the Bundesmann method, which had been introduced a few decades ago, should be retained as the standard test method since specifications such as those for, e.g. uniform fabrics, were based on this well-proven method in many branches of the economy. After further deliberations and an international evaluation of the Bundesmann simulated rain test, ISO Sub-Committee 14 decided at a meeting in 1975 that this procedure should continue to be recommended in view of the fact that a large number of such testers were already in use worldwide and it represented the most reliable and comprehensive test method available. In order to obtain additional information on the suitability and limitations of the method, the Standards Committee NMP 514 ("Test Procedures for the Effect of Water on Textiles") decided in 1982 to carry out a comprehensive interlaboratory trial with the additional participation of several members of the German Association of Manufacturers of Textile and

Leather Auxiliaries, Tanning and Detergent Raw Materials (TEGEWA). According to the report of the Federal Institute for Material Testing in Berlin, the result of this trial justified the international standardization of the Bundesmann test method. This decision was made in relation to ISO Standard 4920 which was of only limited suitability for the evaluation of water repellent properties. The wide distribution of Bundesmann testers was also taken into consideration. International standardization of the Bundesmann method was a particularly useful development since experience had shown that other procedures used up to that time had often led to certain variations or errors (according to Bürlefinger).

An automatic and maintenance-free watertight encapsulated reversing drive is used to control the test head of the Bundesmann tester which can accept up to 4 fabric test specimens (Fig. 2). Each specimen holder on the test head consists of a bevelled tensioning device, a rotating cross-member which rubs against the underside of the test specimen and a collecting cup with an outlet tap. The test specimens are mounted on the cups by means of the bevelled tensioning device. During exposure to simulated rain, the test head rotates and the cross-member executes a to and fro rubbing action on the underside of the test specimen. Uniform pressure of the cross-member is ensured by counter weights. Water penetrating through the test specimen during the test is collected in the cup beneath and can be measured by opening the outlet tap.

Water repellent (hydrophobic). Water drops falling on to a water repellent textile fabric should run off the surface without wetting it. (→ Water repellency test). A water repellent effect suitable for rainwear, dress fabrics, bathing costumes, hosiery, etc. must, of necessity, have good → Air permeability and → Water vapour transmission properties in order to transport perspiration away from the body (see Fig). A "permanent" water repellent finish is resistant to washing and/or dry cleaning, or resistant to washing at the boil. In practice, "hydrophobic" has the same meaning as "water repellent" (→ Water repellent finishing). The term "water repellent" does not apply to water repellent finishes impervious to air since these are more correctly described as → Waterproof.

Fig.: Water droplets being repelled on a water repellent fabric (by Sulzer Rüti).

Water repellent finishes, effect on air permeability The influence of deformation due to swelling on the air permeability of cotton fabrics through the application of water repellants by padding is much greater than the influence of the water repellant product itself. The presence of a water repellant reduces the amount of swelling so that the air permeability is somewhat better than would be the case if the fabric had been padded with pure water alone. In order to reduce the influence of this swelling but nevertheless still be able to conduct comparative tests on various water repellants of importance for the production of hydrophobic finishes on woven cotton fabrics, a low swelling finish was first applied to a textile material followed by the water repellent finish. With this procedure, the silicone products tested here were found to improve the air permeability (compared to the fabric with a low swelling finish alone) by a maximum of 2.6%, whilst paraffin emulsions containing metal salts reduced it by a maximum of 3.4%. Fat-modified synthetic resins also reduced the air permeability by a maximum of 3.5%. Fluorocarbon resins can either somewhat reduce or increase the air permeability depending on the particular commercial product used.

The air permeability of a woven fabric is only influenced to an insignificant extent by the water repellant agent, compared to the considerable reduction in air permeability which results from the padding process. The swelling and deformation associated with the first padding process in particular reduces the air permeability considerably. If this application-specific reduction in air permeability is too great for a particular end use, then a different method of application, e.g. by spraying with less water or by using a solvent system with a lower swelling action must be employed or, alternatively, the fabric construction itself should be modified at the outset to provide higher air permeability. A low swelling finish also has the effect of causing a markedly lower reduction in air permeability (according to Schindler).

Water-repellent finishing Undesirable substances which become deposited on the surface of a textile during use or cleaning represent foreign matter. Textile finishes capable of repelling foreign matter directly from the surface of a textile fabric include (Fig. 2):

1. soil release finishes (effective dry).
2. oil-repellent finishes (effective dry).
3. water-repellent finishes (effective wet).
4. anti-soil-redeposition in washing (effective wet).

A distinction has therefore to be made between those

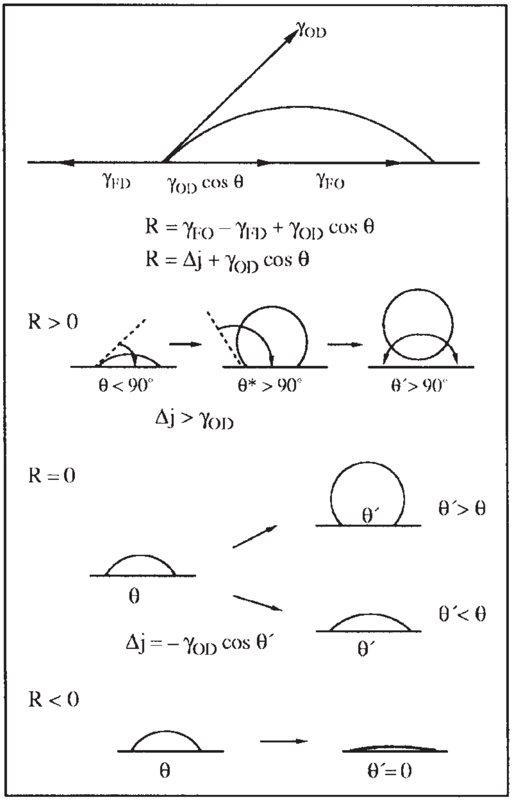

Fig. 1: Young's equation for quantitative representation of the wetting properties of fibre surfaces with liquids (oil or water).

Tab.: Connection between oil-repellency, water-repellency and stain removability.

finishes that are effective at the solid/gaseous (fabric/air) interface in the dry state and those which are effective at the solid/liquid (fabric/liquor) interface in the wet state (e.g. during washing). In this connection, it is necessary to distinguish between the terms lipophilic/lipophobic; oleophilic/oleophobic and hydrophilic/hydrophobic (see Tab.). Products with intermediate properties between these extremes, the surfactants, also have a role to play in water repellent and oil repellent finishes as well as hydrophilic and soil release finishes. Anti-soil finishes are applied to reduce or prevent the soiling of textiles in use. Synthetic fibres are particularly prone to soiling and, for this reason, special fibres capable of repelling soil have been developed for the carpet sector in particular. This development has proceeeded through the following stages:

1st generation: normal polyamide fibres.

2nd generation: soil-hiding fibres.

3rd generation: antistatic fibres.

4th generation: antistatic and fluorocarbon-finished (oil-repellent) fibres.

5th generation: a) 4th generation + stain blocker; b) 4th generation + fluorocarbon + stain blocker; c) fibres with built-in flurocarbons. Stain blockers are polymers which are applied to fibres in order to facilitate the removal of fruit juice stains on carpets (contain ascorbic acid, pH 2.8, so that they are able to exhaust on to polyamide like "acid dyes").

The lower the surface tension of a liquid compared to that of the fibre, the better it is able to spread on the fibre surface. This is expressed by the wetting angle θ. If water is to occupy a 1 cm^2 greater surface area, then work of $7.2 \cdot 10^{-6}$ J/cm^2 is necessary (surface tension). Fluorocarbon compounds and organosilicates have the unique property of reducing the critical surface tension of textile fibres (Fig. 3). If the surface of a textile is wetted (soiled) by a liquid then the liquid must have a lower surface tension than the finish. Consequently, polymers with a high fluorocarbon content are used for oil and water repellent effects and organosilicates for dry soil repellency. Young's equation for surface wettability (Fig. 1) shows how the surface energy of the liquid γ_{OD}, the surface tension (surface work γ_{FO}) and the surface energy of the solid γ_{FD} stand in relation to one another. Spreading occurs if $R < 0$; whereas for repulsion it is necessary for $R > 0$.

The surface energy of a solid material can be considerably reduced by the introduction of fluorocarbon groups which makes the wettability of its surface repel

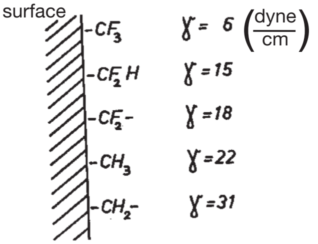

Fig. 3: Effect of fluoride compounds on critical surface tension (dyne/cm = 10^{-3} N/m).

liquids, having a greater surface energy. Conversely, the surface of a fibre can also be modified in such a way that it becomes very accessible to water (water spreads and the material is highly hydrophilic).

Depending on the particular end use of a textile fabric, it may be given either a fully water-impermeable finish (i.e. resistant to water pressure) or a water repellent finish only. In the latter case, the aim is to achieve a substantial water repellent effect together with permeability to air and water vapour. In principle, all these processes are based on the deposition of water repellent and water-insoluble substances on the fibre (Fig. 4). Complete impermeability to water may be achieved by coating. The type of weave and the quality of yarns used in a textile fabric have a considerable influence on the finish.

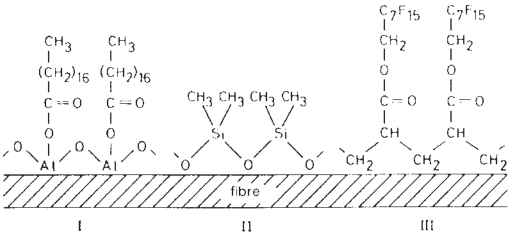

Fig. 4: Arrangement of the various water-repellent finishing auxiliaries on the fibre surface.
I = aluminium salt/paraffin emulsion; II = dimethylpolysiloxane; III = fluorocarbon polymer.

1. Waterproof (water pressure resistant) finishes: these are used for tentings, tarpaulins and other articles. In this case, the interstices of a woven fabric are filled in by the waterproofing agent and the pores closed with the result that air permeability is lost. Fabrics treated in this way, which must be capable of withstanding a water column pressure greater than 1000 mm before penetration with a few drops of water takes place, are no longer “breathable”. In most cases, the handle of fabrics treated in this way is also greatly affected (stiffening). All these finishes must bond firmly with the fabric and should not flake off or crack on bending.

2. Water-repellent or porous water-repellent finishes: these are used for outerwear articles. Such fabrics must have good permeability to air and water vapour after finishing and the products used must not irritate the skin. Suitable polymer products which are impermeable to water yet permeable to water vapour are available. Residues of surface active auxiliaries used in pretreatment can severely impair the water repellent effect in finishing. If possible, therefore, only those surfactants which can be readily washed out should be used in washing treatments. Silicone and fluorocarbon products react more sensitively to residues of anionic auxiliaries than aluminium/paraffin wax finishes, which react more to non-ionic auxiliaries. Three main methods are used for the production of water-repellent finishes:

a) deposition of water repellent agents on the fibre by purely mechanical means. The durability of the effects to washing varies.
b) chemical reaction between hydrophobic substances and the fibre. These effects are durable to washing.
c) formation of water-repellent films on the fibre. These effects are also durable to washing.

Method a) involves the application of salts: the sequence of operations begins by impregnating the textile in a soap solution into which paraffin or wax has also been emulsified. Drying and subsequent impregnation with aluminium formate or acetate solution is possible for the production of a water-repellent finish. However, the single-bath method with stable emulsions of paraffin, waxes and aluminium or zirconium salts is mainly used nowadays. Some of these products also contain glue. By substituting the aluminium salt with a zirconium salt, water repellent impregnations with relatively good durability to washing are obtained. The drying temperature for all these methods after impregnation should be as high as possible so that product migration to the surface of the material can take place.

Method b) which involves chemical reaction with the fibre gives even better durability to washing through esterification or etherification of the cellulose with water repellent auxiliaries of the following types:

- cationic fatty acid derivatives with affinity for the fibre,
- fatty acid derivatives containing metals,
- fat-modified synthetic resins.

The “Inflos” process, which was based on the application of fatty acid chlorides from organic solvents, may be mentioned as the first process of this kind. However, it was not developed commercially for economic reasons. These products only achieved practical significance, in fact, after it became possible to apply them as aqueous emulsions. A textile fabric is impregnated with an emulsion of one of these products on the padder, dried, then subjected to a heat treatment and, if necessary, afterwashed. Another process uses isopropenyl stearate with an acid catalyst. The reaction takes place in a few seconds in hot air at 180°C.

Method c) involves the application of polymers: film-forming products are used for synthetic fibres. Silicones and fluorocarbon derivatives form the basis of such products which are, of course, not only suitable for synthetic fibres but may also be applied to natural fibres. Polysiloxane products, together with fatty acid-modified aminoplasts or epoxy resins to increase their impermeability to water, are applied to cellulosic fibres with melamine precondensates or reactant resins. These water repellent finishes suffer from the disadvantage that the fastness of dyeings, e.g. the colour fastness to light and rubbing, is reduced. Moreover, the finished fabrics are prone to "chalking", i.e. when the fabric is stroked with the finger a lighter stripe remains on the surface. This problem may be remedied by post-calendering. Special products are available for solvent application. Silicones are mainly used (Fig. 5), especially if their elastomer characteristics are an important factor. A special field of application for a water-repellent finish is the application of fluorocarbon compounds to bullet-proof vests. The resistance of woven Twaron fabrics (a highly aromatic polyamide fibre) to penetration by bullets is increased by the application of such a finish since the exclusion of water as a lubricant allows bullets to be intercepted more effectively.

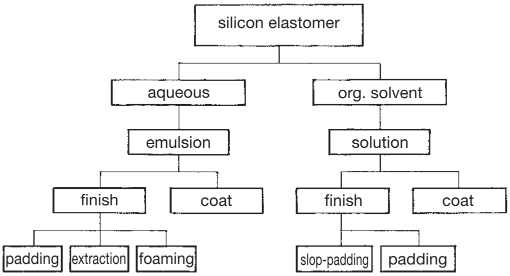

Fig. 5: Silicon elastomer application possibilities for water-repellent finishing.

Evaluation (Fig. 6): a subjective assessment of water repellency is possible by means of the Spray Test AATCC 22-1952 (highest rating 100; for ratings 90–0 the increase in wettability is assessed by comparison against a rating chart). In the 3M Test for the subjective determination of oil repellency, the ratio of paraffin oil and n-heptane which allows oil to penetrate through a finished fabric is evaluated. The highest possible rating corresponds to a proportion of 0 parts paraffin oil (by volume) and a proportion of 100 parts heptane (by volume). For a rating of 0, pure paraffin oil penetrates through the fabric.

Water-repellent finishing auxiliaries Water repellents (see Tab.) are used for → Water repellent textile finishes and consist, as a rule, of paraffin wax emulsions with aluminium or zirconium salts. For water repellent effects with a particularly high durability to washing, however, preparations containing quaternary organic compounds or urea derivatives, fatty acid mod-

ified melamine resins, chromium complex salts as well as silicones are used. They are applied either as aqueous dispersions or from organic solvents. Impregnating agents are used for → Waterproof textile finishes. For this purpose, metallic soaps, based mainly on aluminium or zirconium salts are used in combination with fats, waxes, resins and inorganic fillers. In addition, pore-closing water-insoluble plastics and mixtures of plastics are used which may be applied as aqueous dispersions or from organic solvents.

Water requirements for dyeing and finishing As minimum requirements for dyeing and finishing, a suitable process water must be absolutely clear and transparent, colourless, neutral and as soft as possible. Specific requirements also include freedom from iron, manganese, lead, zinc, tin salts, and especially the absence of nitrates and nitrites as well as a low electrolyte (salt) content.

Water requirements for steam boilers Minimum requirements for boiler feed water include the absence of oil and suspended solids (foaming, spitting, corrosion) as well as the absence of atmospheric oxygen and free carbonic acid (corrosion) and a minimum alkalinity (mg/l caustic soda for water with a low salt content = sodium hydroxide 200–500, for feed water with no phosphate content = 400–2000, for feed water containing phosphates = 100–400). Further requirements include: the lowest possible salt content (test at 15–20°C, 1°Bé = 1000 g salt/m^3) especially salts which form precipitates in the boiler (water hardness salts), low carbonate content (10 mg/l), low content of sulphates and especially silicates, as well as the presence of an excess of hardness precipitating agents (in mg/l = sodium carbonate 50–100, NaOH 20–40, trisodium phosphate 26–120), with no final softening reaction in the boiler if possible.

Boiler feed water specifications differ according to steam pressure ratings as well as the use of continuous or forced circulation steam boilers. This provides the basis to make the most appropriate choice of make-up water treatment, condensate treatment and chemical conditioning from the many variants available. Feed water specifications differ, above all, depending on whether salt-free or salt-containing water is used and whether an alkaline or neutral procedure is applied. Combined processes may also be adopted without objection.

In the feed water specifications for forced circulation boilers, the graduation according to pressure ratings predominates. The type of conditioning required to achieve a pH between 11–12 at pressures up to 5.3 MPa or a pH between 9.5–10.5 at operating pressures > 5.3 MPa is open to choice. The guidelines also take into account whether salt-free or water containing salt is fed to the boiler. With salt-free water, volatile alkaline agents can be used exclusively with limited boiler water conductivity, or a neutral procedure (by adjusting the pH to 7–8 with NaOH) can be followed in addition to the combined application of solid and volatile alkaline agents. In all these guidelines, boiler water conductivity and silicic acid content are given in relation to the pressure ratings. Finally, the necessary steam quality is decided by the requirements placed on the feed water. If attention is paid to deposition problems in the boiler superheater, separate specifications for saturated steam and fresh steam are necessary.

Water Resources Law The Water Resources Law (Wasserhaushaltsgesetz – WHG) of 27.7.1957 which came into force in Germany from 1.3.1960 in accordance with the statutory provisions of Article 75, Clause 4 of the German Constitution controls, with the aid of appropriate amendments, the abstraction, exploitation and drawing of water as well as the cleaning and treatment of effluents within the Federal Republic, in addition to the water legislation of the individual German states. Extract: the use of a water course is subject to the permission or consent of the authorities. Water courses include surface waters, coastal waters and ground water.

I. Pollution control (§ 26):

1. Solid substances must not be introduced into water courses for the purpose of disposal. Substances in the form of sludges or slurries do not count as solid substances.
2. Substances may only be stored or deposited in a water course provided no pollution of the water or other detrimental change in its properties is to be expected. This also applies to pipelines for the transportation of liquids and gases.
3. Whosoever introduces substances into a water course causing harm to the water is obliged to pay compensation for the damage incurred.

II. Biodegradability of detergents (→ Biodegradation of surfactants):

1. § 1: anionic detergents in washing and cleaning agents must be at least 80% biodegradable.
2. § 2: the biodegradability must be determined in accordance with specified measuring procedures.

III. Detergents law (law on detergents and cleaning agents): this law governs the manufacture of → Detergents and their biodegradability (in force since 6.9.1961).

An appendix has been allocated in the WHG to all sectors of industry. Appendix 38 applies specifically to textile finishing. In the new draft of this appendix (1991) more stringent threshold limits have been imposed on textile manufacture resp. finishing. As before, chemical oxygen demand (COD) remains an important parameter to determine the pollution load of effluents due to the presence of oxidizable and mainly organic substances. The pollution load of the water may be estimated from the oxygen consumption of a strong oxidizing agent. The biological oxygen demand (BOD) on the other hand provides an indication of the oxygen consumption to be expected in a waste water treatment plant. The oxygen consumption is determined by inoculating the effluent under test with water that contains microorganisms. The relationship of COD to BOD is dealt with in more detail in Appendix 38.

The colour of effluents must not exceed certain specified intensities. For the determination of colour, a distinction is made between the yellow, red and blue regions of the spectrum and precisely defined wavelengths have been allocated in each case. The intensity is expressed in terms of the spectral absorption coefficient. The requirements placed on the pollution of segregated waste water streams are also given prominence (→ Segregated stream). Segregated streams are effluents from individual production units or individual finishing stages and arise from the following processes in particular:

- desizing,
- bleaching,
- dyeing,
- printing,
- finishing,
- coating or laminating,
- centralized cleaning of drums and containers.

The definition of segregated effluent streams in the textile industry is difficult. Although the further difficulty arises that processes for segregated stream disposal cannot yet be described as state-of-the-art, certain threshold limits have been stipulated, e.g. for hydrocarbons and chromium. Provided the concentrations fall below these limits, a segregated stream treatment is not required. Special regulations also apply to the handling of residual liquors. →: Waste water regulations; Legislation on environmental protection; Water-endangering substances.

Water retention → Moisture behaviour of fibres and yarns.

Water retention in organic solvents The water retention capacity of organic solvents, e.g. in dry cleaning with dry cleaning detergents. The water retention is the quantity of water remaining in the solvent (expressed as a percentage of the quantity used in each case) after 30 min at 20°C. In addition to time and temperature, it is also dependent on a) the type of dry cleaning detergent used; b) the concentration of dry cleaning detergent; c) the type of textile material; d) the water content of the solvent and e) the type of solvent. The textile fibre absorbs virtually no dry cleaning detergent in regions of high water retention; in regions of low water retention, a certain quantity of dry cleaning detergent goes on to the fibre together with the water. Thus, the undesired absorption of dry cleaning detergent by textile materials is dependent on water retention in the solvent.

Water retention of fibres → Moisture behaviour of fibres and yarns.

Water ring vacuum pump A → Liquid ring vacuum pump which uses water as the operating liquid (see Fig.).

Water rollers (starch rollers). In multicolour roller printing, a plain unengraved roller fed from a colour box containing thickened water, e.g. a thin starch paste (hence the alternative term "starch roller"), which is usually positioned in the machine between two engraved rollers printing contrasting colours. Its function is to remove surplus printing paste from the printed fabric in order to minimise contamination of a subsequent engraved printing roller by a colour paste carried over from the previous printing roller. Like the printing rollers, a water roller is also provided with doctor blades.

Water separator In dry cleaning machines, a water separator is a container which may be of variable construction, used for the physical separation of solvent from the cooling and condensed water. The solvent/water mixture carried over by the water has three sources:

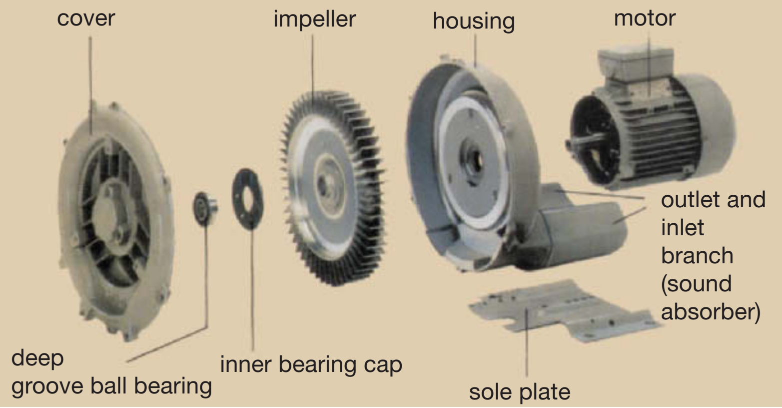

Fig.: Individual parts of an Elmo-G vacuum pump; the impeller rotates friction-free in the housing.

I. From distillation: under favourable circumstances the solvent/water mixture evaporates at the azeotropic boiling point, i.e. evaporation takes place simultaneously at 87.1°C and 1013 mbar = 81.4 (76.5)% tetrachloroethene + 15.9 (23.5)% water (figures in brackets = vol.%).

II. From the drying stage due to the action of blowing warm air through the goods whereby water + tetrachloroethene integrated into the absorbed moisture reaches the cooler as a water/tetrachloroethene mixture.

III. By regeneration of the activated carbon bed during solvent recovery whereby tetrachloroethene deposited on the activated carbon is stripped off with steam and, after condensation in the recooling system, accumulates in the water as a water/tetrachloroethene mixture.

In each case, the water/tetrachloroethene mixture must be cooled, usually in the recooling system, where water runs to the cooling mixture on the countercurrent principle. A complete separation should take place at the critical point.

Conditions for good water separation:

1. The solvent should be at as low a temperature as possible (up to 20°C). In conventional water separators, the temperature range lies between 20–30°C. Under these conditions, 1 kg water takes up 0.16–0.17 g tetrachloroethene. Conversely, the water content in 1 kg tetrachloroethene is 0.072–0.110 g (Tab.).

temperature [°C]	tetrachloroethene in water [mg/l]	water in tetrachloroethene [mg/kg]	water in tetrachloroethene [mg/l]
0	150	40	64
10	160	50	80
20	160	72	115
30	170	110	176
40	180	140	224
50	190	190	304
60	210	250	400
70	224	340	544

Tab.: Effect of temperature on the miscibility of water and tetrachloroethene.

2. The higher the water temperature, the longer it takes for the mixture to separate; the usual dwell time is approx. 10 min.
3. Contact surfaces between the already separated media should be kept as small as possible. Conical constructions, or those provided with a siphon, make it easier for the tetrachloroethene, distributed in the water as droplets, to sink to the bottom and encourage the less dense water to float above it.

Water softening The removal of "hardness" mainly due to calcium and magnesium ions → Water hardness salts. → Water softening processes.

Water softening agents The function of these products is to eliminate the harmful effects of → Water hardness salts and other metal salts by complex formation (use of appropriate sequestering agents). Suitable products are based on salts of polycarboxylic acids, polyphosphates or preparations containing these agents. Such water softening agents are used in all fields of textile dyeing and finishing.

Water softening auxiliaries These additives are only able to assist the water softening process. Such methods are used especially in (outmoded) treatments for water softening by small textile plants with a) soda ash: addition of 2 g per degree of hardness per 100 l, followed by bringing to the boil and skimming off the precipitate formed; b) acetic (or formic) acid: only used to overcome (temporary) carbonate hardness, e.g. by addition of acetic acid 8°Bé = 4.64 g for each 1°d per 100 l. Sulphuric and hydrochloric acids have also been recommended for this purpose (cheaper) but must be added carefully in portions (either alone or combination) where appropriate; c) → Water softening agents, capable of sequestering calcium and magnesium ions, offer a more favourable working pH as well as other advantages in textile wet finishing processes.

Water softening by hydrogen exchange A water softening process based on the principle of desalination by a hydrogen ion exchange process (→ Ion exchanger). With this method, e.g. hydrogen takes the place of a calcium hardness salt. If a neutral exchanger is then used downstream in order to remove the free acid formed at the same time, a softened water results which is free of carbonate hardness.

Water-softening by inactivating additions (hardness binding processes). These processes are based on the chemical inactivation of water hardness salts and other metals (in order to make them harmless) by means of inorganic or organic → Complexing agents (→ Water softening agents) by direct addition to the water.

For water softening purposes, a distinction is made between these products with a sequestering action, and those water softening agents which actually remove water hardness salts from the water.

Water softening processes For the removal of → Water hardness salts.

I. Cultonex process with milk of lime or lime water. In this process, the water hardness is brought down to 2–4°d by stoichiometric dosing.

II. → Lime-soda water softening process with high carbonate and non-carbonate hardness. This process brings the water hardness down to 1–2°d.

III. Soda regeneration process, used specifically for non-carbonate hardness (boiler feed water).

IV. → Trisodium phosphate water softening process: the addition of trisodium phosphate produces a floccular sludge. Water is softened to 0.1°d by this method.

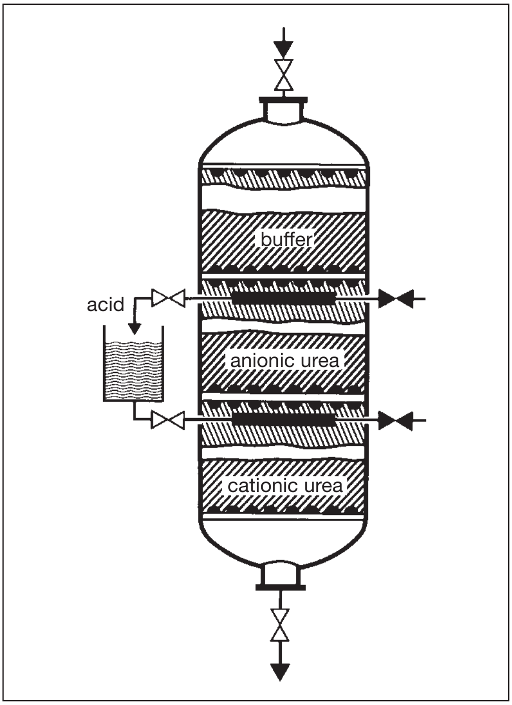

Fig.: Continuous water softener by means of ion-exchange.

V. Baryta process for water with a high non-carbonate hardness (sulphur oxide), residual hardness 1–2°d.

VI. → Ion-exchange processes for complete water softening (Fig.).

Water solubility limit Pure water is a poor conductor of electrical current. Conductivity is, of course, dependent on the degree of dissociation, i.e. on the formation of reactive ions. The addition of certain salts/acids/bases (electrolytes) brings about a considerable increase in conductivity due to electrolytic dissociation. Ionic reactions are some of the most important of all chemical processes (because of their speed). The presence of dissolved substances is of considerable importance in this regard. All solubility processes are temperature-dependent, however, and are also usually influenced by the presence of salts with like ions (e.g. the reverse displacement solubility of calcium chloride by calcium sulphate, or sodium chloride by magnesium chloride) to a greater extent than with salts having unlike ions (= increased solubility, e.g. sodium chloride by magnesium sulphate) and a heat of solution is generated (dependent on concentration). The freezing point, boiling point and vapour pressure of water change in the presence of dissolved salts and other substances (elevation of boiling point and depression of freezing point) so that evaporation leads to concentration and often results in a corresponding increase of activity as well.

Water sorption → Sorption.

Water spotting fastness (colour fastness to water spotting). The resistance of dyeings and prints to spotting with distilled, condensed or rain water. The test guidelines apply to all types of fibres. A few drops of distilled water are worked into the test specimen with a glass rod. Assessment a) after 2 min (wet); b) after drying in air. Results are assessed with the grey scale for change in colour.

Water spotting resistance Resistance of fabrics mainly composed of bright viscose filaments to water spotting which can otherwise cause localized changes in lustre or shade variations in unfinished material (i.e. without a water repellent finish). Such shade variations can be largely attributed to a change in the structure of the fabric surface due to localized swelling which changes the light reflection from the affected area. This has unfortunate consequences in practice since is often difficult or no longer possible to remedy the discoloration by subsequent ironing. Satisfactory resistance to water spotting can be achieved by applying a preventative combination finish, i.e. synthetic resin plus a water repellant. → Water spotting fastness.

Water sprinkling apparatus Pfersee (Bundesmann method). The Bundesmann rain simulation tester is used for the precise evaluation of water repellent impregnations on textiles and offers a high degree of reproducibility. The principle employed in this test method is based on subjecting test specimens to a simulated rain shower falling from a specified height over a specified time. As the test specimens circulate under the shower of water, special wipers consisting of rotating cross members with 4 arms inside the bezels of the cups rub the undersides of the specimens in order to reproduce mechanically the rubbing action which occurs in practice when, e.g. a raincoat is worn. The test is therefore designed to simulate exposure to practical conditions as closely as possible. The Bundesmann tester consists of a multi-nozzle drop producer (atomizing jets with drop forming rods), 4 cups which are covered by textile fabric specimens under slight tension (allows the simultaneous testing of 4 test specimens) and the necessary drive gear. A test exposure of 10 min duration corresponds to the quantity of rain falling as natural rain in 18 h or in a cloudburst in 1 h. The test determines a) the % water uptake of the fabric, b) the quantity of water passing through the fabric in ml during the specified exposure time and c) a visual comparison of the water repellent effect against photographic standards. Manuf.: Pfersee; Erhardt-Leimer.

Water storage reservoir for fire extinguishing In order to prevent environmental pollution due to the contamination of nearby water receiving bodies or water courses by water used for extinguishing chemical fires, it may be necessary to block off certain areas of an industrial plant, depending on the type of chemicals

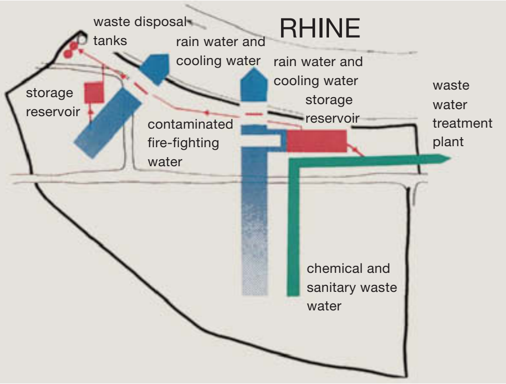

Fig.: Design of water storage reservoir from fire extinguishers in the Sandoz plant, Muttenz.

used in the production processes, and dispose of the contaminated firefighting water within these confined areas in dedicated storage reservoirs (see Fig.).

By means of such dams, contaminated firefighting water can be retained in the drainage system and diverted to a dedicated storage reservoir. Depending on the degree of pollution, it can be subsequently transported to a waste water treatment plant for cleaning or pumped into a disposal tank for intermediate storage.

Water tap test An imprecise test method for water repellent impregnations on (flat) textile fabrics. Procedure: the fabric to be tested is held under slight tension, tilted at an angle, and held approx. 50 cm beneath a water tap where it is subjected to a fine stream of water in one area for approx. 30 s. A good water repellent impregnation should be resistant to wetting under these conditions (wetted areas on dyed or printed goods appear darker).

Water treatment process A distinction is made between processes for the treatment of drinking water and processes for the treatment of industrial water. →: Waste water; Waste water treatment plants.

Water vapour Molecules close to the surface of water can escape from the liquid provided their kinetic energy is sufficient to overcome the forces of attraction. These molecules then pass into the gas phase above the liquid. During this process, the average kinetic energy of the remaining molecules is reduced and the liquid water gives up heat (latent heat of evaporation). This process of evaporation therefore causes cooling (→ Vapour pressure).

Heating causes the temperature of liquid water to increase at first and is accompanied by a slight increase in volume (Fig. 1: transition from state 1 to state 2). On reaching the boiling point evaporation begins. Energy supplied in the form of heat is only used to convert liquid water into the vapour state and the temperature remains constant (Fig. 1: transition from state 2 to state 3) whilst the specific volume is drastically increased. The mixture of boiling liquid and saturated steam is known as wet steam (→ Steam). Only after all the liquid water has evaporated does the temperature of the saturated steam rise to the temperature of superheated steam (Fig. 1: transition from state 4 to state 5).

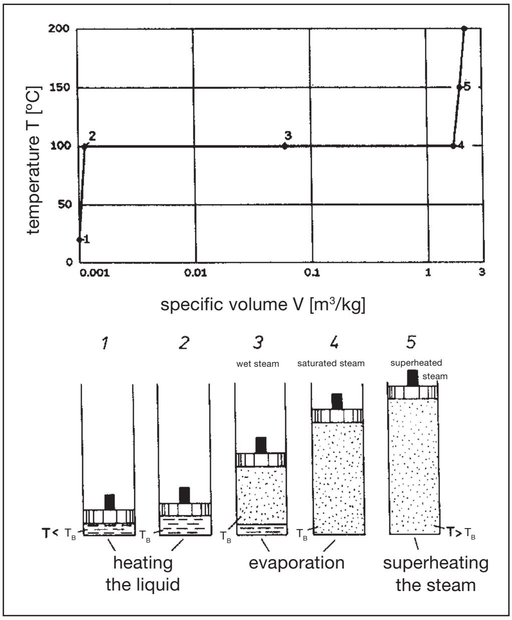

Fig. 1: Evaporation process at a constant pressure of p = 1 bar. T_S = boiling temperature.

The pressure exerted by the evaporated molecules, e.g. against the walls of a vessel, or against the atmospheric pressure, is called the vapour pressure. The energy required to evaporate one mol of a liquid at a specific temperature is called the molar heat of evaporation or evaporation enthalpy (for p = a constant). The relationship between the boiling pressure p_s and the boiling temperature T_s is unambiguous and is described by the vapour pressure curve. The energy required to evaporate 1 kg of liquid at constant pressure is called the evaporation enthalpy Δh_v or the heat of evaporation r. Like the boiling temperature, the evaporation enthalpy is pressure-dependent.

The saturated steam temperature T_s and evaporation enthalpy Δh_v are represented in Fig. 2 as a function of the saturated steam pressure p_s for water. As an example, saturated steam at a pressure of 10 bar has a saturated steam temperature of 179.88°C and an evaporation enthalpy of 2013.6 kJ/kg (→ Water as finishing medium).

Water vapour

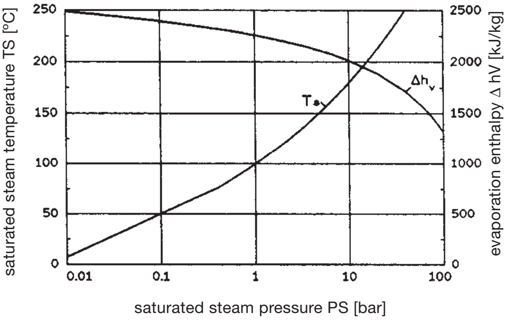

Fig. 2: Saturated steam temperature and evaporation enthalpy.

The opposite process to evaporation is called condensation. In this case, the steam gives up energy, especially the evaporation enthalpy. This principle finds application, e.g. in the indirect heating of a convection drier by means of a steam/air heat exchanger.

When steam condenses (becomes compressed) to the liquid phase, a numerically equal quantity of heat is released. This is called condensation enthalpy (for p = a constant). The higher the concentration of molecules in the gas phase, the more frequently they collide with each other, come into contact with the surface of the liquid phase, and are captured by it. In a state of equilibrium, as many molecules leave the liquid per unit time as condense again. The concentration of molecules in the gas phase (steam space) is constant. The gas pressure of the evaporating liquid is then called the saturation vapour pressure (i.e. the vapour pressure of a vapour in contact with its liquid form).

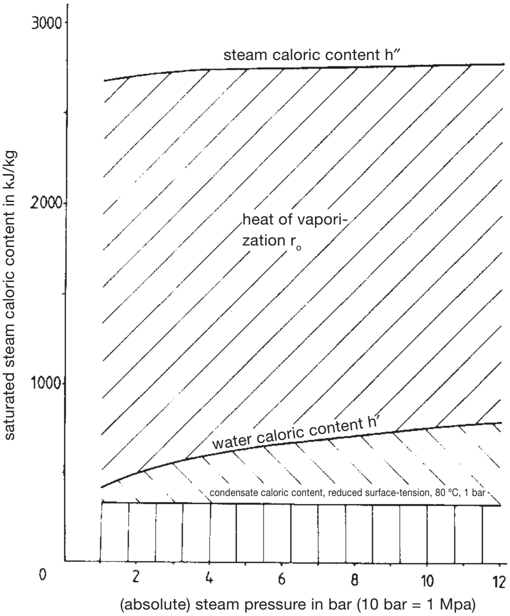

Fig. 3: Saturated steam caloric content, depending on steam pressure.

Water vapour is a true gas (Fig. 3). At low pressures and high temperatures, steam approximates the state of an ideal gas. The more superheated a gas, the more it behaves like an ideal gas. For an isothermal change of state in a closed system, which proceeds at the given temperature T then, according to the second law of thermodynamics, the increase in entropy S of the system is given by:

$$\Delta S = \frac{Q_{rev}}{T} \quad \text{(reversible isothermal processes)}$$

$$\Delta S = \frac{Q_{irr}}{T} \quad \text{(irreversible isothermal processes)}$$

In the above equations, T is the absolute temperature of the system and Q is the heat supplied to the system from its surroundings. If the initial and final states are known one considers, for example, a particular chemical reaction proceeding in accordance with a formula conversion at given values of temperature T and pressure p, then ΔS has a specific value irrespective of whether the reaction proceeds reversibly or irreversibly since S is a state function. The heat Q, on the other hand, is not a state function: it has different values depending on whether a process proceeds reversibly, or irreversibly. This is made clear by the index "rev" or "irr" for Q. For an isothermal process, ΔS can be positive as well as negative. The entropy in such a process can therefore decrease as well. For any processes in closed systems, the first law of thermodynamics requires that:

$$\Delta U = 0 \quad \text{(law of energy conservation)}$$
$$\Delta U = Q + W$$

where U is the internal energy, ΔU the increase in internal energy of the system, and W is the energy performed on the system. A negative value of Q or W means that heat is given up by the system to its surroundings or that work is performed by the system. If the process proceeds under isobaric conditions, i.e. at a constant pressure p, then the reversible volume work supplied to the system is represented by –pΔV, where ΔV signifies the increase in volume of the system. If the work performed on the system is designated W', then as long as it does not exist in the volume work, for an isobaric change of state, the enthalpy H (= U + pV) of a closed system is given by:

$$\Delta H = \Delta U + p\Delta V = Q + W' \quad \text{(isobaric processes)}$$

If the free enthalpy G (= H – TS) of the system is now introduced, then for an isothermal-isobaric change of state in closed systems it follows that:

$$\Delta G = \Delta H - T\Delta S = Q + W' - T\Delta S$$
$$\text{(isothermal-isobaric processes)}$$

By observing the relationship for ΔS, it also follows that:

$\Delta G = W'_{rev}$ (reversible isothermal-isobaric processes)
$\Delta G < W'_{irr}$ (irreversible isothermal-isobaric processes)

Since G (like U, H and S) is a state function (unlike Q, W and W'), the variable ΔG always has the same value for a given initial state and a given final state, irrespective of whether the change of state takes place reversibly or irreversibly. If, therefore, a certain change of state proceeds at a given temperature and given pressure in such a way that work W' can be performed by the system ($W' < 0$, $\Delta G < 0$), e.g. in the form of electrical work, then the work ($-W'_{rev}$) gained in a reversible performance of the process (performed by the system) must be greater than the work gained during an irreversible performance of the process. For this reason, the variable $-W'_{rev} = -\Delta G$ (T,p = a constant) is also called the "maximum effective work".

Steam is a real gas; the state of steam can therefore be described by the following measurable state variables:

- temperature T in K (0 °C = 273.15 K),
- pressure p in Pa or bar,
- volume V in m^3.

For these variables, the following relationship applies to ideal gases according to the kinetic gas theory:

$$p \cdot V = nRT$$

n = quantity of substance
R = the gas constant = 8.314 bar · l/K/mol

The first law of thermodynamics applies to the transition from state 1 to state 2 with the corresponding specific variables (Fig. 4):

$$q_{12} + w_{12} = u_2 - u_1$$

q_{12} = specific heat,
w_{12} = specific work.

The transition from state 1 to state 2 represents a pressure drop from pressure p_1 to pressure p_2 with an increase in volume from V_1 to V_2. The difference between the work components in both states corresponds to the difference in areas $F_1 - F_2$ in the p-V diagram (Fig. 4).

$$p_1 \cdot V_1 - p_2 \cdot V_2 = \underbrace{(p_1 - p_2) \cdot V_1}_{\equiv F_1} - \underbrace{(V_2 - V_1)\, p_2}_{\equiv F_2}$$

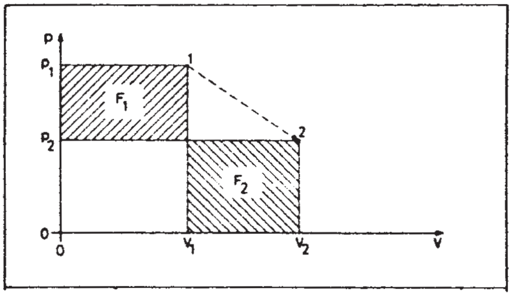

Fig. 4: Change of state in the p-V diagram.
p = pressure; F = area; V = volume.

Work is not a property of a system and is therefore not a state variable either. Work describes a process of exchange between a system with its surroundings. If we consider the volume work $A = -pdV$, then energy is given by the system by the volume. This means that energy flows from one system to another by work. In thermodynamics, the exchange of any non-thermal energy difference is understood as work.

Like work, heat is also not a state variable. Apart from work then, energy in the form of heat can also be exchanged between systems. Heat exchange does not inevitably involve the temperature. This is demonstrated by the example of water evaporating at a constant pressure. Although heat is supplied to the system (as evaporation enthalpy) the temperatures of the liquid water and the vapour remain constant. The heat is transferred between two systems with different temperatures. Heat is the energy which is exchanged without any work mechanism. The entropy always changes in this exchange. The specific heat capacity corresponds to the energy which must be supplied to, or given up by, a substance having a mass of 1 kg or a volume of 1 m^3 (standard cubic metre) in order to raise or lower its temperature by 1 K. In general, the specific heat capacity is dependent on temperature and pressure. In calculations, approximate values or averages between the initial and final temperatures are often chosen. A distinction must be made, especially in the case of gases, as to whether the change of temperature takes place at constant volume or constant pressure. In the first case, the substance (of mass m) is firmly enclosed (V = constant), and the heat supplied increases the internal energy U. The heat capacity is given the index v and is defined by partial differentiation thus

$$c_v = \frac{1}{m}\left(\frac{\partial U}{\partial \Theta}\right)_v$$

Θ = absolute temperature.

In the second case, however, the substance can expand at constant pressure (p = constant) and the energy increases the enthalpy H. The heat capacity is given the index p and is defined by

$$c_p = \frac{1}{m}\left(\frac{\partial H}{\partial \Theta}\right)_p$$

Since, in this case, displacement work is lost or, the molecules of the substance can move away from one another, the rise in temperature is less than in the first case so that, in principle

$$c_p > c_v$$

In order to raise or lower the temperature of a substance, the energy

$$Q = mc\,(\vartheta_2 - \vartheta_1)$$

ϑ = temperature of the substance before or after the supply or loss of energy,
m = mass of the substance,
c = specific heat capacity (c_p or c_v, valid in the temperature range ϑ_1 to ϑ_2).

must be supplied or given up. For an adiabatic system the applied heat, which is also known as sensible heat, causes an increase in temperature (with no heat transfer through the walls) and the following applies:

$$Q_{1,2} = m \cdot c_p \cdot \Delta T$$

If the boiling temperature is reached, the temperature of the liquid/vapour mixture does not change when further heat is supplied as long as liquid water is still present. The heat involved in the process of evaporation is also called latent heat. Water boils at 100°C at a total pressure of 1 bar and has a heat of evaporation Δhv of 2257.3 kJ/kg at this point. The sudden jump in the specific enthalpy of water which takes place on evaporation is shown in the table (definition: h_{aq} (ϑ = 0 °C) = 0):

ϑ [°C]	0	20	50	100 (liquid)	100 (gaseous)
h [kJ/kg]	0	83.6	209	418	2675

The sensible heat of water at 100°C is only just 16% of the latent heat of water vapour at 100°C. For the calculation of internal energy, the work W also contains the displacement work, which often cannot be made use of technically. Thus, the work performed by the substance flowing with and flowing against the surrounding pressure in the form of displacement work W_u is lost. The enthalpy of a substance

$$H = U + pV$$

U = internal energy,
p = pressure,
V = volume.

takes this displacement work into account according to definition. At the same time, therefore, the change in enthalpy

$$H_2 - H_1 = Q_{12} + W_t$$

Q_{12} = supplied heat,
W_t = supplied technical work (on the way from 1 to 2)

represents a different formulation of the 1st law of technical thermodynamics as applies to all heat engines and work machines. For the enthalpy state variable, definition of the null point is also open since, in general, it is only a change in enthalpy that is of interest. In practical applications, the specific enthalpy h = H/m is often used which is related to the mass m of the substance.

The h-x diagram is an equilibrium (phase) diagram for moist air with the parameters h, x and T. The reference mass is 1 kg of dry air and the total pressure $p = p_D = p_L$ (generally = 1 bar) remains constant. The absolute vapour content x of the air is entered on the abscissa and the specific enthalpy h_{1+x} on the ordinate (enthalpy of 1 kg of dry air and x kg of water vapour).

$$h_{1+x} = 1 \cdot h_L + x \cdot h_D$$

For the sake of simplicity, and without limiting its general validity, the enthalpy of dry air of 0°C and that of liquid water of 0°C are both equal to zero (standardized to the zero point on the Celsius scale). For not excessively high pressures, the following equation gives a good approximation in the unsaturated region ($\varphi < 1$):

$$h_{1+x} = C_{p,L} \cdot \vartheta + x\,(\Delta h_V + C_{p,D} \cdot \vartheta)$$

After inserting the substance values for air and water we obtain:

$$h_{1+x} = 1.006 \cdot \vartheta + x\,(2500 + 1.86 \cdot \vartheta)$$

If right-angled coordinates are chosen for the equilibrium (phase) diagram h_{1+x}, x, V, then the important region for unsaturated moist air is represented in an indistinct narrow region. Consequently, an oblique-angled coordinate system is constructed in such a way that the V = 0°C isotherms in the unsaturated region describe a horizontal course.

Steam is generated in textile dyeing and finishing mills in various types of boilers at high or low pressure to supply the plant's requirements. Before leaving the boiler, steam is often further superheated and then used for the generation of electrical energy in a turbine, where its pressure is reduced to a lower pressure rating before it is fed into the steam network. More or less superheat is given up by the steam in the pipelines, depending on their length to the point of consumption and depending on the quality of insulation. If steam is fed into the pipelines with a low degree of superheat, it soon reaches a state of saturation. Further heat loss results in the formation of condensate and the steam becomes wet. Depending on the length of the pipeline and its technical configuration, as well as the steam throughput, pressure losses arise which can be described by the formula

$$\Delta p = \xi \cdot \frac{\rho}{2} \cdot w^2 \; [\mathrm{N/m^2}]$$

ξ = loss correction value,
ρ = density [$\mathrm{kg/m^3}$],
w = flow rate [m/s].

The state of steam at various points of consumption can therefore vary considerably from the state of steam fed into the pipeline network. Because of the many unknown pressure and heat losses which occur in the pipelines and at various finishing machines, the behaviour of steam can be explained more clearly with the h-x diagram than other mathematical procedures such as, e.g. pressure loss calculations.

Changes in the state of steam flowing freely into the atmosphere from machines consuming steam or throttled down steam in decatizing are represented by straight horizontal lines in the h-s diagram, i.e. lines where the heat content of steam h = constant (Fig. 5). This is valid as long as no mixing with the surrounding air takes place. Thus, whilst the enthalpy remains constant when the steam pressure is reduced, the entropy increases since a non-reversible process is involved. All the information relating to the state of equilibrium can be obtained from the groups of curves for constant pressure (isobars), constant temperature (isotherms), constant specific volume (isochores) and constant steam content in the wet steam region. The isobars and isotherms coincide in the wet steam region, i.e. below the saturation isotherm. These are lines with the gradient dh/ds = T. Since open steam is given up by the steam supply network as dry saturated steam, these horizontal lines have their starting point A at the point where the respective high pressure steam curve intersects the saturation isotherm.

For a pressure reduction at the machine, the following cases are possible: (1) steam flows out into the free atmosphere. In this case, the curve starting from point A with h = constant, proceeds to point B which intersects the pressure curve p = 0 bar corresponding to the external air pressure. The superheat temperature up to the intersection point B can be read off the group of temperature curves in the superheated region. (2) The steam pressure is reduced by a reducing valve at the machine to a pressure of p = 2 bar and consumed by the machine at this pressure. In this case, the intersection B' with the p = 2 bar line is decisive. The superheat temperature at B' is higher than at B. (3) The steam pressure is reduced to a pressure of, e.g. p = 6 bar and a further reduction occurs in the machine. Since no heat is lost in this reduction, the intermediate reduction with

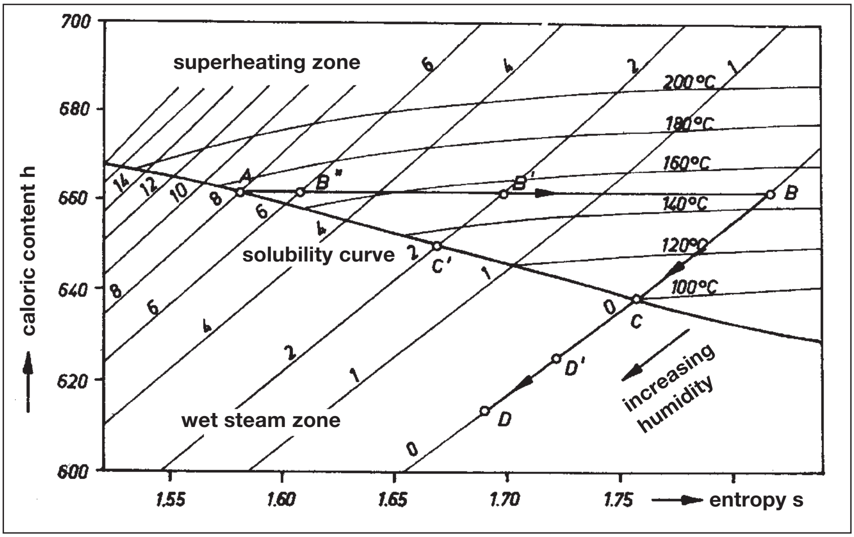

Fig. 5: Progression of the reduction of high pressure steam to low pressure steam and freely escaping steam at a pressure of 0 bar, shown in an h-s diagram. 0–14 = bar overpressure (on isobars).

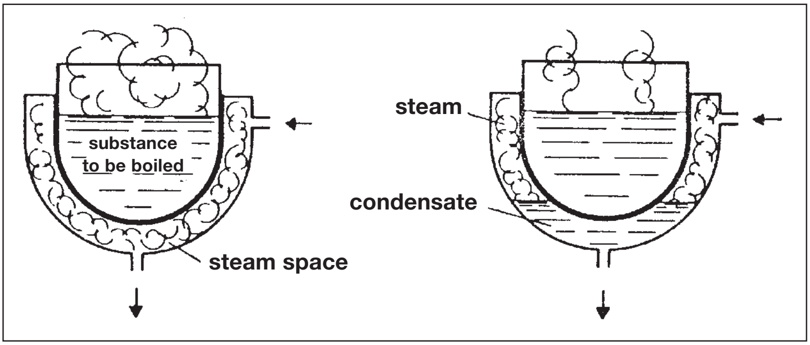

Fig. 6: Indirect heating of a finishing vessel with and without condensate formation.

intersection B' for the superheating has practically no significance. The line A–B'' continues to proceed to the point where it intersects with the pressure prevailing in the machine. From points B, B' and B'', the steam moves from the respective pressure curves to the saturation isotherm at points C, C' due to cooling losses in the machine, and from there it proceeds in the direction of point D in the wet steam region, depending on the degree of cooling, where partial condensation takes place.

During condensation, a condensate forms on the cooling surface as a film or as water droplets depending on the nature of the surface. Heat transmission coefficients of 1–10 kW/m^{2}K are achieved depending on the length of the condenser tubes, the temperature conditions (cooling surface/steam) and the characteristics of the surface, etc. Heat flows if a temperature gradient exists between a liquid or gas and an adjoining wall. In this heat transfer, the molecules of liquid or gas are in motion and transport heat by conduction and convection before giving up their energy through condensation (Fig. 6).

Water vapour pressure That component of atmospheric pressure exerted by the → Water vapour in the atmosphere (→ Water).

Water vapour transmission When applied to textiles, this property is described as "breathable" in the trade. The term "breathable" is, however, somewhat misleading since there is only a passive participation of the textile in its interactions with water in liquid or vapour form. In terms of clothing physiology, therefore, the term "breathable" means permeable to water vapour.

Because of its complicated chemical structure and morphology, one of the characteristics of wool is that the surface of the fibre is hydrophobic or water repellent but, at the same time, contains innumerable tiny pores that allow water vapour to penetrate into the hydrophilic or "moisture-friendly" interior of the fibre. This unusual combination of properties assists the natural cooling mechanism of the human body (evaporation of perspiration through the skin) by promoting the transport of perspiration away from the skin in the form of vapour but not in liquid form (Fig. 1). Wool fibres are very hydrophobic on their surface (repellent to liquid water) but are nevertheless capable of absorbing water vapour and have a high retention potential, i.e. the capacity to absorb, store and desorb moisture in the vapour phase in quantities up to 30% of their own weight without feeling wet.

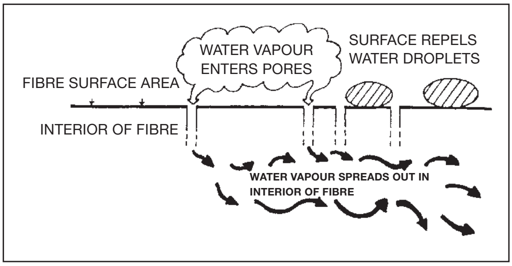

Fig. 1: Sorption properties of woollen fibres towards water vapour and water in liquid form based on the water vapour transmission of the hydrophobic scale layer.

Polyester microfibres are hydrophobic because of their chemical constitution which is based principally on hydrophobic monomers. Consequently, rainwater runs off the surface of a tightly woven fabric made from polyester microfibres whilst water vapour, in the form of perspiration separated from the body, diffuses through the fine pores of the woven fabric as shown in Fig. 2 (water vapour transmission). Tightly woven microfibre fabrics are particularly suitable for active sportswear since they also have a low permeability to air and are therefore able to protect the body against the wind.

Numerous methods to determine the permeability of textiles to water vapour are known. Some of these may differ significantly with regard to

- procedure,
- time required,
- range of application,

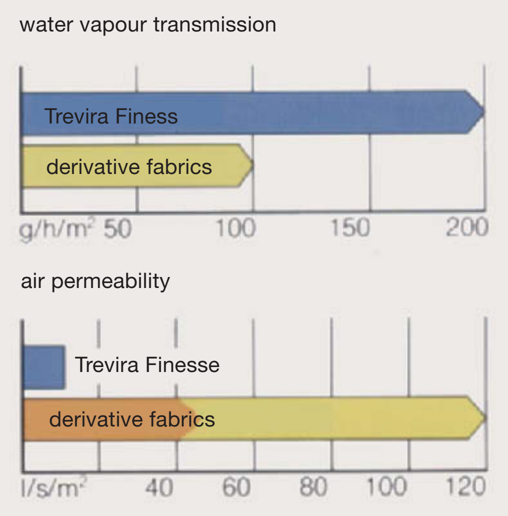

Fig. 2: Comparison of water vapour transmission and air permeability in microfibre fabrics (Trevira Finess, Hoechst) and derivative fabrics.

- reproducibility of results,
- inclusion of accompanying factors.

Depending on the choice of method, therefore, considerable variations in results can arise and, for this reason, the mechanisms and principles involved in a particular test method must be considered in some depth. Numerical ratings are only of value when the test method, as well as the test conditions, are known. As a rule, results obtained from different methods are not transferable. Standard methods, or in-house methods developed by testing institutes, manufacturers or users are usually employed. General requirements for textile testing such as statistically reliable sampling, number of test specimens and air conditioning should always be taken into consideration as far as possible. Only a few of the numerous test methods available can be described here.

For gravimetric methods, water vapour permeability is determined by the weight of water vapour diffusing through one square metre of a test fabric in 24 h under a specified humidity gradient at a particular temperature. The quantity of diffused water vapour is given by the increase in weight of the adsorption medium. Depending on the permeability of the sample, weighings are carried out at fixed intervals of time (e.g. < 24, 24, 48, 96 h). As soon as the increase in weight follows a linear progression, the water vapour permeability can be calculated by the following formula:

$$WDD = \frac{24}{t} \cdot \frac{\Delta m}{A} \cdot 10^4 \quad [g/m^2d]$$

t = time span between 2 weighings,
Δm = difference in weight between the last 2 weighings,
A = area of test specimen in cm^2.

In all these tests it is recommended to include a reference fabric with known values along with the particular fabric under test. This helps to put the results in the correct order and allows the test conditions to be compared. Since the construction of the test apparatus also has an influence on water vapour permeability, appropriate constants must likewise be established from comparative tests. The water permeability values obtained in these tests are not material constants but merely represent a selective description of the behaviour of a specific sample under standard climatic conditions. It is up to the tester to modify the test procedure as required but all test conditions must be recorded and typical sources of error avoided in order to achieve reproducible results. Problems mainly arise in:

- achieving constant climatic conditions,
- air circulation, i.e. in order to ensure that all test specimens are subjected to the same specified conditions,
- carrying out intermediate weighings without affecting the result through variations in the climatic conditions.

Simplified methods are less useful for the measurement of characteristic values than for making a quick comparison of different materials in order to determine trends and ranking order. Gravimetric methods are based on two fundamental principles, i.e.:

- the use of desiccants and diffusion of water vapour into the adsorption medium,
- the use of water-filled vessels and diffusion of water vapour into the external phase.

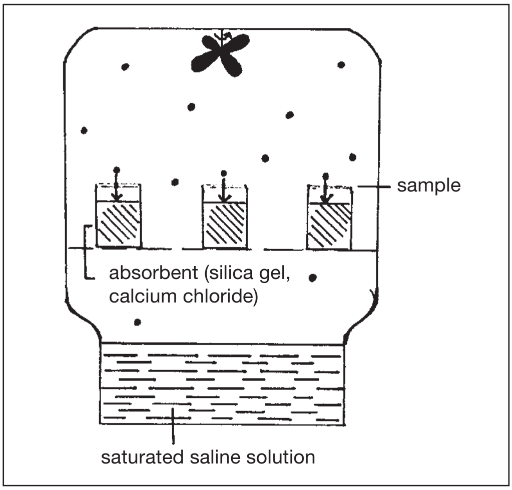

Fig. 3: Gravimetric process following DIN 53 122 (part 1).

Water vapour transmission

The simplest gravimetric method is known as the "beaker method"; a sample is stretched over a beaker filled with a desiccant and stored in a climatic test cabinet. As with other methods, the test is carried out under standard climatic conditions in which a uniform distribution of air humidity is assured by air circulation. The beaker method is carried out with 95% relative humidity at 20°C or 37°C. The in-house method of the Chemische Fabrik Pfersee is carried out in a similar manner but with a relative humidity of 65% and a temperature of 20°C in this case. A gravimetric test method is specified in DIN 53 122, part 1 (Fig. 3).

The adsorption surface, whose relative humidity at the beginning of the test should not exceed 1%, must be sealed by the sample so that moisture can only reach the inside through the sample area. The textile only comes into contact with atmospheric humidity, i.e. water vapour and not water. This method is mainly suitable for materials with a water vapour transmission above 0.5 g/m^2 which is determined by weighing the adsorption medium. As a rule, it takes 24 h to carry out this test. A similar test to DIN 53 122 for the determination of water vapour transmission is described in DIN 53 333 using a different apparatus. Numerous in-house methods are also based on the gravimetric principle using desiccants. Care must be taken to ensure that the desiccant does not become saturated during the test. Simplification of such methods has now reached the stage where a rapid test with silica gel can be carried out within 1 h. In this test (Fig. 4), which was developed by the British Textile Technology Group (formerly Shirley Institute), the results must be regarded with some criticism. A measuring beaker is filled with 10 g silica gel and closed with the sample. The sample is placed over a layer of nonwoven material soaked in distilled water in such a way that no water is present on the upper layer. A humidity of 100% is reached on the surface of the sample through the nonwoven material. The silica gel is carefully removed after 1 h and reweighed. As in other gravimetric methods, the water vapour transmission is calculated from the increase in mass. However, this method appears to be unsuitable for determining absolute values on different materials. On the one hand, a test duration of 1 h does not guarantee a linear increase in water vapour in every case and, on the other hand, it is questionable whether direct contact of the sample surface with the nonwoven layers does not favour the transport of water vapour through compact hydrophilic layers. Capillary action also conducts liquid water to the sample so that the diffusion is intensified for materials subject to swelling. This method clearly demonstrates how the choice of test conditions influences the evaluation of different materials. It is therefore easy to understand why water vapour transmission values are given in numerous publications which do not correlate with each other.

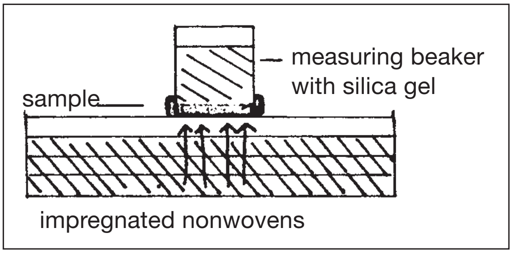

Fig. 4: Determining water vapour transmission in a standard operating environment (Shirley Institute).

Silica gel can not only be used as a desiccant, humidity conditions may also be defined by means of saturated salt solutions. A simplified method for determining the resistance to water vapour transmission has been introduced by the Institut Hohenstein e.V. This so-called "beaker method" is not universally applicable, however, since the thickness of the textile sample must not exceed 10 mm. With this method, the water vapour transmission of the sample is determined from the increase in mass of the measuring beaker. The measured value contains constants for the apparatus, e.g. the resistance values of Gore-tex membranes which must be included in the calculation. With such a method, it is obvious that no water vapour transmission higher than that of a Gore-tex membrane can be determined (Fig. 5).

In the following test methods, the direction of diffusion is reversed as an alternative to the use of desiccants, i.e. water diffuses through a textile sample from a container into an external climate. The simplest method (ASTM Method E 96) functions in a similar manner to the beaker method (Fig. 6). A sample and a reference are tested without covering. The water temperature can be selected in various steps. The main advantage of this method, i.e. its ability to test many samples at the same time with minimum effort, has predestined it for production control purposes. In this application, it is frequently used in conjunction with standards. The ASTM method is therefore used when it is only required to determine trends, but not precise values, with simple equipment. Such a test can also be extended by carrying out an external wetting (Fig. 7).

By using an experimental procedure with a simulated rain tester, the quantity of rain water absorbed by a sample is determined from the difference in weight compared to a test with an empty measuring beaker (Fig. 8).

The CGSB Control Dish Method represents a refinement of the ASTM Method since the external air space is also defined (Fig. 9). A uniform air flow over the sample is ensured by rotation of the container assembly. The transport of water vapour depends not only on the resistance of the material but also on the construction of the apparatus whereby the air spaces above

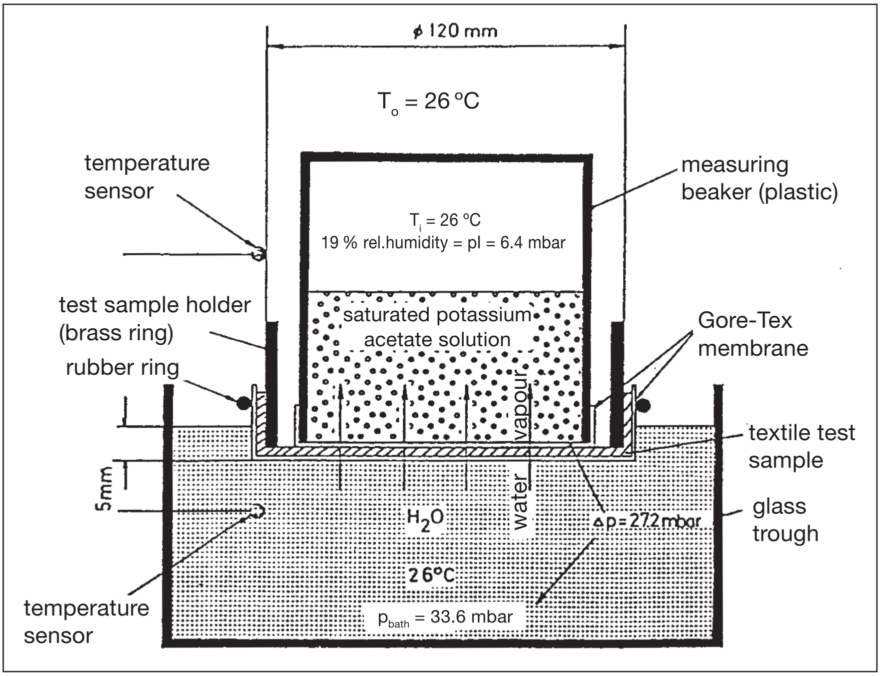

Fig. 5: Beaker method to determine water vapour transmission.

and beneath the sample offer different levels of resistance. The water vapour transmission of hydrophilic coatings is also influenced by the relative and absorbed humidity of the sample. The air spaces of different thickness represent the resistance of the apparatus which must first be determined for all samples. In the CGSB Method, a humidity of 84% is reached on the sample.

The ASTM method involves even higher values which makes the application of such methods difficult

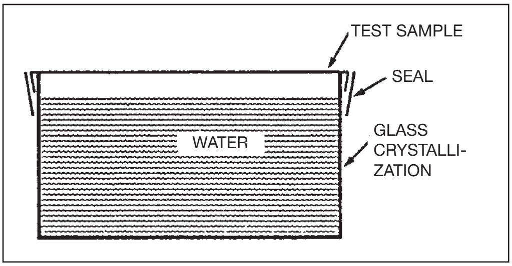

Fig. 6: ASTM Method E 96, method B, water temperature 23°C.

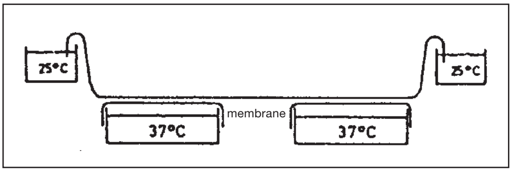

Fig. 7: Determination of water vapour transmission with external damping. Temperature: 25 ± 2°C, rel. air humidity: 50 ± 2%.

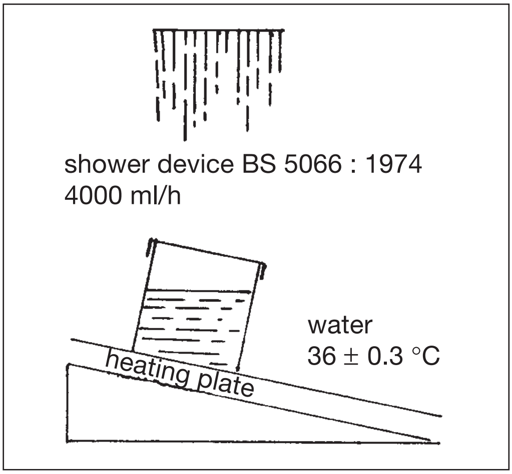

Fig. 8: Experimental arrangement using a shower device. Temperature: 21 ± 2°C, rel. air humidity: 65 ± 2%.

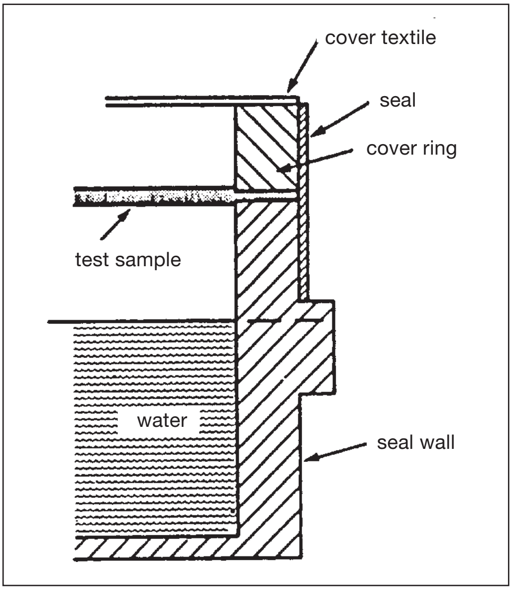

Fig. 9: CGSB (Canadian General Specification Board) Control Dish Method. Temperature: 20 ± 2 °C, rel. air humidity: 65 ± 2%.

or impossible for hydrophilic coatings. No accurate values can be determined since the diffusion varies with the relative humidity.

In the DND method (Fig. 10), the test specimen is placed between two Gore-tex films with the upper film forming the floor of a water reservoir whilst dried air is conducted along the underside of the lower film. With this test method no resistance from the air spaces exists but, as with the beaker method, it is obvious that water vapour permeability values higher than those of a Gore-tex membrane cannot be achieved. Moreover, the effects of the mass of water on the volume of the test specimen are not clear and the entire test apparatus must be weighed. The fact that no conditioned surrounding air is necessary and the samples are easily inserted and suitable for repeat tests are advantages of this method.

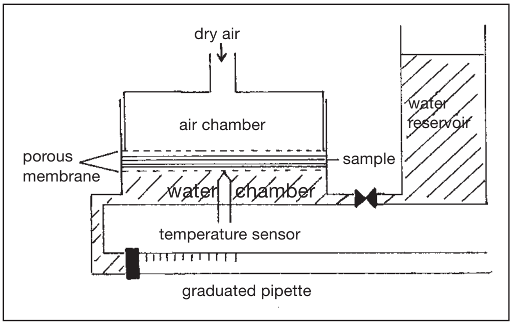

Fig. 11: Water vapour resistance meter.

In order to prevent any load on the sample by the water mass, a reverse principle has been developed (Fig. 11). In this case, the quantity of evaporated water can be determined with a graduated pipette and the water vapour permeability of the sample is calculated dependent on time.

The electrolytic method according to DIN 53 122 (part 2) is suitable for materials with a water vapour permeability lying between 0.01 and 5 g/m^2 and, by adaptation of the measuring area, even higher water vapour permeabilities can be measured. The water vapour permeability is determined with the aid of a Keidel electrolytic hygrometer (Fig. 12). In this electrolysis

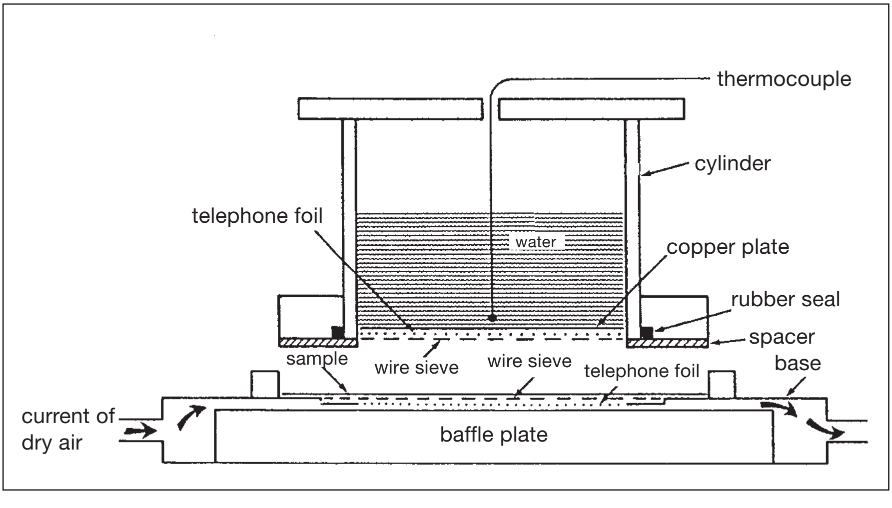

Fig. 10: DND method.

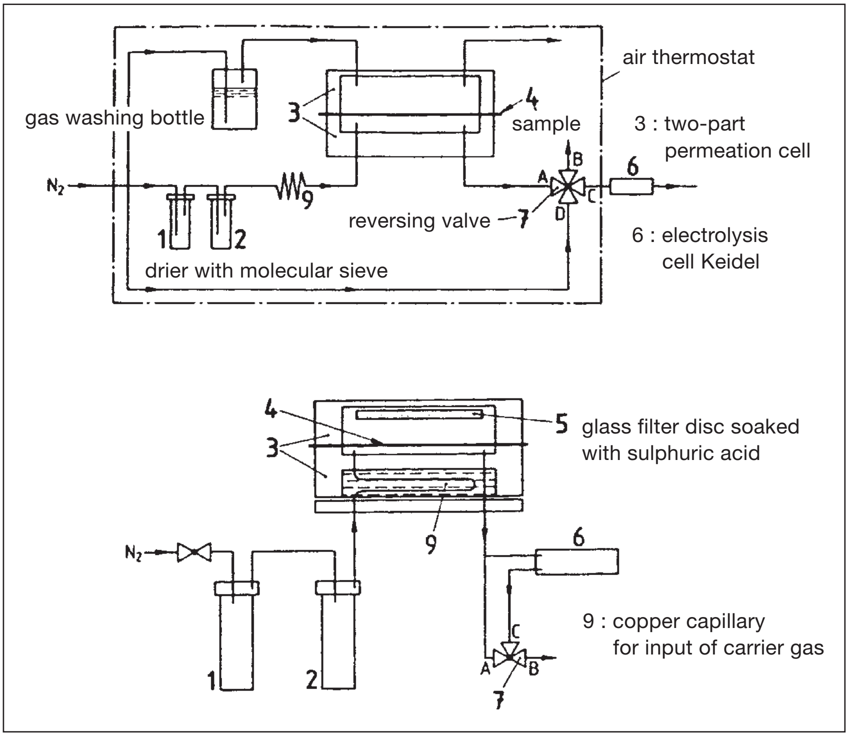

Fig. 12: Process of electrolysis.

cell, water vapour which has permeated through the test specimen is rinsed and electrolytically decomposed into hydrogen and oxygen. The quantity of water vapour per interval of time is calculated from the strength of the electrolytic current. The transport of water vapour is ensured by using a carrier gas (N_2). Measurements are carried out under standard climatic conditions where a constant air humidity can be established with a gas washing bottle (filled with a saturated aqueous salt solution) on the one hand, or a glass filter plate impregnated with sulphuric acid on the other.

The "R-Tube" method is also based on the measurement of humidity. Four moisture sensors are inserted between a dry and a saturated climate contained in a tube. The steadily increasing rise in humidity inside the tube is disturbed by a clamped test specimen, and the discontinuity of this interruption provides a measure of the water vapour resistance.

Water vapour permeability is also calculated by the measurement of humidity in the measuring system illustrated in Fig. 13. The Lyssy Vapor Permeation Tester is based on two compartments separated by the interposition of a test specimen. Compartments 2 contains a saturated atmosphere and the relative humidity in compartments 1 is measured continuously as a function of time at a specific temperature. The change in its humidity is a measure of the water vapour permeability of the test specimen. The short time required (10–20 min) and the continuous recording of measured values on a strip chart are advantages of this method. Threshold limits through which the state of humidity passes are used. The results are converted by reference to a fixed water vapour permeability value, e.g. a Gore-tex membrane.

The DSC (differential scanning calorimeter) method also calculates water vapour permeability as a function of time. In this case, a special type of vessel is divided by a test specimen and a constant temperature of

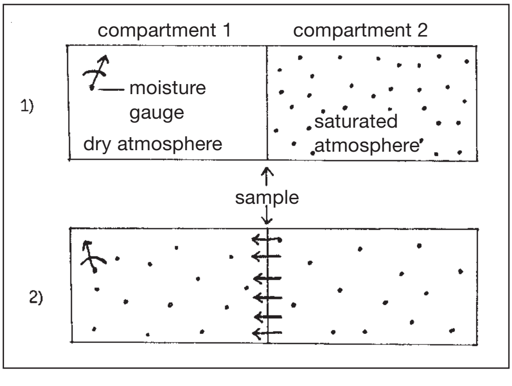

Fig. 13: Lyssy Vapor Permeation Tester.

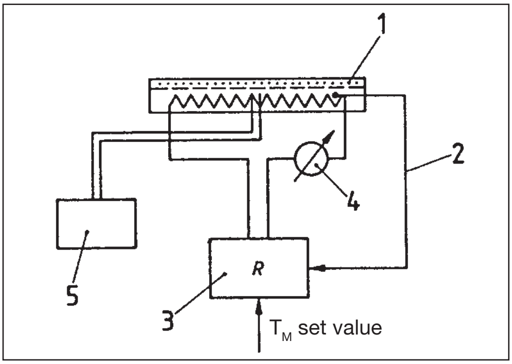

Fig. 14: Principle of the skin model.
1 = sample on heatable, porous measuring surface; 2, 3, 4 = circuit to regulate heating for the transport of water vapour; 5 = water dosage unit.

40 or 80°C is established on both sides of it. This temperature is sufficient to completely evaporate the water contained in one chamber. The moisture is rinsed out of the second chamber with dry nitrogen. The time required to produce a dry state in the original water chamber in a linear relationship to the weighed quantity of water is recorded.

With the aid of the thermoregulation model (skin model), the resistance to water vapour transmission (R_{et}) of a material is determined which allows a derivation of the water vapour permeability. The R_{et} value is a measure of the stationary water vapour transport capacity of a sample and is expressed in $m^2 \cdot mbar/W$. A simplified representation of the procedure specified in DIN 54 101 (part 1) is illustrated in Fig. 14 and is currently the best procedure for measuring absolute values. The surrounding temperature is adjusted to 35°C so that water vapour condensation is avoided under isothermal conditions. The relative humidity of the air then corresponds to 40%. The absorbed heat supplied to the measuring area in a stationary condition serves as a measure for the quantity of water evaporated. With the skin model, stationary conditions may be simulated, i.e. constant flows of heat and humidity or even non-stationary impulses by special modifications to the procedure. In a similar model, the dry and wet heat loss can be determined. The heat flow is dependent on processes of condensation, evaporation, adsorption and desorption (and therefore not only on the material but also on apparatus constants).

Conditions conforming to those encountered in practice are achieved by a modification of the skin model (DIN 54 101) which tests the water vapour permeability with simulated rain and condensation phenomena resulting from temperature differences. → Water repellency of textile fabrics (Bundesmann method).

Watt (Symbol W). The derived unit of power (mechanical, thermal and electrical) in the → SI system of Units named after James Watt (1736–1819). It is defined as the power when work of 1 J is done in 1 s or an equal heat transfer occurs in 1 s. In electrical applications, 1 W is the product of 1 ampere and 1 volt. Derived units of power, electrical energy and heat are all quotients obtained from a statutory unit of energy, work or quantity of heat, and a statutory unit of time.

$$1\ W = 1\ J/s$$
$$1\ W = 1\ Nm/s$$

In the SI system, the watt has now replaced the former unit of mechanical power, i.e. horse power (HP). Conversion: 1 HP = 745.70 W.

Wavy selvedge An undulating selvedge that does not lie flat. Causes: the use of different materials in fabric and selvedge, overturned selvedges due to creased edges, defective beaming, defective temple adjustment on the weaving machine, etc.

Wax A special group of low melting, thermoplastic organic mixtures generally opaque in appearance. Some are hydrocarbons, others are esters of fatty acids and alcohols. Soluble in most organic solvents, insoluble in water. Saponification of saponifiable waxes yields → Fatty acids and → Fatty alcohols. Classification:

I. Natural waxes: most of these are highly complicated chemical mixtures of esters of higher fatty acids with higher monovalent alcohols, besides free acids, free alcohols and hydrocarbons.

a) Mineral waxes, consist chiefly of higher hydrocarbons, e.g. fossil or earth waxes (ozocerite; montan; → Ceresin wax).
b) Vegetable waxes, e.g. → Japan wax or → Carnauba wax.
c) Animal waxes, e.g. →: Beeswax; Spermaceti; Wool fat (→ Lanolin).

II. → Synthetic waxes:

a) Ethylenic polymers and polyol ether esters.
b) Chlorinated naphthalenes.
c) Hydrocarbon types obtained by Fischer-Tropsch synthesis.

Chemical characteristics →: Iodine number; Acid value; Saponification number.

Wax crayons Coloured crayons for retouching purposes which contain a) colorants (inorganic or organic pigments as well as soluble ”aniline-based” dyes), b) binding agents (vegetable oils, waxes, resins or resin soaps) and c) filling agents (usually clay or chalk). Wax crayons of this composition are soft and have a high tinctorial strength suitable for retouching small localized light places after spotting treatments or to cover up any remaining stains. The colour fastness is naturally somewhat limited but may be improved under certain circumstances by subsequent steaming or hot ironing (using a slightly moist ironing cloth).

Waxing A treatment given to threads or yarns to facilitate production/improve stitch formation by making the threads/yarns smoother and more resistant to mechanical stress. During the rewinding process, the yarn is allowed to run against a block of paraffin wax (see Fig.).

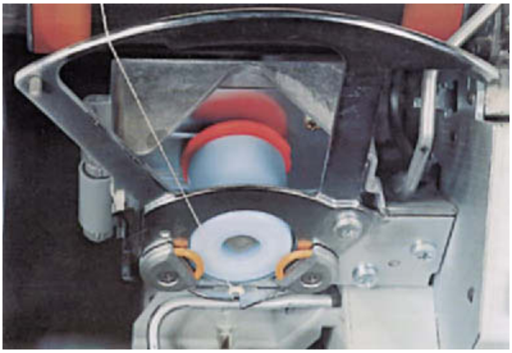

Fig.: Waxer on a Schlafhorst spooler.

Waxing with paraffin wax A → Waxing treatment with paraffin wax which is mainly given to machine knitting yarns. During the rewinding process, the yarn passes tangentially against a solid block of paraffin wax and the abraded wax is distributed unevenly on the yarn. Despite the well-known disadvantages associated with this method, e.g. the non-uniform application mainly on the surface of the yarn, it is still the most widely used procedure. The hairiness of yarns waxed with paraffin wax is more pronounced due to roughening in the machine. Additional monitoring of the wax applicator and its precise adjustment is necessary. During times of high material throughput, variations in the coefficient of friction of yarns waxed with paraffin wax are experienced again and again. These differences are often due to variations in the moisture content of yarn packages after a steaming process. → Wet paraffining.

Wax resist printing (→ Wax resists), batik-like prints with a wax resist suitable for the production of → Africa prints are typically obtained, e.g. by the route shown in the Fig.

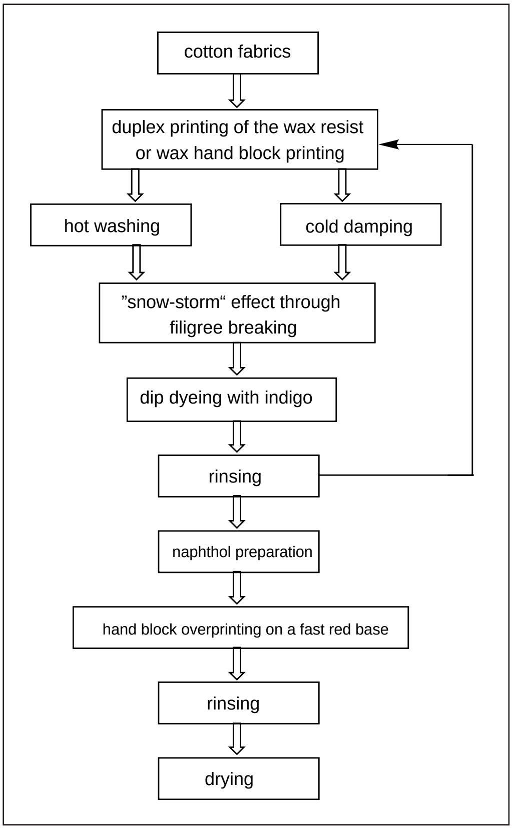

Fig.: Process technology for filigree wax-batique imitation combined with the "snow-storm" effect.

Wax resists (wax and resin resists) are employed as mechanical resists in resist printing (especially batik articles) for the production of pure untinted white effects that are almost impossible to achieve with reductive discharges. Wax resists consist mainly of natural resins (pine resin, colophony), beeswax, ceresin, stearin, spermaceti, tallow, etc. melted with turpentine oil or rectified petroleum. They are applied to bleached fabric by hand block printing or from heated rollers with deep engravings on a printing machine. To avoid sticking and smearing, the printed material is sprinkled with kaolin, diatomaceous earth or fuller's earth. The goods are then dried by hanging in air for 2–3 days, washed cold and subsequently dyed, usually with cationic or selected acid, direct and mordant dyes as well as indigo. The dyes used must not be soluble in benzine or solvents since, after cold dyeing, rinsing and drying, a passage through benzine must be given to remove the wax (only benzine produced from benzene and toluene is suitable, not petroleum spirit). After squeezing-off or centrifuging, the fabric is dried (steamed if necessary) and hung. Cationic dyes are dyed under neutral or weakly acidic (acetic acid) conditions in 2–4 h (and treated in cold tannin and tartar emetic baths if necessary). Acid dyes are dyed with 20% formic acid 90% based on the weight of dye for 30 min followed by another acid addition and dyeing for a further 30 min. For discharge batiks, dyed and batiked silk is allowed to lie in a cold bath containing 20–30 g sodium dithionite, removed after 30–45 min, 4–5 ml/l sulphuric acid 78.5% added, and the fabric treated for 15 min, after which it is rinsed and the cracked wax resists are dyed with another colour in a fresh bath (using acid or substantive dyes).

Wax-soluble dyes → Oil-and-fat soluble dyes.

Wear fastness properties In → Colour fastness testing, a distinction is made between those colour fastness properties that are of particular relevance to the end consumer, e.g. colour fastness to light, washing, chlorinated water, sea water, water spotting, perspiration, rubbing, dry cleaning, etc. i.e. properties which relate to the performance of a dyed or printed textile in use, and those which are only important in textile manufacturing processes, e.g. colour fastness to decatizing, stoving, sublimation, vulcanizing, etc.

Wearing comfort is concerned with aspects of protection and well-being afforded by a textile garment during wear. Wearing comfort is a complex and somewhat subjective term. To the extent that it can be measured in physical terms, wearing comfort is influenced by the fit of a garment, its design, weight, volume, behaviour towards water vapour and humidity, thermal retention, air permeability, stiffness, surface characteristics and its resistance to the build-up of electrostatic charges. Subjective components of wearing comfort include fashion style, colour and the image of the raw material and garment manufacturer. The term wearing comfort can be understood in terms of interactions between factors such as softness, thermal protection and moisture balance. The comfort factor includes clothing characteristics which have a direct influence on the temperature regulation of the human body (chiefly thermal insulation, evaporation and transport of perspiration and air permeability). Wearing comfort is regarded as a generic term which, in addition to the abovementioned factors, also includes other factors such as garment construction, contact between garment and body, influence of textile finishes and clothing physiological characteristics. Some distinguishing features of comfort include: perceptible comfort in wear, impulse-stimulated reactions of the autonomic brain and nervous system to control functions of the body's organs with effects on health and performance, comfort in the care of textiles in the sense of simplifying and reducing the amount of work required.

The primary objective of clothing physiology is regarded as the investigation of relationships between the mechanical body, its clothing and the ambient climate.

The second largest field of investigation in clothing physiology is concerned with the effects of certain specific variable parameters involved in the manufacture of a garment such as:

– type of fibre,
– fibre titre,
– fibre profile,
– type of yarn,
– woven or knitted fabric,
– fabric thickness,
– finish,
– cut of garment.

In addition, clothing physiology is also concerned with developing optimum clothing for specific end uses such as workwear and protective clothing, military service and battledress, sportswear, leisurewear, underwear, bed linen, etc.

The overall objective of clothing physiology is to improve the living standards of human beings by paying special attention to health, hygiene and comfort. Wearing comfort is the result of a balanced interaction between "body, climate and clothing" and is a combination of several components (see Fig.).

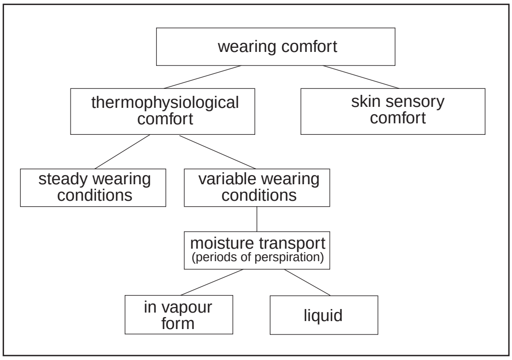

Fig.: Components of clothing wearing comfort.

Thermophysiological wearing comfort is achieved when the transport of heat and moisture from the body through the clothing is controlled in such a way that the so-called "energy balance" of the human body is in equilibrium and when the temperature and moisture levels in the "microclimate" of the garment are experienced as "comfortable" by the wearer.

The thermophysiological wearing comfort of a garment may be described in terms of numerous textile and clothing-specific ratings. A distinction is also made between stationary and non-stationary wearing conditions. Stationary wearing conditions are said to exist when the flow of heat and moisture from the body is constant over long periods of time under reasonable climatic and working conditions. Non-stationary wearing conditions thus occur if the body perspires due to impulse when the body is subjected to stress for a period of time or when a sudden change of temperature (hot/cold) occurs and perspiration leaves the body in the form of liquid or vapour.

Sensations experienced through the skin in contact with a garment arise from the stimulation of sensory receptors located beneath the skin and are concerned with tactile comfort. The sensations conveyed by the touch, thermal and pain receptors make the individual aware of the area and location affected, and the duration of the sensation. A variety of sensations arising from fabric contact may be experienced as a feeling of softness, smoothness, roughness, scratchiness, etc. Discomfiture arising from fabric cling due to a sweaty skin may be followed by a tacky sensation if there is a residue of perspiration. A very smooth fabric surface is more prone to clinging under these circumstances whilst a hairy surface reduces clinging since there is a reduction in the area of fabric contact with the skin. The hairs help to maintain a degree of separation between the fabric and the skin which facilitates drying and thus makes a positive contribution to wearing comfort. Finally, it is possible for a garment worn on the body to become electrostatically charged, which again causes fabric cling, and therefore has a negative impact on wearing comfort (according to Umbach).

Wear resistance → Textile serviceability.

Wear shine, removal of → Stain removal dry cleaning.

Wear, wear and tear When applied to textile materials, the term "wear and tear" refers to the gradual and unintentional wearing away of a textile surface due to specific mechanical effects such as friction (textile wear resistance → Abrasion resistance).

Weathering → Weathering fastness.

Weathering apparatus A testing device designed to carry out accelerated tests for → Weathering fastness, e.g. the → Weather-O-Meter.

Weathering fastness (colour fastness to weathering). Determination of the resistance of dyeings and prints on textiles of all kinds to the action of weathering. Accelerated weathering conditions can be achieved in the laboratory by exposing test specimens to conditions that involve changes in temperature, relative humidity and radiant energy, with or without a direct water spray (simulated rain) in an attempt to reproduce changes in the material similar to those observed after long-term, continuous, outdoor exposure. A suitable test apparatus uses filtered xenon arc radiation and an additional water spray. The test is carried out according to DIN 54 071 and the results are assessed with the blue scale.

Weather-O-Meter A laboratory testing device for determining the resistance of textile materials to weathering.

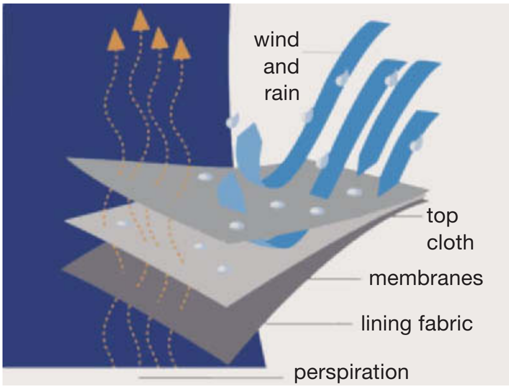

Fig. 1: Weatherproof leisurewear system (Proline).

Weatherproof leisurewear High-tech articles were formerly limited to special applications or specific target groups, e.g. the aeronautics and aerospace industries, the computer industry, military protective clothing, etc. In recent years, however, the worldwide consumer market has changed considerably and high-tech finishes, or the sports and leisurewear to which they have been applied, now represent the fastest growing segment of the clothing industry. Besides the originally predominant "protective" function of sports and leaisurewear, the term "comfort" also plays an important role nowadays and the combined effects of these relatively non-specific concepts is of interest in the protective function of so-called weather-resistant clothing (Fig. 1).

The effects of

- wind resistance,
- water repellency/waterproofing,
- water vapour transmission,

can be achieved with conventional finishes, film laminates (hydrophilic polyester), microfibres or "breathable" coatings.

Waterproofing is a parameter which depends on the effective stresses that an article of clothing will be subjected to in use. The following classification is helpful in this regard:

- resistance up to 1000 mm water column (100 mbar): perfectly adequate for normal weather-resistant clothing (70% of the market),
- resistant up to 1000–3000 mm water column (100–300 mbar): suitable for specific sportswear sectors, e.g. sailing, winter sports, etc. (20% of the market),
- resistance above 3000 mm water column (above 300 mbar): suitable for extreme sports, e.g. mountain climbing, hang gliding, etc. (10% of the market).

Wind resistance is automatically provided by garments whenever a combination of water vapour transmission and water repellency has been achieved. The chemical industry offers suitable systems for specific target groups:

- for resistance above 3000 mm water column (above 300 mbar), coagulated polyurethane (solvent/water),
- for resistance to 1000–3000 mm water column (100–300 mbar), hydrophilic polyurethane (solvent),
- for resistance up to 1000 mm water column (100

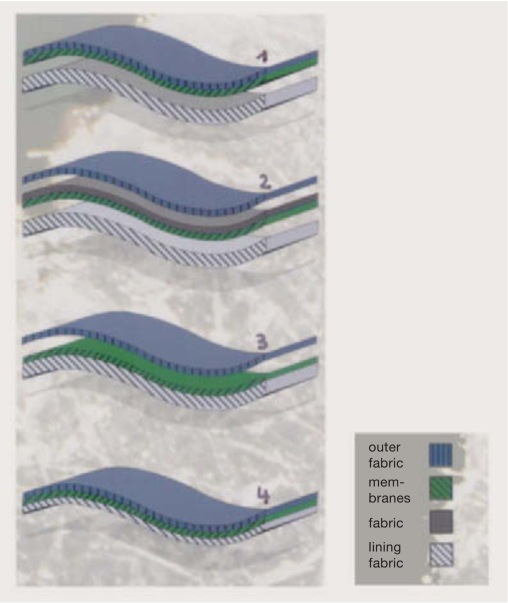

Fig. 2: Various types of weatherproof leisurewear (depending on profile of requirements) (according to Proline).
1 = most waterproof design; 2 = with membrane inserted between lining and outer fabric, requiring fewer seam sealing tapes and allowing shorter garment manufacturing times; 3 = waterproof version processible independently of outer fabric; 4 = windproof, elastic design which keeps out the cold and allows great freedom of movement.

mbar), microporous polyurethane foam (polyurethane with water).

The construction of some variants of weather-resistant clothing is explained in Fig. 2.

Materials made from synthetic fibres or their blends predominate for weather-protective articles and winter sportswear. So-called microporous membranes, e.g. Gore-tex, which confer water and wind resistant properties and good water vapour transmission, are frequently used for this purpose. In most cases, two methods are used to apply the membranes. Either the membrane is laminated to the outer fabric (outer fabric/membrane/lining) or it is applied in the form of an insert laminate (outer fabric/membrane/nonwoven/lining). The membranes are composed of polyester or polytetrafluoroethylene. In addition to the above-mentioned properties, these membranes are characterized by outstanding resistance to water pressure as measured by a high water column rating. As a rule, the outer fabric is either impregnated alone or combined with the membrane. The objective of this process is to achieve excellent water repellency.

Whilst impregnation was still carried out with silicone-based products until a few years ago, a → Fluorocarbon finishing is generally preferred today. Silicone impregnation suffers from the disadvantage that silicones have certain lipophilic properties (greasy, soiled edges) and also impair the laminating effect. These disadvantages are avoided with fluorocarbon finishes which are also characterized by significantly higher durability.

A soft handle continues to be a major requirement for these articles. Consequently, it is necessary to select special softeners capable of producing a good soft handle on the one hand, but which do not impair the waterproofing effect on the other.

In general, it has been assumed that silicone elastomers, which give the best handle effects, are not suitable in combination with fluorocarbon resins. This is only partly true, however, and it is certainly possible to achieve a good soft handle with selected siloxanes.

Weave Or fabric structure, i.e. the pattern of interlacing warp and weft yarns in a woven fabric which is responsible for its durability, design and external appearance. The main basic weaves include (see Fig.):

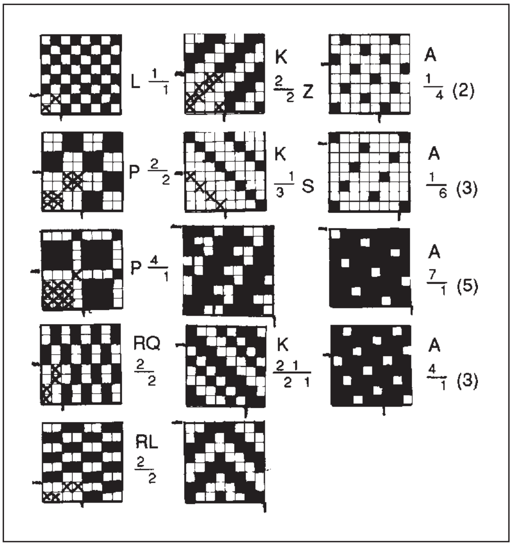

Fig.: Types of ground weave and some derivatives.
Left: plain weaves: basket weave, Panama, patterned Panama, warp ribs. Centre: twill weaves: twill of uniform line, weft twill, steep twill (gabardine), stitched twill, zigzag twill. Right: atlas weaves: two weft and two warp atlases.

a) Plain weave (tabby or taffeta weave). The simplest, shortest and most important of all weave interlacings in which alternating warp yarns are present on both sides of the fabric. The plain weave repeats on two ends and two picks, i.e. the first end passes over the first pick and under the second pick whilst the second end reverses this sequence. A plain weave is used for broadcloth, calico, muslin, print cloth, taffeta and sheeting.

b) Twill weave: a basic weave characterized by a diagonal rib or twill line on the face of the fabric which usually runs from lower left to upper right. Each end floats over or under at least two consecutive picks, and the points of intersection move one outward and one upward or downward on succeeding picks to produce the diagonal line. More prominent and less prominent twill effects are produced by having a predominance of warp yarns on the face side = warp twill, or a predominance of weft yarns on the face side = weft twill. A broken twill is formed when the diagonal lines run in alternating directions.

c) Satin weave: a basic weave in which the yarn crossover or interlacing points are spaced as evenly and widely as possible and in which the yarn crossover points lying between the visible crossover points are more or less covered by yarns lying on the surface (floats). As in the case of twill fabrics, both warp and weft satins are produced. A warp-faced satin contains many more ends than picks. A weft-faced satin is also called a sateen fabric. Satin weaves are produced with 3, 5, 8 and 11 shafts.

d) Derived weaves: all other weaves derived from a) to c) or combinations of these; e.g. basket (panama), repp and gauze or leno weaves are derived from the plain weave; herringbone, fancy and honeycomb weaves from the twill weave; double satin, crêpe and shadow repp from the satin weave.

Weaving The conversion of yarn into fabric by interlacing two independent yarn systems, i.e. the warp and the weft, on a weaving machine or loom. In a weaving machine, the warp yarns are passed from a warp beam (wound warp) to the fabric beam (wound fabric). During this process, each warp yarn is led through an eye on a heald attached to a harness. The harness lifts some of the warp yarns, e.g. the even-numbered warp yarns, and depresses the remainder to form a gap between them known as a “shed” through which the weft is inserted. This operation is known as shedding and the insertion of weft is called “picking”. The sley beats up the weft to the edge of the woven fabric (→: Woven

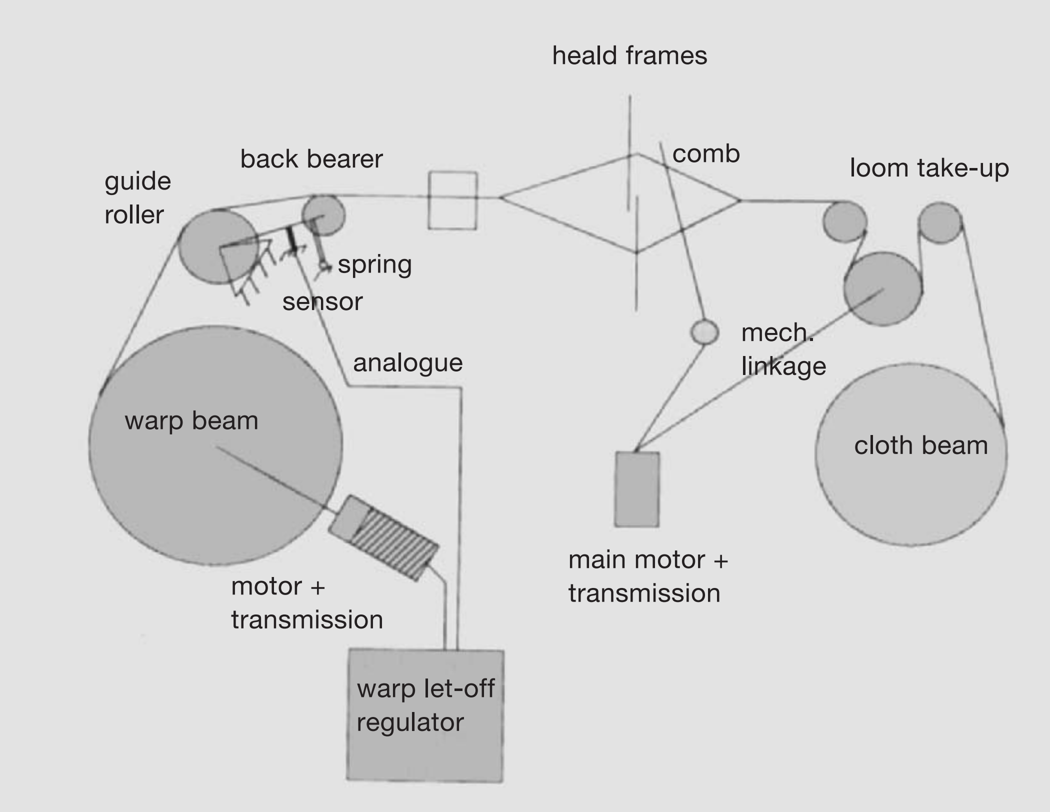

Fig. 1: Principle of a conventional loom drive with control system (Berger Lahr).

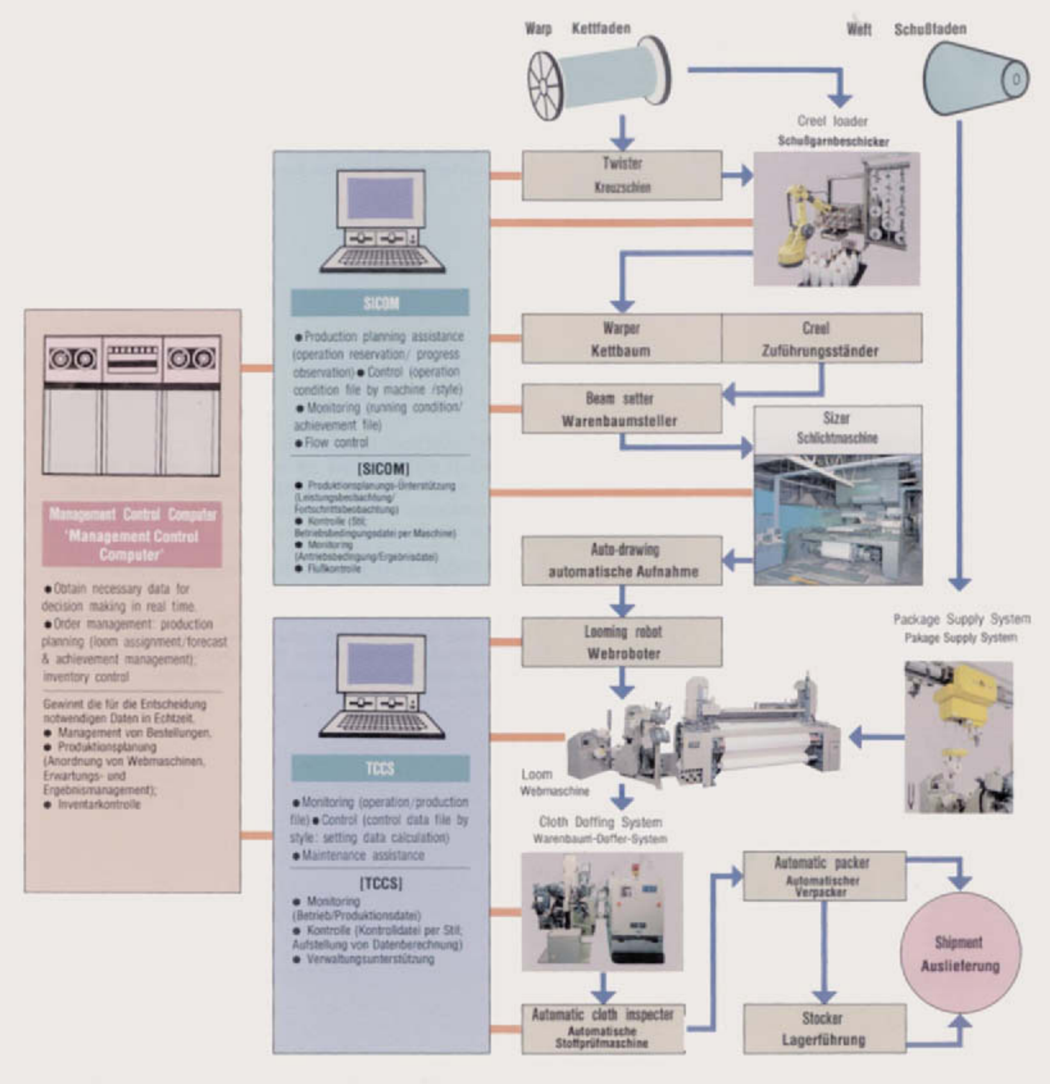

Fig. 2: CIM control of weaving preparation and weaving.

fabric; Weave). Weaving machines are classified according to the type of weft insertion system which at present includes shuttles, rapiers, projectiles, air jets and water jets (→ Weft insertion systems).

The principle of a weaving machine is illustrated in Fig. 1. The main drive is the central drive element and supplies all moving parts such as the head motion, reed, fabric take-up and winding. Selvedge trimming is also coupled to this drive, i.e. the movement of all working parts is synchronized through the main drive. The warp let-off motion is an exception here and is controlled by a dedicated electric drive which only unwinds sufficient quantity of yarn from the warp beam as required for weaving. The tension of the warp yarns is also kept sufficiently constant to ensure an optimum weaving result.

Centralized control of weaving machines through the application of CIM technology, whereby the various operations are organized by an internal network, represents a major technical advance in weaving (Fig. 2). The latest development in weaving technology (Figs. 3–6) is the linear shed weaving-machine (Sulzer).

Weaving performance development A tremendous increase in weaving performance has taken place

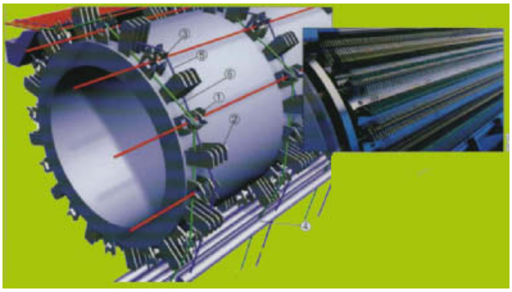

Fig. 3: The shed formation elements in the M8300 linear-shed weavingmachine. The guide bars position the warps so that they are raised above the shed holding elements, thus creating the upper shed, or kept in the lower shed position. ① = shed holding elements; ≠ = weaving reed; ③ = weft channel; ④ = guide bars; ∞ = upper shed; ± = lower shed.

① = fabric support; ≠ = weaving reed.

since 1965 when the production of woven fabrics began to switch over from shuttle weaving with pirns to automatic projectile weaving machines, (Fig. 1). A maximum performance of 6 m^2 fabric per hour per weaving machine was possible with shuttle weaving (for normal densities of worsted fabrics); in 1965, however, a weaver only needed about 1 working hour to weave 100 m of fabric at a (finished) width of 1.50 m on 10 automatic projectile weaving machines operated simultaneously by a single weaver (Fig. 2). In the meantime, automatic rapier and air jet weaving machines now operate at such high speeds that a performance of 25 m^2/h per machine is no longer an exception. Such outstanding performance in weaving has given rise to problems with the yarns used. If only two yarn breaks occur per 100 000 picks = machine stoppages, the weaving efficiency (Fig. 3) falls from 100% at approx. 200 rpm (e.g. old generation of automatic projectile weaving machines) through 95% at 500 rpm (e.g. rapier types) to 93% at 700 rpm (air jet weaving ma-

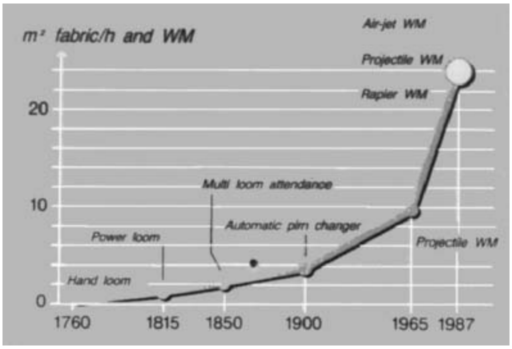

Fig. 1: Development of productivity in weaving.

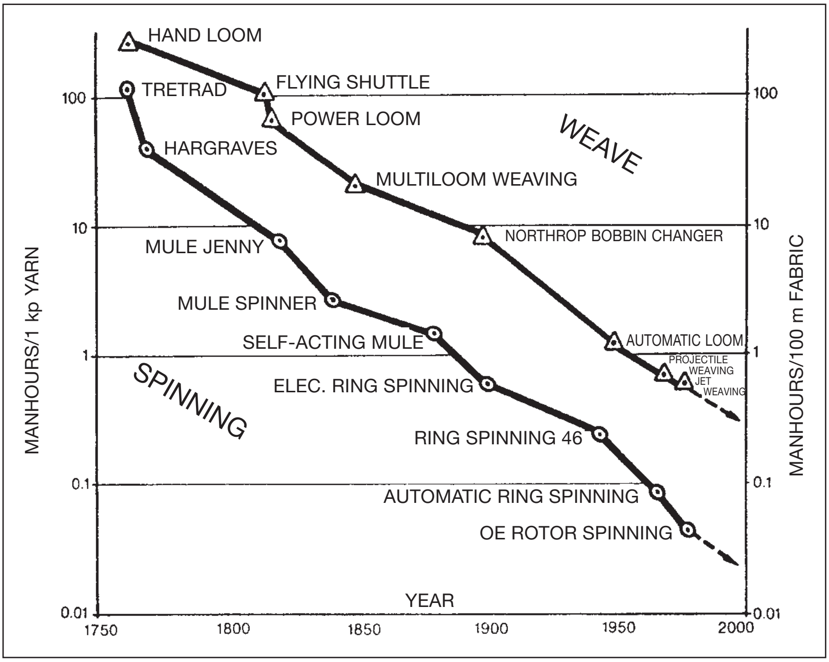

Fig. 2: Development of production in weaving and spinning (according to Krause).

chines). Since, however, yarns of lower strength (due to the use of unconventional yarns besides ring-spun yarns) are being used on an increasing scale by the yarn production sector, the number of yarn breaks per 100 000 picks has risen, e.g. to 10, so that weaving efficiency falls from 93% at 200 rpm through 87% at 500 rpm to 83% at 700 rpm. If the number of yarn breaks per 100 000 picks can be kept low (e.g. by using filament yarns), one weaver can operate a far greater number of machines (Fig. 4): e.g. with 2 yarn breaks/ 100 000 picks on projectile machines about 80 machines, on rapier types about 60 machines and on air jets about 40 machines. These figures fall drastically if the number of yarn breaks rises. Considerations such as these have led to a demand for high quality yarns in weaving in order to achieve optimum weaving performance (according to Weissenberger).

For the finisher of woven fabrics on the other hand, weaving performance involves different criteria. A woven fabric should be as uniform as possible for optimum dyeing and finishing.

One prerequisite for increased productivity, amongst others, is uniform preparation of the starting material to within close manufacturing tolerances. The (physical) uniformity of a textile fibre structure, on the surface of which the finishing-specific processes of

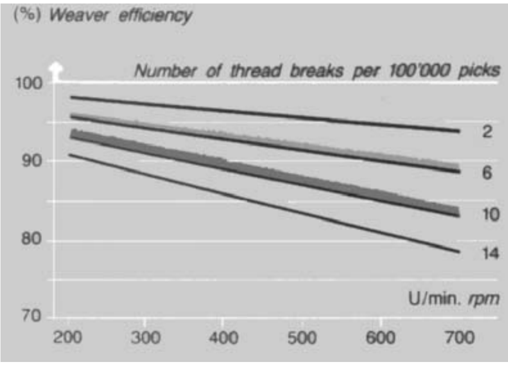

Fig. 3: Effect of rotational speed on weaver efficiency.

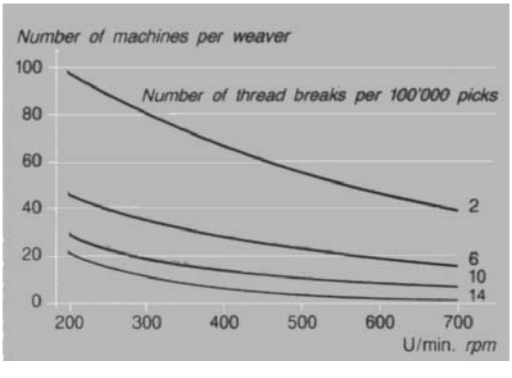

Fig. 4: Effect of rotational speed on weaver distribution.

(dye) mass, liquor and energy transfer take place, is of prime importance to the textile finisher. Experience has shown that uniformity of the fibre structure in a woven fabric is more “disturbed” by side/centre differences in the fabric, i.e. in the weft direction, than in the warp direction. The areas of a woven fabric close to the edges, which are often (relatively) more dense than the middle of the fabric, are generally dyed a lighter shade in continuous dyeing especially, i.e. the denser edges of a woven textile fabric are responsible for shading in dyeing which gives rise to customer complaints. This is the main reason why the textile dyer and finisher requires a highly uniform fibre structure across the width of a textile fabric in order to produce dyeings with a low incidence of customer complaints.

From the weaver’s standpoint, however, the uniformity of a woven fabric across its width is already assured by his production criteria. The percentagewise somewhat higher number of warp yarns in the area of the fabric edges is “contributed” by the modern weaving machine especially when its utilization is optimized by higher weft insertion performance and open fabric constructions. This situation often leads to frustrating discussions on customer complaints between the finisher and the weaver. The finisher cites his lighter dyed edges and the weaver his superficial and (to him) insignificantly higher number of warp yarns in the edge area of the fabric. But for continuous dyeing it is essential that the (weight) ratio of dye liquor to textile material is identical in all parts of the fabric in order to obtain a level dyeing with the same depth of shade throughout. This liquor (weight) ratio is “predetermined” by the fabric’s passage through the gap between the padder rollers where the thickness of the gap is constantly maintained throughout the dyeing run. In “conventional” dye padders, the thickness of the gap is identical even across the full width of the fabric. It therefore follows that a fabric which is identical in both the warp and weft directions will always be loaded with the same liquor (weight) ratio during its passage through the dye padder, i.e. these conditions ensure the production of a level continuous dyeing with the same depth of shade throughout. A somewhat higher number of warp yarns, or a higher fabric weight, in the areas near to the edges of a fabric occurs particularly in high-speed weaving machines with high weft insertion rates. From the weaver’s standpoint, these side/centre differences are insignificant. Even for the garment maker and the exhaust dyer who dyes his fabrics in beam dyeing machines or in rope form, such side/centre differences are insignificant. For continuous dyeing, however, such side/centre differences are extremely detrimental. This becomes clear if the liquor (weight) ratio in the gap between the padder rollers can be imagined. For the same gap thickness, the gap volume between the padder rollers is also the same. It therefore follows that the sum of textile material volume and liquor volume in the gap of the padder is always constant or, it will remain the same for a given padder setting even across the entire width of the fabric. Now, if the weight of the fabric in the edge areas is 2% greater than in the centre of the fabric, then the volume of textile material in the edge areas is also 2% greater and consequently the space available for dye liquor in the edge areas is inevitably reduced by 2%. From this it also follows that in this dyeing location near the fabric edges, the dyeing will always be lighter by double the percentage of the difference in fabric weight between the centre of the fabric and the edges. In this particular numerical example, therefore, a dyeing which is about 4% lighter in the edge areas must be reckoned with. A constant value relationship exists between the fabric weight and the sum of the numbers of warp and weft yarns. Consequently, a measurement tolerance of ± 5% for the fabric weight can be used directly to count the warp and weft yarns. If, for the sake of example, the number of warp or weft yarns is, say 30 yarns/cm, then the number of warp and weft yarns would therefore have to be “accurately” counted to ± 5% of 30, i.e. to ± 0.15 yarns/cm which, according to experience, is totally impractical or could only be carried out after an intolerable amount of time. From this example it can be concluded that the counting of warp and weft yarns as a means of detecting or determining uniformity variations capable of interfering with the dyeing process is unsuitable because it is too “inaccurate” (according to Kretschmer).

Webbing → Automobile safety belts.

Web bonding effect of binders Two different bonding mechanisms are involved here, the consequences of which have an opposing influence on each other under certain circumstances and can therefore have an effect on tensile strength.

1. Cohesive mechanism: this mechanism functions as a result of high binder cohesion which reaches its optimum effect when two fibres are fully included in a crossover point. For this type of bond, the approximate-

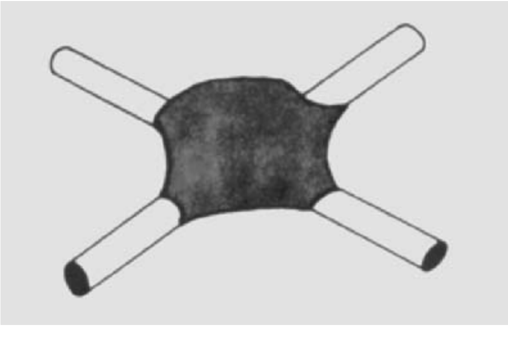

Fig. 1: Model of binder distribution with cohesive bonding.

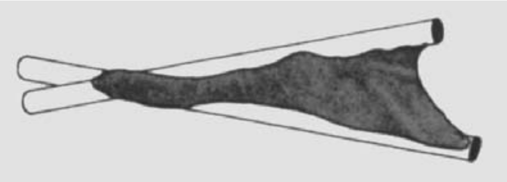

Fig. 2: Model of adhesive binder distribution.

ly spherical interlacing point is ideal for high tensile strength in a nonwoven material (Fig. 1).

2. Adhesive mechanism: this mechanism functions as a result of high binder adhesion forces and achieves its optimum effect usually between fibres or parts of fibres running approximately parallel to each other. For this type of bond, the bonding zone should be as extensive as possible to provide an ideal basis for high tensile strength (Fig. 2).

Various kinds of binder deposits on fibres, dependent on their form of application, are illustrated in Figs. 3 + 4.

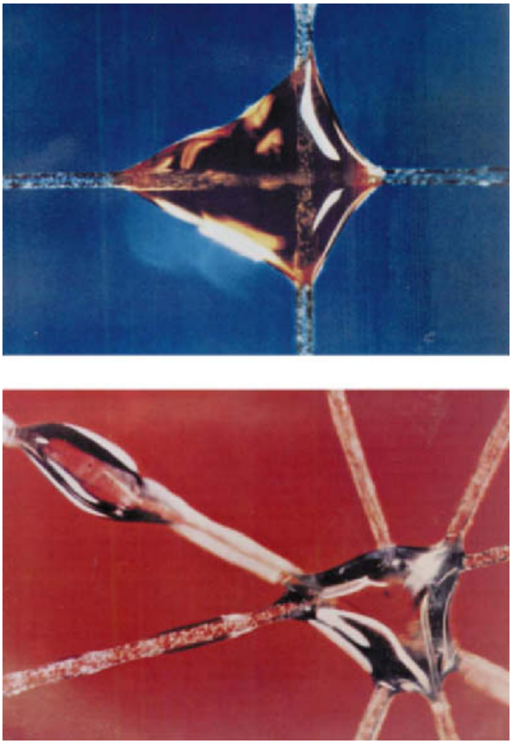

Fig. 3: Differences in binder cover depending on application: Bonding points from dipping (top) and foam application (bottom) (Bayer).

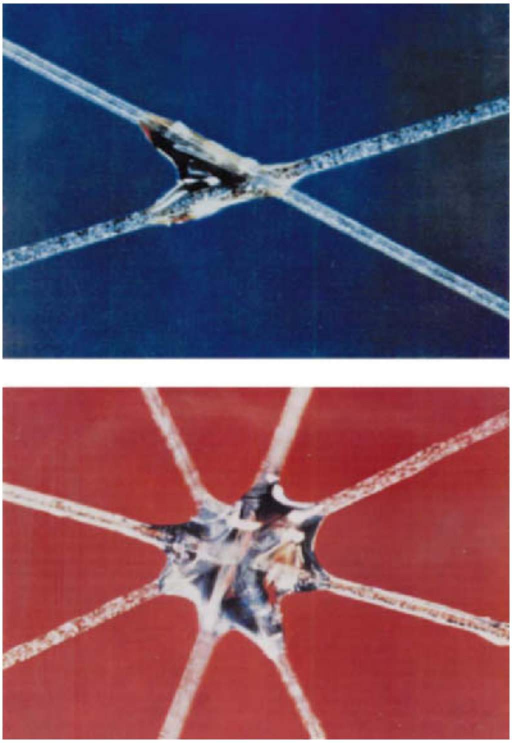

Fig. 4: Sail formation with foam application (top) in contrast to a spherical arrangement (bottom) with spray application (Bayer).

Web guiders, fabric guiders Mechanical (Fig. 1), pneumohydraulic (Fig. 2) or electronically controlled guiding systems are used in textile finishing processes to ensure an edge-straight and crease-free fabric run, especially on printing machines. In many electronic web guiding systems, a sensor detects the web position in relation to a reference value. This is usually the web edge, a printed line or a strong colour contrast on the web. The actual web position value is compared with a set value by the controller. The difference between these two values is sent from the controller as a signal to the system-actuating element which, in turn, adjusts the passage of the web by appropriate corrective action.

Standardized units detect the running fabric across its entire width to align the fabric precisely (Fig. 3). These devices are particularly suitable as centering systems when it is necessary to guide the fabric along the centre-line of a machine, e.g. washing ranges and coating plants. Higher production speeds can be achieved with sliding swivel rollers. Segmented roller guiders resistant to acids, lyes and liquor temperatures up to 104°C are used for many wet processing treatments.

The fabric guider type BF of IFS Systembau (Fig. 4)

Fig. 1: Mechanical web guiders, fabric guiders for dry (top) and wet (bottom) operation of pt Planotex.

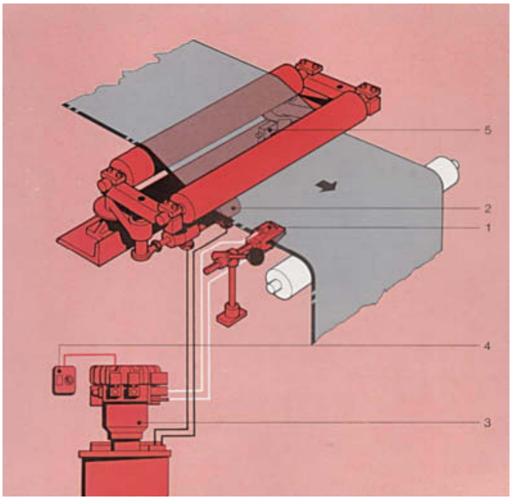

Fig. 2: Erhard & Leimer BS 4-VG 27 fabric guider with pneumohydraulic control according to guidance system.

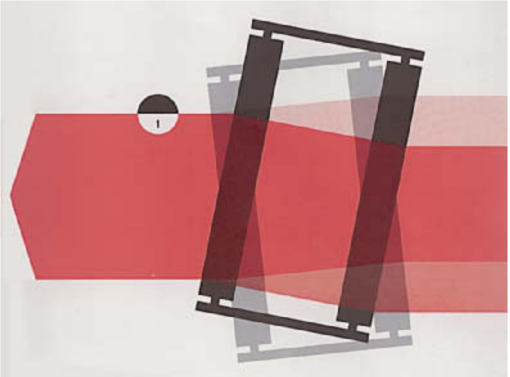

Fig. 3: Diagram showing the principle of the fabric guidance system.
1 = edge feeler.

ensures accurate crease-free single edge or centre-line guiding of textile fabrics even where wide deviations from the target position occur. A short-duration increase in the guiding forces by contact pressure with one of the two groups of brushes to the left or right of the expander roller brings about a rapid correction of the running web even when wide deviations are involved. Long lead paths for the fabric feed are therefore unnecessary. The driven expander roller simultaneously opens out the fabric and corrects curled selvedges if necessary. With wide-band scanning, there is no need for sensor tracking when variations in width arise. In addition to fabric guiding, this system can also carry out width measurements which makes it suitable for integration into production, planning and control systems.

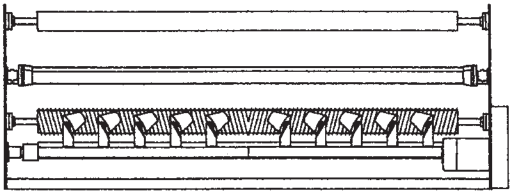

Fig. 4: BFE.1 fabric guidance system with a powered rotary stretcher, electromagnetic actuator and wide-band recognition.

The operating principle of a type BF fabric guider (Fig. 4) is as follows: the fabric first passes over an expander roller and the optoelectronic position-sensing system installed behind this roller emits a digital signal if any deviation in the centre or selvedge position of the fabric occurs. Correction of the fabric position is carried out by the specific application of fabric opening forces by means of controlled pressure brushes so that the fabric is immediately restored to its correct selvedge or centre position again. In all these systems, the contact pressure of the brushes is proportional to the deviation of the running fabric and acts in the opposite direction to the deviation either on the left or right side of the expander roller. This arrangement allows an extremely sensitive and gentle correction of the fabric position. Depending on the particular type of fabric guider, a second expander roller is finally brought into play in order to ensure a fully opened out fabric.

Web guiding systems → Expander.

Web slitting machines (fabric slitting machines), are used to slit running fabrics down the middle or in longitudinal strips of predetermined width. They are designed for installation on production machines.

Wedge-type template For the visual assessment of outlines, contours or sharpness of mark in textile printing. The length of the wedge still printed by a particular print paste is used as a measure (see Fig.). The printing quality of different thickeners or print paste recipes can be compared in this way. The length of the wedge from its lower thick end to its fine tip is divided up into 100%, 80%, 60%, 40% and 20%.

Fig.: Wedge-type template for the assessment of print contours.

Weft → Weft, filling.

Weft cracks Cracks present in individual and sometimes neighbouring weft yarns in woven crêpe fabrics produced from viscose or cupro yarns. Causes: embossing conditions too severe, or fibres weakened by oxidized linseed oil sizes.

Weft distortion is caused by external mechanical forces acting on a woven fabric (mechanical distortion) as well as internal latent tensions already contributed by the yarns themselves, or which have developed during the processes of manufacture (shrinkage distortion). Any force acting on a finished textile material, which has not been applied uniformly across its entire width, causes a displacement of the original right-angled configuration of the warp and weft (Fig. 1). Any non-uniformity in the path between the edges of a running fabric gives rise to a difference in tensile force and has the same consequences. It is therefore necessary to take care that as few partial forces as possible are applied to the textile material and that all the transport elements for processing a woven fabric (rollers, chains, etc.) are always in parallel alignment and equal in length. A distinction is made between:

- Skew distortion: a condition in which one side of the fabric is further advanced in relation to the other thereby causing a diagonal distortion of the weft yarns. Thus, although the warp and weft yarns may still be largely straight, they no longer lie at right angles to each other.

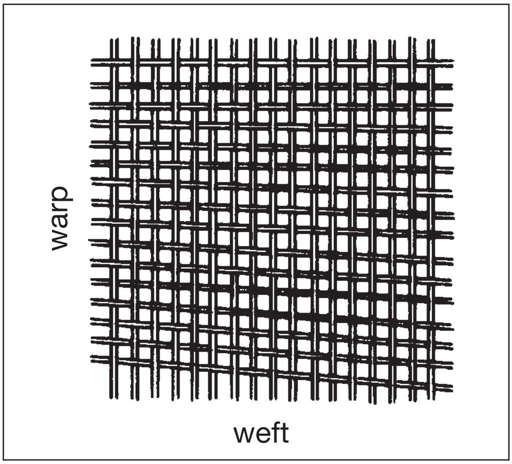

Fig. 1: Weft distortion.

- Bow distortion: a curvature in the path of the weft yarns, i.e. although the left and right ends of the weft yarns are at the same height they are displaced either forwards or backwards in the centre of the fabric in relation to the edges.
- Combined bow and skew distortion: the weft follows a curved path and the ends of the weft yarns are not at the same height.
- S-shaped distortion: the weft is wavy and lies in a series of small curves. It is largely dependent on the weave pattern.
- Irregular distortion: the weft yarns may follow any path across the width of a woven fabric. This type of distortion usually involves a combination of straight skew and various bow-shaped components.

The extent of the distortion is generally expressed in percentage overfeed, i.e. the overfeed of one area of weft yarns in front of another related to the fabric width (example: 160 cm fabric width, 16 cm overfeed: $[16 : 160] \cdot 100 = 10\%$ distortion). For measurement of the overfeed, the following definitions apply (according to international standards):

- The extent of a skew distortion is determined as the distance of one weft yarn from a point on the same selvedge touched by a line from another end of the weft yarn which lies at right angles to the normal position of the warp.
- The extent of a bow distortion is the distance between a line connecting both ends of a weft yarn and the point where the same weft yarn is furthest away.
- The extent of a double or multiple distortion is given as the narrow side of the smallest right angle which can be described around one weft yarn, the long sides of which run parallel to the distortion line between the ends of the weft yarn.

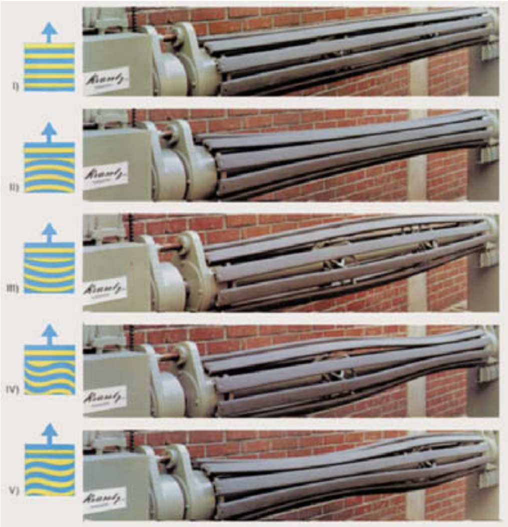

Fig. 2: Krantz fabric rectification roller with flexible laths.

In the main, two possibilities, which can be applied individually or in combination, are available to straighten distorted fabrics during finishing. The most popular solution involves the installation of a typical roller type straightening machine controlled by an automatic scanning and control system between a padder and a stenter drier.

The straightening principle is based on allowing the overfed part of a weft yarn to be held back by causing it to travel over an appropriately longer path distance so that, after this diversion, the lie of the weft yarn becomes synchronized once more (Fig. 2). Straight cylindrical rollers, which can be adjusted diagonally, are used for the correction of skew distortions. As far as the effect is concerned it should, however, be noted that the effective correction is always less than the theoretical diversion. The main reason for this is that the fabric is allowed to stretch to some extent so that only a part of the diversion applied to correct distortion is actually transferred to the fabric. The fabric tension prevailing at the time is particularly important in this regard.

The correction of bow distortion is carried out in the same manner when the axis of the bowed cylindrical rollers is rotated in such a way that, compared to the edges, the centre of the fabric is required to follow a longer or shorter path as required (Fig. 3). In this case also, the effective straightening action is always less than the theoretical diversion. The automatic scanning and control system controls the skew and bow rollers independently to such an extent in the direction of an excessive diversion until the actual position of the weft yarns is straight. This correction can function only as long as the theoretical straightening action can be kept sufficiently large. Certain limitations apply, especially with extensive bow distortions and narrow fabric widths in relation to the nominal width of the machine. The accuracy of this correction is not always sufficient in every case. On the one hand, a running web may contain relatively extensive irregular distortions so that

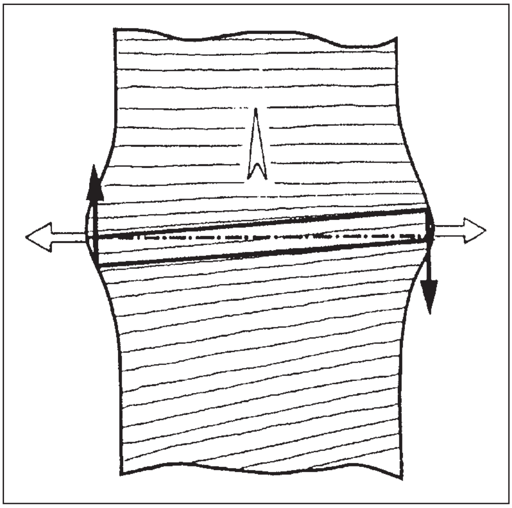

Fig. 3: Pin wheel system: when tensile forces (white arrows) appear, combatting forces (black arrows) guide the weft.

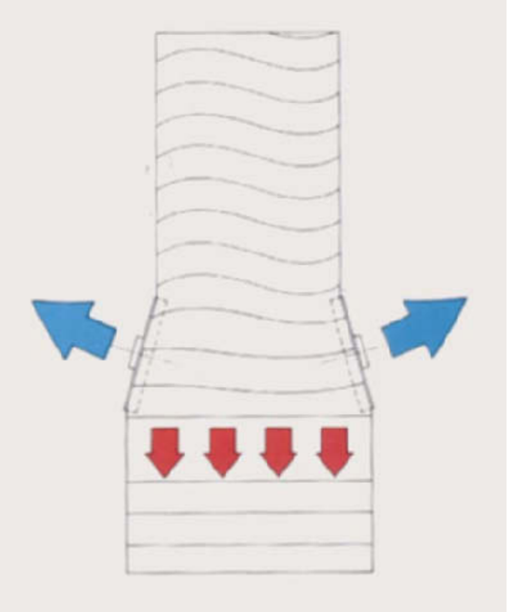

Fig. 4: Tschuiya (Japan) pin wheel principle, based on the Palmer Principle.

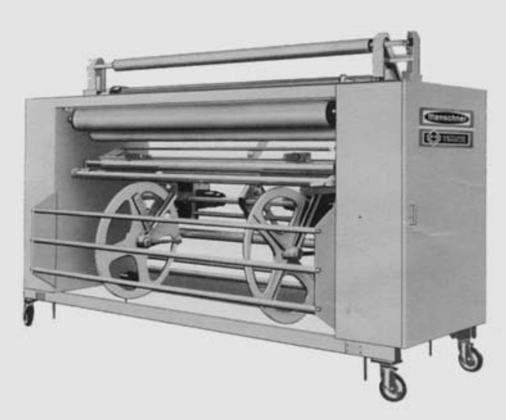

Fig. 5: "Correfix" weft straightener (Menschner).

complete straightening is no longer possible and, on the other hand, some fabrics may become distorted again during their passage through the stenter. In order to straighten residual skew distortions and residual bow distortions, or bow distortions formed in the stenter, a finely tuned straightening system is often applied after a normal straightening machine. In such a system, the correction of skew distortion is achieved by adjusting the running speed of the stenter chains and the bow distortion is corrected by adjusting the speed or the diameter of the delivery roller. Another possibility (now seldom used) is to allow bowed rollers, or rollers with changeable diameters, to "free-wheel" with the fabric.

The pin wheel straightener (Figs. 3–5) is based on the Palmer principle. Straightening is effected by means of two wheels with pins around their circumference to take up the fabric selvedge. These pin wheels are not driven, i.e. both are free running. In addition, the pin wheels are diagonally adjustable in relation to each other. During rotation of the pin wheels, this diagonal position stretches the distorted weft yarns and serves as a control element for the position of both pin wheels in their turning angle to each other. After a turn of 180° between pinning on and pinning off, the weft position is once again at right angles to the warp irrespective of the nature and extent of the distortion.

Weft, filling Threads or yarns running across the width of a → Woven fabric (→ Weaving) from selvedge to selvedge and at right angles to the warp. The weft binds the warp yarns (→ Warp) by interlacing with them to form a woven fabric structure and also serves as a filling material. Each weft yarn is called a pick.

Weft insertion A textile fabric with a system of alternating individually woven stripes and knitted wales. The latter take the form of weft threads which serve to bind the individually woven stripes together into a coherent textile fabric.

Weft insertion systems A distinction is made between the following weft insertion systems used on weaving machines (→ Weaving):

I. → Shuttles, as used in → Shuttle looms.

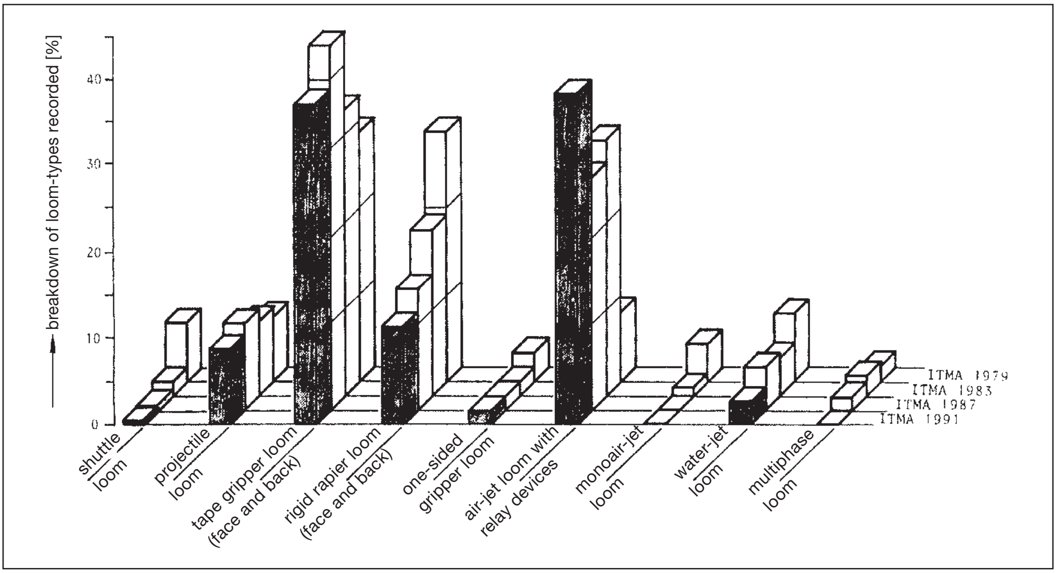

Fig. 1: Breakdown of the weft insertion procedures for weaving machines shown at the ITMA 1979–1991 (hand-operated pattern looms and circular looms were disregarded) (according to Kohlhaas).

II. Projectiles (gripper shuttles) used in projectile weaving machines: the weft yarn is gripped by jaws fitted in a projectile which is then propelled by non-positive action through the shed.

III. Rapiers used in → Rapier looms: the rapier takes the form of a rigid or telescopic rod, or a flexible steel tape with a clamp at the tip (the rapier) and carries pieces of weft yarn positively through the shed to the opposite side.

IV. Jets:

a) Air insertion: an intermittently directed jet of compressed air, with or without additional air jets, is used to transport the weft yarn through the shed. → Air jet weaving machines.

b) Water: an intermittently directed jet of water is used to transport the weft yarn through the shed.

If all the various weaving machines with their weft insertion systems exhibited at ITMA 1991 are taken as a fair reflection of market expectations (and this assumption cannot be fundamentally unsound), it should certainly be possible to discern particular trends for future development from the relative share of the different weft insertion systems exhibited and their development over the last four ITMA cycles. The relative percentage shares of different weft insertion systems for weaving machines exhibited at ITMA during the period 1979–1991 are presented in Fig. 1.

Shuttle weaving machines are now only to be found in a few niche markets. Thus, at ITMA 1991, only one wide weaving machine of this type having a reed width of 11.6 m (manufactured by Jürgens Maschinenbau) with a band-driven shuttle was exhibited. Because of its well-known drawbacks (high noise levels, high consumption of spare parts, low performance limits), weft insertion by shuttles only finds application nowadays for special materials where the above-mentioned limitations are balanced by the advantages which this particular insertion principle has to offer (e.g. extremely wide insertion widths), e.g. for weaving tyre cord lattice fabrics.

The share of projectile weaving machines (gripper shuttles) has remained about the same during the period under review from 1979–1991. The machine maker Sulzer resp. Sulzer-Rüti, is practically synonymous with this type of machine. Even at ITMA 1991 only the projectile weaving machines made by this company were to be seen. With a share of 8.6%, the projectile weaving machine has secured a relatively stable position for itself among the various weft insertion systems.

After air jet weaving machines, flexible rapier weaving machines with insertion from both sides represent the second largest group with a share of just over a third (36.9%). Although still represented at ITMA 1987 with a 42% share, this insertion system has a number of advantages especially with regard to high flexibility and favourable dimensions for wide reed widths. It is therefore not surprising that more than half the machine makers now offer machines of this type.

With a still significant share of more than 11%, rigid rapier weaving machines with insertion from both sides are well represented. However, the share of these machines has continually declined over the last four exhibition cycles due to their displacement by flexible rapier and air jet systems. This group includes all the weaving machines with double action weaving methods (for the production of velvet, velours and carpets with double weft systems) manufactured by machine makers such as Webmaschinenbau Chemnitz, N.V. Michel van de Wiele and Günne Webmaschinenfabrik. Another important representative of this weft insertion system is Dornier with its (positive) controlled weft yarn transfer. The insertion principle with just a single rapier acting from one side, and therefore without yarn transfer in the middle of the fabric, was only to be seen on a few of the machines exhibited. This type of weft insertion is, in principle, not suitable for high weft insertion performance because of the unavoidable empty stroke of the insertion element. Consequently, this system only finds application in special fields; machines of this type are used for the production of conveyor belts and flat carpets with very coarse weft yarns.

Weaving machines with air jet insertion and relay nozzles have the largest share at 38.5%. This weft insertion system has become more and more established because of the high productivity offered by this system

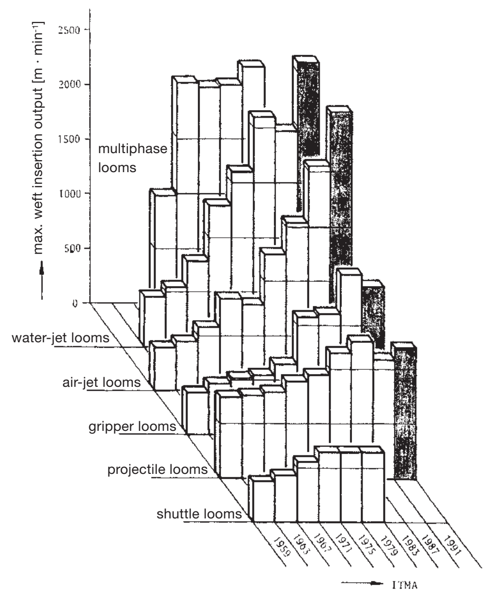

Fig. 2: Maximum weft insertion output of weaving machines at the ITMA settings (according to Kohlhaas).

and its market share shows a positive trend. The range of applications is continuously being extended; even difficult yarns can be used with high insertion efficiencies. An air jet weaving machine with a "demonstration speed" of 1500 rpm (Tsudakoma Corp.) as demonstrated at ITMA 1991 can achieve a weft insertion performance of 2550 m/min. This corresponds to an increased performance of at least 25% compared to ITMA 1987, a rate of increase which was not expected even when allowance is made for the fact that it only represents a "demonstration" performance. Air jet weaving machines with single jet insertion and confusor were no longer represented at ITMA 1991 nor at the one before that. This weft insertion system has two significant characteristics, i.e. a width limitation of approx. 2m and the limited warp density which if exceeded leads to warp stripiness. This principle has now been displaced by the development of other competitive weft insertion systems.

Water jet weaving machines have a share of less than 3%. This weft insertion system holds the record for the maximum achievable weft insertion performance as already demonstrated at the previous ITMA. An example from Tsudakoma Corp. can work with a weft insertion frequency of 1700 rpm which corresponds to a weft insertion performance of at least 2600 m/min at an insertion width of 153 cm. The rate of increase compared to the last ITMA (Fig. 2) was therefore more than 30%. This demonstration performance was, however, only achieved with specially selected weft yarns and fabric parameters and it was also necessary to mount the machine on a special foundation. The small and continually declining share of water jet systems clearly demonstrates that the field of application for this weft insertion system is also quite limited (according to Kohlhaas).

Weft-knitted fabrics → Knitted fabrics in which one or more thread systems run widthwise across the fabric forming all of the loops in each course. Weft-knitted fabrics are produced on flat and circular knitting machines. Typical weft-knit fabrics include double knit, fully fashioned, interlock, jersey, knitted fleece, knitted terry, rib knit, etc.

Weft slubs Consist mainly of short irregularities in the weft direction (easily visible when viewed against the light). Weft slubs are almost always caused by defective material (impurities), spinning defects (variations in yarn count or titre, differences in twist, irregular yarn, uneven yarn thickness), or defective dyeings (streaky dyeings).

Weft straightener, automatic All woven and knitted fabrics are subjected to a variety of stresses and dimensional changes during textile manufacture and finishing processes. These may take the form of distortions as well as displacements in the positions of the yarn which are unevenly distributed in a textile fabric and result in a new distorted state of equilibrium. As a rule, distortions in the weft yarns are involved here. The mechanics of weft straightening are based essentially on the fact that the distortions are produced during individual process stages through changes in length and tension and can therefore be corrected again. Thus, e.g. the overfed part of the weft is straightened by lengthening the path it has to travel relative to the remainder of the weft so that it is restrained. Monitoring of the running fabric with the human eye at high machine speeds is problematic and often impossible. Automatic controllers have therefore been introduced to overcome such problems. Detection of the weft position is accomplished in most cases by photoelectric means, whereby the reflection properties of the fabric surface dependent on the position of the weft and warp yarns, as well as the path of the individual yarn itself, are used as measurement criteria. The angle-dependent reflection of the surface is naturally dependent on the structure and pattern of the fabric whereas measurement of the position of individual yarns is largely free of such limitations, but is only possible as long as the yarns can be made visible in the projection. An angular-position-dependent output signal can be produced by projecting the weft yarns through two narrow slits behind each of which a photoelement is mounted. When the yarns pass under the slits with a certain amount of skew distortion, they produce a light/dark modulation on the photoelements which is all the greater the more parallel the weft is in relation to the slit.

For a normal weft configuration, the modulation of both elements is the same. After analysing the data from all the scanning heads, the system generates matching alternating current signals which can then be amplified, rectified, and subtracted from each other to obtain a position-dependent signal which can be used to display the weft position and control an associated straightening machine at maximum possible speed. From the magnitude and polarity of these signals, a microprocessor inside each scanner processes the initial distortion-related signals and determines the extent of its deviation from the norm. The higher the number of scanning heads, the better the signal communication and reliability of the display. If measures are taken to reduce the dead time of the control loop to negligible proportions by using straightening machines with a small fabric content and by keeping a short distance between the scanning heads and the straightening machine, any distortion which occurs can be corrected within a few metres.

The straightening unit illustrated in the Fig. detects the position of the yarns by optoelectronic means as a light/dark modulation with a photoelectric converter. This detection is contact-free and independent of the machine speed over wide limits. Two to eight scanning heads, with a motor drive to space them evenly across

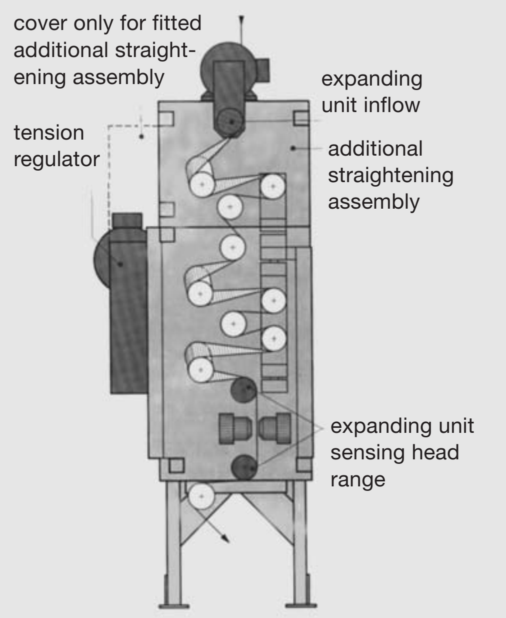

Fig.: Orthomat (Mahlo) straightening unit with additional facilities (cloth passage).

the fabric web, receive the modulated light from the fabric, convert the optical signal into an electrical signal and transmit this information via a transistor amplifier to dedicated display instruments. The number of scanning heads is determined by the width of the widest fabrics and the severity of the distortions. Provided the weft is uniformly skewed or bowed, fewer scanning heads will be required than if it were distorted into an irregular wavy configuration. As a rule, however, the more scanning heads there are, the more accurate the weft line analysis. By comparing the signals from several scanning heads, control commands are generated and adjustment of the bow and skew straightening machine is carried out simultaneously by two electronic controllers independently of each other and at maximum speed. Internal control loops adapt the Orthomat automatically to different fabrics. Transparency and contrast are balanced by changing the total sensitivity and lightness of the light source. The operator of the machine neither needs to preset a base setting nor readjust the system after a batch change. Colour, type of fibre, yarn count, surface effects, print design, pile and machine speed have no influence on the function of the unit. Only absolute impermeability to light and the total absence of any transverse structure impair the function of the Orthomat. The machine operator can view the state of the warp and, above all, the weft position in relation to it, from conveniently sited display units, e.g. at the entry to a drying stenter, but he does not need to do anything.

Weft straightening During textile processing, situations can arise when the weft in a particular fabric is no longer straight and at right angles to the warp (→ Weft distortion) and is either bow-shaped or diagonally skewed in relation to the warp. Weft straighteners (see Fig.) are used as a pretreatment to straighten the weft yarns in woven fabrics before printing, e.g. by running the goods through a levelling stenter or special weft straighteners installed at the entry to a drying machine. Even when, in engraved roller printing, horizontal stripes in a design have been engraved at a slight angle to the horizontal (“slashed”) in order to prevent the edge of the doctor blade digging into the engraved stripe on the printing roller, the weft yarns in the fabric must also be diagonally offset to the same extent before printing.

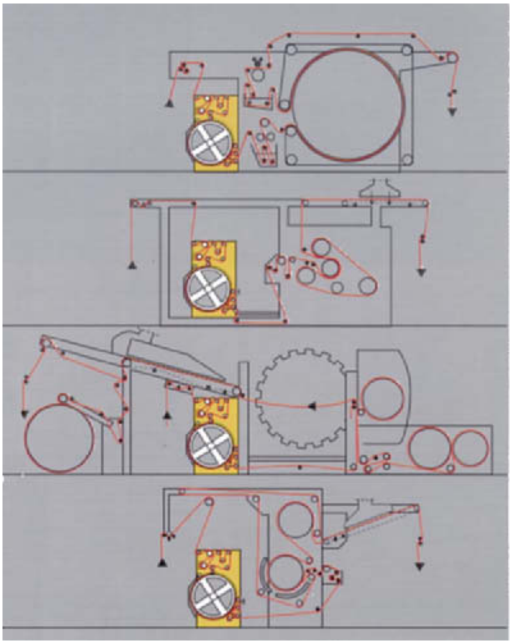

Fig.: Various possible applications of a weft straightener (Correfix).

Weft yarn A soft-twist wool weft yarn produced from hard worsted yarn or Cheviot yarn; not as lustrous as → Lustra fabrics.

Weibull functions in weathering Various models for the change in properties caused by weathering have been proposed, most of which use an exponential curve. The general form of the Weibull function (see Fig.) is

$$y = b_1 \exp\left[-\left(\frac{t+b_2}{b_3}\right)^{b_4}\right] + b_5$$

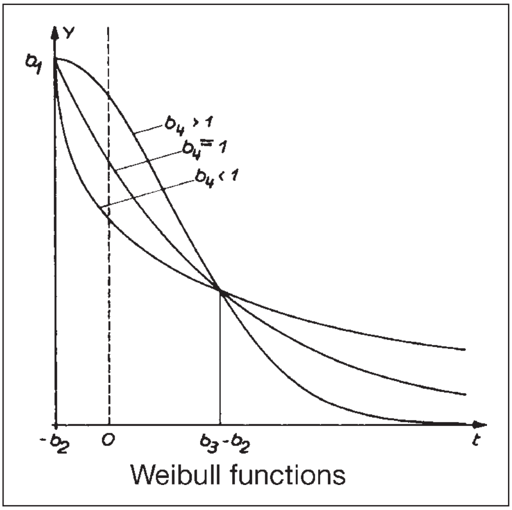

Fig.: Weibull functions.

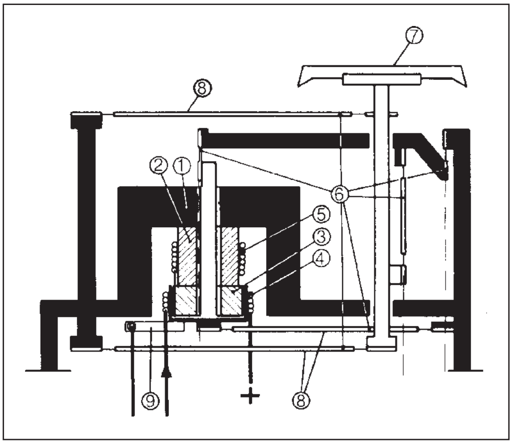

Fig. 2: Mettler electromagnetic force compensation. Schematic diagram of a weighing cell.
1 = magnet yoke and housing; 2 = permanent magnet; 3 = pole shoe; 4 = compensating coil; 5 = temperature compensation; 6 = flection bearings; 7 = weighing pan; 8 = link rods; 9 = position transmitter.

The five parameters describe the damage curve in general terms and can be interpreted physically as follows: b_1 is related to the maximum property to time $t = -b_2$ ($b_1 + b_5 = \text{max.}$); b_2 is the pre or post-ageing, i.e. if b_2 is positive, a certain amount of ageing or damage has already occurred at the beginning of the test corresponding to time b_2; b_3 signifies a kind of half-life period (time of $t = -b_2$ calculated until the property has decreased to 37%); b_4 describes the shape of the curve; $b_4 \leq 1$ quicker initial decrease, $b_4 > 1$ delayed decrease at the beginning; b_5 is an asymptotic value of the property (the value at $t = \infty$). Usually, b_5 is = 0, i.e. the tensile strength is = 0 for any further exposure.

Weighing machine Weighing machines are used for weighing textiles, dyes and chemicals to convert recipes into concrete quantities. Chemicals in solid or liquid form can be dispensed into a previously tared container placed on the platform of a weighing machine (i.e. weighing machine plus empty container set to zero). A suitable weighing machine can be integrated into dispensing systems to weigh out the various products in a colour kitchen or dye store (Fig. 1).

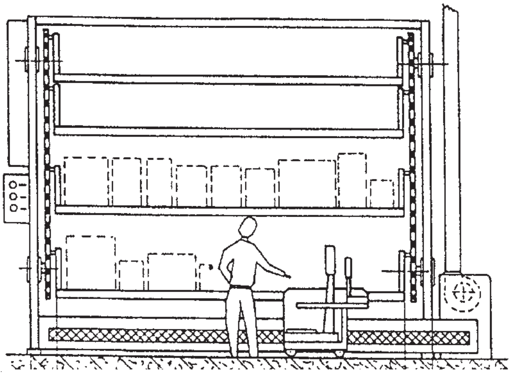

Fig. 1: Chemicals store (paternoster) with weighing up unit.

The weighing range of an industrial weighing machine is selected according to particular requirements. For rapid damping, weighing machines with electronic force compensation systems (Fig. 2) are used. The weighing data for a weighing machine can be transmitted via a computer interface (BCD output), keypad or floppy disk.

Weighing of dyes In order to implement recipes which are stated in % with respect to the weight of goods for exhaustion processes and in g/l for application methods, it is necessary to weigh dyes, etc., following any appropriate calculations. To avoid error wherever possible, the following methods are used:

– a key access card on each drum of dye; before weighing the dye the scales must be unlocked using the card.
– connecting the scales to the (electronic) dye measuring and recipe mixing system, which does not permit weighing of the next dye until the preceding one has been correctly weighed out.
– automatic weighing stations.

The third method offers the additional advantage that, in the case of dyes in powder form, there is no need for any person to come into contact with any dye dust.

In the case of the Color Service System (Figs. 1 and 2), powdered dyes are drawn off from the drums in which they are delivered into 90 litre dispensing con-

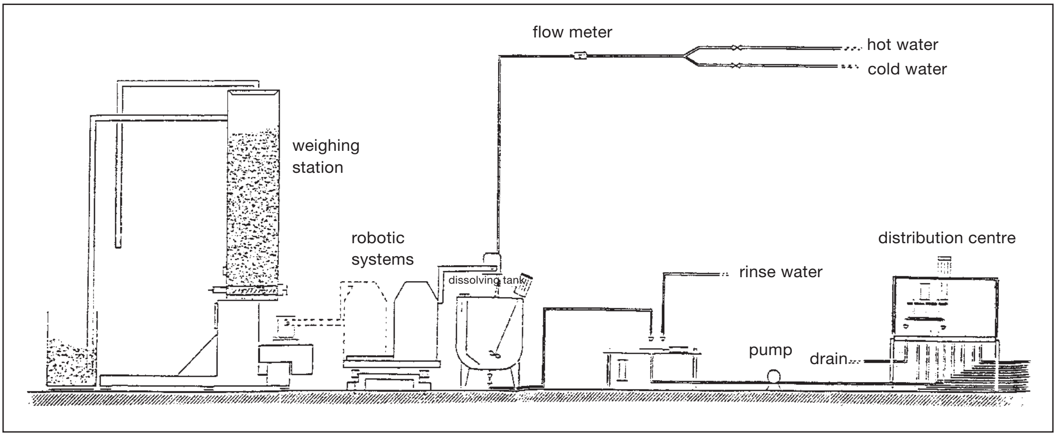

Fig. 1: Color-Service robotized (automatic) weighing station for powdered dyestuffs.

tainers. At the base of each of these containers is a helical screw conveyor which can deliver the dye powder, as required by the recipe, into drums which travel on a track along the row of dispensing containers. Each collecting drum rides along the track on a scale so that the dye can be weighed as it is dispensed from the helical conveyor. Once loaded with the correct amounts of the dyes required, the drum is transferred by robot to the dye dissolving tank in the dye kitchen.

Fig. 2: Robot for transferring weighed dye powder container from scales to dissolving container.

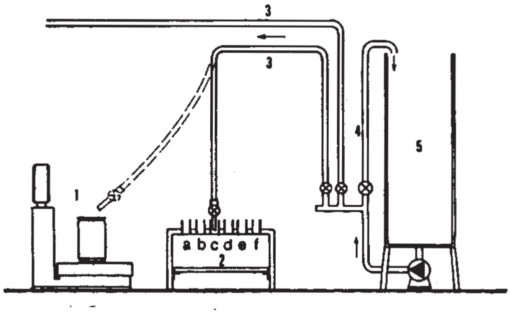

Fig. 3: Conveying thickeners or stock colour pastes to the weighing point (partial automation).
1 = scales; 2 a–f = mountings; 3 = feed pipes from silo to weighing point ; 4 = thickener circulation 5 = silo.

In order to minimize the problems associated with old or residual printing pastes in the print shop, it is important to weigh as accurately as possible only the quantity of dye paste which is absolutely needed. The relative quantities of dye must also match, of course, when weighing stock colour pastes. Under a semi automated system, thickeners and stock colour pastes can be pumped and piped to the weighing station (Fig. 3).

Weighing stations The monitoring of scales, meters and weights is an activity which constantly recurs in textile finishing. At various locations along the route of material flow, scales are used both continuously and non-continuously to weigh quantities. This provides important measured quantitative results for the production information system, while at the same time serving to guarantee consistent quality. Precision electronic and analytical scales have long become standard in the laboratory; of no lesser significance, however, is the increasing importance of exact weighing during production, particularly when the constant increase in raw material costs is considered. Nowadays production can make use of fully electronic industrial scales with a range of up to 6 t and which are accurate enough to permit the application of processes and recipes which have been tested in the laboratory.

The textile finishing material flow may be divided schematically into the entry of goods, warehouse or buffer store, finishing stages, finished product warehouse and despatching. Scales are needed to fulfil different tasks within these functional areas; in addition to use in the actual material flow, this also includes scales employed in analysis in development and quality assurance laboratories. This is by no means an exhaustive listing, serving only to indicate the variety of uses to which scales are put. However, it permits a demand profile to be derived for scales, which function as material sensors.

Simplified, the following features characterise the material flow scale:
- high precision with reproducible results,
- flexibility of use at different stages of the work,
- robust, i.e. suitable for an industrial environment,
- system compatible,
- data saving at all stages.

In dyeing, scale are a component within the entire weighing station (→ Weighing of dyes, see Fig. 1). Dye is drawn off from warehouse containers and weighed on travelling scales according to the recipe for the current batch. Robots equipped with manipulating arms remove the containers with the weighed out dye from the weighing station scales and transfer the dye to the dissolving tanks. The weighing container is rinsed in the dissolving tank and then returned to the scales by the robot. The dissolving tanks are equipped with:
- a circulation pump for dissolving the dye,
- sensors for minimum and maximum level,
- a temperature sensor for the dissolving temperature data,
- direct steam heating,
- litre meters for cold and hot water with a litre scale,
- series of automatic valves for the functions: fill, top up rinse, container rinse, sensor wash (these functions can be carried out using either hot or cold water and are monitored by the litre meter).

Dissolving time and temperature for each dye are specified by the weighing station computer: it determines the highest temperature and the longest time for dissolving as per the recipe and passes them as instructions to the dissolving station. The dye is only tipped into the dissolving tank once a prescribed quantity of liquor for dissolving has been added. The prescribed temperature is achieved by mixing hot and cold water. If the prescribed temperature cannot be achieved by water mixing, the mixture is additionally heated using direct steam. The specified dissolving time does not begin to run until required conditions for dissolving have been achieved. The circulation pump runs continuously while the weighing container is being emptied and during the dissolving time which follows, thoroughly mixing the dye with the liquor and ensuring that it is dissolved to the best effect. Once the dissolving time is over, the liquor circulation is stopped by a three-way valve which empties the dissolving tank. The dissolved dye flows via a distribution station either to mixing tanks at the dyeing machines or into a dye kitchen. Each mixing tank to which the dye is delivered has a separate inlet connection. A rotating arm moves to the correct position, docks and thus connects the dissolving tank with the mixing tank at the machine. A pump controls the flow of the dye from dissolving tank to distribution station. The work sequence then ends with a rinse programme which cleans the dissolving tank and the pipes connecting it to the mixing tank at the machine. A complete weighing and dissolving station supplied with 90 powder dyes performs as follows: on average every three hours, 39 recipes each containing 5 dyes can be weighed out, dissolved and delivered to the mixing tanks at the machines in the dyeing shop.

Weighting,

I. A formerly common practice of artificially increasing the weight of cotton goods by adding kaolin, magnesium sulphate, zinc sulphate, etc., the purpose being to give the illusion of better quality.

II. → Weighting of silk in order to compensate for weight lost during the removal of bast and to achieve particular qualities. Weighting is applied either to the yarn or to the piece. The weighting of pieces was standard practice in the 1930s but then the use was largely discontinued. In the case of tie silk, weighting is a finishing process applied to the yarn. The handle this achieves together with the heavier seeming fabric, contribute to the high value of yarn dyed tie silk. Both vegetable and mineral weighting are known; the former is scarcely represented any more, whereas the tin phosphate-silicate method has proved itself. More common, however, is polymer weighting on the basis of MAA (methylacrylic acid amide), whereby the reaction is triggered using ammonium persulphate. Not only can the loss of weight from the bast be recovered, but an acceptable handle can be achieved at up to 35% above raw material weight (also true for tie silk). Results were first achieved using a jigger, subsequently also a beam dyeing machine.

Weighting finishes Carried out in order to produce a fuller handle in both fabrics and knit goods. The process should no longer be applied for the purpose of falsifying better quality (→ Weighting). Instead of natural products (starch, dextrin and similar), plastics are now used to achieve a fuller handle (resins of polyvinyl, polyacryl, polemetacryl and urea). For effects which are wash fast at high temperatures, soluble ether celluloses are used which are deposited on the fibre using a salt bath.

Weighting of silk In earlier times, silk, in particular, being the most precious and costly of natural fibres, was traded by weight. As a consequence, the high weight loss during degumming often led silk dyers to restore this loss through a weighting process, or even to exceed the raw material weight. Following newly developed fabric constructions, silk is nowadays essentially only weighted to achieve improved sheen, handle, fall or fullness for specific final articles such as ties, edging and embroidery. As a rule, weighting is done before the yarn is dyed in rope form. Silk may be charged (weighted) with:

– metallic salts (tin phosphate-silicate weighting),
– vegetable extracts (tanning agents),
– synthetic resins (e.g. methacrylamide).

I. As yet no substitute has been found for the tin phosphate-silicate weighting process known for decades. This method of weighting nowadays plays only a minor role, but the principle may be explained briefly.

The process comprises various stages which may be repeated several times according to the degree of weighting desired. A "tin weighting" treatment (with tin and phosphate) achieves a weight increase of between 10 and 15%. a) The silk is first treated in a cold 28–32°Bé solution of tin(IV) chloride for 1 to 1.5 hours, spun and then rinsed cold. It is important that soft water is used since water containing calcium leads to precipitation and loss of sheen. b) After rinsing the silk is treated for 1 hour using a 5–9°Bé strong solution of disodium hydrogen phosphate (Na_2HPO_4) at 50–60°C. Depending on the degree of weighting desired, these latter two stages may be repeated 2 to 4 times. c) After the final treatment, the silk is immersed in a bath of 2–7°Bé concentrated silicate at 50–60°C, whereby the basic tin phosphate already formed is converted into wash fast tin-sodium silicate. The water glass treatment achieves in the silk an increase in volume and an essential improvement in sheen and handle as well as in dye uptake. These processes for weighting silk using tin salts, though widespread in earlier times, are seldom carried out nowadays on account of the disadvantages associated with mineral weighting (reduction in the life of the silk, particularly when subjected to mechanical stresses, and the great demands of the multi-stage process) which are greater than the advantages in weight gain and improved handle and fall.

II. Vegetable weighting using tanning agents is easy to carry out and the silk is not damaged in the process. However, large quantities are required to restore the original weight and the greatest increase obtainable is at best 10% above the original.

III. For several years the weighting of degummed silk has been carried out by means of graft polymerisation using monomeric methacrylamide, which leads to results in handle, sheen and fullness comparable to those under I. The polymerisation occurs in a thin aqueous solution of methacrylamide at temperatures below 100°C. It is usually done immediately following degumming, the yarn being in the form of rope or wound on packages, and in advance of dyeing on the dyeing machine. New investigations are concerned with the weighting of fabrics in order to achieve improved care characteristics. Such a weighting is wash resistant and persists after dyeing. Despite consistency in the process conditions great variation in the degree of weighting can arise. Other graft polymerisation processes using vinyl compounds have until now, only be applied to silk in the form of fibre or yarn. Their purpose is not so much to weight the silk as to improve the quality of the silk textile.

General disadvantages of the weighting process, in addition to the costly and cumbersome process, are ecological problems, possible damage to the fibres, poor affinity to dyes and poor wash fastness of the dyed goods. In consequence, silk is nowadays weighted only for use in specific final articles.

Weight per metre → Fabric weight.

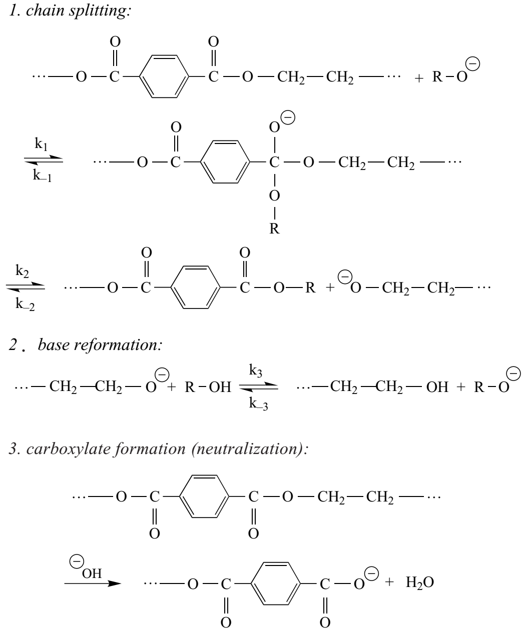
Weight per square metre → Fabric weight.

Weight-reducing (de-weighting). The term refers to a heterogeneous method of → Weight reduction involving alkali hydrolytic treatment of the sheath of polyester fibres. The required heat zone dwelling is carried out, for example, under the pad-roll system (Apolotex Elektron Reactor) or modified processes. Whereas previously only 2–3% of fabric weight was lost during alkaline weight reduction, a 20–30% degree of weight reduction is normal. This is dependent upon liquor concentration, temperature and exposure time. Hoechst process: a continuous process involving highly concentrated alkali in the padding liquor, if possible minimally applied, and then short (1 minute) HT steam treatment (approx. 120–150°C); a loss of tensile strength is noted. The Debaca process reduces the loss of tensile strength by impregnating twice with dilute sodium hydroxide solution as part of a pad steam process (second time in the steamer). → Alkali treatment of polyester.

Weight reduction of polyester fibres The weight reduction of polyester fibres in fabrics derives from patents held in the 1950s by ICI and Dupont and is therefore as old as the large-scale production of polyester fibre. The aim of weight reduction is to produce finer fibres in order to alter the handle and the visual properties of a fabric. This aim is documented by the fact that this finishing effect is also referred to as "silk finish". A lowering of breaking strength is sought as a secondary effect, which leads to a reduction in snag susceptibility as well as, for yarn fabrics, of pilling. In the case of Japanese Shingosen articles, microfibres (which themselves have the finest titres of 0.1 dtex) are alkalised using the pad-steam process to achieve a weight loss of 3–5%, thus obtaining extremely soft polyester articles.

The chemistry of weight reduction is based on the saponification of the polyester to glycol and terephthalate at the surface of the fibre with lyes, whereby the terephthalic acid formed neutralizes sodium hydroxide solution and so leads to a steady fall in the pH of the treatment bath (→ Alkali treatment of polyester).

As a general rule the process makes use of an aqueous sodium hydroxide solution in a more or less long liquor. The rate of weight reduction, of course, increases with liquor concentration and temperature. The



process temperatures lie in the range 9–130°C and treatment times, depending on liquor concentration and temperature, from 1–4 hours. The rate of weight reduction is strongly influenced by the state of the fibre material, such that whenever excess liquor is used in order to achieve a prescribed weight reduction (e.g. 10%), colour matching must be carried out specific to the material, bringing with it a series of associated difficulties not discussed further here. To overcome these difficulties it is necessary to use only sufficient sodium hydroxide solution as is required in stoichiometric terms to achieve the prescribed weight reduction (100% theoretical conversion, Fig. 2).

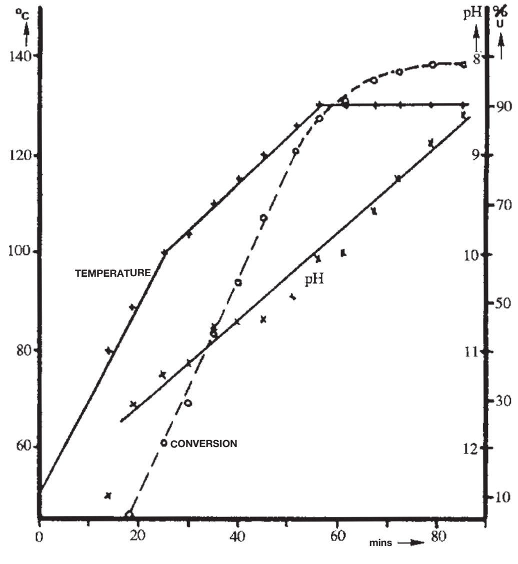


Fig. 1: Progress over time of a polyester fibre alkalization process in a beam dyeing machine; polymer weight reduction in %/min, liquor pH change in pH/min, heating up rate in °C/min.

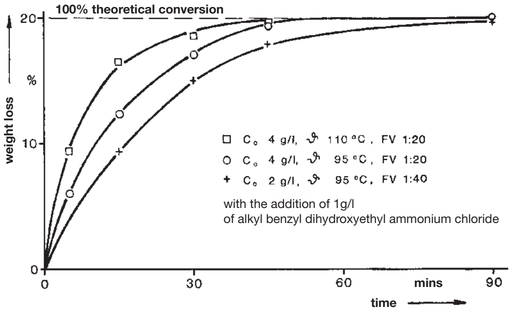

Fig. 2: Polyester polymer weight loss with caustic soda.

For long liquor processes, the low liquor concentration leads either to too long a dwelling time or requires the use of highly effective accelerators. However, these accelerators, as with all other known commercial accelerators, have the disadvantage that their use slightly yellows the goods, which is a disadvantage for white goods, pastel colours and prints on a white ground. Attempts to remove this yellow discolouration using oxidation and/or a reduction have so far failed. The use of higher temperatures in processes with long liquor and consequent relatively long dwelling times leads to a disproportionate loss of strength. When weight reduction is carried out at low temperature (95°C), as well as an excellent weight reduction of approx. 20%, an almost parallel progression can be observed of the maximum tensile force to the highest possible maximum tensile force, which should fall due to the increase in fineness corresponding to the weight reduction. This behaviour can be interpreted in terms of the orientation of the molecules being higher in the outer region of the fibre, thus making a greater contribution to overall fibre strength. At a higher weight reduction temperature (130°C), on the other hand, sodium hydroxide solution diffuses into the fibre core and there hydrolyses the molecules relevant to the strength.

Weight units → SI system of Units.

Weisz's Pore Model Used in the discussion of textile chemical processes, it has the advantage of clarity and offers the experimental textile chemist a mechanical interpretation of events at the molecular level.

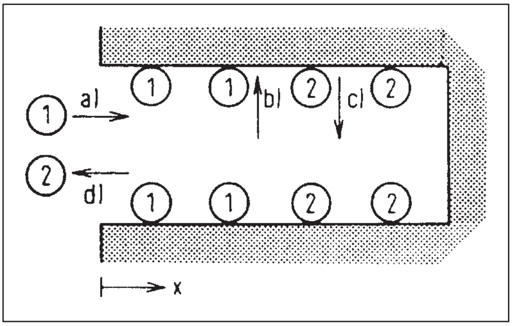

Fig.: Diagram of a textile substrate pore (Weisz's Pore Model).
1 + 2 = various sorptives, e.g. 1 = dye; 2 = retarder.

The Fig. shows a diagram of a pore in a substrate which is to be dyed.

If one assumes good circulation (a sufficiently rapid transportation of the material in the dye bath), the dye process can be paraphrased in general, in terms of the following processes:

a) diffusion of (1) in the substrate,
b) immobilization of (1) (e.g. through adsorption or chemical reaction),
c) mobilization of (2) (e.g. through desorption),
d) diffusion of (2) out of the substrate.

The → Diffusion of the two mobile substances, processes a + d, can be considered static movement processes in the sense of the first → Fick's law of diffusion.

Weld → Natural dyes.

Welding,

I. The uniting of metal parts by heating without the aid of any additional binding agent (in contrast to → Brazing). Autogenous welding is carried out with the aid of an oxy-hydrogen flame, a methane-oxygen flame or an oxy-acetylene flame; welding is also carried out electrically. Argon is used as a shielding gas when welding V4A steel in order to prevent later corrosion of the welding seam.

II. → Heat bonding of thermoplastics.

Welliné (Fr. = waved) A wave-shaped → Ratiné effect. It involves carded yarn ratiné material with a wave-like structure. The waves may be oriented longitudinally, transversely or diagonally. The basic material of the cloth is wool velour. In order to achieve a particularly fine effect, cashmere, mohair, camel hair or alpaca is used as upper weft.

Well water → Ground water.

Wesel triangle A so-called physiological triangle used for calculating and predicting the efficiency of any given item of clothing. It derives its name from the letters WSL, whereby these form the three corners or the triangle and allow for the expression of the relationship between the following three basic tests (W, S and L in German) for →: Heat retention; Perspiration transport measurement; Air permeability. If one enters the measured values on the sides of the wesel triangle, the result is the linear relationships between: heat retention and perspiration transport on the side WS, perspiration transport and air permeability on the side SL, heat retention and air permeability on the side WL. Joined together, the three points create the central ABC field as a measure of "comfort" (clothing physiological basic characteristic), while the triangles I, II and III in the corners W, S and L indicate by means of their form and size the significance of the individual factors heat retention (W), perspiration transport (S) and air permeability (L) (Fig.).

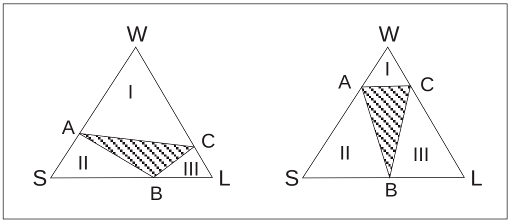

Fig.: Wesel triangle.

Wet aftercleaning treatment A post-treatment in the field of dry cleaning undertaken to remove water soluble residues. It can, depending on the goods and the residues concerned, be a total or partial wet treatment, but is not a form of washing. Wet aftercleaning must fulfil the fundamental requirement of maintaining, as far as possible, the form and finish of the goods. Any goods wet aftercleaned, according to regulations, must retain the character resulting from the dry cleaning process.

Wet brushing machine → Raising machines.

Wet bulb temperature When a wet textile is being dried the temperature in the drying medium at some distance from the fibre may be, for example, 140°C (t_{jet}). However, if the laminar boundary layer was penetrated in the immediate vicinity of the fibre in order to measure its temperature (Fig. 1), it would be found that, so long as surface water remains present, the temperature falls to that of the so-called wet bulb temperature of the fibre. Because this surface water is constantly renewed at the fibre surface due to capillary action during the first drying phase, mass transfer can take place in a way similar to that following the laws of evaporation from an open water surface. If it is imagined that the surface of the goods has a random dimension, then after an initial warming up phase the temperature of a damp textile over which air of low temperature flows will stabilise at a constant value. Through cooling, the

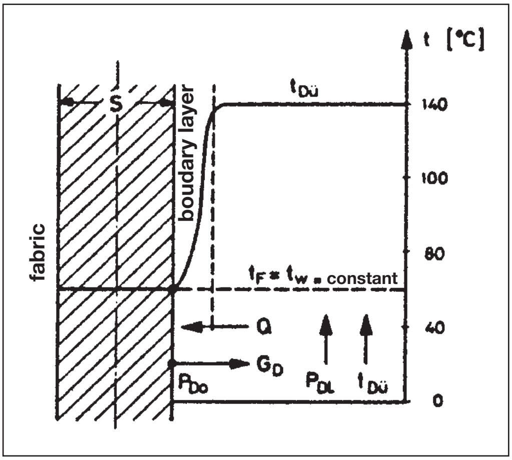

Fig. 1: Temperature curve at the surface of a fibre (in the 1st drying phase).

surrounding air will also tend towards this constant limiting value (thus the term wet bulb temperature).

For the first drying phase it is therefore true that the same temperature is obtained at the surface of damp goods as would be obtained at the open surface of the same liquid, that is to say in the case of drying by hot gas, the so-called surface temperature or adiabatic steady state temperature. According to Kröll, the surface temperature during the first drying phase depends upon the velocity and direction of the air flow in so far as does the relationship of the heat transfer coefficient and the mass transfer coefficient. For a water/air system the adiabatic steady state temperature of the fluid approximates to the wet bulb temperature.

In highly simplified form, the phenomenon of wet bulb temperature may be explained as follows. The temperature difference between the circulating air and the wet goods will tend to fall due to temperature equalisation: liquid and goods tend to acquire the temperature of the circulating air. However, as the water would attain its boiling point in the process, it takes up a large amount of energy for evaporation; this energy is extracted from the goods in the form of latent heat of vaporisation. These two tendencies, heating up to the same temperature as the circulating air versus cooling due to the extraction of latent heat, result in a balance characterised as the wet bulb temperature.

During drying, moisture can be transported to the surface of the goods from the interior in either liquid or vapour form. A migration is, however, only possible in the liquid phase. Once the first reversal point is reached the movement mechanism of the liquid phase at the surface of the goods is interrupted. The drying level, which marks the boundary between the liquid and gaseous phase, migrates into the interior of the goods. Presupposing that the total of small capillaries reaching the surface is significantly greater than the total of larger capillaries, then the small capillaries remain filled with liquid for as long as their capillary action exceeds the friction. As a consequence, liquid flows in the small capillaries during the first drying phase both from the interior of the goods and from the larger capillaries. During this phase the fine capillaries are continuously supplied with liquid from the interior of the goods, and the concentration of this liquid rises accordingly because the solvent evaporates at the open surface while the dispersed particles remain behind. The surface of the goods remains moist for as long as the suction of the capillaries is sufficient to draw enough moisture from the fabric interior as is lost by evaporation at the surface under atmospheric conditions. Once this is no longer the case, the rate of drying is reduced. The various points at which evaporation takes place, which together represent the “drying level”, migrate deeper and deeper into the interior of the goods. In non-hygroscopic materials, this drying level represents the boundary between capillary and gaseous moisture transportation. In the case of a hygroscopic material there is no true drying level in the form of a distinct boundary between dry and moist layers of material, but rather areas of differing moisture content within which a vapour pressure balance is maintained which depends on the particular local temperature and humidity. During the first drying phase, dissolved substances which become transported to the surface with the capillary water concentrate there if they cannot evaporate, and thereby give rise to the phenomenon of migration.

The first breakpoint in the drying curve occurs when the rate at which liquid is transported within the capillary system becomes less than the rate of evaporation. The liquid menisci in the capillaries, and thus also the drying level, retreat deeper into the capillaries towards the interior of the goods. The location of the break in the curve for any given liquid depends on the capillary properties and the temperature of the goods. From this point on the drying curve, the properties of the goods influence the drying process and the second drying phase begins. The transport of water within the textile material continues due to capillary action in the wet material up to the evaporation zone. From that point on the dampness must be transported by gaseous diffusion through the already dried layer to the surface, from where it is removed by the surrounding air. During the second drying phase the rate of drying becomes ever more dependent on thermal conductivity and gaseous diffusion across the dry layer. As a result the drying rate during the first phase can no longer be maintained. As the factors hindering moisture transport increase, ever decreasing quantities of water can be transported to the surface.

During the second drying phase (Fig. 2), both the

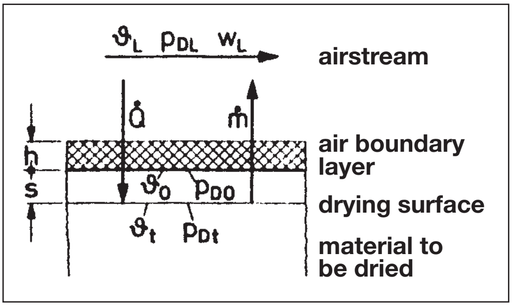

Fig. 2: Heat and material flow in the 2nd drying phase.

transport of heat energy and of mass must take place across increasing distances through the already dried layer of goods by, respectively, the mechanisms of thermal conductivity and diffusion. The heat transition coefficient k and the vapour permeability coefficient σ_D now come into effect.

heat flow: $$\dot{Q} = A \cdot k\,(\vartheta_L - \vartheta_t)$$

mass flow: $$\dot{m} = \frac{A \cdot \sigma_D}{R_D \cdot T}\,(p_{Dt} - p_{DL})$$

with $$k = \frac{1}{\frac{1}{\alpha} + \frac{s}{\lambda_S}}$$

and $$\sigma_D = \frac{1}{\frac{1}{\beta} + \frac{\mu_D \cdot s}{D}}$$

k = heat transfer coefficient (W/m^2K);
α = vapour permeability coefficient (m/s);
ϑ = temperature (°C);
p_{Dt} = vapour partial pressure at the drying level;
μ_D = diffusion resistance coefficient;
t = at the drying level;
L = in the air stream.

During this drying phase, roles are played by both the external diffusion conditions (β and the difference in partial pressure $p_{Dt} - p_{DL}$), which may be influenced both by the temperature and the velocity of the air, and by the diffusion properties μ_D and D of the goods. To the extent that the distance s separating the location of drying within the material from the surface increases, the influence of the heat transfer coefficient α and of the material transfer coefficient β, and thus of the air velocity w_L on the drying rate, decreases. Air velocity has barely any remaining influence on the final drying of thicker goods; the factors time and temperature play a decisive role instead of the difference in partial pressure.

In totally non-hygroscopic goods the final residue of humidity evaporates at saturated vapour pressure and at a drying rate which is greater than zero, the process occurring at the point of greatest distance from the ventilated surface of the goods. In the case of hygroscopic goods the drying rate sinks still further, i.e. a second break occurs in the drying curve and the third drying phase commences. In addition to the constraints in operation during the second drying phase relating to the diffusion of water vapour through the capillaries, moisture transport is now further constrained by diffusion within the fibre material. The drying rate progresses during the final phase towards zero accompanied by a final moisture content which is determined by the sorption properties of the goods together with the relative humidity of the drying air. Drying ceases to operate once the partial vapour pressure in both the goods and the surrounding air are equal. In other words, the final result achieved is in balance with the atmospheric humidity of the surrounding air at that time.

When the humidity within the goods reduces to the point that evaporation at the surface slows down, the temperature of the goods begins to rise. Goods emerging from the drying chamber have a temperature which lies somewhere between the wet bulb temperature and that of the dry air. The temperature profile of the goods is entered on a drying curve as a function of the treatment time t and the speed of the goods v. The length of the treatment chamber L is represented as a line defined by the product of v multiplied by t (Fig. 3).

In the full process cycle the time t_1, the speed of the goods v_1 and the treatment chamber length $L = v_1 \cdot t_1$ are realised. If the speed of the goods v is increased, then to maintain the condition $L = v \cdot t$ the time must be decreased. If, for example, the machine is run with a speed of goods v_2 then only the time t_2 may be taken for

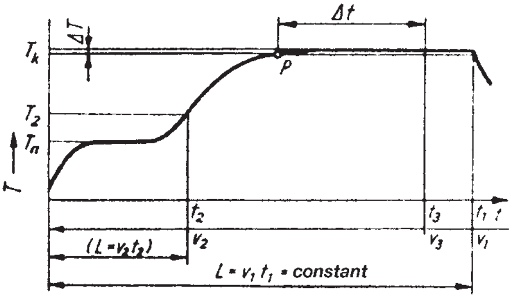

Fig. 3: Temperature of textile fabric T = f(t) in drying and heat setting in one operation.

the process and the resulting goods temperature T_2 characterises the machine purely as a drying machine. The profile of any drying curve does, of course, depend on the type of fibre, but also on the thickness and thus the permeability of the goods. The weight of the goods determines, via the quantity of water absorbed, the drying rate. Should goods be dried which contain not only water but also solutions (e.g. dilute sulphuric acid from carbonising), migration can result.

Wet crease resistance The property of a fabric whereby it does not acquire creases when squeezed in a wet state. Wet crease resistance includes an anti-creasing capacity, in other words the ability of the fabric to lose creases acquired during wear when immersed in water. (This is tested by squeezing the dry fabric in such a way as to cause creases, then laying the fabric in water; if the creases smooth away once wetted, this indicates good crease recovery.) It can be observed that a crease resistant fabric at the same time possesses an anti-creasing capacity, whereas a fabric with a high anti-creasing capacity but poor crease resistance acquires folds during washing. In other words, crease resistance determines whether no creases or only a few creases are present after washing.

Wet crease-resistant finishing A process in resin finishing for improving wet crease resistance. Processes particularly suited for this are those which enable the cross-linking of cellulose when in a swollen state (→ Wet cross-linking process).

Wet cross-linking process A resin finishing process for cross-linking cellulose in a swollen state by means of hydrolysis resistant resin finishing agents in the presence of strong acid, e.g. hydrochloric acid, or strong alkali, e.g. sodium hydroxide solution, at room temperature. Method of working: pad the finishing liquor, batch rotation, dwelling at room temperature, after-washing. Finishing effect: a very good wet crease recovery angle, unaltered dry creasing angle with associated slight loss of strength, in particular of abrasion resistance. When cross-linking in an acid medium, DMDHEU and tetramethylol acetylenediurea are preferred. The reaction time is 16–24 hours. Application is for tablecloths, furnishing fabrics and bedding; the preferred fibres are cotton and linen. Wet cross-linking in an alkaline medium is part of a multi-stage process, and has acquired no practical significance in isolation (in contrast to wet cross-linking in acid medium). The first stage is classical → Dry cross-linking. The second stage is alkaline wet cross-linking with, for example, epichlorhydrin, dichlorpropanol, n-methylolacrylamide, sulphonium compounds. → Ambivalent crosslinking.

Wet decatizing → Decatizing wool in hot water.

Optimum fixation is achieved during wet decatizing when the goods have become able to withstand the finishing processes which follow or when tensions or faults arising from preceding processes (e.g. the snowing of dyes) are removed in a controlled manner. However, the optimum conditions for the fixation of different textile fabrics are themselves different. The finishing process which is to follow also determines the extent of fixation. Thus goods which are to be dyed in rope form must first be treated at boiling or even higher temperatures, whereas an article which will only ever be washed at 40°C needs to be fixed to a lesser degree in order to avoid wash creases. Temperature, time and humidity, when suitably applied, provide for good fixation stability. If the temperature is raised the time must be shortened. The time can also be shortened through the addition of reducing agent at an unchanged or a higher temperature without prejudicing fixation stability. Time and temperature clearly interact together and can vary according to quality. The prerequisite for a regulated process cycle (i.e. one under the control of the finisher) is the optimum setting of the pH value of the goods. In the case of patterned goods, in pursuit of colour fastness at the necessary temperatures of 60–70°C, the pH is by preference adjusted towards acid. However, this means that the optimal conditions for fixation in water are no longer obtained. The nature of cooling which follows the boiling process is of significance for the sought fixation effect. The reduction of temperature at this stage strongly influences the partial removal of crosslinks. The degree of fixation depends during the cooling phase on the state of tension in the fabric; a relaxation of tension is a precondition for good dimensional stability during later processes.

Four different stages of work are carried out in the course of wet finishing, which are falsely generally referred to as boiling. According to the different fixation effects, one should distinguish between the following wet decatizing processes:

- burning,
- crabbing,
- smoothing,
- fixation.

1. Burning refers to the treatment of goods in boiling water followed by immediate total cooling in cold water. The goods may not be cooled on rollers because slight glazed moirés can form. The purpose is to fix the raw goods (increasing the textile stability). This generally tends to guarantee that no significant changes occur to the fabric surface or the body of the fabric as a consequence of subsequent washing. With this end in view a synthetic detergent is added to the liquor. This leads to rapid wetting of the goods and prevents any burning in of the dirt. The liquor is then brought to the boil in the tub and treated thus for 8–12 minutes without the application of pressure. The goods are then drawn off through cold water. To ensure identical treatment of both ends, the fabric may be drawn with numbered end first on the first occasion and with unnumbered end first on the second occasion. Light worsteds,

ladies goods and sometimes even heavy gabardine (for raincoats) are burned in order to retain a clearly defined thread on finishing.

2. Crabbing refers to a treatment of the goods at 40°C on the scouring machine. Crabbing results in the goods swelling and, like burning, precedes the washing process. The treatment serves to prevent breakages of the thread in the washing machine in principally, heavily woven worsteds and goods manufactured from heavily twisted ply-yarns. Again as with burning, a synthetic detergent is added to the crabbing liquor with this end in view. Once cooled, the goods are moved to the washing machine either after a short time or immediately.

3. Smoothing leads to an improvement of the goods in terms of both appearance and handle, becoming smoother, more even and shinier across the surface and both softer and more supple to the hand. The strength of glaze achieved is dependent on the pre-treatment of the goods, the temperature of the water, the duration of treatment, the pressure applied and the length of time for which the goods are cooled on the drum (fixation). In the case of goods which will only be washed, it is sufficient to remove the so-called unevenness by treatment on the scouring machine in water at 45°C. Piece dyed goods, on the other hand, must be treated in water at 50–60°C after dyeing because rope creases originating in the dye shop are difficult to remove. Depending on the type of article, the goods are treated for 5–12 minutes and then allowed to cool on rollers. An excessively long cooling of panama, fresco and gabardine, etc. on batching rollers leads to the formation of glazed moirés or reversed ridging (the cooling time should be at the most 2–3 hours).

4. Piece dyed goods are fixed before dyeing on the scouring machine in water at a temperature of at least 80°C. The fixation effect becomes more favourable the higher the temperature difference chosen between heating and cooling. Treatment above 80°C and, under some circumstances, with the addition of a reducing agent produces stronger fixation. After treatment on the scouring machine the goods are wound onto a roller and completely cooled by being left overnight. Reversing the rolling up during the scouring treatment improves identical effects at both ends.

On grounds of cost effectiveness, smoothing goods following rope and at times also open width washing, fixing rope dyed goods in advance of dyeing and smoothing such goods following dyeing are usually carried out on the Konticrab machine. It is clear, nonetheless, that the results obtained by such a continuous process are not as good as those using a crabbing jack. This is particularly true of articles which are particularly susceptible to rope creases, such as flannel. However, the higher productivity, better integration into the finishing sequence and the evenness of effects at the ends of material argue in favour of accepting the risk of possibly non-removed rope creases on the Konticrab and of only using the crabbing jack in exceptional circumstances. Fixation which differs at the two ends, which can arise easily on the crabbing jack, leads to uneven dyeing of piece dyed articles if the fault arises before dyeing. The end of the piece which was at the bottom of the beam in the crabbing jack (the "tail end") dyes darker in such a case. Differing effects at the two ends result in differences in glaze during smoothing following the dyeing; the end rolled inside the roll of goods has a higher glaze. For these reasons the crabbing jack is rarely used any more for fixation processes in the modern textile finishing plant.

Wet decatizing fastness → Potting fastness.

Wet development → Fixation of dyeings and prints carried out in an aqueous medium. Prints are with vat leuco ester, naphthol and reactive dyes in particular on cotton, linen and viscose.

Wet dwell (batch) process The fixation of compounds (e.g. resin finishes or reactive dyes or peroxide) by dwelling of the goods in a wet state.

Wet extensibility The phenomenon of moisture dependent increase in both width and length of polyamide goods. The polyamide fibre stretches by approx. 2–3% due to the take up of moisture; the effect is reversible.

Wet fastnesses A collective term generally used for the demand that during use dyeings and prints exhibit colour fastness to →: Water, Perspiration, Washing and Wet ironing, whereby more specialist demands also include fastness to →: Alkali fastness of dyeings and prints; Fastness to cross dyeing; Fastness to sea water as well as wet light fastness.

Wet finishing (wet processing). The term encompasses all wet treatment processes such as bleaching, dyeing, printing, impregnation, mercerising, carbonising, milling, etc. in contrast to → Dry finishing of fabrics.

Wet finishing of wool piece goods In the course of wet finishing wool, four varying processes are carried out which are generally described falsely as boiling. They should be distinguished as follows:

I. Burning. This is the treatment of goods in boiling water followed by immediate complete cooling in cold water. The goods may not be cooled on rollers because slight glazed moirés can form. The purpose is to fix the raw goods (increasing the stability of the textile) in order to preclude changes to the surface or the body of the fabric as a consequence of subsequent washing. A synthetic detergent is added to the liquor, as is a reducing agent under some circumstances (to fix the textile), in order to produce rapid wetting and to stabilise the form. The liquor is then brought to the boil in the tub and treated for 8–12 minutes without the application of pressure. The goods are then drawn off through cold water. To ensure identical treatment of both ends, the

Next Page

fabric may be treated for a second time, starting at the opposite end. Light worsteds and sometimes also heavy gabardine (for raincoats) are burned in order to retain a clearly defined thread on finishing.

II. Crabbing. This means the treatment of the goods at 40°C on the scouring machine, synthetic detergent also being added. Crabbing results in the goods swelling and also precedes the washing process. The treatment prevents breakages of the threads in the washing machine in, principally, heavily woven worsteds and goods manufactured from heavily twisted ply-yarns. Once cooled, the goods are plaited down on a batch roller either after a short time or immediately, and then moved to the washing machine.

III. Smoothing. This process leads to an improvement of both appearance and handle. The strength of glaze achieved is dependent on the pre-treatment of the goods, the temperature of the water, the duration of treatment, the applied pressure and the length of time during which the goods are cooled on the drum (fixation). In the case of goods which will only be washed, treatment on the scouring machine in water at 45°C is sufficient. Piece dyed goods, on the other hand, must be treated in water at 50–60°C after dyeing because rope creases originating in the dye shop are difficult to remove. Depending on the type of article, the goods are treated for 5–12 minutes and then allowed to cool partially or completely on rollers. An excessively long cooling of panama, fresco and gabardine, etc. on batching rollers leads to the formation of glazed moirés or reversed ridging (cooling time may last at the most 2–3 hours).

IV. Fixation. Piece dyed goods are fixed before dyeing on the scouring machine at a temperature of at least 80°C. Such a treatment can be seen as a substitute for wet decatizing (in some circumstances with the addition of a textile fixing agent). The fixation effect becomes more favourable the higher the temperature difference between heating and cooling. Treatment above 80°C produces stronger fixation. After treatment the goods are wound onto a roller and completely cooled by being left overnight. Reversing the rolling up during the scouring treatment improves identical effects at both ends. Because of cost effectiveness, smoothing goods following rope, and at times also open width washing, fixing rope dyed goods in advance of dyeing and smoothing such goods following dyeing are usually carried out continuously (see Fig.). It is clear, nonetheless, that the results obtained by such a continuous process are not as good as those using a crabbing jack. This is particularly true of articles which are susceptible to sharp rope creases, such as flannel. However, higher productivity, better integration into the finishing sequence and the evenness of effects at the ends of material argue in favour of continuous processing. Fixation which differs at the two ends, which can arise easily on the crabbing jack, leads to uneven dyeing of piece dyed articles if the fault arises before dyeing, since the “tail end” of the piece usually dyes darker in such cases. Differing effects at the two ends result in differences in glaze during smoothing following the dyeing; the end rolled inside the roll of goods has a higher glaze.

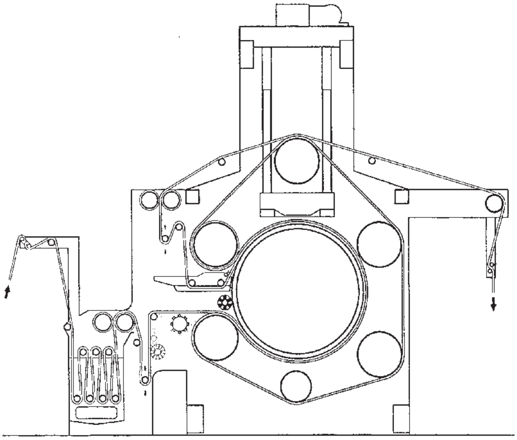

Fig: Continuous fixation machine “Multiset” for wet finishing of wool piece goods (Sperotto Rimar).

Wet fire extinguisher → Water fire extinguisher

Wet fixation process A special fixation process used for prints in which the dye is applied without or with only a proportion of the fixing chemicals, and in which fixation follows without intermediate steaming and in a bath containing no, or only a proportion of, the fixing chemicals. For example: for reactive dyes, a caustic shock process; for vat leuco ester dyes, a nitrite process.

Wet impregnation,

I. → Impregnation.

II. → Water-impermeable finishes.

Wet lamination Instead of using foil to stick together the separate layers (dry lamination), an adhesive is used which is applied to both sides of the middle layer (e.g. by spraying) of the lamination package before it enters the two-bowl padder (see Fig.). Once the adhesive has been heat hardened, the laminate is batched.

Wet modulus Describes the force in cN/dtex which is theoretically required in order to stretch a fibre in a wet state by 100%. The force measured is the force which is required to stretch the fibre in a wet state by 5%, and this figure is then multiplied by a factor of twenty. A high wet modulus serves as a criterion of dimensional stability. → Modal fibres.

Wet-on-dry finishing The application of finishing liquor to dry goods.

Previous Page

fabric may be treated for a second time, starting at the opposite end. Light worsteds and sometimes also heavy gabardine (for raincoats) are burned in order to retain a clearly defined thread on finishing.

II. Crabbing. This means the treatment of the goods at 40°C on the scouring machine, synthetic detergent also being added. Crabbing results in the goods swelling and also precedes the washing process. The treatment prevents breakages of the threads in the washing machine in, principally, heavily woven worsteds and goods manufactured from heavily twisted ply-yarns. Once cooled, the goods are plaited down on a batch roller either after a short time or immediately, and then moved to the washing machine.

III. Smoothing. This process leads to an improvement of both appearance and handle. The strength of glaze achieved is dependent on the pre-treatment of the goods, the temperature of the water, the duration of treatment, the applied pressure and the length of time during which the goods are cooled on the drum (fixation). In the case of goods which will only be washed, treatment on the scouring machine in water at 45°C is sufficient. Piece dyed goods, on the other hand, must be treated in water at 50–60°C after dyeing because rope creases originating in the dye shop are difficult to remove. Depending on the type of article, the goods are treated for 5–12 minutes and then allowed to cool partially or completely on rollers. An excessively long cooling of panama, fresco and gabardine, etc. on batching rollers leads to the formation of glazed moirés or reversed ridging (cooling time may last at the most 2–3 hours).

IV. Fixation. Piece dyed goods are fixed before dyeing on the scouring machine at a temperature of at least 80°C. Such a treatment can be seen as a substitute for wet decatizing (in some circumstances with the addition of a textile fixing agent). The fixation effect becomes more favourable the higher the temperature difference between heating and cooling. Treatment above 80°C produces stronger fixation. After treatment the goods are wound onto a roller and completely cooled by being left overnight. Reversing the rolling up during the scouring treatment improves identical effects at both ends. Because of cost effectiveness, smoothing goods following rope, and at times also open width washing, fixing rope dyed goods in advance of dyeing and smoothing such goods following dyeing are usually carried out continuously (see Fig.). It is clear, nonetheless, that the results obtained by such a continuous process are not as good as those using a crabbing jack. This is particularly true of articles which are susceptible to sharp rope creases, such as flannel. However, higher productivity, better integration into the finishing sequence and the evenness of effects at the ends of material argue in favour of continuous processing. Fixation which differs at the two ends, which can arise easily on the crabbing jack, leads to uneven dyeing of piece dyed articles if the fault arises before dyeing, since the “tail end” of the piece usually dyes darker in such cases. Differing effects at the two ends result in differences in glaze during smoothing following the dyeing; the end rolled inside the roll of goods has a higher glaze.

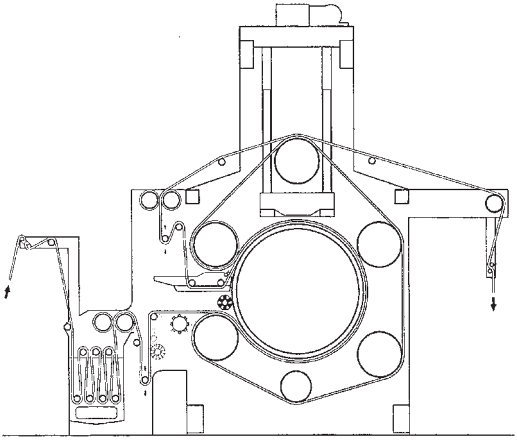

Fig: Continuous fixation machine “Multiset” for wet finishing of wool piece goods (Sperotto Rimar).

Wet fire extinguisher → Water fire extinguisher

Wet fixation process A special fixation process used for prints in which the dye is applied without or with only a proportion of the fixing chemicals, and in which fixation follows without intermediate steaming and in a bath containing no, or only a proportion of, the fixing chemicals. For example: for reactive dyes, a caustic shock process; for vat leuco ester dyes, a nitrite process.

Wet impregnation,

I. → Impregnation.

II. → Water-impermeable finishes.

Wet lamination Instead of using foil to stick together the separate layers (dry lamination), an adhesive is used which is applied to both sides of the middle layer (e.g. by spraying) of the lamination package before it enters the two-bowl padder (see Fig.). Once the adhesive has been heat hardened, the laminate is batched.

Wet modulus Describes the force in cN/dtex which is theoretically required in order to stretch a fibre in a wet state by 100%. The force measured is the force which is required to stretch the fibre in a wet state by 5%, and this figure is then multiplied by a factor of twenty. A high wet modulus serves as a criterion of dimensional stability. → Modal fibres.

Wet-on-dry finishing The application of finishing liquor to dry goods.

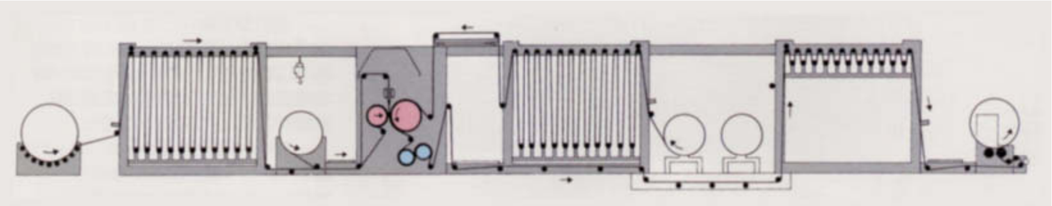

Fig.: Wet lamination plant (Stork).

Wet-on-wet dyeing process In the course of the application of different ingredients in the dyeing process (e.g. reactive dye and alkali, or etching base and naphthanilide) in continuous production each of a series of passes through the padder can involve application onto the wet goods emerging from the preceding pass. As a result, wet goods enter the liquor, which should ideally be additive (for example, 70% moisture content plus a newly acquired 20% moisture content totals 90% wet-on-wet moisture content). The advantages of this dyeing process are a saving in drying energy and a high rate of passage of steam, thus providing a significant cost reduction and making the process particularly suitable for dyeing voluminous textiles such as terry and cord fabrics (see Fig.).

Example: The dry, absorbent terry material (1) is prepared with hot naphthanilide solution on the first padder (2). The preparation cools during the ventilated stage (3). Developing with a diazo solution follows wet-on-wet on the second padder (4). A ventilated stage (5) guarantees complete disengagement. The dyeing is post-treated by passing through several rope washing machines (6) before the terry fabric is opened, de-watered and dried. Under this process it is also possible to work by batch rotating and dwelling the goods following preparation.

The winch dyeing machine / padder process is suited for dyeing tubular knitted goods. The tricot tube is prepared with a highly substantive naphthanilide using the exhaustion process on a jet (or a winch flow or winch dyeing machine). The pieces, stitched together and prepared, and with the tube having been expanded to a balloon by the injection of compressed air, are squeezed on a de-watering padder. Finally, the goods are developed on a second padder using the diazo solution and then laid in a box cart. To achieve complete disengagement the dyeing is allowed to dwell for 15–30 minutes, before being soaped and finished in the usual way on the winch dyeing machine.

Wet-on-wet impregnation The wet-on-wet technique for coating is greatly favoured in some areas of continuous finishing. The reasons for this are to be found in the undeniable advantages such as saving on drying energy and thus costs, as well as the dispensing with a drying pass, a reduction in textile handling requirements and an increase in drying capacity. A disadvantage is seen in the greater complexity arising from the higher demands placed on operating personnel qualifications and on the general level of knowledge concerning recipe and process know-how which must be brought into play. The problem of entrapped air (as in dry-on-wet impregnation = wetting) does not arise here, but instead there are other problems.

In wet-on-wet impregnation without pre-drying there are in theory two possible mechanisms for effecting a constant take-up of chemicals or dye: either a complete fluid exchange or else addition impregnation. In the first case the impregnation liquor is constantly diluted, and the desired concentration in the padding trough must be maintained by adding more strongly concentrated liquor. If wet goods pass through a colour trough, approx. 60% of the liquor will be exchanged. If, instead, a horizontal two-bowl padder is used, liquor exchange is reduced to approx. 10%. Suitable measuring equipment must be deployed in order to ensure an even uptake of chemicals. In the case of “addition impregnation” the goods are squeezed as powerfully as possible (requiring a high performance squeezer) and

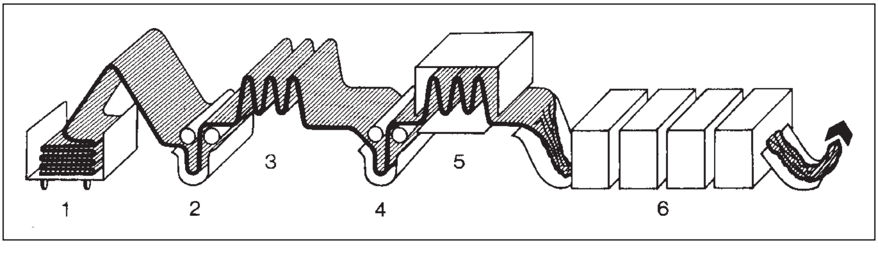

Fig.: Wet-on-wet dyeing process.

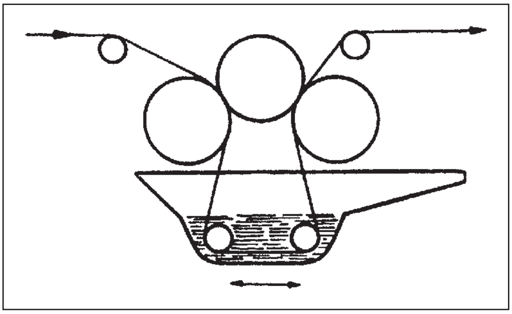

Fig. 1: Wet-on-wet impregnation according to the classical addition pick-up principle.

then impregnated on a padder with the shortest possible immersion path (only possible on a horizontal two-bowl padder) and with a higher level of fluid uptake (Fig. 1). Dilution of the liquor in this case need not be taken into account. In practice this process demands particularly exact monitoring. New principles in addition impregnation were established by the Flexnip process (Fig. 2).

Evac, in the USA, has constructed a vacuum based application technique. During the passage through a padder of a fabric composed of 55% polyester and 45% cotton, a liquor take-up of 55% is achieved. A subsequent pass across a suction slot device reduces the liquor application to 37% while the liquor thus removed is re-circulated back to the padder. Application control is exercised through using two beta radiation sources, one upstream and one downstream of the treatment (as in the Triatex principle in minimum application coating). If the system is used for the reactive dyeing of cotton the reactive dye shows 15–20% more reactivity because excessive water is removed and less hydrolysis therefore takes place. In this case the sequence of distinctive operations is as follows:

1. dye application in padder with 70% liquor application
2. reduction to 50% liquor application by suction
3. wet-on-wet chemical application in second padder (NaOH, salt)
4. reduction to 50% liquor application by suction
5. steaming.

The OK intermediate drying unit from Krantz is also suitable for wet-on-wet liquor application. The wet goods are flamed directly with Osthoff burners, drying the goods to the same extent as that encountered in a normal stenter and thus making a new product application (e.g. using chemical nip padding) possible.

The Küsters Flexnip is used to pre-treat cotton goods with salt solution on a padder. Now wet-on-wet, the goods then descend into a wedge-shaped slot which narrows at the bottom and is closed by two laterally laid horizontal flexible tubes. The interior of the wedge is lined with a hydrophobically treated coated fabric. The content of the wedge varies between 1.8 and 9.5 litres depending on the type of dyeing. Steel wedges are so adjusted with respect to the width of the goods that the two selvedges of the piece almost touch the two side wedges. When the fabric is drawn through the liquor, which is topped up from above via about 35 semi-circular formed feed pipes, it passes through the lips at the bottom of the wedge and in effect aquaplanes on the liquor drawn with it. The result is a constant and relatively high liquor application of 120%. The change of dye liquor is carried out in such a way that the minimum amount of fabric remains undyed.

Continuous pre-treatment processes are often carried out wet-on-wet. Since all intermediate drying is omitted, the cellulose fibres spend the entire pre-treatment phase in a partial or completely swollen state,

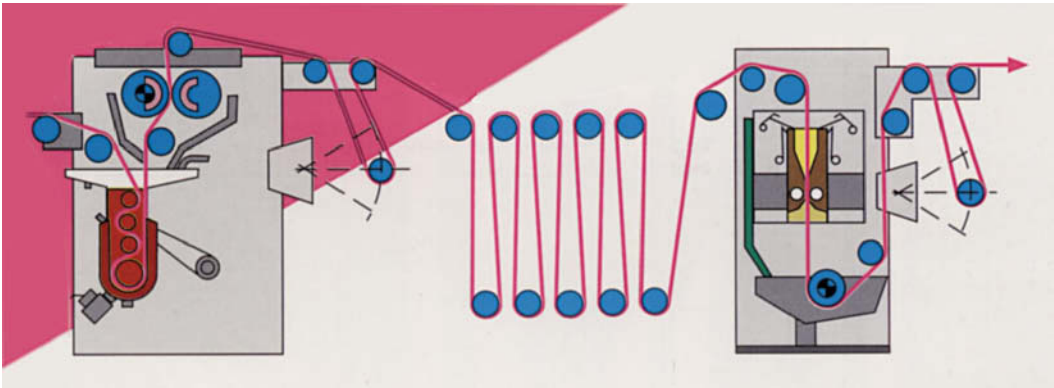

Fig. 2: Addition impregnation using Küsters Flexnip method: left, dry-on-wet Foulard impregnation; right, Flexnip wet-on-wet addition impregnation; e.g. equalized reactive dyeing using reactive dye application and subsequent alkali impregnation.

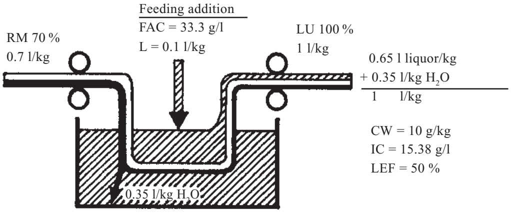

Fig. 3: Impregnating section in a continuous open-width pretreatment unit, wet-on-wet.
RM = residual moisture; FAC = feeding addition concentration; L = loss; LU = liquor up-take, CW = water content; IC = impregnating liquor concentration; LEF = liquor exchange factor.

which in turn has a positive influence on the final result. The processes which take place during wet-on-wet impregnation are relatively easily seen in open-width pre-treatment. Using the example of open-width impregnation in a roller vat, these are the factors which must be observed when calculating both impregnation recipe and the metering of top-up additions (Fig. 3).

The goods are largely de-watered by the entry squeezer in order to ensure the highest possible liquor application difference between entry and exit squeezer. The textile material is impregnated in the treatment liquor in the impregnation section and then evenly squeezed, whereby a liquor uptake of 90–100% is aimed for. The liquor uptake is determined not only by the difference but also by the liquor exchange. By liquor exchange is meant the mixing which takes place between the impregnation liquor and the water which is carried in by the goods themselves. False assumptions are often made regarding the exchange effect and its significance. The exchange effect depends not only on the length of time during which immersion occurs, but equally strongly on the structure of the fabric and the mechanical treatment to which the fabric is exposed in the impregnation section. The viscosity of the impregnation liquor also influences liquor exchange. Even while using a horizontal padder, in which the immersion path is only a few centimetres long, an exchange effect of 10–15% may be achieved; it is some 40–60% when using a simple V-trough, and approx. 70–90% in a roller vat. The exchange effect is distinctly smaller for a light fabric made from hard turned yarns, for example cotton voile, than for a normal cotton fabric. In consequence, such a light fabric contains less chemical in terms of grams per kilogram than does, for example, a cretonne article.

It is not the chemical concentration in the impregnation bath which is decisive for the scouring or bleaching effect, but rather the content of chemicals per kilogram of goods following the exit squeezer. It would therefore be ideal to determine the concentration of chemicals on the goods before the goods enter the reaction chamber. This is entirely possible for control purposes: the facility is stopped briefly, a fabric sample is taken and the chemical load of the goods is determined by titration. The assumption is made here that the chemical concentration on the goods downstream of the exit squeezer remains constant if the concentration in the impregnation section is kept constant. However, this is only true in practice if the liquor content before the exit squeezer and the liquor exchange do not vary at all.

The chemical concentration on the goods, which is decisive for the final effect, results in principle from the difference in liquor content between the entry and exit squeezers and from the exchange effect. Two further factors must also be mentioned which may influence the final effect. It is always assumed in practice that the chemicals used have no substantivity to the fibre, and that no chemical is consumed as a result of any chemical reaction in the liquor itself: however, each of these assumptions will at times be wrong. Account must also be taken of the fact that liquor contents are different from one fabric to another despite constant squeezer settings, which fact is of great importance when calculating the metering of chemical dosing by means of more highly concentrated addition. This causes major problems above all in commission finishing, whereby various fabrics are taken in for treatment. The liquor content at the entry squeezer together with the exchange effect are responsible for dilution of the impregnation liquor. This dilution must be compensated continuously by the addition of chemical in such a way as to ensure that the chemical concentration and the liquor level in the impregnation section remain as constant as is possible. A flawlessly working high performance squeezer, guaranteeing high liquor exchange and a sufficiently large difference in liquor contents, is important here. All these factors influencing the decisive chemical concentration in the fabric in grams per kilogram downstream of the exit squeezer may be listed as follows:

- liquor content,
- liquor exchange effect,
- immersion time in the impregnation liquor,
- mechanics within the impregnation liquor,
- fabric structure.

The above mentioned factors have an influence on the initial concentration in the impregnation section and on subsequent metering. If one takes account, on the one hand of all those factors which decide the chemical concentration on the goods in grams per kilogram, and on the other, of the problem of continuous monitoring, the relative value of all exact mathematical methods for computing the bath concentration and supplementary metering becomes clear.

The chemical concentration in the impregnation section can be kept constant in various ways. Best

Wet-on-wet impregnation

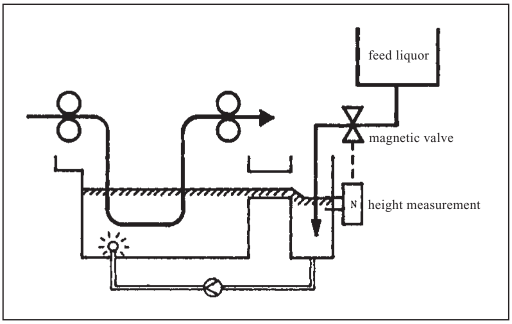

Fig. 4: Wet-on-wet impregnation of a component through level control.

known in practice is the metering of supplementary chemical from more concentrated additive tanks. Older rope and open width bleaching systems are usually equipped with only one tank from which all the chemicals (mixed at enhanced concentration) are added together to the impregnation bath. Such a tank is located in a raised position above the machinery, thus providing a positive head, and an intermediate feeding tank with level control may be included in order to ensure operation at constant pressure. The additional liquor is added to the impregnation section on the entry side, usually through a perforated distribution pipe or over an overflow trough extending across the entire width of the impregnation section. The addition rate is controlled by one of several different methods:

- a simple hand-operated valve
- a flow meter
- a metering pump (allowing the additive tank to be placed directly beside the machine)
- level control (Fig. 4).

Mixing of the additive with the impregnation solution is usually achieved thanks to the motion of the moving fabric itself. Bath circulation produces better results, and metered additives can be delivered into a separate mixing tank included in the liquor circulation system. A lint separator can also be built into such a circulation system. Single component metering often produces major problems with respect to liquor stability, since such highly concentrated baths impose the greatest demands on chemical stability. Newer facilities are therefore often equipped with several additive tanks, thus making possible two component or multiple component metering. For example:

1. Scouring: a) sodium hydroxide solution; b) surfactant, complexing agent or specific extraction agent.
2. Bleaching: a) hydrogen peroxide, organic stabilizers, surfactant; b) sodium hydroxide solution, water glass.

In order to compute the addition of supplements, the liquor contents FA_1 and FA_2 for the entry and exit squeezers are required. The measured or assumed liquor exchange effect must also be included. Calculating the supplement:

$$NF = \frac{(FA_1 - FA_2) + \frac{E}{100} \cdot FA_1}{FA_2}$$

NF = supplement factor
FA_1 = % liquor content at entry squeezer
FA_2 = % liquor content at exit squeezer
E = liquor exchange effect in %.

Liquor contents and liquor exchange effect differ from article to article. Since a specific supplementation cannot be mixed or adjusted to match liquor content in practice for every article, values are used in actual production which correspond to an average of all qualities of goods treated. For this reason a liquor exchange of 100% is often deliberately assumed in practice for an impregnation vat. Then, whether supplementation is controlled by means of a hand-operated valve, a flow meter or a metering pump, the quantity must be calculated which is to be added to the impregnation section per hour or per minute in order to maintain constant concentration. This depends on the one hand on the weight of goods per running metre and on the other hand on the machine speed. A simplification is presented by metering via a level controller, in other words via a float valve, since then both machine speed and running metre length can be discounted. The precondition remains, however, that neither the liquor contents nor the liquor exchange vary significantly. These simple metering systems prove effective so long as sufficiently experienced and reliable operators are available and also long lengths of the same article are pre-treated.

Demands on quality, and quite specifically on the uniformity of pre-treatment of large lengths of fabric, have risen enormously. Compared to J-box or pad-roll systems, the dwelling time in the reaction chambers of newer continuous open width pre-treatment systems are a mere 1–30 minutes, depending on the machine: short period steamer, U-box, conveyor or roller-bed steamer. Shorter reaction times require higher concentrations of chemicals in the impregnation section, in the supplementary additive tanks and on the goods. The baths are not only expensive, but also pose the risk of damage to fibres due to large upward jumps in concentration. The problem is particularly relevant since such expensive facilities are increasingly entrusted to less well trained auxiliary personnel. Through the use of solenoid valves for the addition of chemicals via level controllers, continuously variable metering pumps or a combination of the two, chemicals are added directly to the impregnation bath either undiluted or as concentrated stock solutions. This means that many of the well-known sources of error when working with concentrated supplementation baths no longer apply. In all three of the above systems metering is matched to the fabric weight of the article passing through the system, in other words in grams per kilogram dry weight of goods (Fig. 5). Calculation of the difference in liquor contents is no longer necessary. Metering is controlled by a pulsed timer (e.g. a signal device) which is usually mounted on the exit squeezer, so that the chemicals can be delivered at a rate matching the machine speed. The addition of chemicals rises with increasing machine speed and reduces with decreasing machine speed. If the machine stops, the addition of chemicals automatically stops, too. Water is added independently in order to maintain a constant liquor level.

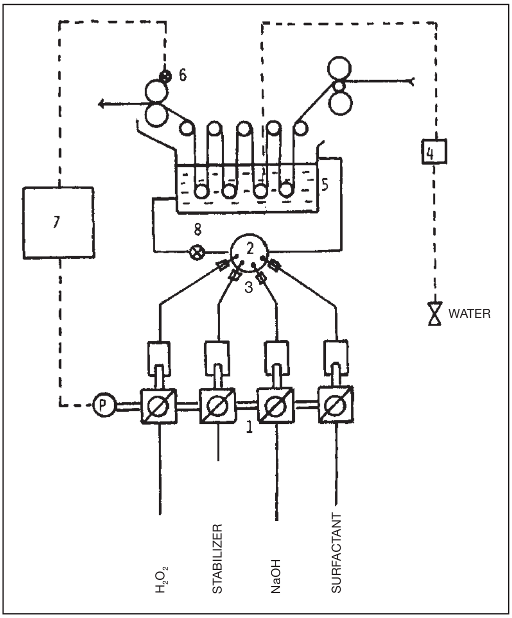

Fig. 5: Bran and Lübbe metering system for scouring and bleaching.
1 = metering pump; 2 = mixing tank; 3 = pressure holding valve; 4 = height regulator; 6 = trigger wheel; 7 = control box with potentiometer; 8 = circulating pump.

Chemicals are metered either pure or from concentrated stock solution. They should not be pumped directly into the impregnation section but instead into a mixing tank through which liquor from the impregnation section circulates constantly. Products are pumped individually into the mixing tank through separate pipes, which makes possible a manual control of the pump delivery settings. Depending on the total of pump heads available, the products can be metered either one at a time or else pre-mixed in any specific ratio, which latter method ensures reliable stability for such concentrated mixtures. In order to permit chemicals to be delivered to the impregnation section via pumps direct from the drums or containers in which they are delivered, they must be made available in low-viscosity trade form and must be easily miscible with water.

Among the various possible ways of metering chemicals in continuous wet-on-wet pre-treatment processes, doing so from more highly concentrated baths of supplement is the most widely used in practice. In such a procedure it is absolutely necessary to monitor the concentration in the impregnation bath continuously. This can be done either by titration or by making use of instrumentation and control technology. The actual values are measured and then compared with predefined target values, and should any deviation be discovered a suitable correction is initiated. Various kinds of instrumentation may be used for the monitoring of concentration, of which the following are examples:

- titration with special electrodes,
- conductivity measurement,
- redox potential measurement,
- thermometric measurement.

Continuous monitoring of the impregnation concentration is also to be recommended in the case of systems in which chemicals are metered in grams per kilogram of textile weight. Deviations are relatively small when working with the same goods over a long period of time, provided that the metering calculations and settings have been carried out exactly; however, should significantly different articles be processed, the liquor exchange changes and thus also the concentration in the impregnation bath (according to Mazenauer).

Wet-on-wet printing The overprinting of two print pastes where the first is not yet dry; a common process.

Wet opener (bleach cake opener, dye cake opener), used to separate the hard mass of fibres produced by squeezing.

Wet paraffining (paraffin lubrication, paraffining apparatus, paraffin wax treatment). A method of paraffining being industrially proved since the beginning of the 1970s and which, because of good results, was widely used as a preferred method for polyacrylonitrile, wool and polyacrylonitrile/viscose mixes (→ Waxing). Its decisive advantage is the uniformity of the coefficient of friction in a batch of yarn and its reproducibility in following batches. As a rule it is sufficient to test only a few packages for friction in order to obtain a result valid for the entire batch. Wet paraffined yarns with a coefficient of friction of less than 0.2 µ may (since the coefficient remains constant) be processed further without problems and, because of their usually uniform lubricant application, are suitable for further processing even at values greater than 0.2 µ. A restriction is that the results using cotton and cotton mixes, e.g. with polyester, are not equally satisfactory; despite good product applications, the coefficients of friction obtained using → Waxing with paraffin wax have not yet been achieved.

Application possibilities:

I. On the smoothing machine: especially for wool and synthetic fibre combed tops. Treatment in the final rinsing bath (antistatic additive in the penultimate rinsing bath) with 20–30 g/l of wet paraffining product and 5–10 g/l of a suitable softener (paying attention to tolerability, otherwise there is a blocking effect), generally at room temperature (if suitable wet paraffining product used) and optimum line speed. Take care with the quantity of product application and with choice of softener. Wet paraffining is recommended in the area of mixing (spray coating) or spinning preparation.

II. On the dyeing machine: results obtained are predominantly good. Wet paraffining application can be controlled to a wide degree, resulting in wet paraffining coatings which make subsequent waxing with paraffin wax in the spinning shop superfluous. Treatment carried out in either open or closed dyeing machines, most often of cross-wound packages (but all standard package types can be accommodated). Specifically: a long liquor of 1 : 18–40 is possible, set at pH 5–7 depending on desired process cycle, using 1.5–3% wet paraffining product in relation to weight of goods (appropriately diluted and added from the mixing or metering tank). Use a reversing liquor circulation with a 3–8 minute cycle, ideally commencing from outside. Control uptake temperature by raising temperature from 20–65°C. Process time is approx. 10–30 minutes, bath exhaustion approx. 70–90%. Possible fault: during the knitting of occasional batches of tricot yarn, colour rings and frequent periodic deviations in tension may occur; examination of the relevant yarn packages will reveal clear differences in the coefficient of friction between outer and inner layers of yarn, and these can be traced back to differing degrees of wet paraffining product coating (the so-called inner/outer effect) caused by poor process control. Origin of the fault: lack of or incorrect liquor circulation (due to incorrect bath conditions or pH), flocculation of the dispersed paraffin (due to high pressure and temperature). Sometimes inadequate lubrication in external dye package areas is also involved. Without exception, such packages have been dried in rapid driers or through driers where momentary overheating, with evaporation of some of the lubricant can arise. Conclusion: exercise optimum monitoring of the application process and in particular the drying process.

III. In a centrifuge by means of spraying onto the centrifuged material.

Wet processing A common term used in various senses, also as wet finishing:

I. Finishing using an aqueous solution (in contrast to → Dry finish employing organic solvent liquor).

II. Wet treatment processes in finishing technology such as wet decatizing, kier-boiling, bleaching, mercerising, carbonising, milling, dyeing, etc.

III. As a pre-treatment for all finishing processes which precede dyeing, in other words in addition to those under II. also, for example, singeing, thermofixation, raising, etc.

Wet sizing Conventional → Sizing in contrast to → Solvent sizing.

Wet spinning A spinning process used in the production of chemical fibres (especially viscose, cupro, polyvinyl alcohol) based on the principal of precipitation fibre formation or coagulation in an aqueous precipitation bath which takes place once the spinning solution has passed out of the spinning nozzle.

Wet steam → Steam containing water droplets, in contrast to → Dry steam.

Wet steamer (booster system tanner), particularly in the continuous dyeing or steaming of larger lengths of light toned material, especially for wet-on-wet processes in vat dyeing, or dye padding on an upstream padder. Reducing agent in the "booster" (the steamer subcomponent) is applied during the pass

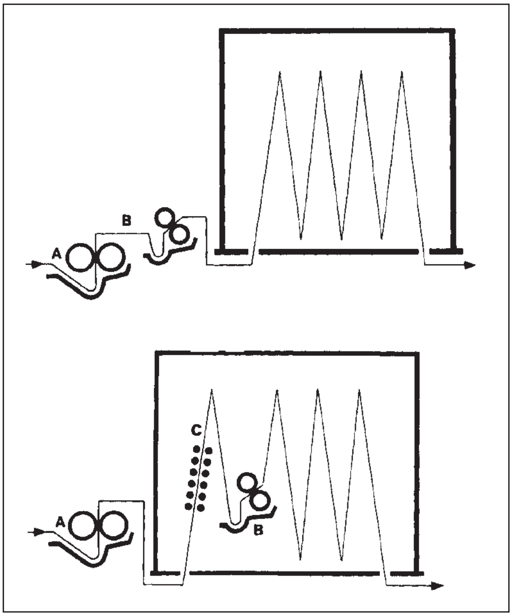

Fig.: Flow diagram showing the wet steam process with reactive dyes and sodium carbonate as the fixing alkali (two-bath process).
Variant 1: A = dye pad liquor; B = chemical pad liquor as wet-on-wet impregnation; Variant 2: A = dye pad liquor; B = chemical pad liquor ("booster"); C = infra-red zone.

through the steam (see Fig.). In this process, which is significantly cheaper than the usual pad steam facility, there is no high temperature flue required for intermediate drying. the best dye fixation is achieved using saturated steam or slightly superheated steam.

Wet strength Analogous to the way in which → Tensile strength in an air dry state is referred to as dry strength (Rt), wet strength (Rn) is determined in the wet state, as is usual in terms of relative wet strength as % of dry strength:

$$\frac{Rn}{Rt} \cdot 100\ (\%)$$

or as wet strength loss in %:

$$\frac{Rt - Rn}{Rt} \cdot 100\ (\%)$$

The material to be tested must be thoroughly wet (1 g wetting agent / litre distilled water, wetting time for cellulose and protein fibres 10 seconds, for acetate and synthetic fibres 2 minutes, for yarns, twists and fabrics 15 minutes). Recognition of relative wet strength more usually has a role with respect to man-made fibres, being as a rule higher than the dry value for cellulose natural fibres but 50–70% lower than the dry value for cellulose man-made fibres. This is determined by the spinning technology in manufacture and the associated extensive loosening of the amorphous regions, such that the inner fibre cohesion falls correspondingly due to swelling processes (sorption) under additional tensile load. On the other hand, a higher degree of crystallization, greater orientation and an increased proportion of longer chain lengths occurs in connection with higher wet strength, as can be seen in viscose high strength fibre at almost 90% and in synthetic fibres with wet strength values between 85–110%. From among the most important fibre materials, the synthetic fibres polyamide, polyester and propylene show high fibre strength, while acetate and triacetate show lower fibre strength. Among the natural fibres, flax, mulberry silk and cotton are the strongest, while wool is not so strong. The highest wet strength is shown by flax, polyester, polypropylene and polyamide, whereby only their relative order changes compared with their fibre strength; lower values are again shown by wool, acetate and triacetate. Only flax (at + 13%) and cotton (+ 5%) have a higher wet than dry strength. The other natural fibres and all man-made fibres have wet strength either the same as or lower than their dry strength. The wet strength falls significantly in comparison with the dry strength in the cases of viscose and cupro (– 40%), acetate and triacetate (– 35%) and wool (– 20%).

Wettability → Wetting agent test methods.

Wettability of differently pretreated fabrics This is dependent on residual fat content and tends to favour those goods which have been pretreated with solvent. For example, the sink test of a polyester-cotton fabric (wettability in seconds):

raw woven cloth	60 s
heat fixed woven cloth	60 s
heat fixed, water washed, bleached	50 s
de-sized, water washed, bleached	35 s
heat fixed, solvent cleaned, bleached	10 s
solvent cleaned, bleached	2 s

Wetting,

I. The tendency of a liquid to spread out across a surface. A → Wetting angle of zero corresponds to being fully spread out. The greater the wetting angle between solution and surface, the poorer the wetting. If we define wetting as a process whereby a solid/vapour interface is replaced by a solid/liquid interface, then wetting becomes the first phase in dispersion. The wetting of solid particles (e.g. pigments) can be considered as a computable combination of →: Adhesion; Immersion; Spreading capacity (see Fig.).

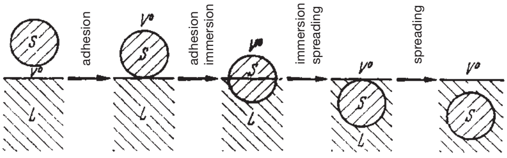

Fig.: Wetting steps (in diagram form): S = substrate; L = solution; V^0 = air.

II. The wetting of a solid body may be described in terms of the angle θ between it and a droplet of liquid, e.g. water, applied to its surface. The defined wetting tension j obtains along the liquid/gas/solid three phase profile as follows:

$$j = \gamma_{13} - \gamma_{23} = \gamma_{12} \cos \theta$$

γ_{13} = solid/air surface tension,
γ_{23} = solid/liquid surface tension,
γ_{12} = liquid/air surface tension,
θ = (static) wetting angle.

If a capillary tube of radius r is immersed into a liquid described by its viscosity η, its surface tension γ and its density ρ, the liquid will rise in the capillary tube as a function of time t. The amount of rise at time t (h_t) is calculated as a function of the variables r, η, γ, s and θ of the dynamic wetting angle.

A textile material may be seen as a large number of capillaries with differing → Wetting properties arranged in parallel and experiencing an exchange of liquid one with another. The individual capillaries are of differing radii, since it is of fundamental importance that account is taken of capillaries formed by fibres within the yarn and of capillaries formed by yarns within the fabric. The wetting process during padding may be considered as a short period wetting process, for which the term “short period” should be understood with respect to the achievement of balanced states. For a limiting case the Washburn relationship approximates (h = elevation) :

$$h_t^2 \approx \frac{\gamma_{12}}{2\eta} \cdot \cos\theta \cdot t \cdot r$$

In the above equation r describes the textile fabric in terms of the average radius of the capillary, $\frac{\gamma_{12}}{2\eta}$ is given by the wetting liquid, and cos θ characterises the fibre/liquid interchange. In practical circumstances the velocity of impinging liquid must also be allowed for. Wetting behaviour can also be influenced by the addition of a wetting agent.

Wetting agent When a textile enters an aqueous finishing liquor, the rapid wetting of the fibre bundles with water is hindered by both a hydrophobic fibre surface and by entrapped pockets of air. As mediators between mutually exclusive phases (liquid and gas, or solid and liquid), wetting agents are chemically constructed such that they possess both hydrophobic and hydrophilic structures within one and the same molecule. By the fact that it occupies evenly the surface which is to be wetted (which in itself is hydrophobic with respect to water) by permitting its hydrophobic parts to be adsorbed onto the surface while exposing its hydrophilic parts to the aqueous phase, the wetting agent reduces the surface tension of the fibre bundle compared with water. As a result the textile becomes wet. At the same time the trapped air escapes because the affinity of the water to the fibre surface (covered with molecules of wetting agent) is now greater than the affinity of the air to the interstitial spaces within the fibre bundle. The natural buoyancy of air bubbles in water assists the air to escape. In order that a wetting agent should diffuse with the wetting liquor face as it flows through the fibre bundle, thus accelerating the wetting process, the wetting agent should be constructed from surfactant molecules which are as spherical and as small as possible. This is achieved by branching of the hydrophobic tail, though this must not result in any reduction of the agents biodegradability. Wetting agents used in acidic or alkaline liquors must be either acid or alkali resistant, again without any reduction in biodegradability.

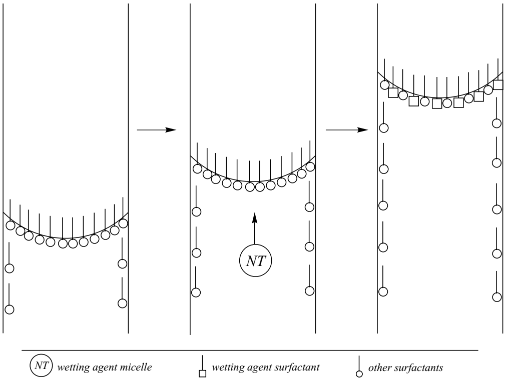

Fig. 1: “caterpillar track” model of the wetting of a capillary.

It is possible to reduce the stability of a micelle of wetting agent as it diffuses at the wetting face by adding a co-surfactant (e.g. tributyl citrate). The advance of the wetting face during the wetting of a strip of fabric may be imagined as in the “caterpillar track” model (Dussan, Davis 1974) (Fig. 1). The advance of the surfactant loaded wetting face slows because, as it rolls forward, surfactant molecules are left behind attached

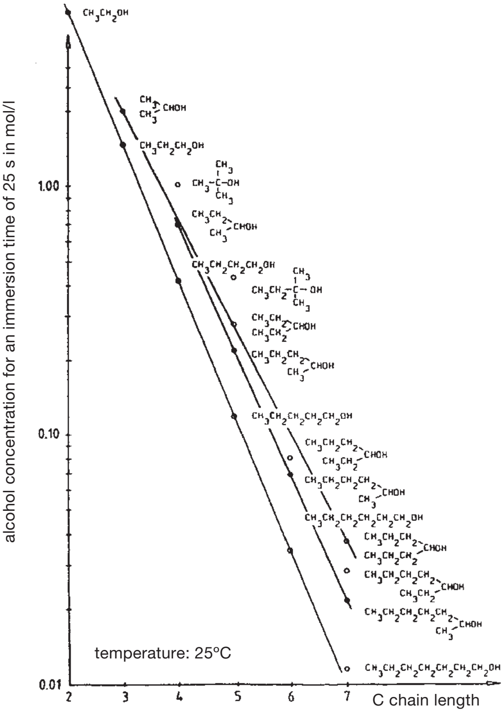

Fig. 2: Increase in the wetting agent effect depending on carbon chain length increase (according to Traber).

to adhesion points on, for example, the wall of the capillary. In this way the surfactant molecules are depleted at the wetting face unless more wetting agent is rapidly delivered by wetting agent micelles. A well-known example of this is provided by the isooctyl ester of succinic acid and the secondary alkyl sulphonate.

Homologous series of linear anionic surfactants show a maximum wetting effect for certain lengths of their hydrophobic tails. Traber shows that alcohols of increasing chain length and with increasing degrees of branching wet more effectively (Fig. 2). However, alkyl sulphates with longer hydrophobic tails are also more effective wetting agents (Fig. 3). Such a maximum is dependent upon external factors. With increasing temperature it migrates towards longer carbon chains if the salt content of the liquor is raised. Other rules apply to polyglycol ether surfactants with respect to length of the hydrophilic head. The purity of surfactants in general, and in particular the narrow distribution of isomers in polyglycol ether surfactants, has a favourable effect on wetting. The most satisfactory effectiveness is found at concentrations near that critical for micelle formation, and specifically for non-ionogenic polyglycol ether surfactants at temperatures lying closely below the cloud point.

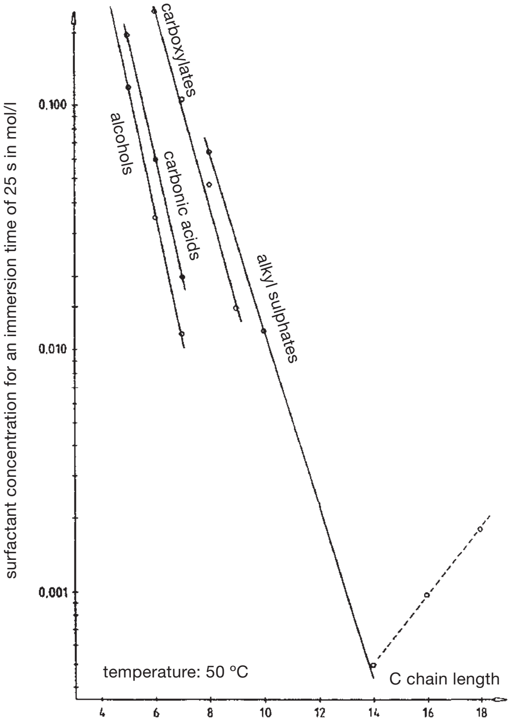

Fig. 3: Connection between wetting effect and alkyl chain length (according to Traber).

Wetting agent action The influence of surfactant substances on the wetting behaviour of cotton fabric is shown in Fig. 1:

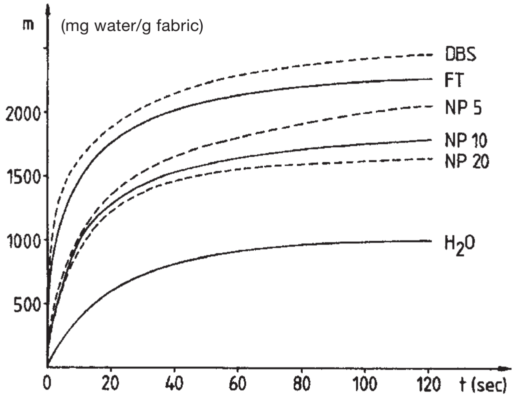

Fig. 1: Weight-time diagram of a cotton fabric upon wetting with various surfactants (see text).

It is clear that it is possible to differentiate between different surfactants. Water uptake with wetting by anionically active dodecylbenzene sulphonic acidic sodium (DBS) and fluorinated surfactant (FT) rises more rapidly than by non-ionogenic nonylphenolethoxylate (NP). In the case of the latter, on the other hand, those with a lower degree of ethoxylation favour wetting more strongly than those with a higher degree. As a result it is possible to use this method of measurement

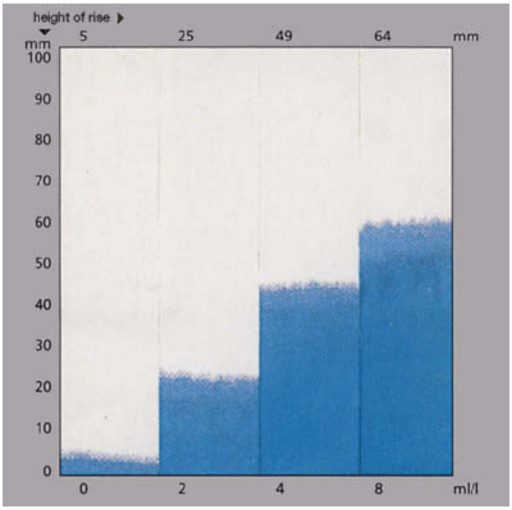

Fig. 2: Varying heights of rise in the horizontal absorbency test for cotton fabrics with various concentrations of wetting agent (Sandoz's Sandopan BFN liquid).

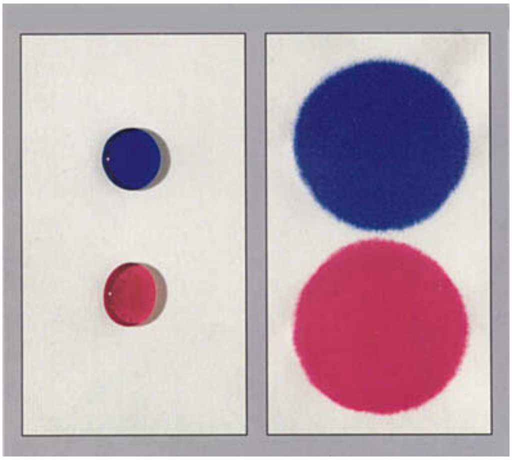

Fig. 3: Demonstration of the wetting of raw cotton with wetting agents (right) and without (left).

with a specified fabric to undertake a classification of wetting agents. Above all during the pretreatment of cotton, wetting agents have a strong influence on the effect, for example in bleaching, with respect to the absorbency of the goods. Thus, for example, certain wetting agents produce higher absorbency when applied in higher concentration (Fig. 2). Raw cotton can be wetted rapidly with red or blue dyed water when a wetting agent is used (Fig. 3).

Wetting agents for dyeing and dyeing oils These increase the wetting capacity of textiles to be dyed. As a rule, a dyeing oil gives the dyed goods an additional softening effect. Product basis: surface-active compounds or preparations based on, e.g. alkyl sulphates, alkyl sulphonates, fatty acid condensation products and sulphonated oils.

Wetting agent test methods,

I. Physical method using measurement of:

a) surface tension (simple to conduct), such as elevation method, bubble pressure method, annular separation method (DIN 53914/1968, → Surface tension).

b) → Wetting angle. Demanding and only of limited validity.

II. Measurements of the wetted textile surface:

a) droplet method: a drop is allowed to fall onto a stretched sample of fabric from a micro-burette, then the patch of liquid is measured.

b) elevation method: strips of fabric, weighted at the bottom, are dipped vertically into the wetting fluid and the height of the wet portion of fabric above the fluid surface is measured after a specified time.

III. Sink (immersion) method, simple and quick:

a) DIN 53 901 or the Draves-Clarkson test (AATCC standard test method 17).

b) hydrometer method: the increase in apparent specific gravity of the fibre is measured while the wetting liquor penetrates the fibre.

IV. Diverse: the wetting process itself is not measured, but rather the results of it, for example swelling, dimensional change, electrical conductance, etc.

(→ Wetting, measurement of).

Wetting angle The angle of contact between a drop of liquid resting in contact with an even surface, the drop of liquid being in a stable state and lens shaped, and the tangent to that surface; or, in a transmission sense, the relationship of a fibre to dirt (wetting angle 90° and often almost 180°). Hydrophilic materials display a wetting angle of 0–90°, and are capable of being wetted by water. Materials which tend to be water repellent display a wetting angle greater than 90° and are thus hydrophobic (e.g. paraffin, ceresin wax with a wetting angle of 105–110°). It is the main function of capillary active agents to reduce wetting angles approaching 90° and above, since pure water cannot attach itself to any fibre displaying such an angle. →: Surface tension; Wetting process.

Wetting angle measurement Measurement based on observation at short time intervals of the physical → Wetting angle between a drop of liquid and a textile substrate. It makes use of a measuring arrangement for determining wettability in which the physical wetting angle can be recorded repeatedly at short intervals of time.

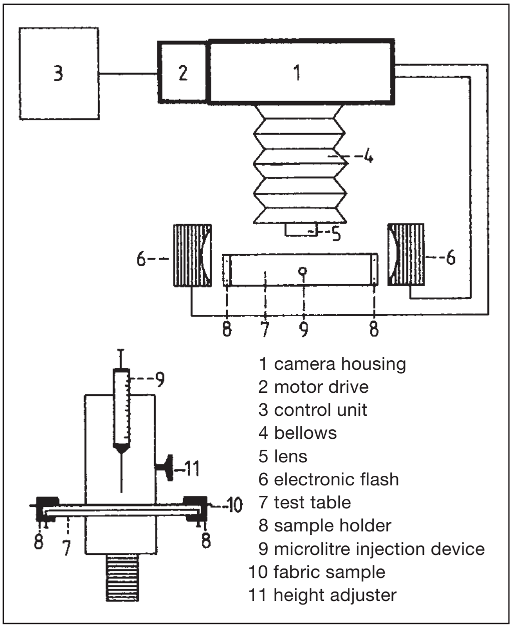

Fig. 1: Measuring apparatus for photographic wetting angle calculation. View of the measuring apparatus and front view of the test table.

The camera is fitted with a motorised drive and optical bellows (Fig. 1). Its magnifying object lens makes a magnification of x12 possible. The photograph sequence timing is governed by a control unit. The test table, on which the fabric to be wetted can be secured using two clamps, is illuminated by means of automatic flash units. A drop of the wetting fluid is applied using a micro-litre syringe, and the camera is started at the same time. From the prints of the resulting photographs the change of the wetting angle over time may be determined.

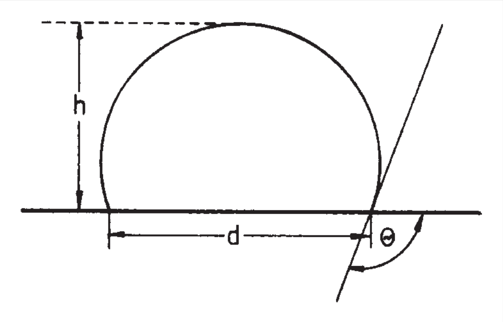

Fig. 2: Diagram of a drop on a solid surface for calculation of the wetting angle.

The wetting angle is calculated using the principle of the spherical segment method (Fig. 2) from the height of the droplet h and the line of contact between droplet and fabric, the droplet base d, according to the equation:

$$\Theta (t) = 2 \arctan \frac{2 h (t)}{d (t)}$$

As can be seen from Young's equation

$$j = \gamma_s - \gamma_{sl} = \gamma_l \cos \theta$$

the quantity which determines the → Wetting process is not the surface tension of the wetting liquid but rather its wetting tension $j = (\gamma_s - \gamma_{sl})$ with respect to a specific material. In order to achieve the greatest possible wetting effect, therefore, the wetting tension must be of the highest possible value. This in itself is achieved through a lowering of the surface tension at the solid/liquid interface (γ_{sl}). In other words, the wetting agent should not reduce the surface tension of the liquid (γ_l) but rather that of the solid / liquid interface (γ_{sl}). If a fabric is wetted with a solution of surfactant, the lowering of the surface tension at the solid/liquid interface (γ_{sl}) depends upon the adsorption of the wetting agent at the liquid/air interface and the solid/liquid interface. In the case of a fabric which has been treated with a wetting agent, surfactant molecules are already adsorbed onto the surface of its fibres (Fig. 3). This means that when wetting with water it is the solid (surfactant loaded)/liquid interface which is decisive in reducing surface tension.

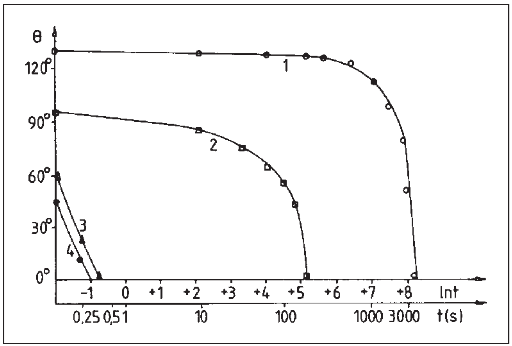

Fig. 3: Effect of wetting pretreatment and of a surface-active liquid on the time rate of change of the wetting angle.
1 = cotton/water; 2 = cotton/0.1%DBS; 3 = wetting pretreated cotton/water; 4 = wetting pretreated cotton/ 0.1%DBS.

Both a solution of surfactant and also water spread out spontaneously in contact with a cotton fabric which has been treated with a wetting agent (curves 3 and 4). The spreading time of water of 0.5 seconds (curve 3) indicates clearly that pretreatment with a wetting agent has a much grater effect on wetting speed as does the addition of a surfactant to the wetting liquid. Combining both methods (curve 4) has only a slight further effect on wetting speed.

Wetting angle progressive/retrogressive The angle of contact measured perpendicular to the surface of the liquid phase is progressive during immersion and retrogressive during withdrawal. Both wetting angles are different for a solid surface. The difference results from angle measurements made of the velocity of immersion and withdrawal; it can be made more precisely using test methods.

Wetting energy, free The work done (i.e. the energy lost) when a surface is isothermically and reversibly wetted without a simultaneous change in its free surface area can be observed in the loss of free energy (wetting energy) from the system and is expressed either in ergs or joules.

Wetting hysteresis The work required in order to immerse an element of a solid physical surface slowly and at constant velocity into a liquid phase differs from the comparable work required in order to withdraw the same element from the liquid phase. The difference between these two quantities, related to surface area, corresponds to a → Hysteresis which is known here as the wetting hysteresis. It is expressed in either ergs or joules and is numerically the same as the difference between the progressive and the retrogressive → Wetting tension.

Wetting, measurement of Surface energy, interface energy and the work done in adhesion have a central role to play in the concept of thermodynamic adhesion. For the release of the adhesive joint of two substances 1 and 2 it is true that:

$$W_A = \gamma_1 + \gamma_2 - \gamma_{1/2}$$

W_A = the thermodynamic work done in adhesion,
γ_1, γ_2 = the free surface energy of substances 1 and 2,
$\gamma_{1/2}$ = the interface tension.

If it is assumed that the intermolecular forces are mutually independent, then both the work done in adhesion and the surface energy may be divided into separate components:

$$W_A = W_A^d + W_A^{sb} + W_A^p + \dots$$

d = dispersion interaction,
sb = acid-base interaction,
p = polar interaction.

If applying the geometric means for the adhesive work done in cohesion for substances 1 and 2, it is true for the dispersion component that:

$$W_A^d = 2(\gamma_1 \gamma_2)^{1/2}$$

If the polar component is disregarded, then for the acid base interaction it is true that:

$$W_A^{sb} = \gamma_1 + \gamma_2 - \gamma_{1/2} - 2(\gamma_1 \gamma_2)^{1/2}$$

The dispersion and the acid-base components of the work done in adhesion may be determined for fibre bundles and for filling material by measuring the wetting angle. Measurement for fibre bundles is done using the elevation method (see Fig.). If laminar flow is present within the pore spaces and if the force due to gravity is disregarded, the following relationship between Δm and time t is true:

$$(\Delta m)^2 = F(c\,\rho^2 \gamma_L \cos\theta; 2\eta)\, t$$

c = the geometry/packing density,
ρ = the density of the measuring liquid,
η = the viscosity of the measuring liquid,
θ = the wetting angle,
γ_L = the surface tension of the measuring liquid.

With

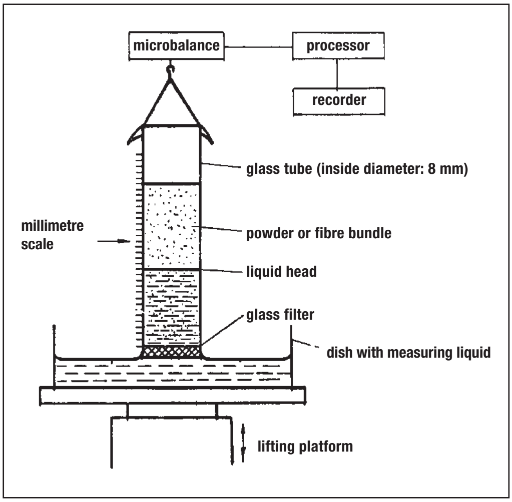

Fig.: Measuring apparatus for wetting measurement by determining wetting angle by capillary lift height (according to Jacobasch).

$$\gamma_L \cos\theta = \gamma_S - \gamma_{SL} \text{ and}$$

$$W_A = \gamma_S + \gamma_L - \gamma_{SL}$$

the work done by adhesion is

$$W_A = \gamma_L (1 + \cos\theta).$$

If non-polar wetting liquids are used only dispersion interchanges occur. As a result the dispersion component of surface energy becomes

$$\gamma_L^d (1 + \cos\theta) = 2(\gamma_S^d \gamma_L^d)^{1/2}.$$

If, on the other hand, test liquids are used which permit specific interchanges, then it is true that

$$W_A^{sb} = \gamma_L (1 + \cos\theta) - 2(\gamma_S^d \gamma_L^d)^{1/2}.$$

From this it is possible to determine both the work done in dispersion and in adhesion (according to Jacobasch).

Wetting power (wetting ability, wetting strength) The degree of capability for → Wetting based on the → Capillary activity of wetting agents. Wetting power is tested according to DIN 53 901 (see Fig.).

Wetting process Water remains as droplets on the surface of hydrophobic fabric. If the wetting of fibres is considered statistically and if one defines, for example, cotton as a solid matrix containing pores, then the total volume of the structure is given as $V = V_M + V_P$ (where V_M = the volume of the matrix, V_P = the volume of the pores). If this total volume is then occupied by a vol-

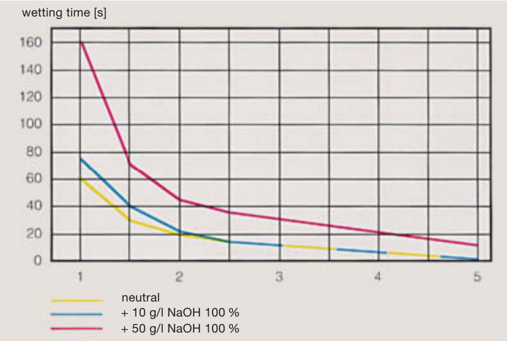

Fig.: Wetting agent (Kieralon CD, BASF) dependency of the content's wetting power (abscissa: g/l) tested according to DIN 53 901 in alkaline liquor.

ume of water V_W then, depending on the volume of water applied, the following two limiting conditions must be considered:

condition 1 between $V_W > V_P$ and $V_W = V_P$
and
condition 2 between $V_W = V_P$ and $V_W < V_P$

Condition 1 describes the state in which the fibre is adequately supplied with water, in other words a uniform flooding of the substrate with finishing liquor is guaranteed. This is the condition under which a traditional continuous product coating technique works, e.g. a padder. Condition 2 relates to an under-provision of the fibre with water, in other words all finishing processes are able to operate which do not require a uniform flooding of the substrate in order to achieve their desired finishes – processes such as softening, softeners, resin finishing and the like. In either case, however, a penetration of the liquor into the fibre mass is necessary.

In the textile area, the wetting process is characterised by the penetration of the liquor into the capillary system of the textile item with an accompanying expulsion of air from the interstitial spaces in the textile. The wetting process is nothing other than the replacement of a solid/gaseous interface with a developing solid/liquid interface. When a textile is being wetted, air bubbles within its capillaries escape (Fig. 1) if the contact angle θ_1 decreases on that side of the bubble on which the meniscus becomes larger due to the advancing movement of the bubble in this direction (Fig. 2), i.e. $\theta_1 > \theta_2$ if there is movement.

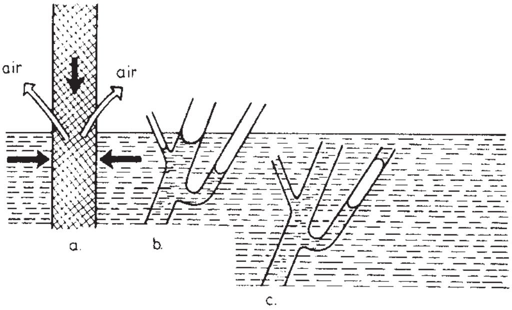

Fig. 1: Ventilation (air) on entry of a dry fabric (vertical arrow) into a liquid which penetrates into the fabric (penetration illustrated by horizontal arrows). In the fabric capillaries (b) the air softens or stays (bad wetting: c).

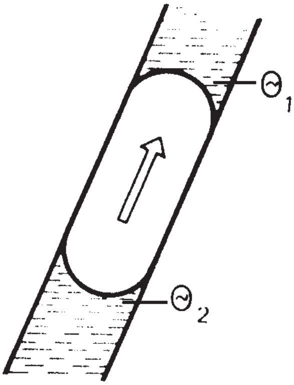

Fig. 2: Air bubble in a textil material capillary advancing on wetting.

If the length of such a capillary is taken as l and the rate of flow of a liquid in this capillary during wetting is taken as w (Fig. 3), then the difference in pressure between the two ends of the capillary is given by Poisseuille's equation and defines the direction (towards decreasing pressure) in which a liquid/air column of length x, measured between the upper and lower menisci, will move.

$$\frac{8\,\eta_l\,x}{r_m^2}\cdot w = \frac{2\,\gamma_{lv}\cdot\cos\theta}{r_m} + H\cdot\rho_l$$

η_l = viscosity of the solution,
ρ_l = density of the solution,
γ_{lv} = surface tension (air/solution),
r_m = capillary diameter.

The left side of the equation describes the influence of the viscosity of the solution. The right side describes the pressure differential arising from the capillary forces: its value becomes negative if the contact angle θ exceeds 90°, in which case wetting is avoided under certain circumstances.

A laminar flow develops as liquor travels through the capillary. When working with higher temperatures, which is done to reduce water viscosity, this laminar flow can result in large temperature differences (Fig. 4).

Wetting process

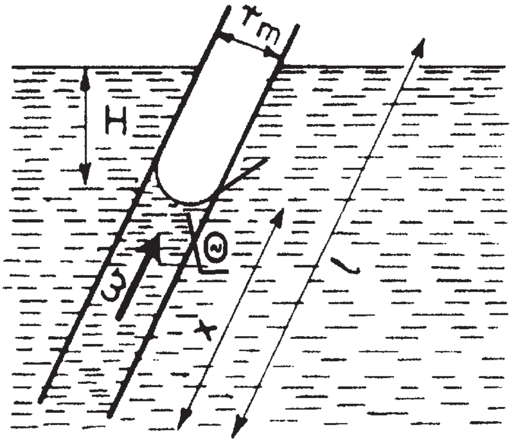

Fig. 3: Parameters which determine the pressures in a capillary upon wetting.
H = height of the remaining liquid columns (hydrostatic pressure); r_m = average diameter of the capillaries.

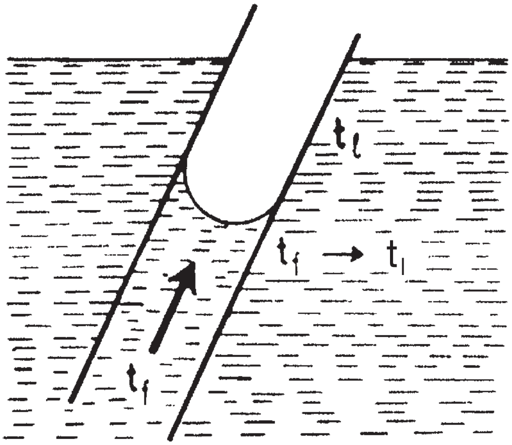

Fig. 4: Temperature differences when a solution at temperature t_l flows in a capillary (at temperature t_f).

When a fibre/solid body surface is wetted with a droplet of liquid (Fig. 5), the rules of Young's equation apply. The wetting tension j applies at the three phase liquid/gas/solid boundary:

$$j = \gamma_S - \gamma_{SL} = \gamma_L \cdot \cos\theta$$

γ_S = surface tension of solid,
γ_{SL} = surface tension between solid and liquid,
γ_L = surface tension of liquid,
θ = wetting angle.

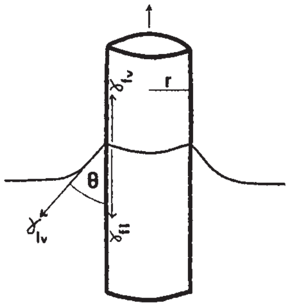

Fig. 5: Diagram of the wetting of solid backings.

The smaller the wetting angle the better the resultant wetting. In the case of immersion wetting, that is, the dipping of a solid body into a liquid, the solid body surface is replaced by the formation of a new solid/liquid phase boundary. The liquid surface remains unchanged, and the energy balance results from the wetting tension j.

$$j = \gamma_S - \gamma_{SL}$$

The same change in energy takes place when a liquid moves within a capillary. The higher the wetting tension the better the resultant wetting. The wetting of a textile material with water may be seen as the opposite of the rolling up mechanism which applies to an oil droplet on the surface of a textile during washing. If a wetting agent is added to an aqueous solution it becomes adsorbed onto the interface and gives rise to a reduction in the surface tension of the liquid γ_L and in the liquid/solid surface tension γ_{SL}, while the surface tension of the solid γ_S remains unchanged. This reduction in γ_L and γ_{SL} promotes wetting: cos θ thus becomes larger in Young's equation, and the wetting angle itself becomes smaller.

Since wetting tension is the determining characteristic in immersion wetting, which is the wetting process most often used in the textile industry, it must acquire values as high as possible, which in turn, are achieved by reducing γ_{SL}. A reduction in the surface tension of the liquid γ_L favours above all spreading out and the displacement of air trapped within the textile. The wetting process of a single fibre (Fig. 5) can be followed in theory by measurement of the wetting angle. However, there are two limitations on the application of the method of measuring wetting angle: it requires a smooth solid surface and it delivers only equilibrium values. In practice a fibre is a structure having a geometrically poorly defined surface; equilibrium values for wetting tension are indeed of interest here, but the dynamics of the wetting process is of far greater importance in textile finishing.

What is needed is a method of measurement from which those quantities influencing the wetting process may be derived. The method which has proved itself with respect to textiles is the so-called elevation method. Basically, this method consists in lowering the lower end of a vertically suspended fabric into the wetting fluid and then measuring the progress of the fluid drawn up by the textile against time. The process may be considered as that of the movement of the fluid within a capillary. Given the Washburn relationship

$$h_t^2 = \gamma_L \cdot \cos\theta \cdot r \cdot t$$

h_t = elevation
γ_L = surface tension (influence of the liquid)
θ = wetting angle (influence of the liquid/substrate interchange)
r = material constant (influence of the textile)
t = rise time

the viscosity η of the liquor (dependent on the temperature) may be entered, which is then given as

$$k = \frac{r \cdot \gamma_L \cdot \cos\theta}{2\eta}$$

While the quantities γ_L and η of the wetting fluid are measured independently, the material constant r only occurs together with the equally unknown quantity cos θ. The quantity r is determined as follows. The measurement is carried out using liquids which spread out on the relevant fibre material, i.e. which do not show a finite wetting angle. This means that $\cos\theta = 1$ and thus r may be determined. Once the value of r has been substituted in the equation, liquids can be measured on the material which form a wetting angle of between 0° and 90°. Cos θ may now be calculated and thus also (using Young's equation) the wetting tension.

The rate of wetting k rises in keeping with the speed at which the surface tension approaches the equilibrium value. At an advancing wetting face, the surface tension is a direct consequence of the adsorption of molecular dissolved surfactant on the newly formed surface and interface. The faster the diffusion (characterised by the diffusion coefficient of the surfactant) to and with the wetting face by constant interfacial activity, the greater the rate of wetting. This requirement is taken into account for the wetting agent involved (by means of a shape for the substance promoting wetting which approaches the spherical) by the fact that wetting agents, in contrast to other surfactants, are heavily branched and show a lesser tendency to form micelles.

Wetting promoters These are textile additives not possessing surface activity but which nevertheless make wetting possible without accompanying generation of foam. They are absorbed by fibres and then impart the wetting process. They are known as special "air removing" wetting agents, in particular phosphoric acid trialkyl ester. Since they are barely soluble in water they are applied as an emulsion or from the vapour phase. In the latter case a metered quantity is condensed onto the goods (cotton, wool) to enable uniform wetting of the goods when subsequently immersed in water. There are many organic compounds which are effective when so used, provided that they have a boiling point favourable to the condensation process.

Wetting properties This is the ability of a textile surface to be wetted. A fibre may be well wetted by water if there are chemical groups on its surface which can take up water, for example because of hydrogen bridges, dipolar forces or ionic forces. Groups such as $-COO^{\theta}$ and $-SO_3^{\theta}$ are strongly hydrophilic; OH, OR, NH_2 and C=O groups are weakly hydrophilic. As a rule hygroscopic fibres are at the same time hydrophilic; wool is an exception, having a hydrophobic surface. Wetting is of particular importance in finishing, especially in minimum application techniques as well as in → Clothing physiology (→ Rendering hydrophilic).

The wetting properties of a fibre derive from the effect of so-called surface tension, where on the one hand a pulling force affects water molecules (a sphere of wa-

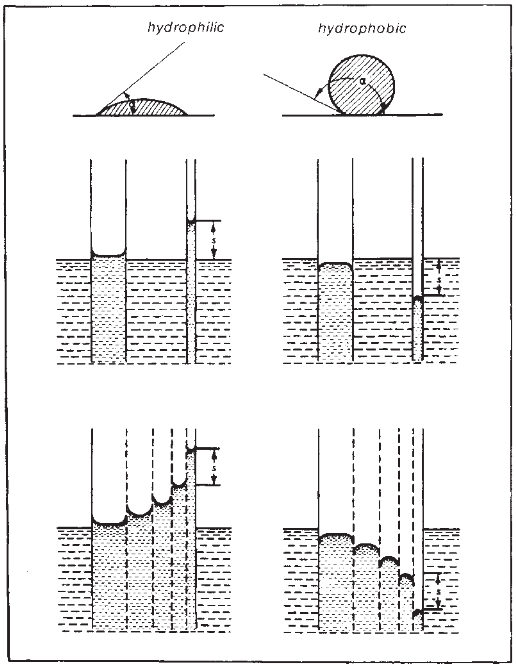

Fig.: Diagram of the effect of wetting properties on moisture transmission. Top: individual droplets on a level surface with the various wetting angles or contact angles. Middle: Separated individual capillaries made of varying material and with varying diameters. Bottom: system of capillaries connected with one another so that each capillary draws water from the neighbouring capillary.

ter) while on the other, a pressure force affects them (a mound of water). When this effect of surface forces is investigated in narrow tubes or capillaries, it is found that in the capillaries of easily wetted materials, there is a considerable suction – or capillary action – due to the tension.

In the first case (see Fig.) the capillary shows a tendency to encourage the water to rise within it, the more so the narrower the tube; conversely in the second case, the narrower the tube the greater the tendency to drive water out of it. In physical terms the pores of a fabric may be imagined as being an interconnected series of larger and smaller capillaries. These do indeed carry out capillary functions, as is seen in daily practice. However, a fabric contains no isolated single capillaries but rather a large number of both fine and large capillaries which are all connected one to another. A result of this is that each capillary draws liquid out of the next largest, leading to a significantly greater rise than would be encountered with an isolated tube. In the case of a hydrophobic surface, ie., poor wetting properties, a similar but opposite effect comes into play, in other words in the sense of the expulsion of water from a capillary. This means in practice that products made from easily wetted synthetic materials show a large capillary action or absorption power, whereas products made from hydrophobic materials, such as wool show a low capillary action or absorption power.

Wetting tension This is the force per unit length which is caused by free → Wetting energy in a liquid-solid system. It is numerically the same as the free wetting energy per unit area and is expressed in dyne/cm or N/m. Wetting tension corresponds to a progressive or retrogressive → Wetting angle. Measurement is done, for example, using a registered tensiometer. A flat piece of textile is immersed slowly into distilled water and the force acting on the sample is recorded using an induction recorder. This force F is the sum of the force exerted due to gravity, the buoyancy and the wetting force. The test apparatus is shown schematically in the Fig. Using the known surface tension of distilled water of 72 mN/m and the length of the steel plate of 36 mm, the wetting force measured gives directly the wetting tension j or the contact angle θ.

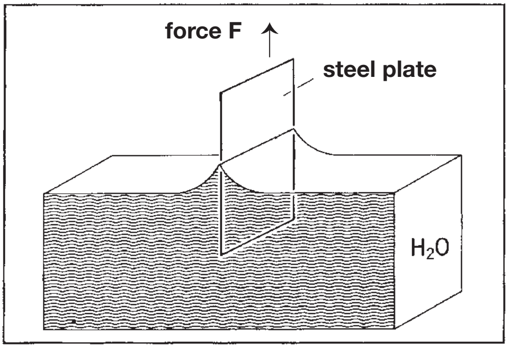

Fig. Diagram of test set-up for measuring wetting force (wetting tension) (according to Wilhelmy).

$$j = F/L = \gamma \cdot \cos\theta$$

An adequately clean steel surface is hydrophilic, which gives a contact angle of 0° and a wetting tension of 72 mN/m. Adsorption of a densely packed film of amphiphilic molecules turns the surface strongly hydrophobic, making the contact angle greater than 90° and the wetting tension less than 0 mN/m. If the surface concentration of amphiphilic molecules is increased further the adsorption film becomes two-layered; the surface then becomes hydrophilic once again and wetting tension increases once more.

Wet tow dyeing A collective term common for the → Gel dyeing of wet-spun and still not dried acrylic spinning tows.

Wet transfer printing A facility for the wet transfer printing process on acrylic, polyamide and wool and comprising an impregnation padder, transfer calender (of the felt calender type) and a J-wash box. Even light and extremely sensitive qualities are suitable for this wet transfer printing process.

Wet transfer printing process In contrast to a dry transfer printing process, the transfer of dye in the wet transfer printing process takes place by migration in the aqueous phase or in an organic phase, formed by wetting or other additives, at temperatures of 100–150°C. Wet post-treatment is usually necessary. → Transfer printing.

WF → Virgin wool, symbol according to the → EDP key system.

WG → Vicuna, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Wheat starch A columnar, crystalline or radioactive powder, forming a pure white homogeneous “flour” (greyer than potato starch). The handle is similar to maize starch. It is often adulterated using potato starch (detectable under magnifying glass or microscope). Its water content is 15–18%. Heating of a suspension results in: swelling at 50°C, agglutination begins at 65°C, agglutination ends at 67.5°C. The agglutinated starch is bluish-white and not as translucent as potato starch (nevertheless with more gluing and stiffening power, though less than rice or maize starch). Its response to chemicals is similar to that of potato starch. Its handle in finishing is harder and more granular than potato starch. It is used as a → Starch.

Wheelchair-resistant Characteristic of a textile floor covering which enables it to withstand the pressure and abrasion imposed by a wheelchair. It is tested according to DIN 54 324.

WHG (Ger.) abbrev. for: Wasserhaushaltsgesetz (→ Water Resources Law).

Whipcord The name immediately indicates an appearance of firmness. These materials appear in the form of worsted yarn warp and weft, worsted yarn warp and carded yarn weft, and occasionally carded yarn warp and weft. The warp yarns at the least are sharply twisted, usually the yarns are a mouliné twist. The binding may be of special gabardine binding; as a consequence these materials have a gabardine like appearance, in other words they have a more or less pronounced corded effect. Their finishing character is bare or clear threaded. These materials are used for riding breeches, sports jackets and trousers and especially for work wear.

Whirled pile finish The treatment of raw goods with special, usually round brushes for the manufacture of whirled plush fabrics (woven imitation furs).

Whitaker process →: Knit-deknit method; Space dyeing.

White A sensory perception; according to Ostwald, the sum of all → Chromatic colours and a body which reflects all visible colours. →: Colorimetric measures; Grey series; Ideal white.

White chate marks ("white abrasion"), rubbed areas on satin-like goods (especially on silk), and also frequently on poplin clothing in dry cleaning and laundry, caused by faulty mechanical influences. It also occurs as abrasion caused by normal wear on pockets, sleeves and the like, and as abraded crossover points (giving rise to an altered reflection of light, which causes separate portions of fibre to appear "white"). It can be reduced or, in favourable circumstances, removed by using → Spirit cleaner.

White content White in relation to → Standard white. As a measure of → Detergency power, white content is the difference in brightness before and after washing (usually measured using a 460 nm filter). It is defined by the whiteness calculated by measuring whiteness (→ Whiteness, degree of). The limit of the eye's sensitivity lies at an approximately 5–10% difference in white content.

White goods → Laundry goods.

White laundry goods White washing in the sense of → Wringable laundry and to a certain extent also body clothes.

White lead test paper Test paper soaked in white lead used as a quick test for hydrogen sulphide.

Whitener → Fluorescent brightening agents.

Whiteness, degree of A dimensionless number giving a measure of → White content and used as a scale for evaluating the effect of bleaching, for example, or the brightening of goods involved in dry cleaning or the colourlessness of lubricating oils and the like. The degree of whiteness is determined by various formulae for → Whiteness, measurement of.

Whiteness formulae Used in calculating the → Whiteness, degree of. Distinction is made between:

I. Whiteness formulae which are based directly on measured physical values, e.g. from Stephansen (not for samples treated with brightening agent): $W_{st} = 2 \cdot R_{46} - R_{62}$.

II. Whiteness formulae which are based on colour values, e.g. from Berger: $W_B = Y + 3.448 \cdot Z - 3.904 \cdot X$. These correspond better to the characteristics of the human eye.

A large number of whiteness formulae have been proposed since not only do differences in sensitivity between observers play a role in the evaluation of shades of white, but also the preferences for specific white nuances. In addition, "optimum" white is dependent on the product.

After years of investigation the CIE has decided to recommend the following whiteness formulae.

CIE whiteness formula for D65/10°:

$$W = Y + 800\,(0.3138 - x) + 1700\,(0.3310 - y)$$

Colour cast (tint):

$$T = 900\,(0.3138 - x) - 650\,(0.3310 - y)$$

- if T is positive the sample has a red cast
- if T is negative the sample has a green cast
- limits of application: $Y > 70$ and $T < \pm 3$.

The CIE confines the application of the formulae to whitenesses of more than 40. White tests with a colour shade wavelength of more than 466 nm are seen as "neutral". The tests are mainly not neutral white but compared with those colour shades reddish or greenish, also the shade (T, tint) as well as whiteness will also be given.

Whiteness index The opposite of → Saturation in → Chromatic colours and not to be confused with → Lightness even though a solid colour may appear brighter the more white it is, for example when it appears under above average illumination which causes an almost total white sensitivity as it approaches the level of being blinding.

Whiteness, measurement of White itself is also a colour which may be determined using colorimetric methods. White differs from the chromatic colours in that white products show a high degree of brightness combined with very low colour saturation. the chromaticity of white, in other words, is very weak. The evaluation of white samples is often fundamentally more difficult than that of chromatic dyeings, the reason lying in the fact that white is a concept of subjective quality subject to a great degree, to the influence of personal taste. A bluish white is preferred to a yellowish white provided that the two differ only in terms of their hue.

The practitioner is faced with the problem of how to evaluate data obtained as a result of spectral photometry measurements. Values can be calculated from standard colour values (or derivatives thereof) with the aid of various whiteness formulae. It is of importance here that each whiteness formula contains a different specific weighting for the three colour characteristics of hue, saturation and brightness: in other words, its evaluation is subjective. As a consequence, the practitioner is less interested in absolute whiteness than in pursuing, as with chromatic dyeings, differences between master samples.

Final checks in whiteness measurement show how brightening relates to the reference sample in terms of brightness, purity and hue. The use of the hue-chromaticity level of the CIELAB colour space has shown its value for the evaluation of samples treated with fluorescent brightening agent. The representation permits a clear localisation of the nuance of a fluorescent brightening agent. In particular, it also shows how the intrinsic colour of a product becomes visible following excessive metering. Chromaticity increases with high concentrations (greening, for example), which makes it feasible to compare products in terms of their price, quantity required and whiteness effect.

The options for an instrumental evaluation of white may be divided crudely into three areas. A purely physical method making use of spectral photometry allows the whiteness effect to be analysed and its various components to be compared qualitatively. It is then possible to distinguish between the contributions of the underlying white of the substrate, the fluorescent brightening agent and any shading dye which may be present. Valuable information is thus obtained for the reproduction of white master samples and for the investigation of faults or inquiries. A triple zone device cannot deliver this information; a spectral photometer is required. The second area entails relative whiteness evaluation, the third entails absolute whiteness evaluation. Absolute evaluation differs from relative evaluation by including an exact definition of the illumination; this means the excitation of the brightening agent corresponding to an average level of daylight, and reference of the degree of whiteness and the hue calculated against an existing scale of whiteness. This method alone offers reproducibility which is adequate to all practical needs and a capacity to compare results obtained using different instruments. An evaluation using the Ganz whiteness formula has the advantage of including a correction for UV.

Whiteness reduction The effect of fluorescent brightening agents in terms of an increase of the degree of whiteness and the brilliance of lighter colours is connected to the effect of fluorescence. All factors which contribute towards a reduction in fluorescence also lead to a reduction in the whiteness effect and are thus undesirable in the brightening process.

The phenomenon which appears as a reduction in fluorescence is often referred to in the literature as simply → Fluorescence quenching. Thus, fluorescence quenching becomes a collective term describing a series of negative final effects which are brought about by, for example, an excessive concentration or the addition of foreign substances (so-called quenchers) to solutions or to absorbing agents. This phenomenon can be observed both with fluorescent dyes and fluorescent brightening agents.

This reduction in brightening effect due to excess concentration is explained by the displacement of the absorbing part of the spectrum into the visible area of the spectrum. Were the concentration of brightening agent to be increased even further, one would have to expect an even deeper displacement of the absorption spectrum into the longer wavelength colours.

The reduction in the degree of whiteness due to the addition of foreign substances must first be ascribed to fluorescence quenching; only when coloured substances are involved, e.g. $FeCl_3$, should the absorption of the primary light and of the secondary light of fluorescence be considered the cause. The lesser reduction in whiteness due to excess concentration of fluorescent brightening agent rarely occurs in practice because the agent can be metered precisely. On the other hand, the influence of foreign substances is far less easy to avoid as these cannot always be controlled directly. It has been shown that traces of some metal ions (especially in solution) can cause fluorescence quenching even when present in the very lowest concentrations. This is particularly noticeable when ions of copper or iron are present in the treatment bath. Spectroscopic investigation has been able to demonstrate the association of fluorescent brightening agents with metal ions to form a complex which itself does not fluoresce.

Whiteness scale A comparative series of textiles treated with brightening agent and used for the evaluation of the intensity of fluorescent brightening agents. The fluorescent brightening agent is applied in increasing concentrations to a number of substrate samples. The differences in concentration are to be chosen such that any two consecutive samples show a clearly visible difference in brightening effect. An arbitrary differentiation by numbers then follows, for example, 200 points for the maximum effect achieved and 0 points for the untreated substrate, the scale being divided in steps of 20 points. The sample of fabric which is to be tested is then compared against samples from the scale and the brightening effect it shows is numerically determined. An experienced tester can (for a scale as described above) reliably judge differences as fine as 2.5 points, even when the fabric structure itself varies. A separate whiteness scale must be established for each type of fibre. When variations occur in the substrate or in hue, saturation or brightness a visual evaluation usually becomes more difficult and depends strongly on the individual tester. There is also often a desire to make visual grading match values achieved instrumentally. →: Textile whiteness scale; Ciba-Geigy white standard.

Whiteness value A number which characterises whiteness as a visual perception of white. Whiteness samples of differing appearance can receive the same whiteness value, for which reason the whiteness value can be calculated more precisely from measurements using the → Whiteness formulae.

White spots (polyacrylonitrile fibre rope). Whitish areas caused by uneven drying during manufacture; they have a loose structure and show reduced physical-mechanical properties between intact and defective fibres.

White toner → Fluorescent brightening agents.

White, visual assessment of The visual assessment of white is influenced by the colour of the surroundings and of the background (a light grey - i.e. neutral - plate, coloured ground or bleached and not brightened paper or cotton are best), by the angle of observation (45° to the observer is optimum), by changes of position of the samples and by personal factors. Sampling should be done in a cabin kept neutrally grey and under standard lighting. Method a): hold the samples one in each hand at an angle of 45°; exchange the samples several times from hand to hand. Method b): wind the samples around a glass or plastic sheet free of fluorescing or UV absorbing compounds and hold as in a; the samples overlap alternately. Method c): lay the samples next to each other flat on a white or light grey ground free of optical brightener and press flat using a glass sheet which does not absorb UV; change positions several times. → Whiteness scale.

Wicking-test A test of the absorbency of fabrics following pretreatment for dyeing or finishing. Strips for testing are suspended vertically with their lower ends in the test liquid, and the elevation with time is measured (the wick effect). The test is important in the assessment of fabrics in minimal application techniques.

Width stretching (stretching out). The lateral stretching of milled goods if the lateral contraction has become too great and the longitudinal contraction has not yet reached an acceptable maximum.

Wild silks In addition to the → Silk obtained from the mulberry silkworm, other silks obtained from various nocturnal moths found in both Asia and Africa are of interest in textile processing. The cocoons are as a rule larger than those of the mulberry silkworm and often not suitable for reeling. The chemical properties of these wild silks are very similar indeed to those of so-called true silk, but they are more resistant to both acid and alkali and are not as easy to bleach or dye (having a higher content of natural dye). The cement found in the silk threads, sericin, is difficult to remove. The morphology of wild silks is distinctly less regular than that of true silk (individual threads with flat or wedge sections, longitudinal grooves, twists in the cocoon thread). Because of these features the thread is thicker and less regular and the goods have a stiffer and more grainy feel with a broken glaze. Tensile strength and expansion coefficient are both lower than those of true silk. Those wild silks important in textile processing include →: Anaphe silk; Eri silk; Fagara silk; Muga silk; Tussah silk; Yama-mai silk.

Williams Unit A variant of a type of → Roller vat which has an extremely restricted liquor volume. Each assembly comprises four vertical stainless steel containers, each of a U-shaped form. While temporarily removing the sheet suspended in each U-unit, piece goods are introduced and guided between upper and lower rollers arranged across the bend in the U. The separation between the casings inside the U is only 0.5 cm, meaning that there is an extremely short liquor ratio. The liquor is heated by a steam jacket to temperatures of 90–95°C (or to temperatures above 100°C if high pressure steam or hot oil is used). The speed of goods varies between 50–150 m/min, producing strong turbulence in the liquor and promoting good dye penetration. A Williams unit holds 350 litres of liquor and approx. 10 metres of goods with a throughput time of 6–8 seconds. The liquor circulation and the movement of the goods are according to the counterflow principle. It can be combined freely for continuous machines (e.g. in a pad-steam process). Dye consumption, liquor exhaustion, dye penetration, evenness, savings on steam and so on are favourable.

Winch (reel, windle, winder). A device, mechanically powered or hand driven, of adjustable circumference used to wind on or off (batching, reeling) rope or yarn. According to DIN/ISO a winch is: a rotating guide or transporting structure, the circumference of which is composed of individual carrying elements. The winch may be an open or closed structure.

Winch beck (piece dyeing vat, piece vat). A device for the dyeing of piece goods, especially lighter and thinner materials, jersey knits, etc., not suitable for dyeing on a jigger. A carpet winch dyeing machine is used for carpets. The principle is as follows: The beck, or vat, has a narrow boiling chamber at the side which can also serve for the addition of dye and the like, and which is separated from the remaining liquor and the goods by means of a perforated dividing wall. Situated above the beck and nearest to the dividing wall is a guide roller, a rake with teeth for separating the individual ropes of goods, and then a rotating round or oval winch with an adjustable speed drive. In special cases a swing-mounted vertical squeezer roller is also located above the winch and can be engaged once dyeing is completed. Specially constructed fully enclosed superstructures are also known, complete with a transparent vapour hood (containing an vapour flap valve and a ventilation shaft for escaping vapour) and a sliding door for servicing. The piece goods, sewn together at their ends into endless parallel ropes, are transported by the winch through the dye bath, over the guide roller, through the rake, over the winch and back into the dye bath, and so on. The winch is set higher or lower, depending on the goods. In the age of the jet, soft or overflow machine, the winch beck is easily seen as backward; however, it remains valid in several areas of textile finishing. Its flexibility of use, simple construction, ease of operation and unlimited size, together with improved details such as circulation pumps, mean that it retains a place all over the world in the dyeing of carpets, furnishing fabrics and terry fabrics.

Winch dyeing machine history The winch beck is the oldest dyeing machine. Originally constructed as an open beck, or vat, with a directly heated heating wall (Fig. 1), it was equipped with a large circular or oval drive winch above its rear portion and a smaller guide winch in the vicinity of the heating wall. Even after the head space was enclosed to avoid steam and mist (Fig. 2), temperature distribution within the vat of liquor remained poor (Fig. 3). The need to dye at temperatures above boiling point forced the use of a boiler construction with pressurized operation and liquor circulation system (Fig. 4). A particular problem was the passage of goods through a continuously operating series of

vats in pressurized after-washing or in the pretreatment of circular knitted goods (Fig. 5).

More than any other, Brückner concentrated on improving the design and equipping of the winch vat. As a result the Haspelflow B (Fig. 6) for tubular goods was optimised in terms of its liquor exchange in that the dye liquor was drawn off from the trough through a pipe and circulated through a lint filter. The liquor was pumped over a bare tube heat exchanger, through a riser pipe and then flowed over an overflow weir onto the goods.

For the dyeing of tufted pile carpets, Brückner adapted the winch vat to an open width dyeing machine (Fig. 7), and then later transferred the knowledge gained to woven fabrics. These planar fabrics, however, are difficult to guide in open width, which was done by means of a special airflow system in the front ex-

plied special methods which allowed for significantly shorter liquor ratios. Krantz produced the Espa-Surfer, a type of winch beck which was extended to the rear to incorporate a special transport track (Fig. 12).

Winch machines → Winch.

Winding,

I. The reeling or winding on of yarns (see Fig.) on → Yarn package winding machines. Usually the yarn is at the same time cleaned and thin or thick sections are removed using mechanical or electronic yarn cleaners.

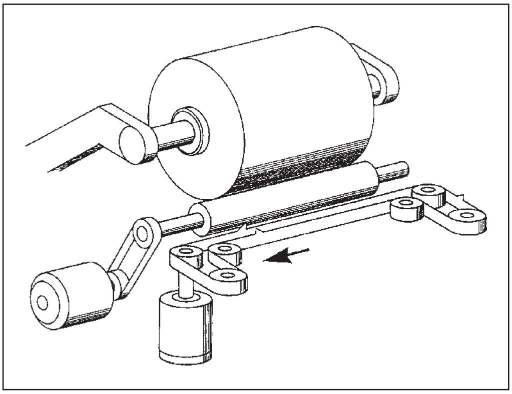

Fig.: Winding head with belt thread guides (Hacoba).

II. The looping of a thread around the core of a package. →: Package winding systems; Yarn packages, preparation.

Winding machine for card/emerizing rolls A machine for uniformly winding card strips or emery paper strips onto card or emerizing rollers (see Fig.).

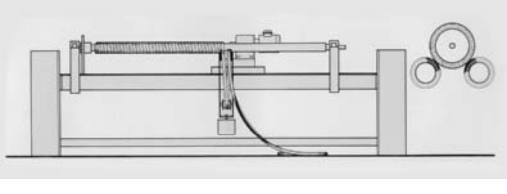

Fig.: Menschner's winding machine for card/emerizing rollers.

Winding spindle, batching-off shell A rotating cylindrical object with either an uninterrupted axial bore or with lugs fastened to each end which is used in the batching off of goods (DIN/ISO 5248).

Window In textile finishing this means the sample pattern at the end of a piece for the colour matching of dyed or printed samples, for example when dyeing on a jigger.

Window curtaining fabrics (curtain fabrics) → Net curtain fabrics and decorative materials made from wool, polyamide, polyester, cellulose, polyacrylonitrile, glass fibres and mixtures.

Wipes When used for special purposes, for example in dusting microchips, the wipe itself must not create dust, i.e. must not deposit fragments of fibre. The surface of the wipe must also be indestructible in terms of the fibre used. The wipe must not take any electrostatic charge, which means that no finishing agent may be used since its antistatic nature must be permanent.

Kanebo has achieved this by mixing ultra-microfibres (Fig. 1) as fine as 1–5 Ïm with carbon coated polyester fibres (Fig. 2) which on the one hand conduct away any electrostatic charge and on the other protect the surface from damage. The super-microfibres absorb dust reversibly.

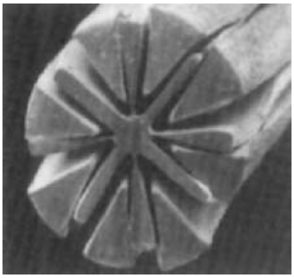

Fig. 1: Super-microfibres for wipes, made from 29% polyamide and 71% polyester.

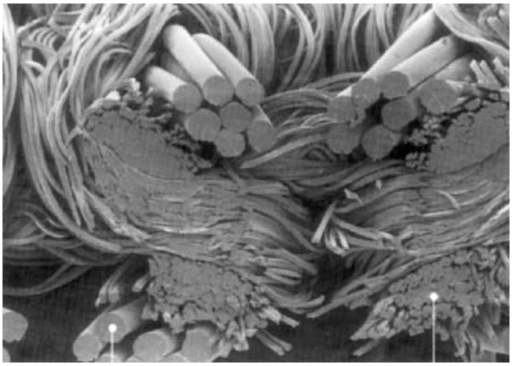

Fig. 2: Electron microscopic photograph of a cross-section through a Kanebo wipe.
Belima C = carbon vapour-blasted polyester yarn; Belima X = super-microfibres (see Fig. 1).

WIRA An English textile research institute; → Technical and professional organizations.

Wire card →: Raising; Raising elements.

Wire carpets Machine woven carpets with three warp thread systems (pile warp, filling warp and binding warp) and two or three weft thread systems. Steel pile wires are included during weaving such that the warp yarn is not merely laid around the weft yarn but at the same time formed by the presence of the metal wire into a loop. As soon as the pile is tied securely below the wires, these wires are pulled out and then re-included for the purpose of creating further loops. If the wires are equipped with knives they cut open the loops when withdrawn, resulting in a wire pile carpet (velour carpet). Examples are →: Bouclé carpets; Brussels carpet; Tapestry carpet; Tournay carpet.

Wire raising machine A roller raising machine, brush raising machine or universal wire raising machine fitted with metal wire cards in order to work as a raising tool. → Raising.

Wire sleeve A flexible dyeing sleeve made from stainless steel wire used as a package during the treatment of yarns which may shrink significantly.

WK → Camel hair, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

WL → Llama hair, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

WM → Mohair, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

WN → Rabbit hair, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

WO → Wool, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Wo → Wool, → Textile fibre symbols, according to DIN 60 001 until 1988, from 1991 → WO.

W/O Abbrev. for oleaginous. → Emulsions, i.e., water in oil system.

Woad A blue → Natural dyes (a vat dye) obtained from the leaves of the golden flowering woad plant (weld, dyer's weed) and squeezed into the form of a ball. Its working ingredient is → Indigo. Woad was superseded by indigo, which has 30 times the concentration of dye, at the beginning of the nineteenth century.

Woad vat The oldest type of vat, it contains a mixture of → Woad with bran and madder (as a fermentation agent). Processing is carried out using bran and lime. → Fermentation vat.

Wollsiegel-Verband e.V. Trademark association of the International Wool Secretariat (IWS) in Düsseldorf. It is responsible for issuing licences for the use of the international woolmark, monitoring the observance of contractual duties by contract partners, carrying out quality control checks and dealing with all questions concerning the laws on competition.

Wood dyes These are dyes used in the dyeing of various types of wood and are usually cationic dyes, acid dyes and metal complex dyes.

Wood pulp A product obtained through the extraction of cellulose from wood and which remains after encrusted substances (lignin) have been removed. It is composed principally of α–cellulose (approx. 89%), the remaining 11% being provided by the hemicellulose forms β–cellulose and γ–cellulose. Among other uses, wood pulp is exploited on a large scale in the manufacture of viscose fibre.

Wood spirit → Methanol.

Wood turpentines → Turpentine oils. Also found in this group is → Pine oil.

Woody fibre These are the fibres in deciduous trees which lend them their strength and also serve to transport air and water. They are 0.5–1.5 mm in length, are narrow and have thick walls. Their ends are pointed. An analogy is found in components of the central lamella in →: Bast fibres; Hard fibres.

Wool A textile fibre belonging to the group of → Natural protein fibres. Only the hair of sheep can be referred to as wool. The amount of wool which grows on 1 cm^2 of skin is about 10 000 hairs and a single sheep produces about 100 million hairs and about 20 km or 6 g (3 dtex) every day. The fur of all other animals used for production of fibres is referred to as hair. In general, there is no basic difference between wool and hair in terms of substance. Rather, the difference lies in the appearance and fine structure. Wools are curly, bulky and fairly fine. Hairs, on the other hand, are straight, smooth and predominantly coarser and longer. There are also the so-called fine → Animal hair fibres (Cashmere, etc.).

Breeding has made it possible to produce a type of hair with (depending on the breed of sheep) uniform properties. Basically, there are three different types:

- fluffy or woolly hair: fine, soft, curly, short mat and fleshy;
- long coarse hair: coarser, more brittle, straighter, longer, glossier and hollow;
- short bristly hair: coarse, hard, straight, stiff, short, smooth, glossy, white and rough.

The fluffy or woolly hair and the long, coarse hair are wools in every sense. Depending on the breed and breeding, they exist separately or even as a mixture in the animal's coat. The short bristly hair is not fully hair and in all breeds only occurs singly and at particular places on the body of the animal where the bones lie directly beneath the skin or where the animal has been injured. Old animals and animals where the breeding has been neglected have a larger amount of short bristly hair. Because of its internal structure, it dyes differently or not at all; the dye is not even retained well in the fibre lattice. Normally, this is undesirable and is separated out but occasionally it is very much desired as a fashion effect.

The climatic conditions in which the sheep live and the associated soil conditions (basis for nutrition) are decisive in the build-up of wool hairs. There is a difference between the following two main categories:

1. Mountain sheep: of all sheep, the merino breed is essentially the most important. Its natural home is Spain where the living conditions are those of a high altitude climate, hot during the day and cold at

night. The animal's coat is able to compensate for the large fluctuations in temperature. Merinos supply fluffy or woolly hair with lengths ranging from about 40–150 mm and finenesses from around 17–24 µm. The main representative of this breed is the Australian merino; the purest breed on the other hand is the Rambouillet.

2. Lowland sheep: these develop in damp, mild but rough oceanic climates. Their natural home is England and the islands of the North Sea. They are mainly represented by the English countryside breeds such as the Lincoln, Leicester and Cheviot sheep, chiefly producing long coarse hair with lengths ranging from 120–300 mm and, in the case of particularly long wools, lengths up to 550 mm. Finenesses range from 24–48 µm.

The so-called "Crossbreds" have been developed by crossing the English Lincoln breed with the fine-woolled merino. This mixed breed has proved itself to be particularly resilient in regard to climate and disease, etc. In spite of the increased shearing yield, it is possible to increase the coarseness of the wool of these crossbreds by back-breeding with merinos. These back-bred sheep are called "Comebacks".

Shearing takes place either twice a year (half-shear), once a year (full-shear) or three times in two years (three-quarter shear). Virgin wool is wool which has been shorn from the animal while it is alive. The coherent coat which is produced during sheep shearing is called the fleece. This is divided up into different wool qualities depending on the part of the sheep's body from which it has been shorn. The different areas of the fleece listed below are shown in Fig. 1

- range I: best quality;
- range II: good average wool;
- range III: somewhat coarse, frequently brittle and open, greasy, dirty and fleshy;
- range IV: coarse, short and knotted;
- sorting: short, permeated with bristles and frequently felted.

After shearing, the fleece is divided up (by tearing it apart) and sorted by a practised hand into the various wool qualities.

The fineness is defined as the diameter of the fibre in µm. This is classified into the following categories:

– fine merino wools	17–20 µm
– merino wools	20–24 µm
– fine crossbreds	24–28 µm
– medium crossbreds	28–37 µm
– coarse crossbreds	more than 37 µm

Because wool occurs in different fibre thicknesses and the finer wools are always shorter and the coarser wools always longer, in practice, the fibres are also classified according to their fineness (see range IV). The English classification (e.g. 66's) signifies the Number English (Ne) worsted yarn to which the wool could be spun. The German is arbitrary and uses the capital letters of the alphabet (e.g. AA/A).

merino wools:	80's	or AAA
	70's	or –
	64/70's	or AA
	64's	or A
	60's	or A/B
crossbred:	58/60's	or B
	56/58's	or B/C 1
	50/56's	or C 1
	50's	or C 2
	48/50's	or D 1
crossbred coarse:	48's	or D I/D 2
	46's	or D 2/E 1
	40/46's	or E 1/E 2
	36's	or F 1

The layer of scales which can be seen under an electron microscope is characteristic of the morphology of the

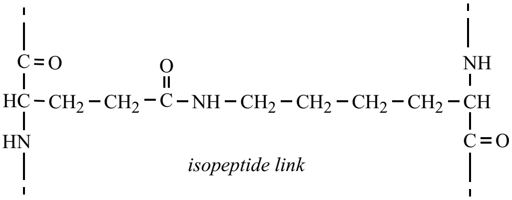
wool fibre (Fig. 2). The o-p-Cortex structure is made visible by skilfully producing fibre cross sections (Fig. 3). A stronger magnification of the cross section shows the different structure of the scale layer (Fig. 4); two scale layers can be recognized. From outside to inside, the components are as follows:

- extremely sulphur-rich A-layer (Ag contrasting),
- sulphur-rich exocuticle,
- endocuticle,
- cell-membrane complex (between the cuticle layers).

Wool chemistry In molecular fibre science, physical, chemical and technological properties are attributed to the primary structure of the linear macromolecules, their conformation (secondary structure) and the interactions between the certain parts of the macromolecules, the side-chain groups in particular (tertiary structure). The tertiary structure is effectively fixed by the intra- and interchenaric bonds (crosslinks). No other textile fibres – such as keratin hair which includes human hair – show so many different aspects in their crosslink chemistry as does wool, as it is made up of 18 different amino acid residues as monomers, of which approximately half act as a source of reactive side-chain groups. There is a difference between primary and secondary valence links but, in many cases, it is not possible to differentiate clearly between the two. A further distinction can be made between natural crosslinks produced in the wool by the biosynthesis and synthetic links, which do not appear until they are formed during the reactions which occur later. The insolubility of the cell membrane is explained by the presence of glycoproteins and isopeptide links.



$$\overset{\overset{|}{C=O}}{\underset{\underset{|}{HN}}{HC}}-CH_2-CH_2-\overset{O}{\overset{\|}{C}}-NH-CH_2-CH_2-CH_2-CH_2-\overset{\overset{|}{NH}}{\underset{\underset{|}{C=O}}{CH}}$$

Even the intermacrofibrillar material appears to be stabilized by the isopeptide links. The keratin of wool may be summarized as shown in Tab. 1. If hair or wool is left to swell in hot water, it is possible to stretch it by around 100%. On relaxation, it contracts again to approximately its original length. According to X-ray photographs, modified keratin occurs in two different forms: the α-keratin of the unstretched wool, where the

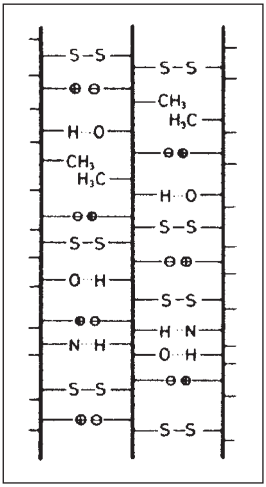


Fig. 1: Diagram of the chemical construction principle of wool showing its "ladder pattern" (by Zenko Stary). The main chains are linked to one another through disulphide (cystine) bonds, salt linkages, hydrogen bonds and also hydrophobic interactions.

polypeptide chains are folded together in a particular way and are therefore shortened, and the β-keratin, where the polypeptide chains occur as in silk. In 1928, Zenko Stary developed the ladder model to help understand the chemical structure of wool (Fig. 1).

In α-keratin, the polypeptide chain is wound in the shape of a spiral or screw (Fig. 2). The side chains are oriented towards the outside and each amino acid has an intramolecular hydrogen bond between it and the third neighbouring group in the direction of the helix, thus stabilizing the molecule.

chemical composition: 80% keratin proteins;
19% non-keratin proteins
1% internal lipids
molecular masses: 9000 to 60 000
intermolecular forces: cystine bonds, hydrogen bonds and salt linkages;
hydrophobic interactions
isoionic point: pH 4.9
moisture pick-up: 18%
crystal structure (30%): α-helix
fibre period: 0.51 nm
amorphous sections: non-helical segments in microfibrils; matrix in macrofibrils; non-keratin proteins
microfibrils: 7 to 11 nm
macrofibrils: 50 to 200 nm
pore volumes: 35%
biological composite structures: cortex, cuticle
glass temperature dry: + 174 °C
wet: - 5 °C
decomposition temperature: 250 °C

Tab. 1: Summary of wool properties.

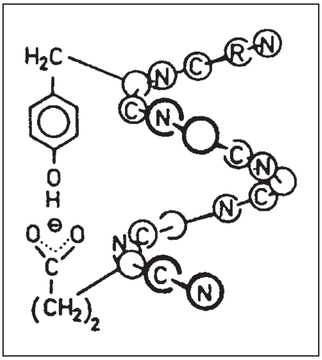

Fig. 2: Diagram of an intrahelical H-bond between a phenol hydroxyl group and a carboxylate anion of the wool keratin, representing α-keratin.

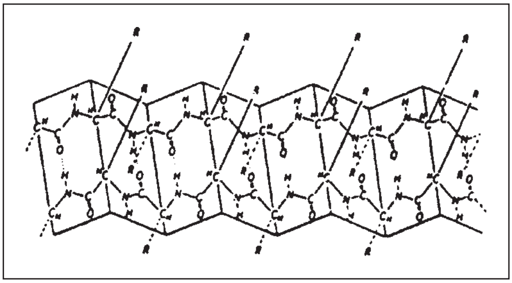

Fig. 3: Pleated sheet structure according to Pauling and Corey, based on inter-chain H-bonds between the antiparallel arranged polypeptide chains of silk, similar to the β-keratin in stretched wool hairs.

The helical structure of α-keratin, however, only occurs in wool fibre in its unstretched state. When the fibre is stretched, the α-keratin structure is converted to the “pleated sheet” structure of β-keratin (Fig. 3), while the intramolecular hydrogen bonds break and reform as intermolecular links between two different polypeptide chains. This process is reversible, i.e., α-helix is produced again as soon as the wool hair can relax (Fig. 4). This so-called α-β switchover is the reason for the elastic properties of wool.

Apart from keratin, wool also contains non-keratin proteins. Among these are molecular substances such as lipids. The non-keratin proteins, which are characterized by a lower cystine content in comparison to keratin proteins, are cell-core, cytoplasmic and cell-membrane proteins chiefly found in the cell-membrane complex, the intermacrofibrillar cement and the endocuticle. In spite of the fact that lipids are involved in only 1% of the total chemical structure of the wool, they are still important as they make up 35% of the cell-membrane complex. The chemical composition in terms of amino acid content is shown as a percentage in Tab. 2.

The terms “acid” and “basic” amino acids only refer to the chemical structure of the nondissociated and dissociated carboxyl groups –COOH of the aspartic acid and glutamic acids or nonprotonated groups in the lysine, histidine and arginine.

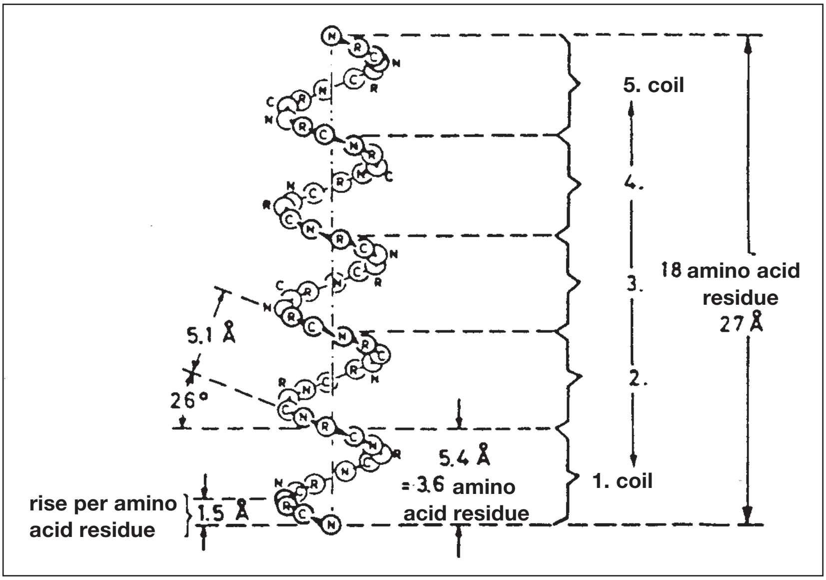

Fig. 4: Secondary structure of proteins: diagram of the α-helix according to Corey and Pauling.

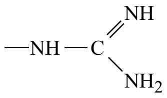
$\sim NH_2$

$—N=$



$-NH-C(=NH)-NH_2$

Since both “acid” and “basic” groups exist simultaneously in amino acids, they react with each other to form “salt linkages” (Fig. 5). The “acid” amino acid in the salt linkage, glutamic acid, no longer exists in its acidic form but rather in its basic carboxylation form and the “basic” amino acid arginine in the salt linkage no longer exists in its basic form but in its protonated guanidinium form.

Proteins are termed polyampholytes because they contain many cationic and anionic groups at the same time. Proteins, therefore, are highly effective buffers which are able to chemically neutralize both acids and alkalis which have been added to the system, such as hydrochloric acid or sodium hydroxide.

The isoionic point is the point at which the same number of anions and cations exist in a molecule at the same time. From the outside, the molecule appears to

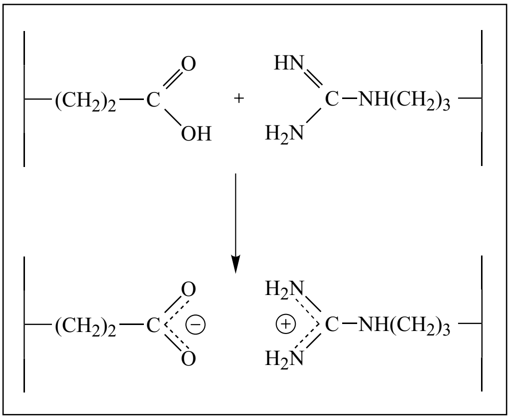


Fig. 5: Diagram of the formation of a “salt linkage” through reaction of the “acid” amino acid glutamic acid with the “base” amino acid arginine in a protein.

Tab. 2: Amino acid composition of delicate Merino wool. The description “acid” and “base” amino acids relates only to the chemical structure of the non-dissociated carboxyl group –COOH in aspartic and glutamic acid or of the non-protonated groups.

be uncharged, a state which is determined by the ratio of acid and basic groups in the molecule. The acid and base bonding capacity can be established using titration curves (Fig. 6).

Instead of showing the isoionic point, the titration curve spreads across a broad pH range (isoelectric zone) within which neither the acid nor the base is in the bonded state. This is explained by the formation of the → Electrical double layer which hinders the penetration of hydrogen ions. By adding salt, this double layer is suppressed and the fibre is able to bond to larger amounts of acids or alkalis.

The isoelectric point of wool is at pH 4.9 (at 20°C) or pH 4.6 (at 90°C). Wool has its lowest reactivity at its isoelectric point. Consequently, it is in its most stable state because it is at the point where its salt-link formation capacity is at its maximum.

Although the surface of the wool has hydrophobic properties, it is a typical hygroscopic fibre which is capable of absorbing moisture from the air or, when wet, to release moisture to the air (desorption). The amount of bound water in relation to dry weight of the fibre can be as high as 33% (saturation humidity) and is dependent on the humidity of the air and the temperature, and on whether the equalization is taking place from the wet or dry state (→ Hysteresis). As water is absorbed, the fibre swells (increases in volume). At the isoelectric point, fibre swelling is at its minimum but increases as the pH increases or decreases. Swelling mainly takes place in the non-oriented, amorphous zones of the fibre and increases the fibre's susceptibility to attack from air, light and chemical agencies. The reason for this is that water is absorbed by the numerous hydrophilic groups in the wool molecule such as amino, carboxylic and hydroxyl groups. These hydrophilic groups while interacting with each other are partially exposed by the water and are surrounded by water molecules. At the same time, the hydrogen bonds between the neighbouring polypeptide chains are removed. The hydrophilic fibre stem is enveloped with the hydrophobic cuticle in the form of overlapping scales (coarser wools frequently have a pulp layer as well, know as the medulla). The top side of cuticle cells is called the exocuticle and the under side the endocuticle. The epicuticle, a thin skin with cells terminating on the outside, lies on top of the scales' cells (→ Wool structure).

During textile finishing, the wool passes through different finishing processes where it is treated with, amongst others, alkalis, acids, oxidation agents and reducing agents. Alkali is added, for example, in the soda-alkali raw-wool scouring step or during alkaline milling. Sulphuric acid is used to hydrolyse the vegetable impurities during the carbonizing stage. Under certain circumstances, reducing agents are used during chemical decatizing and oxidizing agents are used during oxidative bleaching and antifelting finishing. Behaviour in regard to these substances will be described briefly in the following.

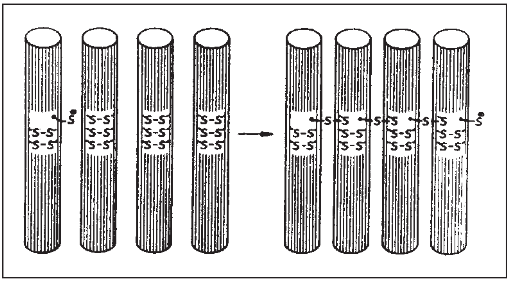

Fig. 7: Diagram of the self cross-linking of 4 protofibrils (gram-molecular weight approximately 40 000) in wool through chain disulphide exchange.

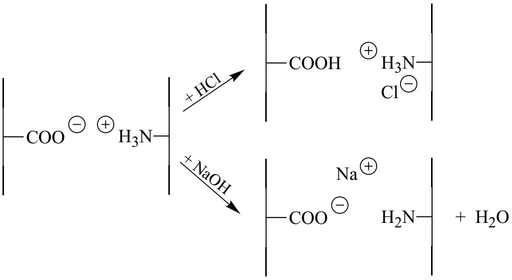
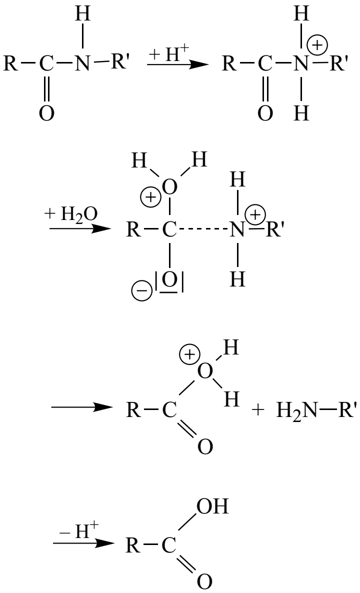
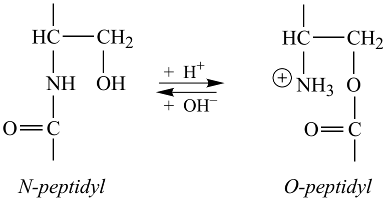
As proteins contain many cationic and anionic groups at the same time, they are proper buffers and are able to neutralize both acids and alkalis.



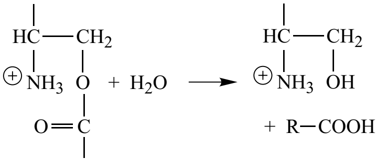
Among the characteristic properties of wool is its resistance to mineral acids. However, in the presence of water, peptides can be hydrolyzed by concentrated acids. This happens, for example, if carbonizing is not properly controlled:



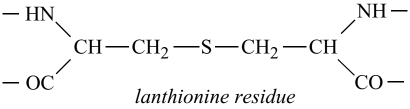
An N→O peptide shift is also possible:



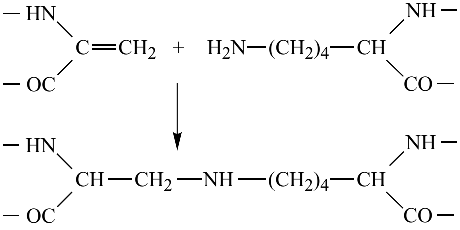
The peptide ester is in far greater danger of hydrolysing than the carbonamide group:



The effectiveness of an alkali in splitting the hydrogen bond, altering the amino acid chains and converting the peptide and disulphide links differs according to its concentration and temperature (Fig. 7). While concentrated alkalis dissolve wools by breaking the peptide links, during relatively mild treatment with alkali, the fibre structure remains intact. However, some of the cystine sulphur splits off in the form of hydrogen sulphide as the amount of cystine decreases. The sulphur that is left exists in another form:



Since this is a bond of low reactivity, the new crosslink, R–CH$_2$–S–CH$_2$–R’ is relatively resistant to alkalis. Additional crosslinking is obtained by the formation of lysinoalanine from an integral aminoacrylic acid and the free side chain of the lysine residue.



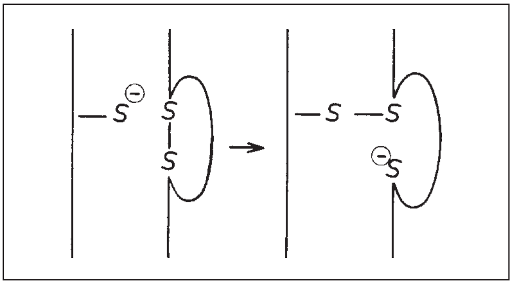


Fig. 8: Crosslinking of wool molecules with inter-chain disulphide bonds through disulphide exchange.

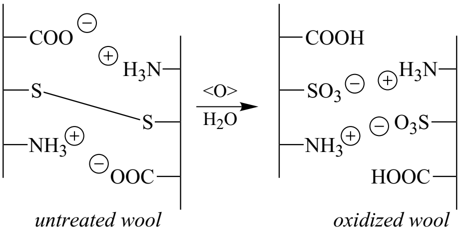
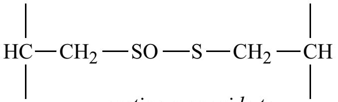
Burley considered the lack of any decrease in cystine content on careful treatment with alkali, but possible decrease in urea-bisulphite solubility, to be due to the formation of a new crosslink system (Fig. 8). During this reaction, an intrachenaric –S–S bond is attacked by a neighbouring SH group to form a new interchenaric cystine link.

The behaviour of wool towards oxidation agents is essentially determined by the disulphide links. Complete oxidation of the cystine groups not only means that the covalent bonds are broken but also the salt linkages:

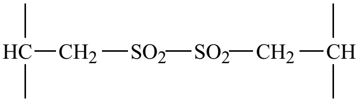


An increase in cysteic acid is characteristic of an oxidative change. During oxidative antifelt finishing and bleaching, the drastic oxidative decomposition of cystine links is highly undesirable due to the associated damage and loss in weight. For this reason, work must always be carried out under mild conditions where the oxidation of cystine can take place without the breaking of links:



$$HC{-}CH_2{-}SO{-}S{-}CH_2{-}CH$$

cystine monoxide to cystine tetroxide



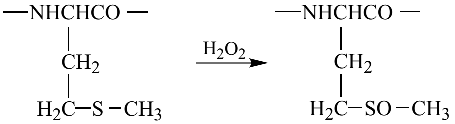
$$HC{-}CH_2{-}SO_2{-}SO_2{-}CH_2{-}CH$$

Other amino acids susceptible to oxidation are, e.g.:

cysteine

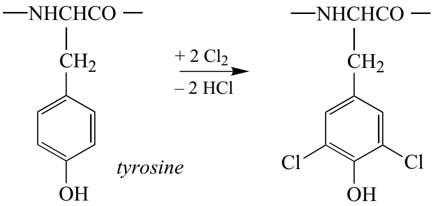
$$\textcircled{W}-SH + HS-\textcircled{W} \xrightarrow{-2\,H} \textcircled{W}-S-S-\textcircled{W}$$

methionine

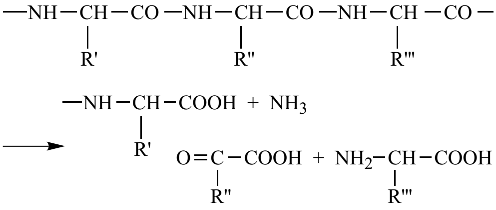


$$\begin{array}{c}\mathrm{-NHCHCO-}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{H_2C-S-CH_3}\end{array} \xrightarrow{H_2O_2} \begin{array}{c}\mathrm{-NHCHCO-}\\ |\\ \mathrm{CH_2}\\ |\\ \mathrm{H_2C-SO-CH_3}\end{array}$$

Oxidizing agents can attack the molecule at several locations: the phenolic hydroxyl group can be oxidized and the reactive hydrogen atoms on the phenolic ring can be substituted. In the end, via an intermediate product, this can lead to a break in the peptide chain on the tyrosyl residue:



On the main chain, oxidative cleavage between the NH group and the R–CH residue may take place,



$$\mathrm{-NH-\underset{R'}{\underset{|}{CH}}-CO-NH-\underset{R''}{\underset{|}{CH}}-CO-NH-\underset{R'''}{\underset{|}{CH}}-CO-}$$

$$\longrightarrow \mathrm{-NH-\underset{R'}{\underset{|}{CH}}-COOH} + \mathrm{NH_3} \quad \mathrm{O=\underset{R''}{\underset{|}{C}}-COOH} + \mathrm{NH_2-\underset{R'''}{\underset{|}{CH}}-COOH}$$

which can then lead to the formation of chloramine

$$R-NH_2 + Cl_2 \longrightarrow R-NHCl + HCl$$

and chloramide.

$$\mathrm{-CONH-} + Cl_2 \longrightarrow \mathrm{-\underset{Cl}{\underset{|}{CON}}-} + HCl$$

During chlorination, the N-chlorine links are formed first and this is followed by oxidation of the disulphide bonds and cleavage of the tyrosyl links.

Unlike oxidation, the reducing agent will attack the cystine sulphur in preference. The reductive cleavage of cystine links is utilised in the fixation of the surface of woollen fabrics. During the first stage of chemical fixation, the disulphide links are broken. Various different reducing agents can be used for this purpose:

a) sulphitolysis (sodium hydrogen sulphite)

$$\textcircled{W}-S-S-\textcircled{W} \xrightarrow{NaHSO_3} \textcircled{W}-SH + \textcircled{W}-S-SO_3Na$$

b) hydrolysis (water, alkali and heat)

$$\textcircled{W}-S-S-\textcircled{W} \xrightarrow{H_2O} \textcircled{W}-SH + \textcircled{W}-S-OH$$

c) thiolysis (hydrogen sulphide)

$$\textcircled{W}-S-S-\textcircled{W} \xrightarrow{H_2S} \textcircled{W}-SH + \textcircled{W}-S-SH$$

d) mercaptolysis (thioglycolic acid: $HOOC–CH_2–SH$)

$$\textcircled{W}-S-S-\textcircled{W} \longrightarrow \textcircled{W}-SH + \textcircled{W}-S-S-CH_2-COOH$$

The thiol groups which are produced react with the neighbouring disulphide links during the second stage, in a so-called thiol-disulphideexchange, leading to a rearrangement of the sulphur links. During the last stage, the disulphide links are closed again by oxidation, thereby stabilizing the new fibre structure.

In 1955, Burley suggested a theory for the mechanism of wool fixation. According to this, the permanent fixation relies on the action mechanism of a thiol-catalysed disulphide exchange. The formation of thiol groups brought about by the cleavage of disulphide bonds follows the set up below:

$$R-S-S-R + NaHSO_3 \rightleftharpoons R-SH + NaSO_3-S-R$$

There is only a small number of thiol groups in wool fibre. Their number is increased by reaction with reducing agents or hot water, steam or alkali. In the case of stretched fibre, the thiol bond is formed in the vicinity of a disulphide bond. During this process, the disulphide bond is broken by the free thiol group, while a new thiol group and a new disulphide bond are formed. The new free thiol group also cleaves a disulphide link, while again a free thiol group and a new disulphide link are produced.

A schematic of the “zip-fastener” mechanism by which the thiol-catalysed disulphideexchange reactions promote and stabilize fixation is shown in Fig. 9.

Wool fibres are not only stabilized by covalent bonds but also, and more particularly, by hydrogen bonds. The function of fixing agents consists of cleaving enough disulphide links to weaken the stability of the wool fibres. This eases deformation.

Under the influence of moisture and high temperature or hydrogen-bond cleaving agents such as urea, fixation is brought about by re-orientation of the hydrogen bonds.

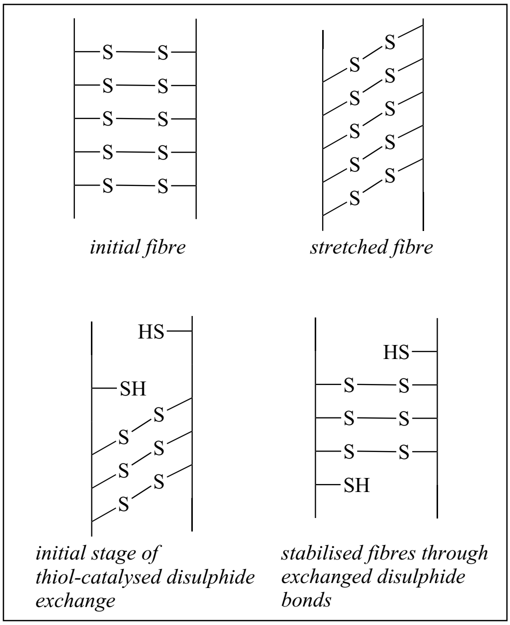


Fig. 9: The thiol-catalysed disulphide exchange mechanism.

With Kier decatizing, a process has been available for permanent fixation of woollen fabrics since the mid 1960's. The permanent fixation of stretched woollen fabric can be summarized as follows. The stretching process stresses the interactions which stabilise the keratin lattice. Hot water or steam splits the hydrogen bonds and salt linkages. This process has a loosening and weakening effect on the molecular structure. Reducing agents can penetrate to the covalent bonds more easily and faster and cleave them according to the thiol-catalysed, disulphideexchange mechanism. After the wool fibre has been deformed and the hot water or steam has been removed, new hydrogen bonds and salt linkages are formed which stabilise the newly imposed shape of the wool fibres.

In drawing up a list of fixation processes in order of their intensity, it is possible to say, with some reservation, that the effects of treatments using mild conditions – which merely consist of reorienting the hydrogen bonds and the effects of treatments using strong conditions (which also involves modification of the disulphide bonds) – increase in intensity in accordance with the following sequence:

- crease formation while the woollen article is being used,
- shrinkage on the London shrink unit,
- drying on the stretching machine,
- pressing,
- finish decatizing,
- press luster decatizing,
- kier decatizing,
- chemical fixation.

According to this, chemical fixation is the most intensive form of treatment as the moisture and sulphite-based reducing agent softens the sulphur-rich keratin matrix. The softened material can therefore be easily deformed under pressure. After deformation, the softening effects are easily removed by oxidation, in the simplest case, by hot air followed by drying, and the material is therefore fixed in the newly imposed shape.

Wool/cotton union, acidic single-bath dyeing The dyeing of wool/cotton unions using the single-bath method with union dyes or with wool dyes and direct dyes in acetic acid liquor, plus suitable levelling and retarding agents. Advantages: gentle treatment of wool, improved handle of fabric, tone-in-tone dyeings or two-colour effects achieved when the choice of dye is appropriate. Even condition largely retained in the case of wool/mohair plush.

Wool/cotton union/polyamide, dye range All union dyes are suitable. For plain dyeing, the addition of special retarding agents is beneficial for the avoidance of strong adsorption of mixed wool dyes on to polyamide. For bicolour dyeing, it is imperative.

Wool damage → Fibre damage (wool), tests for.

Wool dyeing The presence of acid and basic functional groups on the side chains of the fibre protein are a basic requirement for the dyeing of wool with anionic and cationic dyes (Fig. 1). The dyes which are suitable for colouring wool are classified in accordance with their chemical structure and behaviour as follows:

- acid dyes (world-wide, approx. 0.4 million t),
- metal-complex dyes (1 : 1 complex: world-wide, approx. 0.1 million t; 1 : 2 complex: approx. 0.4 million t),
- chrome dyes (world-wide, approx. 0.6 million t),
- reactive dyes (world-wide, approx. 0.1 million t, trend increasing).

Important factors for the even dyeing of wool are:

- affinity,
- dye uptake (substantivity),
- migration properties,
- degree of dispersion of the dye.

The exhaustion rate of dyes (Fig. 2) is mainly determined by their diffusion properties. Due to their high diffusion rates, dyes with small molecules have a fast exhaustion rate whereas those with large molecules have a relatively low exhaustion rate. The exhaustion rate is also dependent on the degree of affinity between the fibre and the dye.

As a general rule for the migration capacity of dyes, those with small molecules (levelling dyes), due to their lower bonding capacities arising from van-der-Waal forces and because of their high diffusion capacity, migrate relatively well and therefore compensate for the disadvantages of a high exhaustion rate. Dyes with

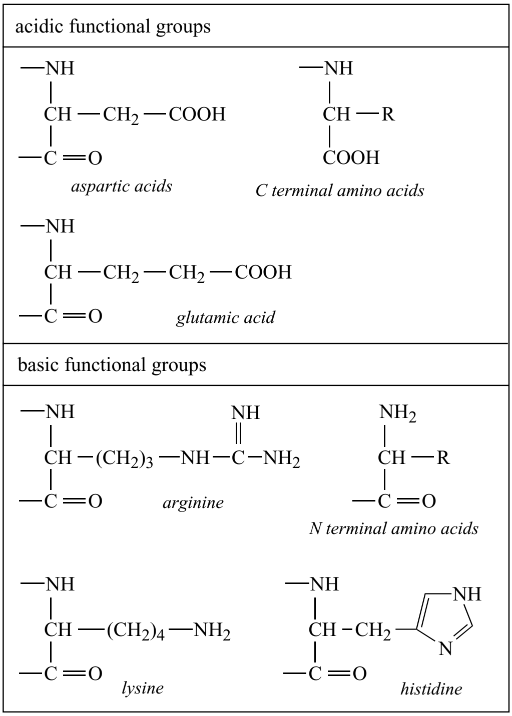

Fig. 1: Possible functional wool groups which can react with dyes.

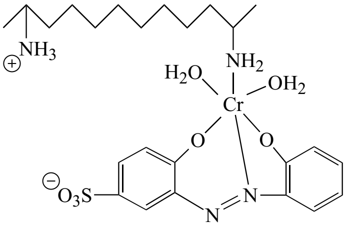
large molecules (milling dyes and 2 : 1 metal complex dyes), on the other hand, hardly migrate at all or only migrate a little because of their high affinity and low diffusion capacity, and because of their relatively low rate of adsorption, can easily dye unevenly. The wet fastnesses of wool dyeings are directly related to the migration capacities of the dyes (Fig. 3).

The dye/fibre bond is determined by physical and chemical interactions which more or less result in the dye being immobilized. Apart from the hydrogen bonds, van-der-Waal forces and hydrophobic interactions, the most important bonding forces, are as follows (Fig. 4):

1. Ionic bonding: in the case of anionic dyes, the ionic bond is derived from the electrostatic attraction between the positively charged amino groups on the wool and the negatively charged dye ions. The ionic bond is relatively weak and can be removed by modifying the charge on the wool (by increasing the pH). Additional forces are therefore necessary to achieve an adequate fastness.
2. Coordinate bonding: for chrome dyes and 1 : 1 metal complex dyes, apart from the forces already mentioned, coordinate bonds are formed between the chrome atom of the dye complex and the amino and imino groups on the wool.



With 1 : 2 metal-complex dyes, this possibility does not exist because the coordination sites on the chrome atom are both taken up by the two associated dye molecules. Formation of the metal complex

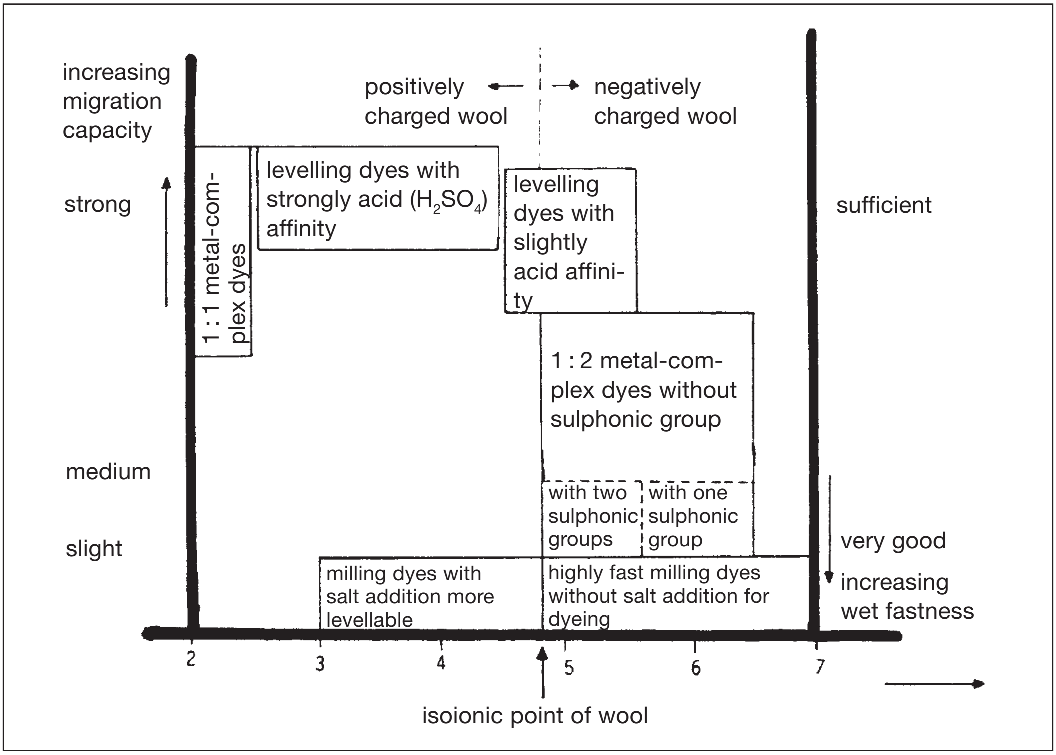

Fig. 3: Connection between migration capacity and wet fastnesses of dyes.

does not take place until it is rinsed with weak acid, the amino groups which are capable of reacting, only being formed in the acid range where they exist as ammonium ions.

3. Covalent bonding: reactive dyes can also form covalent bonds with the reactive groups on the wool. Under dyeing conditions, it is supposedly the thiol, amino and imino groups which become available as the reaction partner (Fig. 5).

Mechanism of the dyeing process: under strongly acid conditions, the carboxyl groups on the wool are protonated first. The acid anions rapidly diffuse into the fibre

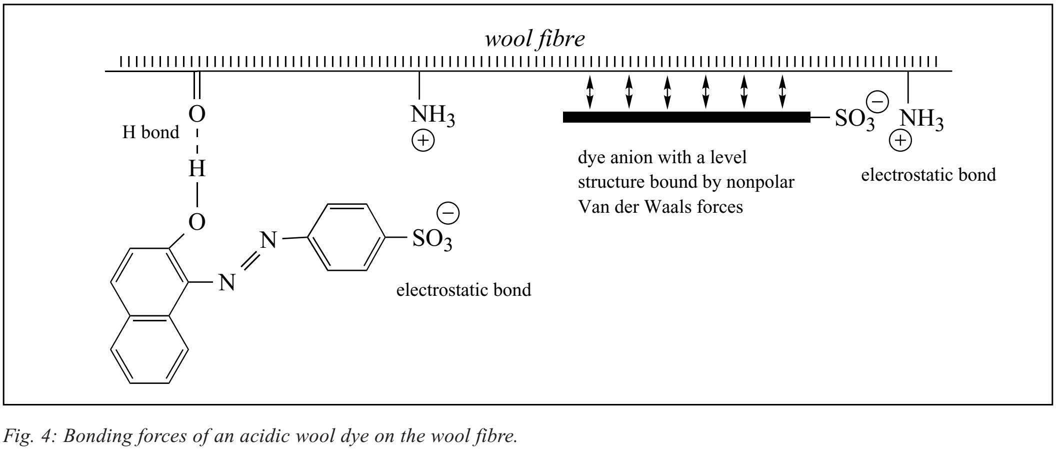

Fig. 4: Bonding forces of an acidic wool dye on the wool fibre.

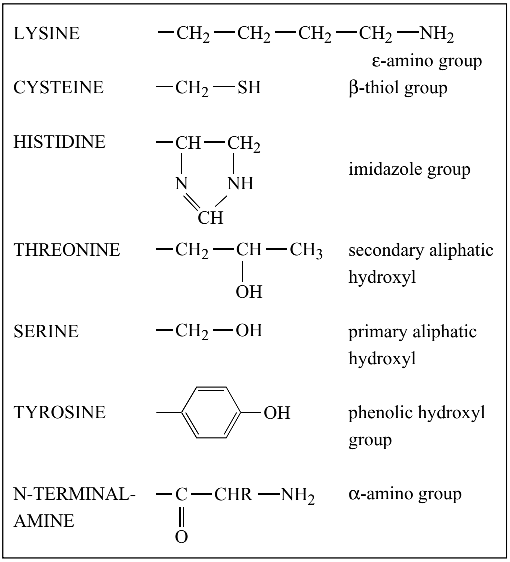

Fig. 5: Wool side chains which can react with reactive dyes.

to produce a state of electro-neutrality. Due to the affinity between the dye and fibre, the slowly diffusing dye anions replace the inorganic anions as the dyeing time increases, i.e. the dye is bonded to the fibre in an ion exchange reaction. These type of dyeing conditions are mainly to be found in the case of dyes with a lower affinity for wool, such as levelling acid dyes. The high concentration of cationic groups at pH 2 provides the necessary attraction for the dye anions. Under these conditions, the addition of salt, for example sodium sulphate, may have a levelling effect. Because of their superiority in numbers, the additional sulphate ions compete with the dye for the cationic ammonium groups on the wool. Fig. 6 shows the effect of using sodium chloride or hydrochloric acid against dyeing time.

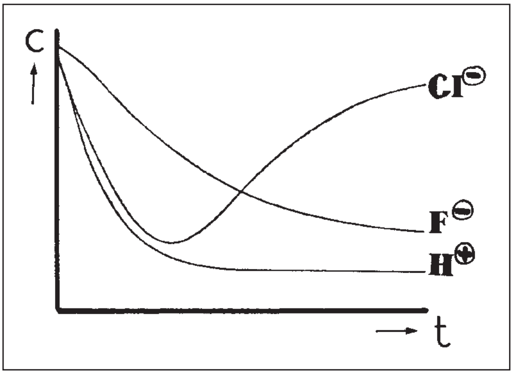

Fig. 6: Diagram of the variation with time of the concentration of dye, hydrogen and chloride ions in a wool-dyeing acid dye bath.
c = concentration; t = dyeing time.

For dyes with higher affinities, such as 1 : 2 metal complex dyes, the non-polar interactions between the dye and the fibre are sufficient for adsorption, so dyeing can be carried out under neutral conditions. The dye anions adsorb on to the fibre first and the sodium ions follow in order to ensure electro-neutrality. In this case, the sodium salt of the dye is bound. Adding sodium sulphate usually leads to the “salting out” of dye on to the fibre, i.e. instead of producing a retarding, levelling effect, adding sodium sulphate leads to a larger degree of exhaustion of the dyebath.

Levelling agents: as already mentioned, in strongly acid conditions, sodium sulphate takes on the role of a levelling agent. In the case of dyes with high affinity, to achieve even dyeings, it is appropriate to add levelling agents which

- temporarily reduce affinity,
- reduce the exhaustion rate,
- improve the migration capacity,
- equalize differences in affinity on the wool.

By means of their ionic character and affinity, levelling agents are classified into either fibre-affinity or dye-affinity auxiliaries. Non-ionic and amphoteric auxiliaries which have a high affinity for dyes are important for 1 : 2 metal-complex dyes.

Under the normal conditions of wool dyeing in the weak acid range, the driving force for bath exhaustion is the potential difference between the dyes with negatively charged SO_3 groups and the positively charged wool (Fig. 7).

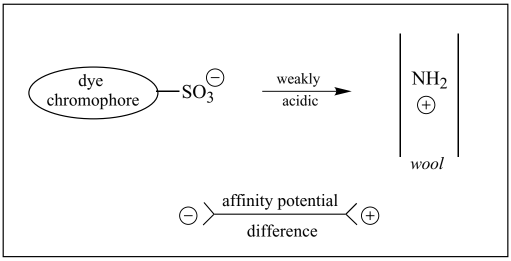

Fig. 7: Normal condition of an acidic wool dyeing without levelling agent using dyes containing SO_3 groups.

Dyeing in the presence of a levelling agent (Fig. 8) can result in a dye/auxiliary complex, the total negative potential of which produces increased dye affinity. This increases bath exhaustion, deepens dyeing, reduces the effluent produced and makes the dyeing process more economic.

Levelling is achieved by the complex, which has

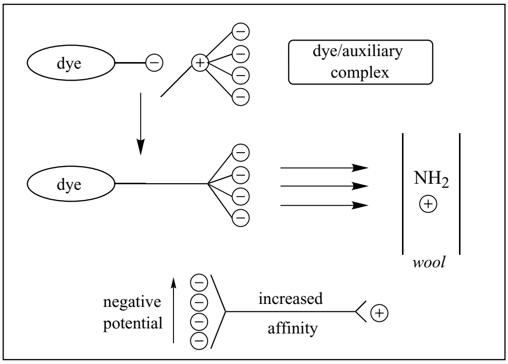

Fig. 8: Dyeing method using levelling agent and dyes containing SO_3 groups (according to Stockhausen).

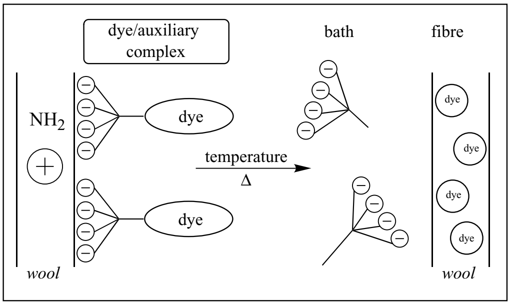

Fig. 9: Levelling mechanism at the boil with dyes containing SO_3 groups (according to Stockhausen).

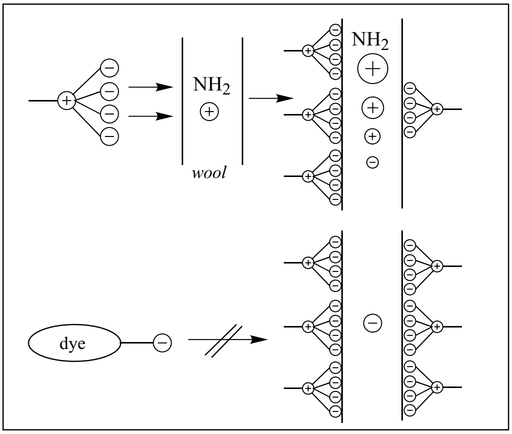

Fig. 10: How a levelling agent acts as a retarder through transpolation of the wool fibre charge (according to Stockhausen).

adsorbed on to the fibre at low temperature (Fig. 8), decomposing at the higher fixing/boiling temperature (Fig. 9), so that the dye can diffuse into the fibre while the levelling agent remains in the liquor.

If wool dyes are used which are free of SO_3 groups, then routes are possible for the dye/levelling agent/fibre interaction: the retarding properties of the auxiliary may dominate when it has a high affinity for the fibre and reverses or decreases the polarity of the charge on the fibre (Fig. 10).

Increasing the temperature gradually removes the fibre-affinity auxiliary and the fibre gradually recovers its positive charge; the dye fills up slowly (with levelling).

The dye affinity of the auxiliary is less important (Fig. 11). A surfactant micelle is produced which incorporates the dye. Due to its hydrophilic properties, this micelle is oriented towards the liquor (the micelle is very soluble) and has limited mobility in the bath due to its large volume.

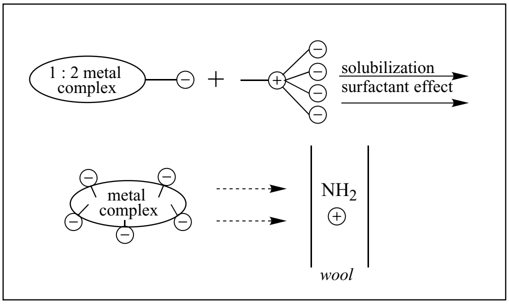

Fig. 11: Dye affinity of an auxiliary towards dyes not containing SO_3 groups (according to Stockhausen).

Damage to the fibre: during treatments involving boiling, wool is subject to changes to its chemical and mechanical properties. In addition to this, the pH difference at the isoelectric point of wool and the time factor at the boiling temperature are also important dyeing conditions. If the pH deviatiates slightly from the pH at the isoelectric point, reversible cleavage of the salt-linkages and hydrogen or hydroxide ion bonds will take place but may be reversed by rinsing under neutral conditions.

Irreversible damage is caused by highly concentrated acids or alkalis as well as by long treatment times at higher temperatures. When dyeing under strongly acid conditions, the peptide links experience hydrolytic attack which is characterised by decomposition of the fibre protein to their amino acids via simple peptides (→ Degradation). In preference, this takes place on the amino groups of aspartic acid and serine. As the wool degrades, protein fragments are released from the fibre in the form of wool gelatine. Due to its high swelling capacity, the wool gelatine comes from the non-ker-

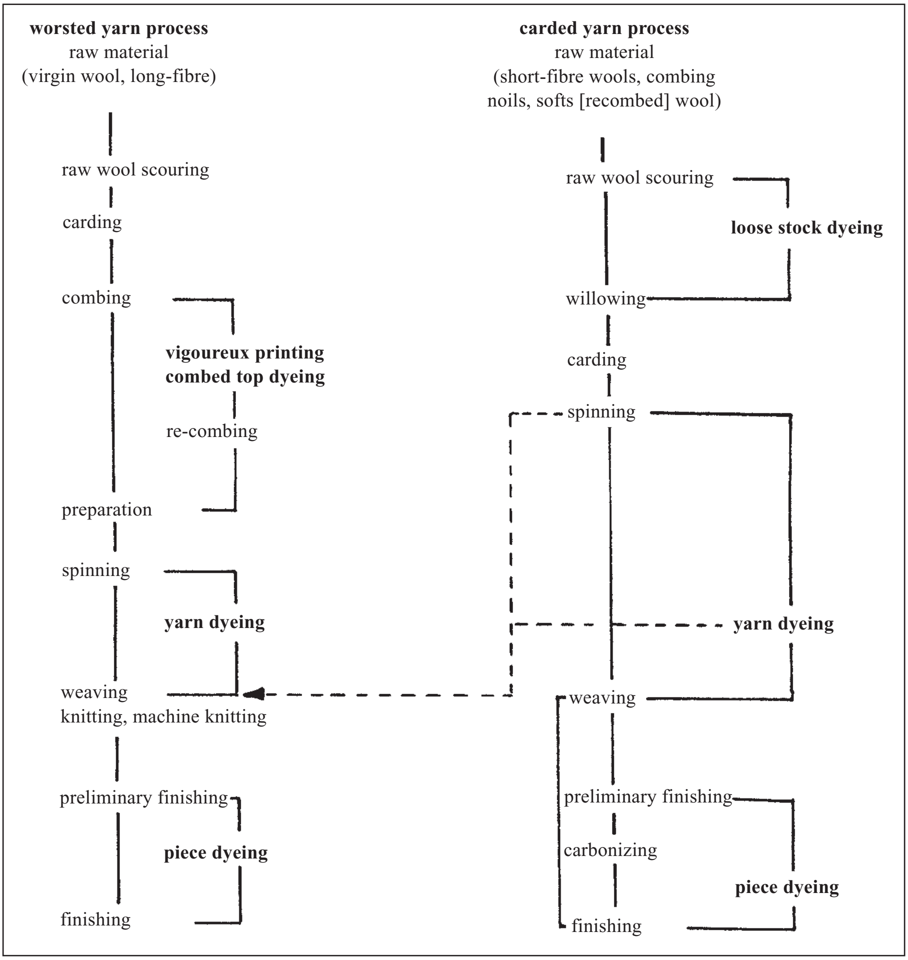

Fig. 12: Wool make-up forms for dyeing at various finishing stages.

atin proteins. In addition to this, the cell-membrane complex of the cortex is attacked in the strongly acid range and the endocuticle is probably attacked in alkali. Under alkaline conditions, almost all types of bond are attacked but especially those of cystine. Different decomposition and intermediate products are produced and new crosslinks, such as lanthionine, are formed at the same time.

Make-ups: wool appears in different make-ups depending on the finishing stage during which dyeing is to be carried out (Fig. 12). For reasons of economy, storage and delivery time, etc., an effort is made to finish the wool as near to the final article as possible. Thus, piece dyeing and the dyeing of ready-to-wear knitwear has become considerably more important. It is possible to dye the web or knitwear in wide or rope form. The deciding factors in this choice are the properties of the fabric, such as its tendency to crease and felt. The requirements for piece dyeing are as follows:

- surface evenness, especially if different wool qualities have been used,
- the possibility of correcting defective dyeings,
- maintenance of wool quality,
- fastness requirements both during manufacture and during use.

Dyeing method: by exploiting all the technical understanding in terms of dyeing and materials, the dyeing process should be controlled so as to produce reproducible, even and economic dyeings with as little damage to the wool as possible. The starting point is the method of controlled adsorption which is split into the process steps shown in Fig. 13.

1. Combination compatibility: in order to avoid variations in shade and unevenness, dyes should be selected which have similar exhaustion curves.
2. Final bath exhaustion: if this is high, it will result in good reproducibility, high dye yield and low effluent loadings. Bath exhaustion is limited by the de-

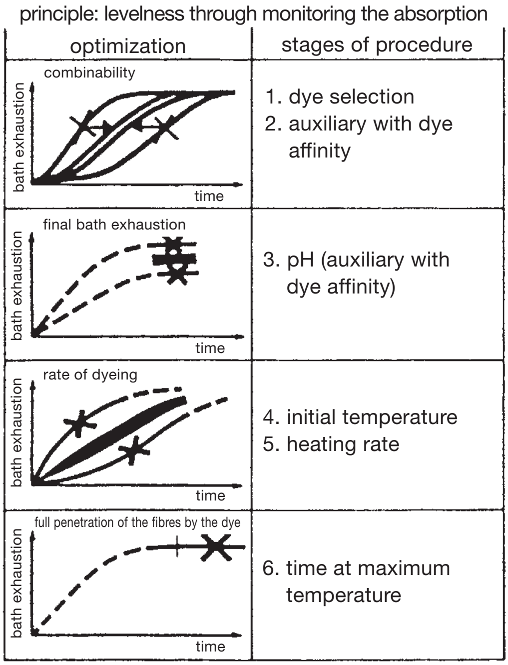

Fig. 13: Systematic wool dyeing process (by Bayer).

gree of evenness which is to be achieved. It is dependent on the operating conditions, type of dye, depth of dyeing and the affinity of the wool and should be controlled by the pH and the auxiliary.

3. Starting temperature: the starting temperature must be selected to achieve slow exhaustion (dead time) while avoiding an initial adsorption which is too fast and non-uniform. Also to be taken into account is that the wool is more accessible at higher temperatures and dye aggregation decreases.
4. Exhaustion rate: this should be selected so that the adsorption of 80% of the dye is controlled. The exhaustion range should be 50°C, as calculated from the starting temperature. Dye adsorption can also be controlled by metering the dye or the acid, in which case the difference between the start temperature and the dyeing temperature can be reduced and the exhaustion rate can be increased.
5. Penetration dyeing: the reduction in dyeing time at maximum temperature is limited by the penetration of dye into the fibre and a uniform scale structure.

Wool dyeing, afterchrome process When dyeing wool according to the afterchrome process, only those dyes can be considered which contain functional groups capable of forming ultra complexes. In most cases, these are hydroxyl groups which are situated in the ortho position in relation to the azo group on the aromatic ring (→ Wool dyes).

During the dying process, the dye first adsorbs on to the wool fibre like an acid dye. The fastness of the wool dyeing is significantly improved by fixing the acid dye with Cr^{3+} ions. When afterchroming using $K_2Cr_2O_7$, a redox reaction takes place with the wool. As the potassium dichromate is a strong oxidizing agent, it is capable of reacting with the amino acid, cystine (Fig. 1). Because of their anionic nature, sulphonic acid groups can either act as a source of surface charge or, in their role as charged functional groups, soften the scale structure by absorbing water into the outer regions of the wool fibre by osmosis.

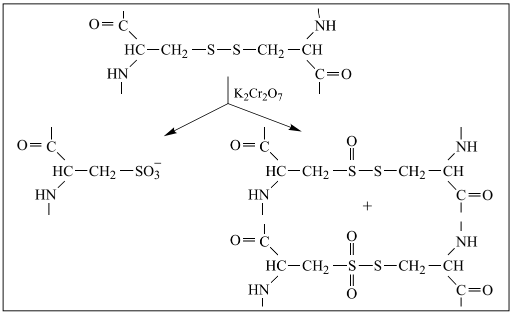

Fig. 1: Possible oxidation products of cystine on aftertreatment with potassium dichromate.

The Cr^{3+} ions produced are complexed by the dye ligands and the functional groups of the wool. Direct use of Cr^{3+} salts prevents complex formation with the dye molecules as the hydrolysed Cr^{3+} ion is relatively inert to substitution and adsorbs very poorly on to the wool.

When afterchrome dyeing, it must be ensured that exhaustion of the dye from the dye liquor is, if possible, complete, otherwise the dye remaining in the bath will afterchrome as well and then deposit onto the fibre surface. This will result in diminished rubbing fastness for the dyed goods.

During the afterchrome dyeing of wool, crosslinking is also possible between the protein chains due to the effect of potassium dichromate (for example, by complexing two dye ligands bonded to two different protein chains). As mentioned before, potassium dichromate is a strong oxidizing agent. This means that, in the case of amino acids which are sensitive to oxidation such as cystine, the redox reactions which take place can yield a large number of oxidation products.

Currently, afterchrome dyes cannot be replaced mainly because of the level of fastness. Apart from that, using afterchrome dyes is significantly cheaper than using reactive dyes. However, when using chrome dyes, a decrease in the effluent loading must be

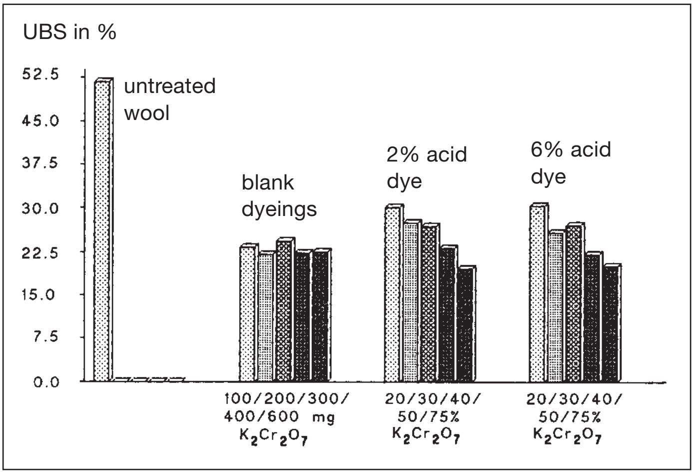

Fig. 2: Urea bisulphite solubility of wool combed tops after blank dyeing and dyeing with an afterchrome dye with the addition of various quantites of potassium dichromate (according to Höcker et al.).

achieved by using the smallest quantity of chrome salts (by observing the chrome factor).

The urea bisulphite solubility steadily decreases with increasing amounts of potassium chromate. This is indicative of the appearance of new crosslinking sites during afterchroming, as the acid dye which is used does not lead to any change in the bisulphate solubility in relation to the dye concentration (Fig. 2).

It can be presumed that, after the addition of potassium dichromate, redox reaction takes place between the wool and the dichromate anion, during which Cr^{3+} ions are formed, which are not yet solvated. In a competitive reaction, these chrome ions can form ligands both with water and dye molecules. Even a few functional groups on the wool, such as the ε-amino group of lysine, can provide donor ligands and form a complex with the chrome ion. It is certain that the dye molecules will predominantly react with the formation of Cr^{3+} ion complexes, as the formation of chelate complexes is thermodynamically more favourable than the formation of mono-dentate ligands such as water. The formation of 1:2 metal complex dyes on the wool results in new crosslinking sites when the two dye ligands are bonded to two different protein chains. These additional crosslinking sites may explain the decrease in keratin solubility found in solutions containing urea bisulphite.

In the case of the amino acids serine and threonine, which have a single aliphatic hydroxyl group on the amino acid side chain, using potassium dichromate may result in the oxidation of the OH group of the aldehyde or carboxyl group. The aldehyde group produced may react further during crosslinking, which may explain the reduced solubility seen in the urea bisulphate test. A possible reaction of the aldehyde group may take place with the free amino groups of the proteins (for example, with the ε-amino group of lysine) during the formation of a Schiff base (Fig. 3).

Very little is known about the possible reactions between potassium dichromate and wool during afterchroming, so further work is needed in order to clarify the position in regard to these reactions and their products (according to Virnich).

Wool dyeing at the isoelectric point Wool can be dyed particularly gently by using selected dyes (Fig. 1)

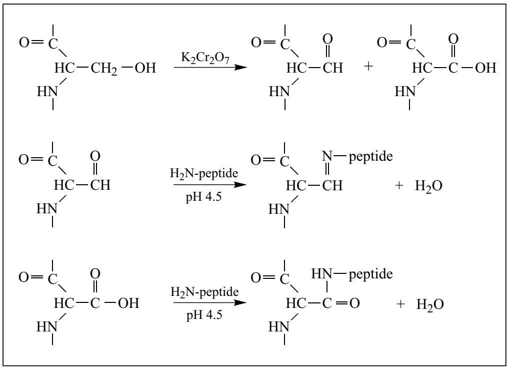

Fig. 3: Possible crosslinking between proteins through the influence of potassium dichromate.

which combine well in the vicinity of the isoelectric point, i.e. exhaust at the same rate, and suitable auxiliaries (Fig. 2). Fig. 3 shows the relevant dyeing trend in comparison with one for conventional dyeing methods at pH 6–7.

Wool dyeing, isothermal The amino groups of wool are positively charged in the acid range. This means that it is possible to dye wool using anionic acid dyes. The maximum adsorption of acid 1 : 2 metal-complex dyes in a neutral pH range, which is mild for wool fibre, can be achieved by using salts which increase the ionic strength of the solution. The titration curve mirrors the corresponding bonding capacities of acid and caustic with and without the addition of salt.

Of course, the reaction of wool with dyes in the acid range not only relies on an ion-exchange mechanism, there are other complex interactions which influence the dyeing process just as much. Although a titration curve for wool makes it possible to control the exhaustion of the dye from the bath in a manner which is common practice in industry (Fig. 1), i.e. via specified temperature/time trends, a dyeing method which is isothermal is just as conceivable, if the acid addition is regulated using a closed-loop control circuit and the course of the bath exhaustion consciously controlled. A process such as this presupposes the use of mechanical devices which, apart from recording changes in the conditions, colour, pH, conductivity and liquor throughput in

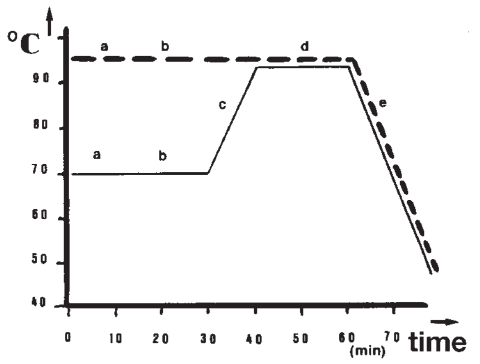

Fig. 1: The dyeing process with the isotherm (dotted line) and classical dyeing methods, using Isolan S dyes (Bayer), press thickness 540 g/l of the yarn packages. a = prewetting; b = acid addition; c = heating; d = setting; e = rinsing.

the dyeing machine by means of suitable sensors, also contain efficient controllers (Fig. 2).

In the dyeing of polyamide fibres in carpet dyeing using the exhaustion method, the current technology is to control bath exhaustion at boiling point by metering the acid. Only the end groups and carbonamide groups react with acid in the case of polyamides, so the behaviour of the complex side-chain structure of wool in response to the metered acid is the reason for pH-controlled wool exhaustion dyeing having so far only been used in practice in batch processes. Mosimann has done the most detailed work on the pH control of wool dyeing where, as usual, the bath temperature was raised continually together with a decrease in pH produced by adding sulphuric acid. The technical advantage of pH-controlled wool dyeing is realized as follows: the negative effects of fluctuating process-water quality or the effects of the alkali or acid residues in the substrate from the initial stages cause the actual pH to deviate from the set-point pH. Timely correcting these deviations using measurement and control systems means that the dyeing result of the batch in question is not put at risk.

Wool dyeing (loose wool dyed articles) Unlike → Piece dyeing or → Yarn dyeing, this refers to articles which are dyed in the flock (carded yarn) or in the combed top (Worsted yarn). → Loose stock dyeing.

Wool dyeing under strongly acidic conditions Dyeing with 1 : 1 metal-complex dyes at pH 2 leads to significant damage to the wool fibre due to hydrolysis and extraction of parts of the cell membrane complex (Fig. 1).

When wool undergoes hydrolytic degradation at pH 2 and temperatures from 80–120°C, it is known that peptides hydrolyse, N-terminal acetyl groups split off and protein fragments leach out of the wool in the form of wool gelatine. This produces the following relationships: in all cases, the temperature dependence is quadratic and time dependence is linear. Cleavage of the acetyl groups follows a similar trend.

1912	BASF develops and patents the first 1 : 1 MCD, though without colouristic application
1915	The Gesellschaft für Chemische Industrie [Chemical Industry Society] in Basel First patent application for 1 : 1 MCD on wool

Tab. 1: How 1 : 1 metal-complex dyes (1 : 1 MCD) for wool developed.

Until now, approx. 50% mono- and disulphonic acid levelling dyes and approx. 50% 1 : 1 metal complex dyes (under strongly acid dyeing conditions) have been used in piece dyeing. 1 : 2 metal complex dyes and re-

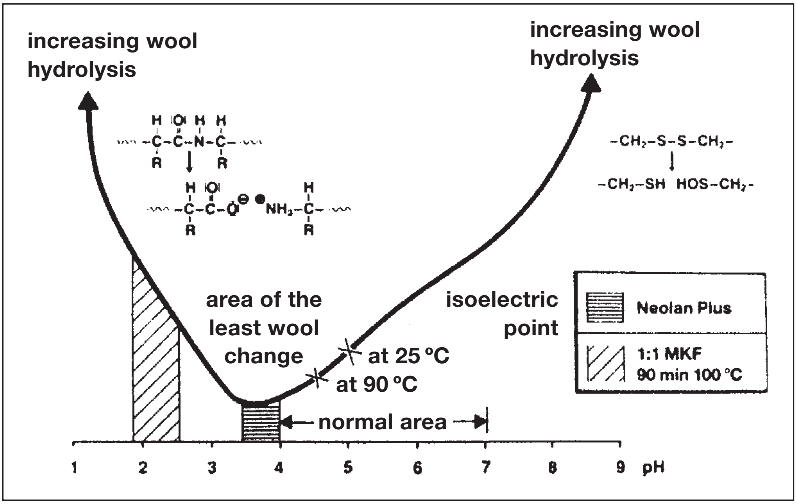

Fig. 1: Wool hydrolysis and the area of the least wool change depending on the pH of the dye bath at 100°C.

active dyes are relatively little used as they highlight deficiencies or defects in the pre-treatment of piece goods.

1 : 1 metal complex dyes have been used in the piece dyeing of wool for about 70 years (Tab. 1). To some extent, they have replaced acid dyes, particularly in the case of middle to dark shades.

Advantages:

- good levelling and penetration, even in the case of closely woven goods,
- dyeing of carbonised, non-acid-free goods,
- better wet fastnesses than acid dyes for middle to dark shades.

Disadvantages:

- strongly acid (sulphuric acid) dyeing conditions have a negative effect on fibre properties such as wear resistance and stretching,
- in the case of dark shades, residual sulphuric acid in the goods has to be buffered.

During the past 15 years, some progress in optimising the process has been made, such as dyeing with reduced amounts of sulphuric acid using special auxiliaries or replacing the sulphuric acid with sulphamic acid (1982). However, these can only be regarded as partial solutions.

Established criteria and boundary conditions have led to a dyeing system consisting of the three following extended components:

- a small gamut of 8 modified 1 : 1 metal complex dyes (yellow to black);
- a special auxiliary,
- pH 3.5–4 for all colour depths and make-ups, adjusted using formic acid.

Modified 1 : 1 metal complex dyes, an example of which is the oldest representative, Neolan Blue 2G, commercially available since 1924, demonstrate the possibilities of a ligand exchange at the trivalent chrome atom with a coordination number of 6 (Fig. 2).

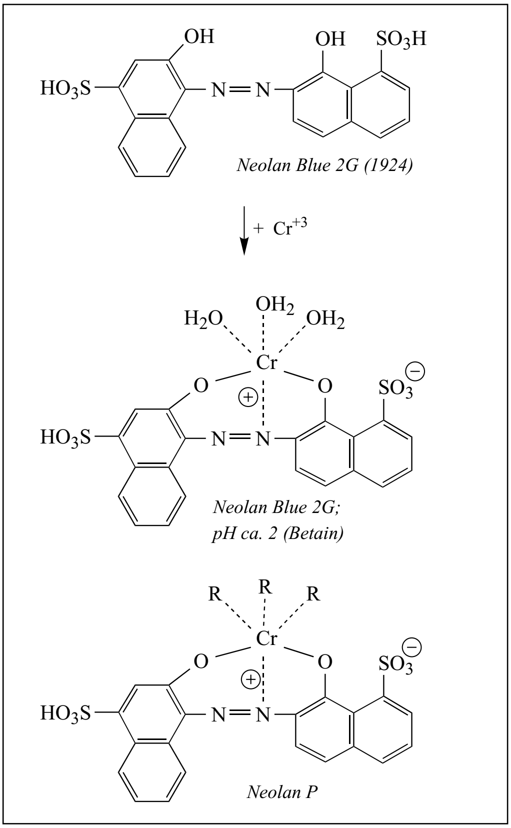

Fig. 2: New modified 1 : 1 metal-complex dyes.

Modified 1 : 1 metal complex dyes contain fluorosilicate. The modification is produced when the dye is dissolved in almost boiling water (minimum final temperature 80°C) in relatively concentrated form. 1 : 1 metal complex dyes such as these can used for the gentle dyeing of fibres at pH 3.5–4 in the presence of special levellers (with formic acid).

Tab. 2: IWS minimum requirements for woolmark products.

and at pH 3.5–4 using modified 1 : 1 metal complex dyes is shown in Fig. 3.

The relationship between different easy care steps and wet fastnesses required for them has been clearly established (Tab. 2). While good wash fastness is sufficient for care step 1, care steps 2–3, i.e. felt-free finished qualities, require a wash fastness of 30°C ; for care step 4 (superwash standard) specific regulations such as perspiration fastness and wash fastness with perborate apply, the difficulty being that chlorine or resin finished accompanying material must also be used at the same time.

Felt-free finishing wool also introduces colour problems and even problems in terms of evenness and fastness. A chlorination treatment, such as that used for the type of finishing considered here, recognizably increases the adsorption rate of dyes and reduces their wet fastness. Although using dyes with good migration properties produces a result with a high level of uniformity, problems arise with reproducibility or wet fastness. If, on the other hand, wet-fast dyes with lower migration capacities are used, the reproducibility and wet-fastness problems are avoided but difficulties arise with uniformity, especially when dyeing high-twist hand-knit yarns and knitwear. The cause of these difficulties lies in the chemical nature of wool dyes as these are characterized either by high wet fastness or good levelling properties.

The diagram in Fig. 4 shows the relationship between the dyeing properties of the most important group of wool dyes and their wet fastness. The sulphuric-acid adsorbing dyes, which have outstanding migration properties but correspondingly low wet fastness, are at the top left of the diagram (the equilibrium tends towards the dyebath). The neutral-adsorbing 2 : 1 metal complex dyes, which tend to migrate less and have correspondingly high wet fastnesses, are on the bottom right of the diagram. Dyes are now being

Dye classes: 1 = dyes with sulphuric acid affinity; 2 = dyes with formic acid affinity; 3 = dyes with acetic acid affinity; 4 = 1 : 1 metal-complex dyes; 5 = acid dyes; 6 = disulphonated 1 : 2 metal-complex dyes;
7 = monosulphated 1 : 2 metal-complex dyes; 8 = neutral dyeing acid dyes.

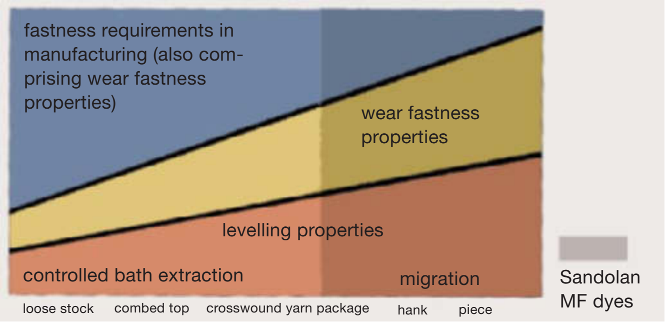

Fig. 5: The dependency of wear fastness properties and fastness requirements in manufacturing (not including light fastness) on affinitative and migrational behaviour (by Sandoz).

sought which can satisfy higher requirements in regard to wet fastness but still have good migration properties. Based on a classification of acid dyes according to migration and adsorption behaviours, a dyeing diagram can be prepared which exactly complies with these requirements, characterized by Zone 5 in Fig. 4. On shrinkproof finished wool, they actually make it possible to achieve the required wet strengths for care level 3 (machine washable to 30°C, gentle action wash). In many cases, for wool which has been antifelt finished according to an additive process it is possible to achieve the level of fastness required for care level 4 (machine washable to 40°C).

Due to the good levelling properties and high degree of reproducibility of these dyes and their high level of compatibility when used in combination, they are making headway particularly when used in the women's outerwear and men's and boys' outerwear sector for yarn and piece dyeing, i.e. for articles which are dyed in the final stage of production, where manufacturing fastness is no longer crucial but only wear-fastness properties (Fig. 5).

Wool dyeing with reactive dyes In principle, reactive dyes are acid dyes with several sulphonic acid groups and a reactive group which is capable of reacting with the functional groups of protein while forming a covalent bond. Reactive dyes are characterized by their particularly high fastness when the unreacted residues of the dye have been removed by an alkaline post treatment.

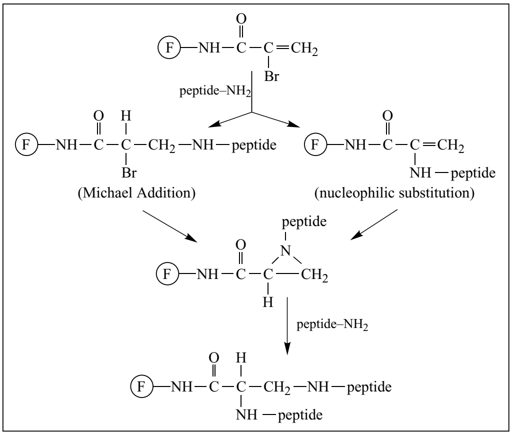

Fig. 1: Possible reactions between a bromoacrylamide dye and the lysine amino acid side chain.

The possible reactions can be described using the bromoacrylamide dyes as an example (Fig. 1). Different protein chains can be crosslinked via the intermediate product which contains the aziridine ring. Difluoropyrimidine dyes can also react forming crosslinks at the reactive groups by double substitution of the fluorine atoms.

Fig. 2 shows the possible bonding sites for reactive dyes on wool (in comparison to cotton).

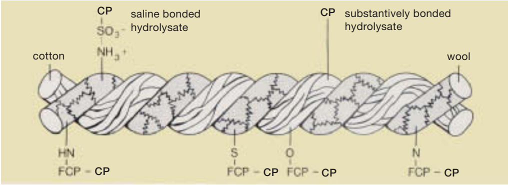

Fig. 2: Possible bonds of Levafix EA dyes;
FCP = 2.4-difluoro-5-chloropyrimidine (by Bayer).
CP = chromophore part.

When dyeing wool unions, after dyeing, the non-reactive hydrosylate is found on both fibre components apart from the reactive bonded dye. The bond on cotton is substantive whereas that on wool, like that of an acid dye, is formed via the sulphonic acid group of the chromophore. This part, which increases with increasing depth of colour, must be removed by the post treatment stage in order to achieve the required level of fastness.

A boiling post-wash treatment, such as that generally prescribed for articles made of pure cotton, harbours the risk of serious damage to the wool if used after the alkaline dyeing process.

Crosslinking wool with bifunctional reactive dyes results in a decrease in solubility of the urea bisulphite (Fig. 3).

Wool dyes Acid, 1 : 1 metal-complex, 1 : 2 metal-

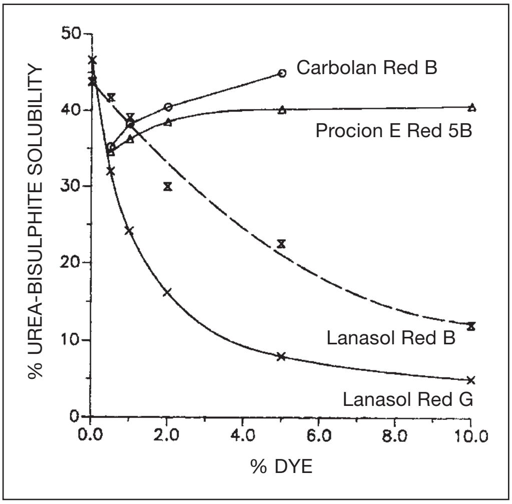

Fig. 3: Urea bisulphite solubility as a function of the dye concentration for the dyes Lanasol Red B and Lanasol Red G (Ciba Geigy), Procion Red E-5B (ICI) and Carbolan Red B after dyeings at a pH of 4.4 (by Virnich).

complex, chrome and reactive dyes are all used for dyeing wool. Mono- and disulphonic acid levelling dyes and 1 : 1 metal-complex are mainly used in wool piece dyeing. 1 : 2 metal-complex and reactive dyes are used to a lesser degree as they highlight insufficiencies or defects in the pretreatments of piece goods.

I. Metal-complex dyes: metal complexes involve the bonding of a metal ion via ligands, i.e. with a particle (ion or molecule), containing one or more free electron pairs. Bi- and polyfunctional ligands can occupy two or more coordination sites on the metal ion to form ring-shaped complexes called chelates.

1. 1 : 1 metal-complex dyes are chrome complex salts in which case the dye molecule contains a chrome atom. These dyes bond to the basic groups on the wool via salt-type and complex-type bonds. The advantages of these dyes are good wet fastness, high migration capacity and very good light fastness. The pH of the dyebath is around 2.5.
2. In the case of 1 : 2 metal-complex dyes without sulphonic acid groups, a single metal ion is linked to two dye molecules. They contain, for example, $-SO_2CH_3$ or $-SO_2NH_2$ groups as water soluble functions, as anions would cause adsorption to be too rapid and non-uniform. Because of their high affinity, these dyes are used at pH 4–5 with a levelling agent.
3. 1 : 2 metal-complex dyes with a single sulphonic acid group were developed especially with the dyeing of polyamide/wool mixtures in mind. Because of their high affinity, they adsorb rapidly and highlight differences existing in the fibres. Dyeing is carried out at pH 4.5–5.
4. 1 : 2 metal-complex dyes with two sulphonic acid groups are used for dyeing loose stock and combed top, as non-uniformities produced during spinning can be smoothed out. Unlike the metal-complex dyes not containing sulphonic acid groups, these can be used to produce brilliant shades. The light and wet fastness of these dyes are good. The dyebath should be weakly acidic with a pH of around 5–6.

II. Acid dyes: these belong to a larger group of anionic dyes of relatively low molecular weight containing one to three sulphonic acid groups. In the acid dyebath, some of the wool's own carboxylic acid groups are neutralized and adsorb a counter ion to maintain electro-neutrality.

$$\textcircled{W}-\mathrm{COO}^{\ominus}\,{}^{\oplus}\mathrm{H_3N}-\textcircled{W} \xrightarrow[\mathrm{HSO_4^-}]{\mathrm{H^+}}$$

$$\textcircled{W}-\mathrm{COOH} + \mathrm{HSO_4^{\ominus}}\,{}^{\oplus}\mathrm{H_3N}-\textcircled{W}$$

The actual dyeing process consists of an ion exchange between the counter ion and the dye anion because the affinity of the dye anion for the substrate is greater than that of the acid residue – the greater the affinity the dye has, the weaker the acid conditions needed to cause the dye to adsorb.

Fibre/dye bond:

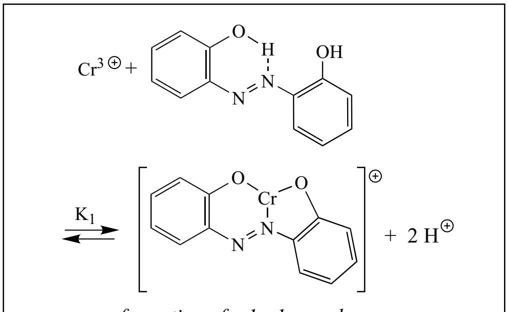
$$\textcircled{W}-\mathrm{NH_3}^{\oplus}\,{}^{\ominus}\mathrm{O_3S}-\textcircled{F}$$

Acid dyes are classified in regard to their adsorption behaviour as follows:

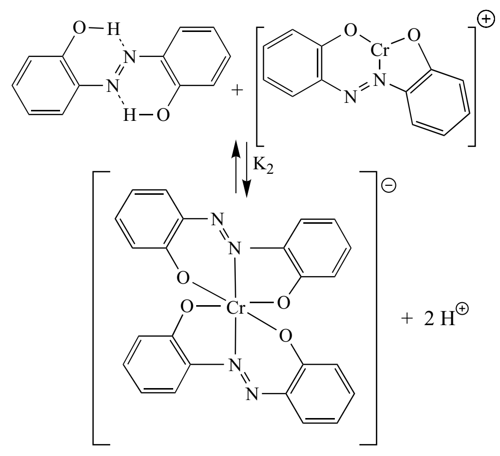
1. Strong-acid adsorbing levelling dyes have a low affinity for fibre and must therefore be applied under strong acid conditions. They are characterized by high migration capacity but rather moderate wet strength.
2. Weak-acid adsorbing levelling dyes are used at pH 4.5–5.5 because of their greater affinity caused by their larger molecular structure.
3. Due to their large molecular weight, milling dyes have distinctly lower migration capacities. The dye is bonded to the fibre via salt-type bonds, van-der-Waal forces and hydrogen bonds. For this reason, their wet fastness is so good that they are capable of withstanding mild milling.

III. Because of certain reactive groups, reactive dyes are in a position to form covalent bonds with wool. In this case, the functional groups on the wool taking part are the amino, hydroxyl and thiol groups. This type of bond produces excellent wet fastness. Another advantage of this class of dye is brilliance of the shades produced.

IV. Afterchrome dyes are characterized by their having the best fastness which is only matched by vat or reactive dyes. The dye adsorbs on to the fibre like an acid dye from acid liquor (pH 3.5–4). After the bath has become exhausted, a dye/chrome complex forms on the fibre due to treatment with chrome salts (Fig.).



formation of a 1 : 1 complex



formation of a 1 : 2 complex

Fig.: Formation of chromium complexes (any excess charges of the complexes are counter-balanced by integrated counter-ions).

This treatment also improves light fastness as well as reducing the solubility of the dye by adding more coordinate bonds to the functional groups on the wool.

Wool fast dyes,

I. Frequently-used term for individual dyes.

II. Range of light, water, milling, and sea water acid dye ranges.

Wool fat (lanolin). Before further processing, raw wool must be freed from wool fat, sweat, dirt and, if possible, smaller pieces of vegetable matter. Contamination varies according to the origin of the raw wool which contains

15–72%	wool hair,
12–47%	wool fat and sweat, of which 2–4% consists of water-soluble calcium salts,
3–24%	vegetable matter (burrs and straw, etc.) and dirt (faeces, sand and loam, etc.),
2–24%	moisture.

Wool fat, a secretion of the sebaceous glands, is a greasy, often sticky, yellow to brown paste. It consists of a mixture of fatty acids, waxy esters and hydrocarbons of approximately the following composition: 50–55% fatty acid esters, 40–45% unsaponafiables and 1–2% free fatty acids. Wool fat is not actually a fat but more a wax which protects the wool hair from external effects.

Sweat and wool fat are the main components which are removed during the scouring process (→ Raw wool scouring). Scouring must be carried out so as to cause as little harm to the wool fibre as possible, both from the chemical and the mechanical (felting) point of view. In large raw-wool laundries, it must also be possible to recover the lanolin – a component of wool fat of great value to the cosmetic industry.

Wool fat extraction The effluent from a raw-wool scouring line (Fig. 1) is largely contaminated by wool fat (lanolin) in addition to other contaminants. It is worthwhile recovering the lanolin from the primary scouring baths and using it in cosmetic creams or hygienic fat emulsions.

After separating the wash water and rinsing water in wool scouring, the waste water treatment essentially consists of the following steps:

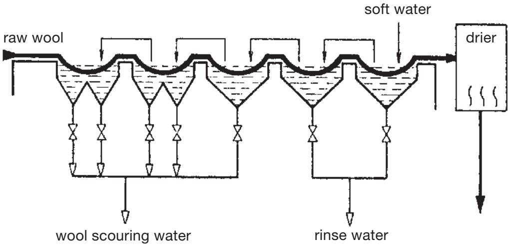


Fig. 1: BWK (Bremen Wool-Combing Works) process wool scouring machine.

1. Sedimentation and partial degreasing of the wool washings while recycling the partially degreased washing water (Fig. 2).
2. Evaporation and combustion of the organically highly contaminated wool washings while
   - recycling the evaporator condensate,
   - recovering the energy in the form of steam and electrical power,
   - purifying the flue-gas.

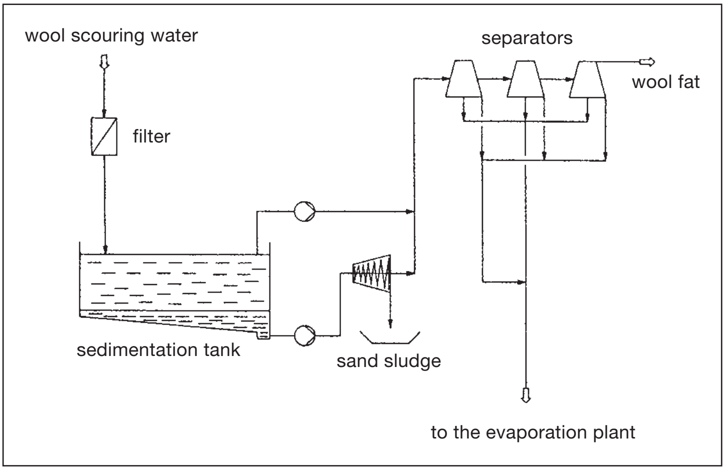

Fig. 2: Sedimentation tank and wool fat extraction.

3. Biological purification of all process waters in an effluent treatment plant.

The dwell time for wool washings in the sedimentation tank is around 30 h. and the sedimented sand sludge is thickened further to 70% dry solids in a centrifuge. About 40% of the wool fat is removed from the pre-purified wool washings by a series of three separators connected in series before it is pumped into the evaporation and combustion plant. Some of the degreased wool washings are returned to the wool-washing process.

Wool felt → Felting propensity of wool.

Wool fibre evenness Term used for the property of wool hair of having evenly distributed thickness and crimp along its entire length: → Abnormal fibre (wool).

Wool grease, suint Component of → Raw wool (greasy wool). Sum of all wool contaminants which can be removed by scouring (liquid excretions from the skin, wool-grease, salts, sand, dirt and faecal matter, etc.).

Woollen cloth General term for woollen fabrics (made from carded yarn or worsted yarn, as well as worsted-yarn warp and carded-yarn weft) to some extent also in twill or satin weave (twill or satin cloth). Surface produced by roughening, milling, shearing, brushing, steaming and pressing. Used for women's outerwear and men's and boys' outerwear.

Wool man-made fibre → Keratose.

Woolmark International wool mark introduced in 1964 by the International Wool Secretariat (IWS) and lodged in more that 100 countries all over the world for legal protection. Guarantees pure → Virgin wool and other quality characteristics. Only valid if the label is firmly sewn in and provided with a code number.

Wool, nonfelting The anti-felting effects achieved by the traditional wool chlorinating process using chlorotriazine-type products have so far not been achieved by any alternative method or product. However, components of wool or substances which accompany wool (such as lubricants) and which are either soluble right from the start or become soluble after conversion, form absorbable organic chlorinated compounds with chlorotriazines at a concentration which will restrict their future use in Germany to a limited degree. In the meantime, their substitution with AOX-free products has become possible for batch → Antifelting finish without any significant loss in quality. It is only in the case of continuous combed-top finishing and print pretreatment that there is a need for further development.

Peroxysulphate compounds (such as caroat) are freely soluble salts which are not only free of halogens but also free of a few other problems produced by chlorine.

Advantages and disadvantages of caroat in comparison to chlorine:

- no AOX,
- no yellowing,
- improved levelling properties,
- almost no smell,

but:

- antifelting properties not so effective,
- paler print.

Fig. 1 shows how yellowing increases with increased chlorination strength (Basolan DC) whereas, under treatment with caroat (+ sulphite, Basolan 2448) this at least stays constant or even decreases. This is not only of benefit to white or white/coloured goods but also to plain dyed goods because yellowing often causes a

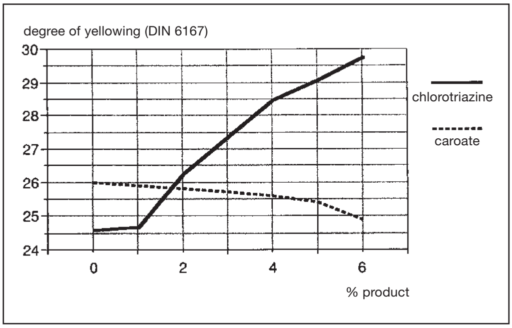

Fig. 1: Effect of antifelting products (BASF) on the degree of yellowing of wool.

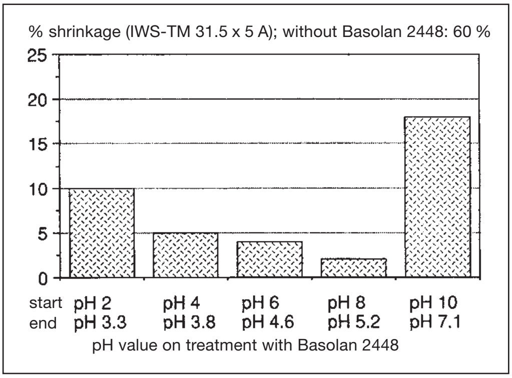

Fig. 2: Effect of the application quantity of Basolan 2448 (BASF) on the felting shrinkage of knitted piece goods (coloured knitgoods, aftertreatment with 4% Basolan MW, BASF.)

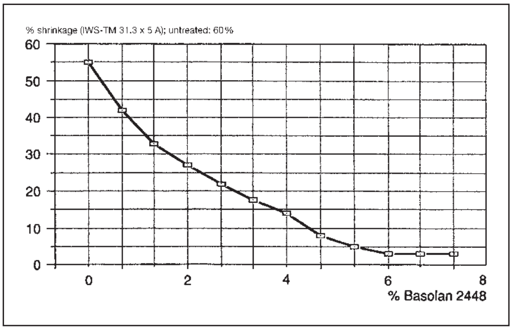

Fig. 3: Effect of pH in a bath with Basolan 2448 (BASF) on felting shrinkage (coloured knitgoods, 5% Basolan 2448, 4% Basolan MW, BASF).

shift in the colour shade. By using caroat treatment instead of chlorination, it is even more possible to carry out the treatment after dyeing. Only now and again are there woollen goods which felt so much that chlorination has to be used. For these cases, a combination of chlorine and peroxide is indicated which is at least low in AOX.

Treatment with caroat not only avoids yellowing, but also attacks dye less frequently than treatment with chlorine. Among the many wool dyes which have been tested so far for their suitability for this form of oxidative/reductive aftertreatment, only four have proved to be unsuitable because of a shift in colour and a further four were found to be of limited suitability.

The following dyes are unsuitable for aftertreatment using caroat/sulphite:

- C.I. Acid Red 42,
- C.I. Acid Yellow 221,
- C.I. Acid Blue 72,
- C.I. Acid Blue 333.

The following dyes are of limited suitability:

- C.I. Acid Green 104,
- C.I. Reactive Blue 2,
- C.I. Reactive Blue 177,
- C.I. Reactive Blue 69.

Basically, all fibre mixtures with wool can be finished according to the caroat method. From the point of view of colour, mixtures with cellulose fibres require special attention as it is known that cellulose dyeings are sensitive to oxidation or reduction. But it is also true that the effect on colour shade is less than it is for chlorine. The potential deterioration in wet fastness of wool dyeings is of the same order as that for chlorine. This happens during treatment both before and after dyeing. This deterioration may amount to more than a single point and may require aftertreatment.

As shown in Fig. 2, the amount of peroxysulphate used has a considerable effect on shrink resistance during washing but this is so only up to 6% wool by weight.

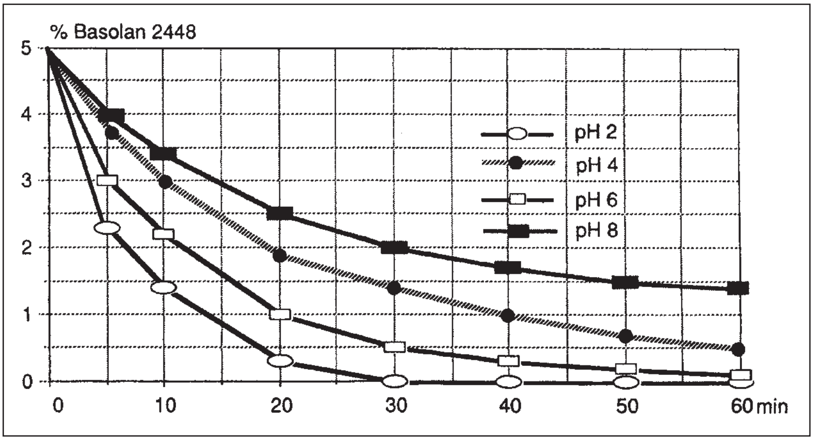

Fig. 4: Effect of pH in a bath with Basolan 2448 (BASF) on the reaction speed (coloured knitgoods, 1 : 20, 25 °C).

(Fig. 4) applies to the effects of pH in the peroxymonosulphate bath. This does not have as much relevance to antifelting as chlorination. Under certain circumstances, the addition of formic acid to a bath which is already acid reacting is recommended. This produces a pH of around 3. According to Fig. 3, the addition is not necessary as 5% caroat produces a pH of around 4 on dyed wool, which is adequate.

Wool origins, analysis As well as the different genetic and climatic conditions in the various countries of origin (provenances), the quality of wool is also affected by the different feeding and breeding conditions.

The sheep breeds and climate zones of wool export countries are distributed on a percentage basis as follows (r/y = rainfall per year):

I. Australia: predominantly merino sheep (approx. 77%). Climate: a) pastoral zone: 25 cm r/y; b) wheat/sheep zone: 25–65 cm r/y; c) high rainfall zone: 50–100 cm r/y.

II. New Zealand: South Island: mainly merino/Lincoln crossbreds (Corriedale) or merino/border Leicester crossbreds. Climate: very rainy and damp. North Island: 80% Romney Marsh and Southdown. Climate: more rainy than South Island but milder.

III. South Africa: 85–90% merino sheep. Remainder: caracul, coarse wool, fat-tailed sheep, native, dorper, Dohne merino, dormer and Persian fat-tailed sheep. Climate: a) Karoo: 12.5–75 cm r/y, b) Lesotho: 50–80 cm r/y; c) highland areas: 100 cm r/y, very cold during winter; d) Natal (400 m over N.N.): 30–60 cm r/y.

IV. Argentina: 33% Lincoln, 32% merino, 18% Romney Marsh and 7% Corriedale. Special: Chubut Province (southern zone): 100% merinos. Climate: a) southern zone: dry, exposed to strong winds, 5–25 cm r/y; b) central zone: flat savannah, grassland, approx. 25 cm r/y; c) northern zone: flat land, much rain.

V. Uruguay: 22% Corriedale; 11% merino, 11% Romney Marsh, 2% Lincoln. Remainder: others. Climate: warm, up to 150 cm r/y, northern and central area dry, with occasional periods of drought.

Vl. Brazil: 20% merinos, 15% Romney Marsh, 10% Corriedale. Climate: northern tropical, southern subtropical, windward side of mountains rainy, lee side and valleys dry.

VII. South Chile: 50% Criolla, 20% Hampshire Down, 20% Romney Marsh and 10% others. Climate: strong fluctuations in climate, dry hot tropical climate in the north and oceanic cold in the south.

VIII. Germany: 43% German merinos, German merino mutton, marsh, heath and mountain sheep (Goggel, Zackel, Bergamo). Climate: European transition climate, rain all times of the year, decreasing further west and more in the summer, fluctuations in temperature stronger towards the east.

IX. Hungary: 71% Hungarian merinos, 19% crossbreds, 7% Tsigai and 3% Zackel.

While the quality of wool in the classical wool-producing countries, Australia, South Africa and New Zealand is constantly monitored and a high standard is consistently maintained through strict selection among the herds, in many other countries, such as the South American states both the examination and selection of sheep according to particular wool properties is completely absent.

Objective qualitative assessment of the wool is mainly carried out with the help of a table drawn up by Henning which gives the characteristics of wool-fibre in the fibre bundle or as individual fibres.

Classification of fibre properties according to Henning:

I. Properties of the individual fibre:
  1. vectorial properties:
     a) geometric characteristics:
        – average fineness,
        – fineness variation coefficient,
        – shape of cross-section,
        – average fibre length,
        – fibre-length variation coefficient,
        – proportion of short fibre,
        – number of crimping arches,
        – depth of crimp;
     b) tensile strength properties:
        – crimp contraction – degree of crimp,
        – crimp-straightening tension,
        – crimp resistance,
        – modulus of elasticity,
        – stress-strain relationship,
        – plasticity;
     c) strength properties under stress reversal:
        – durability;
     d) bending properties:
        – bending modulus,
        – bending strength,
        – bending endurance,
        – crease recovery;
     e) colour:
        – white content,
        – number of pigmented hairs,
        – bristle content,
     f) lustre;
     g) coefficient of friction.
  2. properties of fibre substance (scalar):
     a) chemical composition;
     b) solubilities;
     c) hygroscopicity;
     d) admixtures, extracts, pH, acid content.

II. Properties of fibre in the bundle:
  1. fibre bulge:
     a) compressive stress;
     b) compressibility;
     c) softness;
     d) bulge elasticity.
  2. felting properties.

3. presence of contaminants and proportion of burrs.

While the physical (vectorial) characteristics, fineness, fibre length, crimp, lustre, colour, bending strength, bulge elasticity and tensile strength have already been used by wool traders for assessing the quality of wool, scalar properties such as solubilities, chemical composition of fibre, hygroscopicity and admixture were not introduced into quality assessment until the last few decades. As the factors, genetics, climate, solid condition, nourishment and breeding fluctuate more or less from country to country, the question also arises whether wools of different origin should be characterized according to their wool quality as well. An additional factor affecting the assessment of South American wools is that these wools predominantly reach the world market in an already scoured and combed state.

Of particular interest to the textile industry is the question of provincial deviations in wool quality. In this case, knowledge of the characteristics of a certain batch of wool which are relevant to practice (and gained at the earliest possible moment) could enable problems which may arise during the processing stage to be assessed as the wool is being purchased, so that the different wool qualities could then be used for applications which are more appropriate.

During the last 30 years, a large number of analytical methods have been developed which enable a wool to be characterized down to its molecular structure. Many of these methods are used in wool research. Thus, with the aid of screen electron microscopy it is now possible, for example, to photograph and document surface modifications of the wool which, until now, have mainly been identified using staining tests which are more or less specific. Another possible application for screen electron microscopy is the measurement of scales in the cuticle (shape, height and expansion), and this can be used to explain properties such as the lustre and felting behaviour of the wool.

The quantitative measurement of fluorescence intensity, using fluorescence microscopy is used, among other things, to investigate the problem of wool yellowing and its causes. Scanning photometer microscopy makes it possible to monitor and quantify the diffusion processes. This is of particular importance during dyeing where it can be used to discover the possible causes of differences in the resulting shades of otherwise identically treated wools.

Until now, thermoanalysis (such as differential scanning calorimetry measurements) have mainly been carried out in order to determine how the thermal behaviour of wool changes in response to the effect of different chemicals.

Other methods such as atomic absorption spectroscopy, amino acid analysis and gel electrophoresis can be used to work out the composition of wool fibre in terms of its amino acids, trace elements and proteins (according to Kleiker).

Wool or silk poplin Poplin-type wool or silk material.

Wool printing To achieve the optimum print results, proper pretreatment is important for all classes of dye to the same extent. To this end, the following procedural steps are necessary (Fig. 1):

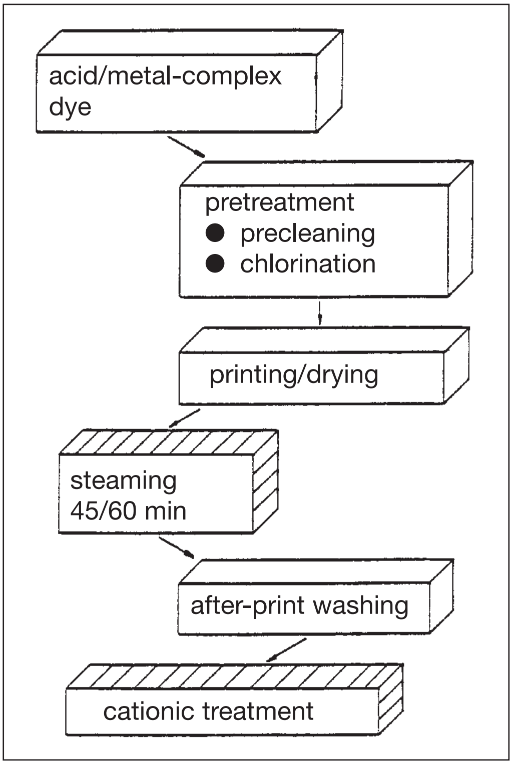

Fig. 1: Process of operation for direct printing on wool.

1. Cleaning the fibre material:
   - singeing,
   - shearing,
   - prewashing.
2. Stabilizing and pre-fixing the goods:
   - crabbing,
   - annealing.
3. Increasing the dye affinity:
   - chlorination,
   - bleaching,
   - optical brightening.

Of these, the most important process step is the chlorination process which must be carried out with great care (or may even be omitted as shown in Fig. 2). Chlorination yields the following benefits:

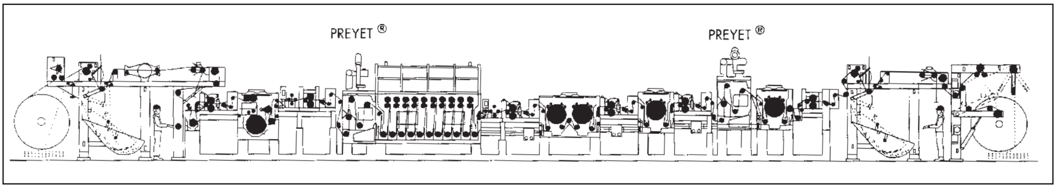

Fig. 2: Kleinewefers KTM Preyet (Azeta version) for shrinking, short bleaching and wool fixation (crabbing).

- increased dye affinity: colour build and brilliance,
- improved printing properties: evenness,
- improved dimensional stability: prevention of felting and shrinkage.

However, chlorination will have to be replaced by other printing pretreatments which do not produce effluents loaded with AOX.

In the following, the technical differences encountered in using vinylsulphone dyes in comparison with acid and metal-complex dyes will be examined as vinylsulphone dyes, unlike chlorotriazine reactive dyes, do not contaminate the effluent from the print washings with AOX.

The two classes of dye differ only in their fixing times and, in the case of acid and metal-complex dyes, an additional cationic posttreatment.

Although the total cost of wool printing is made very expensive by this elaborate pretreatment, the main contribution to the costs is still the actual printing process: pre-treatment 15%, design preparation and screen making 15%, coloration, formulation and paste preparation 20%, machine preparation and drying 30%, fixing, washing and drying 10% and finishing 10%.

Standard printing pastes have the composition shown in Fig. 3.

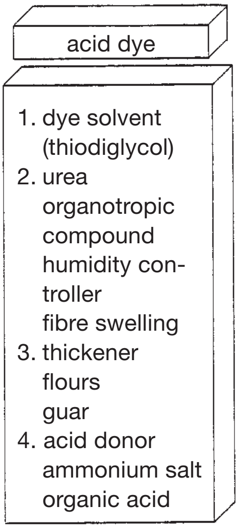

Fig. 3: Print paste composition.

When dissolving acid and metal-complex dyes, it is frequently necessary to add so-called dye solvents such as thiodiglycol, because a few of the dyes are only slowly soluble. It is also necessary to use hot water for dissolving. Dissolving often takes place at the inlet pipe. In this case, vinylsulphone dyes offer the advantage of requiring neither special dyestuff solvents nor hot water as they are already soluble as powder-granule or fluid brands. Vinylsulphone dyes can also be added by means of the sprinkling method. Here, the dye is worked into a prepared thickener containing all the necessary auxiliaries, such as chemicals, using a high speed stirrer. This eases work in the dye kitchen.

Urea, a hydrotropic agent, is used both with acid and metal-complex dyes as well as vinylsulphone dyes as a solubilizer in the printing paste. It also promotes water absorption and assists as a fibre-swelling agent during steaming. Acid resistant thickeners are used in the case of acid and metal-complex dyes. These are usually in the form of flour or guar derivatives. In the case of vinylsulphone dyes, alginate thickeners can also be used as the addition of acid to the printing pastes ceases.

The acid and metal-complex dyes are fixed in acid media, where either the acid donor, for example, ammonium sulphate or organic acids, such as citric acid, are added to the printing paste. Vinylsulphone dyes are fixed using sodium acetate as the alkali donor. High durabilities are achieved for the printing pastes when sodium acetate is used. Sodium-m-nitrobenzenesulphate is added to protect reactive dyes from reducing effects. Saturated steam is required for fixing both acid and metal-complex dyes as well as vinylsulphone dyes. Prints should not be over dried before steaming. Alternatively, they can be moistened again with sprays before entering the steamer.

Regarding the necessary fixing times, vinylsulphone dyes have advantages in comparison to acid and metal-complex dyes. Vinylsulphone dyes can be fixed within 10–20 min depending on the quality of saturated steam, whereas acid dyes and metal-complex dyes have to be steamed for 45–60 min. Using vinylsulphone dyes, it is possible to use continuous steaming which produces further advantages:

- reduction in steam consumption,
- higher utilisation efficiency of the continuous steamer,

- savings in time when preparing pattern remnants/collections,
- lower costs as a result of machine stoppages when preparing machine remnants, etc.

As a rule, a temperature of 40°C is not exceeded during after-print washing in the case of acid and metal-complex dyes, as there is a danger of strongly ionic-bonded dyes becoming detached, which can lead both to undesirable areas of lighter shades and an increased risk of contamination of the ground by the detached dye. In the case of vinylsulphone dyes, the temperature is raised to 70–80°C after the initial cold and warm rinse in order to remove the small proportion of non-reactively fixed vinylsulphone dye from the fibre and ensure that fastness is high. Acid and metal-complex dyes require special auxiliaries to protect the white ground from being stained by the colours bleeding on to it during the initial rinse.

In most cases, the process is followed by cationic aftertreatment to improve fastness. This also has the advantage of improving the fastness to water and perspiration by an average of one grade. The disadvantages which must be taken into account are that cation active aftertreatment auxiliaries can reduce light fastness by about one grade, particularly in the case of pale shades. The cationic fibre surface shows a high affinity for detached dyes which are present in the wash liquor (mordant effect). Cationic aftertreatment is not a permanent finish either because the complex becomes less stable with each wash. When cationic aftertreatment is carried out in the presence of a softener, the products must be matched to ensure they are compatible. Vinylsulphone dyes require only 1–2 g/l conc. ammonia solution to deactivate any reactive dye which has not been fixed, protect the white ground from contamination and achieve the required level of fastness.

The ionic bond of an acid dye can be regarded as relatively weak and can be removed by raising the pH. Other specific bonds are possible through

- dipole forces,
- hydrogen bonds,
- van-der-Waal forces.

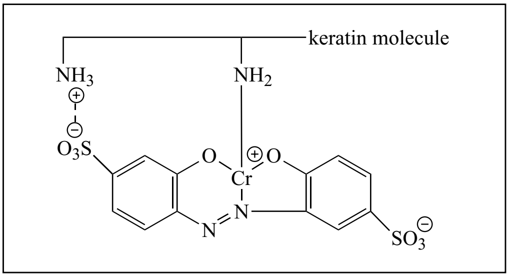

Fig. 4: Dye/fibre bonding with 1 : 1 chromium-complex dyes.

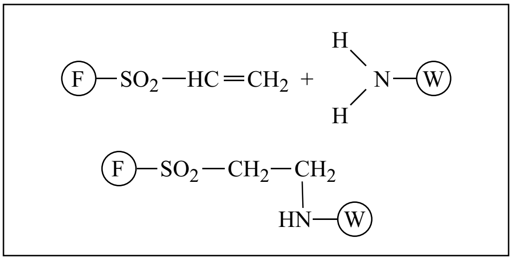

Fig. 5: Covalent bonding of vinylsulphone dyes with wool.

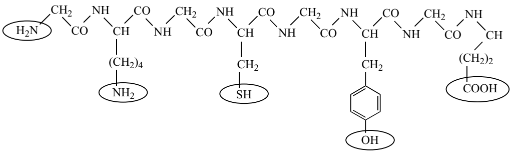
In the case of 1 : 1 metal-complex dyes, there is an additional coordinate bond between the chrome atom of the dye complex and, for example, the amino group on the wool in addition to the bonds already mentioned (Fig. 4). The bonding forces are therefore somewhat higher than those of acid dyes.

Vinylsulphone dyes, on the other hand, form genuine covalent bonds with the wool fibres. Fig. 5 shows the reaction of the amino groups of the wool with the reactive groups of the vinylsulphone dye.

Other classes of wool which react with vinylsulphone dyes are indicated in the diagram below:



Higher colour yields are obtained for vinylsulphone dyes due to their higher reactivity with wool.

Wool protection against insect attack During storage, woollen textiles can be at risk from different species of insect. These are mainly the larvae of carpet beetles and moths but also occasionally include fur beetles. Agents for permanent finishing or for treatment with limited duration of effect are available for the protection of woollen textiles against these pests. A significant contribution to the protection of wool flocks, yarns and textiles can be made by practising good storage hygiene. Periodic cleaning of the storage facilities prevents the long-term accumulation of deposits of wool, which has not been given sufficient protection in corners, under stands and pallets and which enable whole generations of pests to develop. When storing in old buildings, it must be ensured that wool deposits cannot find their way between the floors and in cavity walls. Even insulation material of vegetable origin, which can serve as nourishment for textile pests, must be removed. → Moth proofing.

I. Permanent protection: heavy woollen textiles such as carpets, woollen blankets and uniform materials as well as pullovers, socks and gloves made from coarse yarns can be protected for many years against insects by using proper industrial finishes. A prerequisite for this is that a suitable finishing aid is used and that its concentration is adjusted to the carpet beetle which is the most commonly occurring textile pest in Europe. If the textile has been properly treated, aftertreatment with insecticides will not be necessary.

II. Temporary protection: this may be advisable for textiles where the storage period is foreseeable, for light textiles or those which have already undergone permanent finishing and have to be stored after occasional wear and cleaning. Light fabrics and thin yarns cannot be protected with an oral poison or feeding deterrent as they may be damaged with a single bite. These require a treatment using a fast-acting, insect-specific poison which also has a permanent effect.

At the right concentration, products based on phosphoric acid esters can provide protection for six months. The disadvantage of these substances is, for purely preventative use, the relatively high vapour pressure of the active substance, which means that they can concentrate in confined spaces. Substances such as pyrethroids are also suitable for this application. They can be used both for permanent finishing and for aqueous and organic sprays. They act as neurotoxic contact insecticides, they are not toxic to humans and adsorb well on to the fibre. The disadvantages of pyrethroids are their high toxicity to fish and their wide use. Natural and synthetic pyrethroids are used all over the world for the protection of plants, forests and in storage and material protection as well as being used against household pests, ectoparasites and hygiene pests. Resistance must be expected in the long term, therefore, especially in the case of carpet beetles.

Apart from this, a long-term and high level of protection of textiles is possible using aqueous sprays based on growth regulators. From the ecological point of view, products such as these may limit the use of solvents as well as pyrethroids which are toxic to fish. However, the use of aqueous products means in practice that the treated textiles must be dried well before stacking in order to avoid damage to the wool due to residual moisture and fungi. For the control of existing insect infestations, growth regulators must be mixed with respiratory, contact or oral insecticides in order to achieve rapid cessation of damage before the next larvae hatch.

In order to use insecticide more sparingly, insect infestation in loosely stored textile lots can be controlled using short-term shock freezing. A temperature of – 26°C for 2 h will result in the death of clothes moths, fur beetles and carpet beetles at all their stages of development. A temperature of – 20°C for 74 h, however, is not sufficient to kill beetle larvae (according to Graf and Lanz).

Wool scour → Washing wool fabric.

Wool scouring →: Raw wool scouring; Washing wool fabrics.

Wool scouring effluent In addition to recoverable wool grease (or more precisely, wool wax) wool-scouring effluent contains so many harmful substances that a typical COD would be 40 000 mg O_2/l. The equivalent BOD is around 6000 mg O_2/l. The high proportion of non-biological substances mainly comes from wool wax. But apart from wool wax there are also pesticides (0.2 mg/l) and a certain number of compounds containing halogens (sources of AOX) which account for some of the high loadings of pollutant in wool-scouring effluent. This kind of effluent can be treated in different ways, as shown in Tab.

pretreatment of wool scouring water	*final treatment of the overall waste water*
- wool fat extraction (acid cleavage)	none
- sedimentation - wool fat extraction through separators	aerobic biology
- sedimentation - wool fat extraction through separators - evaporation plant and furnace	aerobic biology

Tab.: Raw wool scouring waste water treatment possibilities.

Wool scouring machines →: Leviathan; Smoothing machine.

Wool scouring range Loose wool can be washed very gently (i.e. without felting or alkaline damage) in accordance with the water-extraction through-flow

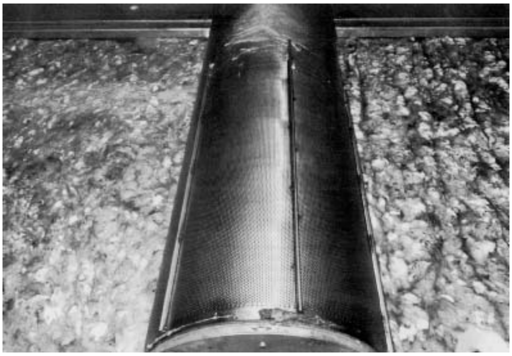


Fig.: Fleißner's suction-drum rawwool washing unit.

principle using 4–5 sieve-drum washing machines in a row. The wool floats through the plant as a well spread-out fleece (Fig.).

Wool setting Strived for in wool finishing and wool yarn finishing. Water, both as a liquid and in the form of steam, can affect the structure of interactions between the protein chains in the morphological system of the fibres. Hydrogen bonds, salt-type linkages, hydrophobic interactions and disulphide links can be re-oriented according to conditions. This is used to convert the wool fibres in the matrix of the textile goods, for example, either in the yarn or the fabric. At the same time, under certain circumstances, the hygralic expansion of the fibre is also affected which, for example, if increased, can lead to problems in regard to being able to shape the fabric in ready-to-wear clothing. It is difficult for the finisher to assess the degree of fixing of a woollen fabric: he wants to guarantee

- good shrinkage values during ironing,
- a low tendency to bagginess,
- good handle and optimum lustre,
- satisfactory wear properties.

It is important to define the slight differences in the degree of fixing.

The following distinctions are made:

- Permanent fixing: resistant to 30 min treatment at 70°C (elsewhere 1 h boiling),
- Cohesive fixing: not resistant to water (30 min, 20°C) but stable in air at room temperature,
- Temporary fixing: not resistant to hot water or steam but very resistant to cold water.

If the term “glass transition temperature (Tg)” is used for wool, then cohesive fixing is defined as the re-orientation of hydrogen bonds above the glass transition temperature, which remains stable as long as any subsequent treatment is carried out below the glass transition temperature. Each heat treatment using hot air is followed by cohesive fixing. Relaxation shrinkage occurs if tensions (creases and over-stretching) are fixed by cooling during cohesive fixing. These relax, for example, as soon as the fabric is steamed while the fabric is not under tension. Apart from the drier, cohesive fixing is also achieved using a rotary cloth-press, a plate press or a calender, so pressed fabrics must be fixed in their pressed state before the effect is lost again through water or steam.

The method of cooling after finish decatizing can have a significant effect on the extent of cohesive fixing. The temperature while batching off or unreeling has a profound effect on fixing: if the goods in the package are cooled by suction, cohesive fixing takes place in the fabric while in the sandwich state (formed from back grey and wool fabric). If the fibres are still above the glass transition temperature “in steam” as the fabric leaves the decatizing process, the fabric tends to take up the relaxed state of the fibres. Alternatively, the fabric can be run out “in steam”, shock-cooled via the suction roller. Relaxation and “freezing” take place simultaneously while the fabric is run out in the most relaxed state possible so that some of the cohesive fixing produced by shock cooling is retained. In general, to summarize, cohesive fixing mainly depends on the water content of the fabric, as this significantly affects the glass transition temperature (Fig. 1).

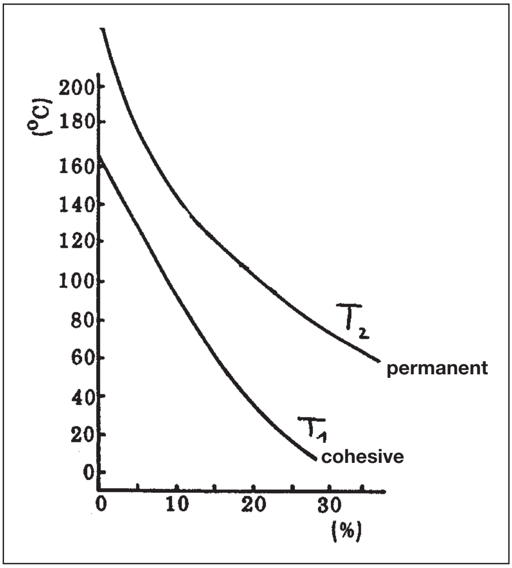

Fig. 1: First order (T_1) and second order (T_2) glass transition temperature depending on the wool fabric moisture content (by CSIRO).

According to this, the glass transition temperature of wet wool is below room temperature, which is why the shape of air-dried fibre is cohesively fixed. Every form of cohesive fixing found in the raw fabric, such as the fixing of mechanical tensions which have been introduced into the fibre during spinning and weaving, becomes relaxed during washing. More extensive than this wash-relaxation is the relaxation and permanent fixing of fibres in textile goods during classical crabbing (a treatment using boiling water) because the fibre-to-fibre friction is more effectively removed during this process, so that the fibre can be “accommodated” in a position which is free of tension. This type of relaxation reduces the bending and shear stiffness of the fabric, which is why the elasticity of the weave increases. The shear and bending hysteresis is reduced by the permanent fixing process to below the value of fabrics which have not been fixed. Piece dyeing, kier decatizing and chemical fixing produce this effect to the same extent as crabbing. The resulting reduction in yarn interactions, on the other hand, allows the effect of hygralic expansion with increasing water content in the fibres (swelling), which is why the corresponding fabrics bulge (particularly at the seams and at front-fixed places) or straighten out or do not maintain the shaped-up form.

The swelling of fibres caused by the absorption of moisture from the air increases their diameter and the radius of bend of the fibres in the fibre matrix, such as the yarn. This causes bent fibres to straighten and the fabric to become longer. In the case of fabrics which have not been fixed, i.e. non-relaxed fabrics, this swelling force is exceeded by the fibre-to-fibre frictional forces in the yarn and the swollen yarns produce longer looping routes for crossing yarns (either the warp or the weft), which is why the fabric is forced to shrink (through hygralic expansion). The dimensional changes in the moisture angle of fixed or unfixed fabrics, i.e. their hygralic expansion, is always a result of the state of equilibrium between the yarn de-crimping (elongation) and the shrinkage due to swelling (shortening) (Fig. 2). Permanent fixing therefore increases the effect of hygralic expansion, which is why kier decatizing does not necessarily lead to the stability of a surface dimension during the ironing test. Thus, the ironing test actually stipulates a difference between shrinkage due to relaxation (during steaming) and shrinkage which is measured initially as a result of hygralic expansion due to storage under climatic conditions.

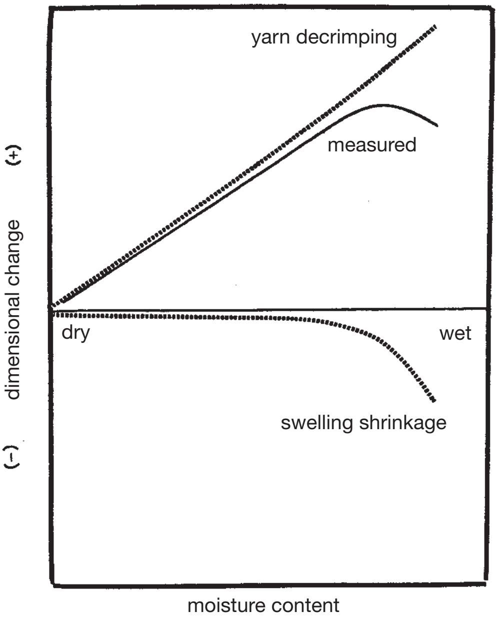

Fig. 2: Dimensional change mechanism of wool fabrics with moisture changes following hygralic expansion.

Permanent fixing of wool requires that the hydrogen bonds, such as those which are formed during cohesive fixing, are re-oriented and that the disulphide links undergo reductive cleavage and oxidative reorganization. High temperatures and humidity as well as the use of reducing media promote permanent fixing, as more thiol groups are formed which force the reorganization of covalent sulphur links through thiol-catalysed disulphide exchange.

The temperature required for permanent fixing, i.e. the inclusion of disulphide links, is much higher than the corresponding glass transition temperature at the same humidity (Fig. 1), which suggests that other factors also take part. The "conversion temperature" required to achieve permanent fixing depends both on the moisture content and the pH.

Permanent fixing in the kier decatizing process can be envisaged as shown in Fig. 3.

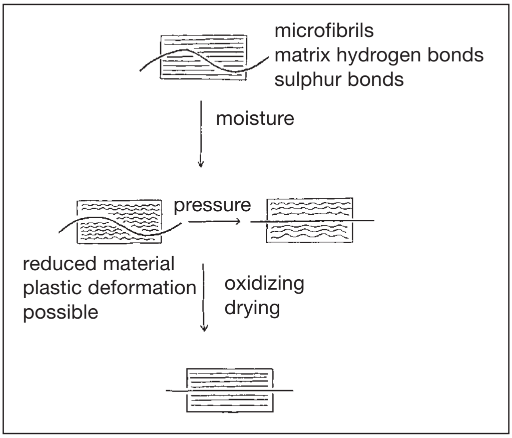

Fig. 3: Diagram showing the sequence and mechanism of flat setting (according to Wortmann).

Moisture and reducing agents soften the sulphur-rich matrix keratins. Material softened in this way can be deformed under pressure. After deformation, the softening effect is removed by oxidation (in the simplest case, by the air), heat and drying and the material is fixed in its new shape. During the fixing process, the tension or compression experienced by the fibre at the time of treatment has a significant effect on the extent of fixing. Speakman has already demonstrated the effect of super-contraction with subsequent detachment of fibres during steaming.

The stress/strain curve of a wool fibre may be divided up into the following sections:

- the area representing Hook's Law behaviour with high stress absorption,

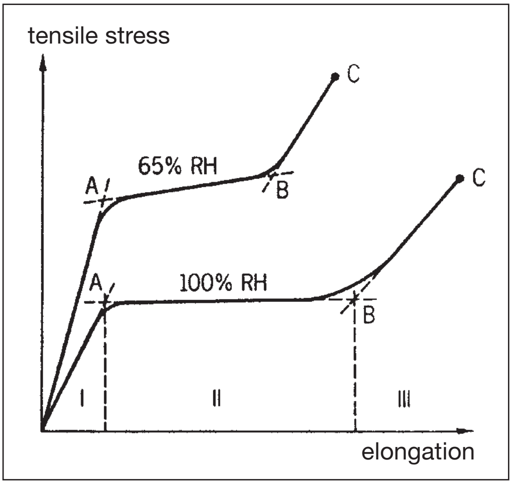

Fig. 4: Stress/elongation curves of hairs at varying humidities (RH).
I = Hookean zone; II = plasticity zone; III = postplasticity zone; A = Hookean limit; B = flex point; C = tear point.

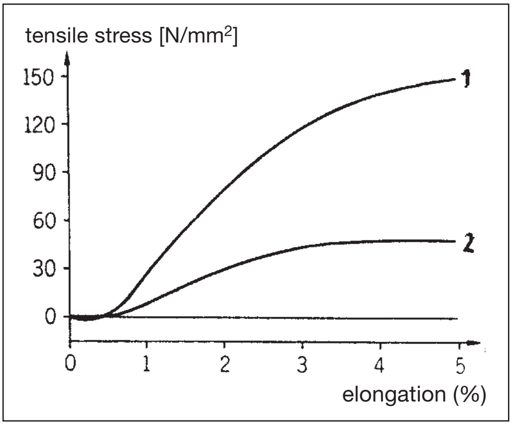

Fig. 5: Hookean zones of stress/elongation curves for determination of the elasticity modules.

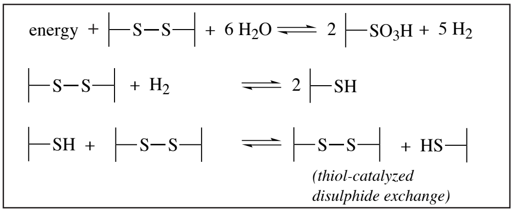
- the area representing yield with a significant amount of strain,
- the area representing renewed stiffening to fracture at high stretch.

Before the fracture point is reached, the denaturing of keratin (α-keratin converts to β-keratin) is reversible. As moisture increases, this S-shaped curve is shifted downwards parallel to the stress axis, while the two inflections remain approximately the same in relation to the strain axis (Figs. 4 and 5).

As the fibre dries out, its stiffness increases. An increase in temperature reduces the modulus of elasticity (seen as an increase in the Hook's Law area of the curve), i.e. there is a decrease in the tensile strength of the fibre, especially above the glass-transition temperature (Tg). Until the fibre stretches by approx. 2%, both the hydrogen and the disulphide bonds absorb the stress without breaking. The hydrogen bonds do not break until higher extensions are reached below the glass transition temperature and the transition from α-keratin to β-keratin begins. This "hydrolysis" of the hydrogen bonds requires less energy in the presence of more water – the "enemy of hydrogen bonds" (Fig. 5). Up to this point, all the processes which have been described are reversible, as it is only the reorganization of hydrogen bonds which is involved at the most. If the process takes place above the glass-transition temperature (e.g. when Tg = 65°C) then the disulphide links are rearranged and the stretch is irreversible.

If during kier decatizing in the presence of cotton back grey, its surface structure (molleton or satin) and its batching tension are of crucial importance for the decatizing/fixing result, then it is mainly the effect on the stress/strain curve of the fibre which makes the presence of the back grey indispensable (unlike the rubber blanket back greys in the case of continuous decatizing).

The question also arises as to how kier decatizing produces such good fixing effects at around 130°C. Under certain circumstances, in its capacity as a reducing medium, steam may react with wool in the following manner:



$$\text{energy} + \vdash S-S \dashv + 6\,H_2O \rightleftharpoons 2 \vdash SO_3H + 5\,H_2$$

$$\vdash S-S \dashv + H_2 \rightleftharpoons 2 \vdash SH$$

$$\vdash SH + \vdash S-S \dashv \rightleftharpoons \vdash S-S \dashv + HS \dashv$$

(thiol-catalyzed disulphide exchange)

So far however, cysteic acid has not been found in kier decatized wool. In addition, in the absence of a redox counterpart such as wool, steam will only split into a reducing species (and oxygen) in accordance with the equation below at too high temperatures for wool:

$$296\ \text{kJ/mole} + H_2O \rightleftharpoons H_2 + {}^{1}/_{2}\,O_2$$

Wool structure Because → Wool is an animal hair, it represents the keratin fibres of many different types of sheep. The term keratin is not definite. It is used to describe the proteins of wool and hairs which, in the untreated state, are immune from attack by proteolytic enzymes. It mainly occurs in the macrofibrils in the cortex and the exocuticle. Proteins which are not

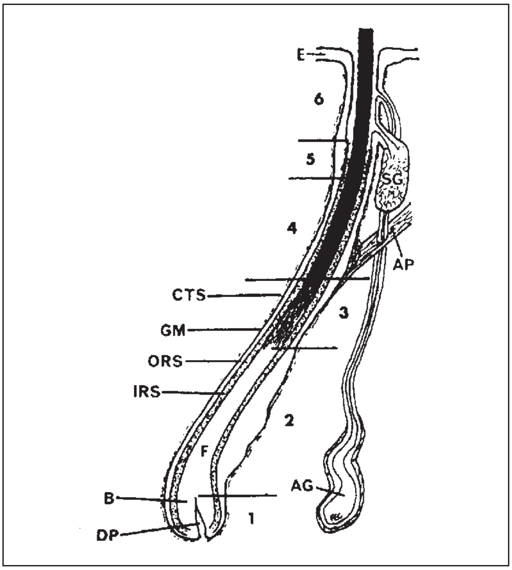


Fig. 1: Diagram of a wool follicle.
DP = papilla made from corium (dermis), B = bulb, F = wool fibre, IRS = inner root sheath, ORS = outer root sheath, GM = glassy membrane, CTS = connective tissue stratum, E = epidermis, AG = sweat gland, AP = hair erector muscle, SG = sebaceous gland; 1–6 wool fibre formation zones: 1 = bulb, 2 = keratin-forming zone, 3 = the hardening processes (keratinisation) cease, 4 = inner root sheath is decomposed, 5 = inner root sheath and cells from the outer root sheath are expelled, 6 = wool fibre canal.

keratins are those of the marrow (medullary) cells, the inner root-sheath of the hair (coleorhiza), the endocuticle, the intermacrofibrillar material and the residues of the cell nucleus. These are decomposed by proteolytic enzymes and solubilized.

Like other animal hair and human hair, wool fibres are formed by follicles (Fig. 1). These are introversions of the epidermis of the skin upon which are based the papillae made up of mesodermal cells. The malpighian layer is responsible for the development of the wool hair. The hair papille are formed in the sack-like pits in the skin, so-called hair shafts, from which grow the wool hairs. The duct to the sebaceous gland, which supplies the hair with grease, leads out to the top layer (the epidermis). The sweat gland opens out at the exit to the hair shaft. In the event of danger, a hair-follicle muscle hermetically seals the exit to the hair shaft. The hair grows in phases and, as it leaves the malpighian layer, it is almost formed.

Follicles are dynamic organisms in which different processes take place at the same time. These are: division, differentiation and upward movement of the cells which form the fibre (trichocytes), as well as biosynthesis of the monomeric amino acids for the wool proteins (Fig. 2) as gene products and finally self ordering of the monomers for the supermolecular structures and their “keratinization” (cornification) through the formation of disulphide crosslinks. As well as this, cells from the root sheath are broken down.

The different stages of development of the growing

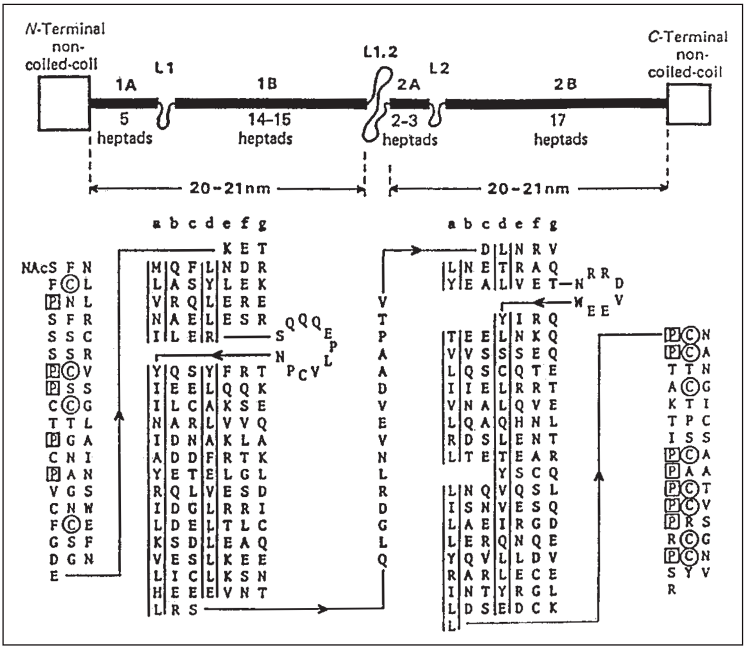

Fig. 2: Primary structure, i.e. amino acid sequence in wool protein 8 c-l according to Dowling.

wool fibre (Fig. 3) in the follicle can be divided up into six zones (Fig. 1). Even in the upper part of zone 1, around 8–12 nm fine → Intermediate filaments (microfibrils) (Fig. 4) and trichohyalin granules form. The filaments come together as macrofibrils between zones 1 and 2. Matrix proteins rich in sulphur are deposited in the macrofibrils of the paracortex cells. Amorphous protein aggregates (approx. 30 μm diameter) are formed in the cuticle cells of the wool in zone 2. A filament-matrix structure can be found in the orthocortex cells (Fig. 5). At the end of zone 2, the cuticle cells are

already hardened (Fig. 6) while final keratinisation of the whole fibre does not begin until zone 3 (Fig. 7).

Observing an individual polymer chain of the keratin of the intermediate filaments (Fig. 8), it will be found to be poor in sulphur in two 20 µm long sections lying between two terminal blocks which are rich in sulphur. These filaments are bonded to the matrix via disulphide links from the sulphur-rich terminal blocks.

Reliable identification of wool and fine animal hair is becoming increasingly important from an economic point of view. At the same time, the distinction between yak and cashmere, alpaca and mohair, for example, or wools of different provenance is of particular interest, as financial losses due to undeclared blends continue to increase. The height of the scale edge can be used as a distinguishing criterion (wool approx. 1 µm and cashmere approx. 0.5 µm) (Fig. 9). As a characteristic "database" for each individual, the DNA is basically predestined for the unambiguous identification of the species. However, DNA analysis has so far been used in the analysis of wools with caution, as the isolation and unambiguous identification of genetic material in the hairs has been made more difficult by processes such as bleaching.

High molecular DNA (1.4 x 10^7 Dalton, approx. 20 000 base pairs) can be recovered from the hair shafts, so statements about the origin of unknown wool samples can be made (Fig. 10). DNA are mainly to be found in the highly crosslinked exocuticle (Fig. 11), but not in the cell residues of the p-cortex.

At higher humidities, the wool fibre is able to absorb up to 33% of its own weight in water (Fig. 12). In comparison to the hydrophilic fibre stem, which readily absorbs steam, the surface of wool is extremely hydrophobic to water in its liquid state. It is the "epicuticle" which is considered responsible for these hydrophobic properties. At high water adsorption, water is incorporated via hydrogen bonds among others. The high humidity perception limit of 13% can be explained by the immobilization of water. These factors are very important for the physiology of the clothing.

The morphology of the wool can be broken down stepwise into a two-component structure (Tab.). The

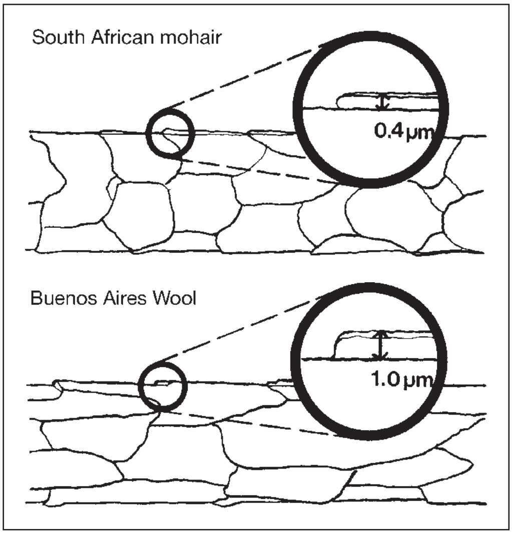

Fig. 9: Height of scale edges of mohair (top) and wool (bottom).

Tab: Morphology of wool as a combination of two-component structures.

Composite	Type *	1st components	2nd components
wool fibre	r/c	cuticle	cortex
cortex	f/m	cortex cells	cell mebrane complex
cortex cell	f/m	macrofibrils	intermacrofibrillar cement
macrofibril	f/m	microfibrils	matrix

* r/c = ring/core structure, f/m = filament/matrix structure

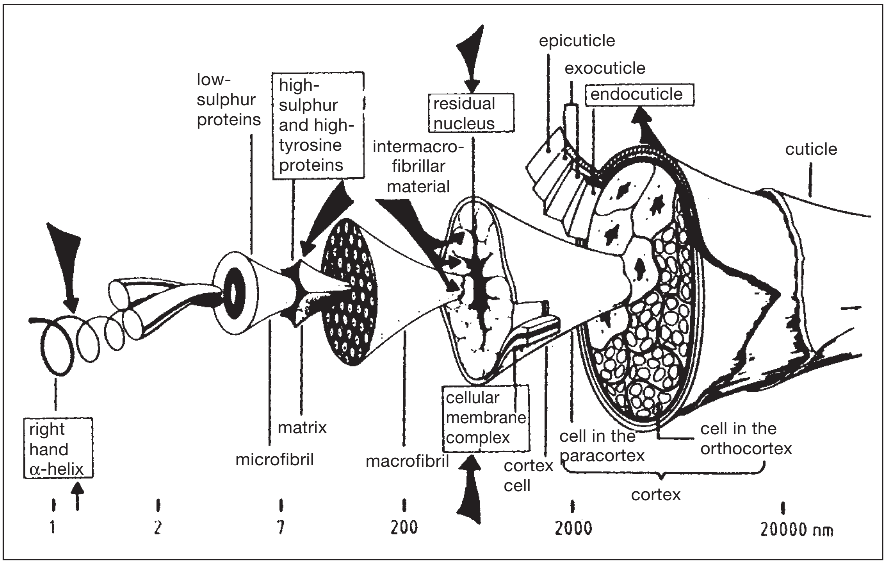

Fig. 13: Hierarchy of a fine Merino wool fibre (CSIRO Melbourne). Arrows indicate the weak points of the biological structure and peptide chains.

outer sheath of the wool fibre consists of flattened out, scale-shaped cuticle cells which are made up of extremely thin (only 2–10 µm thick) epicuticle, exocuticle (rich in disulphide crosslinks – exocuticle A = 35% cystine; exocuticle B = 15% cystine) and the softer endocuticle (3% cystine). The intercellular cement contains only 1% cystine.

The principle of the composite structure is described as follows (Fig. 13):

Component 1: the α-helix exists in the crystalline phase in the subfilaments which form continuous filaments in the direction of the fibre.

Component 2: the matrix containing all the remaining non-crystalline material, i.e. both the interfilament material visible under the electron microscope and the part of the keratin intermediate filament without a helical structure.

The elastic properties of the composite material are determined by the different crystalline or amorphous ratios of its components.

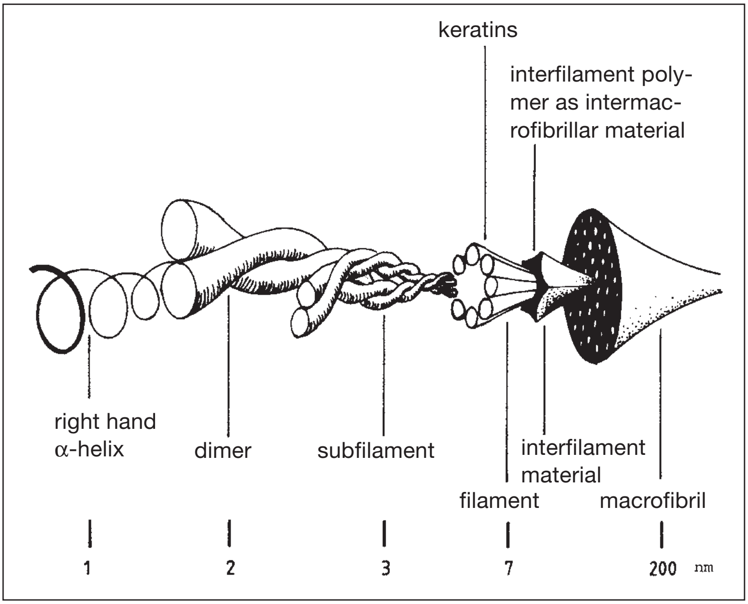

Fig. 14: Fine structure of a macrofibril in wool or human hair, modified representation (magnification of Fig. 13) following the Fraser wool model (according to Zahn).

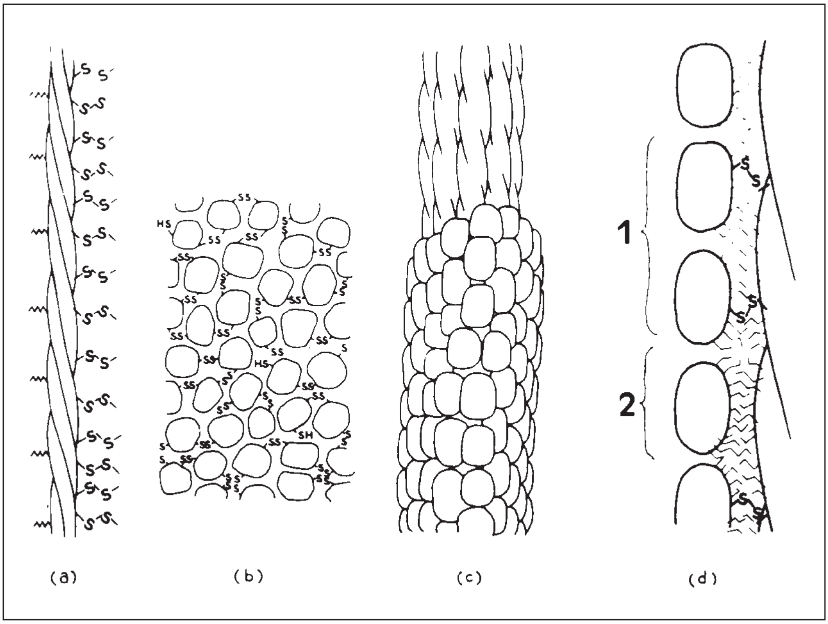

Fig. 15: Diagram of possible structures in wool cortex cells. 1 = stretched in the postyield area; 2 = stretched in the yield area; a = protofibril with acid-labile (wavy line) crosslinkages and disulphide bonds; b = matrix with intermolecular disulphide bonds; c = single microfibril, surrounded by "matrix" molecules; d = microfibrils and matrix molecules exert mutual reaction on their side chains including disulphide bridges (according to Crewther).

A wool fibre which is free of marrow is an example of the complex structure (Fig. 14) which reflects the structural principle of all biological and many synthetic materials, made up of components with different properties united to form a material which is optimally suited to its purpose. As chemical constituents, the α-keratins are insoluble, hard substances with high elastic moduli. They are present in the macrofibrils in the form of two components – the microfibrils and the matrix. The matrix consists of proteins rich in tyrosine and sulphur, while the main component of the microfibrils is represented by proteins poor in sulphur. The mechanical-elastic behaviour of the composite is demonstrated by a two-phase model (Fig. 15), according to which, the different morphological components are assembled into two phases:

1. the α-helices aggregate in the microfibrils as continuous, elastic filaments,
2. the matrix which is composed of all the remaining non-crystalline viscoelastic material, including the intermacrofibrillar cement, cell-membrane complex and cuticle.

Because wool not only predominantly consists of helical crystalline microfibrils but also an amorphous region, it is possible to associate it with a glass-transition temperature (Fig. 16). The glass-transition temperature of wool depends on the amount of water absorbed.

Knowledge of the glass-transition temperature T_G of wool as a function of its water content is of vital importance for understanding its viscoelastic fibre properties (Fig. 17), especially under fluctuating moisture and

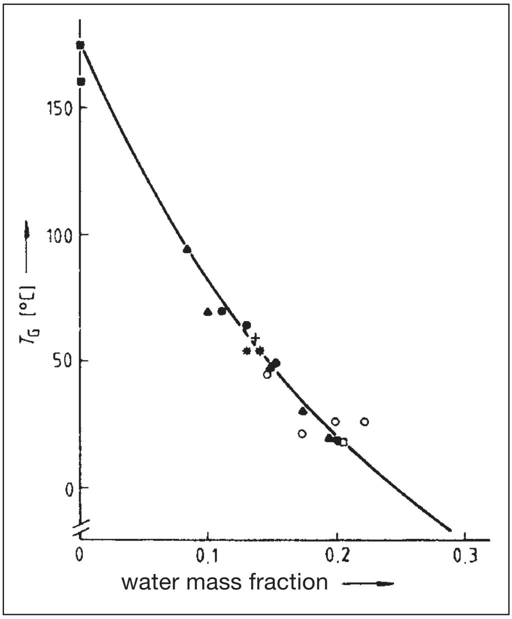

Fig. 16: Wool glass temperature dependency on the water weight share of the fibre.
The T_G values as a function of the water content were determined by Wortmann from documented data via the temperature dependency of the following physical properties:
● recovery of torsional setting; ■ torsion properties;
❐ recovery of elongation setting; ▲ dielectric properties;
✳ crease recovery of fabrics; ○ adiabatic calorimetry;
+ force at 4% stretch (Zahn, Altenhofen, Wortmann, 1983).

Fig. 18: Diagram, drawn from electron microphotographs, of reconstructed microfibrils from low-sulphur wool proteins in thiol form (Thomas, Conrads and Phan 1985).

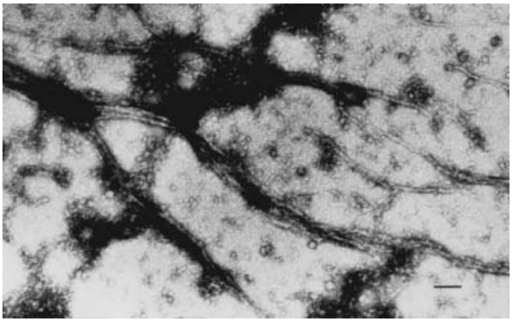

Fig. 19: Wool intermediate filaments as an in vitro reconstruction (according to Thomas and Phan). Bar = 100 nm.

temperature conditions such as those encountered during the processing and wearing of woollen fabrics, as well as being important for understanding the ageing and temperature processes in woollen fabrics – not to mention creasing at high moistures and temperatures and ironing and decatizing.

Although microfibrils were discovered early using electron microscopy (Zahn 1941), it has not been possible until now to reconstruct microfibrils from the proteins (which are poor in sulphur) from which they are made (Figs. 18 +19). This is now possible as the methods used in cell biology to form intermediate filaments from the dissolved intermediate proteins have been

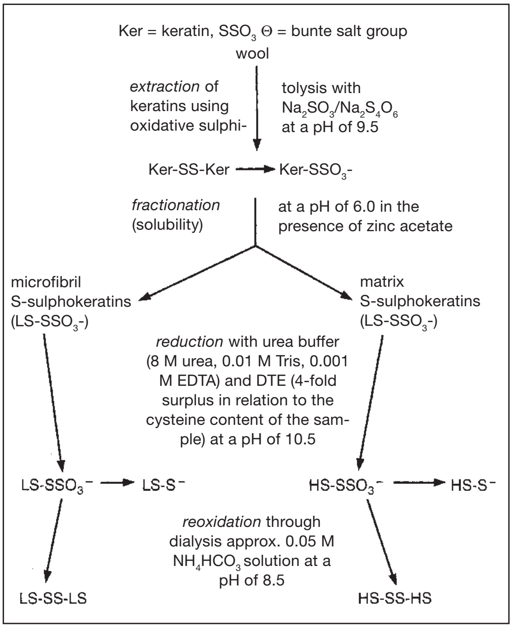

Fig. 20: Diagram of steps for the isolation of the low sulphur (LS) and high sulphur (HS) wool proteins in disulphide form (according to Hüskens).

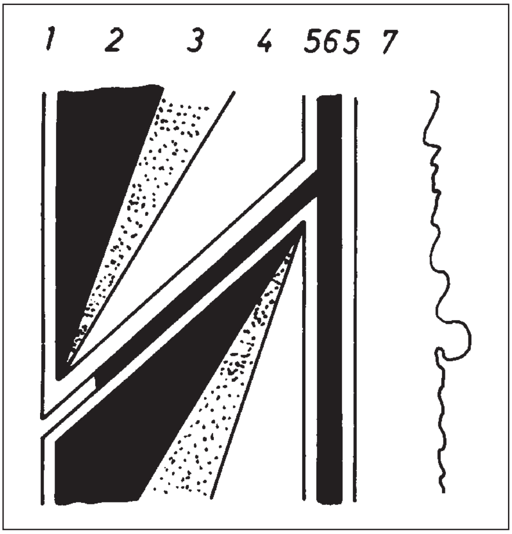

Fig. 21: Surface coating of a wool fibre in the scale over-lap zone (according to Lehnen).
1 = epicuticle; 2 = exocuticle; 3 = mesocuticle; 4 = endocuticle; 5 = cell membranes; 6 = intercellular cement; 7 = cortex.

adopted and new methods have been found to remove wool proteins gently from the fibre without irreversible attachment at the cystein sulphur atom (Fig. 20).

If the cuticle is mechanically removed by shaking the fibres with corundum grinding powder in a water/propanol mixture, then it is possible to separate the microfibrils and the matrix by reductive extraction and by converting the dissolved cortex proteins into the bunte salt (sodium alkylthiosulphate). If the S-sulphonate protective group is then split again by thiodisulphide exchange, unprotected microfibrils and matrix proteins are obtained and these can be re-oxidized selectively.

The histological and chemical composition of wool has a decisive effect on the behaviour of the textile fibre during the numerous finishing stages in wool processing.

The cell-membrane complex (Fig. 21) stretches throughout the whole fibre as the so-called “interpenetrating polymer network”. The exact mechanism of the formation of the cell-membrane complex during keratinisation is still not explained. The development of the cell-membrane complex can be illustrated as shown in the scheme in Fig. 22. A distinction can be made between the soft, easily swellable “intercellular cement” composed of proteins with few crosslinks, a lipid component and a chemically resistant protein membrane which surrounds each cuticle and cortex cell. The epicuticle is part of this membrane. Then an intracellular layer can be identified which can be recognized most clearly in the scheme according to the fibre (Fig. 22).

The lipid components of the cell-membrane complex of wool are made up of free fatty acids (Fig. 23), free sterols and polar lipids such as cholesterol sulphate and sphingolipids. Unlike the cortex cell, cuticle cells

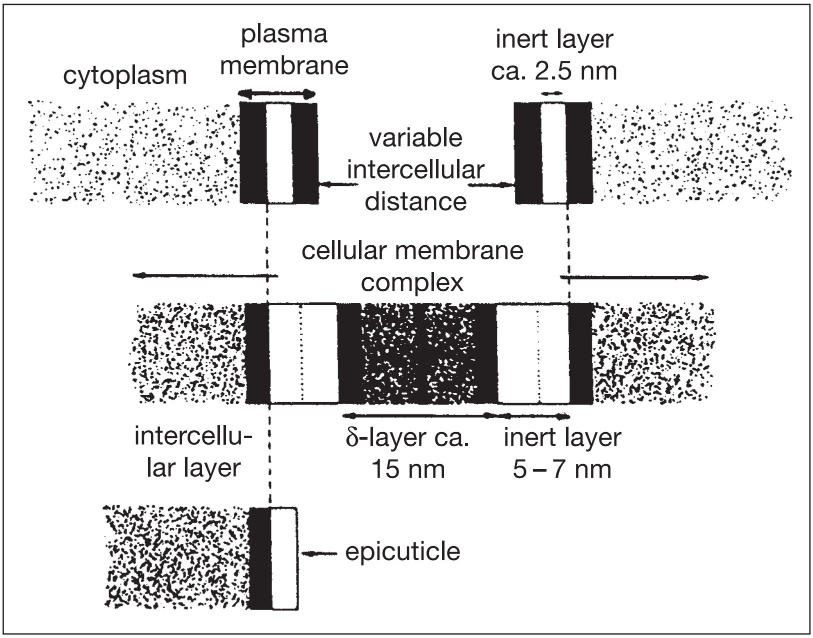

Fig. 22: Cellular membrane complex in the scale layer (according to Fraser).

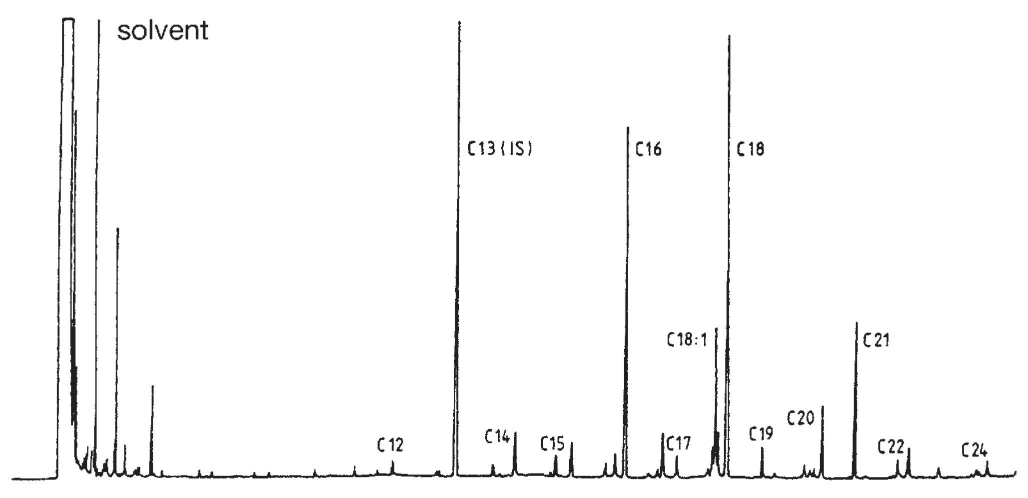

Fig. 23: Separation of the fatty acids of wool cell membrane lipids using capillary chromatography: fatty acids are found in the chain length zone of 12–24 C-atoms (C12–C24; C21 = 18 methyleicosanoic acid; C13 = tridecanoic acid methyl ester as an internal standard; LM = solvent) (according to Körner and K. Rouette).

contain a fatty acid with 21 carbon atoms. This acid, unlike the free fatty acids, stearic, oleic or palmitic acid, can be extracted from the intact fibre to only a small degree. The existence of a covalent bond between the C_{21} acid and the proteins of the fibre surface has already been postulated; it is suspected that this bond could be in the form of an ester link to a serine residue. The C_{21} acid is released in the fibre by papain/dithioerythritol and treatment with alkali. It is then found in the free fatty acid.

The wool fibre is regarded as a composite made up of cuticle and cortex cells and is held together by the cell-membrane complex. The stability of the wool fibre is determined not only by the cortex cells from which it is formed but also and to a much greater extent by the forces acting between the cells. As in a chain, the stability of the composite structure is determined by its weakest component. The cell-membrane complex represents just such a weak link, as it is the only continuous phase of the wool fibre and possesses only a small amount of mechanical and chemical stability.

Because the structure is made up of the cortex and the cuticle, the wool fibre can be regarded as a core/mantle-type bi-component fibre. The effects of this type of structure are reflected in the properties of the wool.

An argument for the significance of the cell-membrane complex is supported by the fracture morphology of wool and mohair fibres which have been stretched in liquid nitrogen, air and warm water at 60°C (Fig. 17). Fractures which have occurred in liquid nitrogen have irregular profiles such as those seen in composite materials which have a statistical distribution of similar weak sites (statistical failure). Fracture routes which follow the morphology of the material have not been found. When the fracture has occurred in air, the site has a granular texture at right angles to the fibre axis. These are typical of a fracture in composite materials which have pronounced interfaces between the components of the material. Deviation from the primary fracture route is seen at the projecting piece of cuticle. This indicates that adhesion between the cuticle and the cortex is relatively weak.

The fracture surfaces resulting from fibre breaks in water at 60°C look quite different. In this case, an extensive longitudinal crack appears resembling a fracture in simple composite materials, which is the result of weak interfaces between the “matrix” and the components which carry the bulk of the load. In fact, the longitudinal route of the crack runs predominantly along the length of the cell membranes and border lines of the macrofibrils. It is the non-keratin areas of the fibre which are weakened in preference, due to the combined effect of heat and water.

Macrofibrils consist of microfibrils. These fibre-axial oriented cylinders, with diameters of around 7 nm, are embedded in the matrix. The structural element of the microfibrils, effectively acting mechanically as a filament, is the proportion of α-crystalline helixes, which are regarded as the smallest building blocks of the fibre (diameter approx. 1 nm). Approx. 50% of the microfibrils, which can be reproduced using an electron microscope, consist of helical domains forming the continuous crystalline filaments due to their ar-

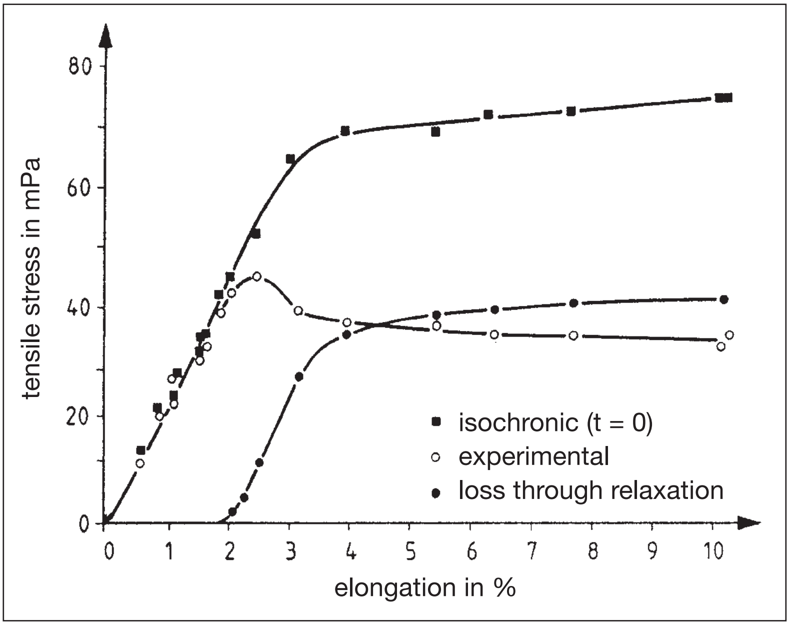

Fig. 24: Elastic and viscoelastic portion of the stress/elongation diagram of the matrix phase of a wool fibre under normal climactic conditions (60% rel. humidity, 20°C). The curves and viscosity values are calculated through analysis of the non-linear viscoelastic relaxation behaviour using the two phase model as a basis (according to Wortmann).

rangement into increasingly complex, rope-like superlattices (dimers and tetramers). Although the helices only make up approx. 30% of the total structure of wool, they represent the whole fibre in regard to its deformation in the linear elastic range of extensions up to about 2%. This is of more importance in wool processing than greater elongations (Fig. 24) (contributed by Zahn, Wortmann, Thomas and team).

Wool sulphur determination → Benedict-Denis reagent.

Wool testing → Fibre damage (wool), tests for.

Wool union Term used for mixtures of wool and cotton and mixtures of animal hairs and natural or regenerated cellulose fibres in general (wool, mohair and other animal hairs mixed with cotton, viscose and cupro fibres). The mixing ratios of the two types of fibre can vary considerably. The term wool union is used almost exclusively in dyeing technology.

Wool union/acetate dyes Commercial range of neutral-dyeing mixtures of acetate dispersion and wool-union dyes, for dyeing acetate-containing wool-union fibre mixtures the same shade.

Work Physics: product of force and distance: SI unit = joule.

Work allocation In textile finishing, when certain work is done outside rather than by the companies own staff (as an order = commission finishing) the systems used must be compatible with the company's own machinery and/or computer system.

Working life → Forming time of glues and coating compounds, etc. Term originating from wood gluing (formerly the melting of glutine-based glue in pots in a hot water bath).

Working platform In dyehouses, the working platform separates the section used for the charging of the dyeing machine from section giving access to the drive and energy supply "under floor". On the working platform, the operators operate the service equipment such as the crane for charging and emptying the dyeing machine. Under the working platform, the service personnel carry out repairs and overhaul the dyeing machine.

Working position After receiving the appropriate command, machine tools adopt the work position in or-

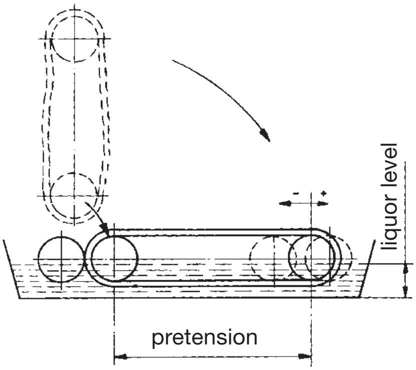

Fig.: Tension rollers swinging down into the operating position or preliminary tension position in a hank yarn mercerizing line.

der to carry out the textile finishing step for which they have been designed. Otherwise, they remain in the rest position (see Fig.).

Working pressure In a pipe, for example, the permitted working pressure (operating pressure) is the maximum pressure (N/mm^2) under which a pipe, which has been designed for a certain → Nominal pressure, must be operated, subject to the operating temperature and material used. If the starting material used is that intended according to the dimensional standard, then at 20°C, the permitted working pressure equals the nominal pressure. The highest permitted working pressure is the steam pressure laid down in the permit in bar in the steam chamber of a steam generator before entering the superheater or, in the case of once through boilers, the pressure at the end of the superheater.

Working voltage The electrical voltage of plant components operating locally between two conductors.

Workplace illumination → Illumination of factory work areas.

Works laboratory An important control centre in the textile finishing works. Purpose: to monitor the dyes and auxiliaries used and carry out quality control of the raw goods and finished goods, to develop and perfect methods/processes and supply information to the purchasing and sales departments as well as the production and design departments (→ Laboratory). On the other hand, the cost of works having their own research laboratory are so high that even for the major textile groups, they do not pay off, except when they concentrate on very specific restricted areas.

Workwear Clothing worn for work, the wearer himself being responsible for its general condition, as opposed to → Industrial protective clothing. The rules are different in Germany for personnel working in hospitals and shopping centres, etc. (representation workwear). In this case, for reasons of safety at the workplace (particularly for personnel working near moving or rotating parts) the following rules apply: workwear must always be in perfect condition including footwear (non-slip soles).

Worm-like grooving (worms). Faults which appear in crêpe fabrics like irregular breaks, folds or ribs. Examples of causes are: unsuitable preparation, tension, twisting, uneven introduction of the crêpe material into the crêping bath (folds = crêpe breaks). Avoided by crêping the previously embossed raw material against paper using a suitable pattern at approx. 80°C. This can produce a better evening-out effect.

Worn Denim Look Fashion trend for casual wear, particularly for → Jeans made from denim fabric such as blue warp (grey weft). Gives the impression of previously worn garments which must not only be produced by the "washout" effect (indigo-colour with the typical appearance of frequent washing = washed jeans) but also may be produced by use in wearing ("controlled" abrasion effect). This can also be achieved by gently treating with enzymes.

Worsted fabric Fabrics made from (single or twist) worsted spun yarns in the warp and the weft. In most cases, relatively fine thread, light to medium weight, smooth and napless cloth qualities. Anything from pure virgin wool, viscose or man-made fibres, including mixtures, can be used. The fabrics can be wool, yarn or piece-dyed. A particular characteristic is the smoothness of thread achieved by worsted-spun yarns and napless finish. In comparison to carded materials, because of fine and smooth yarns, the appearance of the weave is more elegant and neat. In spite of the relatively low weight of the cloth, worsted fabrics are hard wearing. This is particularly true in the case of high-quality merino virgin wool qualities; crossbred virgin wool qualities, on the other hand, are more crease resistant but less abrasion resistant.

Worsted spinning High quality threads prepared from staple fibre. The origin of the textile fibre can be natural or synthetic. In the main, wools and wool mixtures are spun with polyester, polyacrylonitrile or other man-made fibres. The fibres are single or twisted during weaving or knitting to produce the fabrics. The cloth and knitwear is most widely used in ladies' and men's outer clothing.

The most important process steps in the production of worsted yarn can be listed as follows:

1. Bale breaking: loosening up pressed wool.
2. Opening, willowing: opening the wool flocks.
3. Mixing: production of a large homogeneous mass of fibres by intensive mixing.
4. Scouring: removal of impurities.
5. Drying: reduction of wool moisture.
6. Lubricant: adjustment of friction parameters relevant to the process.
7. Carding: parallelizing and fine opening; production of a fibre ribbon (card sliver).
8. Drawing: similar treatment to the card slivers or combed tops by twisting and drawing; reduction in weight of the fibre bundles; sliver formation.
9. Combing: separating out short fibres (combing noils), non-fibre inclusions and knops.
10. Drawing: as 8 above.
11. Possible combed-top dyeing (such as vigoureux printing).
12. Mixing: uniform mixing of individual fibre or colour components.
13. Drawing: reduction or sliver thickness; production of a rove.
14. Fine spinning: spinning the yarn on combed-top spinning machines.

Steps 1–6 are part of the general preparations for spinning. The actual combed-top spinning starts at step 7. The fibre material is subjected to high stress due to friction between the fibre and metal predominantly during combing and this reduces the average length of staple (hauteur). In order to control this, it is necessary to apply a suitable lubricant before combing. To produce large coloured batches and yarn effects in particular (colour blends), the wool or man-made combed-top, which are supplied in the undyed state, are dyed before the actual spinning process. After dyeing, the combed-tops show comparable properties to wool after raw-wool scouring. The slivers are rough, stumpy and brittle; so that they can be processed further, they are now softened (modification of the static and dynamic friction behaviour, softening, antistatic finishing). Depending on requirements, different methods are available for softening, which can be carried out in the dyehouse. In practice, the following methods are mainly used:

- backwashing treatment,
- final brightening in the dyeing machine.

The purpose of backwashing treatment is to wash the combed-tops emerging from the dyeing process in a continuous process. Unfixed dye residues and dye auxiliaries are removed during this process. Highly curled wool is straightened out at the same time and the wool becomes more “sized”. This property is beneficial for the draught process and, to some extent, for the nature of the yarn. The backwashing process involves a series of 4–5 washing and rinsing baths connected in sequence, followed by a sieve-drum drier. Some of the auxiliary required for spinning is applied in the final rinsing bath. Softening is carried out according to the forced-application method. The application is controlled via the quantity of liquor dragged in by the combed-top (squeezing effect). The ionicity of the lubricant in this form of application is insignificant.

In order to reduce the high costs of the backwashing process, the worsted yarn industry is occupied with the development of alternative methods of applying lubricant to the combed-top. Basically, it is possible to carry out post-treatment processes according to forced-application processes or exhaustion processes. In the forced application case, the auxiliaries are diluted and sprayed on to the combed-top, for example, according to the pressure drier or the centrifuge method. In the exhaustion case, after thorough rinsing in fresh liquor in the dyeing machine, products are used which are oppositely charged to that of the substrate. This property gives the products an affinity for the fibre. Here, either genuine or pseudocationic lubricants are preferably used.

When lubricating polyesters in the dyeing machine, suitable steps must be taken to reduce the oligomers. During the rinsing stage in the dyeing machine, the combed-tops which are present in the form of yarn packages act as filters and make the removal of oligomers more difficult. Oligomers which may still be in the combed-top, have a tendency to deposit on the stretch-pressure cylinders of the gill boxes which follow and cause frequent coiling and non-uniform slivers. On the backwashing machines where the combed-tops are washed continuously in ribbon form, this problem does not appear so often.

In order to achieve the optimum spinning results, it is necessary to re-lubricate both the undyed and the dyed and softened combed-tops during the spinning of worsted yarn. This fine tuning satisfies different requirements in regard to adhesion and friction, electrostatics and moisture management. Particularly in the case of mixtures of wool and man-made fibres, there are significant differences in the friction properties of the individual fibres in relation to each other. The Fig. shows the places where lubrication or softening can be applied. To ensure that the lubricant is well distributed on the substrate, lubrication must take place as far in advance of the comber or ring-spinning frame as possible. Spraying is carried out on the stretching passages two or four times, depending on the operational requirements. Lubrication normally takes place on the delivery side to avoid coiling on the stretching machine rollers. The lubricant is always applied by aqueous dilutions, mainly to improve the distribution of the products and to even out the distribution of moisture in the fibre.

The combed-tops of the wool-combing plant are put together as a spinning batch, taking into account the properties the yarn will have later on and the efficient

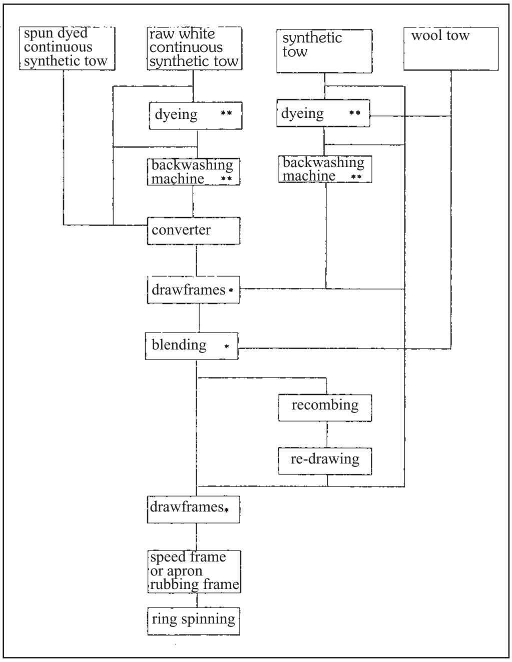

Fig.: Points at which lubricant (*) or spin finish (**) can be applied in worsted yarn spinning/dyeing.

use of raw materials. The mixing process, which is purely mechanical, is accomplished by repeated bringing together and combined drawing. There are three different methods:
a) the French or continuous system,
b) the English or Bradford system,
c) the German system, which is a combination of a & b.
The main differences between the systems is the way the different types of twist are introduced into the rove. While the French system involves introducing a false twist, in the case of the other systems the rove is given a genuine twist. The fineness of the spun yarn depends on the fineness of the rove and the draw.

The machine most widely used for spinning worsted yarn is the ring-spinning frame. The rove which is produced in rove spinning is initially pre-stretched in the ring-spinning frame using a high performance stretching mechanism. The yarn is then given a twist which is produced by an eye-shaped traveller running on a ring. This rotates around a fast-running, vertically aligned spindle with a winding bobbin and is rotated by the pull of the thread coming from the bobbin. The speed of the spindle depends on the fineness being attempted for the yarn (partially contributed by Bekker).

Worsted yarn Yarn produced in → Worsted spinning where the short fibres (combing noils) are removed by the combing process. This produces a smooth even yarn.

Wound (yarn) package → Package.

Woven carpets Carpets which are woven by machine or on hand looms (→ Machine-woven carpets).

Woven fabric Textile fabric formed by threads crossing each other at right angles consisting of at least two thread systems (warp and weft). → Weave.

WP → Alpaca, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Wrap fibre The so-called covering fibres of rotor-spun yarns which, among other things, improve the abrasion resistance during practical use. Research has shown that the total number of wrap fibres is smaller for a larger rotor and that coarser and longer fibres form approximately four times as many wrap fibres as finer and shorter fibres.

Wringable laundry Washing classification term according to the finishing work, i.e. → Laundry which can be put through a mangle, such as bed linen, table linen, hand towels, with possible sub-classifications into large and small pieces.

Wrinkle Recovery Tester American instrument for determining the → Crease recovery angle. Consists of a solid disc with graduations from 0–180° and rotatable, transparent measurement disc with vertical setting mark. The longer leg of the broken test strip is fastened in the centre of the instrument, while the freely movable short leg can stand upright. After appropriate adjustment of the rotatable front disc, the current crease recovery angle can be read directly off the solid disk. Manuf.: Monsanto.

WRONZ Wool Research Organization of New Zealand Inc., New Zealand. Textile research organization. → Technical and professional organizations. Scope of activities: wool research (→ WRONZ wool scouring process), information service, commercial test projects, annual report and report series.

WRONZ wool scouring process Process used to achieve slight destabilization of wool-fat emulsions:

1. Small wash trough with $^1/_3$ of the usual bath capacity, vigorous bath circulation and mechanical movement of wool. The system includes the removal of flocks and solid particles, fat recovery and utilization of waste heat.
2. Breaking the emulsion using N-pentanol.

WS → Cashmere, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

W type, man-made fibres from wool type.

WU → Guanaco, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

WV → Virgin wool, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

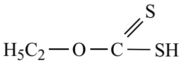
WY → Yak, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

X

Xanthane Natural polysaccharide consisting of a chain of glucose units with complexed mannose and glucuronic acid units. It is used as a thickening agent.

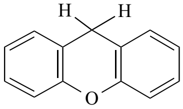
Xanthangumme This is the name given to the bacterium “xanthomonas campestris”, which causes xanthane gum to build up from (mono, di and oligo) polysaccharide units on a sugar solution as a result of microbiological synthesis. Xanthane gum has a polyanionic function and is used primarily as a thickening agent in carpet printing and space dyeing.

Xanthate A salt of xanthogenic acid. It is produced as a result of the effect of carbon disulphide on sodium alcoholate. → Cellulose xanthate.



$$H_5C_2{-}O{-}\overset{\overset{\textstyle S}{\|}}{C}{-}SH$$

Xanthene dyes An alternative term for → Phthaleins, as these are mostly derived from xanthene. They are derivatives of triphenyl methane carboxylic acid or triphenyl carbinol carboxylic acid, in particular phenolphthalein, fluorescein, eosine and rhodamine.



Xantho-protein reaction The yellowing of proteins containing the amino acids tyrosine or tryptophan after a short period of boiling in 10% nitric acid (→ Nitric acid solubility test). During this process, nitro groups enter the benzene ring in the amino acids, causing yellow “nitro dyes” (xanthoproteins) to be produced. Since non-protein fibres remain undyed, the xanthoprotein reaction can be used to test for fibres of animal origin. These are dyed more or less strongly yellow; so too are the protein inclusions in the lumen of non-protein fibres.

Xantho-, xanth- (Gk.: xanthos), yellow.

Xe Element symbol for xenon (54).

Xenon arc lamp →: Light fastness testing; Xenotest Light Fastness Tester.

Xenon high pressure lamp (UV lamp), the spectral ray density distribution largely corresponds with that of an overcast sky, with a high proportion of UV radiation. The colour bleaching effect is greater than the effect on a light exposure gauge. → Xenotest Light Fastness Tester.

Xenotest Light Fastness Tester Instrument for → Light fastness testing. The basis of these instruments, which can vary in size, is 1 or 3 vertically arranged xenon emitters surrounded by variable optic filter systems that allow the spectral distribution to be varied from “unlight through a window” (light fastness) to “sunlight in the open air” (weather fastness). A high correlation to sunlight can be achieved. This means that the light fastness results achieved correspond closely with those that occur naturally. The advantage is that the high level of radiation means that the test duration is shorter (ratio approx. 1 : 9 for the central European climate) (Tab.).

type	Xenon emitter output in kW*	number of test sample carriers	test sample area in cm^2**	size of the illuminated area per test sample carrier (mm)
150 S	1.3	10	900	100 x 45
450	4.5	22	3600	180 x 45
1200	13.5 (3 x 4.5)	(***)	approx. 20 000	(***)

Tab.: Xenotest devices.
** due to decreasing radiation intensity, the suggestion is for 1500 h worth of working hours, resulting in a drop of less than 10%; ** test sample area in the reverse run (front and back filled with test samples); *** larger test samples can also be illuminated.*

The sample holders have spring clamps to hold the samples affixed to opaque cardboard with the masking screen. During the test, the sample holders rotate approx. 5 times a minute around the emitter, which means that the required radiation mix is guaranteed even when the filter system is changed (IR filter, UV filter, poss. window glass). The lower UV limit behind the UV filters is approx. 310–320 nm. The IR filters ensure a high level of absorption between 700–1000 nm, so that the test temperature does not rise too high. The sample holders turn during rotation once per rotation by 180°

(simulation of day and night, sample cooling), but they can be operated directly without rotation. All instruments have a cooling system that is installed separately, which should be set at a constant low temperature. Additionally, all the instruments have devices (ultrasound water atomizers) so that the test environment can be set at a constant humidity (up to max. 95% relative humidity). There are also devices that generate precipitation onto the samples, so that weather fastness can be tested with an artificial xenon arc lamp (xenotest W).

The company Heraeus has developed a portable device for rapid illumination sun testing to test the behaviour of material under the influence of light. The test is quick, however it does not comply with DIN. There is an increased UV ratio, which means that any sample size up to a max. 500 cm^2 can be tested within a short time, and since the testing and acquisition costs are low, even smaller companies can afford to carry out light fastness testing. The sample being tested is in a test chamber, in which there is a parabolic reflector to ensure even distribution of radiation over the entire surface of the sample. The emitter (1.1 kW) has a radiation strength of 765 W/m^2 (at max. level of UV filtering for 1 < 800 nm) and can be cooled down by approx. 10°C using an additional sample table with a cooling facility. Various different filters (UV filters or special window glass) ensure that radiation is adjusted the same as natural sunlight (D_{65}). An overflow system for cyclic wetting is also available (according to Wehlow).

Xerogels Gels that have lost their liquid as a result of vaporization, extraction by suction, etc., and are below their glass temperature state. They are not gels in the true sense (→ Lyogel). Since they have the spatial structure of a polymer and are filled with air, they can be classified as (hard) foams. The best known xerogel is silica gel. The swelling of a xerogel occurs in the same way as the dissolution of a non-crosslinked polymer. The diffusion process is controlled by the common diffusion coefficient of the network and the swelling liquid; this can for instance be determined in a purely mechanical way by the penetration speed of the swelling agent. However in contrast to the dissolution of a non-crosslinked polymer, the swelling of a crosslinked polymer does not progress to the point of complete dissolution, because elastic restoring forces are present as a result of crosslinking (according to Elias).

XPS X-ray photoelectron spectroscopy; → Spectroscopy.

X-ray fluorescence Principle: any element that is subjected to electron or X-ray radiation with sufficient energy emits X-rays at around 0.1 nm. The fluorescence lines so generated can be identified and measured using an X-ray spectrometer, which means that qualitative and quantitative analysis of the elements present in the sample is possible. The lower the atomic number of the element, the lower is the energy in the fluorescence radiation, which makes analysis more difficult. X-ray spectrometer: high performance X-ray tubes irradiate the sample at close range (e.g. fabric), and the fluorescence radiation is broken down by suitable crystals. The fluorescence radiation is collected in a scintillation or gas flowmeter, and the individual impulses are summarized using a specially designed meter. The device can be used for quantitative and qualitative dye analysis on textile substrates on the basis of the so-called tracers that are present in the dye but not at all or only in small quantities on the fabric. The most important tracers are as follows, with the fluorescence line Kα shown in nm:

sulphur	0.536
chlorine	0.472
cobalt	0.179
nickel	0.166
copper	0.154
bromine	0.104

The results are relative values. They can be converted to absolute values by means of calibration, where the content is defined by analysis or preparation. Low quantities of tracers are almost always present in fabrics. This causes residual fluorescence in the fabric, which has a negative influence on analysis. The resulting blank value for sulphur (on cotton) = approx. the same as for 0.1% dyeing, for cobalt (on cotton) = approx. the same as for 0.03% dyeing. For this reason results can be inaccurate at a low dye concentration. If the fabric is pretreated, the blank values can be reduced, e.g. by boiling in distilled water. Advantages: the test can be carried out easily, and it is possible to obtain evidence regarding the evenness of penetration dyeing in the fabric.

X-ray fluorescence spectroscopy This refers to the possibility of inducing an element to emit characteristic X-rays as a result of being subjected to radiation.

X-ray photoelectron spectroscopy (XPS). The basis of this is an X-ray tube with a monochromatic illuminator; the monochromatic X-rays strike the sample and produce photoelectrons that originate from the inner shell of the elements within the sample (hydrogen and helium are not detected as they only have an external electron shell). The kinetic energy (Fig. 1) of the photoelectrons leaving the atoms can be defined, firstly by the (known) energy of the X-rays hitting the sample, and secondly by the bonding energy of the photoelectrons which is specific to each element, and also by means of the elements chemical environment in its chemical compound. The second principal component of this equipment is the analyser, which discriminates against the photoelectrons according to their kinetic energy. The result is an outline spectrum, which shows the different elements in the surface, and the peak values can be used for quantification.

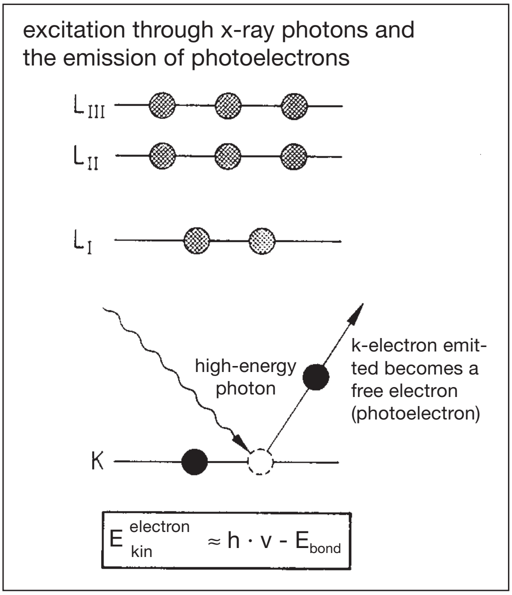


Fig. 1: Principle of X-ray photoelectron spectroscopy (XPS).

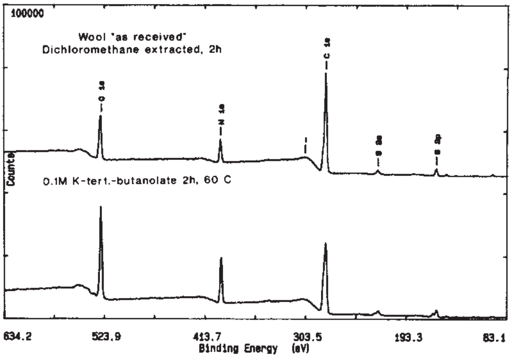

Fig. 2: XPS, general spectrum of wool. Top: untreated, dichloromethane extracted wool, bottom: wool treated with potassium tert.-butanolate (according to Höcker et al.).

The upper spectrum in Fig. 2 is of untreated wool fibre that has been extracted with dichloromethane, and the lower one is of wool fibre after treatment with potassium tert. butylate. With this treatment, a fatty acid bonded to the surface, that causes the wool fibre to be hydrophobic, is split off. This can be seen clearly by the fact that the carbon peak drops off.

The high resolution of the peak (Fig. 3) also shows that it is actually the aliphatic carbon level that has declined relatively during treatment.

In the case of treatment with alkali, the disulphide bridges have obviously partially oxidised. This effect becomes even more apparent if the wool tested has been exposed to the weather or UV radiation. In this situation the carbon curve changes only slightly, on the other hand the surface oxygen content increases significantly. The high-resolution spectrum (Fig. 4) shows that the bands of carbon remain relatively unchanged, while a clear SO_2 sulphur band occurs next to the disulphide band. Bonding forces can be assigned by means of model substances (according to Höcker).

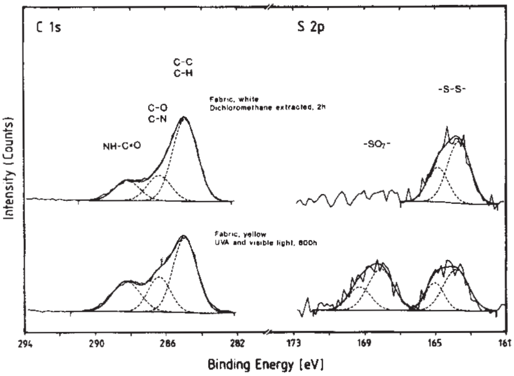

Fig. 3: XPS of wool, high resolution of carbon and sulphur lines (according to Höcker et al.).

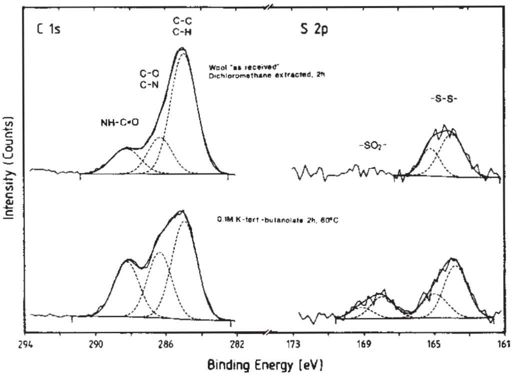

Fig. 4: XPS of wool, before and after weathering/UV radiation, high resolution of carbon and sulphur lines (according to Höcker et al.).

X-rays X-rays consist of a bundle of rays (travelling at a speed of 300 000 km/s) produced on the same principle as cathode rays (and reflected by the anode opposite the cathode) that can penetrate substances and enable their structure to be detected. They are stopped to a greater or lesser degree by solid substances (e.g. metals), broken down into a clearly defined line spectrum by crystals. The wavelength or oscillation count for each atom is characteristic (in direct ratio to the atomic charge and number).

Xylene (dimethyl benzene). $C_6H_4(CH_3)_2$, density 0.856; flashpoint –115°C; boiling point 136–140°C. Colourless liquid with a characteristic odour. Has highly refractive properties, flammable (the flame produces a high level of soot). Not particularly soluble in water, easily soluble in alcohol, ether, benzene, benzine, etc. In quantity it is the most significant component of pure benzene. Properties/application: → Benzine; Benzene.

XYZ Colour measurement system → : Colorimetric measures; Colorimetry; Chromaticity diagram.

Y

Y Element symbol for Yttrium (39).

Yak Hairs that are categorized as fibres of animal origin (see Fig.) from the Tibetan yak; these are the long hairs on the belly and tail.

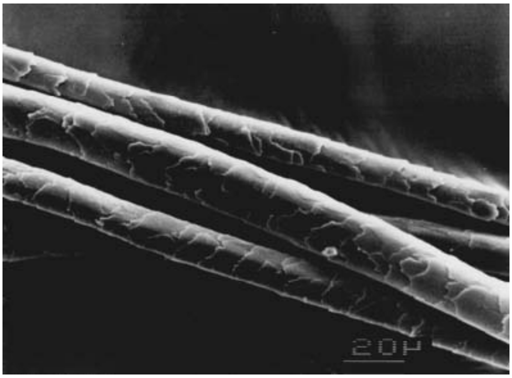

Fig.: Yak hairs (SEM photograph).

Yama-mai silk → Wild silks originating from the Japanese tussah spider, which is extremely similar to real silk in lustre and fineness. It is regular, and is white, yellowish or greenish in colour.

Yard (yd), English unit of length:

1 yd = 0.9144 m; 1 m = 1.0940 yd.

Yarn → Thread consisting of individual fibres produced by spinning and twisted to a greater or lesser degree.

There are different types depending on use: crochet, sewing, knitting yarns. Double or multiple yarns are known as → Ply-yarn.

Yarn bulking and steaming unit For the dyeing, printing and bulking of individual threads. Up to 8 threads are drawn off the take-off spool individually, continuously treated and then rewound again.

Yarn bundling press Packaging device for yarns in batch form that are pressed and threaded up into a → Bundle pack.

Yarn carriers This can mean:

I. Perforated inserts on which the yarn is wound.

II. Spindles or perforated tubes onto which the yarn packages are put so that the liquor can flow through them.

III. Moveable material carriers that can be inserted into the dyeing machine, with a hollow base into which the spindles or dyeing tubes can be inserted.

I. Yarn carriers in the form of inserts can be conical or cylindrical in form, and made of plastic or metal. The profile of requirements for contemporary plastic yarn carriers is essentially defined by steps towards rationalisation and improved quality for the user. These include good start-up properties (Fig. 1) with optimum spool construction, for further processing the guaranteed thread reserve for compression dyeing, and the guarantee that all the yarn will be used up with no wastage. The development strategy to achieve these requirements is agreed in co-operation with users, manufacturers of textile machines and producers of inserts. The results of calculations, for instance the profile of the insert, are put into the tool production process (Fig. 2). The choice of plastic is particularly important. The use of optimum plastic types suitable for specific pur-

poses has an influence on the mechanical properties, e.g. the properties of the press, or the stability of the dye tubes in the dyeing column.

II. Yarn carriers in the form of spindles or dyeing tubes (Fig. 3): when conical yarn packages are put onto spindles using robots (Fig. 5), spacers and a seal are necessary to ensure that the resulting dye column is properly sealed. In compression technology using axi-

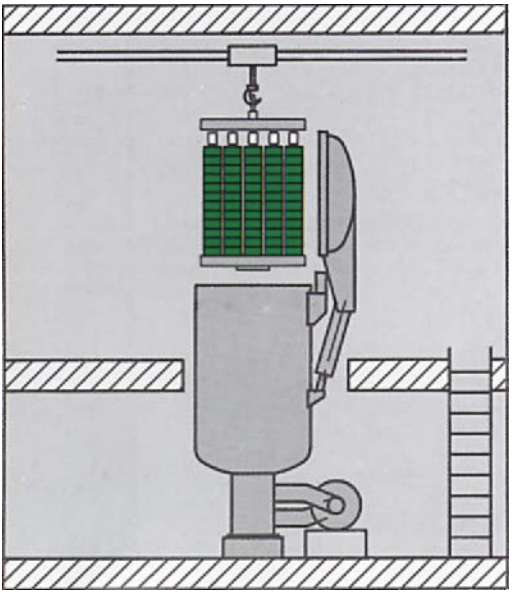

Fig. 6: Crane loading a vertical yarn dyeing machine with yarn carriers.

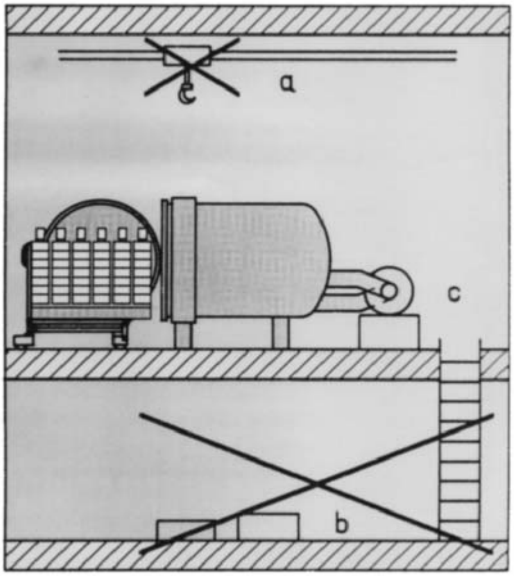

Fig. 7: Yarn carrier for horizontal dyeing machines.

al-flexible cylindrical tubes, dyeing tubes form the core of the dyeing column.

III. Yarn carriers used as dye tubes for yarn dyeing autoclaves are charged with yarn packages outside the machine. If the compression column technique is used, the individual columns are removed from the material carrier with a crane, where they are centred by spindles. The dyed pressure columns are centrifuged while still wet and HF dried (Fig. 4).

Dyeing machines for yarn packages are available as standing machines, which can be loaded or unloaded from above with a crane. In this type of machine the yarn carrier is round and has a cone in its hollow base that fits onto a matching cone in the base of the dyeing vat (Fig. 6).

Right-angled yarn carriers are used if horizontal machines have to be loaded automatically in certain circumstances (Fig. 7). In this case, the seal is situated in the head side in the hollow base to connect the material carrier to the liquor circulation.

Yarn composites Flexible, porous fabrics (→ Bonded fabrics) made from threads or thread layers and bonded by sewing, glueing, plasticizing, fibre bonding, or combinations of these techniques.

Yarn counts → Linear density of fibres and yarns.

Yarn dryer, air stream This type of dryer is used for drying yarn packages (on perforated inserts) in columns on spindles or perforated tubes as a discontinuous process. If yarn packages with a large quantity of wound yarn are used in the compression column dyeing process, the yarn packages have a high level of flow resistance, and for this reason they are dried using a high frequency dryer after continuous centrifugal drying.

These are the different types of flow dryer:

I. Rapid dryers, which suck in air from outside through a fan, which is then heated, blown through the yarn packages in the drying tank, and discharged externally in the form of exhaust without a heat recovery process. As a result the state of the drying air before it enters the material carrier is dependent on the humidity, temperature, air pressure and purity of the external air that is sucked in.

II. Air circulation dryers, where as soon as a certain level of humidity in the circulating air is reached (caused by flowing through the yarn packages), some of the air is discharged as exhaust and replaced with fresh air.

III. Pressure dryers, which operate as a completely sealed system, where the circulating air is heated on entry in the wet package columns, and then the moisture is removed in a condenser as the air leaves the package columns (cold water indirect heat exchanger in the form of a cooler or spray condenser, in which the moist warm air is cooled by cold water vapour by means of direct heat exchange).

The principles of flow drying are based on the property of water to absorb water in a gaseous state up to saturation point. The heat content per kg of moist air can be raised by an increase in temperature, density and humidity ratio, which is utilized in this drying technology. In flow drying, the effectiveness of these parameters as well as the air throughput volume or flow quantity is de-

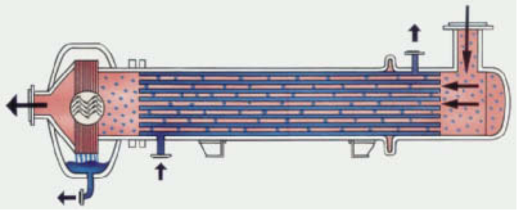

Fig. 3: Direct (Thies) heat exchanger which sprays cold water into the warm stream of damp air.

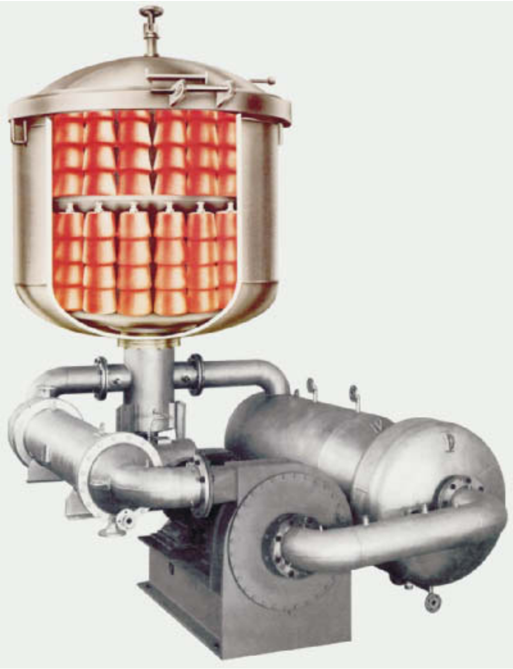

Fig. 4: Thies pressure dryer.

pendent on the textile. The air throughput volume is orientated to the level of flow resistance through a yarn package, and it is dependent on the type and size of package, the fibre and yarn parameters, the package density representing weight/volume, the parameters of the drying air, such as pressure, temperature and humidity ratio, as well as the ratio of humidity in the yarn package and its temperature. If the air throughput volume for each individual drying section is known, an approximate prediction of the drying process can be calculated.

Modern pressure dryers are supplied with computerized controllers. The user is guided by an interactive program and requires neither knowledge of programming nor parallel coding lists. Pressure dryers designed in this way are made for instance by Scholl (Fig. 1) as well as Thies (Figs. 2–4) and Then.

Yarn dyed Dyed in yarn make-up, e.g. in hank form (→ Dyeing of yarn in hank form), as a yarn package, or spool, and in continuous form.

Yarn dyeing In the past it was standard practice to dye only conical yarn packages (Fig. 5), warp beams (Fig. 4), and yarn in hank form (Fig. 1). The dye tub can take up to 40% more weight if yarn packages on axial-flexible dye tubes are used (Fig. 6), because over 25% increase in yarn density can be achieved by compressing the dye columns. With modern yarn package winding machines it is no longer necessary to break (round off) the edges of the package if cylindrical yarn packages are used. For production reasons it is practical for the packages to be as large as possible, but at certain dimensions even the most powerful pumps are not able to force the liquor through the yarn layer. If the yarn pack-

ages have been wound on strong dye tubes, they are put onto spindles (deflecting bars), or if they are wound on flexible spring sleeves, onto tubes. The spindles and tubes (Fig. 7) are located on a hollow plate (the carriers are connected to the liquor entry area via a conical link). With stiff inserts, several packages are stacked above one another with spacers for sealing; with flexible dye tubes, the packages seal themselves. This is also the case with insert-free systems, where the inserts used for winding are removed before dyeing. If the production volume is sufficient, it may be worth acquiring a robot-type automatic device for loading and unloading the material carrier (Fig. 11). To utilize the dyeing machine to an optimum, enough yarn carriers must be

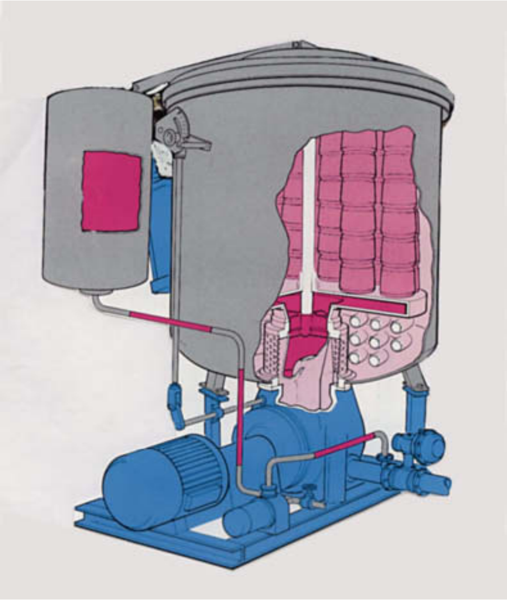

Fig. 7: Longclose yarn dyeing machine (the material carrier's hollow floor is highlighted in the cross-sectional cut-out).

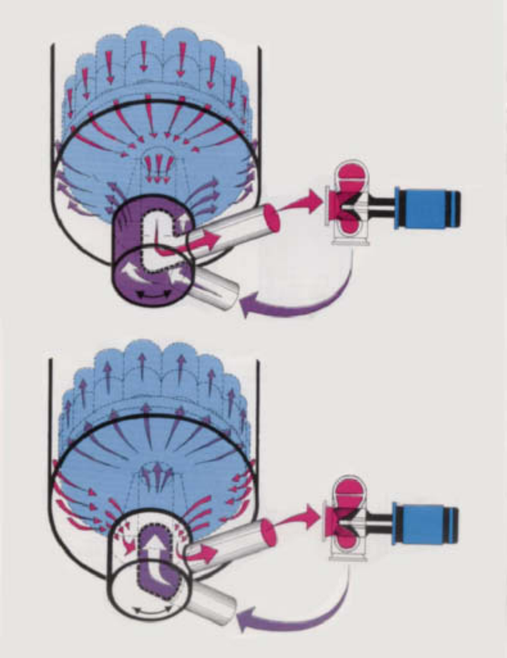

Fig. 8: Automatic liquor change unit in cross-wound yarn package dyeing with the Krantz Alterator (below: inside to outside; top: outside to inside).

available to ensure that there are no waiting periods. There are special yarn carriers for yarn in forms other than packages (Figs. 2 + 3). The yarn carrier loaded with the packages enters the calorifier in the circulation system, where it is placed on the liquor supply aperture. Most calorifiers can be sealed, and can sometimes be used at pressures of up to 4 bar.

The dye liquor is pumped under pressure from inside to outside or vice versa (Fig. 8) through the hollow base and the packages. Usually the liquor direction is alternated at certain intervals. Modern circulation systems are constructed in such a way that the liquor ratio can be kept as short as possible, and the liquor throughput, i.e. l liquor/min and kg of textile, is high. Throughput should be adjusted to suit the dye uptake speed. For dyes with efficient levelling, this figure will be about 15 l/min/kg. With modern machinery, these parameters can be exceeded by a long way (up to 50 l/min/kg). High-speed dyeing machines circulate the entire liquor about 6–10 times per min. This means that the liquor can be heated and cooled quickly.

Liquor throughput:	l liquor per kg textile per minute
Circulation rate:	number of circulations per min for the entire liquor

However there are limits to the circulation rate, and if these limits are exceeded, the yarn wind starts to become deformed. There are gauges in the system itself to measure flow and differential pressure, but they do not necessarily provide information regarding the liquor

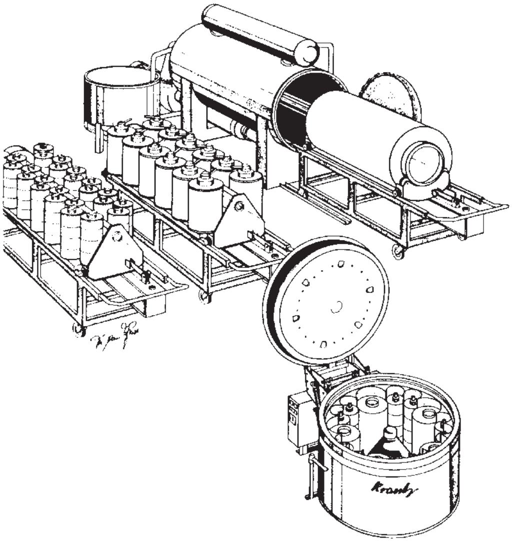

Fig. 9: Krantz horizontal dyeing machine for yarn (and piece dyeing).

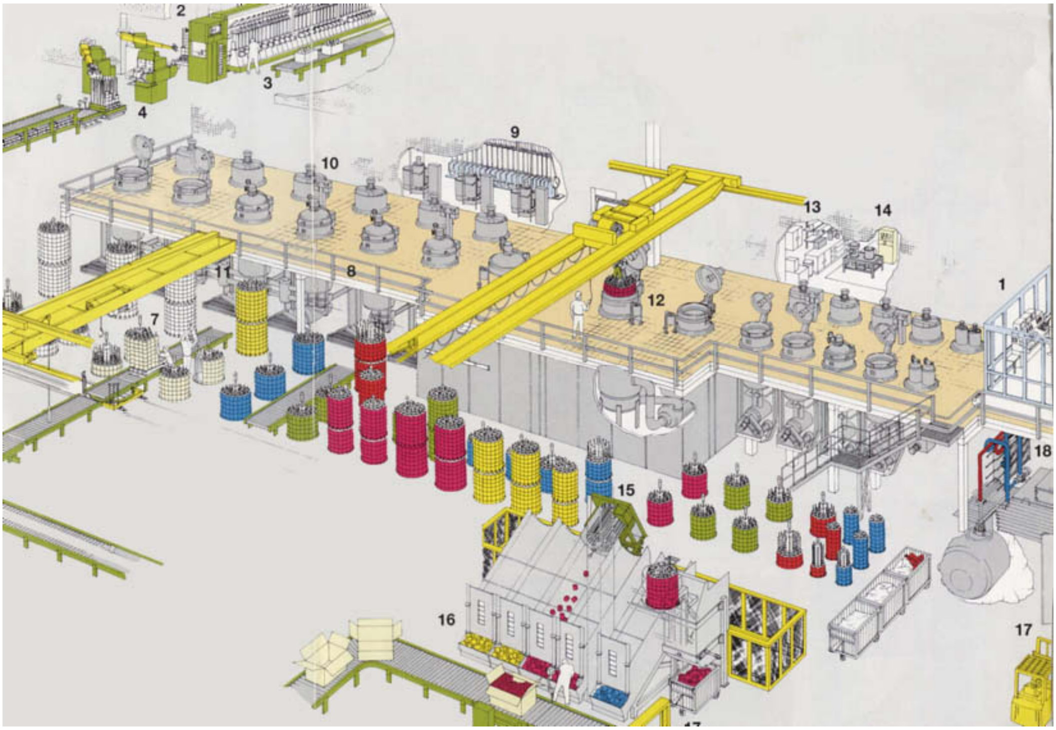

Fig. 10: Jasper yarn dyehouse.

circulation within the yarn packages. Hoechst has designed a machine for measuring the differential pressure for individual packages. The liquor direction through the yarn package is alternated at pre-defined intervals. The usual values are alternately 2 min internal/external and 3 min internal/external. In individual processes, circulation can also take place from inside to outside. The quantity of liquor circulated in the period up to the point of direction change is the crucial factor. If the direction alternation is too rapid, it causes the cores of the packages to be too light in colour. In the case of machines that have centrifugal pumps fitted, the liquor alternation is carried out by means of a 4-way device, which nowadays operates automatically but used to be manual (Fig. 8). If axial pumps are used, the device is redundant, because the direction change can be activated by pole reversal in the motor. The Serracant JM dyeing machine has an original variant, with a piston pump situated inside the dye container, which pumps the liquor backwards and forwards through the yarn.

With new equipment, liquor heating and cooling takes place outside the dye container with heat exchangers, which guarantees evenness of temperature throughout the whole liquor. It is important to de-aerate the yarn before starting dyeing in standard processes, because the air within the fibre hinders liquor access. De-aeration agents make the removal of air from the fibre easier. Another way is the technique recommended by Obermaier of vacuum dyeing by creating a vacuum in the machine. Examples of this type of system are: Burlvac (Thies), Rapid Reversal (Gaston County), Flashflow (Mortensen). With the correct inserts, these circulation machines can be used for dyeing yarn packages, warp beams, hanks and soft packages (Figs. 1–6). Almost all machines have a vertical dye container, but there are some with a horizontal cylinder (Fig. 9). In the Pozzi system, the dye tube turns on its own axis during dyeing. The trend towards saving energy and water has led to machines being redesigned in the past years. Shortening the piping system and fitting a pump in the base of the calorifier resulted in a significant shortening of the liquor ratio. This type of machine is supplied by Brückner, Krantz, Then, Thies, Scholl, for example. A further stage was the allocation of a separate dye container for each spindle, thereby eliminating wasted space. Examples of this type are: Turborapid (MTM Obermaier), CS and Favorit (Frauchiger), Steam jector (Mortensen). Machines where only the liquor is in the sump and the actual yarn to be dyed is outside it, constitute the final stage of liquor shortening. In this situation, the only liquor direction possible is inside/outside. Sump dyeing is possible in most machines with alter-

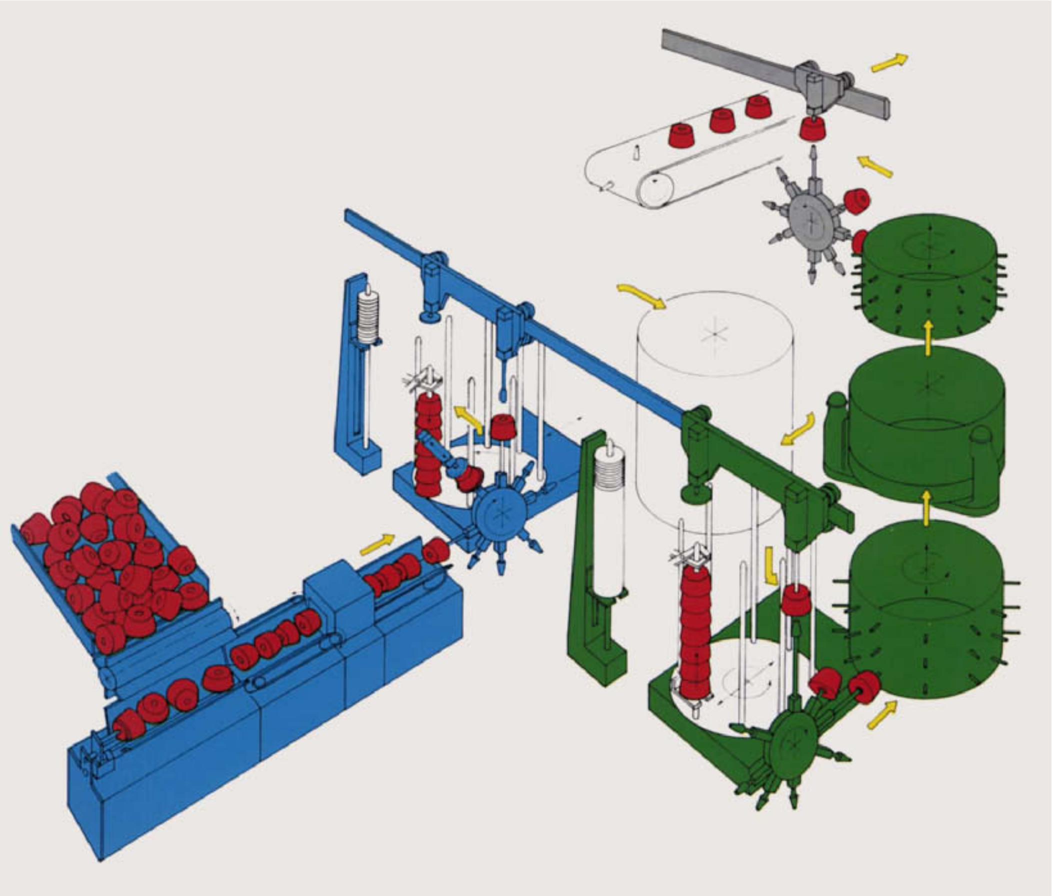

Fig. 11: Officine Minetti, automatic yarn package carrier loading.

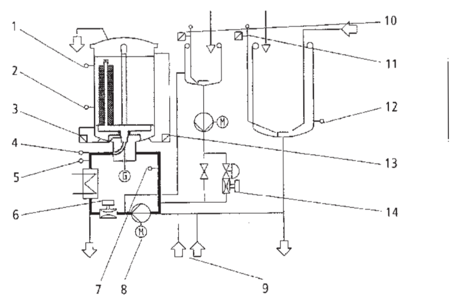
nating liquor circulation if the liquor direction is restricted to inside/outside. Jasper takes a different approach, with the option of compressing the yarn package columns in the machine when it is closed. Open circulation machines are becoming less common in dyeing. With these machines there is the constant hazard of vapour bubbles forming in the pump suction pipes (cavitation), which reduces circulation.

For this reason, sealed HT machines are preferable, even when dyeing at temperatures above boiling point is not required. HT machines are manufactured in all sizes. Different individual machines can also be linked together to dye large batches under uniform conditions (Fig. 10). Colour matching in non-pressure machines is carried out by batching off the yarn from one or preferably several packages. In HT machines this is done using a lock. In some machines, bypass devices have been fitted, in which a sample package is dyed. Dyeing uniform shades on a continuous thread, i.e. from package to package, is mainly of importance for the manufacture of sewing thread. Immaculate winding is a crucial factor for successful warp beam dyeing. The diameter of the winding cylinder (standpipe) must be set to suit the warp length, because the layer thickness of the yarn winding must not exceed a maximum thickness. Standpipes are available with diameters from 100 to 500 mm. The perforation holes usually have a diameter of 5 mm, but 20 mm holes are also in existence. The usual winding thickness is 380–420 g/dm^3, for dyes with good levelling properties up to 520 g/dm^3. Liquor flow direction inside/outside approx. 16 l/kg/min. Excess pressure when the pump is started or when the flow direction is alternated can be prevented by using pumps with a gentle start or bypass devices. Uneven yarn dyeing is caused by non-uniform package winding or uneven arrangement of different sized packages.

Yarn dyeing automation: In comparison with other production processes the degree of automation in yarn finishing is relatively high (Fig. 11), with the result that the innovations and further developments presented



Fibre material	cotton	cotton	polyester	polyacrylic	wool	polyamide

concern the refinement or improvement of the measuring and control technology as well as computer-assisted systems for organisational planning, control and monitoring of the production flow. There are many reasons for the application of automation systems in production and in administration. One important aim is to increase productivity by lowering production costs, and also to improve flexibility. Besides this, the rising quality demands also play an important role. The question is, however, what degree of automation will best meet the individual requirements of the mill in question. Often the ideal solution is to find a compromise that is, of necessity, orientated towards the objectives and the conditions prevailing in each individual company.

Measuring and control technology (Fig. 12) is instrumental towards automation of the production flow. Flow rate measuring and control instruments, controlled circulation pumps, level measuring equipment for optimum filling of the dye vessel, as well as differential pressure measuring and control equipment is state-of-the-art with most machine manufacturers. In most cases, measuring and controlling the pH value, redox potential and salt concentration is carried out manually or semi-automatically.

A further important area of automation is dominated by production planning and control systems (Fig. 13) (PPS). The control of the machines, transport systems, robots but also the control of machines and plant hierarchies is effected via efficient microprocessors. Stored programme control systems (SPC) are used as an interface between the industrial PC and the dyeing machines, and are today state-of-the-art with virtually all manufacturers. Most companies opt for central control of the process sequence via SPC. In this respect, Then (D) have taken a different route. With their new control concept "TLON", the control functions of the entire dyeing range are no longer effected centrally via SPC, but are divided into several small, parallel sub-functions. Production planning and control (PPS) has an important task within CIM (computer integrated manufacturing). Some machine builders have, therefore, already gone one step further. The resulting demands on a CIM concept include efficient software systems which can effectively deal with the quantity and quality of requisite information, the administrative expenditure and a relatively high degree of automation.

The term CIM usually conjures up a picture of a fully automated, computer-controlled mill. There are in the meantime systems on the market which offer a wide range of functions and, with their further developments, meet CIM requirements. In this sector development is right at the beginning. CIM subsystems and units, e.g. PPS, CAD, CAP systems and automatic handling and transport equipment are already available. These include the components of information technology (operating systems, communication and development systems). The CIM subsystems have already achieved a high level of sophistication and enjoy widespread use, with a whole range of connection and integration potential. Other systems fulfil the basic PPS

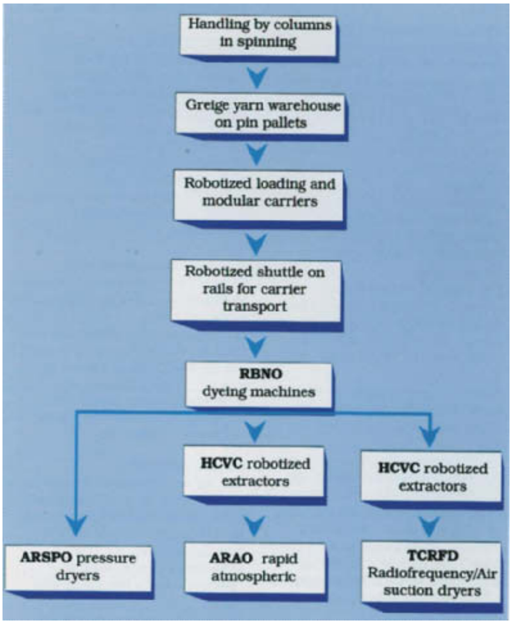

Fig. 13: Production planning and control system in a yarn dyehouse.

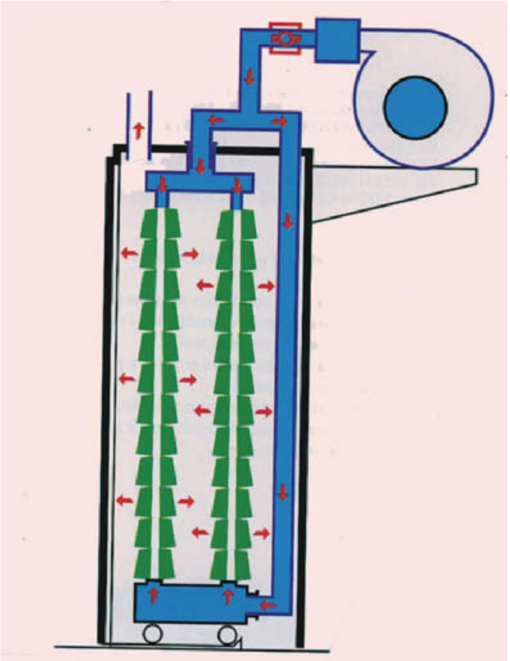

Fig. 14: Cone dryer (Loup).

functions at a high level, exhibiting optimum flexibility where modification is concerned.

The concept of modular carriers (by Bellini) operates with modular interchangeable carriers. Dyeing machine and drying systems may contain one, two or three carriers in series. The base module is exchanged therefore between machines of different sizes. The interchangeability of carriers means an outstanding operating flexibility for just-in-time operation, as it enables a dyehouse to dye all kinds of materials, for instance in the worsted industry to dye both yarn packages (Fig. 14) and tops or bumps, or in the upholstery industry to dye packages of medium diameter for cotton and viscose yarns and very large diameter for textured polyester yarns by fully exchangeable carriers.

Yarn dyeing automation → Yarn dyeing.

Yarn dyeing machines →: Rope dyeing machines; Spray dyeing machine.

Yarn finish Cotton or linen sewing thread is soaked in starch and wax or paraffin, dried, stretched (lustred) and brushed to give it a smooth surface. → Glossing; Lustring.

Yarn hairiness Yarn → Hairiness.

Yarn handling Yarn finishing usually involves complicated handling because of the small individual components (packages or hanks), and for this reason process automation is ideal for yarn finishing. Robots are used to load and unload centrifuges, made by Robotel (Bobex), Pozzi (Mov-ex), Dettin (Berta 24), Frauchiger (Transroc) or Calvanin (Carousel) and Obem (centrifuging horizontal yarn package columns in the hydro-extractor IC 5/A). Even and rational compression of the yarn is a decisive factor for the usual dyeing machine compression techniques, i.e. the loose yarn should be compressed in such a way that densities of

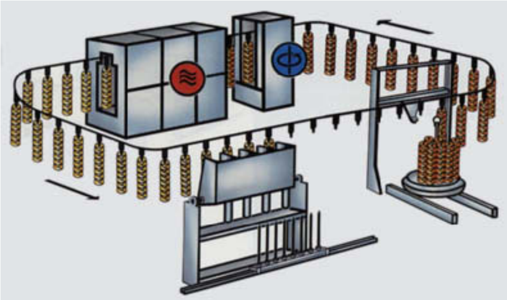

Fig. 1: Suspended yarn package column (with dyeing tubes) transport through the Thies centrifuge hydroextractor and high frequency dryer.

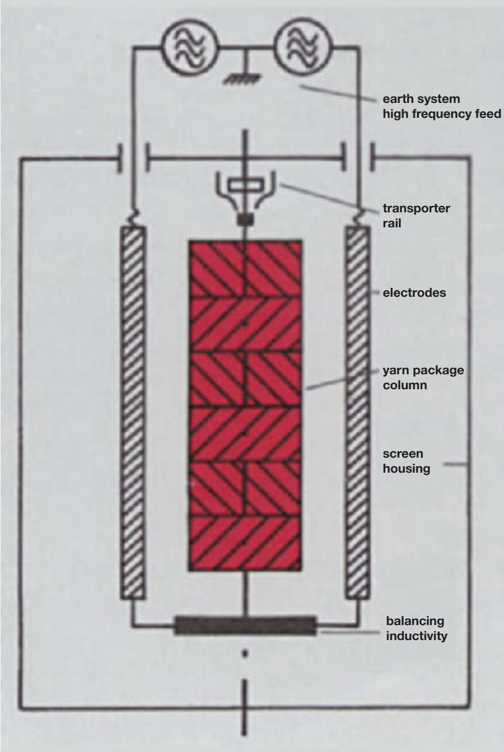

Fig. 2: Diagrammatic view of the suspension transport system for yarn package columns in the Thies high frequency dryer.

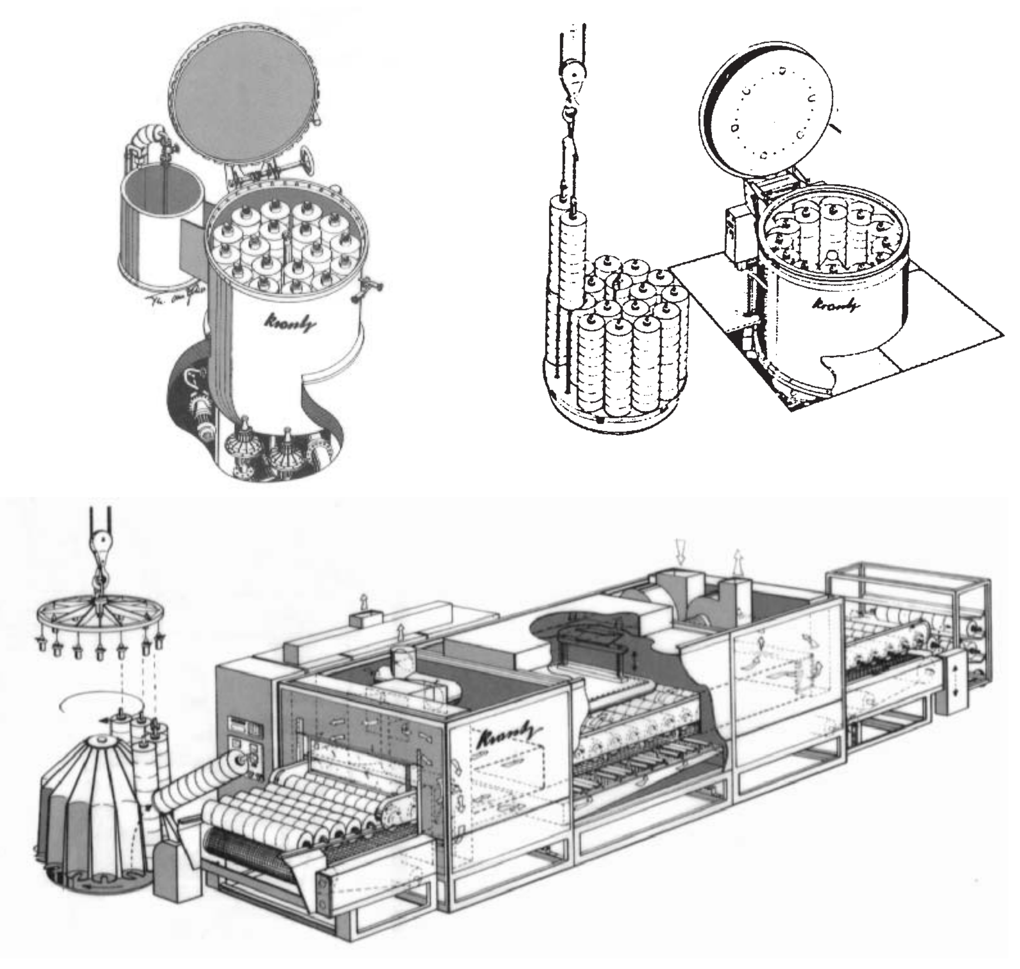

Fig. 3: Operational sequence and yarn column transport in Krantz hydroextraction and high frequency drying, with yarn columns upright round the centrifuge periphery, and yarn columns laid on their sides in the high frequency dryer.

400 kg/m^3 can be achieved. The Jasper TOP (transport without personnel) system offers an elegant method of compressing package columns, which is almost an upside-down dyeing vat. The dyeing vat is cylindrical and open at the bottom, and is lifted using hydraulics for loading and unloading the system, so that the yarn carrier, which is located on the fixed lower part, can be removed. After the lower part has been reloaded with the new yarn carrier, which contains cylindrical packages with axial-flexible dye tubes that have not yet been compressed, the package columns are pressed onto the yarn carrier when the upper part of the vat is shut. After the yarn packages have been dyed, they should be spun (pre-dried) and dried (Fig. 3). When columns with compressed packages on axial-flexible cylindrical dye tubes are used, the principle of leaving the dye tubes in the columns for as long as possible applies. The Krantz system packs the columns into a centrifuge and spins off most of the water from a dye batch. Then robots put the columns onto the conveyor belt of a high-frequency dryer. The dry dye columns are then put onto transport trolleys to take them to the next section.

Thies takes a different approach, in which the package columns coming out of the dyeing machine on the dye tube are hung up to be transported through a spin-dryer (Fig. 1). They are dried there by revolving each column on its longitudinal axis at high speed. Next the transport system (Fig. 2) takes the hanging columns through the high-frequency dryer.

There are also continuous yarn finishing processes. In this way, cotton yarn can be mercerized with liquid ammonia using the Prograde process. Raising knitting yarn on yarn raising machines is another typical example of a continuous treatment process.

Yarn humidifying agent These are used for humidifying yarns, to set the required humidity level and maintain it during the course of subsequent textile finishing processes, as well as to cause an increase in strength or shape retention. Stabilized wetting agent solutions with added preservatives, bactericides or anti-fungal products are usually used.

Yarn length calculations If the yarn count of a batch remainder is known, the available yarn length L can be calculated using the following formula (weight G in kg):

Tex system: $$L = G \cdot \frac{10\,000}{\text{dtex}} \text{ km}$$

Denier system: $$L = G \cdot \frac{9\,000}{\text{den}} \text{ km}$$

Metric system: $$L = (G \cdot \text{Nm}) \text{ km}$$

For warp beam yarns, this length should be divided by the number of threads.

Yarn liquoring machine (straining machine, starching machine). This is used for sizing and dyeing (e.g. vat pad process for strongly twisted yarns, naphthol dyeing), for preparing, unwinding, rinsing, soaping, etc. of yarn hanks. It consists of a trough on each side (short liquor heated/cooled), a rubber compression roller, a collar roller, and a metal skeleton roller that can be adjusted by a lever for taking up 1 kg of hank yarn, which is stretched, divided, immersed/printed, lifted again, de-tensioned and removed when ready. Time setting is possible for all of these. Newer models are also available with a trough carousel.

Yarn lubrication Additional yarn scrooping (additional lubrication) in two-for-one twist yarns. Increasing processing speeds and a growing proportion of synthetic fibre repeatedly leads to processing problems in yarn manufacturing and processing. These problems can be seen in the form of a negative influence on strength, a significant tendency to generate dust and increased yarn roughness. Problems like this are caused in particular by insufficient lubrication of fibres or threads at the point of contact with fibre/yarn guiding devices of all types. In addition to this, synthetic fibres have a greater level of sensitivity to abrasion compared with natural fibres when subjected to friction under standard high-speed conditions (25 m/s). Yarn lubrication is intended to prevent this type of fibre damage. It can either be done as offline yarn lubrication: manual or mechanical soaking (spraying the yarn packages or brushing the lubricant onto the abutting face of the yarn packages before the twisting process) or inline yarn lubrication: automatic addition of lubricant to the thread as it passes through the twisting machine. Inline yarn lubrication has numerous advantages, and for this reason it is constantly becoming more significant. There are different types of lubricant and lubrication systems. The minimum application quantity is dependent on the lubricant and yarn type. For delicate yarn types (yarns that contain low-pill polyester) the application quantity needs to be higher than for non-delicate yarn types.

Yarn make-up For the purpose of further processing or packaging. Make-up forms: →: Bobbins; Pirn; Warp beam; Cop; Package; Yarn package; Winding; Skeins; Hank; Bundle pack.

Yarn mercerizing → Mercerizing plays an important part in the pre-treatment of yarn. Yarns are mercerized continuously in hank form (Fig. 1) or as a continuous run of yarn. For yarns in hank form the following method is still in use in some cases: yarn is soaked in caustic soda solution 25–50°Bé (at 10–20°C), it is squeezed off and tensioned to the original length. Washing takes place under tension. This type of finishing is wrongly known as tension-free mercerizing. Lye treatment of the tensioned yarns is more important. Here there are two types of mercerizing – raw yarn

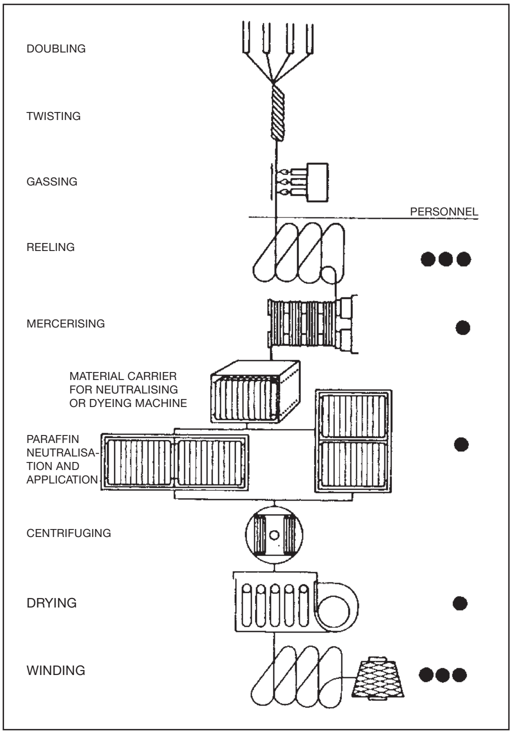

Fig. 1: Yarn finishing for knitwear fabrics before knitting.

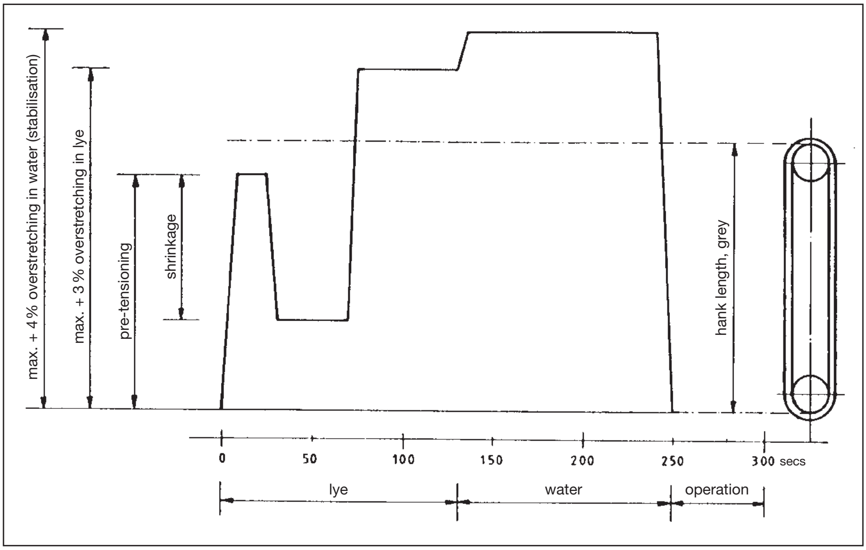

Fig. 2: Hank length change during yarn mercerizing and stabilization.

mercerizing (dry mercerizing) and boiled yarn mercerizing (wet mercerizing). With the first type, a wetting agent, often known as a “mercerizing booster”, has to be added to the lye, to achieve even penetration of the dry yarn.

One disadvantage of dry mercerizing is that the lye becomes soiled quickly. In wet mercerizing, the yarn has been boiled and spun but is still damp when it enters the lye. The same effect is achieved in both processes. The principal component of a yarn mercerizing machine is the pair of rollers used as a yarn carrier, each with one fixed rotating roller and one tensioning roller, which can be positioned at the required interval from the fixed roller by means of a weighted lever or hydraulic pressure, so that the yarn can be tensioned (Fig. 2) and shrinking can be prevented. There is a third roller positioned against the fixed roller, which acts as a squeezing roller to squeeze off most of the lye (Fig. 3). Smaller machines have 1 or 2 pairs of rollers like this; larger ones have 6–8 pairs arranged around a common axis. On modern machines, such as the Neutromercer (Kleinewefers-Jaeggli), the cotton yarn is not only rinsed, but also treated with acid at the end. The Jaeggli-Meccanotessile hank yarn mercerizing machine is charged with the yarn hanks via two metal sheets, which pull it up onto the two treatment rollers that are each situated on one side. During charging the roller pairs are arranged vertically, and they move back to a horizontal position for treatment, where mercerizing takes place under tension. The roller pairs fold into a vertical position again to remove the hanks, where the metal sheets come into action for removal in the same way as for charging. It is quite clear that with this machine, automation offers protection from potentially hazardous handling of caustic soda solution; the staff are only required to operate the charging/removal sheets.

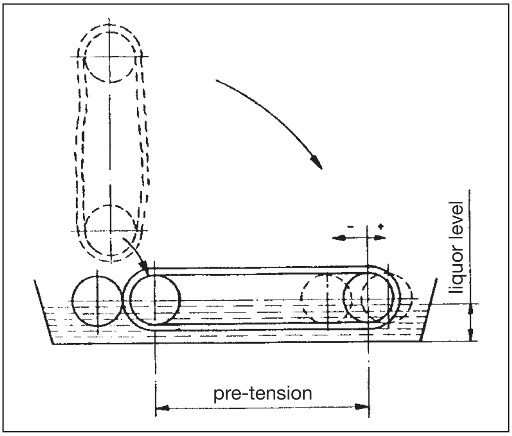

Fig. 3: Swinging the tensioning rollers into the operating position or the pre-tension position during yarn mercerizing.

The tension ratio of the yarn during mercerizing is important; the tension has an influence on the orientation of the cellulose crystallites or their size. As the tension increases, the strength increases up to a maximum point, and the elongation reduces. The lustre and handle of the mercerized yarn is further improved after drying by beating the hanks hard by hand on the wringing post or mechanically using a stretching machine. Cotton yarns are primarily mercerized for use in the knitgoods industry.

It is expensive to unwind yarn from cones into

hanks and back onto cones after mercerizing. Cost savings can be achieved by using large hanks (800 g instead of 300–400 g), which can be manufactured on special winch machines. Some systems also mercerize a continuous thread (Fig. 4). A large number of parallel threads run through machines in a similar way to the mercerization of woven fabrics (warp-free system). In the Prograde process, individual threads are treated with liquid ammonia (Fig. 5).

Yarn number systems → Linear density of fibres and yarns.

Yarn package,

I. Piece make-up: piece goods wound onto a yarn package carrier (→ Batching roller).

II. Yarn make-up: → Package where the support (spindle or insert) is removed when the process is finished, a yarn spool or winding structure without an insert.

Other winding forms for commercial purposes are clews or skeins (for crochet, knitting and embroidery yarns), reels (for sewing silk) and other winding structure for wide-wound yarns (DIN/ISO 5248).

Yarn packages in dyeing When dyeing yarn on packages, the type and quality of winding, but also the package and insert system, have a particular influence on the quality of dyeing. Conical yarn inserts continue to be used widely even though they have some disadvantages in comparison with modern cylindrical insert systems:

- uneven package flow,
- insert/spacer leaking,
- low batch weight,
- unfavourable liquor ratio,
- high personnel costs for loading and unloading the carrier,
- unsuitable environment for using robots for loading and unloading.

The reason behind the uneven flow in conical yarn packages is to do with the varying radii of the insert between the tip and base of the cone. On one hand the radial liquor flow reduces as the internal diameter becomes smaller, and on the other hand the conical form causes

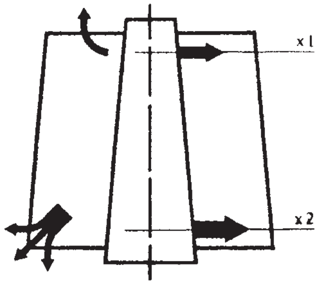

Fig. 1: Liquor flow through conical yarn packages.

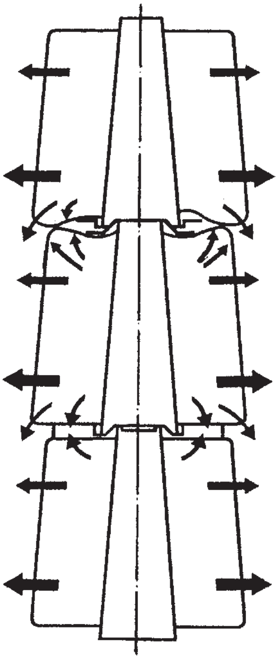

Fig. 2: Liquor flow in a cone column, with (top) and without star spacers.

differences in the winding density, because the winding speed and thread tension at the base of the cone are greater due to the larger circumference than at the tip of the cone (Fig. 1).

As a result, the dye and chemical supply for the fibres is uneven, which can lead to problems with evenness, particularly at the edges. A further problem, if conical dye tubes are used, is liquor wastage. One way in which liquor is wasted is as a result of axial flow within the yarn package, where the liquor leaks out through the abutting surfaces of the package and is lost. It is also caused by leakages at the spacers and column seals (Fig. 2). Liquor wastage can total over 50%.

Further disadvantages of dyeing conical yarn packages are handling and the strain on the system. First, all the packages have to be chamfered to reduce the hazard of liquor loss at the edges. When loading and unloading a dyeing machine, each dyeing column must be constructed and dismantled with packages and spacers. This takes time and is awkward. Conical yarn packages cannot be compressed. This situation, in combination with the relatively low weights of the packages, reduces the optimum utilization capacity of the machine, as well as the financial viability.

A conical yarn package (Fig. 3) is defined by:

- radii,
- overall volume,
- winding density.

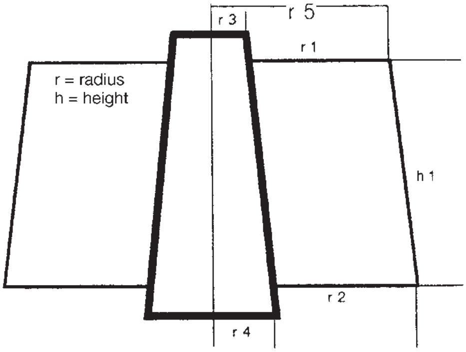

Fig. 3: Build-up of a conical yarn package.

Calculation of package radius:
$(r_1 + r_2) : 2 + (r_3 + r_4) : 2 = \text{radius } r_5$

Calculation of volume:
$r_5^2 \cdot \pi \cdot hl = V_{total}$ (total volume of yarn with insert)

$[(r_3 + r_4) : 2]^2 \cdot \pi \cdot hl = V_{insert}$ (volume of inserts).

$V_{total} - V_{inserts} = V_{yarn}$ (net yarn volume).

Calculation of density:
Weight of package with insert – insert = net yarn weight.

Weight (net in kg) : volume (net in cm^3) = density g/cm^3.

Conical yarn packages have so-called “dead zones”, where liquor shortages can occur as a result of the package shape (Fig. 4). In order to achieve a more even supply of liquor at the peripheral areas of the package, and therefore reduce or eliminate the hazard of uneven dyeing, packages of this type need to be chamfered (Fig. 5).

Because cylindrical dye tubes are symmetrical in shape, a more even distribution of winding density can

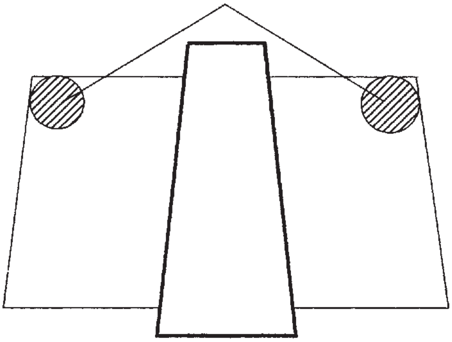

Fig. 4: “Dead zones“ in a cone.

Yarn packages in dyeing

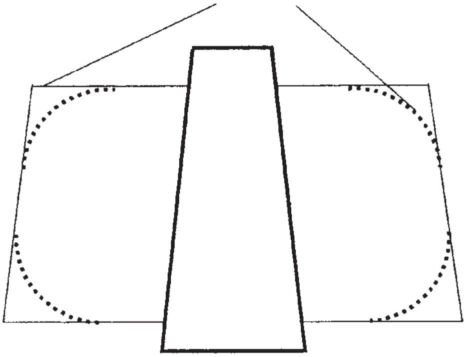

Fig. 5: Conical yarn package before and after chamfering.

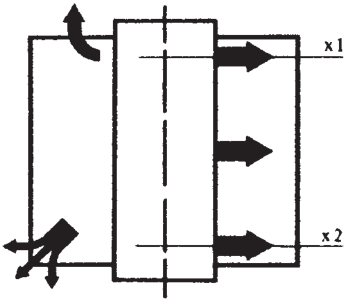

Fig. 6: Pressure distribution in a cylindrical yarn package.

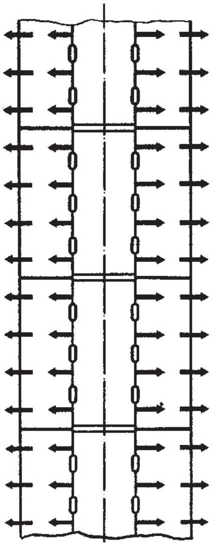

Fig. 7: Compressed dyeing columns made up of cylindrical yarn packages.

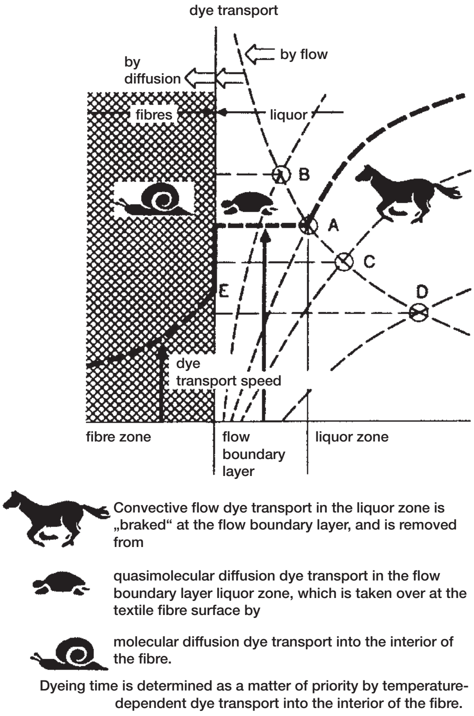

Convective flow dye transport in the liquor zone is „braked“ at the flow boundary layer, and is removed from

quasimolecular diffusion dye transport in the flow boundary layer liquor zone, which is taken over at the textile fibre surface by

molecular diffusion dye transport into the interior of the fibre.

Dyeing time is determined as a matter of priority by temperature-dependent dye transport into the interior of the fibre.

Fig. 8: Dyeing kinetics in yarn dyeing after Kretschmer (didactically reduced).

be achieved when winding onto packages, and for this reason better liquor flow can be achieved than when using conical dye tubes (Fig. 6).

Telescopic cylindrical inserts provide the opportunity to compress this type of package on the dyeing column. Several advantages are associated with this:

- no liquor wastage through the abutting surfaces of the package or leakage between packages,
- higher batch weights, more favourable liquor ratios,
- overall better utilization of the machine,
- the use of modern handling systems is possible.

A compressed column of cylindrical yarn packages is theoretically a homogeneous structure, which behaves in the same way as a warp beam for the purpose of dyeing. The flow resistance is theoretically almost the same at all points, and the flow direction is almost exclusively radial (Fig. 7).

Dyeing kinetics: a package constitutes a large fibre surface area that has to be supplied with dye evenly from the aqueous liquor. For this reason, transport of the dye flowing through a yarn package is of great significance for even dyeing. The quality-related context of dye transport is explained in Fig. 8.

In the “galloping horse” area, the dye is transported through the liquor to overflow and at high speed. As a result of the friction at the fibre surface, this speed is reduced greatly until it drops to a much lower velocity, which is quasim… molecular diffusion dye transport in the liquor area denoted by the tortoise. The thickness of this flow boundary film is dependent on the speed of the liquor flowing through the fibre and the speed of the diffusion substance flow. The greater the liquor flow and the diffusion substance flow, the thinner the flow boundary film, which ultimately results in a more rapid dye transport. In the “snail” fibre area, the dye is transported with molecular diffusion substance flow. This speed is significantly lower than in the previous zones, and can not be influenced by the flow velocity. For this reason the dyeing time is primarily dependent on the speed of the molecular diffusion substance flow, which increases disproportionately in line with temperature, because the kinematic viscosity of the liquor becomes lower. Even dyeing of the fibre can only occur if the quantity of dye being transported through the flow boundary film is exactly the same size as the quantity that diffuses into the fibre.

When yarn packages are being dyed there are great differences in liquor supply in some areas of the package. The areas near to the dye tube are subjected to abundant liquor flow and dye, however, often only a fraction of this quantity of liquor is available to the edge areas. Fig. 9 shows an example of synthetic fibre dyeing under idealized conditions, the external and internal dye distribution with respect to the fibre as well as the liquor.

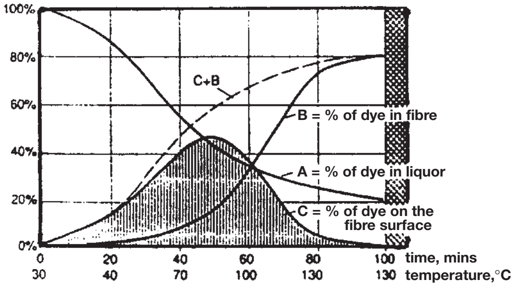

Fig. 9: Dye distribution in fibre and liquor.

The curves A and B represent the dye uptake properties. The A curve relates to the time/temperature-related reduction in dye concentration, curve B relates to the simultaneous dye absorption by the fibre. Curve C reflects the extent of dye absorption at the fibre surface. In principle this curve is not useable, because the parameters represented are not practical or possible to record in the experiment. Surplus liquor is absolutely necessary to ensure even dyeing with even shade depth where flow of a yarn package occurs convectively. It also serves as a buffer by compensating or alleviating the unevenness between the flow-dependent and temperature-dependent transport of dye, with the aim of achieving even dyeing of the yarn package.

Modern winding machines are mostly automated, so that yarn packages with the same dimensions and weight can be manufactured. However, even with optimum adaptation to the substrate it is not possible to avoid differences in winding density. In practice, differences in winding densities of 5–8% are considered quite normal if the conditions relevant for yarn processing are fulfilled, such as good running properties, guaranteed thread reserve, and minimal loss equality in yarn length. In yarn dyeing, up to 10% differences in winding density within a batch have to be taken into account with the same yarn substrate, fineness and package shape. However, in practice it can not be assumed that the radial winding density in yarn packages is evenly distributed. In the area near the dye tube the density is often 30–50% higher than in the outer layers, because the tensile forces in the yarn during winding cause radial compression. Compression is necessary because the shape retention properties of the yarn package are higher than the friction coupling actuated by adherence in the yarn at the crossing points, of which a standard yarn package has approx. 10–20 million. If the liquor flows through the yarn package, it breaks up the friction coupling at the yarn crossing points, causing the layers of yarn near to the insert to be sealed even more efficiently. The auxiliaries necessary for dyeing can increase this effect further because of their consistency, which has anti-friction properties. A further reason can be found in the shear forces generated by the liquor flow on the fibre surface. These cause additional radial pressure in the zone nearest the insert and therefore pressure forces and sealing, which occur particularly when the liquor direction changes. The differences in winding density resulting from these causes can not be prevented or noticeably reduced with today’s state of yarn package technology, as long as the current type of yarn package system is dyed.

Since radial differences in winding density in yarn packages cannot be eliminated, it poses the question as to how such differences will affect the dyeing properties and final result. To establish this, the relationship between liquor throughput, differential pressure and shear stress in a yarn package that is subject to radial flow needs to be investigated. The liquor throughput volume of a dyeing machine is usually measured in the supply pipe to the dyeing vat, showing the quantity of liquor in litres. Differential pressure is caused when the yarn packages create resistance to the liquor, which is being supplied by a pump, and the resistance causes build-up pressure between the pump and the yarn being dyed. With differential pressure, the pressure behind and in front of the yarn is measured and indicated. The resistance of the yarn winder is caused by the so-called shear stress, which is generated by the friction from the liquor flowing past the fibre surface. The differential pressure displayed on the manometer is therefore a measurement of the (liquid) friction in the package loading and therefore for the shear stress, which is a significant factor in the transport of dye to the package surface.

Kretschmer carried out extensive tests on the mathematical connection between radial winding density, differential pressure and shear stress, and he came to the conclusion that yarn dyeing batches with varying winding densities or heights at the same differential pressure have different levels of liquor flow. Fig. 10 elucidates this statement. The numeric values relate to cylindrical cotton packages, however the general conclusions can also be applied to other substrates and package types. Fig. 10 shows how great the liquor flow difference is when dyeing takes place at the same differential pressure with varying densities (top and middle of package) and volumes (top and bottom). However, the shear stress τ_U is a more important factor for even dyeing, because in principle this parameter reflects the conditions of dye transport. The values recorded were practically identical.

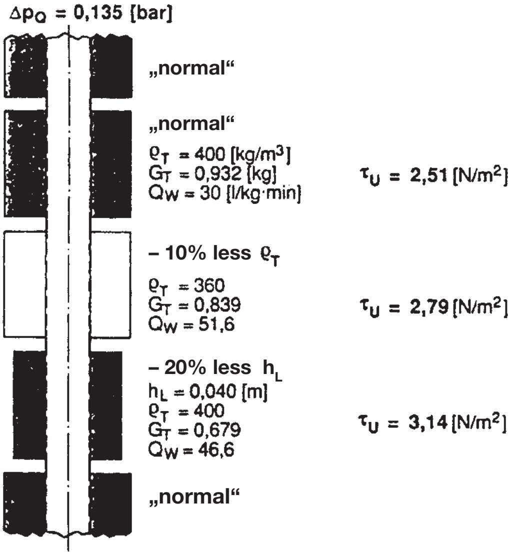

Fig. 10: Effects of different winding densities and winding heights.
Δp_Q = differential pressure in bar; ρ_T = density in kg/m^3; G_T = weight in kg; Q_W = liquor quantity flowing through in l/kg/min; τ_U = dye transport conditions in N/m^2 (shear stress); h_L = winding height in m.

Further experiments were carried out in the different winding zones to provide more information regarding the relationships between winding density, differential pressure and shear stress in yarn package dyeing. The experiments prove the theoretical assumptions that the winding density increases in the area adjacent to the dye tube. The differential pressure and therefore the shear stress in the inner layers are of more significance in yarn dyeing. Only 16.5% of the package weight causes 62% of the differential pressure and 75% of the shear forces. In the area near to the dye tube, it can be said that there is an “over-supply” of dye in relation to the shear forces. In the zones away from the dye tube in a package, shear stress and differential pressure are low, so that an “under-supply” of dye would occur if dye transport to the fibre surface were slower than the diffusion dye transport into the fibre. This type of effect is accentuated in practice by inconvenient package shapes (e.g. conical dye tubes) and the associated liquor wastage via the abutting surfaces, spacers and column seals.

Air flow measurements are used to record the increase in winding density of a yarn package as a result of pretreatment, compression and dyeing. To do this, a package is measured before and after pretreatment or dyeing. Essential conditions for this are that the packages are of equal weight, or identical in their dry state, as well as constant differential pressure and the same amount of air in the measuring gauge. Flow resistance measurements on yarn packages are carried out using a modified textile meter usually used for woven fabrics, designed by Kretschmer. The measured values are shown in 0.1 s. The suction aperture of the textile meter is uncovered when the fabric tensioning device is uninstalled. A conical rubber ring creates an airtight link

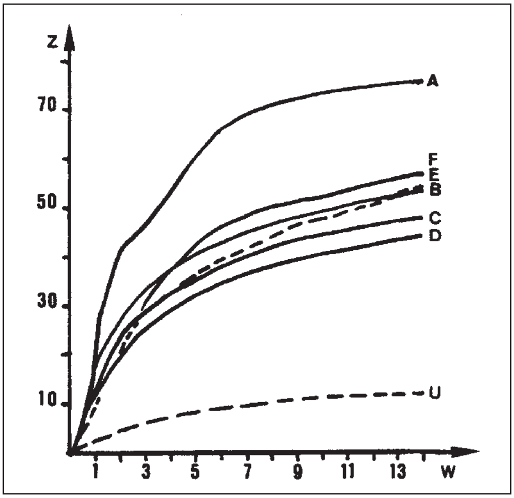

Fig. 11: Flow through profile (ordinate Z = time in s in order to suck 1 l of air through a yarn package; abscissa W = winding zone) of 6 compressed yarn packages (see Fig. 12) from a compression column (A–F) as compared with an uncompressed yarn package (U).

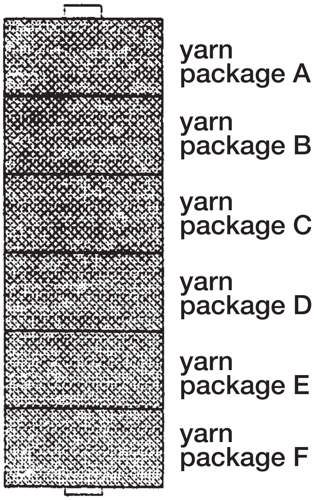

Fig. 12: Structure of a compression column (see Fig. 11).

between the base of the package insert and the suction aperture; the top of the insert is sealed with a standard rubber stopper. All points of connection must be greased before assembly to ensure the maximum possible seal quality. The textile meter is designed to compare the measured values with each other, e.g. to identify flow differences within a package batch before or after dyeing. However air flow measurement does not provide any conclusive evidence relating to the flow properties of water through the yarn packages, since its physical properties are different.

It has been established (Fig. 11) that neither the differences in winding density within the package column or within the individual yarn packages are balanced; the compression process can only even out variations in density at the edges and abutting surfaces of the package. The density of the other zones in the package, e.g. the winding zones adjacent to the insert, is increased by means of axial compression, but not balanced. It is noticeable that the first and last package in the column (Fig. 12, packages A and F) have the highest winding density for all types of insert system. The packages in the middle were subjected to a lesser degree of pressure; as a result they have lower winding densities. This can be explained by the fact that the package column is subjected to the highest pressure from the package compression device from above and beneath. The pressure drops towards the middle of the column. However if the package level of the middle packages is considered (packages B to E) after the compression or fixing process, it can be seen in almost all cases that it is lower compared with the top or bottom package.

Yarn packages, preparation The processing of yarn cops into yarn packages. The essential purpose of a yarn package winding machine is to ensure that the yarn package is calibrated from the point of view of density, shape and weight, as well as to the machines and processes for the subsequent finishing phases, so that production is guaranteed. Perforated → Dye tubes are used as a yarn carrier, usually made of plastic, either disposable or re-usable, and either conical or cylindrical in shape (Fig. 2: on axialy flexible inserts). There are two different winding methods, random winding and precision winding (Fig. 1).

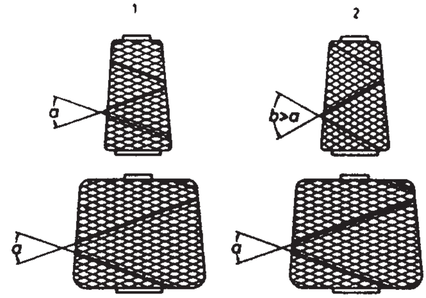

Fig. 1: Yarn package winding systems: 1 = random winding; 2 = precision winding.

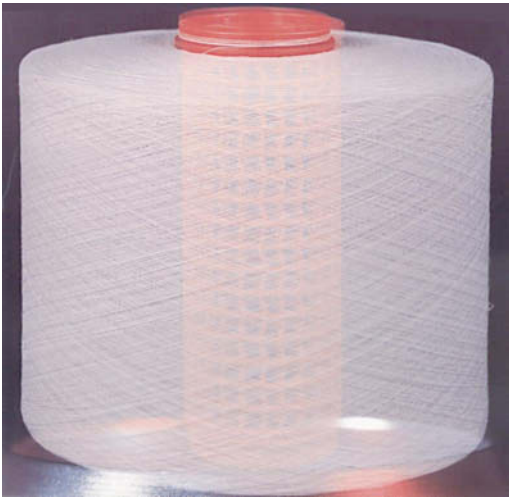

Fig. 2: Cylindrical yarn package with axially flexible dyeing tube.

1. In random winding, the thread cross-over angle is almost identical in all zones of the package. Thread guiding in this type of winding is done by a grooved drum, which also drives the package. In random winding, the package density can essentially only be influenced by the tracking force exerted by the package on the grooved drum and the thread tension. It is

not possible to control these settings automatically during the winding process. For this reason it is also not possible to achieve an even winding density on the whole package. The yarn turning points must not be exactly on top of each other to ensure that the edges are softer. For this reason most winding machines have a device for edge displacement, which displaces the yarn turning points by means of an oscillating axial movement of the packages.

2. In precision winding, the yarn is controlled by a thread guider. When yarn is wound onto a dye tube, the cross-over angle of the yarn reduces as the diameter of the package increases, and the winding density in the area adjacent to the dye tube is lower for instance than is the case with random winding, and for this reason provides ideal liquor throughflow conditions during dyeing. Furthermore, the overall package density can be increased using this winding technique, which means that a higher yarn weight per package is possible, thereby improving the economic viability of the dyeing machine.

The most up-to-date systems that use the precision winding method, e.g. the Schweiter Digicone system and the Schlafhorst Digipac system, use a thread guide that can be controlled. This technique enables a package to be manufactured that has identical yarn cross-over angles, even winding density and optimized dyeing qualities. In spinning, the objective is always to reduce the manufacturing costs of yarn. One option is to increase the performance of the ring spinning machine. However there are limits to this because of the necessity to comply with regulations. Another possibility is to introduce automation into the production process. An example of that is a combination system consisting of a ring spinning machine and an automatic winder.

This combi system has several significant advantages:

- faster yarn throughput without the danger of confusion or the necessity of manual transport,
- interim storage, containers and trolleys for cops are not necessary; there is a reduced requirement for dye tubes,
- personnel costs and spatial requirements per kg of yarn produced are lowered,
- the use of long ring spinning machines with automatic stripping provides ideal conditions for processing small cop formats that were previously uneconomical.

Since most of the machines in current use are not suitable for the ring spinning machine/winding machine combination, the combination system is primarily reserved for new investments. If this system is used, there are several consequences that should be taken into account:

- the climate for spinning and winding can not be adjusted separately for the two process phases in combination;
- the cops need to be wound without any down time and without steaming;
- since there is no interim storage for the cops, the yarn must be available from the ring spinning machine;
- as the dye tubes are running continuously, i.e. they circulate at short intervals, they need to be of good quality;
- the building needs to have enough available space for the long machine combination.

Yarn package winding machines Automatic yarn package winding takes on an important function in the textile production process. A package must be properly wound in order to be suitable for productivity in subsequent stages, whether for twisting, warping, weaving or knitting. “Quality packages” reduce the frequency of out-time and avoid errors.

A modern package winding machine for manufacturing yarn packages is described as follows, using the Schlafhorst Autoconer 238 as an example. There is a splicer at each winding point. The periods of time required for the breaking and splicing during splicing are set by input into the central control system (M.I.C.). Automatic splicing means that the thread ends can be severed cleanly and a good overlap in the splicing zone can be achieved, which means that the splice connections are slim and almost level with the yarn, which contributes towards increased yarn strength. The splice connections on each package are controlled by an electronic cleaning unit, located in the thread path above the splicer. There is also an option of stopping the yarn package with a switch to carry out a manual check.

A separately controlled waxing device ensures even wax application independent of the height and weight of the paraffin roller. If the waxing device is situated above the cleaning unit, it is not possible for paraffin to be deposited in the measuring field of the cleaning unit.

At the start of the winding point (see Fig.), a frequency controlled motor ensures that the thread guiding drum starts smoothly and is gentle on the yarn, and does not slip through under the yarn package, whether the package diameter is small or large or whether a high or low winding speed is used. This avoids the occurrence of randomly wound layers.

Electronic ribboning prevention is adjusted to suit the yarn package conditions in each case, i.e. it is automatically adjusted to the diameter of each package. The required intensity can be programmed into the controller centrally from the winding points and machine. Ribboning prevention is generated by periodically switching the motor at each winding point on and off. The standard version of this winding machine also incorporates edge displacement to avoid hard edges. The motor changes its direction of rotation in order to pick up the upper thread with a suction jet, and rotates the thread guide drum and yarn package backwards at varying

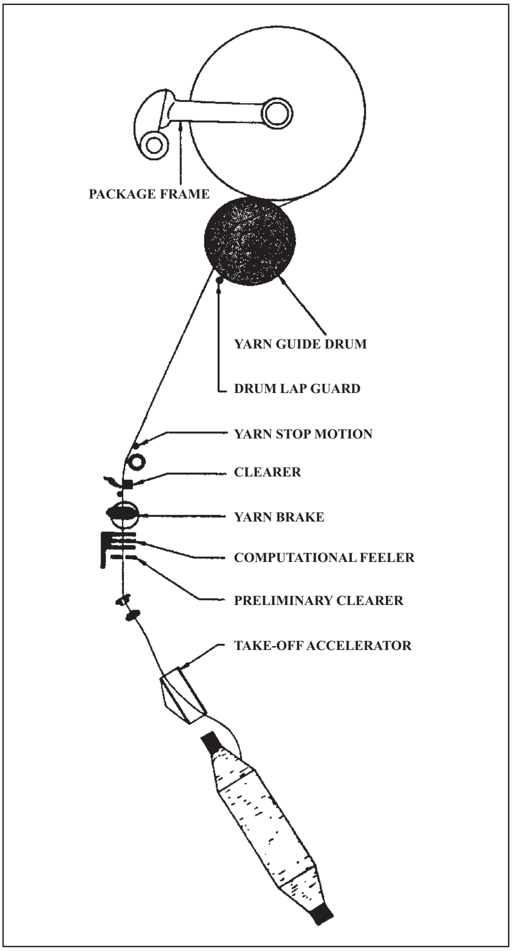

Fig.: Winding position (Schlafhorst).

speeds depending on the diameter of the yarn package. The thread end on the yarn package is presented at least twice during the search process while the suction jet is travelling backwards, which reduces malfunctions.

Another variant is the Autoconer-Dicopac, a fully automatic yarn package winding machine operating on the stage precision winding process. Dicopac is a joint development by the companies Schweiter and Schlafhorst based on the Schweiter Digicone. In this system, as with random winding, the yarn package is powered by means of friction around its circumference. The winding ratio is changed by layer rather than continuously as is the case with random winding, by controlling the movement of the thread guide. This ensures that each yarn layer is wound on the principle of precision winding. Winding is controlled by a microprocessor. The crossing angle changes only within narrow limits within each layer. It stays consistent across the whole package structure independent of the package diameter.

The Dicopac machine combines the advantages of random winding with those of precision winding. These are

- almost constant cross-over angle,
- constant, high winding density,
- even tensile thread strength,
- stable yarn package,
- no ribboning zones,
- precise thread laying,
- almost equal thread length per double hub.

These advantages result in

- high draw-off speeds,
- low level of thread breakages,
- good dyeing properties.

(according to Thomas).

Yarn polishing machine (yarn lustring or glossing machine) → Lustring.

Yarn preparations,

I. Making a preparation (demonstration object).

II. In the textile industry, preparation or → Spin finishes means substances or compounds that are intended to make subsequent fibre processing easier, e.g. scrooping, textile lubricants and spray oils. Fibres and yarns are treated with spin finishes to reduce friction resistance during the subsequent spinning, winding and twisting processes. The proportion of the product that adheres to the fibre or yarn surface is significant for subsequent processing. The proportion that diffuses into the fibre is no longer available in the form of a lubricant. When preparations are applied to a thread in continuous motion via dispensers, the level of application varies. These variations occurring all along the thread, which are frequently periodic, are superimposed by the free migration of the preparation in the package. As a result, the preparation is distributed non-homogeneously in an insular way. The way in which the distribution of the preparation could be changed is dependent on a range of parameters (chemical structure of the preparation, viscosity, wetting properties, package capillary system, etc.) (see Fig.).

Pre-oiling is a thread preparation for a low level of oil application. It is used when winding dyed yarns from the dye package to prevent dye deposits on the thread brake or other thread deflection points. Oligomer deposits are also bonded as a result of pre-oiling. When the thread balloon is touched with a porous sinter ceramic element situated between the feed spool and the thread insulation, the yarn takes up a small quantity of oil. The fixed sinter ceramic element is supplied with oil per machine or per field. Dry waxing is used primarily for spun knitting yarn, and occasionally also for weaving yarns. A yarn that has been waxed to the ideal friction coefficient of 0.13–0.15 μ guarantees trouble-free subsequent processing in knitting and weaving. As

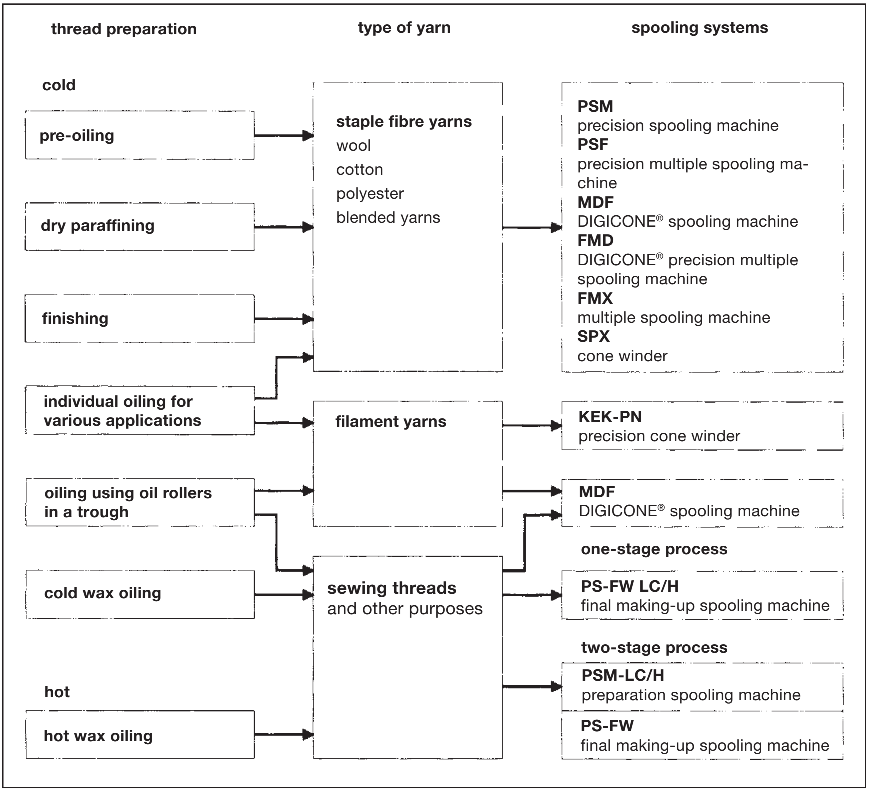

Fig.: Outline of the possibilities of thread preparation with regard to the various types of yarn and spooling systems (Schärer Schweiter Mettler).

well as improving the lubrication properties, dry waxing also results in a slight reduction in fly. Waxing rolls with different levels of hardness (melting point and penetration), as well as wax application that can be set to the optimum friction coefficient, mean that thread preparation can be adapted ideally for subsequent processing. The waxing device operates individually per spindle, and is normally located in the thread triangle between the thread insulation and the automatic batching spool.

For scrooping, yarn preparations with a low level of oil application are used (max. 1%) when winding staple fibre yarns onto flat bobbins. Scrooping using a powered oil application roller improves running properties in the twisting process and reduces fly. Furthermore soiling of the two-for-one spindle is reduced. The oil application roller is usually situated in the thread triangle between the insulation and the automatic batching spool, and is supplied with oil per machine or field.

Individual oiling for different purposes is a universal thread preparation with a powered oil roller for staple fibre yarns and filaments. There are various subsequent processes that require oiled yarn, e.g. twisting to prevent fly. If oiling is carried out individually, the required level of oil application can be controlled per spindle for each application area. The oil roller is driven per spindle and can be controlled individually with infinite variability via an interactive electronic control panel. Depending on machine type or field, the oil supply is from four spindles at a time.

To give filament yarns better running properties for further processing, they are oiled on different yarn winding machines by a powered oil roller (kiss roll), which is immersed in the preparation. The preparation liquid is in a trough that spans four spindles. In order to meter the precise quantity required for oil application, the revolution count of the oil roller can be varied infinitely. The trough is positioned between the feeder rollers and the thread insulation, with a moisture application roller per winding point. The reason for oiling sewing yarn is to achieve optimum lubrication properties to reduce the needle temperature and to reduce fibre crocking on the eye of the needle in industrial sewing machines.

For technical reasons, a variety of spin finishes are applied to the fibre during the course of wool processing. In the combing section, for instance, oils with variable ingredients are used before teasing and combing the scoured wool. Spin finishes are then applied again for worsted spinning. The composition of the residual fat on the surface of the wool, the lubricating oils applied and also any reaction products produced during processing are of great interest when trying to establish causes of quality faults during manufacture. When the residual fat is being extracted from the wool surface using organic solvents, the extract contains a complex mixture of spin finishes, native wool wax and internal lipids. Natural wool wax consists mainly of fatty alcohol and stearin esters with long chains. The rest consists of free and oxidized stearins, free alcohols, free fatty acids and hydrocarbons.

Yarn printing Yarn printing is done to cause certain fuzzy coloured patterns after weaving, knitting or tufting. For this technique, yarns are printed either in hank form (single shade/pearl printing, or multi-colour/ombré printing), or in warp form (→ Warp printing) or in knitted form (→ Space dyeing).

Yarn printing machine Parallel winched hanks are printed under tension with relief print rollers (→ Hank yarn printing machine).

Yarn raising A yarn raising machine is suitable for raising yarns for hand and machine knitting in the range Nm 20 and coarser. The raising process is carried out by raising rollers on individual threads (Fig. 1). The raising intensity can be altered by changing the speed and contact of the raising rollers, as well as by the selection of covering for the raising rollers. Raising rollers are available with pins, wires or brushes. The rollers are interchangeable with each other. The yarn is wound onto conical inserts using the random winding method. The thread being wound is displaced by a thread guide, providing ideal winding conditions.

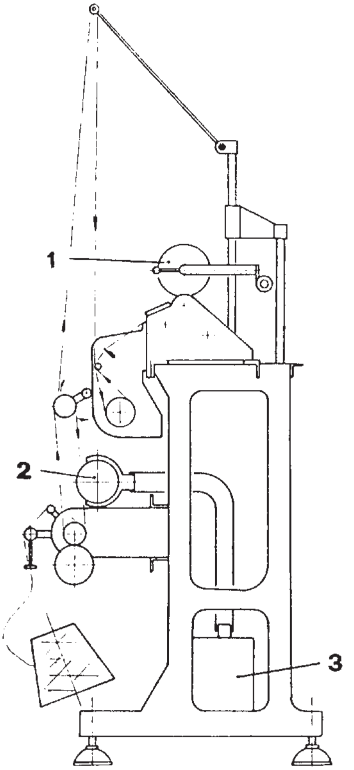

Fig. 1: Tangential raising roller contact with straight-running yarn .
1 = cone winding unit; 2 = raising unit; 3 = extraction.

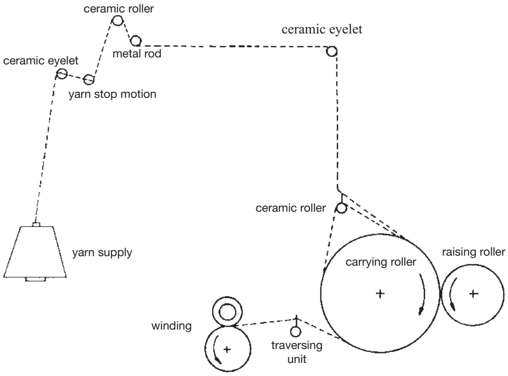

Fig. 2: Tangential raising roller contact with the yarn, which is running round a drum.

The yarn can loop one or several times around a central cylinder, against which the raising roller rotates rapidly at defined intervals (Fig. 2).

Yarn singeing machine → Gassing machines.

Yarn spray-dyeing machine → Spray-dyeing machine.

Yarn steamer → Batch steamers.

Yarn steaming Various forces arise in the yarn as a result of spinning and winding. These cause a certain instability in the yarn. In a free state, the yarn has the tendency to untwist or to form loops and snarls. To enable wool to be fixed, a minimum temperature of 90°C is required; synthetic fibres on the other hand require fixation temperatures of 110–140°C. It is only possible to overcome the problem posed by these differences in fixation temperatures for wool blend yarns due to the fact that wool is able to withstand higher fixation temperatures at a low pH without yellowing. Increasingly large packages are being produced on spinning and twisting frames. Crosswound yarn packages which are processed as weft yarn therefore need to be fixed well. Vapour penetration of wound yarn packages, type of steam, temperature accuracy and reproducibility of programmes have all become more significant in yarn steaming. Yarn fixation is generally carried out in pressure steam chambers with vacuum and excess pressure ranges. The steam is supplied either directly from the

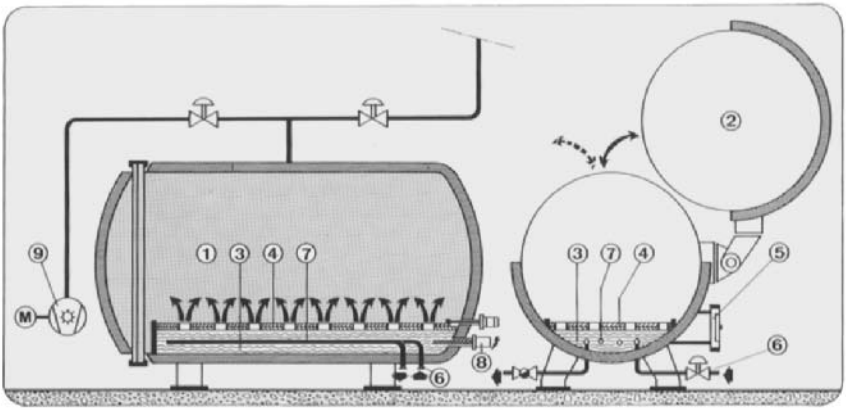

Fig. 1: Xorella yarn steamer (batch type) with water bath.
1 = steaming chamber; 2 = lid; 3 = water bath; 4 = water bath cover; 5 = level control; 6 = steam, hot water or heating oil; 7 = heater coil; 8 = electric heating; 9 = vacuum pump.

steam network or indirectly via an integrated water bath (Fig. 1).

The machines have automatic program control and charging the machines for either a one-way or continuous operation is also an automatic process (Fig. 2). The yarn make-up depends on the effect to be achieved. Textured yarns are fixed to achieve a high bulk with minimum tension. The treatment time depends primarily on the penetration of the yarn package. As the package size increases and the winding becomes denser and harder, the treatment time needs to be extended. The steam penetrates the yarn package at a variable rate from the surface inwards. If the yarn carriers are perforated or deformed, it can also penetrate from the side of the yarn carrier. An intermediate vacuum in the first third of the treatment time facilitates even penetration. An insufficiently long treatment time and varying package density result in widely varying properties along the fibre, which become very noticeable on further treatment.

Yarn twist → Twist of spun yarns.

Yb Chemical element for ytterbium (70).

Yeasts (saccharomycetes). Microbes which produce a mould film on the surface of liquids, causing the fermenting process. Occur as harmless → Saprophytes (→ Moulds), potentially pathogenic. Also present in perspiration.

Yellowing during wear This is caused by insufficient light-fastness, perspiration and urine, combined with the effects of dry cleaning and laundering due to auxiliary residues, including optical brightening agents which have been removed, insufficiently fixed, or have altered fastness properties, and are generally more visible after finishing treatments (ironing, pressing, mangling). For measuring techniques: the grey/whiteness measurement using whiteness measuring devices is not sufficient as deposits, which tend to be yellow to brown, play a significant part in the altered fabric appearance as "yellowing". It is true that grey with a blue cast appears more pleasing, "whiter" (optical brightening agent) to the eye than grey with a yellow cast with the same degree of greying. To be able to measure both greying and yellowing of a strip of test fabric, this is graded on a blue-grey-yellow scale: it is neutral grey if

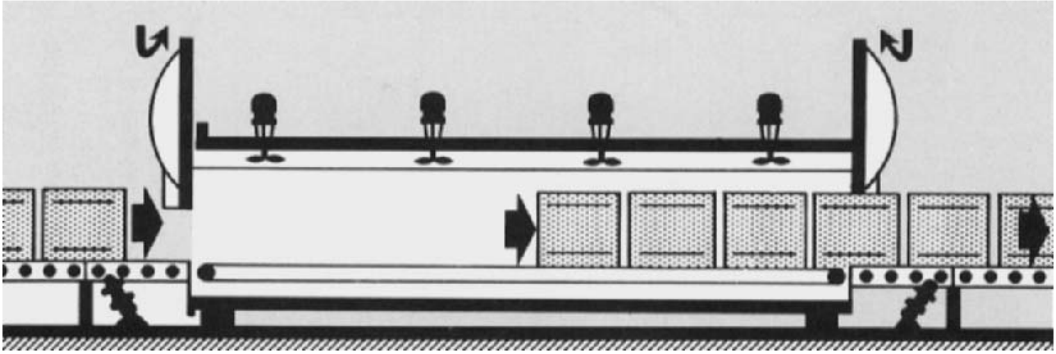

Fig. 2: Hemmer continuous yarn steamer for boxes of cops.

it reflects light of different wavelengths to an equal degree; i.e. it has a constant degree of whiteness when various filters are placed in front of it. The assessment scale is two-dimensional, reflecting breadth and depth. The “degree of yellowing” should be broad (a negative “degree of yellowing” would have a blue cast) and the “degree of greying” deep. Both values are measured by exchanging the filters. Green filter (G) = degree of whiteness; green filter minus blue filter (B) = “degree of yellowing”. Negative differential values (with blue cast) only tend to occur with optical brightening agents. It is the degree of yellowing, rather than the degree of greying in itself, which is crucial in assessing the final fabric appearance. Occurs in particular with woollen or silk goods. Optical brightening agents do not prevent yellowing, but tend to intensify the effect.

Yellowing of wool Environmental influences on fibrous materials include:

- solar radiation, artificial light sources etc. (→ Light exposure damage),
- temperature,
- oxygen,
- water (sorption water, water vapour, etc.),
- various harmful pollutants e.g. pollutant gases (ozone, nitrogen, sulphur oxide etc.), solvents.

These factors may occur in a wide range of combinations and at varying intensities and exert different effects on wool. The physical values of radiation and temperature represent key functions for the photochemical changes to the wool fibre (Tab. 1). By thermal exposure of wool, the extremely damaged scale structure of the fibres can be clearly identified. Wool samples tested were exposed for three cycles in accordance with DIN 75 202; this resulted in a loss of breaking strength of approx. 70%. Tab. 1 shows the distribution of the energy radiation of the sun and its effect on wool. Tab. 2 shows the surface temperatures measured.

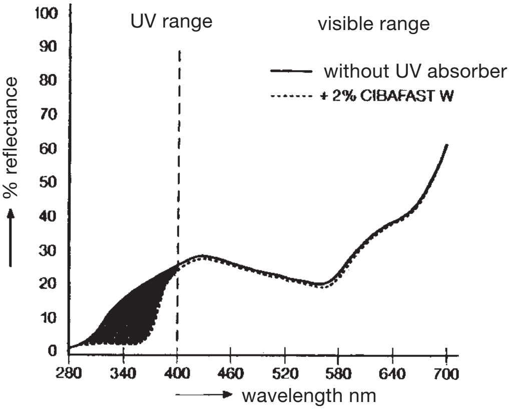

Fig. 1: Reflectance spectra of two identical wool dyeings with and without Cibafast W (Ciba Geigy).

When wool is exposed to radiation from the sun (or similar light sources in the spectrum), two apparently opposite processes can be observed: wavelengths of between approx. 280–400 nm result in yellowing and fibre degradation, whereby the short-wave, higher-energy portion of 280–330 nm (blocked by window glass) has a significantly more damaging effect than the range of approx. 330–400 nm (Fig. 1). The range of approx. 400–460 nm has a photo-bleaching effect, on the other hand. When wet wool is exposed to radiation, photo-bleaching and photo-yellowing is accelerated. With finished wool, there is not only a change to the absorption of solar radiation in the visible range – depending on the dyestuff, optical brightener etc., the same occurs in the UV and IR range. Heat alone tends primarily to have a yellowing effect on wool; fibre degradation is low.

In practice, wool tends to be dyed, and its absorption spectrum for radiation is therefore altered to a

wavelength [nm]	intensity of irradiation [W/m^2]		proportion [%]		range	effect on wool
< 280	0		0		ultra-violet	
280– 320	5	68	0,5	6,1		**photochemical effect**

1000–1400	173		15,5			
1400–3000	143		12,7			**thermal effect**

Tab. 1: Strength of vertical incidence global radiation and its effect on wool (radiation varies according to location, time, weather and thickness and composition of the atmosphere etc.).

flat woven wool fabric (dyeings with metal complex dyes)	undyed	bright yellow (1/20 RT)	yellow (1/1 RT)	bright bordeaux (1/20 RT)	bordeaux (1/1 RT)	navy	beige (0.1 % dye)	dark brown (3.3 % dye)
surface temperature	38.8°C	40.2°C	49.2°C	41.7°C	51.9°C	58.5°C	44°C	51.5°C

Tab. 2: Surface temperature of variously dyed flat woven fabrics measured in the open air in sunshine (non-contact measurement, double layers, outside temperature 34.5°C). RT = standard depth.

greater or lesser extent. Tab. 2 gives temperatures which have been measured on woollen fabrics which have been dyed with various metal-complex dyes. These differences in temperature are caused by the altered radiation absorption of the fabrics in particular in the visible, longer wavelength range and near-infrared. Heat accelerates the photochemical degradation processes of wool. This fact should be noted e.g. when using these fibres in cars.

The mechanisms and chromophores arising in connection to photochemical yellowing and fibre degradation are largely unknown. The amino acid analyses of

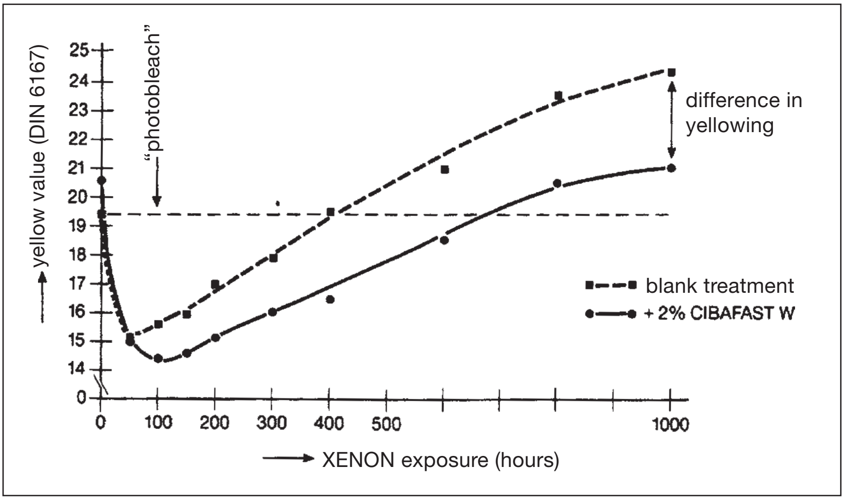

Fig. 2: Change in the basic white of wool on exposure in accordance with SN-ISO 105-B02 (xenon) which contained no Cibafast W (Ciba Geigy) or contained 2%. The yellow values were calculated in accordance with DIN 6167 [woven serge fabric blank treated by the Lanaset process (Ciba Geigy)].

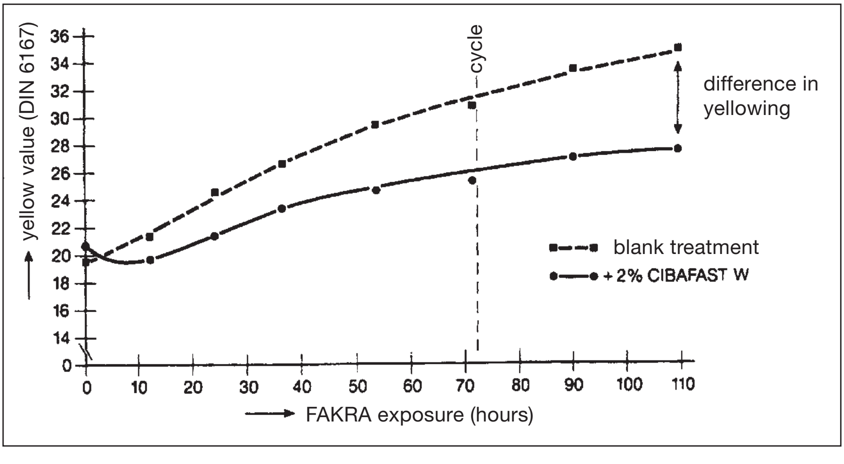

Fig. 3: Change in basic white of wool on hot exposure in accordance with DIN 75 202 (FAKRA) which contained no Cibafast W (Ciba Geigy) or contained 2%. The yellow values were calculated in accordance with DIN 6167 [woven serge fabric blank treated by the Lanaset process (Ciba Geigy)].

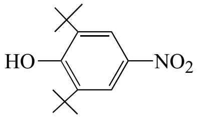
carefully irradiated wools demonstrate characteristic changes in the cases of the amino acids tryptophane, tyrosine, histidine, cystine and methionine. Stronger irradiation causes almost all amino acids to deteriorate. Numerous mechanisms are known in relation to photochemical yellowing: on the one hand, reactions of the amino acids altered on radiation, and on the other the occurrence of ketone compounds, double bonds or reactions in non-protein areas.

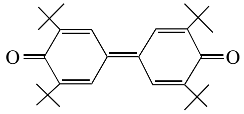
The aim of protecting wool against the negative effects of light, in particular against yellowing, i.e. improving the light-fastness of wool and its dyes in the UV-range (Fig. 2) has been achieved by means of a UV-absorber of the o-hydroxy-phenyl-benzotriazole type (Fig. 3) (according to Reimert).

Yellowing on storage In the wide majority of cases of white goods yellowing on storage, three yellow components were found. These yellow components occurred individually, but also in varying blending ratios. These yellow components have been identified as one nitrophenol derivative and two quinone compounds.



compound I
2.6-di-tert.butyl-4-nitrophenol

This yellow body forms easily due to the effect of nitrogen oxides on the sterically hindered phenol 2,6 di-tert.butyl-4-nitrophenol. The formation of compound I is also possible if there is a substituent in p-position, however.



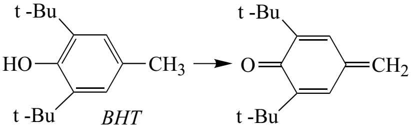
compound II
3.3‘.5.5‘-tetra-tert.butyl-4.4‘-diphenoquione

Compound II is formed on oxidation of compound I with potassium hexacyanoferrat in a caustic alkaline solution and also under mild reaction conditions. This formation of II from I explains the fact that when testing incidences of yellowing, compounds I and II are repeatedly found side by side.

Identifying the yellowing products also led to insight into the reaction mechanism of yellowing on storage. According to this, yellowing which occurs when ultra-white or pastel-coloured textiles are stored is due to reaction products in the storage atmosphere in the majority of cases (nitration and/or oxidation) with sterically hindered phenols. This reaction mechanism is not only limited to sterically hindered phenols – it naturally also applies to other phenols. Seen from a purely theoretical point of view, other phenols could therefore possibly cause the formation of yellowing components on textiles.

Oxidation of sterically hindered or other phenols is known and has been investigated in depth. Sterically hindered phenols are widespread as anti-oxidants and anti-agers and may therefore cause a yellow cast on textiles through packaging materials such as foils or rubber threads which come into contact with textiles.

One phenol compound often used as an anti-oxidant for polyethylene foil is sterically hindered 2,6-di-tert.butyl-4-methylphenol, generally known as “butylated hydroxytoluene” or “BHT”.



While it would appear sensible to regard BHT as an intermediate product in the formation of stilbene quinone due to its low stability, it is extremely surprising that it has been possible to isolate this compound from garments which have yellowed on storage.

To clarify why only the polyester sewing thread yellowed on storage, rather than a made-up garment, it has been assumed that the sewability improver on the sewing thread is much more likely to be capable of absorbing and retaining volatile phenol compounds than the base fabric which had no final finishing. The phenol compounds therefore yellow due to the effect of nitrogen oxide in the atmosphere.

Rinsed yarns and polyester fabrics finished with neither oils nor softeners absorbed little nitrophenol in the test, whereas yarns with slipping properties absorbed sufficient nitrophenol to become clearly yellow. This is an exact reproduction of what happens when phenol yellowing occurs on storage.

Various measures to reduce the risk of phenol yellowing to a minimum include:

- Finishing the textiles in an acid medium with a non-volatile acid such as citric acid, as the presence of alkalis constitutes an additional factor to convert BHT to stilbene quinone.
- Using top quality phenol-free cardboard boxes or recyclable synthetic packaging.
- Minimising the nitrogen oxide content in the storage rooms.
- Ensuring that any packaging materials coming into direct contact with the textiles do not contain any volatile phenol anti-oxidants and that no nitrogen oxides and phenol compounds could affect them.

– Wherever possible, working with finishing agents which have minimal affinity for volatile phenol compounds.

Yellow prussiate of potash → Potassium hexacyanoferrat (II).

Yellow weed Mordant dye. → Natural dyes.

Yield Yield, pure substance content, output, efficiency rate. Raw sheep's wool yield = pure wool content after removal of wool grease, suint and contaminants. Spinning yield = fibre yield from spinning.

Y-machine Drum washing machine with a → Y partition.

Young's equation When a fibre surface is wetted with a liquid droplet, Young's equation applies:

$$\gamma_S - \gamma_{SL} = \gamma_L \cdot \cos\theta$$

γ_S = surface tension of the solid (fibre),
γ_{SL} = surface tension between the solid and liquid,
γ_L = surface tension of the liquid,
θ = wetting angle.

Where the liquid is water and a surfactant is dissolved in this, γ_L and γ_{SL} are reduced by the adsorption of the surfactant, while γ_S remains unaffected. It can be inferred from the equation that the wetting angle is consequently reduced. This can result in $\theta = 0$ and the liquid may therefore spread spontaneously across the surface. →: Surface-active compounds; Wetting.

Young's modulus This is used to characterise the elasticity of fibres. Gradient of the tangents on the stress-strain curve through its origin (approx. elasticity modulus).

If the stress-strain curve of a glass fibre is observed compared to other fibres (see Fig.), the linear gradient of the measuring curve can be identified until the point at which the fibre breaks. The fibre has a high initial modulus, which accounts for the stiffness of components manufactured from this, but has virtually no permanent elongation.

Y partition Type of → Drum partitions in the form of a three-section inner drum with three chambers in the drum cross-section in garment dyeing machines.

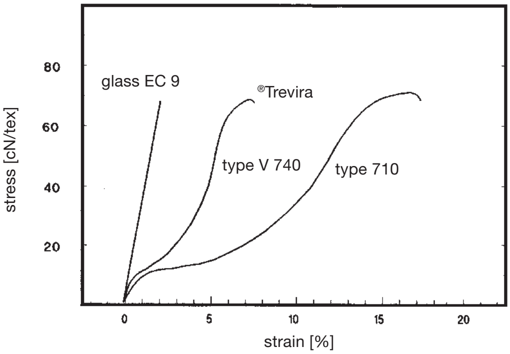


Fig.: Stress-strain diagrams.

Yucca fibres Similar to → Sisal, a leaf bast fibre which is obtained from the 25–60 cm long leaves of the yucca plant (yucca filamentosa L.) e.g. from the native family Liliaceae of southern North America. They are harvested twice a year. Fibres are developed either chemically (lime preparation) or by boiling under pressure, which releases lignin from the yucca fibre to a large extent. Short elementary fibres (approx. 1.3–1.5 mm), breaking length 40–67 cN/tex. Use: for twine, agricultural twine, also for carpet fabrics, tarpaulins, etc.

Yuzen printing (Ju-Sen printing). Artisanal printing process practiced in Japan. A forerunner to modern screen printing. Named after its inventor, the artist Yuzensai Miyasaki (1654–1736). Papery sheets are produced from the bast of the mulberry tree by pasting together several layers, these are stiffened, then made watertight with oil. The screens are manufactured from these by cutting out the motives. Print paste is applied in various ways e.g. hair brush, besom, doctor blade and spray nozzles on paper funnels. This method is used to produce high-quality prints on kimono materials. Depending on the process technique used, direct print or resist effects are obtained.

Z

Zahn Wellens Test For determining the eliminability (also called “apparent biological degradability”) of refractory contamination in waste water, in accordance with DIN 38 412 L 25. The test is carried out to enable forecasts to be made on eliminability in practical waste water treatment plants. The usual test periods of 14 and 28 days appear to be too long on account of the numerous possible adaptation phenomena. In view of the waste water management framework regulation, which mentions the test as the sole degradation test, a test period of 7 days is suggested.

There is a range of possibilities for forecasting the degradation/elimination behaviour of compounds in waste water treatment plants for the laboratory scale. The usual waste water simulation tests (e.g. coupled unit test) have proved themselves with surfactants among other detergent content substances, but they work in a concentration range of 10–20 mg/l of DOC at a high experimental cost and with long familiarisation and adaptation times which can have a considerable effect on the result.

The static Zahn Wellens Test works in a substrate concentration range which is realistic for substances in textile waste water. There are however different regulations and standards or variants for practical implementation (e.g. the EMPA test), so that uniform conduct of the tests and evaluation of the results is not always guaranteed, especially as the test regulations, particularly the OECD guideline, often allow wide latitude in test conditions (e.g. seeding density and test concentrations).

The Zahn Wellens testing process can be used on water-soluble, non-volatile organic substances and on waste water containing such substances. The basic principle of the process is using activated sludge from a waste water treatment plant and a mineral nutritive substance solution together with the test substance over a longish period (up to 28 days) at 22 ± 3 °C. Elimination can be controlled by determining the dissolved COD or DOC value. Two parallel formulations are tested with the test substance. Biocoenosis behaviour must be monitored with the reference substance, to which end diethylene glycol is suitable, since degradation of this substance also requires 5–7 days, and runs parallel to the tests. Under certain circumstances, testing the blank test without sludge is dispensed with if the samples to be tested contain no significant quantities of volatile substances. The test formulation is made with 21 volumes and a content of 1 g of dry substance over 7 days, the COD being determined after 3, 6, 24, 48, 72 and 168 hours.

Eliminability is currently determined from

$$D_t = \left(1 - \frac{C_t - C_{Kt}}{C_a}\right) f \ [\%]$$

D_t = eliminability of the test substance and the waste water at time t [%],

C_t = DOC and COD value of the test formulation at time t [mg/l],

D_{Kt} = DOC and COD value of the control sludge formulation at time t [mg/l],

C_a = DOC and COD value of the test substance at the start of the test [mg/l],

f = conversion factor, f = 100.

Zanella Smooth, highly lustrous, Atlas construction lining fabric (cotton and also cotton warp + worsted yarn weft = wool/cotton union-Zanella),

Zardozi Old Indian gold embroidery (silk yarn wrapped with metal foil) on heavyweight fabrics.

Zarts solution Dyestuff mixture for differentiating between cupro (violet/blue colouration) and viscose fibres (= pink/red colouration) in fibre blends. Reliable method of differentiation.

Zaza-printing method Yarn sheet printing process (similar to the vigoureux printing process), in which yarn sheets run between a relief and a felt roller which is supplied with printing paste from the printing paste trough via a rubber roller, printing paste being transferred to the yarn material in raised places of the relief through felt roller contact pressure. Five shades can be produced with one ground colour and four pairs of rollers.

ZE → Zein fibre, DIN 60 001 symbol up to 1988.

Zefir → Zephyr.

Zein Vegetable protein from maize (botanical = zea). Used for producing adhesives, plastics and fibres.

Zein fibre Man-made protein fibres from the zein contained in maize meal. Spun by the wet spinning process (precipitating bath: dilute sulphuric acid, acetic acid and zinc sulphate). Dry strength 11 cN/tex at 40% elongation. Used in a blend with cellulosic and other fibres (increases elasticity, improves crease resistance) for warp and weft knitted fabrics and woven pile fabrics.

Zeolites Inorganic silicate ion exchangers and therefore cation exchangers (→ Ion exchanger) which are also suitable for neutral exchange. Natural zeolites: crystallised, water-containing alumina silicates of differing composition, frequently so-called greensands. Artificial zeolites: melting of alumina silicates with sodium carbonate or sodium aluminium silica gel precipitates (Permutit type). In zeolites of the sodium aluminium silicate type ($NaO_2 \cdot Al_2O_3 \cdot 3\,SiO_2 \cdot 5\,H_2O$), the H_2O is not chemically bonded but distributed over hollow spaces between SiO_4 tetrahedrons which give it off continuously on heating, and re-absorb it to moist air. Natural zeolites are water resistant up to 35°C, while artificial zeolites can only be charged with cold water. Achievable residual hardness 0.1–0.05°d. Filter wear with natural zeolites is approx. 4–5% per year.

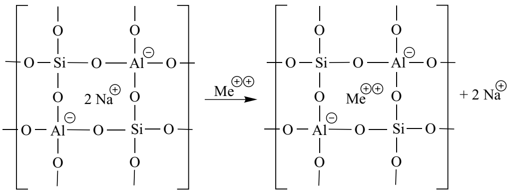

Fig. 1: Ion exchange through zeolite A.

Synthetic crystalline zeolite type A (Fig. 1) is represented by the following formula:

$$Na_{96}[(CAlO_2)_{96} \cdot (SiO_2)_{96}] \cdot 216\,H_2O$$

The ratio SiO_2/Al_2O_3 is about 2 : 1, a relatively large number of exchangeable cations being present. The spatial network structure of zeolite A is characterised by a large hollow space with openings (0.4 nm diameter). This structure develops in a complicated reaction: first of all aluminosilicate by reorientation of the primary components AlO_4 and SiO_4, resulting in secondary aggregations in the form of so-called sodalite grid units

$$- Na_8[Cl_2(AlSiO_4)_6] -$$

with small hollow spaces which then combine to form zeolite type A (Fig. 2).

Zeolites used as detergent components are of such a small particle size (a few ∝m) that they can precipitate neither during the washing process nor during discharge of the used washing liquor.

From Japan comes a processing variant for antibacterial finishing which utilises the properties of zeolites. These are inorganic compounds which are capable of working as ion exchangers and of storing molecules. The processes can be selectively carried out depending on the structure of the zeolite. By storing silver ions in specific zeolites and subsequent spinning into polymers, it is possible to achieve a very low concentration of silver ions on the fibre surface. Since silver ions diffuse slowly out of the fibre interiors on to the surface, an antibacterial finish is produced over a lengthy period.

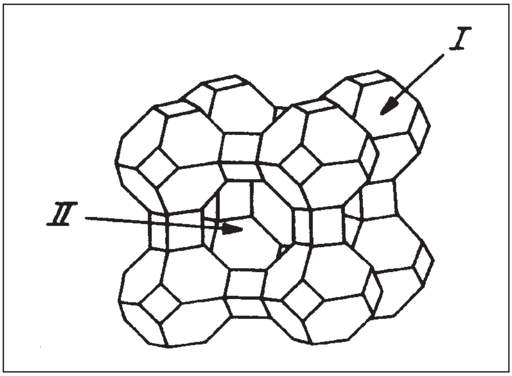

Fig. 2: Sodalite unit with small cavity (I); large cavity with aperture (II); diameter 0.4 nm.

Zephyr,

I. Thick, soft twisted (mostly multifold) worsted yarn (fine Merino wool) for warp and weft knitting and embroidery purposes.

II. Dense, fine thread (cotton, silk, union silk) plain weave fabric (fine varieties) cambric. Designation in accordance with fibre type and use (cotton zephyr, blouse zephyr, shirting zephyr and dress zephyr).

Zeta potential (ζ potential) → Electrokinetic interfacial potential. Where solids are in contact with aqueous electrolyte solutions, there is, at the phase boundary, a different distribution of electrically charged particles from that in the interior of the solid and liquid phases. A concentration of charged particles at the phase boundary is possible for polymers through the dissociation of relevant molecule groups at the phase boundary and a variously high degree of adsorption of anions and cations at the interface. The charged particles found on the solid surface interact with the ions in the electrolyte solution, forming an electrochemical double layer (Fig. 1).

For describing the potential difference at the phase boundary of the solid polymer/electrolyte solution, the Stern double layer model is generally used as a basis. After that, ions are firmly adsorbed at the interface. The charge of these ions, and also through dissociation of relevant molecule groups found at the interface, is compensated by counterions, which are found fixed opposite the ions at the interface, and also through counteri-

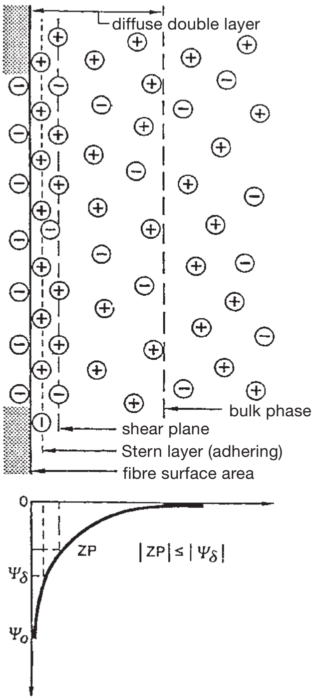

Fig. 1: Model of the electrochemical double layer.

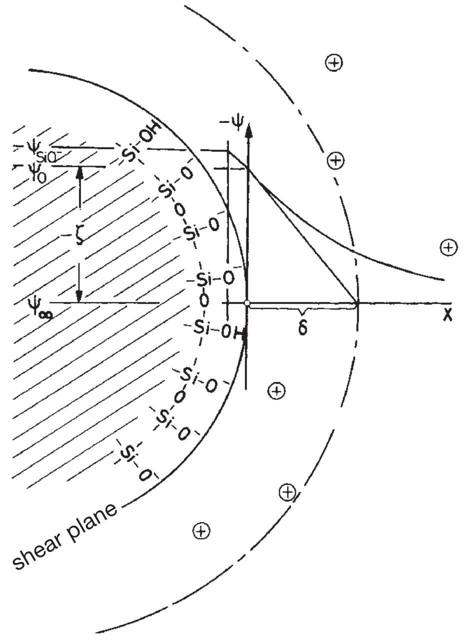

Fig. 2: Potential run and charge distribution on the surface of a SiO_2 particle.

ons which are found at a greater distance from the interface due to thermal agitation. The electrochemical double layer is divided by Stern into a “rigid” and a “diffuse” part. The interaction between polymers dissolved or dispersed in aqueous solutions etc. is affected by the electrical charge conditions on the polymer surface, by the potential difference in the double layer, and by the charge density at the interface and at the boundary rigid/diffuse double layer. This applies particularly to dispersed solids, dyes and textile auxiliary agents.

SiO_2 particles dispersed in water can be used for quantitative interpretation (Fig. 2). These particles have silanol groups on the surface which can dissociate in polar solvents, the negative charge remaining on the surface. Since there is electroneutrality outside, the charge of the solid and particle surfaces (in this case the negative charge of the SiO_2 groups) has to be compensated by a positive charge of identical amount, e.g. by the dissociated protons. The shear plane separates the part of the charge fixed on the surface from the movable part of the charge, i.e. the part freely movable in the double layer.

The abscissa x in Fig. 2 has its origin on the particle surface (phase boundary), and points from it vertically into the interior of the solution. The ordinate ψ is the tangent to the particle surface at the intersection of the abscissa x with the surface. The electrical potential ψ falls from the value $\psi_{SiO_2^-}$ at the particle surface to a value of ψ_0 at the shear plane. From that point, it decreases exponentially to the interior of the solution, reaching a value of ψ_∞ at infinity, as the charged particles have a Boltzmann distribution in the diffuse layer, which is connected to the shear plane. Resulting from this is the electrophoretic mobility B, caused by an external electrical field. The mobility B of the particles is defined as the quotient of the velocity of migration v of the particles and the external field strength E:

$$B = \frac{v}{E}.$$

The electrokinetic behaviour of the SiO_2 particles is characterised by the electrokinetic potential ζ (zeta potential), which should be equal to the potential difference between an imaginary shear plane and the interior of the liquid phase. It should therefore be equated with potential difference $(\psi_0 - \psi_\infty)$. The potential $\psi_{SiO_2^-}$ of the potential-determining groups at the surface is not generally identical with the potential ψ_0 of the shear plane. If the thickness of the diffuse charge layer is great compared with the layer of the potential-determining ions, this additional potential difference $(\psi_{SiO_2^-} - \psi_0)$ can be ignored. The connection between mobility

B and zeta potential is obtained by the following relationship:

$$\zeta = B \cdot \frac{\eta}{\varepsilon \cdot \varepsilon_0}$$

This relationship applies in general only when the quotient of viscosity η and dielectric constant ε is constant within the diffuse charge layer. Since the rational system of units is used for the calculation, the dielectric displacement constant ε_0 has to be taken into account.

By zeta potential measurement, the potential distribution in the diffuse double layer can be determined relative to the valency and concentration of the electrolyte. Most of the electrokinetic trials on fibre materials have been conducted in accordance with the streaming potential method principle. Electrokinetic measuring methods are characterised by the fact that, when an electric field is applied to solids dispersed in electrolyte solutions, the dispersed solid particles (electrophoresis) or the electrolyte solution (electro-osmosis) move, or that, with the relative motion of solution and dispersed phase, an electric field occurs (streaming potential or sedimentation potential). It is an accepted fact that, when an electric field is applied, the charged particles of the rigid part of the electrochemical double layer remain on the solid, endowing it with a surplus charge, which is responsible for electrophoretic migration, and that the ions of the diffuse double layer migrate in the electric field, bringing about the electro-osmotic liquid motion.

Errors of measurement particularly concern inexact determination of the pore geometry of the diaphragm, failure to take account of the flow resistance in the measuring capillaries in electro-osmotic measurement, and inexact measurement of the electrical values. By excluding these sources of error, the zeta potentials determined on fibres in electrolytic solutions are independent of packing density and the voltage applied or the pressure difference. The measurement and evaluation method to be employed is primarily oriented to the type of fibre and the measured solution. For synthetic fibres in neutral diluted electrolytic solutions, the most reliable values are obtained by the streaming flow method with the use of Ag/AgCl electrodes. In an alkaline medium, preference is to be given, under otherwise identical conditions, to the streaming potential method using precious metal electrodes. On the other hand, electro-osmosis offers advantages for swelling fibres (cellulose, wool, asbestos).

fibre	water absorption at 100 % rel. humidity [%]	Zeta potential [mV] ζ_0	ζ_∞
viscose filament	45.0	16.60	3.20
cotton	22.0	54.00	30.20
mercerised cotton	33.0	74.00	24.40
silk fibroin	28.0	59.90	23.46
2.5-acetate

glass fibre	0.5	41.10	35.19

Tab.: Zeta potential and water absorption according to Kanamaru.

According to Kanamaru, the zeta potential of any fibre is reduced by its water absorbency, the kinetics of this reduction being expressed by the relationship:

$$-\ln \frac{\zeta - \zeta_\infty}{\zeta_0 - \zeta_\infty} = k \cdot t$$

ζ_∞ is the value of the zeta potential to which the ζ-t-curve approaches asymptotically; ζ_0 is the value determined immediately after introducing the dry fibre test specimen into the measuring solution; k is a constant. It has been additionally established by Kanamaru that the value of ($\zeta_0 - \zeta_\infty$) of water uptake at 100% relative humidity is proportional, i.e. the potential reduction is proportional to the water uptake (Tab.). The constant k is dependent on the fibre structure, and is therefore smaller below the freezing temperature (T_G) of a fibre than above it. The cause of zeta potential reduction due to water uptake is seen by Kanamaru in a change in the dielectric constants of the fibre materials.

Typical measuring cells (Figs. 3 + 4) for zeta potential determination consist of two silver/silver chloride electrodes with ceramic frit and an ion meter with an input resistance of 10^{13} Ω. Adsorption phenomena on the silver chloride surface are prevented by the presence of potassium chloride bridges. The zeta potential is calculated from the streaming potential in terms of the Smoluchowski equation:

$$\zeta\,[\mathrm{mV}] = \frac{6.75 \cdot 10^7 \cdot 4\,\pi\,\eta \cdot E \cdot X}{\varepsilon \cdot \Delta p}$$

Δp = pressure difference (measured in front of and behind the test specimen),
E = streaming potential.

This zeta potential is not however regarded as an absolute value, but merely as a comparison parameter for the different test specimens, because the conditions

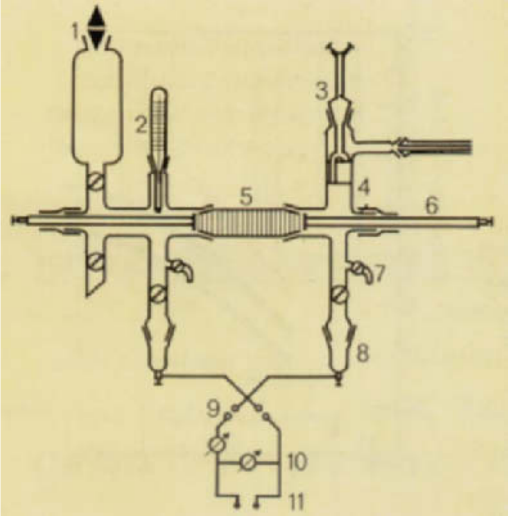

Fig. 3: Measuring cell for determining the zeta potential of fibres (according to Stackelberg).
1 = pressure gauge; 2 = air pressure; 3 = thermometer; 4 = diaphragm; 5 = measuring capillary; 6 = conductivity vessel; 7 = movable electrode; 8 = rinsing tap; 9 = platinum electrode; 10 = commutating switch; 11 = circuit breaker.

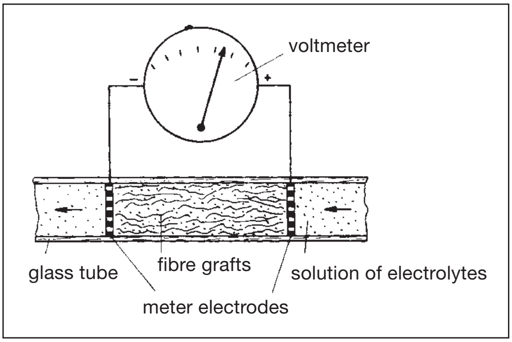

Fig. 4: Measuring arrangement for detecting the unsteady flow potential.

for the validity of the Smoluchowski equation are not complied with:

- the test specimen is only approximately capillary shaped,
- its surface is not in equilibrium with the solution,
- wetting, hydration and desorption phenomena may predominate,
- other parameters, such as the viscosity at the fibre surface, may vary from that of the water.

In a study of the zeta potential of wool fibres, Capablanca and Watt demonstrated that wool is positively charged below the isoelectric point, and negatively above it (Fig. 5).

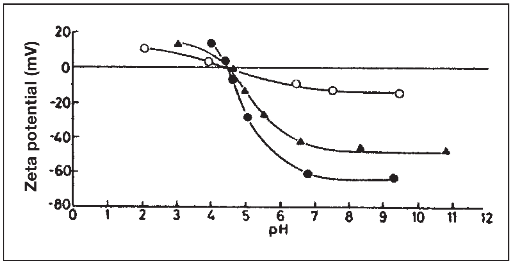

Fig. 5: Dependency of the zeta potential of wool on the pH of the flowing liquor.

The importance of the streaming potential for textile finishing processes is uncertain. It seems reasonable to assume that the electrochemical double layer on the surface of fibres affects the exhaustion behaviour of ionic dyes, since the adsorption of dye anions is made more difficult by negative zeta potential, and is made easier by positively charged dye anions. The zeta potential of fibre materials also changes during the adsorption of dye ions on the fibre surface by nature, while, at the end of the dyeing process, it again reaches the value of the undyed fibre, because all the dye ions are diffused into the interior of the fibre. According to Jacobasch however, zeta potential measurements are not very meaningful as regards the dyeing process, since the dye molecules are bonded less by electrostatic than by van der Waal forces (direct dyes). In addition, the speed-determining step in the dyeing process of cotton is not dye adsorption but diffusion in the fibre. On the other hand, the dye uptake of variously heat set polyester fibres correlates with their max. zeta potential in potassium chloride solutions.

Exhaust processes are selected for finishing with cationic softeners because the negative zeta potential of the fibres to be finished possibly produces affinity between softener and fibre. This kind of affinity is not observed for anionic auxiliary agents (except for wool), and they are applied in the coating process for that reason. Nevertheless, there are no study results which unambiguously cover this electrochemical double layer effect. In washing processes, the addition of anionic surfactants increases the electrokinetic potential of the fibres, to the surface of which the surfactants are adsorbed via their hydrophobic residue. Because the negative zeta potential of pigment dirt in water is also increased by anionic surfactants, the washing effect in such systems can be attributed to the reinforced electrostatic repulsion of fibre and dirt. This also explains the wash inactivity of cationic surfactants at lower application concentrations.

Zibeline Imitation sable fur. The fine, silvery and mainly lustrous hair tips are characteristic of the animal fur, and are imitated in zibeline by wool blended with fine mohair (also by short bristly hair perhaps). These materials mostly have a lengthwise raised finish zigzag meander conformation in accordance with the model. Used for womenswear, costumes and overcoats.

Zickzack-Mäander-Konformation (Zigzag meander conformation). With non-ionic surfactants, a structural change takes place with average chain lengths between 9 and 12 ethoxy units from the zigzag to the meander form in flowing transition under contraction (Fig. 1). In addition, telescoping or denticulation of long, meander form chain lengths into the zigzag form of the shorter chain lengths due to radiographically determined interplanar spacing has been calculated for chain length distributions over a range of approx. 10–15 ethoxy units (Fig. 2).

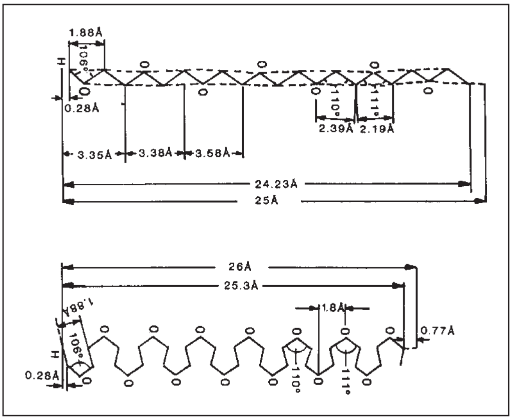

Fig. 1: Conformation of a single zigzag meander polyethylene oxide chain (according to Rösch). 1Å = 0.1 nm.

Due to the aryl group volume ratio, interdenticulation of the pure meander polyethylene oxide chains is held to be possible in the case of alkyl aryl-containing ethoxylated surfactants. In contrast, in comparison with pure polyethylene oxide chains, transition to the meander form in the case of ethoxylated fatty alcohols by the fatty alcohol residues suspended at one end of the ethylene oxide chain is blocked.

Zinc (Zn). Atomic weight 65.4. Bluish white metal, fast to atmospheric influences, fairly brittle, extensible, can be drawn and rolled at 100–150°C, brittle again above 200°C. Melting point 420–430°C. Easily soluble in diluted acids (hydrogen production), lyes and ammonia. Non-metallic compound: divalent; gives colourless salts with colourless acid anion. Water-soluble as zinc sulphate, zinc chloride; insoluble as zinc sulphide, zinc carbonate, zinc phosphate and zinc oxyphosphate. Precipitations mostly soluble in diluted acids (exception: zinc sulphide). Zinc oxyhydrate soluble in excess caustic lye or ammonia; forms salts with acids and concentrated bases = zincates. Use: as metal, → Zinc dust (for dithionites and discharge agents in printing), non-metallic compounds for paints, and in textile printing. Salts as mordants and/or white resists (zinc acetate, zinc chloride, zinc carbonate).

Zincates → Zinc.

Zinc carbonate $ZnCO_3$. Molecular weight 125.4. Use: in textile printing (mordants, white resists, discharge agents in printing, the latter for weighted silks).

Zinc chloride $ZnCl_2$. Molecular weight 136.2. White salt, extremely hygroscopic, easily soluble in water. Easily splits off hydrochloric acid when heated. Use: in textile printing (for white resists on bromine indigo etc), (rarely) antiseptic for sizes and chemical finishes etc.

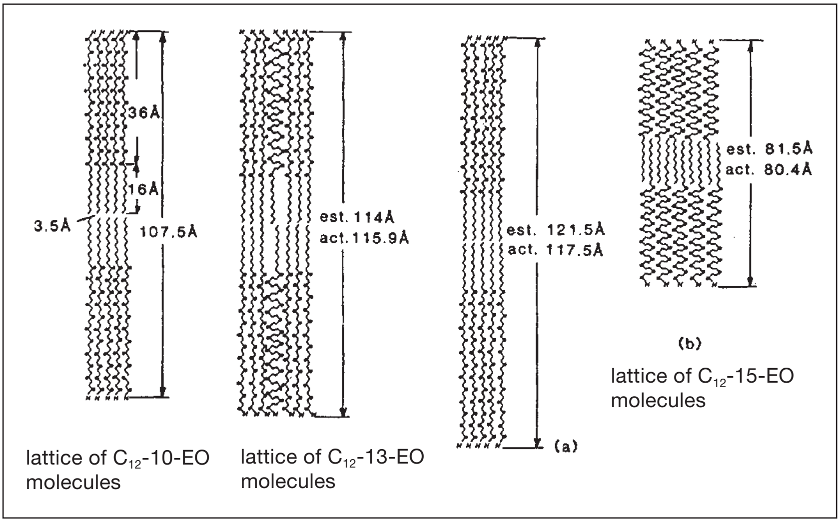

Fig. 2: Conformation of many zigzag meander polyethylene oxide chains (according to Rösch). 1Å = 0.1 nm.

Zinc chloride/formic acid solution Used in fibre identification. 100 ml of zinc chloride solution, density 1.566 (produced by dissolving 100 g of moisture-free $ZnCl_2$ in 100 ml of water, and setting the density to 1.566) are mixed with 6 ml of 98–100% formic acid. Use:

I. Solution cold: differentiating between 2.5 acetate and triacetate (2.5 acetate = dissolved, triacetate = merely slightly swollen). Polyamide 3, polyamide 6 and polyamide 6.6 produce Koch's → contraction reaction at room temperature. Vinylal fibres reveal the same reaction as with zinc chloride-iodine solution but faster and with no staining. Polyacrylonitrile is insoluble.

II. Solution at 70°C (10 min) dissolves silk, slowly dissolves regenerated cellulose, does not dissolve wool, regenerated protein fibres, cotton and bast fibres.

Zinc chloride-iodine solution Dissolve 66 g anhydrous zinc chloride and 6 g potassium iodide in 34 ml water. Next add iodine until the solution is saturated. The solution should be stored in a dark bottle as it is light-sensitive. Reactions with fibres:

a) Cellulosic fibres: blue colouring, regenerated cellulose shows a deeper blue colouring than natural cellulose; woody cellulose = yellow; material which has been well broken down = blue. X- and v- transverse splits in bast fibres are heavily dyed. Natural celluloses swell, cottons show a similar reaction to that in cuprammonium.
b) Animal fibres are not dyed.
c) Acetate: dissolution with yellow colouring and no swelling.
d) Polyacrylonitrile: dissolution with poss. swelling. Insoluble types also exist. No yellow colouring.
e) Polyamide, polyurea fibres: yellow colouring and → Koch's contraction reaction without dissolution.
f) Polyester, polyvinyl chloride: no yellow colouring or dissolution.
g) Polyvinyl alcohol: initially greyish-blue, then the fibre core becomes a strong blue and is distorted into a zigzag formation. Eventually becomes straight again and generally yellow in colour.

Zinc chloride solubility test This is a solution of zinc chloride (54°Bé) or 100 g molten zinc chloride + 85 ml water + 4 g zinc oxide at 100°C dissolved in approx. 15 min. Only dissolves pure silk (not tussah-silk) and acetate (gelatinous type is dissolved) in fibre blends.

Zinc chlor-iodide solution Compound consisting of iodine, potassium iodide and zinc chloride. Use: to test for acetate, cupro and viscose in fibre blends. The following colourings occur: yellow = acetate; brown = cupro; green = viscose; other fibres do not change colour.

Zinc dust Grey powder, finely divided metallic → Zinc (some zinc oxide). Strong reducing agent. Use: for producing indigo vats, and for discharges in textile printing.

Zinc dust discharges Only rarely used → Reductive discharges; → Discharge printing.

Zinc formaldehyde sulphoxylate → Sulphoxylates.

Zinc-lime-vat Used in indigo dyeing, mainly for ordinary cotton yarn, lighter-weight piece goods and paste resist printing (→ Vat dyes in resist printing). Disadvantages as compared with indigo sodium dithionite vat: not salt-free, higher reduction losses. Produces a somewhat redder shade. Dye vat: 1000 l contain 400 g of zinc dust (flushed with water) + 2 kg of dissolved lime (mixed to a paste), left to stand overnight, indigo addition as necessary. In the case of yellow vat dye, begin with dyeing.

Zinc oxide (zinc white). ZnO. Molecular weight 81; density 5.78. Loose white powder, practically insoluble in water, soluble in acids (salt formation); temporarily yellowing when heated (slightly luminescent in the cooled state). Use: much used pigment for viscose delustring (fixated with fatty sulphonates; dyed with cationic or direct dyes for coloured delustring); for sodium dithionite resists; resist for aniline black in printing; for producing damask effects in printing; for neutralising naphthol-diazo- solution; production of cements, drying agents etc.

Zinc soaps Formation like → Lime soap by water hardness salts.

Zinc sulphate (white vitriol) $ZnSO_4 \cdot 7\,H_2O$. Molecular weight 288. Colourless crystals; weakly acid. Use: alkali binders in naphthol dyeing, for printing mordants, as an antiseptic for sizes and chemical finishes (out of date).

Zinc sulphoxylates → Sulphoxylates.

Zinc vitriol → Zinc sulphate.

Zinc white → Zinc oxide.

Zip-fastener finishing The material used for zip fastener fabrics (such as polyamide) and the incorporated teeth of the zip fasteners make it possible to colour the yard goods batched on the beam. The textile components of the zip fasteners – the velcro tapes (hook and loop) – must be subjected to nip padding on the reverse to make sure they do not fray. Diluted polyester polyurethane, mixed with the crosslinking agent polyaziridine, is padded on. A subsequent fixing treatment crosslinks the polyester system effectively without impairing its elasticity (according to Stahl).

Zirchrome process Combined mineral dyeing and chemical finishing process for woven cotton fabrics. Principle: formation of chromium and zirconium oxide complexes using Cr-chloride, Zr-ammonium carbonate and ammonium oxalate. Result: greenish khaki shades; the fabrics are simultaneously protected against bacterial attack.

Zirconia element → Zirconium sensor.

Zirconium (Zr). Atomic weight 91.22; density 6.52; melting point 1860°C. Metallic element. Pure,

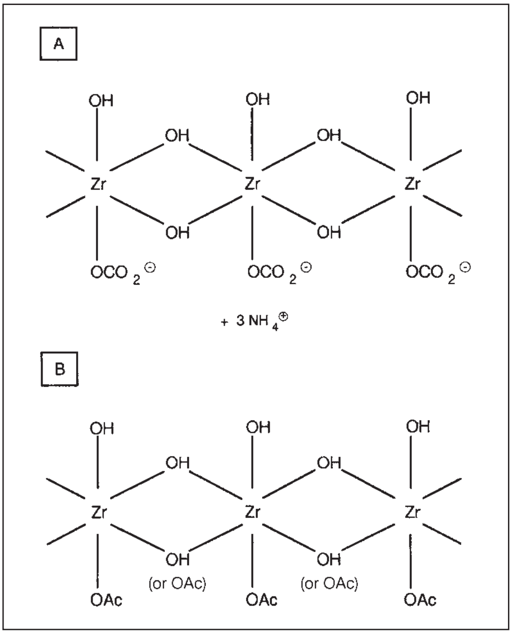

Fig.: Ammonium zirconium carbonate (A) and zirconium acetate (B) structures, according to McAlpine.

massive zirconium (hardness 7–8) is melted until it is pliable and steel-bright (processable into rolled sheet and wire), as a fine powder, black. Massive zirconium is resistant to water and hydrochloric, nitric and phosphoric acid and lyes, for example. Rapidly soluble in hydrofluoric acid at room temperature, hot concentrated sulphuric acid and nitrohydrochloric acid. Is attacked by molten caustic lyes, chlorine and suchlike substances. Zirconium compounds (Fig.) are generally tetravalent (2, 3), preferentially colourless and non-toxic. Zirconium alloys can attain unusual degrees of hardness. Use: crucibles and fire-resistant equipment (ZrO_2); alloy components; for textile water repellent agents (zirconium chloride, basic zirconium formiate, zirconium acetate etc); dye and pigment binders for printing pastes; for leather tanning (Zr sulphate) etc.

Zirconium salt/paraffin emulsions → Water impermeability testing.

Zirconium sensor For measuring the oxygen content in the air. If this changes owing to water vapour or any other gas in the air, the zirconia element (Fig.) indicates the change in relation to the air. The heated sensor has two electrodes, one of which is exposed to the process air, the other to the air in the room. Depending on the process air moisture and polluting (e.g. chemical finishes) vapour content, the sensor sends a specific voltage signal. This signal is processed in the measuring amplifier for further processing by the evaluating electronics, which calculates from the measuring amplifier signals with the aid of a microcomputer the sum of process air moisture (water vapour) and polluting vapour content. The unit of measurement is g/kg (grammes of water + equivalent polluting vapour content/kilogram of dry air).

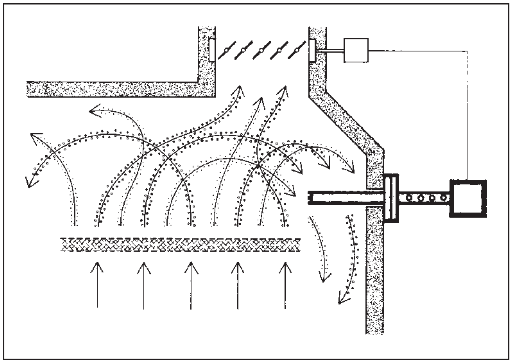

Fig.: Measuring device based on zirconium sensor for determining the oxygen content of a gas (Pleva).

Zirpro process → Flame retardant finishing of wool by applying titanium/zirconium salt. Application is basically possible in any wool processing stage, i.e. as loose stock, tops, yarn (hank or yarn package), piece goods (woven or knitted fabric), carpets, and can be effected by the following processes:

1. exhaust process.
2. pad/dwell/rinse/dry process.
3. pad/steam/rinse/dry process.
4. dip/squeeze/dwell/dry process.
5. solvent process.

Zirpro finishing is predominantly effective in the solid stage through the increased formation of insulating carbon.

Advantages:

- small quantity of applied chemicals,
- low chemical cost,
- handle is not impaired,
- colour fastness and physical properties are not impaired,
- simple application,
- finish is resistant to washing and dry-cleaning,
- Zirpro-finished wool fabrics meet smoke development standards,
- possibility of combination with other processes.

Disadvantages:

- Zirpro/titanium treatment causes slight yellowing.

Zn Element symbol for zinc (30).

Z-Polyethylene Gravure printed polyethylene after its inventor Ziegler.

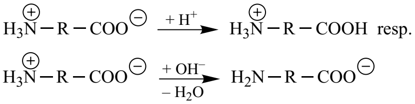
Zr Element symbol for zirconium (40).

ZTDI Textile documentation and information centre; → Technical and professional organizations.

Z twist Spun yarn twist.

ZW Abbreviation of the no longer admissible concept → Rayon staple fibre.

Zwitterions Term borrowed from colloquial speech for compounds which have in the same molecule a positively charged group (ammonium and sulphonium ions, more rarely carbenium or phosphonium ions), and also a negatively charged group, and can therefore be understood as intramolecular salts. The negative charge is mostly localised on oxygen atoms by the giving off of a proton of carboxyl or sulpho-groups, phosphoric acid esters, acidic phenolic or enolic hydroxyl groups. Zwitterions behave like ampholytes, which appear as uncharged towards the outside at a characteristic pH – the isoelectric point – and do not therefore migrate in the electrical field, and act as buffers with the addition of acids and bases:



$$H_3\overset{\oplus}{N}-R-COO^{\ominus} \xrightarrow{+\,H^+} H_3\overset{\oplus}{N}-R-COOH \text{ resp.}$$

$$H_3\overset{\oplus}{N}-R-COO^{\ominus} \xrightarrow[-\,H_2O]{+\,OH^-} H_2N-R-COO^{\ominus}$$
